Manifolds with positive curvature operators are space forms

Christoph Böhm and Burkhard Wilking

Abstract. We show that the normalized Ricci flow evolves metrics with positive curvature operator on compact manifolds to limit metrics of constant positive sectional curvature. In this note we only indicate the proof, the details will be published somewhere else.

Mathematics Subject Classification (2000). Primary 53C44; Secondary 53C25.

Keywords. Ricci flow, positive curvature operator, space forms.

1. Introduction

The Ricci flow has been introduced by Hamilton in 1982 [H1] in order to prove that a compact 3-manifold admitting a Riemannian metric of positive Ricci curvature is a spherical space form. The unnormalized Ricci flow is the geometric evolution equation

$$\frac{\partial g}{\partial t} = -2\,\mathrm{Ric}(g) \tag{1}$$

for a curve g_t of Riemannian metrics on a compact manifold M^n.

Using moving orthonormal frames, this leads to the following evolution equation for the curvature operator $\mathrm{R}_t\colon \Lambda^2 T_pM \to \Lambda^2 T_pM \cong \mathfrak{so}(T_pM)$ of g_t (cf. [H2]):

$$\frac{\partial\,\mathrm{R}}{\partial t} = \Delta\,\mathrm{R} + 2(\mathrm{R}^2 + \mathrm{R}^{\#}), \tag{2}$$

where $\mathrm{R}^{\#} = \mathrm{ad}\circ(\mathrm{R}\wedge\mathrm{R})\circ\mathrm{ad}^*$ and $\mathrm{ad}\colon \Lambda^2(\mathfrak{so}(T_pM)) \to \mathfrak{so}(T_pM)$ is the adjoint representation. For the details we refer the reader to Section 2. By Hamilton's maximum principle certain dynamical properties of the partial differential equation (2) can be derived from the dynamical properties of the corresponding ordinary differential equation

$$\frac{d\,\mathrm{R}}{dt} = \mathrm{R}^2 + \mathrm{R}^{\#}. \tag{3}$$

In dimension four Hamilton showed that compact 4-manifolds with positive curvature operators are spherical space forms as well [H2]. More generally, Chen showed that the same conclusion holds for compact 4-manifolds with 2-positive curvature

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

operator [Che]. Recall that a curvature operator is called 2-positive, if the sum of its two smallest eigenvalues is positive. In arbitrary dimensions it was shown by Huisken [Hu], that there is an explicit open cone in the space of curvature operators such that the normalized Ricci flow evolves metrics whose curvature operator at each point is contained in that cone into metrics of constant positive sectional curvature.

All of these results are also based on the maximum principle. The main reason why they are more involved is that the ordinary differential equation (3) is not that well understood in dimensions $n > 3$ and in particular not for $n > 4$.

Hamilton conjectured that in all dimensions compact Riemannian manifolds with positive curvature operators must be space forms. We can confirm Hamilton's conjecture. More generally, we can show the following

Theorem 1. *Let (M, g) be a compact Riemannian manifold with 2-positive curvature operator. Then the normalized Ricci flow evolves g to a limit metric with constant positive sectional curvature.*

The theorem is known in dimensions below five and our proof only works in dimensions above two. Since the proof solely relies on Hamilton's maximum principle it carries over to orbifolds.

Let us mention that this is no longer true in dimension two. By the work of Hamilton [H4] and Chow [Cho] it is known that the normalized Ricci flow converges to a metric of constant curvature for any initial metric in the manifold case. However, there exist two dimensional orbifolds with positive sectional curvature which are not covered by a manifold. On such orbifolds the Ricci flow converges to a nontrivial Ricci soliton [CW].

There is a wealth of different techniques in geometry to prove sphere theorems. Here we only mention the theorem of Micallef and Moore [MM] that a simply connected manifold with positive isotropic curvature is a homotopy sphere. It is well known that a 2-positive curvature operator has positive isotropic curvature. However, the techniques of Micallef and Moore do not allow to get restrictions for the fundamental groups or the differentiable structure.

Let us turn to the proof of Theorem 1. The major obstacle is to understand the ordinary differential equation (3). Here we establish a new algebraic identity which should be useful in other context as well. We study how the differential equation changes if we pull it back by an equivariant linear map $1\colon S^2_B(\mathfrak{so}(n)) \to S^2_B(\mathfrak{so}(n))$, where $S^2_B(\mathfrak{so}(n))$ denotes the space of curvature operators satisfying the Bianchi identity. For $n \geq 4$ this space decomposes into three pairwise inequivalent $\mathrm{O}(n)$-invariant irreducible subspaces

$$S^2_B(\mathfrak{so}(n)) = \langle I \rangle \oplus \langle \mathrm{Ric}_0 \rangle \oplus \langle \mathrm{W} \rangle.$$

Here $\langle I \rangle$ denotes multiples of the identity, $\langle \mathrm{W} \rangle$ curvature operators with vanishing Ricci curvature and $\langle \mathrm{Ric}_0 \rangle$ are the curvature operators of traceless Ricci type. Given such a curvature operator R we let R_I, $\mathrm{R}_{\mathrm{Ric}_0}$ and R_{W}, denote the projections onto $\langle I \rangle$, $\langle \mathrm{Ric}_0 \rangle$ and $\langle \mathrm{W} \rangle$, respectively.

Since we can always scale the linear map l by a factor it is not much of a restriction to consider maps of the form

$$\mathrm{l}_{a,b}(\mathrm{R}) = \mathrm{R} + 2(n-1)a\,\mathrm{R}_I + (n-2)b\,\mathrm{R}_{\mathrm{Ric}_0}. \tag{4}$$

Notice that $\mathrm{l}_{a,b}$ induces the identity on the space $\langle \mathrm{W} \rangle$ of Weyl curvature operators.

The following result is crucial.

Theorem 2. *Let* $\mathrm{R} \in S^2_B(\mathfrak{so}(n))$ *be a curvature operator,* $\mathrm{Ric} \in S^2\mathbb{R}^n$ *its Ricci curvature,* Ric_0 *the traceless part of* Ric*, and let*

$$D_{a,b} = \mathrm{l}_{a,b}^{-1}\big((\mathrm{l}_{a,b}\,\mathrm{R})^2 + (\mathrm{l}_{a,b}\,\mathrm{R})^{\#}\big) - \mathrm{R}^2 - \mathrm{R}^{\#}.$$

Then

$$\begin{aligned} D_{a,b} = {} & \big((n-2)b^2 - 2(a-b)\big)\,\mathrm{Ric}_0 \wedge \mathrm{Ric}_0 + 2a\,\mathrm{Ric} \wedge \mathrm{Ric} + 2b^2\,\mathrm{Ric}_0^2 \wedge \mathrm{id} \\ & + \frac{\mathrm{tr}(\mathrm{Ric}_0^2)}{n + 2n(n-1)a}\big(nb^2(1-2b) - 2(a-b)(1-2b+nb^2)\big)\,I. \end{aligned}$$

In particular, $D_{a,b}$ *is independent of the Weyl curvature of* R.

The theorem often allows to construct new invariant curvature conditions by considering the image of a known invariant curvature conditions under the linear map $\mathrm{l}_{a,b}$ for suitable constants $a, b \in \mathbb{R}$. Recall that an invariant curvature condition is a convex subset of $S_B(\mathfrak{so}(n))$ which is invariant under the ordinary differential equation (3) and hence, by Hamilton's maximum principle, invariant under the partial differential equation (2).

As already mentioned this note only contains indications of proofs. The details will be published somewhere else. We expect that the new algebraic identity on curvature operators (Theorem 2) and its Kähler analogue should give rise to further applications. This will be the subject of a forthcoming paper.

2. Preliminaries

For a Euclidean vector space V we let $\Lambda^2 V$ denote the exterior product of V. We endow $\Lambda^2 V$ with its natural scalar product; if $e_1, \ldots, e_n$ is an orthonormal basis of V then $e_1 \wedge e_2, \ldots, e_{n-1} \wedge e_n$ is an orthonormal basis of $\Lambda^2 V$. Notice that two linear endomorphisms A, B of V induce a linear map

$$A \wedge B\colon \Lambda^2 V \to \Lambda^2 V, \quad v \wedge w \mapsto \tfrac{1}{2}\big(A(v) \wedge B(w) + B(v) \wedge A(w)\big).$$

We will identify $\Lambda^2\mathbb{R}^n$ with the Lie algebra $\mathfrak{so}(n)$ by mapping the unit vector $e_i \wedge e_j$ onto the linear map $L(e_i \wedge e_j)$ of rank two which is a rotation with angle $\pi/2$ in the plane spanned by e_i and e_j. Notice that under this identification the scalar product on $\mathfrak{so}(n)$ corresponds to $\langle A, B \rangle = -1/2\,\mathrm{tr}(AB)$.

We let $S^2(\mathfrak{so}(n))$ denote the space of selfadjoint endomorphisms of $\mathfrak{so}(n)$ and $S^2_B(\mathfrak{so}(n))$ the subspace of operators satisfying the Bianchi identity. Recall that $S^2_B(\mathfrak{so}(n))$ is given by the orthogonal complement of $\Lambda^4\mathbb{R}^n$ in $S^2(\mathfrak{so}(n))$. We use the convention that the curvature operator of the round sphere is the identity of $\mathfrak{so}(n)$. This explains the extra factor 2 in the evolution equation (2), cf. [H2].

Hamilton observed that for two elements $\mathrm{S}, \mathrm{R} \in S^2(\mathfrak{so}(n))$ one can define a new element $\mathrm{S}\,\#\,\mathrm{R} \in S^2(\mathfrak{so}(n))$. This can be done invariantly by putting

$$\mathrm{S}\,\#\,\mathrm{R} := \mathrm{ad} \circ (\mathrm{S} \wedge \mathrm{R}) \circ \mathrm{ad}^*$$

where $\mathrm{ad}\colon \Lambda^2\mathfrak{so}(n) \to \mathfrak{so}(n),\ X \wedge Y \mapsto [X, Y]$ is the adjoint representation and ad^* is its dual. Following Hamilton we use the abbreviation $\mathrm{R}^{\#} = \mathrm{R}\,\#\,\mathrm{R}$. For a generic $\mathrm{R} \in S^2_B(\mathfrak{so}(n))$ neither R^2 nor $\mathrm{R}^{\#}$ are in $S^2_B(\mathfrak{so}(n))$. However, Hamilton showed that the sum is in $S^2_B(\mathfrak{so}(n))$ and hence the ordinary differential equation (3) leaves $S^2_B(\mathfrak{so}(n))$ invariant.

Recall that an $\mathrm{O}(n)$-invariant subset C in the space of curvature operators is invariant under the Ricci flow, if the Ricci flow evolves metrics on compact manifolds whose curvature operator lies in C at any point into metrics with the same property.

Theorem 2.1 (Hamilton, [H2]). *A closed convex $\mathrm{O}(n)$-invariant subset $C \subset S_B(\mathfrak{so}(n))$ of curvature operators is invariant under the Ricci flow if it is invariant under the ordinary differential equation*

$$\frac{d\,\mathrm{R}}{dt} = \mathrm{R}^2 + \mathrm{R}^{\#}.$$

We recall that if $e_1, \ldots, e_n$ denotes an orthonormal basis, then

$$\mathrm{Ric}(\mathrm{R}^2 + \mathrm{R}^{\#})_{ij} = \sum_{k,l} \mathrm{Ric}_{kl}\, \mathrm{R}_{kijl} \tag{5}$$

where $\mathrm{R}_{kijl} = \langle \mathrm{R}(e_i \wedge e_k), e_j \wedge e_l \rangle$, see [H1], [H2].

Finally let us mention that we learned from Huisken that the trilinear map

$$\mathrm{tri}(\mathrm{R}_1, \mathrm{R}_2, \mathrm{R}_3) := \mathrm{tr}\big((\mathrm{R}_1\,\mathrm{R}_2 + \mathrm{R}_2\,\mathrm{R}_1 + 2\,\mathrm{R}_1\,\#\,\mathrm{R}_2)\,\mathrm{R}_3\big) \tag{6}$$

is symmetric in all three components $\mathrm{R}_1, \mathrm{R}_2, \mathrm{R}_3 \in S^2(\mathfrak{so}(n))$. Moreover (3) corresponds to the gradient flow of the function $\frac{1}{6}\,\mathrm{tri}(\mathrm{R}, \mathrm{R}, \mathrm{R})$.

3. On the proof of Theorem 2

In this section we show that the difference tensor $D = D_{a,b}$ does not depend on the Weyl curvature of R. The precise formula in Theorem 2 then follows from a calculation. We view D as quadratic form in R. By

$$B(\mathrm{R}, \mathrm{S}) := \tfrac{1}{4}\big(D(\mathrm{R} + \mathrm{S}) - D(\mathrm{R} - \mathrm{S})\big)$$

we get the corresponding bilinear form.

Let $S = W \in \langle W \rangle$. We have to show $B(R, W) = 0$ for all $R \in S^2_B(\mathfrak{so}(n))$. We start by considering $R \in \langle W \rangle$. Then $l_{a,b}(R \pm W) = R \pm W$. It follows from the formula (5) for the Ricci curvature of $R^2 + R^\#$ that $(R \pm W)^2 + (R \pm W)^\#$ has vanishing Ricci tensor. Hence $(R \pm W)^2 + (R \pm W)^\#$ is a Weyl curvature operator and accordingly fixed by $l^{-1}_{a,b}$. Therefore $B(R, W) = 0$.

Next we consider the case that $R = I$ is the identity. Notice that

$$(I + W)^2 + (I + W)^\# - (I - W)^2 - (I - W)^\# = 4W + 4W \# I = 0.$$

The last equation follows by a straightforward computation for $n = 4$. Since there is a natural embedding of the Weyl tensors of $S^2_B(\mathbb{R}^4)$ to the Weyl tensors of $S^2_B(\mathbb{R}^n)$ the same holds for $n \geq 5$. Clearly the equation implies $B(W, I) = 0$.

It remains to consider the case of $R \in \langle \mathrm{Ric}_0 \rangle$. Using the symmetry of the trilinear form (6) we see for each $W_2 \in \langle W \rangle$ that

$$\mathrm{tri}(W, R, W_2) = \mathrm{tri}(W, W_2, R) = 0$$

because $W W_2 + W_2 W + 2 W \# W_2$ lies in $\langle W \rangle$ and $R \in \langle \mathrm{Ric}_0 \rangle$. Combining this with $\mathrm{tri}(W, R, I) = 0$ gives that $WR + RW + 2W \# R \in \langle \mathrm{Ric}_0 \rangle$. Using once more that $l := l_{a,b}$ is the identity on $\langle W \rangle$ we see that

$$l(W)\, l(R) + l(R)\, l(W) + 2\, l(W) \# l(R) = l(WR + RW + 2W \# R).$$

This clearly proves $B(W, R) = 0$.

4. On the proof of Theorem 1

We call a continuous family $C(t)_{t \in [0,1)} \subset S^2_B(\mathfrak{so}(n))$ of closed convex $\mathrm{O}(n)$-invariant cones of full dimension a pinching family, if

1. each $R \in C(t) \setminus \{0\}$ has positive scalar curvature,
2. $R^2 + R^\#$ is contained in the interior of the tangent cone of $C(t)$ at R for all $R \in C(t) \setminus \{0\}$ and all $t \in (0, 1)$,
3. $C(t)$ converges in the pointed Hausdorff topology to the one-dimensional cone $\mathbb{R}^+ I$ as $t \to 1$.

Using Theorem 2 we can show that

Theorem 4.1. *There is a pinching family $C(t)_{t \in [0,1)} \subset S^2_B(\mathfrak{so}(n))$ such that $C(0)$ is given by the cone of 2 nonnegative curvature operators.*

Outline of the proof of Theorem 4.1. Here we only show that we can stay away from the boundary of the cone C of 2 nonnegative curvature operators.

$$b \in \left(0, \tfrac{\sqrt{2n(n-2)+4}-2}{n(n-2)}\right] \quad \text{and} \quad 2a = 2b + (n-2)b^2$$

We claim that then the set $\mathrm{l}_{a,b}(C)$ is invariant under the ordinary differential equation. We have to show that for $\mathrm{R} \in C$ the curvature operator

$$X_{a,b} = \mathrm{l}_{a,b}^{-1}(\mathrm{l}_{a,b}(\mathrm{R})^2 + \mathrm{l}_{a,b}(\mathrm{R})^{\#})$$

is contained in the tangent cone $T_{\mathrm{R}}C$ of C at R. Notice that by assumption we have $\mathrm{R}^2 + \mathrm{R}^{\#} \in T_{\mathrm{R}}C$. Thus it suffices to show that $D_{a,b} = X_{a,b} - \mathrm{R}^2 - \mathrm{R}^{\#}$ lies in $T_{\mathrm{R}}C$. For that it is clearly sufficient to show that $D_{a,b}$ is positive definite. We know that $\mathrm{Ric}(\mathrm{R}) \geq 0$ for any $\mathrm{R} \in C$. Looking at the formula for $D_{a,b}$ in Theorem 2 it suffices to show that

$$0 \leq b^2\big(n(1-2b) - (n-2)(1-2b+nb^2)\big)$$

holds in the given range. This is a straightforward computation.

It is not hard to see that for $b = \frac{\sqrt{2n(n-2)+4}-2}{n(n-2)}$ and $n \geq 4$ the closed cone $\mathrm{l}_{a,b}(C)$ is contained in the open cone of positive curvature operators. Thus it suffices to prove the existence of a pinching family of cones with $C(0)$ being the cone of nonnegative curvature operators. Theorem 2 combined with a calculation, which will be carried out somewhere else, shows that such a family can be constructed in the form

$$C(t) := \mathrm{l}_{a(t),b(t)}\big(\big\{\mathrm{R} \mid \mathrm{R} \geq 0, \mathrm{Ric}(\mathrm{R}) \geq p(t)\tfrac{\mathrm{scal}(\mathrm{R})}{n}\big\}\big)$$

for suitable functions $a(t)$, $b(t)$ and $p(t)$. □

Theorem 1 then follows from Theorem 4.1 combined with

Theorem 4.2. *Let $C(t)_{t\in[0,1)} \subset S^2_B(\mathfrak{so}(n))$ be a pinching family of closed convex cones, $n \geq 3$. Suppose that (M, g) is a compact Riemannian manifold such that the curvature operator of M at each point is contained in the interior of $C(0)$. Then the normalized Ricci flow evolves g to a constant curvature limit metric.*

On the proof of Theorem 4.2. Since M is compact and the family of cones is continuous we can assume that for a sufficiently large h_0 and a sufficiently small ε we have for the curvature operator R_p of (M, g) at each point $p \in M$ that

$$\mathrm{R}_p \in \{\mathrm{R} \mid \mathrm{scal} \leq h_0\} \cap C(\varepsilon).$$

We now consider to h_0 and ε the intersection F of all convex subsets which contain the above set and which are invariant under the ordinary differential equation (3). Clearly F is then invariant under the ordinary differential equation and one can show that for each t the set $F \setminus C(t)$ is relatively compact.

Thus F is a generalized pinching set similarly to Hamilton's concept.

From the maximum principle we know that the Ricci flow evolves g to metrics g_t whose curvature operators at each point are contained in F. We do also know that the solution of the Ricci flow exists as long as the curvature does not tend to infinity. Furthermore it follows from the maximum principle that the unnormalized Ricci flow exists only on a finite time interval $t \in [0, t_0)$. By Shi it follows from the maximum principle applied to the evolution equations for the i-th derivatives of the curvature tensor that

$$\max \|\nabla^i R_t\|^2 \leq C_i \max \|R_t\|^{i+2}$$

for all $t \in [t_0/2, t_0)$.

We now rescale each metric $g(t)$ to a metric $\tilde{g}(t)$ such that the maximal sectional curvature is equal to 1. From the above estimates it follows that we have a priori bounds for all derivatives of the curvature tensor of the metric $\tilde{g}(t)$ for $t \in [t_0/2, t_0)$.

We now look at a point $p_t \in (M, \tilde{g}_t)$ where the sectional curvature attains it maximum 1. We pull the metric via the exponential map back to the ball of radius π in $T_{p_t}M$. We identify this ball with the ball $B_\pi(0) \subset \mathbb{R}^n$ by choosing a linear isometry $\mathbb{R}^n \to T_{p_t}M$. We let $\bar{g}_t$ denote the induced metric on $B_\pi(0)$. From the above estimates on the derivatives of the curvature tensor it is clear that for any sequence t_n converging to t_0 there is a subsequence of $\bar{g}_{t_n}$ converging in the C^∞ topology.

The curvature operator at each point of the limit metric is contained in the set $\bigcap \frac{1}{\lambda_n^2} F = \mathbb{R}^+ I$, where λ_n denote the scaling factors which by assumption tend to infinity. Thus the limit metric on $B_\pi(0)$ has pointwise constant sectional curvature and by Schur's theorem it has constant curvature one, where we used $n \geq 3$.

It is now easy to deduce that the minimal sectional curvature of $(M, \tilde{g}_t)$ tends to 1 as well for $t \to t_0$. In particular for t close to t_0 we can apply Klingenberg's injectivity radius estimate for quarter pinched manifolds. Hence the universal cover of M has injectivity radius $\geq \pi$. This shows that the volume of the manifold does not converge to zero. It is then well known that we get a smooth limit space of constant curvature and that (M, g_t) is close in the C^∞-topology to this limit space. □

Finally we remark that the above proof carries over to orbifolds. In addition to Klingenberg's injectivity radius estimate one needs

Proposition 4.3. *Suppose (M, g) is compact orbifold with sectional curvature K. If $1/4 < K \leq 1$ and $\dim(M) \geq 3$ then M is the quotient of a Riemannian manifold by a finite isometric group action.*

The proof of the proposition is not related to the Ricci flow at all. It should rather be viewed as a generalization of Klingenberg's injectivity radius estimate.

Elliptic and parabolic problems in conformal geometry

Simon Brendle

Abstract. I will review recent results regarding two questions that arise in connection with the Yamabe problem. The first problem is concerned with the conformal deformation of Riemannian metrics by their scalar curvature. This leads to a parabolic evolution equation, which can be interpreted as the flow of steepest descent for the Yamabe functional. I will provide conditions which guarantee that the flow converges to a metric of constant scalar curvature as $t \to \infty$. The second problem is concerned with the set of constant scalar curvature metrics in a given conformal class. I will discuss under what conditions this set is compact. A recurring theme in the study of both problems is that blow-up can be ruled out by means of the positive mass theorem provided that the dimension is less than 6, whereas the Weyl tensor plays a crucial role in higher dimensions.

Mathematics Subject Classification (2000). Primary 53C21; Secondary 53C44.

Keywords. Scalar curvature; conformal deformation of Riemannian metrics; blow-up analysis.

1. The uniformization theorem and the Ricci flow in dimension 2

To begin with, I will discuss some results concerning the Ricci flow in dimension 2 and their relation to the uniformization theorem.

Theorem 1.1. *Let M be a compact manifold of dimension 2 without boundary. Given any metric g_0 on M, there exists a metric g which is pointwise conformal to g_0 and has constant curvature.*

Recall that two metrics g_0 and g on a manifold M are said to be pointwise conformal if there exists a smooth function $w\colon M \to \mathbb{R}$ such that $g = e^{2w}\, g_0$. If M is two-dimensional, then the Gaussian curvature of g is related to the Gaussian curvature of g_0 by the formula

$$K_g\, e^{2w} = K_{g_0} - \Delta_{g_0} w, \tag{1}$$

where Δ_{g_0} denotes the Laplacian relative to the metric g_0. Hence, the uniformization theorem in dimension 2 is equivalent to the solvability of the nonlinear elliptic equation

$$\Delta_{g_0} w - K_{g_0} + k\, e^{2w} = 0, \tag{2}$$

where k is a constant. Solutions to (2) can be constructed using variational methods (see e.g. [18], [19]). This approach is based on the observation that every solution

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

of (2) is a critical point of the functional

$$E_{g_0}(w) = \frac{1}{2} \int_M |dw|^2_{g_0} \, d\text{vol}_{g_0} + \int_M K_{g_0} \, w \, d\text{vol}_{g_0} \\ - \pi \, \chi(M) \, \log \bigg(\int_M e^{2w} \, d\text{vol}_{g_0} \bigg), \tag{3}$$

where $\chi(M)$ denotes the Euler characteristic of M. The functional $E_{g_0}(w)$ was introduced by M. Berger in his work on the uniformization problem [5], and is known as the Liouville energy. It has a geometric interpretation in terms of the log determinant of the Laplacian associated with the conformal metric $e^{2w} \, g_0$ (see [27]).

The partial differential equation (2) is closely related to the Ricci flow in dimension 2. In dimension 2, the normalized Ricci flow takes the form

$$\frac{\partial}{\partial t} g(t) = -(K_{g(t)} - k_{g(t)}) \, g(t), \tag{4}$$

where $K_{g(t)}$ denotes the Gaussian curvature of $g(t)$ and

$$k_{g(t)} = \frac{2\pi \, \chi(M)}{\int_M d\text{vol}_{g(t)}}$$

is the mean value of the Gaussian curvature on M. The evolution equation (4) can be reduced to a nonlinear partial differential equation of parabolic type. Hence, given any initial metric g_0 on M, the evolution equation (4) has a smooth solution on a small time interval. The evolution equation (4) was first studied by R. Hamilton [14]. The longtime behavior of the flow is characterized by the following result due to R. Hamilton [14] and B. Chow [9]:

Theorem 1.2. *Let M be a compact manifold of dimension 2 without boundary. Given any initial metric g_0 on M, the evolution equation (4) has a global solution. The solution converges exponentially to a metric of constant curvature as $t \to \infty$.*

The convergence of the Ricci flow follows from the maximum principle if $\chi(M) \leq 0$. The case $\chi(M) > 0$ is more subtle. To prove Theorem 1.2 in this case, Hamilton assumed that the initial metric has positive curvature. This condition is preserved by the flow, and guarantees that the entropy

$$\int_M K_g \log K_g \, d\text{vol}_g$$

is well defined. It is shown in [14] that this functional is decreasing along the Ricci flow (see also [9]). In view of the Harnack inequality established in [14], this implies that the curvature is uniformly bounded from above. This is sufficient to prove Theorem 1.2 for initial metrics of positive curvature. The remaining cases were settled by B. Chow [9].

In a subsequent paper, Hamilton observed that the constant in the isoperimetric inequality improves along the Ricci flow [16]. This estimate can be used to give an alternative proof of Theorem 1.2. M. Struwe, building upon earlier work of X. Chen [8], provided another proof of Theorem 1.2 based on concentration-compactness arguments [39].

There are essentially two ways to generalize these results to higher dimensions. One is E. Calabi's problem concerning the existence of Kähler–Einstein metrics (or, more generally, extremal Kähler metrics). The other one is the Yamabe problem, which will be discussed below.

2. The Yamabe problem

In 1960, H. Yamabe [42] conjectured that the uniformization theorem can be generalized in the following way:

Theorem 2.1. *Let M be a compact manifold of dimension $n \geq 3$ without boundary, and let g_0 be a Riemannian metric on M. Then there exists a metric g which is pointwise conformal to g_0 and has constant scalar curvature.*

Theorem 2.1 was proved by T. Aubin [1], R. Schoen [29], and N. Trudinger [40]. A. Bahri gave an alternative proof of Theorem 2.1 in the locally conformally flat case [3].

As in the two-dimensional case, the Yamabe problem can be reduced to the solvability of a nonlinear elliptic equation. Indeed, if two metrics g_0 and g are related by $g = u^{\frac{4}{n-2}} g_0$ for a smooth positive function u, then the scalar curvature associated with g can be calculated from the scalar curvature associated with g_0 by means of the identity

$$R_g \, u^{\frac{n+2}{n-2}} = R_{g_0} \, u - \frac{4(n-1)}{n-2} \, \Delta_{g_0} u \tag{5}$$

(see [2]). Here, R_{g_0} denotes the scalar curvature associated with g_0, and Δ_{g_0} is the Laplace operator relative to g_0. Hence, if u is a positive solution of the partial differential equation

$$\frac{4(n-1)}{n-2} \, \Delta_{g_0} u - R_{g_0} \, u + r \, u^{\frac{n+2}{n-2}} = 0, \tag{6}$$

then the metric $g = u^{\frac{4}{n-2}} g_0$ has constant scalar curvature r. The solutions of (6) can be characterized as the critical points of the functional

$$E_{g_0}(u) = \frac{\int_M \left(\frac{4(n-1)}{n-2} \, |du|^2_{g_0} + R_{g_0} \, u^2 \right) d\,\mathrm{vol}_{g_0}}{\left(\int_M u^{\frac{2n}{n-2}} \, d\,\mathrm{vol}_{g_0} \right)^{\frac{n-2}{n}}}. \tag{7}$$

The functional $E_{g_0}(u)$ is called the Yamabe energy. It follows from (5) that $E_{g_0}(u) = \mathcal{E}(u^{\frac{4}{n-2}}\, g_0)$, where

$$\mathcal{E}(g) = \frac{\int_M R_g \, d\mathrm{vol}_g}{\big(\int_M d\mathrm{vol}_g\big)^{\frac{n-2}{n}}} \tag{8}$$

denotes the normalized Einstein–Hilbert action. The Yamabe constant of a metric g_0 is defined as the infimum of the Yamabe energy in the conformal class of g_0:

$$Y(M, g_0) = \inf_{0<u\in C^\infty(M)} E_{g_0}(u). \tag{9}$$

The Yamabe constant is closely related to the optimal constant in the Sobolev embedding of $W^{1,2}(M, g_0)$ into $L^{\frac{2n}{n-2}}(M, g_0)$. It is not difficult to show that $Y(M, g_0) \leq Y(S^n)$, where $Y(S^n) = n(n-1)\,\omega_n^{\frac{2}{n}}$ denotes the Yamabe constant of the standard metric on S^n. The key step in the proof of Theorem 2.1 is the following result, which is due to Aubin and Schoen:

Theorem 2.2. *Let M be a compact manifold of dimension $n \geq 3$ without boundary, and let g_0 be a Riemannian metric on M. Suppose that (M, g_0) is not conformally equivalent to the standard sphere S^n. Then $Y(M, g_0) < Y(S^n)$.*

Aubin proved Theorem 2.2 under the additional assumption that $n \geq 6$ and (M, g_0) is not locally conformally flat. The remaining cases were solved by Schoen using the positive mass theorem.

3. The Yamabe flow

R. Hamilton proposed a heat flow approach to the Yamabe problem [15]. Hamilton considered the following evolution equation for the Riemannian metric g:

$$\frac{\partial}{\partial t} g(t) = -(R_{g(t)} - r_{g(t)})\, g(t). \tag{10}$$

Here, $R_{g(t)}$ denotes the scalar curvature associated with the metric $g(t)$. Moreover, the normalization constant $r_{g(t)}$ is defined as the mean value of the scalar curvature on M:

$$r_{g(t)} = \frac{\int_M R_{g(t)} \, d\mathrm{vol}_{g(t)}}{\int_M d\mathrm{vol}_{g(t)}}.$$

This choice of the normalization constant ensures that the volume of M does not change under the evolution. Note that the value of the normalization constant $r_{g(t)}$ may change during the evolution.

The evolution equation (10) can be viewed as a generalization of the Ricci flow in dimension 2 and is often referred to as the Yamabe flow. Like the Ricci flow in dimension 2, the Yamabe flow can be reduced to a parabolic equation for a scalar

function. To see this, we fix a background metric g_0 in the conformal class of the initial metric. Since the Yamabe flow preserves the conformal structure, we may write the time-dependent metric in the form $g(t) = u(t)^{\frac{4}{n-2}}\, g_0$, where $u(t)$ is a positive function on M. Using the relation (5), one can show that the function u satisfies the partial differential equation

$$\frac{\partial}{\partial t} u^{\frac{n+2}{n-2}} = \frac{n+2}{4} \left(\frac{4(n-1)}{n-2}\, \Delta_{g_0} u - R_{g_0}\, u + r_g\, u^{\frac{n+2}{n-2}} \right), \tag{11}$$

which can be viewed as a parabolic analogue of the Yamabe equation (6). It follows from standard parabolic regularity theory that the Yamabe flow has a smooth solution which is defined on a small time interval. Hamilton proved that the Yamabe flow has a global solution for every initial metric [15]. Moreover, he showed that the scalar curvature satisfies the pointwise bound $|R_{g(t)}| \leq C$, where C is a constant that depends only on the initial metric (but not on t).

The discussion of the asymptotic behavior of the flow can be divided into two cases which are distinguished by the sign of the Yamabe constant $Y(M, g_0)$. If $Y(M, g_0) \leq 0$, one can apply the maximum principle to show that the Yamabe flow converges exponentially to a metric of constant scalar curvature.

One of the first results in the case of positive Yamabe constant is due to B. Chow [10]. Chow showed that the flow converges to a metric of constant sectional curvature provided that (M, g_0) is locally conformally flat and the initial metric has positive Ricci curvature. The proof is inspired by Hamilton's work on the Ricci flow in dimension 3 (see [13]), and is based on pinching estimates for the eigenvalues of the Ricci tensor.

R. Ye [43] proved the convergence of the flow for all initial metrics, assuming only that (M, g_0) is locally conformally flat. To this end, he established a gradient bound for the Yamabe flow on locally conformally flat manifolds. The proof of the gradient estimate is based on the method of moving planes and uses the injectivity of the developing map (see [34]).

A different approach was developed by H. Schwetlick and M. Struwe [36]. Among other things, Schwetlick and Struwe proved that the scalar curvature approaches a constant in the sense that

$$\lim_{t \to \infty} \int_M |R_{g(t)} - r_{g(t)}|^p \, d\mathrm{vol}_{g(t)} = 0 \tag{12}$$

for all $p \geq 1$. Using (12), they showed that the Yamabe flow cannot form a singularity unless volume concentration occurs. Moreover, if volume concentration occurs, then the metric can be rescaled in such a way that the rescaled metrics converge to the standard metric on S^n.

Lemma 3.1. *Let $\{t_\nu : \nu \in \mathbb{N}\}$ be a sequence of times such that $t_\nu \to \infty$ as $\nu \to \infty$. Moreover, let $u_\nu = u(t_\nu)$. After passing to a subsequence if necessary, we can find a non-negative integer m and sequences $\{x_{k,\nu} : \nu \in \mathbb{N}\}$, $\{\varepsilon_{k,\nu} : \nu \in \mathbb{N}\}$, $k = 1, \ldots, m$,*

such that

$$u_\nu(x) - \sum_{k=1}^{m} \varphi_{x_{k,\nu}}(x) \left(\frac{4n(n-1)}{r_\infty}\right)^{\frac{n-2}{4}} \left(\frac{\varepsilon_{k,\nu}}{\varepsilon_{k,\nu}^2 + d(x_{k,\nu}, x)^2}\right)^{\frac{n-2}{2}} \to u_\infty(x)$$

in $W^{1,2}(M, g_0)$. *Here,* r_∞ *is defined as the limit of the normalization constant* $r_{g(t)}$ *as* $t \to \infty$. *The function* u_∞ *is a non-negative smooth solution of the partial differential equation*

$$\frac{4(n-1)}{n-2} \Delta_{g_0} u_\infty - R_{g_0}\, u_\infty + r_\infty\, u_\infty^{\frac{n+2}{n-2}} = 0.$$

Finally, $\varphi_{x_{k,\nu}}$ *is a cutoff function such that* $\varphi_{x_{k,\nu}}(x) = 1$ *for* $d(x_{k,\nu}, x) \leq \delta$ *and* $\varphi_{x_{k,\nu}}(x) = 0$ *for* $d(x_{k,\nu}, x) \geq 2\delta$.

This result is due to Schwetlick and Struwe (see [36], Lemma 3.4, and [38]). The proof uses a theorem due to M. Obata, which asserts that every conformal metric on S^n with constant scalar curvature has constant sectional curvature (see [12] or [26]).

Moreover, Schwetlick and Struwe were able to rule out volume concentration provided that $n \leq 5$ and the Yamabe energy of the initial metric is below a certain threshold. The latter condition precludes the formation of a singularity with more than one "bubble". The formation of a singularity with exactly one "bubble" can be ruled out by means of the positive mass theorem.

It was shown in [7] that the condition $n \leq 5$ implies the convergence of the Yamabe flow for all initial metrics (regardless of their Yamabe energy):

Theorem 3.2. *Let* M *be a compact manifold of dimension* $n \geq 3$ *without boundary, and let* g_0 *be a Riemannian metric on* M. *Suppose that* $n \leq 5$ *or* (M, g_0) *is locally conformally flat. Given any initial metric in the conformal class of* g_0, *the Yamabe flow has a global solution which converges to a metric of constant scalar curvature as* $t \to \infty$.

In the locally conformally flat case, this provides an alternative proof of Ye's theorem. The proof of Theorem 3.2 rests on the following key lemma:

Lemma 3.3. *Suppose that* $n \leq 5$ *or* (M, g_0) *is locally conformally flat. Moreover, let* $\{g(t) : t \geq 0\}$ *be a solution of the Yamabe flow on* M. *Then there exist positive real numbers* γ, C, *and* t_0 *such that*

$$r_{g(t)} - r_\infty \leq C \left(\int_M |R_{g(t)} - r_{g(t)}|^{\frac{2n}{n+2}}\, d\mathrm{vol}_{g(t)}\right)^{\frac{n+2}{2n}(1+\gamma)} \tag{13}$$

for $t \geq t_0$.

Suppose for simplicity that the volume is normalized to 1. Then the number $r_{g(t)}$ coincides with the Yamabe energy at time t. Hence, the number r_∞ can be interpreted

as the limit of the Yamabe energy as $t \to \infty$. The difference $r_{g(t)} - r_\infty$ can be expressed as a space-time integral

$$r_{g(t)} - r_\infty = \frac{n-2}{2} \int_t^\infty \int_M (R_{g(\tau)} - r_{g(\tau)})^2 \, d\mathrm{vol}_{g(\tau)} \, d\tau. \tag{14}$$

Hence, we can use (13) and Hölder's inequality to derive a differential inequality for the function $r_{g(t)} - r_\infty$. This implies

$$\int_0^\infty \left(\int_M (R_{g(t)} - r_{g(t)})^2 \, d\mathrm{vol}_{g(t)} \right)^{\frac{1}{2}} dt < \infty. \tag{15}$$

This estimate can be used to rule out volume concentration. More precisely, given any positive real number η, we can find a real number $r > 0$ such that

$$\sup_{x \in M, \, t \geq 0} \int_{B_r(x)} u(t)^{\frac{2n}{n-2}} \, d\mathrm{vol}_{g_0} \leq \eta,$$

where $B_r(x)$ denotes a geodesic ball in the background metric g_0. In light of the results of Schwetlick and Struwe, it follows that

$$\sup_{x \in M, \, t \geq 0} u(x,t) < \infty.$$

Thus, the Yamabe flow converges to a metric of constant scalar curvature as $t \to \infty$. Moreover, if (13) holds with $\gamma = 1$, then the flow converges to the limiting metric at an exponential rate.

To prove Lemma 3.3, we need to find a positive real number ε_0 and a family of auxiliary functions $\bar{u}_{(p,\varepsilon)}$ ($p \in M$, $0 < \varepsilon < \varepsilon_0$) such that

$$E_{g_0}(\bar{u}_{(p,\varepsilon)}) \leq Y(S^n) \tag{16}$$

and $\bar{u}_{(p,\varepsilon)}$ has the "right" asymptotic behavior as $\varepsilon \to 0$. For $n \leq 5$ the existence of such a family of test functions follows from work of R. Schoen [29]. The same approach works if (M, g_0) is locally conformally flat.

Another ingredient in the proof of Lemma 3.3 is an inequality for real-analytic functions due to Lojasiewicz. This inequality was used in the work of L. Simon on the asymptotic behavior of gradient flows [37]. The Lojasiewicz inequality is typically applied to prove the uniqueness of the asymptotic limit of a gradient flow once a-priori estimates have been established.

We cannot, in general, expect (13) to be true for $\gamma = 1$. Indeed, if (13) holds for $\gamma = 1$, then the flow converges to the limiting metric at an exponential rate. This is unlikely to be true in the presence of degenerate solutions.

4. Convergence of the Yamabe flow in dimension greater or equal to 6

We next consider the case $n \geq 6$. In order to prove that the Yamabe flow approaches a metric of constant scalar curvature as $t \to \infty$, we need to construct a family of test functions $\bar{u}_{(p,\varepsilon)}$ that satisfy the inequality (16) among other technical conditions. To this end, it is natural to impose conditions on the Weyl conformal curvature tensor. For example, if we assume that $|W(p)| > 0$ for all $p \in M$, then we can use a result due to Aubin [1] to prove the existence of a family of auxiliary functions with the desired properties.

More generally, suppose that p is a point on M, and let $d = [\frac{n-2}{2}]$ be the largest integer less than or equal to $\frac{n-2}{2}$. If the Weyl tensor does not vanish to an order greater than $d-2$ at p, then we can take advantage of the local geometry to construct a test function with Yamabe energy less than $Y(S^n)$. On the other hand, if the Weyl tensor vanishes to an order greater than $d-2$ at p, we expect that the positive mass theorem can be used to push the energy of the test function below $Y(S^n)$. This motivates the following definition.

Definition 4.1. Let l be a positive integer. We denote by $Z_l(g_0)$ the set of all points $p \in M$ such that

$$\lim_{x \to p} d(x, p)^{2-l} \, |W(x)| = 0,$$

where $W(x)$ denotes the Weyl tensor associated with the metric g_0, and $d(\cdot, \cdot)$ denotes the geodesic distance relative to that metric.

Observe that the set $Z_l(g_0)$ depends only on the conformal class of g_0. It is easy to see that $Z_l(g_0)$ is a compact subset of M. Moreover, we have $M = Z_1(g_0) \supset Z_2(g_0) \supset \cdots$.

Theorem 4.2. *Suppose that $n \geq 6$ and $Z_d(g_0) = \emptyset$ for $d = [\frac{n-2}{2}]$. Then, for every initial metric in the conformal class of g_0, the Yamabe flow has a global solution which approaches a metric of constant scalar curvature as $t \to \infty$.*

To prove Theorem 4.2, we consider an arbitrary point $p \in M$. By a result of J. Lee and T. Parker, we can find a metric g in the conformal class of g_0 such that

$$\det g(x) = 1 + O(|x|^{2d+2}) \tag{17}$$

in geodesic normal coordinates around p (see [21] or [35]). This is called the conformal normal coordinate system. Working in conformal normal coordinates serves two purposes: first, the condition (17) allows us to simplify some of the calculations. Second, it can be shown that the metric agrees with the flat metric to the maximal order permitted by the Weyl tensor. More precisely, if $p \in Z_d(g_0)$, then $g_{ik}(x) = \delta_{ik} + O(|x|^{d+1})$ in conformal normal coordinates. (Conversely, if $g_{ik}(x) = \delta_{ik} + O(|x|^{d+1})$ for any metric conformally equivalent to g_0, then clearly p belongs to the set $Z_d(g_0)$.)

It is convenient to write the Riemannian metric in the form $g(x) = \exp(h(x))$, where $h(x)$ is a symmetric 2-tensor satisfying

$$\operatorname{tr} h(x) = O(|x|^{2d+2}). \tag{18}$$

We denote by $H_{ik}(x) = \sum_{2 \le |\alpha| \le d} h_{ik,\alpha}\, x^\alpha$ the Taylor polynomial of order d associated with the function $h_{ik}(x)$. Since $p \notin Z_d(g_0)$, at least one of the polynomials $H_{ik}(x)$ $(1 \le i, k \le n)$ is not identically zero.

Given a positive real number ε, we define a function $u_\varepsilon : \mathbb{R}^n \to \mathbb{R}$ by

$$u_\varepsilon(x) = \left(\frac{\varepsilon}{\varepsilon^2 + |x|^2}\right)^{\frac{n-2}{2}},$$

so that

$$\Delta u_\varepsilon + n(n-2)\, u_\varepsilon^{\frac{n+2}{n-2}} = 0. \tag{19}$$

Our aim is to construct a test function $\bar{u}_{(p,\varepsilon)}$ which is close to u_ε and has Yamabe energy less than $Y(S^n)$. To this end, we exploit the saddle point structure of the Einstein–Hilbert action near the standard metric on S^n (see [6], Section 4G). We first choose a vector field $V^\varepsilon : \mathbb{R}^n \to \mathbb{R}^n$ such that

$$\sum_{k=1}^n \partial_k \Big[u_\varepsilon^{\frac{2n}{n-2}} \left(H_{ik} - \partial_i V_k^\varepsilon - \partial_k V_i^\varepsilon + \frac{2}{n} \operatorname{div} V^\varepsilon\, \delta_{ik} \right) \Big] = 0 \tag{20}$$

for $i = 1, \dots, n$. This is a linear elliptic system. In order to construct a solution to (20), it suffices to minimize the functional

$$\int_{\mathbb{R}^n} u_\varepsilon^{\frac{2n}{n-2}} \sum_{i,k=1}^n \left(H_{ik} - \partial_i V_k - \partial_k V_i + \frac{2}{n} \operatorname{div} V\, \delta_{ik} \right)^2$$

over all vector fields $V : \mathbb{R}^n \to \mathbb{R}^n$.

In the next step, we define a function $v_\varepsilon : \mathbb{R}^n \to \mathbb{R}$ by

$$v_\varepsilon = \sum_{k=1}^n \partial_k u_\varepsilon\, V_k^\varepsilon + \frac{n-2}{2n}\, u_\varepsilon \operatorname{div} V^\varepsilon.$$

It follows from (20) that the function v_ε solves the linearized equation

$$\Delta v_\varepsilon + n(n+2)\, u_\varepsilon^{\frac{4}{n-2}}\, v_\varepsilon = \sum_{i,k=1}^n \frac{n-2}{4(n-1)}\, u_\varepsilon\, \partial_i \partial_k H_{ik}. \tag{21}$$

The fact that v_ε is a solution of the linearized equation (21) suggests that $u_\varepsilon + v_\varepsilon$ is a

good candidate for a test function. Indeed, one can show that

$$\begin{aligned}&\int_{B_\delta(0)} \Big(\frac{4(n-1)}{n-2}\,|d(u_\varepsilon+v_\varepsilon)|_g^2 + R_g\,(u_\varepsilon+v_\varepsilon)^2\Big) \\ &\quad\leq \bigg(\int_{B_\delta(0)} (u_\varepsilon+v_\varepsilon)^{\frac{2n}{n-2}}\bigg)^{\frac{n-2}{n}} Y(S^n) \\ &\qquad - \theta \sum_{2\leq|\alpha|\leq d} \sum_{i,k=1}^n |h_{ik,\alpha}|^2\,\varepsilon^{2|\alpha|} + C(\delta)\,\varepsilon^{n-2}\end{aligned} \tag{22}$$

if n is odd. A similar estimate holds if n is even: in this case, we have

$$\begin{aligned}&\int_{B_\delta(0)} \Big(\frac{4(n-1)}{n-2}\,|d(u_\varepsilon+v_\varepsilon)|_g^2 + R_g\,(u_\varepsilon+v_\varepsilon)^2\Big) \\ &\quad\leq \bigg(\int_{B_\delta(0)} (u_\varepsilon+v_\varepsilon)^{\frac{2n}{n-2}}\bigg)^{\frac{n-2}{n}} Y(S^n) \\ &\qquad - \theta \sum_{2\leq|\alpha|\leq d-1} \sum_{i,k=1}^n |h_{ik,\alpha}|^2\,\varepsilon^{2|\alpha|} \\ &\qquad - \theta \sum_{|\alpha|=d} \sum_{i,k=1}^n |h_{ik,\alpha}|^2\,\varepsilon^{n-2}\,\log\frac{1}{\varepsilon} + C(\delta)\,\varepsilon^{n-2}.\end{aligned} \tag{23}$$

In both inequalities, θ is a positive constant that depends only on n. It remains to extend the function $u_\varepsilon + v_\varepsilon$ to all of M. In view of (22) and (23), this can be done in such a way that the Yamabe energy of the resulting function is less than $Y(S^n)$ if ε is sufficiently small. The details will appear in a forthcoming paper.

We expect that the conclusion of Theorem 4.2 is still valid without the condition $Z_d(g_0) = \emptyset$. A proof of this conjecture will likely involve the positive mass theorem. The positive mass theorem was first proved in dimension 3 by R. Schoen and S.T. Yau using minimal surface techniques [33]. This argument can be extended up to dimension 7, cf. [31]. E. Witten gave an alternative proof of the positive mass theorem based on spinor methods [41]. (This approach works only for spin manifolds.) R. Bartnik extended Witten's arguments to prove the positive mass theorem for spin manifolds of any dimension [4]. J. Lohkamp recently announced a proof of the positive mass theorem in arbitrary dimension, which does not require the manifold to be spin [24].

5. Compactness of the set of constant scalar curvature metrics in a given conformal class

In this section, I will review several recent results concerning the set of solutions to (6). In particular, I will discuss under what conditions the set of solutions is compact. These

results are remarkably similar to those stated in the preceding sections. As above, we assume that M is a compact manifold of dimension $n \geq 3$ without boundary.

Theorem 5.1. *Suppose that $n \leq 7$ or (M, g_0) is locally conformally flat. Moreover, we assume that (M, g_0) is not conformally equivalent to the standard sphere S^n. Let r be a fixed real number, and let u be a positive solution of* (6). *Then there exists a constant C, depending only on g_0 and r, such that $\|u\|_{C^2(M,g_0)} \leq C$ and $\inf_M u \geq 1/C$.*

This compactness result was proved by R. Schoen in [30] (see also [31] and [32]). Y. Y. Li and M. Zhu gave an alternative proof in dimension 3 [23]. The extension to dimensions 4 and 5 is due to O. Druet [11]. The cases $n = 6$ and $n = 7$ were solved independently by Y.Y. Li and L. Zhang [22] and F. Marques [25].

M. Khuri and R. Schoen [20] recently established a compactness result in arbitrary dimension. Among other things, Khuri and Schoen proved that the Weyl tensor vanishes to an order greater than $[\frac{n-6}{2}]$ at each blow-up point. In particular, if $Z_d(g_0) = \emptyset$ for $d = [\frac{n-2}{2}]$, then blow-up cannot occur.

Theorem 5.2. *Suppose that $n \geq 8$ and $Z_d(g_0) = \emptyset$ for $d = [\frac{n-2}{2}]$. Moreover, let r be a fixed real number. Then there exists a constant C, depending only on g_0 and r, such that $\|u\|_{C^2(M,g_0)} \leq C$ and $\inf_M u \geq 1/C$ for every positive solution of* (6).

A special case of Theorem 5.2 was proved in a recent paper by Y. Y. Li and L. Zhang [22]. Li and Zhang assumed that $n \geq 8$ and $|W(p)| + |\nabla W(p)| > 0$ for all $p \in M$. (This condition is equivalent to $Z_3(g_0) = \emptyset$.) The proof of the main result in [22] uses special properties of conformal normal coordinates established by E. Hebey and M. Vaugon [17].

Moreover, Khuri and Schoen showed that the condition $Z_d(g_0) = \emptyset$ can be removed by means of the positive mass theorem. Since the positive mass theorem holds for spin manifolds of any dimension, this yields the following result:

Theorem 5.3. *Suppose that M is a spin manifold and (M, g_0) is not conformally equivalent to the standard sphere S^n. Moreover, suppose that u is a positive solution of* (6) *for some fixed real number r. Then $\|u\|_{C^2(M,g_0)} \leq C$ and $\inf_M u \geq 1/C$, where C depends only on g_0 and r.*

It is shown in [20] that the compactness result remains true if the equation (6) is replaced by a family of subcritical equations. This is useful in some applications. For example, this can be used to obtain results concerning the number of constant scalar curvature metrics in a given conformal class.

It is interesting to compare the results above to the following result of D. Pollack (see [28], Theorem 0.1):

Theorem 5.4. *Suppose that $Y(M, g_0) > 0$. Given any positive integer N, there exists a Riemannian metric g with the following properties:*

(i) $\|g - g_0\|_{C^0(M,g_0)} \leq 1/N$.

(ii) *The equation* $\frac{4(n-1)}{n-2}\,\Delta_g u - R_g\,u + u^{\frac{n+2}{n-2}} = 0$ *has at least N positive solutions.*

It follows from the results mentioned above that Theorem 5.4 cannot hold if the C^0-norm is replaced by the C^l-norm for a sufficiently large integer l (which may depend on the dimension n). The reason is that the a-priori estimates for solutions of (6) are stable under perturbations of the background metric that are small in the C^l-topology.

The topology and geometry of contact structures in dimension three

Ko Honda *

Abstract. The goal of this article is to survey recent developments in the theory of contact structures in dimension three.

Mathematics Subject Classification (2000). Primary 57M50; Secondary 53C15.

Keywords. Tight, contact structure, bypass, open book decomposition, mapping class group, Dehn twists, Reeb vector field, contact homology.

In this article we survey recent developments in three-dimensional contact geometry. Three-dimensional contact geometry lies at the interface between 3- and 4-manifold geometries, and has been an essential part of the flurry in low-dimensional geometry and topology over the last 20 years. In dimension 3, it relates to foliation theory and knot theory; in dimension 4, there are rich interactions with symplectic geometry. In both dimensions, there are relations with gauge theories such as Seiberg–Witten theory and Heegaard–Floer homology, as well as to dynamics.

1. Tight vs. overtwisted

A contact structure ξ on a 3-manifold M is a (maximally) nonintegrable 2-plane field distribution. In this paper we assume that M is oriented and ξ is the kernel of a global 1-form α which satisfies $\alpha \wedge d\alpha > 0$. (Such a contact structure is often called *coorientable*.) Although ξ is locally $\mathrm{Ker}(dz - ydx)$ by a classical theorem of Pfaff–Darboux and hence has *no local geometry*, the global study of contact structures is rather complicated, in a way that echoes the intricacies of symplectic geometry.

One of the fundamental questions is to determine π_0 of the space $\mathrm{Cont}(M)$ of contact 2-plane fields on M – this is often called the "classification" of contact structures on M. The work of Bennequin [2] (later clarified by Eliashberg [12]) indicated that contact structures, in dimension three, come in two flavors: *tight* and *overtwisted*. We define an *overtwisted disk* to be an embedded disk $D \subset M$ such that $\xi_x = T_x D$ for all $x \in \partial D$. An overtwisted contact structure is one which admits an *overtwisted disk*,

*Supported by an Alfred P. Sloan Fellowship and an NSF CAREER Award.

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

whereas a tight contact structure is one which does not. What Bennequin showed is that the local model $(\mathbb{R}^3, \mathrm{Ker}(dz - ydx))$ is tight – hence locally every contact structure is tight, although globally it may not be. (Showing that a contact structure is tight is highly nontrivial, because one must show that *no* overtwisted disk exists, no matter how complicated the embedding!) Let $\mathrm{Cont}^{\mathrm{OT}}(M)$ be the space of overtwisted contact 2-plane fields on M and $\mathrm{Cont}^{\mathrm{Tight}}(M)$ be the space of tight contact 2-plane fields on M. Eliashberg showed in [13] that $\pi_0(\mathrm{Cont}^{\mathrm{OT}}(M))$ is the same as the homotopy classes of 2-plane fields on M.

The space of tight contact structures, on the other hand, is more intimately related to the topology of M. Eliashberg [12] gave the first classification result for tight contact structures, namely that $\mathrm{Cont}^{\mathrm{Tight}}(S^3)$ is connected. The analysis of tight contact structures on various 3-manifolds has become more manageable in recent years, with the introduction of *convex surfaces* by Giroux [32] and *bypasses* by the author [43]. The world of tight contact structures, as we understand it now, is a veritable zoo!

Two important subcategories of tight contact structures are the *weakly symplectically fillable* ones and the *Stein fillable* ones. In the former case, (M, ξ) bounds a symplectic 4-manifold (X, ω) and $\omega|_\xi > 0$. In the latter, (M, ξ) bounds a Stein domain (X, ω, J) and $\omega = d\alpha$ on M for a contact 1-form α that defines ξ. Fillable contact structures (of either type) are tight by a theorem of Gromov [36] and Eliashberg [14]; this was proved using Gromov's theory of J-holomorphic curves. Prototypical examples of weakly symplectically fillable contact structures are the perturbations of taut codimension 1 foliations, as explained in Eliashberg–Thurston [19]. Etnyre and the author [23] showed that there exist tight contact structures which are not weakly symplectically fillable. Other examples were later obtained by Lisca–Stipsicz [51], [52]. Eliashberg [15] showed that there are weakly symplectically fillable contact structures on the 3-torus T^3 which are not Stein fillable. Further examples were given on torus bundles by Ding–Geiges [11].

$$\text{Tight} \supsetneq \text{Weakly symplectically fillable} \supsetneq \text{Stein fillable}$$

It is known that not every 3-manifold admits a tight contact structure. Etnyre and the author [22] showed that the Poincaré homology sphere with orientation opposite to the one induced on the link of an algebraic singularity has no tight contact structure. Lisca and Stipsicz [54] have since shown that the Poincaré homology sphere can be incorporated into a larger class of small Seifert fibered spaces which do not admit tight contact structures. Since all these examples of 3-manifolds without tight contact structures are Seifert fibered, it is natural to ask whether tight contact structures exist on all hyperbolic 3-manifolds. It turns out that *universally tight* contact structures, i.e., contact structures ξ on M that pull back to tight contact structures on the universal cover of M, do not always exist on hyperbolic 3-manifolds [47]. Compare this to foliation theory where Roberts–Shareshian–Stein [66] have shown that there are

infinitely many hyperbolic 3-manifolds which do not admit Reebless codimension 1 foliations. There is related work of Calegari–Dunfield [4] and Fenley [25], as well as a different approach using Seiberg–Witten Floer homology, due to Kronheimer–Mrowka–Ozsváth–Szabó [50]. However, it is still conceivable that every hyperbolic 3-manifold has a tight contact structure. (The Weeks manifold – the closed hyperbolic 3-manifold with the smallest known volume – *does* have Stein fillable contact structures with either orientation. This can be easily seen by appealing to surgery on the Borromean rings as in Gompf [34].)

Next we turn our attention to the question of classification. For simplicity, assume that M is irreducible. Colin [6] and Kazez, Matić and the author [44], independently, have shown that $\pi_0(\mathrm{Cont}^{\mathrm{Tight}}(M))$ is infinite for a *toroidal* 3-manifold M, namely one which admits an embedded torus for which $\pi_1(T) \hookrightarrow \pi_1(M)$. On the other hand, if M is not toroidal, then $\pi_0(\mathrm{Cont}^{\mathrm{Tight}}(M))$ is finite by a theorem of Colin, Giroux and the author [7], [8]. The latter generalizes an earlier theorem, due to Kronheimer–Mrowka [48], which states that there are finitely many homotopy classes of 2-plane fields which carry symplectically fillable contact structures.

2. Open book decompositions

A fundamental advance in contact geometry is the work of Giroux [33] (building on earlier work of Thurston–Winkelnkemper [69], Bennequin [2], Eliashberg–Gromov [18], and Torisu [70]), which relates contact structures and open book decompositions. We briefly summarize this work, and then describe the developments that have taken place since Giroux's ICM 2002 article [33].

Let (S, h) be a pair consisting of a compact oriented surface S with nonempty boundary and a diffeomorphism $h\colon S \to S$ which restricts to the identity on ∂S, and let K be a link in a closed oriented 3-manifold M. An *open book decomposition* for M with *binding* K is a homeomorphism between $((S \times [0,1])/_{\sim_h}, (\partial S \times [0,1])/_{\sim_h})$ and (M, K). The equivalence relation $\sim_h$ is generated by $(x,1) \sim_h (h(x),0)$ for $x \in S$ and $(y,t) \sim_h (y,t')$ for $y \in \partial S$. We will often identify M with $(S \times [0,1])/_{\sim_h}$; with this identification $S_t = S \times \{t\}$, $t \in [0,1]$, is called a *page* of the open book decomposition and h is called the *monodromy map*. Two open book decompositions are *equivalent* if there is an ambient isotopy taking binding to binding and pages to pages. We will denote an open book decomposition by (S, h), although, strictly speaking, an open book decomposition is determined by the triple (S, h, K). There is a slight difference – if we do not specify $K \subset M$, we are referring to isomorphism classes of open books instead of isotopy classes.

Every closed 3-manifold has an open book decomposition, but it is not unique. One way of obtaining a different open book decomposition of the same manifold is to perform a positive stabilization. (S', h') is a *positive stabilization* of (S, h) if S' is the union of the surface S and a band B attached along the boundary of S (i.e., S' is obtained from S by attaching a 1-handle along ∂S), and h' is defined as follows.

Let γ be a simple closed curve in S' "dual" to the cocore of B (i.e., γ intersects the cocore of B at exactly one point) and let $\mathrm{id}_B \cup h$ be the extension of h by the identity map to $B \cup S$. Also let R_γ be a *positive* or *right-handed* Dehn twist about γ. Then for a *positive* stabilization h' is given by $R_\gamma \circ (\mathrm{id}_B \cup h)$. It is well-known that, if (S', h') is a positive stabilization of an open book decomposition (S, h) of (M, K), then (S', h') is an open book decomposition of (M, K') where K' is obtained by a Murasugi sum of K (also called the *plumbing* of K) with a positive Hopf link.

A contact structure ξ is said to be *supported* by the open book decomposition (S, h, K) if there is a contact 1-form α satisfying the following:

1. $d\alpha$ restricts to a symplectic form on each fiber S_t;
2. K is transverse to ξ, and the orientation on K given by α is the same as the boundary orientation induced from S coming from the symplectic structure.

Thurston and Winkelnkemper [69] showed that any open book decomposition (S, h, K) of M supports a contact structure ξ. Moreover, the contact planes can be made arbitrarily close to the tangent planes of the pages (away from the binding).

The following result provides a converse (and more) due to Giroux [33].

Theorem 2.1 (Giroux). *Every contact structure (M, ξ) on a closed 3-manifold M is supported by some open book decomposition (S, h, K). Moreover, two open book decompositions (S, h, K) and (S', h', K') which support the same contact structure (M, ξ) become equivalent after applying a sequence of positive stabilizations to each.*

2.1. Concave symplectic fillings. Consider a closed 2-form ω_0 on the contact 3-manifold (M, ξ) for which $\omega_0|_\xi > 0$. (Such a 2-form ω_0 is often called a *dominating* 2-form for ξ.) A *concave symplectic filling* for (M, ξ, ω_0) is a symplectic 4-manifold (X, ω) for which $\partial X = -M$ and $i^*\omega = \omega_0$, where $i\colon M \to X$ is the inclusion.

The use of open book decompositions enabled Eliashberg [16] and Etnyre [20] to construct concave symplectic fillings for any contact 3-manifold (M, ξ) together with a dominating 2-form ω_0. This turned out to be the only missing ingredient in Kronheimer–Mrowka's proof of Property P for knots [49].

Theorem 2.2 (Kronheimer–Mrowka). *If $K \subset S^3$ is a nontrivial knot and $S^3_1(K)$ is the three-manifold obtained by $+1$-surgery along K, then $\pi_1(S^3_1(K)) \neq 0$.*

In the 1980's Gabai [27] proved that $M = S^3_0(K)$ admits a taut foliation $\mathcal{F}$ ($\neq$ the foliation of $S^1 \times S^2$ by $\{pt\} \times S^2$) if K is not the unknot. By Eliashberg–Thurston [19], $\mathcal{F}$ can be perturbed into a pair ξ_+, ξ_- of positive and negative contact structures, and $X = M \times [0, 1]$ admits a symplectic structure ω for which $\omega|_{\xi_+} > 0$ at $M \times \{1\}$ and $\omega|_{\xi_-} < 0$ at $M \times \{0\}$. This used to be called a *symplectic semi-filling* of (M, ξ_+) since ∂X had more than one component. (We no longer have the need to use the "semi" terminology, thanks to Eliashberg and Etnyre.) The work of Eliashberg and

Etnyre enabled one to fill both of the components of ∂X so that (M, ξ_+) was now embedded in a closed symplectic manifold X'. Kronheimer and Mrowka were then able to appeal to: (i) the work by Taubes [67] on the nontriviality of Seiberg–Witten invariants of X'; (ii) the work by Feehan and Leness (see [24], for example) relating the Seiberg–Witten and Donaldson invariants; (iii) a stretching argument in instanton Floer homology; and (iv) Floer's exact triangle [26] for instanton Floer homology.

Another application of the existence of concave symplectic fillings is progress by Etnyre [21] on the following problem: Given a contact manifold (M, ξ), what is the minimum genus amongst all the pages of open books corresponding to ξ? Etnyre has shown that many interesting classes of tight contact structures (among them perturbations of taut foliations) do not admit planar open book decompositions.

2.2. Heegaard–Floer homology. Another important application of the open book framework is the definition of the *contact class* $c(\xi)$ in the Heegaard Floer homology of Ozsváth–Szabó [59], [60]. Using open book decompositions, Ozsváth and Szabó [61] defined an invariant of the contact structure (M, ξ), which is an element $c(\xi) \in \widehat{HF}(-M)$. Among the many properties enjoyed by $c(\xi)$, we have the following:

1. If ξ is overtwisted, then $c(\xi) = 0$.

2. If (M', ξ') is obtained from (M, ξ) by Legendrian (-1) surgery, and $c(\xi) \neq 0$, then $c(\xi') \neq 0$.

3. If ξ is weakly symplectically fillable, then $c(\xi) \neq 0$ (provided "twisted" coefficients are used).

Lisca and Stipsicz [53] showed that the contact class was surprisingly good at detecting tight contact structures – Heegaard–Floer homology could now be used to prove the tightness of many contact structures which were hitherto only conjectured to be tight. This area is currently an active area of research, with contributions from Ghiggini [30], [31], Plamenevskaya [62], [63], etc.

3. Right-veering

We will now seek to explain the roles of tightness, weak symplectic fillability, and Stein fillability in the open book context. Except for Theorem 3.1, this is joint work with W. Kazez and G. Matić and further details can be found in [45], [46].

Let S be a compact oriented surface with nonempty boundary and denote by $\mathrm{Aut}(S, \partial S)$ the group of (isotopy classes of) diffeomorphisms of S which restrict to the identity on ∂S. We have the monoid $\mathrm{Dehn}^+(S, \partial S) \subset \mathrm{Aut}(S, \partial S)$ of products of positive Dehn twists. The following is due to Giroux [33], inspired by the work of Loi–Piergallini [55]:

Theorem 3.1 (Giroux). *A contact structure ξ on M is Stein fillable if and only if ξ is supported by some open book (S, h, K) with $h \in \mathrm{Dehn}^+(S, \partial S)$.*

We remark that the theorem does not say that *every* open book (S, h) for (M, ξ) Stein fillable satisfies $h \in \mathrm{Dehn}^+(S, \partial S)$.

There is another monoid, namely the monoid $\mathrm{Veer}(S, \partial S)$ of *right-veering* diffeomorphisms, which is intimately connected with the tight contact structures. Given two properly embedded oriented arcs α and β with the same initial point $x \in \partial S$, we say α is *to the left* of β if the following holds: Isotop α and β, while fixing their endpoints, so that they intersect transversely (this include the endpoints) and with the fewest possible number of intersections. We then say α is to the left of β if either $\alpha = \beta$ or the tangent vectors $(\dot\beta(0), \dot\alpha(0))$ define the orientation on S at x. Then h is *right-veering* if for every choice of basepoint $x \in \partial S$ and every choice of α based at x, $h(\alpha)$ is to the right of α. One easily sees that $\mathrm{Dehn}^+(S, \partial S) \subset \mathrm{Veer}(S, \partial S)$.

Theorem 3.2 (Honda–Kazez–Matić [45]). *A contact structure (M, ξ) is tight if and only if all of its open book decompositions (S, h) are such that $h \in \mathrm{Veer}(S, \partial S)$.*

This theorem is an improvement over the "sobering arc" criterion for overtwistedness, given by Goodman [35].

Now recall Thurston's classification of surface diffeomorphisms [68], which improved upon earlier work of Nielsen [56], [57], [58]. A diffeomorphism $h\colon S \to S$ satisfies one of the following:

1. h is *reducible*, i.e., there exists an essential multicurve γ such that $h(\gamma)$ is isotopic to γ.
2. h is homotopic to a *periodic homeomorphism* ψ, i.e., there is an integer $n > 0$ such that $\psi^n = \mathrm{id}$.
3. h is homotopic to a *pseudo-Anosov homeomorphism* ψ.

We will now define the *fractional Dehn twist coefficients*, extensively studied by Gabai and Oertel (see for example [28]) in the context of essential laminations. Suppose for simplicity that ∂S is connected and $h \in \mathrm{Aut}(S, \partial S)$ is homotopic to a pseudo-Anosov representative ψ. (The periodic case is analogous.) Let $H\colon S \times [0, 1] \to S$ be an isotopy from h to ψ, i.e., $H(x, 0) = h(x)$ and $H(x, 1) = \psi(x)$. On the boundary of S, ψ has $2n$ fixed points, n attracting and n repelling. Let us label the attracting fixed points $x_1, \ldots, x_n$ in order around ∂S. Now define $\beta\colon \partial S \times [0, 1] \to \partial S \times [0, 1]$ by sending $(x, t) \mapsto (H(x, t), t)$. It follows that the arc $\beta(x_i \times [0, 1])$ connects $(x_i, 0)$ and $(x_{i+k}, 1)$, for some k. We call β a *fractional Dehn twist* by an amount $c \in \mathbb{Q}$, where $c \equiv k/n$ modulo 1 is the number of times $\beta(x_i \times [0, 1])$ circles around $\partial S \times [0, 1]$ (here circling in the direction of ∂C is considered positive). Form the union of $\partial S \times [0, 1]$ and S by gluing $\partial S \times \{1\}$ and ∂S. By identifying this union with S, we construct the homeomorphism $\beta \cup \psi$ on S which is isotopic to h, relative

to ∂S. (We will assume that $h = \beta \cup \psi$, although ψ is usually just a homeomorphism, not a diffeomorphism.)

Theorem 3.3 (Honda–Kazez–Matić [45]). *If h is periodic, then h is right-veering if and only if $c \geq 0$. If h is pseudo-Anosov, then h is right-veering if and only if $c > 0$.*

Theorem 3.2 is not completely satisfactory – ideally one should just need to look at one (S, h) (instead of its equivalence class under stabilizations) to determine whether (S, h) is tight, fillable, etc. To this end, let us consider the case of the once-punctured torus S. Suppose h is pseudo-Anosov. Then the following hold:

1. If $c \leq 0$, then h is overtwisted.
2. If $c > 0$, then h is tight.
3. If $c \geq 1$, then h is weakly symplectically fillable and universally tight.
4. For any $c > 0$ there exist $h \in \mathrm{Veer}(S, \partial S) - \mathrm{Dehn}^+(S, \partial S)$ whose fractional Dehn twist coefficient is equal to c.

For the once-punctured torus, $c > 0$ is equivalent to $c \geq \frac{1}{2}$, since the pseudo-Anosov representative ψ will have $n = 2$ attracting fixed points. (2) is proved using Heegaard–Floer homology. (3) is proved by showing that the taut foliations constructed by Roberts in [64], [65] can be perturbed to the contact structure adapted to the open book. (4) is proved by looking at a function on the Farey tessellation called the *Rademacher function* (see for example [29]). It is very plausible that many, if not all, of the $h \in \mathrm{Veer}(S, \partial S) - \mathrm{Dehn}^+(S, \partial S)$ never become products of positive Dehn twists after (repeated) stabilization, and that such (S, h) are indeed not Stein fillable.

Once we restrict our attention to right-veering (S, h), calculations in *contact homology* and *Heegaard–Floer homology* both become more manageable. In the rest of the paper, we focus on contact homology, leaving the Heegaard–Floer aspects for another occasion.

4. Contact homology

Given a contact form α for (M, ξ), there is a corresponding *Reeb vector field* R defined as follows: $i_R d\alpha = 0$, $i_R \alpha = 1$. One of the motivating questions in the study of the dynamics of Reeb vector fields is the following Weinstein conjecture (in dimension three):

Conjecture 4.1 (Weinstein conjecture). Let (M, ξ) be a contact 3-manifold. Then for any contact form α with $\mathrm{Ker}(\alpha) = \xi$, the corresponding Reeb vector field R admits a closed periodic orbit.

The fundamental step was taken when Hofer [37] studied J-holomorphic disks in the symplectization $(\mathbb{R} \times M, d(e^t\alpha))$, and proved that there is always bubbling (and hence a closed periodic orbit) when (M, ξ) is overtwisted or $\pi_2(M) \neq 0$. This showed that the Weinstein conjecture holds for overtwisted contact structures and 3-manifolds with $\pi_2(M) \neq 0$. (Hofer also showed that the Weinstein conjecture holds for S^3.) Hofer's work has subsequently bubbled off a large industry in contact dynamics, and we mention only a few highlights. The properties of holomorphic curves in symplectizations were analyzed by Hofer–Wysocki–Zehnder [39], [40], [41]. Also Eliashberg, Givental and Hofer [17] have suggested a *Symplectic Field Theory*, a Floer-type theory involving closed orbits of Reeb vector fields and holomorphic curves "bounding" these closed orbits. The technical details of this theory have finally started to appear – see [42].

The Weinstein conjecture in dimension three has been verified for contact structures which admit planar open book decompositions [1] (also see related work of Etnyre [21]), for certain Stein fillable contact structures [5], [71], and for certain universally tight contact structures on toroidal manifolds [3]. We also refer the reader to the survey article by Hofer [38].

In [9], Colin and the author prove the following:

Theorem 4.2 (Colin–Honda [9]). *The Weinstein conjecture holds for contact structures (M, ξ) which have open books (S, h) with periodic monodromy.* (*Here S may have many boundary components.*)

Suppose ∂S is connected. If the fractional Dehn twist coefficient $c < 0$, then (M, ξ) is overtwisted by Theorem 3.3 above. If $c = 0$, then M is a connected sum, and if $0 < c < \frac{1}{2g(S)-1}$, then the universal cover of M is S^3. Here $g(S)$ is the genus of the closed surface obtained by capping off S with a disk. In all the above cases, the Weinstein conjecture has been settled by Hofer [37].

It remains to examine the case where $c \geq \frac{1}{2g(S)-1}$. The following is the main result in [9]:

Theorem 4.3 (Colin–Honda [9]). *The cylindrical contact homology of (M, ξ), as defined below, exists and is nonzero if $c \geq \frac{1}{2g(S)-1}$.*

The nontriviality of the cylindrical contact homology for (M, ξ) implies the Weinstein conjecture for (M, ξ).

Contact homology is the simplest version of Symplectic Field Theory which takes place in the symplectization $(\mathbb{R} \times M, d(e^t\alpha))$ and counts punctured J-holomorphic spheres $\tilde{u}\colon \Sigma \to \mathbb{R} \times M$ with one positive end and many negative ends. (Here t is the coordinate for $\mathbb{R}$.) *Cylindrical* contact homology, if it exists, is a version which only counts J-holomorphic cylinders, i.e., spheres with two punctures. The cylindrical theory exists, if the following condition holds:

Condition 4.4. There exists a nondegenerate Reeb vector field R for which no contractible periodic orbit γ with Conley–Zehnder index $\mu(\gamma) = 0$, 1 or 2 bounds a finite energy plane (at the positive end) in the symplectization $\mathbb{R} \times M$.

Assuming Condition 4.4, we now define the *cylindrical contact homology*.

Let α be a contact 1-form for which R is a nondegenerate Reeb vector field, and let J be an almost complex structure on $\mathbb{R}\times M$ which is *adapted* to the symplectization: If we write $T_{(t,x)}(\mathbb{R}\times M) = \mathbb{R}\frac{\partial}{\partial t}\oplus\mathbb{R}R\oplus\xi$, then J maps ξ to itself and sends $\frac{\partial}{\partial t}\mapsto R$, $R\mapsto -\frac{\partial}{\partial t}$. Let $\mathcal{P}$ be the collection of closed orbits of R. (We may need to omit certain closed orbits, but we will not worry about these technicalities here.)

If γ is a contractible periodic orbit which bounds a disk D, then we trivialize $\xi|_D$ and define the *Conley–Zehnder index* $\mu(\gamma, D)$ to be the Conley–Zehnder index of the path of symplectic maps $\{d\phi_t : \xi_{\gamma(0)} \to \xi_{\gamma(t)}, t\in[0,T]\}$ with respect to this trivialization, where ϕ_t is the time t flow of the Reeb vector field R and T is the period of γ. In our case, M is Seifert fibered and $\pi_2(M)=0$, so $\mu(\gamma)$ is independent of the choice of D. If γ, γ' are not contractible, but belong to the same *free homotopy class* $[\gamma]=[\gamma']$, then let Z be the cylinder between γ and γ'. Trivialize $\xi|_Z$ and define the *relative* Conley–Zehnder index $\mu(\gamma,\gamma')$ to be the Conley–Zehnder index of γ minus the Conley–Zehnder index of γ', both calculated with respect to this trivialization. Again, in our case, $\mu(\gamma,\gamma')$ does not depend on our choice of Z.

Define the moduli space

$$\mathcal{M}(J,\gamma_+,\gamma_-) = \left\{ \begin{array}{c} J\text{-holomorphic cylinders } \tilde{u}=(a,u)\colon \mathbb{R}\times S^1\to\mathbb{R}\times M, \\ \lim_{s\to\pm\infty} u(s,t)=\gamma_\pm(t), \quad \lim_{s\to\pm\infty} a(s,t)=\pm\infty \end{array} \right\}.$$

Here, $\gamma_\pm(t)$ refers to some parametrization of the trajectory $\gamma_\pm$. The convergence for $u(s,t)$ and $a(s,t)$ is in the C^0-topology. The complex structure j on $\mathbb{R}\times S^1$ is the usual one: if (s,t) are coordinates on $\mathbb{R}\times\mathbb{R}/\mathbb{Z}$, then $j\colon \frac{\partial}{\partial s}\mapsto\frac{\partial}{\partial t}$. We choose a *regular* J (still adapted to the symplectization) for which $\mathcal{M}(J,\gamma_+,\gamma_-)$ is a transverse zero set of the $\overline{\partial}$-operator and has the expected dimension $\mu(\gamma_+,\gamma_-)$.

The chain group is the $\mathbb{Q}$-vector space $C=\mathbb{Q}\langle\mathcal{P}\rangle$ generated by $\mathcal{P}$. Now the boundary map $\partial\colon C\to C$ is given on elements $\gamma\in\mathcal{P}$ by:

$$\partial\gamma = \sum_{\gamma'\in\mathcal{P},\ \mu(\gamma,\gamma')=1} \frac{n_{\gamma,\gamma'}}{\kappa(\gamma')}\ \gamma',$$

where $\kappa(\gamma)$ is the multiplicity of γ. If $\mu(\gamma,\gamma')=1$, then $\mathcal{M}(\gamma,\gamma')$ is a 1-dimensional moduli space and we quotient out by translations in the $\mathbb{R}$-direction. Then $n_{\gamma,\gamma'}$ is a signed count of points in $\mathcal{M}(\gamma,\gamma')/\mathbb{R}$, following a coherent orientation scheme given in [17]. If γ, γ' are multiply covered, then each non-multiply-covered holomorphic curve $\tilde{u}\in\mathcal{M}(\gamma,\gamma')/\mathbb{R}$ contributes $\pm\kappa(\gamma)\kappa(\gamma')$ to $n_{\gamma,\gamma'}$. If $\tilde{u}$ is a k-fold cover of a somewhere injective holomorphic curve, then it is counted as $\pm k(\kappa(\gamma)\kappa(\gamma'))$. The definition of ∂ is extended linearly to all of C. (For the purposes of Theorem 4.3, we can restrict attention to the portion of $\mathcal{P}$ consisting of non-multiply-covered orbits, so we may work with $\mathbb{Z}/2\mathbb{Z}$-coefficients.)

With the above restriction (Condition 4.4) on the Conley–Zehnder indices of contractible periodic orbits, it can be shown that $\partial\circ\partial=0$, hence the cylindrical contact

homology is well-defined. Moreover, it does not depend on the choice of generic J or on the choice of nondegenerate R, provided Condition 4.4 is satisfied.

We now indicate some elements of the proof of Theorem 4.3. The well-definition of cylindrical contact homology is proved by projecting a finite energy plane $\tilde{u} = (a, u) \colon \mathbb{R}^2 \to \mathbb{R} \times M$ to M, observing that $u \colon \mathbb{R}^2 \to M$ is positively transverse to the Reeb vector field R except at complex branch points, and using (a generalization of) the Rademacher function. A similar technique gives restrictions on pairs γ, γ' which admit holomorphic cylinders between them. Since we have enough restrictions on the boundary maps, an Euler characteristic argument gives the result.

In the pseudo-Anosov case we expect the analog of Theorem 4.3 to hold when $c > \frac{1}{n}$, where n is the number of attracting (= number of repelling) periodic points. (These are currently being worked out in [10].) It still remains to consider $c = \frac{1}{n}$ in the pseudo-Anosov case….

Acknowledgements. The author wholeheartedly thanks Francis Bonahon for many suggestions on improving the exposition.

Generalized triangle inequalities and their applications

Michael Kapovich*

Abstract. We present a survey of our recent work on generalized triangle inequalities in infinitesimal symmetric spaces, nonpositively curved symmetric spaces and Euclidean buildings. We also explain how these results can be used to analyze some basic problems of algebraic group theory including the problem of decomposition of tensor products of irreducible representations of complex reductive Lie groups. Among the applications is a generalization of the Saturation Theorem of Knutson and Tao to Lie groups other than $\mathrm{SL}(n, \mathbb{C})$.

Mathematics Subject Classification (2000). Primary 22E46, 20G15, 53C20; Secondary 14L24, 20E42.

Keywords. Symmetric spaces, buildings, tensor product decomposition.

1. Introduction

As we learn in school, given 3 positive numbers a, b, c satisfying the familiar triangle inequalities $a \leq b + c$, etc., one can construct a triangle in the Euclidean plane whose side-lengths are a, b and c. A brief contemplation shows that the same elementary geometry proof works in the hyperbolic plane and, more generally, in all simply-connected complete nonpositively curved Riemannian manifolds.

At the first glance, it appears that this is all one can say about the triangle inequalities. Note however that in all negatively curved simply-connected symmetric spaces, the *metric length* of a geodesic segment is a complete congruence invariant. On the other hand, in higher rank symmetric spaces, the congruence classes of oriented segments are parameterized by the Weyl chamber Δ. We will refer to the parameter $\sigma(\gamma) \in \Delta$ corresponding to an oriented segment γ as its Δ-*length*. The same notion of Δ-length can be defined in Euclidean buildings, where Δ is the Weyl chamber for the finite Weyl group in the associated Euclidean Coxeter complex. In this survey we discuss our recent work appearing in a series of papers with Bernhard Leeb and John Millson ([KLM1], [KLM2], [KLM3], [KM1], [KM2]). It originates with the following basic question:

Question 1.1. Suppose that X is a nonpositively curved simply-connected symmetric space or a Euclidean building. What restrictions on the triples $(\lambda, \mu, \nu) \in \Delta^3$ are

*During the writing of this paper the author was partially supported by the NSF grant DMS-04-05180.

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

necessary and sufficient for existence of an oriented geodesic triangle in X whose Δ-side lengths are λ, μ, ν?

We will see how this question (and related problems) connects to the theory of algebraic groups over real, complex and nonarchimedean valued fields as well as to representation theory of complex reductive Lie groups.

Acknowledgments. I am grateful to all my collaborators for the joint work. I am especially grateful to John Millson for our continuous collaboration in the last 13 years.

2. Metric spaces modelled on Coxeter complexes

Let A be a (finite-dimensional) Euclidean space and W_{aff} be a group of isometries of A generated by reflections in a family of hyperplanes $H \subset A$ (called *walls*). A *half-apartment* is a closed half-space in A bounded by a wall. By choosing the origin $o \in A$ and taking linear parts of the elements of W_{aff} we obtain a group $W = W_{\mathrm{sph}}$ fixing an origin o in A. We require W to be finite. Then W is a finite Coxeter group and the group W_{aff} is called an affine Coxeter (or Weyl) group. The pair (A, W_{aff}) is called a *Euclidean Coxeter complex*. We let $\Delta \subset A$ denote a fundamental domain of the reflection group W: it is a convex cone in A with vertex at o. A point $x \in A$ is called *special* if its stabilizer in W_{aff} is isomorphic to W. It turns out that each Euclidean Coxeter complex has a special point; in what follows we will always assume that $o \in A$ is special.

Example 2.1. Suppose that W is a finite Coxeter group and $W_{\mathrm{aff}} = W \ltimes V$, where V is the full group of translations of A. Such affine Coxeter groups appear naturally in the context of symmetric spaces. Another useful example to keep in mind is given by $W \ltimes Q(R^\vee)$, where W is the finite Weyl group associated with a root system $R \subset V^*$ and $Q(R^\vee) \subset V$ is the coroot lattice of R. In this case W_{aff} is discrete. Such examples appear in the context of Bruhat–Tits buildings associated with groups $\underline{G}(\mathbb{K})$, where $\underline{G}$ is a reductive algebraic group and $\mathbb{K}$ is a field with discrete valuation.

Let Z be a metric space. A *geometric structure* on Z *modelled on* the Euclidean Coxeter complex (A, W_{aff}) consists of an atlas of isometric embeddings $\varphi\colon A \hookrightarrow Z$ satisfying the following compatibility condition:

> For any two charts φ_1 and φ_2, the transition map $\varphi_2^{-1} \circ \varphi_1$ is the restriction of an element of W_{aff}.

The charts and their images, $\varphi(A) \subset Z$, are called *apartments*. We will require that any two points in Z lie in a common apartment. All W_{aff}-invariant notions introduced for the Coxeter complex (A, W_{aff}), such as walls, special points, etc., carry over to geometries modelled on (A, W_{aff}).

Thickness of a space X modelled on (A, W_{aff}) is the cardinality of the set of half-apartments adjacent to a wall in X. In all examples considered in this survey, thickness will be independent of the wall in X. The space X is called *thick* if it has thickness ≥ 3.

Examples of geometric structures modelled on (A, W_{aff}) are provided by simply-connected symmetric spaces of nonpositive curvature (in which case W_{aff} acts transitively on A), Euclidean buildings and *infinitesimal symmetric spaces* $\mathfrak{p}$. The latter is equal to the tangent space to a symmetric space, $\mathfrak{p} = T_o X$. Apartments in $\mathfrak{p}$ correspond to Cartan subalgebras (i.e., the maximal abelian subalgebras) in $\mathfrak{p}$, where $\mathfrak{g} = \mathfrak{p} \oplus \mathfrak{k}$ is the Cartan decomposition of the Lie algebra $\mathfrak{g}$. Although, as a metric space, $\mathfrak{p}$ is nothing but a Euclidean space, its natural group of automorphisms is smaller than $\text{Isom}(\mathfrak{p})$, it is the *Cartan motion group* $K \ltimes \mathfrak{p}$.

Remark 2.2. *Discrete* Euclidean buildings (i.e. the ones with the discrete structure group W_{aff}) can be thought of as both geometric and combinatorial objects. From the combinatorial standpoint, one regards buildings as *polysimplical complexes*. The distance between cells is then a certain W_{aff}-valued function, paths in buildings are replaced by *galleries*, etc. Geometric viewpoint appears more powerful as far as the problems raised in this paper are concerned. For one thing, one can do analysis (rather than combinatorics) on such spaces. As another example, one can *stretch* a piecewise-linear path in an apartment via a homothety while there is no obvious stretching construction for galleries. Importance of stretching will become apparent in Section 5.3.

An important example of a symmetric space to keep in mind is Sym_n, the space of positive-definite symmetric $n \times n$ matrices with real coefficients. Then $\text{Sym}_n = \text{GL}(n, \mathbb{R})/\text{O}(n)$ and the Weyl group of this space is the permutation group S_n.

Similarly, one defines metric spaces modelled on spherical Coxeter complexes. The most important examples of such spaces are spherical buildings.

For a metric space Z modelled on (A, W_{aff}), we define the Δ-valued distance function

$$d_\Delta \colon Z \times Z \to \Delta$$

as follows:

> Given points $x, y \in Z$, find an apartment $\varphi \colon A \to A' \subset Z$ whose image contains x and y. Then consider the vector $\varphi^{-1}(v)$ in A with the tip y and tail x and project this vector to the Weyl chamber Δ via the quotient map $A \to A/W = \Delta$.

Clearly, this definition is independent of the choice of an apartment $\varphi(A)$ containing x, y.

Example 2.3. If $Z = \text{Sym}_n$, then $d_\Delta(x, y)$ is the set of eigenvalues of the matrix $x^{-1}y$, counted with multiplicity and arranged in the decreasing order.

Given the notion of Δ-valued distance between points in Z we can also define the Δ-*length* for piecewise-geodesic paths p in Z by taking the sum of the Δ-lengths of the geodesic subsegments of p.

Observe that the Δ-distance function d_Δ is not (in general) symmetric, however

$$d_\Delta(x, y) = (d_\Delta(y, x))^*,$$

where the vector $v^* = w_0(-v)$ is contragredient to the vector v. (Here w_0 is the longest element of W.)

It follows from the Cartan decomposition that in the case when Z is a (nonpositively curved) symmetric space or an infinitesimal symmetric space, then d_Δ is a complete congruence invariant of an oriented geodesic segment $\overline{xy} \subset Z$:

> There exists an automorphism $g \in \mathrm{Aut}(Z)$ which carries $\overline{x_1y_1}$ to $\overline{x_2y_2}$ if and only if $d_\Delta(x_1, y_1) = d_\Delta(x_2, y_2)$.

The situation in the case of Euclidean buildings is more subtle, we will return to this in Section 4.

Definition 2.4. Given a space X modelled on an affine Coxeter complex, we let $D_n(X)$ denote the collection of tuples $(\lambda_1, \dots, \lambda_n) \in \Delta^n$ such that there exists an oriented geodesic polygon in X with the Δ-side lengths $\lambda_1, \dots, \lambda_n$.

Thus Question 1.1 in the introduction is asking for a description of $D_3(X)$ for the given space X.

3. Generalized triangle inequalities

Suppose that X is either a nonpositively curved simply-connected symmetric space, an infinitesimal symmetric space or a thick Euclidean building, modelled on (A, W_{aff}). A priori, $D_n(X)$ is just a subset in Δ^n. The following theorem establishes basic structural properties of this set.

Theorem 3.1 ([KLM1], [KLM2]). 1. *$D_n(X)$ is a convex homogeneous polyhedral cone.*

2. *$D_n(X)$ depends only on the pair (A, W) and nothing else, not even the type of the space X (i.e., whether this is an infinitesimal symmetric space, symmetric space or a building).*

Corollary 3.2. 1. *If $\mathfrak{p} = T_oX$, where X is a nonpositively curved symmetric space, then $D_n(\mathfrak{p}) = D_n(X)$.*

2. *Suppose that $\underline{G}$ is a split reductive algebraic group, $G_1 = \underline{G}(\mathbb{C})$, $G_2 = \underline{G}(\mathbb{R})$ and $K_i \subset G_i$ are maximal compact subgroups, $i = 1, 2$. Then*

$$D_n(G_1/K_1) = D_n(G_2/K_2).$$

Since $D_n(X)$ is a convex homogeneous cone, it is defined by a system of homogeneous linear inequalities which we will refer to as *generalized triangle inequalities*. Theorem 3.1 reduces the computation of these inequalities to the case of symmetric spaces. Since, clearly, $D_n(X \times \mathbb{R}^m) = D_n(X) \times \mathbb{R}^m$, it suffices to consider spaces $X = G/K$, so that the identity component G of $\mathrm{Isom}(X)$ is semisimple. One of the main results of [KLM1] is a description of $D_n(X)$ in terms of the Schubert calculus in the Grassmannians associated to complex and real Lie groups G (i.e., the quotients G/P where P is a maximal parabolic subgroup of G).

The *Tits boundary* $\partial_{\mathrm{Tits}} X$ of X is a spherical building modelled on a spherical Coxeter complex (S, W) with spherical Weyl chamber $\Delta_{\mathrm{sph}} \subset S$. It is formed by equivalence classes of geodesic rays in X; the metric on $\partial_{\mathrm{Tits}} X$ is given by the *Tits angle* $\angle_{\mathrm{Tits}}$, see for instance [Ba]. We identify S with an apartment in $\partial_{\mathrm{Tits}} X$. Let Δ denote the Weyl chamber of X. We identify Δ_{sph} with $\partial_{\mathrm{Tits}} \Delta$.

Let B be the stabilizer of Δ_{sph} in G. For each vertex ζ of $\partial_{\mathrm{Tits}} X$ one defines the generalized Grassmannian $\mathrm{Grass}_\zeta = G\zeta = G/P$. (Here P is the maximal parabolic subgroup of G stabilizing ζ.) It is a compact homogeneous space stratified into B-orbits called *Schubert cells*. Every Schubert cell is of the form $C_\eta = B\eta$ for a unique vertex $\eta \in W\zeta \subset S^{(0)}$ of the spherical Coxeter complex. The closures $\overline{C}_\eta$ are called *Schubert cycles*. They are unions of Schubert cells and represent well defined elements in the homology $H_*(\mathrm{Grass}_\zeta, \mathbb{Z}_2)$.

For each vertex ζ of Δ_{sph} and each n-tuple $\vec{\eta} = (\eta_1, \ldots, \eta_n)$ of vertices in $W\zeta$ consider the following homogeneous linear inequality for $\xi \in \Delta^n$:

$$\sum_i \xi_i \cdot \eta_i \leq 0 \qquad (*_{\zeta;\vec{\eta}})$$

Here we identify the η_i's with unit vectors in Δ.

Let $I_{\mathbb{Z}_2}(G)$ be the set consisting of all data $(\zeta, \vec{\eta})$ such that the intersection of the Schubert classes $[\overline{C}_{\eta_1}], \ldots, [\overline{C}_{\eta_n}]$ in $H_*(\mathrm{Grass}_\zeta, \mathbb{Z}_2)$ equals $[pt]$.

Theorem 3.3 ([KLM1]). *$D_n(X) \subset \Delta^n$ consists of all solutions ξ to the system of inequalities $(*_{\zeta;\vec{\eta}})$ where $(\zeta, \vec{\eta})$ runs through $I_{\mathbb{Z}_2}(G)$.*

Remark 3.4. This system of inequalities depends on the Schubert calculus for the generalized Grassmannians G/P associated to the group G.

Typically, the system of inequalities in Theorem 3.3 is redundant. If G is a *complex* Lie group one can use the complex structure to obtain a smaller system of inequalities. In this case, the homogeneous spaces Grass_ζ are complex manifolds and the Schubert cycles are complex subvarieties and hence represent classes in *integral* homology. Let $I_{\mathbb{Z}}(G) \subset I_{\mathbb{Z}_2}(G)$ be the subset consisting of all data $(\zeta, \vec{\eta})$ such that the intersection of the Schubert classes $[\overline{C}_{\eta_1}], \ldots, [\overline{C}_{\eta_n}]$ in $H_*(\mathrm{Grass}_\zeta, \mathbb{Z})$ equals $[pt]$.

The following analogue of Theorem 3.3 was proven independently and by completely different methods in [BS] and in [KLM1]:

Theorem 3.5 (Stability inequalities). *$D_n(X)$ consists of all solutions ξ to the system of inequalities $(*_{\zeta;\vec{\eta}})$ where $(\zeta, \vec{\eta})$ runs through $I_{\mathbb{Z}}(G)$.*

As we will see in the next section, these inequalities generalize the system of inequalities used by Klyachko in [Kly1] to solve Weyl's problem on eigenvalues of sums of Hermitian matrices.

It was proven by Knutson, Tao and Woodward [KTW] that in the case $G = \mathrm{SL}(n, \mathbb{C})$ the system of inequalities appearing in Theorem 3.5 is irredundant; on the other hand, for the root systems B_2, G_2, B_3, C_3 this system is still redundant, see [KLM1] for the rank 2 computations and [KuLM] for the rank 3 computations. P. Belkale and S. Kumar in [BK] deformed the product structure on $H_*(\mathrm{Grass}_\zeta)$ to make a smaller system of inequalities defining $D_n(X)$, which is irredundant for all root systems of rank ≤ 3. Conjecturally, the new system of inequalities is irredundant for all root systems.

4. Algebraic problems

Let $\mathbb{F}$ be either the field $\mathbb{R}$ or $\mathbb{C}$, and let $\mathbb{K}$ be a nonarchimedean valued field with discrete valuation ring $\mathcal{O}$ and the value group $\mathbb{Z}$. For simplicity, let us consider here only split reductive group $\underline{G}$ over $\mathbb{Q}$, we refer the reader to [KLM3] for the discussion in the general case. Below we consider the following four algebraic problems, labeled by *linear algebra* interpretation in the case when $\underline{G} = \mathrm{GL}(n)$. We refer the reader to Fulton's survey [Fu] for the detailed discussion of these linear algebra problems. We note here only that Problem Q1 in the case $G = \mathrm{GL}(n, \mathbb{C})$ is asking for the restrictions on eigenvalues of sums of Hermitian $n \times n$ matrices A and B, provided that the eigenvalues of A and B are given.

- **Q1. Eigenvalues of a sum.** Set $G := \underline{G}(\mathbb{F})$, let K be a maximal compact subgroup of G. Let $\mathfrak{g}$ be the Lie algebra of G, and let $\mathfrak{g} = \mathfrak{k} + \mathfrak{p}$ be its Cartan decomposition. Give necessary and sufficient conditions on $\lambda, \mu, \nu \in \mathfrak{p}/Ad(K)$ in order that there exist elements $A, B, C \in \mathfrak{p}$ whose projections to $\mathfrak{p}/Ad(K)$ are λ, μ and ν, respectively, so that
$$A + B + C = 0.$$

- **Q2. Singular values of a product.** Let G and K be the same as above. Give necessary and sufficient conditions on $\lambda, \mu, \nu \in K\backslash G/K$ in order that there exist elements $A, B, C \in G$ whose projections to $K\backslash G/K$ are λ, μ and ν, respectively, so that
$$ABC = 1.$$

- **Q3. Invariant factors of a product.** Set $G := \underline{G}(\mathbb{K})$ and $K := \underline{G}(\mathcal{O})$. Give necessary and sufficient conditions on $\lambda, \mu, \nu \in K\backslash G/K$ in order that there

exist elements $A, B, C \in G$ whose projections to $K\backslash G/K$ are λ, μ and ν, respectively, so that

$$ABC = 1.$$

- **Q4. Decomposing tensor products.** Let $\underline{G}^\vee$ be the Langlands dual group of $\underline{G}$. Give necessary and sufficient conditions on highest weights λ, μ, ν of irreducible representations V_λ, V_μ, V_ν of $G^\vee := \underline{G}^\vee(\mathbb{C})$ so that

$$(V_\lambda \otimes V_\mu \otimes V_\nu)^{G^\vee} \neq 0.$$

Notation 4.1. Throughout this paper we will denote by Sol(Qi, G) the set of triples (λ, μ, ν) which are solutions of Problem Qi for the group G.

Remark 4.2. Assuming that the field $\mathbb{K}$ is local (and hence its residue field is a finite field of order q) we can reformulate the condition that $(\lambda, \mu, \nu) \in$ Sol(Q3, G) as

$$m_{\lambda,\mu}(\nu^*) \neq 0,$$

where the m's are the structure constants of the spherical Hecke ring associated with the group $G = \underline{G}(\mathbb{K})$. We will discuss the geometric meaning of the constants m in the end of this section.

It turns out that the first three algebraic problems are closely related to the geometric problems discussed in the previous section. Consider for instance Problem Q2. Let $X = G/K$ be the corresponding nonpositively curved symmetric space; the group G acts on X by left multiplication, preserving the function d_Δ. Let $o \in X$ be the point stabilized by K. We identify Δ with the double coset $K\backslash G/K$.

Given elements $A, B, C \in G$ we define the polygonal chain in X with the (four) vertices

$$o, x = A(o), \quad y = AB(o), \quad z = ABC(o).$$

Since G preserves the Δ-distance, we conclude that

$$d_\Delta(o, x) = \lambda, \quad d_\Delta(x, y) = \mu, \quad d_\Delta(y, z) = \nu,$$

where A, B, C project to the vectors λ, μ, ν in Δ. If $ABC = 1$, the polygonal chain yields a geodesic triangle in X; conversely, if $z = o$ then, by multiplying C by an element of K if necessary, we get $ABC = 1$. Therefore

$$D_3(X) = \text{Sol(Q2, } G), \quad \text{for the symmetric space } X = G/K.$$

The same arguments work for the infinitesimal symmetric space $X' = T_oX$:

$$D_3(X') = \text{Sol(Q1, } G).$$

The situation in the case of Problem Q3 is more subtle. It is easy to see that

$$\text{Sol(Q3, } G) \subset D_3(X),$$

where X is the (discrete) Bruhat–Tits building corresponding to the group G. There are two straightforward restrictions on the elements of Sol(Q3, G) $\subset D_3(X)$:

- **O1.** $\mathrm{Sol}(\mathrm{Q3}, G) \subset L^3$, where L is the cocharacter lattice of a maximal torus in $\underline{G}$.
- **O2.** For each triple $\sigma = (\lambda, \mu, \nu) \in \mathrm{Sol}(\mathrm{Q3}, G)$ we have

$$T(\sigma) := \lambda + \mu + \nu \in Q(R^\vee).$$

We let $\Lambda \subset L^3$ denote the set of triples σ satisfying $T(\sigma) \in Q(R^\vee)$. Then

Theorem 4.3 ([KLM3]). 1. $(\lambda, \mu, \nu) \in \mathrm{Sol}(\mathrm{Q3}, G)$ *if and only if there exists a geodesic triangle* $\tau \subset X$ *whose vertices are* special points *of* X *and whose* Δ*-side lengths are* λ, μ, ν.

2. *"Conversely", if* $\sigma \in D_3(X) \cap \Lambda$ *then there exists a geodesic triangle* $\tau \subset X$ *whose vertices are* vertices *of* X *and whose* Δ*-side lengths are* λ, μ, ν.

Note that the vertices of the triangle τ in Part 2 of this theorem need not be special vertices of X, unless the root system R is of type A when *all vertices of* X *are special*. The latter is ultimately responsible for the equivalence of all 4 algebraic problems in the case of $\underline{G} = \mathrm{GL}(n)$.

The basic reason why one should not expect the equality

$$\mathrm{Sol}(\mathrm{Q3}, G) = D_3(X) \cap \Lambda$$

in general, is lack of homogeneity of Euclidean buildings X: The Δ-valued distance function is not a complete congruence invariant of pairs of points in X. One can remedy this by introducing the *refined distance function* $d_{\mathrm{ref}}(x, y)$ between points $x, y \in X$. The new distance function takes values in $A \times A/W_{\mathrm{aff}}$ (see [KLM2]).

Theorem 4.4 (Transfer Theorem, [KLM2]). *Suppose that* X, X' *are thick Euclidean buildings modelled on the same Euclidean Coxeter complex* (A, W_{aff}). *Then for each geodesic polygon* $[x_1, \ldots, x_n, x_{n+1} = x_1] \subset X$ *there exists a geodesic polygon* $[x_1', \ldots, x_n', x_{n+1}' = x_1'] \subset X'$ *so that*

$$d_{\mathrm{ref}}(x_i, x_{i+1}) = d_{\mathrm{ref}}(x_i', x_{i+1}'), \quad i = 1, \ldots, n.$$

Corollary 4.5 ([KLM3]). $\mathrm{Sol}(\mathrm{Q3}, G)$ *is independent of the field* $\mathbb{K}$. *If* $\mathbb{K}$, $\mathbb{K}'$ *are nonarchimedean valued fields with the valuation group* $\mathbb{Z}$, *then*

$$\mathrm{Sol}(\mathrm{Q3}, \underline{G}(\mathbb{K})) = \mathrm{Sol}(\mathrm{Q3}, \underline{G}(\mathbb{K}')).$$

Relation to representation theory. First notice that the Langlands dual group $G^\vee = \underline{G}(\mathbb{C})$ appears naturally in the context of problems Q3 and Q4: The character lattice of a maximal torus in $G^\vee$ is the cocharacter lattice of the corresponding maximal torus in G.

The following theorem was originally proven in [KLM3] via Satake correspondence; new proofs were given by Tom Haines in [Ha1] and in the work with John Millson [KM1] (along the same lines one can give yet another proof using the results of S. Gaussent and P. Littelmann [GL]).

Theorem 4.6. $\mathrm{Sol}(\mathrm{Q4}, G^\vee) \subset \mathrm{Sol}(\mathrm{Q3}, G)$.

Thus we can summarize the above results and Theorem 3.1 as:

Theorem 4.7.

$$\begin{aligned} D_3(X) &= \mathrm{Sol}(\mathrm{Q1}, \underline{G}(\mathbb{C})) = \mathrm{Sol}(\mathrm{Q1}, \underline{G}(\mathbb{R})) = \mathrm{Sol}(\mathrm{Q2}, \underline{G}(\mathbb{C})) \\ &= \mathrm{Sol}(\mathrm{Q2}, \underline{G}(\mathbb{R})) \supset \mathrm{Sol}(\mathrm{Q3}, \underline{G}(\mathbb{K})) \supset \mathrm{Sol}(\mathrm{Q4}, \underline{G}^\vee(\mathbb{C})), \end{aligned}$$

where $X = \underline{G}(\mathbb{C})/K$.

Remark 4.8. Different proofs of the equalities

$$\mathrm{Sol}(\mathrm{Q1}, \underline{G}(\mathbb{F})) = \mathrm{Sol}(\mathrm{Q2}, \underline{G}(\mathbb{F}))$$

were given (in case $\mathbb{F} = \mathbb{C}$) for classical groups by A. Klyachko [Kly2], for all complex Lie groups by A. Alexeev, E. Meinrenken, C. Woodward [AMW] and for all real groups by S. Evens, J.-H. Lu [EL].

To which extent can the last two inclusions in Theorem 4.7 be reversed? The restrictions O1, O2 provide necessary conditions for triples (λ, μ, ν) to belong to $\mathrm{Sol}(\mathrm{Qi}, G)$, $i = 3, 4$. The natural question is if they are also sufficient. On the negative side:

Theorem 4.9 ([KLM3]). 1. *In the case of the groups* $\mathrm{Sp}(4)$ *and* G_2 *the inclusion* $\mathrm{Sol}(\mathrm{Q2}, \underline{G}(\mathbb{R})) \cap \Lambda \supset \mathrm{Sol}(\mathrm{Q3}, \underline{G}(\mathbb{K}))$ *is proper.*

2. *For all non-simply laced groups the inclusion*

$$\mathrm{Sol}(\mathrm{Q3}, \underline{G}(\mathbb{K})) \supset \mathrm{Sol}(\mathrm{Q4}, \underline{G}^\vee(\mathbb{C}))$$

is proper.

It turns out however that one can reverse both inclusions at the expense of *multiplication by a saturation factor*. Let θ be the highest root of the root system R (associated with the group $\underline{G}$)). Then we have the expansion

$$\theta = \sum_{i=1}^{\ell} m_i \alpha_i,$$

where the α_i's are the simple roots in R (corresponding to the chamber Δ).

Definition 4.10. Define the *saturation factor* k_R to be the least common multiple of $m_1, \ldots, m_\ell$.

Below are the values of k_R for the irreducible root systems.

Root system R	Group G	k_R
A_ℓ	$\mathrm{SL}(\ell+1), \mathrm{GL}(\ell+1)$	1
B_ℓ	$\mathrm{SO}(2\ell+1)$	2
C_ℓ	$\mathrm{Sp}(2\ell)$	2
D_ℓ	$\mathrm{SO}(2\ell)$	2
G_2	G	6
F_4	G	12
E_6	G	6
E_7	G	12
E_8	G	60

Theorem 4.11. 1. $\mathrm{Sol}(\mathrm{Q2}, \underline{G}(\mathbb{R})) \cap k_R\Lambda \subset \mathrm{Sol}(\mathrm{Q3}, \underline{G}(\mathbb{K}))$ (*see* [KLM3].)

2. $k_R \cdot \mathrm{Sol}(\mathrm{Q3}, \underline{G}(\mathbb{K})) \subset \mathrm{Sol}(\mathrm{Q4}, \underline{G}^\vee(\mathbb{C}))$. *Moreover, if at least one of the weights* λ, μ, ν *is a sum of minuscule dominant weights, then*

$$(\lambda, \mu, \nu) \in \mathrm{Sol}(\mathrm{Q3}, \underline{G}(\mathbb{K})) \iff (\lambda, \mu, \nu) \in \mathrm{Sol}(\mathrm{Q4}, \underline{G}^\vee(\mathbb{C})).$$

(*See* [KM1].)

3. *Therefore*

$$D_3(X) \cap k_R^2\Lambda \subset \mathrm{Sol}(\mathrm{Q4}, \underline{G}^\vee(\mathbb{C})),$$

where X *is the symmetric space of* $\underline{G}(\mathbb{F})$.

In particular, in the case when $\underline{G}$ has type A_ℓ (e.g. $\underline{G} = \mathrm{SL}(\ell+1)$) we obtain a new proof of the *Saturation Theorem* of A. Knutson and T. Tao [KT] (another proof of this theorem was later given by H. Derksen and J. Whyman in [DW]):

Theorem 4.12. *The semigroup* $\Sigma := \mathrm{Sol}(\mathrm{Q4}, \mathrm{SL}(\ell+1, \mathbb{C}))$ *is* saturated*, i.e., a triple* $\sigma = (\lambda, \mu, \nu) \in \Lambda$ *belongs to* Σ *if and only if there exists* $N \in \mathbb{N}$ *so that* $N\sigma$ *belongs to* Σ.

Proof. Since the cone $D_3(X)$ is homogeneous, the semigroup $D_3(X) \cap \Lambda$ is clearly saturated. However, according to Part 3 of Theorem 4.11, $\Sigma = D_3(X) \cap \Lambda$ in our case. □

Remark 4.13. The equality

$$\mathrm{Sol}(\mathrm{Q3}, \mathrm{GL}(\ell, \mathbb{C})) = \mathrm{Sol}(\mathrm{Q4}, \mathrm{GL}(\ell, \mathbb{C}))$$

was known since the 1960s, see [K1], [K2]. However these proofs do not generalize to other root systems.

Except for the case of the root system of type A, the constants which appear in Theorem 4.11 are (conjecturally) not optimal:

Conjecture 4.14 ([KM1], [KM2]). 1. $D_3(X) \cap k\Lambda \subset \mathrm{Sol}(\mathrm{Q4}, \underline{G}^\vee(\mathbb{C}))$, where $k = 1$ in the case when the root system R is simply laced and $k = 2$ otherwise.

2. Suppose that all three dominant weights λ, μ, ν are *regular*, i.e., belong to the interior of the chamber Δ. Then

$$(\lambda, \mu, \nu) \in D_3(X) \cap \Lambda \iff (\lambda, \mu, \nu) \in \mathrm{Sol}(\mathrm{Q4}, \underline{G}^\vee(\mathbb{C})).$$

This conjecture holds for the rank 2 simple Lie groups (see [KM2]); it is also supported by some computational experiments.

A less ambitious form of Conjecture 4.14 is

Conjecture 4.15 (S. Kumar). If $\mathrm{Sol}(\mathrm{Q4}, \underline{G}^\vee(\mathbb{C})) \neq D_3(X) \cap L^3$, then there exists a triple

$$(\lambda, \mu, \nu) \in D_3(X) \cap L^3 \setminus \mathrm{Sol}(\mathrm{Q4}, \underline{G}^\vee(\mathbb{C})),$$

so that at least one of the vectors λ, μ, ν is non-singular.

Counting triangles. Let X be a Bruhat–Tits building of thickness $q + 1 < \infty$, i.e., $q + 1$ is the number of half-apartments adjacent to each wall in X. Equivalently, q is the number of elements in the residue field of $\mathbb{K}$. Our goal is to relate the number of geodesic triangles in X with the given Δ-side lengths to the dimensions of the space of $G^\vee$–invariants

$$n_{\lambda,\mu,\nu}(0) = \dim(V_\lambda \otimes V_\mu \otimes V_\nu)^{G^\vee}.$$

Let $o \in X$ be a special point, for instance, the unique point stabilized by $\underline{G}(\mathcal{O})$. Let $f(q) := m_{\lambda,\mu,\nu}(0)$ denote the number of oriented geodesic triangles $[o, x, y]$ in X with the Δ-side lengths $\lambda, \mu, \nu \in P(R^\vee) \cap \Delta$.

Remark 4.16. The Hecke ring structure constant $m_{\lambda,\mu}(\nu^*)$ is the number of geodesic triangles as above for which the vertex y is fixed.

Given the root system R and the set R^+ of positive roots (determined by Δ), let ρ denote the half-sum of the positive roots.

Theorem 4.17 ([KLM3]). *$f(q)$ is a polynomial function of q of degree $\leq q^{\langle \rho, \lambda+\mu+\nu \rangle}$ so that*

$$f(q) = n_{\lambda,\mu,\nu}(0) q^{\langle \rho, \lambda+\mu+\nu \rangle} + \textit{ lower order terms}.$$

5. Geometry behind the proofs

5.1. Weighted Busemann functions and stability. Let X be a symmetric space of nonpositive curvature or a Euclidean building. Recall that the ideal boundary $B = \partial_{\mathrm{Tits}} X$ has the structure of a spherical building, the metric on B is denoted by $\angle_{\mathrm{Tits}}$. Given a Weyl chamber Δ in X, we get a spherical Weyl chamber $\Delta_{\mathrm{sph}} = \partial_\infty \Delta \subset \partial_{\mathrm{Tits}} X$. We will identify Δ_{sph} with the unit vectors in Δ. We have a canonical projection $\theta\colon \partial_{\mathrm{Tits}} X \to \Delta_{\mathrm{sph}}$.

Take a collection of weights $m_1, \dots, m_n \geq 0$ and define a finite measure space $(\mathbb{Z}/n\mathbb{Z}, \nu)$ where the measure ν on $\mathbb{Z}/n\mathbb{Z}$ is given by $\nu(i) = m_i$. An n-tuple of ideal points $(\xi_1, \dots, \xi_n) \in B^n$ together with $(\mathbb{Z}/n\mathbb{Z}, \nu)$ determine a *weighted configuration at infinity*, which is a map

$$\psi\colon (\mathbb{Z}/n\mathbb{Z}, \nu) \to \partial_{\mathrm{Tits}} X.$$

The *type* $\tau(\psi) = (\tau_1, \dots, \tau_n) \in \Delta^n$ of the weighted configuration ψ is given by $\tau_i = m_i \cdot \theta(\xi_i)$. Let $\mu = \psi_*(\nu)$ be the pushed forward measure on B. We define the *slope* of a measure μ on B with finite total mass $|\mu|$ as

$$\mathrm{slope}_\mu(\eta) = -\int_B \cos \angle_{\mathrm{Tits}}(\xi, \eta)\, d\mu(\xi).$$

To see where the slope function comes from, consider the *μ-weighted Busemann function* on X

$$b_\mu(x) := \int_B b_\xi(x) d\mu(\xi)$$

where $b_\xi\colon X \to \mathbb{R}$ is the Busemann function on X corresponding to the point $\xi \in \partial_{\mathrm{Tits}} X$. We normalize all Busemann functions to vanish at a certain point $o \in X$. The function b_μ is a convex $|\mu|$-Lipschitz function on X which is *asymptotically linear* along each geodesic ray $\rho = \overline{o\eta}$ in X. Then

$$\mathrm{slope}_\mu(\eta) = \lim_{t\to\infty} \frac{b_\mu(\rho(t))}{t}$$

is the *asymptotic slope* of b_μ in the direction of η.

Remark 5.1. Weighted Busemann functions are a powerful tool for studying asymptotic geometry of nonpositively curved spaces, see for instance [BCG].

In what follows we will consider only measures μ with finite support.

Definition 5.2 (Stability). A measure μ on B is called *semistable* if $\mathrm{slope}_\mu(\eta) \geq 0$ and *stable* if $\mathrm{slope}_\mu(\eta) > 0$ for all $\eta \in B$.

There is a refinement of the notion of semistability motivated by the corresponding concept in geometric invariant theory.

Definition 5.3 (Nice semistability). A measure μ on B (with finite support) is called *nice semistable* if μ is semistable and $\{\text{slope}_\mu = 0\}$ is a subbuilding or empty. In particular, stable measures are nice semistable.

A weighted configuration ψ on B is called *stable, semistable* or *nice semistable*, respectively, if the corresponding measure $\psi_*\nu$ has this property.

For our purposes, nice semistability is a useful concept in the case of symmetric spaces and infinitesimal symmetric spaces only. We note however that for these spaces, existence of a semistable configuration ψ on $\partial_{\text{Tits}}X$ implies existence of a nice semistable configuration on $\partial_{\text{Tits}}X$, which has the same type as ψ, see [KLM1].

Example 5.4. Let B be a 0-dimensional spherical building. Then a measure μ on B is stable iff it contains no atoms of mass $\geq \frac{1}{2}|\mu|$, semistable iff it contains no atoms of mass $> \frac{1}{2}|\mu|$, and nice semistable iff it is either stable or consists of two atoms of equal mass.

Suppose now that G is a reductive complex Lie group, $K \subset G$ is a maximal compact subgroup, $X = G/K$ is the associated symmetric space. Then the spaces of weighted configurations in $\partial_{\text{Tits}}X$ of the given type $\tau \in \Delta^n$ can be identified with products

$$F = F_1 \times \cdots \times F_n$$

where F_i's are smooth complex algebraic varieties (generalized flag varieties) on which the group G acts transitively. Hence G acts on F diagonally.

In case X is the symmetric space associated to a complex Lie group, the notions of stability (semistability, etc.) introduced above coincide with corresponding notions from symplectic geometry, and, in the case when τ_i's are fundamental weights, they also coincide with the concepts of stability (semistability, etc.) used in Geometric Invariant Theory, see [KLM1].

Define the subset $\Delta^n_{\text{ss}}(B) \subset \Delta^n$ consisting of those n-tuples $\tau \in \Delta^n$ for which there exists a weighted semistable configuration on B of type τ. One of the central results of [KLM1] is

Theorem 5.5. *$\Delta^n_{\text{ss}}(B)$ is a convex homogeneous cone defined by the linear inequalities $(*_{\zeta;\vec{\eta}})$.*

This theorem generalizes the results of A. Klyachko [Kly1] (in the case of $\text{GL}(n)$) and A. Berenstein and R. Sjamaar [BS] in the case of complex semisimple Lie groups.

5.2. Gauss maps and associated dynamical systems. We now relate polygons in X (where X is an infinitesimal symmetric space, a nonpositively curved symmetric space or a Euclidean building) and weighted configurations on the ideal boundary B of X, which plays a key role in [KLM1] and [KLM2].

Consider a (closed) polygon $P = [x_1, x_2, \dots x_n]$ in X, i.e., a map $\mathbb{Z}/n\mathbb{Z} \to X$. The distances $m_i = d(x_i, x_{i+1})$ determine a finite measure ν on $\mathbb{Z}/n\mathbb{Z}$ by $\nu(i) = m_i$. The polygon P gives rise to a collection Gauss(P) of *Gauss maps*

$$\psi : \mathbb{Z}/n\mathbb{Z} \to \partial_{\mathrm{Tits}} X \tag{1}$$

by assigning to i an ideal point $\xi_i \in \partial_{\mathrm{Tits}} X$ so that the geodesic ray $\overline{x_i \xi_i}$ (originating at x_i and asymptotic to ξ_i) passes through x_{i+1}.

Remark 5.6. This construction, in the case of the hyperbolic plane, appears in a letter of Gauss to Wolfgang Bolyai, [G]. I am grateful to Domingo Toledo for this observation.

Taking into account the measure ν, we view the maps $\psi : (\mathbb{Z}/n\mathbb{Z}, \nu) \to \partial_{\mathrm{Tits}} X$ as *weighted configurations* of points on $\partial_{\mathrm{Tits}} X$. Note that if X is a symmetric space and the m_i's are all non-zero, there is a unique Gauss map. On the other hand, if X is a Euclidean building then there are, in general, infinitely many Gauss maps. However, the corresponding weighted configurations are of the same type, i.e., they project to the same weighted configuration on Δ_{sph}.

The following crucial observation explains why the notion of semistability is important for studying closed polygons.

Lemma 5.7 ([KLM1], [KLM2]). *For each Gauss map ψ the push forward measure $\mu = \psi_* \nu$ is semistable. If X is a symmetric space or an infinitesimal symmetric space then the measure μ is nice semistable.*

Polygons in infinitesimal symmetric spaces X'. Let $X' = T_o X$ be the infinitesimal symmetric space. Then

Theorem 5.8 ([KLM1]). 1. *ψ is nice semistable iff the corresponding weighted Busemann function b_μ attains its minimum on X, iff b_μ has a critical point in X.*

2. *Suppose that b_μ attains its minimum at the origin $o \in X$. Identify the ideal points ξ_i with the unit vectors $\bar{\xi}_i$ in the tangent space $X' = T_o X$ via the exponential map.*

Then the gradient of b_μ at o satisfies

$$0 = \nabla_o(b_\mu) = \sum_{i=1}^{n} m_i \bar{\xi}_i.$$

Thus, in Part 2 of the above theorem, we obtain a closed polygon in the infinitesimal symmetric space X' whose Δ-side lengths are $m_i \theta(\xi_i)$.

Corollary 5.9. $\Delta^n_{\mathrm{ss}}(\partial_{\mathrm{Tits}} X) = D_n(X')$.

Polygons in nonpositively curved symmetric spaces and buildings. Our goal is to "invert Gauss maps", i.e., given a semistable weighted configuration $\psi\colon (\mathbb{Z}/n, \nu) \to B$, we would like to find a closed geodesic n-gon P so that $\psi \in \mathrm{Gauss}(P)$. The polygons P correspond to the fixed points of a certain dynamical system. For $\xi \in \partial_{\mathrm{Tits}} X$ and $t \geq 0$, define the map $\phi := \phi_{\xi,t}\colon X \to X$ by sending x to the point at distance t from x on the geodesic ray $\overline{x\xi}$. Since X is nonpositively curved, the map ϕ is 1-Lipschitz. Then, given a weighted configuration $\psi\colon (\mathbb{Z}/n\mathbb{Z}, \nu) \to \partial_{\mathrm{Tits}} X$ with non-zero total mass, define the map

$$\Phi = \Phi_\psi\colon X \to X$$

as the composition

$$\phi_{\xi_n, m_n} \circ \cdots \circ \phi_{\xi_1, m_1}.$$

The fixed points of Φ are the first vertices of closed polygons $P = [x_1, \ldots, x_n]$ so that $\psi \in \mathrm{Gauss}(P)$. Since the map Φ is 1-Lipschitz, and the space X is complete and has nonpositive curvature, the map Φ has a fixed point if and only if the dynamical system $(\Phi^i)_{i\in\mathbb{N}}$ has a bounded orbit, see [KLM2]. Of course, in general, there is no reason to expect that $(\Phi^i)_{i\in\mathbb{N}}$ has a bounded orbit: For instance, if the support of the measure $\mu = \psi_*(\nu)$ is a single point, all orbits are unbounded.

Problem 5.10. Suppose that X is a CAT(0) metric space and the weighted configuration ψ is nice semistable. Is it true that $(\Phi^i)_{i\in\mathbb{N}}$ has a bounded orbit?

Although we do not know an answer to this problem in general, we have:

Theorem 5.11. 1. *Suppose that X is a nonpositively curved simply-connected symmetric space. Then ψ is nice semistable if and only if $(\Phi^i)_{i\in\mathbb{N}}$ has a bounded orbit, see* [KLM1].

2. *Suppose that X is a Euclidean building. Then ψ is semistable if and only if $(\Phi^i)_{i\in\mathbb{N}}$ has a bounded orbit. This was proven for locally compact buildings in the original version of* [KLM2]*, for* 1*-vertex buildings in* [KLM2] *and by Andreas Balser* [B] *in the general case.*

Corollary 5.12 ([KLM1], [KLM2]). *Suppose that X is a symmetric space of nonpositive curvature or a Euclidean building. Then $D_n(X) = \Delta^n_{\mathrm{ss}}(\partial_{\mathrm{Tits}} X)$.*

Now we can explain Part 2 of Theorem 3.1. For instance, let $X_i' = T_o(X_i)$, $i = 1, 2$, be infinitesimal symmetric spaces. Then

$$D_n(X_i') = D_n(X_i') = \Delta^n_{\mathrm{ss}}(\partial_{\mathrm{Tits}} X_i), \quad i = 1, 2,$$

see Corollaries 5.9 and 5.12. Let Y_i denote the 1-vertex Euclidean building which is the Euclidean cone over the spherical building $\partial_{\mathrm{Tits}} X_i$, $i = 1, 2$. Then, $\partial_{\mathrm{Tits}} Y_i = \partial_{\mathrm{Tits}} X_i$ and hence, according to Corollary 5.9,

$$D_n(Y_i) = \Delta^n_{\mathrm{ss}}(\partial_{\mathrm{Tits}} X_i), \quad i = 1, 2.$$

Finally, according to the Transfer Theorem 4.4,

$$D_n(Y_1) = D_n(Y_2),$$

since these buildings are modelled on the same Euclidean Coxeter complex (A, W), where W is the finite Weyl group of X_i, $i = 1, 2$. By combining these equalities we obtain

$$D_n(X_1') = D_n(X_2').$$

5.3. Relation to representation theory. We now explain the connection of geodesic triangles in Euclidean buildings to the representation theory which appears in [KM1]. The key instrument here is *Littelmann's path model*. Given a thick Euclidean building X modelled on (A, W_{aff}) (and associated with a nonarchimedean Lie group $G = \underline{G}(\mathbb{K})$) and a special point $o \in X$, we define the projection

$$f\colon X \to \Delta,\ f(x) = d_\Delta(o, x).$$

This projection restricts to an isometry on each alcove $a \subset X$. Moreover, f preserves the Δ-length of piecewise-geodesic paths in X. Given a geodesic triangle $[o, x, y] \subset X$, we obtain a *broken triangle*

$$f([o, x, y]) \subset \Delta$$

which has two geodesic sides $\overline{of(x)}$, $\overline{f(y)o}$ and a broken side $p = f(\overline{xy})$. The Δ-lengths of the above paths are $\lambda = d_\Delta(o, x)$, $\nu = d_\Delta(y, o)$ and $\mu = d_\Delta(x, y)$ respectively. One of the main results of [KM1] is an intrinsic description of the piecewise-geodesic paths p which appear as the result of the above construction. They turn out to be closely related to *LS paths* introduced by Peter Littelmann in [Li].

The LS paths are defined by two axioms: The first one requires existence of a certain *chain* between the tangent vectors $p'_-(t)$, $p'_+(t)$ to the path p at each breakpoint $p(t)$. The second axiom is a maximality condition for such a chain. This axiom is vacuously true if $p(t)$ is a special point of (A, W_{aff}). In [KM1] we define *Hecke paths* p in A as piecewise-geodesic paths satisfying the 1st of Littelmann's axioms. Below are the precise definitions.

Let (A, W_{aff}) be a Euclidean Coxeter complex with V the vector space underlying A; let $W' \subset W_{\mathrm{aff}}$ be the stabilizer of a point in A. By looking at the linear parts of the elements of W', we identify W' with a subgroup

$$l(W') \subset W \subset W_{\mathrm{aff}},$$

where W is the stabilizer of the origin in W_{aff}. Let $\Delta \subset V$ be a Weyl chamber of W. Then a *W'-chain in V from $\eta_0 \in V$ to $\eta_m \in V$* is a sequence of pairwise distinct vectors

$$\eta_0, \ldots, \eta_m \in V$$

so that for each i there exists a reflection $\tau_i \in l(W')$ which sends η_i to η_{i+1} and whose fixed-point set separates η_i from Δ.

Axiom 1. A piecewise-linear path $p\colon I \to A$ is a *Hecke path* if for each $t \in I$ there is a $W_{\mathrm{aff},p(t)}$-chain from $p'_-(t)$ to $p'_+(t)$.

Here and below $W_{\mathrm{aff},x}$ is the stabilizer of x in W_{aff}.

Axiom 2. A path p satisfies the *maximality property* if for each $p(t)$ the above $W_{\mathrm{aff},x}$-chain can be found which is a *maximal W-chain* from $p'_-(t)$ to $p'_+(t)$.

Definition 5.13. A path p in A is said to be an *LS path* if it satisfies Axioms 1 and 2.

Here maximality is understood in the set-theoretic sense.

Theorem 5.14 ([KM1]). *A path p in Δ is the projection (under f) of a geodesic path in X if and only if p is a Hecke path.*

Remark 5.15. An analogous result was independently proven in [GL] by Gaussent and Littelmann in the context of *folded galleries*.

On the other hand, Littelmann proved in [Li] the following fundamental

Theorem 5.16.

$$\dim((V_\lambda \otimes V_\mu \otimes V_\nu)^{G^\vee})$$

is the number of polygons $P \subset \Delta$, each of which is the concatenation of the paths $\overline{o\lambda}$, p, $\overline{\nu^* o}$, where p is an LS path of the Δ-length μ.

Given this we immediately see that

$$\mathrm{Sol}(\mathrm{Q4}, G^\vee) \subset \mathrm{Sol}(\mathrm{Q3}, G),$$

since each LS path is also a Hecke path.

The converse relation is not as clear, since Hecke paths in general are not LS paths (maximality axiom may fail). Nevertheless, suppose for a moment that μ is an integer multiple of a fundamental coweight ϖ_i. Then the geodesic segment $\overline{xy}$ (having special end-points and Δ-length μ) crosses walls of X only at vertices of X. Therefore, each break-point $p(t)$ of the path $p = f(\overline{xy})$ is a vertex of the Coxeter complex (A, W_{aff}). One can easily see from the definition of the constant k_R (Definition 4.10) that for each vertex v of (A, W_{aff}),

$$k_R v \text{ is a special vertex of } (A, W_{\mathrm{aff}}).$$

Therefore, the rescaled path $k_R \cdot p$ satisfies the 2nd Axiom of an LS path, while the 1st Axiom is preserved by integer scalings. Hence $k_R \cdot p$ is an LS path and thus, by Littelmann's Theorem

$$(V_{k_R\lambda} \otimes V_{k_R\mu} \otimes V_{k_R\nu})^{G^\vee} \neq 0.$$

This establishes Part 2 of Theorem 4.11 provided that the coweight μ is a multiple of some fundamental coweight. The general case is more subtle, we refer the reader to [KM1] for the details.

6. Other developments

Restriction problems. The *Restriction Problem* is, in a sense, even more fundamental for the representation theory than the tensor product decomposition problem:

$$(V_\lambda \otimes V_\mu \otimes V_\nu)^G \neq 0$$

if and only if the restriction of the product representation of $G \times G \times G$ to the diagonal $G \subset G \times G \times G$ has a nonzero invariant vector.

Problem 6.1 (Restriction Problem). Let $H \subset G$ be a complex reductive subgroup in a complex reductive group G. Given an irreducible representation V_μ of G, decompose its restriction $V_\mu | H$ into irreducible factors.

Considerable progress on the general restriction problem and its infinitesimal geometric analogue (determining the projection of a cotangent orbit in the dual of the Lie algebra of a compact group to the dual of the Lie algebra of a subgroup) was made in [BS]. However it appears very difficult to prove saturation results in this generality. Below are two major obstacles in extending the results of [KLM1], [KLM2], [KLM3], [KM1] to the general restriction problem:

1. Given a subbuilding $Y \subset X$ in a Euclidean building X, there do not seem to be natural 1-Lipschitz retractions $X \to Y$. The nearest-point projection does not appear to be a good choice.

2. There is (at present) no analogue of Littelmann's path model for the general restriction problem: Littelmann's solution in [Li] of the restriction problem applies only to Levi subgroups.

It turns out, however, that the entire analysis of the *generalized triangle inequality* problems as well as the corresponding algebra problems Q1–Q4 outlined above, can be extended to the restriction problem in the case of Levi subgroups $H \subset G$. This generalization is carried out in the joint work with John Millson and Tom Haines [HKM]. Geodesic polygons are replaced with ideal geodesic polygons, for their infinite sides, the Δ-valued distance function is replaced with Δ-valued Busemann function, etc.

For instance, we obtain a generalization of the Saturation Theorem 4.11 described below.

Let G be a complex reductive Lie group, L be the character lattice of its maximal torus, $Q(R)$ be its root lattice. Let $M \subset G$ be a Levi subgroup; let $\Delta \subset \Delta_M$ be the Weyl chambers of G and M. Set

$$\mathcal{L} := \{(\lambda, \mu) \in L \times L : \lambda + \mu^* \in Q(R^\vee)\}.$$

Let k_R denote the saturation factor for the root system R of the group G, see Definition 4.10. Then there exists a convex polyhedral cone $D(M, G) \subset \Delta_M \times \Delta$ so that:

Theorem 6.2 ([HKM]). 1. *If* λ, μ *are dominant weights of* M *and* G *respectively so that*

$$V_\lambda \subset V_\mu|M,$$

then $(\lambda, \mu) \in \mathcal{L} \cap D(M, G)$.

2. *If* $(\lambda, \mu) \in \mathcal{L} \cap D(M, G)$, *then for* $k = k_R^2$,

$$V_{k\lambda} \subset V_{k\mu}|M.$$

Remark 6.3. In the case $R = A_\ell$, $k_R = 1$, and hence the above result is the analogue of the Knutson–Tao saturation theorem and in fact implies their saturation theorem.

Problem 6.4. Prove an analogue of Theorem 6.2 for arbitrary reductive subgroups H of G with constant k_R^2 replaced by a suitable number k computable in terms of G and H.

Note that even the case of $G = \mathrm{SL}(n, \mathbb{C})$ is extremely interesting in view of possible applications to P $\neq$ NP, see [MS1], [MS2].

Structure of the sets Sol(Qi). Despite the description of the convex cone Sol(Q1, G) via the linear inequalities $(*_{\zeta;\vec{\eta}})$, its structure remains somewhat mysterious. The case understood best is when $G = \mathrm{SL}(n, \mathbb{C})$.

1. For $\mathrm{SL}(n, \mathbb{C})$ there exists a procedure for computing the inequalities $(*_{\zeta;\vec{\eta}})$ by induction on the rank: This procedure was first conjectured by R. Horn in the 1960s; it was proven in a combination of works by A. Klyachko [Kly1] and A. Knutson and T. Tao [KT]. An alternative proof was later given by P. Belkale [Be2].

Problem 6.5. Generalize Horn's recursion formula to groups other than $\mathrm{SL}(n, \mathbb{C})$.

Such a generalization would give a more practical algorithm for computation of Sol(Q1, G) than the generalized Schubert calculus.

2. While the facets of the cone Sol(Q1, G) are given by the inequalities $(*_{\zeta;\vec{\eta}})$, the edges of this cone have not been described, except in the SL(n) case, see [KTW], [Be4].

3. Concerning Problems Q3 and Q4 one can reasonably ask "what a computation of the sets Sol(Q3), Sol(Q4) might mean?"

The following theorem was proven by C. Laskowski in [La] for Problem Q3 and in [KM2] for Problem Q4:

Theorem 6.6. *For each* G, *the set* Sol(Qi, G) $(i = 3, 4)$ *is a finite union of* elementary sets.

The notion of an elementary subset of L^3 comes from logic: It is a set given by a finite collection of linear inequalities (with integer coefficients) and congruences. Therefore one can interpret Problems Q3, Q4 as

Problem 6.7. Find the inequalities and congruences in the description of Sol(Q3) and Sol(Q4) as unions of elementary sets.

An example of such description is given in [KM2] for Sol(Q4, G), $G = \mathrm{Sp}(4, \mathbb{C})$, $G = G_2$. Note that for these groups, Sol($\mathbf{Qi}$, G), $i = 3, 4$, are not elementary sets themselves.

Note that if Conjecture 4.14 holds, then for each simply-laced group $\underline{G}$ the sets Sol(Q3), Sol(Q4) are elementary and are both equal to

$$D_3(X) \cap L^3,$$

where $X = \underline{G}(\mathbb{C})/K$.

Quantum product problems. Throughout this paper we restricted our attention only to noncompact Lie groups and nonpositively curved spaces. However Problem Q2 has a straightforward generalization in the case of compact Lie groups.

Let K be a maximal compact subgroup in a complex semisimple Lie group G. Then an alcove a of the associated affine Weyl group parameterizes conjugacy classes in K. The following is an analogue of Problem Q2.

Problem 6.8. Find necessary and sufficient conditions on elements $\lambda, \mu, \nu \in a$ in order that there exist elements $A, B, C \in K$ whose projections to a are λ, μ and ν, respectively, so that $ABC = 1$.

This problem was solved independently by S. Agnihotri and C. Woodward [AW] and P. Belkale ([AW], [Be1]) in the case $K = U(n)$. This solution was generalized to all simple groups G by C. Teleman and C. Woodward in [TW]. The solution is given in a form of *nonhomogeneous* linear inequalities analogous to $(*_{\zeta;\vec{\eta}})$, where Schubert calculus is replaced with *quantum Schubert calculus*. An analogue of Horn recurrence formula for this problem was established by P. Belkale in [Be3].

Problem 6.9. 1. Solve the analogue of Problem 1.1 for compact symmetric spaces.

2. Is there an analogue of Problem Q3 in the setting of compact groups?

In the context of compact Lie groups, Problem Q4 generalizes to the problem about *product structure of the fusion ring $R_\ell(G)$ at level ℓ*, which is a certain quotient of the representation ring of the group G. For the characters $\mathrm{ch}(V_\lambda)$, $\mathrm{ch}(V_\mu)$, $\mathrm{ch}(V_\nu)$ in the ring $R_\ell(G)$ consider the decomposition of the triple product:

$$\mathrm{ch}(V_\lambda) \cdot \mathrm{ch}(V_\mu) \cdot \mathrm{ch}(V_\nu) = \sum_\delta \tilde{n}_{\lambda,\mu,\nu,\ell}(\delta)\mathrm{ch}(V_\delta).$$

Problem 6.10. Give necessary and sufficient conditions on λ, μ, ν in order that

$$\tilde{n}_{\lambda,\mu,\nu,\ell}(0) \neq 0.$$

P. Belkale proved in [Be3] an analogue of the Knutson–Tao saturation theorem for Problem 6.10, thereby establishing equivalence between Problem 6.10 and the multiplicative Problem 6.8:

Theorem 6.11. *For λ, μ, ν so that $\lambda + \mu + \nu \in Q(R)$,*

$$\tilde{n}(N\lambda, N\mu, N\nu, N\ell) \neq 0, \quad \text{for some } N \in \mathbb{N},$$

if and only if

$$\tilde{n}(\lambda, \mu, \nu, \ell) \neq 0.$$

Conjecture 6.12 (C. Woodward). The above saturation theorem holds for all simply-laced groups.

The asymptotic geometry of negatively curved spaces: uniformization, geometrization and rigidity

Bruce Kleiner*

Abstract. This is a survey of recent developments at the interface between quasiconformal analysis and the asymptotic geometry of Gromov hyperbolic groups. The main theme is the extension of Mostow rigidity and related theorems to a broader class of hyperbolic groups, using recently developed analytic structure of the boundary.

Mathematics Subject Classification (2000). Primary 30C65; Secondary 20F57.

Keywords. Quasiconformal geometry, geometric group theory, rigidity.

1. Introduction

The celebrated Mostow rigidity theorem [49] states that if X and X' are symmetric spaces of noncompact type with no de Rham factors isomorphic to the hyperbolic plane, and $\Gamma \subset \mathrm{Isom}(X)$, $\Gamma' \subset \mathrm{Isom}(X')$ are uniform lattices, then any isomorphism $\Gamma \to \Gamma'$ between the lattices is the restriction of a Lie group isomorphism $\mathrm{Isom}(X) \to \mathrm{Isom}(X')$. This theorem and its proof have many important implications, and have inspired numerous generalizations and variants (e.g. [53], [47], [32], [59], [57], [27], [35], [51], [44], [2]) most of which concern lattices in semi-simple groups. Mostow's proof was based on the asymptotic geometry of symmetric spaces, more specifically the quasiconformal or combinatorial structure of the boundary at infinity. Recent developments in analysis on metric spaces and quasiconformal geometry have begun to create the technical framework needed to implement Mostow's proof in a much more general context, yielding new Mostow-type rigidity theorems. The goal of this article is to survey some of these developments and their group theoretic applications.

Organization of the paper. Section 2 discusses some general issues in geometric group theory. Section 3 covers basic facts about Gromov hyperbolic spaces and their boundaries. Section 4 reviews a selection of recent work related to quasiconformal geometry in a metric space setting, and some applications of this are covered in Section 5. Quasiconformal uniformization is discussed in Section 6, and quasiconformal geometrization in Section 7. The last section presents some open problems.

*The author gratefully acknowledges support from NSF grants DMS-0224104 and DMS-0505610.

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

The survey by Mario Bonk in these Proceedings provides a complementary viewpoint on some of the material presented here.

Acknowledgements. I would like to thank Mario Bonk, Marc Bourdon, Juha Heinonen, and John Mackay for numerous helpful comments on an earlier version of this article.

2. Rigidity and geometrization in geometric group theory

The ideas presented in this section are strongly influenced by the work of Gromov [32], [31], [34].

The asymptotic viewpoint in geometric group theory. One of the guiding themes in geometric group theory is that one can often understand the algebraic structure of a group by finding the right geometric realization of the group as a group of isometries. For instance it is very constructive to think of nonabelian free groups as groups acting on trees, and lattices in semi-simple Lie groups as groups of isometries acting on the associated symmetric space. Every finitely generated group has a plentiful supply of isometric actions, namely the actions on its Cayley graphs. Recall that if Σ is a finite generating set for a group G, then the *Cayley graph* of (G, Σ), denoted $\mathrm{Cayley}(G, \Sigma)$, is the graph with vertex set G, in which two group elements $g, g' \in G$ are joined by an edge if and only if $g = g'\sigma$ for some $\sigma \in \Sigma$. The action of G on itself by left translation extends to an action $G \curvearrowright \mathrm{Cayley}(G, \Sigma)$ by graph isomorphisms; one may view this as an isometric action by equipping the Cayley graph with the path metric where each edge has length 1. As a tool for understanding the original group G, Cayley graphs have a drawback: there are too many of them. Nonetheless their asymptotic, or large-scale, structures are all the same. To formalize this idea, we now recall a few definitions.

Definition 2.1. A (possibly discontinuous) map $f : X \to X'$ between metric spaces is a *quasi-isometry* if there are constants L, A such that for every $x_1, x_2 \in X$,

$$\frac{1}{L} d(x_1, x_2) - A \leq d(f(x_1), f(x_2)) \leq L d(x_1, x_2) + A, \tag{2.1}$$

and every $x' \in X'$ lies within distance at most A from a point in the image of f. Here and elsewhere we will use the generic letter "d" for metric space distance functions when it is clear in which metric space distances are being measured. Two metric spaces are *quasi-isometric* if there exists a quasi-isometry from one to another; this defines an equivalence relation on the collection of metric spaces.

A metric space is *proper* if every closed ball is compact. An isometric action $G \curvearrowright X$ on a metric space X is *discrete* if for every ball $B = B(x, r) \subset X$, the set

$$\{g \in G \mid gB \cap B \neq \emptyset\} \tag{2.2}$$

is finite, and *cocompact* if there is a compact subset $K \subset X$ such that

$$X = \bigcup_{g \in G} gK. \tag{2.3}$$

The fundamental lemma of geometric group theory ties these together:

Lemma 2.2. *Suppose G is a finitely generated group, X, X' are proper geodesic spaces, and $G \overset{\rho}{\curvearrowright} X$, $G \overset{\rho'}{\curvearrowright} X'$ are two discrete, cocompact, and isometric actions of G. Then X is quasi-isometric to X'. Moreover one may find a quasi-isometry $f: X \to X'$ which is "quasi-equivariant" in the sense that there is a constant D such that*

$$d(f(gx), gf(x)) < D \tag{2.4}$$

for all $g \in G$, $x \in X$.

If Σ is a finite generating set for a group G, then the action $G \curvearrowright \mathrm{Cayley}(G, \Sigma)$ is discrete, cocompact, and isometric; therefore the collection of actions covered by the lemma is nonempty for any finitely generated group G. This means that there is a well-defined quasi-isometry class of geodesic metric spaces associated with each finitely generated group G, which we will refer to as the quasi-isometry class of G. Another implication of the lemma is that the universal cover of a compact, connected Riemannian manifold M (equipped with the Riemannian distance function) is quasi-isometric to $\pi_1(M)$; this follows from Lemma 2.2 because the deck group action $\pi_1(M) \curvearrowright \tilde{M}$ is discrete, cocompact, and isometric. Thus in addition to Cayley graphs, one has an abundance of other metric spaces representing the quasi-isometry class of the group.

The asymptotic approach to geometric group theory is to study groups by identifying quasi-isometry invariant structure in their quasi-isometry class.

Some asymptotic problems. One of the first quasi-isometry invariants of a metric space X is its *quasi-isometry group*, denoted $\mathrm{QI}(X)$. This is defined to be the collection of equivalence classes of quasi-isometries $f: X \to X$, where two quasi-isometries f, f' are declared to be equivalent if and only if their supremum distance

$$d(f, f') := \sup_{x \in X} d(f(x), f'(x))$$

is finite, and the group law is induced by composition of quasi-isometries. The group $\mathrm{QI}(X)$ is quasi-isometry invariant because a quasi-isometry $X \to X'$ between two metric spaces induces an isomorphism $\mathrm{QI}(X) \to \mathrm{QI}(X')$ by "quasi-conjugation". By Lemma 2.2 it therefore makes sense to speak of the quasi-isometry group of a finitely generated group G.

We now discuss several problems which are central in geometric group theory.

Question 2.3.

A (QI classification of groups). What are the finitely generated groups in a given quasi-isometry class?

B (Classification of QI's). Given a finitely generated group G, what is the quasi-isometry group of G?

C (Uniformization/Recognition). Given a model group, find a criterion for deciding when another group is quasi-isometric to it.

Question A has led to some remarkable mathematics. In each case where it was resolved successfully, new geometric, analytic, combinatorial, or topological ingredients were brought into play. Here are few examples:

• A finitely generated group is quasi-isometric to $\mathbb{Z}^n$ if and only if it is virtually $\mathbb{Z}^n$, i.e. it contains a finite index subgroup isomorphic to $\mathbb{Z}^n$. The proof relies on Gromov's theorem on groups of polynomial growth [33], Pansu's description of asymptotic cones of nilpotent groups [50], and Bass's formula for the growth of a nilpotent group [1]. We note that a new proof was found recently by Shalom [55]; it uses a simpler approach, but it is still far from elementary.

• A finitely generated group quasi-isometric to a free group F_k is virtually free. This is due to Gromov, and uses Stallings' theorem on ends of groups [56].

• A finitely generated group quasi-isometric to a symmetric space X of noncompact type admits a discrete, cocompact, isometric action on X. This follows from combined work of Sullivan, Gromov, Tukia, Pansu, Kleiner–Leeb, and Gabai, Casson–Jungreis. The proofs involve asymptotic geometry – quasiconformal structure on boundaries, asymptotic cones, and Tits geometry.

Question A is related to Question B because if a group G' is quasi-isometric to G, then there is a homomorphism $G' \to \mathrm{QI}(G') \simeq \mathrm{QI}(G)$, and one can approach Question A by studying subgroups of $\mathrm{QI}(G)$.

In most of the cases when Question B has been answered satisfactorily, the approach is to identify a "canonical" or "optimal" metric space X which is quasi-isometric to G, and then argue that the homomorphism $\mathrm{Isom}(X) \to \mathrm{QI}(X)$ is an isomorphism, i.e. that every quasi-isometry of X lies at finite distance from a unique isometry [51], [44], [12]. When this happens, one says that the metric space X is *quasi-isometrically rigid*. This leads to:

Question 2.4. When can one find a quasi-isometrically rigid space in the quasi-isometry class of a given finitely generated group G?

In general, an answer to this question has two parts. The first part is geometrization: finding a candidate for the optimal/rigid metric space in the given quasi-isometry class. In most of the earlier rigidity theorems, geometrization was easy because there was an obvious model space to consider. The second part is to show that the candidate space is actually rigid, which requires one to exploit appropriate asymptotic structure.

Quasi-isometric rigidity may fail because the quasi-isometry group is too large, which is what happens for $\mathbb{Z}^n$, free groups F_k, or lattices in $\mathrm{Isom}(\mathbb{H}^n)$. Nonetheless in

many cases a weaker form of rigidity survives: there is a proper metric space X in the quasi-isometry class such that any group in this class admits – possibly after passing to a finite index subgroup – a discrete, cocompact, isometric action on X. To put it another way: any group quasi-isometric to X is virtually a lattice in $\mathrm{Isom}(X)$, when one topologizes $\mathrm{Isom}(X)$ using the compact-open topology. So although individual quasi-isometries are not rigid, sufficiently large groups of quasi-isometries may turn out to be rigid. When this weaker form of rigidity holds, one may ask if the analog of Mostow rigidity is true.

Question C has a satisfactory answer for only a few classes of groups, such as free groups, free abelian groups, and surface groups. For instance, a finitely generated group G is virtually free if for every Cayley graph $\mathcal{G}$ there are constants r, R such that any two points $x, y \in \mathcal{G}$ at distance at least R lie in distinct components of the complement of some r-ball $B(z, r) \subset \mathcal{G}$. An important unresolved case of Question C, which is tied to conjectures in 3-manifold topology, is to find a characterization of groups quasi-isometric to hyperbolic 3-space $\mathbb{H}^3$. This is discussed in Section 6.

In the remainder of this paper, we will focus on these questions and related mathematics in the context of negatively curved manifolds, or more generally Gromov hyperbolic spaces.

3. Gromov hyperbolic spaces and their boundaries

In this section we review some facts about Gromov hyperbolicity, see [31], [30], [16], [34], [41]. Gromov hyperbolic spaces form a robust class of metric spaces to which much of the theory of negatively curved Riemannian manifolds applies. They have a boundary at infinity, which plays an essential role in rigidity applications. Much of their asymptotic structure is encoded in the quasiconformal (or quasi-Möbius) structure of the boundary; this fact enables one to exploit the analytic theory of quasiconformal homeomorphisms.

We recall that a geodesic metric space X is *Gromov hyperbolic* if there is a constant δ such that every geodesic triangle in X is δ-*thin*, in other words, each side lies within the δ-neighborhood of the union of the other two sides. Gromov hyperbolicity is a quasi-isometry invariant property for geodesic metric spaces [16]. A finitely generated group is *Gromov hyperbolic* if its quasi-isometry class is Gromov hyperbolic, see Lemma 2.2 and the ensuing commentary.

Except when it is explicitly stated to the contrary, for the remainder of this paper X will denote a proper Gromov hyperbolic geodesic metric space and δ its hyperbolicity constant.

Prime examples of Gromov hyperbolic spaces are complete simply-connected Riemannian manifolds of sectional curvature bounded above by a constant $\kappa < 0$, equipped with their Riemannian distance functions, and more generally, simply-connected Alexandrov spaces of curvature $\leq \kappa$ [16]. Metric trees and piecewise

Euclidean polyhedra satisfying appropriate link conditions also provide many examples of group theoretic interest [31], [30], [16].

Two geodesic rays $\gamma_1, \gamma_2 \colon [0, \infty) \to X$ are *asymptotic* if the Hausdorff distance between their images is finite; this defines an equivalence relation on the collection of geodesic rays in X. The *boundary* of X, denoted ∂X, is the collection of equivalence classes. Pick $p \in X$. Given $[\gamma] \in \partial X$, there is a unit speed geodesic ray starting from p which is asymptotic to γ; thus one may identify ∂X with the collection of asymptote classes of geodesics rays starting at p. Given unit speed geodesic rays $\gamma_1, \gamma_2 \colon [0, \infty) \to X$ starting from p, their *Gromov overlap* is defined to be

$$\langle \gamma_1 \mid \gamma_2 \rangle := \lim_{t \to \infty} \frac{1}{2} \left(2t - d(\gamma_1(t), \gamma_2(t))\right) \in [0, \infty]. \tag{3.1}$$

To within an additive error comparable to the hyperbolicity constant δ, the overlap of two rays is the infimal $t \in \mathbb{R}$ such that the distance from $\gamma_1(t)$ to $\gamma_2(t)$ is $> \delta$.

Visual metrics. A *visual metric* on ∂X is a metric ρ such that for some constants $a > 0$ and C (a is called the visual parameter of ρ), and some $p \in X$,

$$\frac{1}{C} e^{-a\langle \gamma_1 | \gamma_2 \rangle} \leq \rho(\gamma_1, \gamma_2) \leq C e^{-a\langle \gamma_1 | \gamma_2 \rangle} \tag{3.2}$$

for every pair of rays γ_1 and γ_2 starting at p. This condition is independent of the choice of basepoint used to define the overlap. When a is small compared to $1/\delta$, visual metrics with visual parameter a always exist.

Henceforth when we refer to the boundary ∂X, we will mean the set ∂X equipped with some visual metric, unless otherwise stated. Here are some examples of visual metrics (note that the assertions apply to a particular choice of visual metric):

• The boundary of $\mathbb{H}^n$ is bi-Lipschitz homeomorphic to the sphere S^{n-1} equipped with the usual metric.

• The boundary of complex hyperbolic space $\mathbb{CH}^n$ is bi-Lipschitz homeomorphic to S^{2n-1} equipped with the usual Carnot metric. We recall that this metric is defined as follows. Let Δ be the usual contact structure on S^{2n-1} induced by the embedding of S^{2n-1} into $\mathbb{C}^n$. The Carnot distance between two points $p, q \in S^{2n-1}$ is the infimum of the lengths of integral curves of Δ which join p to q. This metric on the $(2n-1)$-sphere has Hausdorff dimension $2n$.

• Let T be a trivalent simplicial tree where each edge has length 1. Then ∂T is a Cantor set.

• Let M be a compact Riemannian 3-manifold of constant sectional curvature -1 with nonempty totally geodesic boundary, and let X be its universal cover equipped with the Riemannian distance function. Then X isometrically embeds in $\mathbb{H}^3$ as a convex subset C bounded by a countable collection of disjoint totally geodesic planes, and ∂X may be identified with the limit set of C in the sphere at infinity of $\mathbb{H}^3$. The limit set is obtained by removing a countable disjoint collection of round spherical caps from the 2-sphere, and is homeomorphic to the Sierpiński carpet.

There is not much one can say about boundaries of Gromov hyperbolic spaces in general since every compact doubling metric space is isometric to the boundary of a proper Gromov hyperbolic space equipped with a visual metric, see [13, Section 2]. However, if X admits a discrete, cocompact, isometric action, then the boundary structure is much more restricted – it is *approximately self-similar* in the following sense. There are constants $L,\ D > 0$ such that if $B(p,r) \subset \partial X$ is a ball with $0 < r \leq \operatorname{diam}(\partial X)$, then there is an open subset $U \subset \partial X$ of diameter $> D$ which is L-bi-Lipschitz homeomorphic to the rescaled ball $\frac{1}{r}B(p,r)$. This approximate self-similarity has many implications for the topology and geometry of ∂X. Before stating them, we need several definitions.

Definition 3.1. A metric space Z is *Ahlfors Q-regular* if there is a constant C such that the Q-dimensional Hausdorff measure of any r-ball B satisfies

$$\frac{1}{C}r^Q \leq \mathcal{H}^Q(B) \leq Cr^Q, \tag{3.3}$$

provided $r \leq \operatorname{diam}(Z)$.

Note that an Ahlfors Q-regular space has Hausdorff dimension Q. Examples of Ahlfors regular spaces are $\mathbb{R}^n$ and S^{2n-1} equipped with standard Carnot metric.

The next definitions are scale-invariant, quantitative versions of standard topological conditions.

Definition 3.2. A metric space Z is *linearly locally contractible* if there is a constant $\lambda > 0$ such that for all $x \in Z$, $0 < r \leq \operatorname{diam}(Z)$, the inclusion

$$B(x, \lambda r) \to B(x, r) \tag{3.4}$$

is null-homotopic. Linear local contractibility excludes examples where the metric topology looks worse and worse at smaller and smaller scales. For instance, a metric on a two sphere which has a sequence of "fingers" of smaller and smaller diameter, for which the ratio of the diameter to the circumference tends to infinity, will not be linearly locally contractible.

A metric space Z is *uniformly perfect* if there is a constant $\lambda > 0$ such that if $p \in Z$, $0 < r \leq \operatorname{diam}(Z)$, then $B(p,r) \setminus B(p, \lambda r)$ is nonempty.

A metric space Z is *linearly locally connected*, or LLC (not to be confused with "linearly locally contractible"), if there is an L such that for all $p \in Z$, $0 < r \leq \operatorname{diam}(X)$, the inclusions

$$B(p,r) \to B(p, Lr), \quad X \setminus B(p,r) \longrightarrow X \setminus B\left(p, \frac{r}{L}\right) \tag{3.5}$$

induce the zero homomorphism on reduced 0-dimensional homology. This is a standard type of condition in quasiconformal geometry, and is a quantitative version of local connectedness and absence of local cut points.

Theorem 3.3 (Structure of the boundary). *If X is a proper, geodesic, Gromov hyperbolic space which admits a discrete, cocompact, isometric action, then:*

1. *∂X is either empty, has two elements, or is uniformly perfect.*
2. *∂X is Ahlfors Q-regular for some Q* ([26]).
3. *If ∂X is connected, it is LLC* ([4], [15], [58], [7]).
4. *If ∂X is homeomorphic to S^k, then ∂X is linearly locally contractible.*
5. *If X is a contractible n-manifold, then ∂X is a homology $(n-1)$-manifold with the homology of the $(n-1)$-sphere* [4], [3]. *When $n \leq 3$ then ∂X is a sphere.*

Induced homeomorphisms between boundaries. In applications to group theory and rigidity, a key property of the boundary is that quasi-isometries between Gromov hyperbolic spaces induce homeomorphisms between their boundaries. To formulate this more precisely we need the following definition, which is due to Väisälä.

Definition 3.4 ([63]). The *cross-ratio*, $[z_1, z_2, z_3, z_4]$, of a 4-tuple of distinct points (z_1, z_2, z_3, z_4) in a metric space Z is the quantity

$$[z_1, z_2, z_3, z_4] := \frac{d(z_1, z_3)d(z_2, z_4)}{d(z_1, z_4)d(z_2, z_3)}. \tag{3.6}$$

This is a metric space version of the familiar cross-ratio in complex analysis. A homeomorphism $\phi\colon Z \to Z'$ between metric spaces is *quasi-Möbius* if there is a homeomorphism $\eta\colon [0,\infty) \to [0,\infty)$ such that for every quadruple of distinct points $(z_1, z_2, z_3, z_4) \in Z$,

$$[\phi(z_1), \phi(z_2), \phi(z_3), \phi(z_4)] \leq \eta([z_1, z_2, z_3, z_4]). \tag{3.7}$$

Such a homeomorphism η is called a *distortion function* for the homeomorphism ϕ. Intuitively, a homeomorphism is quasi-Möbius if it distorts cross-ratios in a controlled way.

Compositions and inverses of quasi-Möbius homeomorphisms are quasi-Möbius, so every metric space Z has an associated group of quasi-Möbius homeomorphisms, which we denote by $\mathrm{QM}(Z)$.

Theorem 3.5 ([52]). *Every quasi-isometry $f\colon X \to X'$ between Gromov hyperbolic spaces induces a quasi-Möbius homeomorphism $\partial f\colon \partial X \to \partial X'$ between their boundaries. The distortion function η for ∂f can be chosen to depend only on the hyperbolicity constants of X and X', the constants for the visual metrics on ∂X and $\partial X'$, and the quasi-isometry constants of f.*

In particular, the full isometry group of a Gromov hyperbolic space acts on its boundary as a group of quasi-Möbius homeomorphisms with uniform distortion function.

The proof of Theorem 3.5 has two ingredients. The first is the "Morse Lemma", which implies that f maps each geodesic segment (respectively ray) in X to within controlled Hausdorff distance of a geodesic segment (respectively ray) in X'. This yields the induced set-theoretic bijection $\partial f\colon \partial X \to \partial X'$. To verify that ∂f is quasi-Möbius, the idea is to associate to each 4-tuple of points in ∂X a configuration in X consisting of a pair of geodesics and a shortest geodesic segment connecting them. The cross-ratio is determined by the length of the connecting geodesic segment, and the latter is preserved to within a factor by the quasi-isometry.

Under mild assumptions, for instance if X is quasi-isometric to a nonelementary hyperbolic group (a hyperbolic group which does not contain a finite index cyclic subgroup), the homomorphism $\mathrm{QI}(X) \to \mathrm{QM}(\partial X)$ given by taking boundary homeomorphisms is an isomorphism. Thus one can translate questions about quasi-isometries into questions about quasi-Möbius homeomorphisms of the boundary. This has the additional advantage of eliminating some ambiguity (an equivalence class of quasi-isometries is replaced by a single quasi-Möbius homeomorphism), as well as providing extra structure – the group $\mathrm{QM}(Z)$ has a natural topology.

Questions A–C in Section 2 translate to:

A′. What are the hyperbolic groups whose boundary is quasi-Möbius homeomorphic to a given metric space Z?

B′ What is the group of quasi-Möbius homeomorphisms of the metric space ∂G?

C′. Given a boundary ∂G, how can one tell if another boundary (or space) is quasi-Möbius homeomorphic to it?

The latter two questions make perfect sense and are interesting for spaces other than boundaries, e.g. self-similar spaces like the standard square Sierpinski carpet or the Menger sponge.

4. Quasiconformal homeomorphisms

This section presents some recent results on quasiconformal homeomorphisms. The material was selected for its applicability to rigidity and group theoretic problems, and does not represent a balanced overview. See [38], [37], [61], [25] for more discussion. The somewhat separate topic of uniformization is discussed in Section 6.

We begin with some definitions.

Definition 4.1. Let $f\colon X \to X'$ be a homeomorphism between metric spaces, and $p \in X$. The *dilatation of f at p* is

$$H(f, p) := \limsup_{r\to 0} \frac{\sup\{d(f(x), f(p)) \mid x \in B(p, r)\}}{\inf\{d(f(x), f(p)) \mid x \notin B(p, r)\}}. \tag{4.1}$$

The homeomorphism f is *C-quasiconformal* if $H(f, p) \le C$ for every $p \in X$, and *quasiconformal* if it is C-quasiconformal for some C.

Heuristically, a homeomorphism is quasiconformal if it maps infinitesimal balls to sets of controlled eccentricity.

Definition 4.2. Let (Z, μ) be a metric space equipped with a Borel measure μ, and $p \geq 1$. If Γ is a collection of paths in Z (i.e. continuous maps $[0, 1] \to Z$), then a Borel measurable function $\rho\colon Z \to [0, \infty]$ is Γ-*admissible* if

$$\int_\gamma \rho \, ds \geq 1 \tag{4.2}$$

for every rectifiable path $\gamma \in \Gamma$, where ds denotes the arclength measure. The *p-modulus of* Γ is the infimum of the quantities

$$\int_Z \rho^p d\mu \tag{4.3}$$

where ρ ranges over all Γ-admissible functions on Z. If E, F are subsets of Z, then the *p-modulus of* (E, F), denoted $\mathrm{Mod}_p(E, F)$, is the p-modulus of the collection of paths running from E to F. When Z is an Ahlfors Q-regular space and no measure is specified, we will be using Q-dimensional Hausdorff measure by default.

Modulus is an old and important tool in conformal and quasiconformal geometry, due to its conformal invariance and the fact that it permits one to relate infinitesimal with global behavior of homeomorphisms. One checks by a change of variable computation that a conformal diffeomorphism $M \to M'$ between Riemannian manifolds preserves modulus of curve families, and that a diffeomorphism which preserves modulus is conformal. More generally, the effect of a diffeomorphism on modulus can be controlled by its dilatation.

Quasiconformal homeomorphisms between domains in $\mathbb{R}^n$ have a number of important regularity properties.

Theorem 4.3 ([62]). *Let $f\colon U \to U'$ be a quasiconformal homeomorphism between domains in $\mathbb{R}^n$, $n \geq 2$. Then f belongs to the Sobolev space $W^{1,n}_{\mathrm{loc}}(U, U')$, it is differentiable almost everywhere, and maps sets of measure zero to sets of measure zero. Furthermore, f is ACL; this means that for every direction $v \in \mathbb{R}^n$, for almost every line L parallel to v, the restriction of f to $U \cap L$ is absolutely continuous with respect to 1-dimensional Hausdorff measure $\mathcal{H}^1$. Furthermore, inverses and compositions of quasiconformal homeomorphisms between such domains are quasiconformal.*

The following theorem shows that there are many characterizations of quasiconformal homeomorphisms. This is important because different characterizations are useful in different situations, and also because it demonstrates that this notion is robust.

Theorem 4.4 (see [62]). *Let M and M' be Riemannian manifolds of dimension $n \geq 2$. Then the following conditions on a homeomorphism $f\colon M \to M'$ are quantitatively equivalent:*

1. *f is C-quasiconformal.*
2. *f distorts n-modulus of curve families by a factor at most L.*
3. *f belongs to the Sobolev space $W^{1,n}_{\mathrm{loc}}(M, M')$ and the distributional derivative Df satisfies $|Df|^n \leq C\,\mathrm{Jac}(f)$ almost everywhere, for some C, where $\mathrm{Jac}(f)$ denotes the Jacobian of f with respect to the Riemannian structures on M and M' (the infinitesimal volume distortion factor).*

If one assumes in addition that M and M' are compact, then one may add quasi-Möbius to this list of quantitatively equivalent conditions:

4. *f is η-quasi-Möbius.*

These two theorems show that quasiconformal homeomorphisms are very nicely behaved in a Riemannian context, when $n \geq 2$. Unfortunately, for general metric spaces, or even general Ahlfors regular metric spaces, Definition 4.1 is not necessarily equivalent to the quasi-Möbius condition, and does not lead to a useful theory. Examples show that it is necessary to impose further conditions on the structure of the metric space in order to prove anything akin to Theorem 4.4. After earlier work on Carnot–Carathéodory geometry [49], [45], [48], the breakthrough paper [38] introduced natural conditions for precisely this purpose, and by now they have been shown to imply most of the properties above. The essential requirement on the space is a quantitative link between infinitesimal structure and global structure, which is expressed by a relation between moduli of pairs (E, F) and their relative distance. The *relative distance* between two subsets E, F of a metric space is

$$\Delta(E, F) := \frac{\mathrm{dist}(E, F)}{\min\left(\mathrm{diam}(E), \mathrm{diam}(F)\right)}, \tag{4.4}$$

where

$$\mathrm{dist}(E, F) := \inf\{d(x, y) \mid x \in E,\ y \in F\}. \tag{4.5}$$

This is a scale invariant measure of the separation between two subsets.

Definition 4.5. Let Z be an Ahlfors Q-regular metric space. Then Z is *Q-Loewner* if there is a positive decreasing function $\phi\colon (0, \infty) \to (0, \infty)$ such that

$$\mathrm{Mod}_Q(E, F) \geq \phi(\Delta(E, F)), \tag{4.6}$$

whenever $E, F \subset Z$ are disjoint nondegenerate continua. We recall that a *continuum* is a compact, connected, subset, and a nondegenerate continuum is one of positive diameter. Recall that for Q-regular spaces, Q-dimensional Hausdorff measure is the default measure used to calculate modulus.

Examples of Loewner spaces include Euclidean spaces, compact connected Riemannian manifolds, Carnot groups, and complete connected Riemannian manifolds of nonnegative Ricci curvature.

We remark that for Ahlfors Q-regular spaces, one always has an upper bound on modulus of the following form. There is a function

$$\psi : [0, \infty) \to [0, \infty] \tag{4.7}$$

with $\lim_{t\to\infty} \psi(t) = 0$ such

$$\mathrm{Mod}_Q(E, F) \leq \psi(\Delta(E, F)) \tag{4.8}$$

for any pair of closed subsets E, F. Combining (4.6) and (4.8), one can say that for a Q-Loewner space, the modulus for a pair of disjoint continua is quantitatively controlled by their relative distance.

The paper [38] introduced Definition 4.5, and together with subsequent work [61], [39], [25], most of the facts in Theorems 4.3 and 4.4 have now been proved for quasiconformal homeomorphisms between Loewner spaces.

Theorem 4.6. *Let Z, Z' be compact Q-Loewner spaces for some $Q > 1$.*

1. *Quasiconformal homeomorphisms $Z \to Z'$ are absolutely continuous, i.e. map sets of measure zero to sets of measure zero.*
2. *Every quasiconformal homeomorphism $f : Z \to Z'$ is ACL in the following sense. There is a collection of paths Γ of Q-modulus zero such that if $\gamma : [0, 1] \to Z$ is a path, $\gamma \notin \Gamma$, then $f \circ \gamma : [0, 1] \to Z'$ is absolutely continuous with respect to 1-dimensional Hausdorff measure on the target.*
3. *Every quasiconformal homeomorphism $Z \to Z'$ belongs to the Sobolev space $W^{1,Q}(Z, Z')$.*
4. *For a homeomorphism $f : Z \to Z'$, conditions 1, 2, and 4 of Theorem 4.4 are quantitatively equivalent.*
5. *The inverse of a quasiconformal homeomorphism is quasiconformal.*

In the paper [61] it was shown that quasi-Möbius homeomorphisms between compact Q-regular spaces distort Q-modulus in a controlled way; in particular the Q-Loewner property is invariant under quasi-Möbius homeomorphisms.

The paper [38] also showed that when $Q > 1$, for compact Ahlfors Q-regular spaces, the Q-Loewner condition is equivalent to a $(1, Q)$-Poincaré inequality. This is an analytic condition which relates upper gradients to mean oscillation. We refer the reader to [37] for more on this topic.

Another breakthrough was the paper [25] which established a notion of differentiability for Lipschitz functions on doubling metric measure spaces satisfying a Poincaré inequality, in particular for compact Q-Loewner spaces. This has the remarkable implication that there is a *cotangent bundle* T^*Z for such metric measure spaces, which is a measurable vector bundle equipped with a canonical measurably varying fiberwise norm. Any bi-Lipschitz homeomorphism $(Z, \mu) \to (Z', \mu')$ preserving measure classes induces a derivative mapping $T^*Z' \to T^*Z$, which is a

measurable bundle isomorphism which distorts the norms by a factor controlled by the bi-Lipschitz constant. The paper [39] extended this assertion to Sobolev functions, and showed that quasiconformal homeomorphisms $Z \to Z'$ between Q-regular, Q-Loewner spaces also have a well-defined Cheeger derivative, when $Q > 1$. Using this the author showed [43] that under the same assumptions, the dilatation of a quasiconformal homeomorphism is controlled quantitatively by the dilatation of its derivative mapping $T^*Z' \to T^*Z$; the latter is defined relative to the canonical fiberwise norms on T^*Z and T^*Z'.

5. Applications to rigidity

We now discuss applications of the analytic results in the previous section to rigidity theorems.

The first is Mostow rigidity in the negatively curved case:

Theorem 5.1. *Suppose X and X' are rank* 1 *symmetric spaces of noncompact type other than $\mathbb{H}^2$, and G and G' are cocompact lattices in* $\mathrm{Isom}(X)$ *and* $\mathrm{Isom}(X)$ *respectively. Then any isomorphism $G \to G'$ extends to a Lie group isomorphism* $\mathrm{Isom}(X) \to \mathrm{Isom}(X')$.

The outline of the proof goes as follows. Identifying the two groups G and G' using the isomorphism, one obtains discrete, cocompact, isometric actions $G \curvearrowright X$ and $G \curvearrowright X'$. These induce uniformly quasi-Möbius (in fact Möbius in the $\mathbb{H}^n$ case) boundary actions $G \curvearrowright \partial X$, $G \curvearrowright \partial X'$. By Lemma 2.2 one gets a "quasi-equivariant" quasi-isometry

$$f : X \to X', \tag{5.1}$$

which has a quasi-Möbius boundary homeomorphism $\partial f : \partial X \to \partial X'$. The quasi-equivariance of f implies that ∂f is equivariant with respect to the actions $G \curvearrowright \partial X$ and $G \curvearrowright \partial X'$. By using the equivariance and the dynamics of the group action, one then argues that the derivative of ∂f, which is defined almost everywhere because ∂X and $\partial X'$ are Carnot spaces [49], [45], [48], [51], must actually be conformal almost everywhere. This implies that $\partial f = \partial h$, for a unique isometry $h : X \to X'$. It follows readily that h is G-equivariant, and induces the desired isomorphism $\mathrm{Isom}(X) \to \mathrm{Isom}(X')$.

Pansu used a similar outline to show that for rank 1 symmetric spaces other than the hyperbolic and complex hyperbolic spaces an even stronger rigidity result holds:

Theorem 5.2 ([51]). *Suppose X is a quaternionic hyperbolic space or the Cayley hyperbolic plane, and X' is a rank* 1 *symmetric space of noncompact type. Then any quasi-isometry $X \to X'$ is at bounded distance from a unique isometry.*

The proof of this theorem also uses boundary geometry. The boundary homeomorphism $\partial f : X \to X'$ for a quasi-isometry is quasiconformal, and Pansu shows

that for the spaces in question, the derivative is forced to be conformal even without invoking an equivariance assumption as in Mostow's proof.

This kind of argument was used in a "non-classical" setting in work of Bourdon, Bourdon–Pajot, and Xie, proving a Pansu-type rigidity result for Fuchsian buildings:

Theorem 5.3 ([8], [11], [12], [9], [64]). *Every quasi-isometry between Fuchsian buildings is at finite distance from an isomorphism.*

Here a *Fuchsian building X* is a special kind of 2-dimensional polyhedral complex. It is a union of subcomplexes called *apartments*, each of which is isomorphic to the Coxeter complex associated with a fixed Coxeter group acting on $\mathbb{H}^2$. We refer the reader to the papers above for the precise definition. The proof of this rigidity result also uses the quasiconformal structure on the boundary, but in this case the boundary is a Loewner space homeomorphic to the Menger sponge, and much of the theory in Section 4 is brought into play.

Another result in a spirit similar to Mostow rigidity is:

Theorem 5.4 ([57], [32], [59], [51], [22]). *Suppose G is a finitely generated group quasi-isometric to a rank* 1 *symmetric space X other than* $\mathbb{H}^2$. *Then G admits a discrete, cocompact, isometric action on X.*

The outline of the proof goes as follows. The group G acts by isometries on a Cayley graph $\mathrm{Cayley}(G, \Sigma)$, and a quasi-isometry $\mathrm{Cayley}(G, \Sigma) \to X$ allows one to "conjugate" this isometric action to a "quasi-action" by quasi-isometries $G \curvearrowright X$. Passing to the boundary, one obtains an action $G \curvearrowright \partial X$ by uniformly quasi-Möbius homeomorphisms, in particular uniformly quasiconformal homeomorphisms. By a lemma of Sullivan, this action $G \curvearrowright \partial X$ is actually conformal with respect to some bounded measurable Riemannian structure on $T^*\partial X$; recall that ∂X is a Loewner space and therefore has a Cheeger cotangent bundle $T^*\partial X$ whose fiberwise norm can be used to express the boundedness condition on the Riemannian structure. By using the dynamics of the action and a rescaling argument, one shows that modulo quasi-Möbius conjugation, this Riemannian metric can be taken to be standard. This means that the action is actually conformal in the usual sense, and is therefore induced by an isometric action $G \curvearrowright X$.

Now suppose Z and Z' are compact Q-Loewner metric spaces, where $Q > 1$. The differentiation theory for quasiconformal homeomorphisms enables one to make the following definition:

Definition 5.5. Suppose $\langle \cdot, \cdot \rangle$, $\langle \cdot, \cdot \rangle'$ are measurable Riemannian structures on T^*Z and T^*Z'. A homeomorphism $f\colon Z \to Z'$ is *conformal* with respect to these structures if it is quasiconformal and its derivative

$$Df(z)\colon (T^*_{f(z)}Z', \langle \cdot, \cdot \rangle') \to (T^*_z Z, \langle \cdot, \cdot \rangle) \tag{5.2}$$

is conformal for almost every $z \in Z$. The *conformal group of* $(Z, \langle \cdot, \cdot \rangle)$, denoted $\mathrm{Conf}(Z, \langle \cdot, \cdot \rangle)$, is the group of conformal homeomorphisms

$$(Z, \langle \cdot, \cdot \rangle) \to (Z, \langle \cdot, \cdot \rangle). \tag{5.3}$$

By the lemma of Sullivan quoted above, any countable group of uniformly quasiconformal homeomorphisms of Z is conformal with respect to some bounded measurable Riemannian structure on T^*Z. In particular, if G is a Gromov hyperbolic group whose boundary is quasi-Möbius homeomorphic to a Q-Loewner space for $Q > 1$, then G may be viewed as a group of conformal homeomorphisms in this sense. For such a group, the full conformal group $\mathrm{Conf}((Z, \langle \cdot, \cdot \rangle)$ provides a natural substitute for the ambient Lie group that one has in the case of lattices in rank 1 Lie groups. The following result shows that in this case the homomorphism $G \to \mathrm{Conf}((Z, \langle \cdot, \cdot \rangle)$ is canonically attached to G:

Theorem 5.6 (Mostow rigidity for Loewner groups [43]). *Suppose G is a Gromov hyperbolic group, and*

$$G \overset{\rho}{\curvearrowright} (Z, \langle \cdot, \cdot \rangle), \quad G \overset{\rho'}{\curvearrowright} (Z', \langle \cdot, \cdot \rangle') \tag{5.4}$$

are conformal actions of G on Loewner spaces which are topologically conjugate to the action of G on its boundary ∂G. Then ρ is conformally equivalent to ρ'.

The proof is identical to that of Theorem 5.4 until the last step, which requires one to exploit delicate infinitesimal structure of the Loewner space.

6. Uniformization

The uniformization problem for spheres. A Riemannian metric g is *bounded* if there is a C such that

$$\frac{1}{C} g_0(v, v) \leq g(v, v) \leq C g_0(v, v) \quad \text{for all } v \in TS^2. \tag{6.1}$$

We recall the following extension of the Koebe uniformization theorem to measurable conformal structures:

Theorem 6.1 (The measurable Riemann mapping theorem). *If g is a bounded measurable Riemannian metric on the 2-sphere, then g is conformally equivalent to the standard metric g_0, i.e. there is a quasiconformal homeomorphism $f : S^2 \to S^2$ such that the derivative*

$$Df(x) : (T_x S^2, g) \to (T_x S^2, g_0) \tag{6.2}$$

is conformal almost everywhere. Moreover the uniformizing homeomorphism is unique up to post-composition with Möbius transformation.

Theorem 6.1 and a version for parametrized families of Riemannian metrics are fundamental tools in Kleinian groups and complex dynamics.

It is very tempting to extend Theorem 6.1 to a more general setting. An approach based on a type of coverings ("shinglings") was introduced by Cannon [17], and further developed in [19], [20], [21], [18]. In a metric space setting, one is naturally led to the following quasi-Möbius uniformization problem:

Question 6.2. When is a metric n-sphere quasi-Möbius homeomorphic to the standard n-sphere $\mathbb{S}^n$?

Here a *metric n-sphere* means a metric space homeomorphic to the n-sphere.

One arrives at the $n = 2$ case of this question starting with Question C from Section 2, in the $\mathbb{H}^3$ case, since a geodesic space quasi-isometric to $\mathbb{H}^3$ is Gromov hyperbolic and has boundary quasi-Möbius homeomorphic to S^2. The question is also tied to one approach to:

Conjecture 6.3 (Thurston's Hyperbolization Conjecture). Every closed, aspherical, irreducible, atoroidal 3-manifold M admits a Riemannian metric of constant curvature -1.

The relation with Question 6.2 is as follows. Gabai–Meyerhoff–Thurston [29] reduced Conjecture 6.3 to showing that $\pi_1(M)$ is isomorphic to the fundamental group of a hyperbolic manifold (a closed Riemannian manifold of constant curvature -1). When $\pi_1(M)$ is Gromov hyperbolic, [4] implies that the boundary of $\pi_1(M)$ is homeomorphic to the 2-sphere. Therefore the Gromov hyperbolic case of Conjecture 6.3 is implied by:

Conjecture 6.4 (Cannon). If G is a Gromov hyperbolic group and ∂G is homeomorphic to the 2-sphere S^2, then G admits a discrete, cocompact, isometric action on hyperbolic 3-space $\mathbb{H}^3$.

By Theorem 5.4 and the converse of Theorem 3.5, it follows readily that Cannon's conjecture is equivalent to the following case of Question 6.2:

Conjecture 6.5. If G is a Gromov hyperbolic group and ∂G is homeomorphic to S^2, then it is quasi-Möbius homeomorphic to the standard 2-sphere.

Although Thurston's conjecture appears to have been solved by Perelman, Conjecture 6.4 remains very interesting – it is logically independent of the Hyperbolization Conjecture, and moreover it provides an approach to an old unsolved problem due to Wall: Is every 3-dimensional Poincaré duality group is a 3-manifold group?

Necessary conditions for uniformization. The uniformization problem above was discussed in [60], where two necessary conditions were identified. A metric n-sphere which is quasi-Möbius homeomorphic to the standard n-sphere must be doubling and linearly locally contractible. Recall that a metric space is *doubling* if there is a constant N such that every ball can be covered by at most N balls of half the radius. We note that if the boundary of a hyperbolic group is homeomorphic to a sphere, then it satisfies both of these conditions since Ahlfors regular spaces are always doubling, see Section 3. When $n = 1$ these two necessary conditions are sufficient:

Theorem 6.6 ([60]). *A doubling, linearly locally contractible metric circle is quasi-Möbius homeomorphic to the standard circle.*

However, when $n \geq 2$, the conditions are not sufficient. One can show that $\mathbb{R}^2$ with the homogeneous distance function

$$d((x_1, y_1), (x_2, y_2)) := |x_1 - x_2| + |y_1 - y_2|^{\frac{1}{2}} \tag{6.3}$$

is not locally quasi-Möbius homeomorphic to $\mathbb{R}^2$, and it is possible to construct a doubling linearly locally contractible metric on S^2 which is locally isometric to the metric (6.3) near some point.

Sufficient conditions for uniformization. Motivated by considerations relating analytic properties of a space and the existence of good parametrizations, Semmes made the following conjecture:

Conjecture 6.7 ([40]). If Z is an Ahlfors 2-regular, linearly locally contractible 2-sphere, then Z is quasi-Möbius homeomorphic to the standard 2-sphere.

This conjecture was proven in [5]. Recall that the Hausdorff dimension of any metric space is always greater than or equal to its topological dimension. For linearly locally contractible 2-spheres, one can strengthen this to the quantitative assertion that every r-ball has 2-dimensional Hausdorff measure at least comparable to r^2, for $r \leq \operatorname{diam}(Z)$. Thus the Ahlfors 2-regularity condition in the hypothesis of Conjecture 6.7 provides a competing upper bound on the Hausdorff measure; in some sense this tension is the key to the proof. We remark that this result is optimal in several respects. First, Semmes had shown in [54] that the analogous assertion is false in higher dimensions: for every $n \geq 3$ there are Ahlfors n-regular, linearly locally contractible metric n-spheres which are not quasi-Möbius homeomorphic to the standard n-sphere. Also, the conclusion cannot be strengthened to bi-Lipschitz homeomorphism, due to examples of Laakso [46]. Finally, the Ahlfors 2-regularity condition cannot be relaxed to Q-regularity because by using metrics as in (6.3) one can get examples which are Ahlfors 3-regular.

Nonetheless, one can relax the 2-regularity condition if one imposes a Loewner condition:

Theorem 6.8 ([5]). *If Z is a Q-Loewner metric 2-sphere, then $Q = 2$ and Z is quasi-Möbius homeomorphic to the standard 2-sphere.*

In particular, as indicated above, Cannon's conjecture is true for those hyperbolic groups whose boundary is quasi-Möbius homeomorphic to a Loewner 2-sphere. The higher dimensional analog of Theorem 6.8 is false, because the Carnot metric on S^3 is 4-Loewner but not quasi-Möbius homeomorphic to S^3.

Quasi-Möbius characterizations of the 2-sphere. In [5], the proofs of Theorem 6.8 and Conjecture 6.7 invoked a more general necessary and sufficient condition. To formulate this, we require a combinatorial version of modulus, and the related definitions.

Suppose $\mathcal{G}$ is a graph with vertex set $V = V(\mathcal{G})$, and Γ is a collection of subsets of V; in our context, the elements $\gamma \in \Gamma$ will be the vertex sets of certain connected subgraphs of Γ. A function $\rho\colon V(\mathcal{G}) \to [0, \infty)$ is Γ-*admissible* if for every $\gamma \in \Gamma$,

$$\sum_{v \in \gamma} \rho(v) \geq 1. \tag{6.4}$$

If $Q \geq 1$, the Q-*modulus of* Γ is the infimum of

$$\sum_{v \in \mathrm{Vertex}(\mathcal{G})} \rho^Q(v) \tag{6.5}$$

where ρ ranges over all Γ-admissible functions.

Pick $Q \geq 1$. Now suppose Γ is a path family in a metric space Z, and $\mathcal{U}$ is an open cover of Z. Then the Q-*modulus of* Γ *with respect to* $\mathcal{U}$, denoted $\mathrm{Mod}_Q(\Gamma, \mathcal{U})$, is defined as follows. We let $\mathcal{G}(\mathcal{U})$ be the nerve of the open cover $\mathcal{U}$, which is the graph with vertex set $\mathcal{U}$ whose edges correspond to pairs $U, U' \in \mathcal{U}$ with nonempty intersection. Then we let $\Gamma(\mathcal{G})$ be the collection of subsets of the vertex set $V(\mathcal{G})$ of the form

$$\{U \in \mathcal{U} \mid U \cap \mathrm{Im}\, \gamma \neq \emptyset\},$$

where γ ranges over all paths $\gamma \in \Gamma$. Note that each element of $\Gamma(\mathcal{G})$ is the 0-skeleton of a connected subgraph if $\mathcal{G}$. We then define $\mathrm{Mod}_Q(\Gamma, \mathcal{U})$ to be the Q-modulus of $\Gamma(\mathcal{G})$ in $\mathcal{G}$. Finally, if $E, F \subset Z$ are subsets, we let $\mathrm{Mod}_Q(E, F; \mathcal{U}) := \mathrm{Mod}_Q(\Gamma(E, F), \mathcal{U})$, where $\Gamma(E, F)$ denotes the family of paths joining E to F.

Theorem 6.9 ([5]). *Let Z be a doubling, linearly locally contractible metric 2-sphere, and let $\{r_i\}$ be a sequence of positive numbers converging to 0. For each i, let V_i be a maximal r_i-separated subset of Z, and let*

$$\mathcal{U}_i := \{B(v, r_i)\}_{v \in V_i} \tag{6.6}$$

be the corresponding open ball cover. Then the following conditions are equivalent.

- *Z is quasi-Möbius homeomorphic to $\mathbb{S}^2$.*
- *There is a function $\psi\colon [0, \infty) \to [0, \infty]$ tending to zero at infinity, and a number L, such that if $E, F \subset Z$ are closed subsets, then*

$$\mathrm{Mod}_2(E, F; \mathcal{U}_i) \leq \psi(\Delta(E, F)) \tag{6.7}$$

for every i satisfying

$$\min(\mathrm{diam}(E), \mathrm{diam}(F)) \geq L\, r_i.$$

Here $\Delta(E, F)$ denotes the relative distance as before.

- *There is a positive decreasing function* $\phi\colon [0,\infty) \to (0,\infty)$ *and a number* M *such that if* $E, F \subset Z$ *are continua, then*

$$\mathrm{Mod}_2(E, F; \mathcal{U}_i) \geq \phi(\Delta(E, F)), \tag{6.8}$$

for every i *satisfying*

$$\mathrm{dist}(E, F) \geq M\, r_i.$$

The theorem says that Z is quasi-Möbius equivalent to the standard 2-sphere if and only if, for a sequence of combinatorial approximations, the combinatorial 2-modulus behaves as in $\mathbb{S}^2$, i.e. it can be bounded below or above by functions of relative distance. The idea of the proof is to associate, for each i, a topological triangulation $\mathcal{T}_i$ of Z whose 1-skeleton is quasi-isometric to the nerve of $\mathcal{U}_i$ (with quasi-isometry constants independent of i). Then one can apply classical uniformization to the equilateral polyhedron associated with $\mathcal{T}_i$ to produce a map $f_i\colon V_i \to \mathbb{S}^2$. The crux of the argument is to show that the maps f_i, when appropriately normalized, are uniformly quasi-Möbius, and hence subconverge to a quasi-Möbius homeomorphism by the Arzela–Ascoli theorem.

Other uniformization problems. One may formulate uniformization problems for spaces other than spheres. The case of Sierpinski carpets is especially interesting, where there are remarkable uniformization and rigidity results. We refer the reader to Mario Bonk's article in these Proceedings for a treatment of this topic.

7. Geometrization

Minimizing Hausdorff dimension. Geometrization – the problem of finding optimal or canonical geometric structures – appears in many contexts in mathematics: for example, the Yamabe problem (finding conformally equivalent metrics of constant scalar curvature), Thurston's Geometrization conjecture for 3-manifolds, Thurston's characterization of rational maps, and the Calabi conjecture. For each of these problems there are cases where there is no solution: the Yamabe problem for the "teardrop" 2-orbifold has no solution, and any closed 3-manifold whose prime or torus decomposition is nontrivial does not admit a Thurston geometry. The goal is to show that geometrization is always possible unless some alternate structure appears, on which the failure can be blamed (such as a bad conformal group in the case of the teardrop, or an essential decomposition in the 3-manifold geometrization problem).

In the metric space context, a natural geometrization problem is to minimize the Hausdorff dimension in an attempt to optimize shape. This leads to the following notion, which is a minor variant of a definition of Pansu:

Definition 7.1. The *conformal dimension of a metric space* Z is the infimal Hausdorff dimension of the Ahlfors regular metric spaces quasi-Möbius homeomorphic to it. We denote this by $\mathrm{Confdim}(Z)$.

Visual metrics on boundaries of hyperbolic groups are Ahlfors regular, so

$$\mathrm{Confdim}(\partial G) < \infty$$

for every hyperbolic group G. Likewise

$$\mathrm{Confdim}(Z) < \infty$$

for every self-similar space Z. Every Q-Loewner metric space (Definition 4.5), and more generally Q-regular metric spaces with nontrivial Q-modulus, are solutions to the geometrization problem, because they minimize Hausdorff dimension in their quasi-Möbius homeomorphism class:

Theorem 7.2 (Bonk–Tyson, see [37, Theorem 15.10]). *Suppose Z is a compact Ahlfors Q-regular metric space which carries a family of nonconstant paths of positive Q-modulus. Then any metric space quasi-Möbius homeomorphic to Z has positive Q-dimensional Hausdorff measure, and in particular $Q = \mathrm{Confdim}(Z)$.*

The following theorem of Keith–Laakso shows that the converse is nearly true:

Theorem 7.3 ([42]). *If Z is an Ahlfors Q-regular metric space where*

$$Q = \mathrm{Confdim}(Z) > 1,$$

then some weak tangent of Z carries a nontrivial curve family of positive Q-modulus.

Here a *weak tangent* is a pointed Gromov–Hausdorff limit of a sequence of rescalings of Z, see [42], [6]. If one adds the hypothesis that Z is self-similar, or approximately self-similar like a visual metric on the boundary of a hyperbolic group, then one can map open subsets of a weak tangent to Z itself, and thereby conclude that Z itself has a nontrivial curve family of positive Q-modulus. Therefore Theorem 7.2 has a converse in the self-similar case. The idea of the proof of Theorem 7.3 is to show that if the conclusion of the theorem fails for some Q-regular space Z, then one can use a construction of Semmes (a "Semmes deformation") to produce an Ahlfors regular metric of strictly smaller Hausdorff dimension.

For spaces quasi-Möbius homeomorphic to boundaries of groups, a much stronger statement holds:

Theorem 7.4 ([6]). *If Z is an Ahlfors Q-regular metric space where*

$$Q = \mathrm{Confdim}(Z) > 1,$$

and Z is quasi-Möbius homeomorphic to the boundary of some hyperbolic group G, then Z is Q-Loewner.

The proof of this theorem uses Theorem 7.3, work of Tyson [61], and a dynamical argument to show that for a large supply of ball pairs $B \subset B'$ the pair $(B, \overline{Z \setminus B'})$ has Q-modulus bounded away from zero. The main work consists in showing that this "ball-Loewner" condition implies the usual Loewner property in Definition 4.5.

Theorem 7.4 connects the problem of realizing the conformal dimension with results such as Theorems 5.6 and 6.8, since one would like to know for which hyperbolic groups the boundary is quasi-Möbius homeomorphic to a Loewner space.

Examples where the conformal dimension is (not) realized. Suppose G is an infinite hyperbolic group and $Q = \mathrm{Confdim}(\partial G)$ can be realized by an Ahlfors Q-regular metric. If $Q < 1$ then one can argue that G must be virtually infinite cyclic. If $Q = 1$, then it is not difficult to deduce that ∂G is homeomorphic to a circle, and hence by [23], [28] it is virtually a surface group. If $Q > 1$, then Theorem 7.4 implies that ∂G is quasi-Möbius homeomorphic to a Loewner space, which implies that it is connected and has no local cut points. These two conditions are equivalent by [4], [15], [58], [14] to saying that G does not virtually split over a virtually cyclic group.

Any hyperbolic group G which splits over a finite group has disconnected boundary, so unless G is virtually cyclic, the previous paragraph implies that the conformal dimension of ∂G cannot be realized. A free group of rank at least two is such an example.

Pansu showed that if one takes two copies of a surface of genus 2 and glues them along a homotopically nontrivial simple closed curve, the fundamental group of the resulting 2-complex is a hyperbolic group G where $\mathrm{Confdim}(\partial G) = 1$. Since G is not a virtual surface group, this group provides another example where the conformal dimension cannot be realized. In the case of self-similar spaces (not arising as boundaries of group), it was shown by Laakso that the Sierpinski gasket has conformal dimension 1, but it cannot be realized.

Much deeper examples were constructed by Bourdon and Pajot [13], [10]. These are hyperbolic groups which do not virtually split over virtually cyclic groups, and whose boundaries are not quasi-Möbius homeomorphic to Loewner spaces. These examples are very intriguing, and have led Marc Bourdon to speculate that the nonexistence of Loewner structure implies the presence of fibration-like structure in ∂G which is invariant under the group of quasisymmetric homeomorphisms.

A further necessary condition for the conformal dimension to be realized. Suppose Z is a compact doubling metric space, and $Q > 1$. Then Z satisfies the *combinatorial Q-Loewner property* if the following combinatorial analog of (4.6) and (4.8) holds. There are functions $\phi\colon [0, \infty) \to (0, \infty)$, $\psi\colon [0, \infty) \to [0, \infty]$ and a constant $\lambda > 0$, with the following properties:

- ϕ is a positive decreasing function, $\psi(t) \to 0$ as $t \to \infty$, and $\phi \leq \psi$.
- For every $0 < r \leq \mathrm{diam}(Z)$, if V is a maximal r-separated net in Z, $\mathcal{U}$ is the corresponding r-ball cover, and $E, F \subset Z$ are disjoint nondegenerate continua where $r \leq \lambda \min(\mathrm{diam}(E), \mathrm{diam}(F))$, then

$$\phi(\Delta(E, F)) \leq \mathrm{Mod}_Q(E, F; \mathcal{U}) \leq \psi(\Delta(E, F)), \tag{7.1}$$

where $\mathrm{Mod}_Q(E, F, \mathcal{U})$ is the combinatorial modulus defined just before Theorem 6.9.

Using arguments from [38], [5] is not hard to see that if Z is a Q-Loewner space, then Z satisfies the combinatorial Q-Loewner property. Based on current evidence, the following seems plausible:

Conjecture 7.5. Suppose Z is a self-similar space, or quasi-Möbius homeomorphic to the boundary of a hyperbolic group. If Z satisfies the combinatorial Loewner property, then Z is quasi-Möbius homeomorphic to a Loewner space.

Currently there is no example of a compact doubling space satisfying the combinatorial Loewner property, which is known not to be quasi-Möbius homeomorphic to a Loewner space.

The conjecture is intriguing, because the author has shown that several examples, including the standard square Sierpinski carpet, the standard Menger sponge (obtained from the unit cube in $\mathbb{R}^3$), and boundaries of certain hyperbolic Coxeter groups satisfy the combinatorial Loewner property. Therefore the conjecture would provide new examples of Loewner spaces.

8. Open problems

We conclude with some open problems. These are questions which seem to be key to making further progress with the central themes of this article.

Question 8.1. Let Z be the boundary of a hyperbolic group, or more generally an "approximately self-similar" space. When is the conformal dimension of Z realized?

Question 8.2. Suppose G is a Gromov hyperbolic group. Suppose G does not virtually split over a virtually cyclic group, or equivalently, that ∂G is connected and has no local cut points. Is every quasiconformal homeomorphism of ∂G quasi-Möbius?

Question 8.3. Is the standard square Sierpinski carpet quasi-Möbius homeomorphic to a Loewner space? What is its conformal dimension?

The author and independently [42] have shown that usual metric does not realize the conformal dimension. The author has shown that the square carpet satisfies the combinatorial Q-Loewner property, where Q is its conformal dimension, see Section 7.

Question 8.4. If G is a random hyperbolic group, is the homomorphism $G \to \mathrm{QI}(G)$ an isomorphism?

See [24], [41] for discussion of random groups.

Question 8.5. What are the quasi-isometry groups of the Gromov–Thurston examples [36]?

Lagrangian submanifolds: from the local model to the cluster complex

François Lalonde

Abstract. In these notes, I will present collaborative works on Lagrangian submanifolds that I realised mainly with Octav Cornea (the cluster complex, which naturally leads to a universal Lagrangian Floer theory), but also, at an earlier stage, with Jean-Claude Sikorav. To cover the subject in a more complete and adequate way, I will also mention very recent works by Barraud–Cornea and by Welschinger, closely related to the subject of these notes. The aim of the cluster machinery is to resolve the well known problem of real codimension 1 bubbling off of disks in the Gromov–Floer theory; see Fukaya–Oh–Ohta–Ono (especially the two lectures by Oh and Ono in these proceedings) for a different, earlier, approach.

Mathematics Subject Classification (2000). Primary 53D12; Secondary 53D40.

Keywords. Lagrangian submanifold, cluster homology, Floer complex, J-holomorphic curves, Morse theory.

1. Introduction

By Weinstein's theorem, a sufficiently small neighbourhood of any Lagrangian submanifold $L \subset M$ of a symplectic manifold is symplectomorphic to a neighbourhood of the zero section of the cotangent T^*L of L through a diffeomorphism that sends L to the zero section. The study of Lagrangian submanifolds, which play a fundamental role in our understanding of symplectic geometry, therefore breaks down into two parts:

Local model: study of exact Lagrangian submanifolds in cotangent spaces.

General case: study of Lagrangian submanifolds in general symplectic manifolds.

From a heuristic point of view, these two cases correspond to the following dichotomy in studying Lagrangian submanifolds: either we are in a case where "real bubbling off" of disks is prohibited or not. The former case is much simpler, and the simplest case in which bubbling off cannot occur is the one of closed embedded exact Lagrangian submanifolds in cotangent spaces $L \subset T^*V$ where V is any (not necessarily closed) manifold and where T^*V is equipped with the exact symplectic form $\omega = d\lambda$, with λ the Liouville form on T^*V. Recall that λ is equal to the form $\sum_i p_i dq_i$ in local coordinates where the q_i's are coordinates on V and the p_i's the coordinates naturally induced on the fibers of the cotangent bundle by the q_i's. A

Proceedings of the International Congress of Mathematicians, Madrid, Spain, 2006

submanifold $L \subset T^*V$ is *Lagrangian* if the restriction of ω to L vanishes identically, and it is *exact* if the restriction of λ (which is therefore closed on L) is exact on L. In a general symplectic manifold (M, ω), the notion of a Lagrangian submanifold is defined similarly, and the exactness is replaced by the notion of *weakly exact* meaning that the restriction of ω to $\pi_2(M, L)$ vanishes. It is obvious, by Stokes' Theorem, that an exact Lagrangian submanifold is weakly exact. However, as far as analytic techniques are concerned, there is not much difference between the two concepts (although the geometry might be quite different). See [10] for the definition of (generic) almost complex structures J's on a symplectic manifold tamed by ω. By definition, for such J's, J-invariant real 2-planes in the tangent space of any symplectic manifold are ω-positive – thus non-constant J-pseudoholomorphic curves, also called J-curves, (i.e. those for which the real differential commutes with the complex structure i on the Riemann surface at the source and the J-structure at the target space) have strictly positive symplectic area. *Real bubbling off* is the phenomenon that occurs when a J-curve with boundaries on a finite set of Lagrangian submanifolds of a symplectic manifold degenerates to the connected union of a J-curve connecting the same set of Lagrangian submanifolds and a J-pseudoholomorphic disk with boundary on one of the submanifolds. Thus real bubbling off can only happen if at least one of the classes in $\pi_2(M, L_i)$, for at least one i, has strictly positive symplectic area. Hence there is no bubbling off in (weakly) exact Lagrangian submanifolds, which makes the analytic study much simpler. See [2] for a survey on Lagrangian submanifolds.

2. Exact Lagrangian submanifolds

The most obvious examples of Lagrangian (exact) submanifolds are the graphs, in T^*V, of closed (exact) 1-forms defined on V. It turns out that exact Lagrangian submanifolds behave in a much more rigid way than other Lagrangian submanifolds, so much that the following statement seems a reasonable (although very strong) conjecture:

Conjecture A (see Lalonde–Sikorav [14]). Any closed exact Lagrangian submanifold of a cotangent space is isotopic, through a Hamiltonian isotopy, to the zero section.

A *Hamiltonian isotopy* is a very constraining condition: it requires that the isotopy be Lagrangian at each moment and that the symplectic area of the cylinder spanned by any non-contractible loop during any time interval in the isotopy be zero. Note that this conjecture implies that there is no closed exact Lagrangian submanifold in the cotangent of an open manifold, a fact proved in [14]. Actually, we proved in [14] that the projection $L \to V$ must be surjective in the exact case. This is a consequence of the following "Property 4" of [14]:

Let $K \subset V$ be a closed manifold. Then any closed exact Lagrangian submanifold L must intersect the conormal νK of K in the following two cases: (i) *K is the*

fiber of a submersion $V \to B$ where B is a closed submanifold; (ii) *K is homotopic to a point in V.*

Since the conormal of a point $q \in V$ is the fiber $T^*_q V$ at that point, surjectivity follows from (ii) (see below for a more direct proof). From (i), one may deduce that any two closed exact Lagrangian submanifolds L_0, L_1 must intersect in the cotangent of any homogeneous space $V = G/H$. Indeed, by fiber product, one easily assigns to L_0, L_1 two closed exact Lagrangian submanifolds L'_0, L'_1 of T^*G with a natural bijection between $L_0 \cap L_1$ and $L'_0 \cap L'_1$. But the latter is in bijection with

$$(L'_0 \times L'_1) \cap \Delta_{T^*G} \subset T^*G \times T^*G$$

or, equivalently, with $(L'_0 \times -L'_1) \cap A$ where $A \subset T^*G \times T^*G$ is the anti-diagonal. But $T^*G \times T^*G = T^*(G \times G)$, A is the conormal of Δ_G which is a fiber of the submersion $(g, h) \mapsto gh^{-1}$, so the fact that $(L'_0 \times -L'_1) \cap A$ is not empty is a consequence of Property 4 (i) above.

Conjecture A has many other consequences, that could happen to be true while the conjecture itself might turn out to be false. Denoting by L a closed exact Lagrangian submanifold of T^*V, here are some of these consequences:

(I) L is diffeomorphic to V.

(II) The Maslov index of L vanishes.

(III) The map induced at the π_1-level by the projection $L \to V$ is onto.

(IV) The projection $L \to V$ has degree ± 1.

Except in cotangent spaces of surfaces ($n = 2$), the first of these consequences seems out of reach for the moment. Actually, in the case $n = 2$, many of these properties have been solved and all of them have been established for the torus. Indeed, it is not difficult to see that the formula for the number of double points of an immersed Lagrangian submanifold must be

$$\frac{d^2\chi(V) - \chi(L)}{2}$$

in the orientable case, which implies that the formula $\chi(L) = d^2\chi(V)$ must hold for an embedded Lagrangian submanifold (here d is the degree of the projection $L \to V$). Hence, in dimension 2, (I) is a consequence of (IV) (a similar formula mod 2 holds in the non-orientable case as well). It turns out that (IV) was established for T^2 in [14], and that, for surfaces, the degree $L \to V$ was proved to be always non-zero with the sole exception of an eventual exact degree 0 Lagrangian embedding of the 2-torus in the cotangent of the 2-sphere, a case ruled out by Viterbo a few years later (see [23]) using Floer techniques (or equivalently techniques related to the cohomology of the free loop space).

Let me now briefly explain, from [14], how one can prove all of these consequences, except the first one, in the cotangent of the n-torus, starting from the following basic results proved by Gromov using pseudoholomorphic curves:

Theorem 1 (Gromov [10]). (1) *A closed exact Lagrangian submanifold must intersect the zero section.*

(2) *A closed exact Lagrangian submanifold must intersect any submanifold obtained as the image of itself by a Hamiltonian isotopy.*

(The second statement in Gromov's theorem has been pushed much further by Floer, but this is not relevant at this moment).

We will also use Audin's conjecture, whose proof has recently been announced by several authors, stating that any Lagrangian embedding $L = T^n \to \mathbb{R}^{2n}$ has Maslov number 2 (i.e. there is a loop on L whose Maslov index is 2). Actually, we do not need such a strong conjecture for our present purposes: any bound, say the one found by Viterbo in [22], stating that there is a loop with Maslov index in $[2, n+1]$ for any such embedding, is enough.

Here is how to prove (III) for a closed exact Lagrangian submanifold L in $M = T^*T^n$. First note that the index of $\pi_\#(\pi_1(L))$ in $\pi_1(V)$ is always finite: otherwise, denoting by $V_1 \to V$ the covering corresponding to $\pi_\#(\pi_1(L))$, one could then lift L to a Lagrangian embedding $L_1 \subset T^*V_1$. If the index were infinite, one would then get a closed exact Lagrangian submanifold in the cotangent of an open manifold. The image of the projection $L_1 \to V_1$ would not be surjective. But this is impossible: indeed, if it were not onto, one could then define a Morse function f on V_1 with all of its critical points outside the subset $\pi(L_1)$ of V_1. Translating L_1 by a sufficiently large multiple of df in the fibers of T^*V_1 would produce an exact Lagrangian submanifold that would no longer intersect the zero section, a contradiction with Theorem 1 (1) above.

Now let us show that $f_\#\colon \pi_1(L) \to \pi_1(V)$ must actually be surjective when V is a Lie group. This will prove (III) (and therefore (IV) when V is a torus, if we know that L is also a n-torus). The basic geometric idea is that, if this map were not surjective, one would get more than one disjoint lifts of the same Lagrangian submanifold in the cotangent space of some covering V' of V corresponding to the subgroup $\pi_\#(\pi_1(L))$ in $\pi_1(V)$. But the deck transformations of that covering are induced by translations of the Lie group, and are therefore isotopic to the identity. Thus the group of automorphisms, at the cotangent level, of $T^*V' \to T^*V$, consists of Hamiltonian diffeomorphisms (this is because the differential of any diffeomorphism ϕ of a manifold V' induces a symplectic diffeomorphism of T^*V' and one sees easily that this symplectomorphism is Hamiltonian isotopic to the identity if ϕ is isotopic to the identity). This shows that one gets many disjoint exact Lagrangian embeddings of L, all Hamiltonian isotopic to each other, a contradiction with Theorem 1 (2).

Finally, the second consequence (the vanishing of the Maslov class) for an exact n-torus in the cotangent of the n-torus is proved using the geometric composition $j \circ i$ of two Lagrangian embeddings $i\colon L \to T^*V$ and $j\colon V \to (\mathbb{R}^{2n}, \omega_0)$ given by extending j to a small neighbourhood of the zero section by Weinstein's theorem and then composing after contraction of i in the fibers. The Maslov class formula is $\mu(j \circ i) = \mu(i) + f^*(\mu(j))$ where f is the projection of L on V. One can

start with the standard embedding j and iterate the construction. By the surjectivity of $f_\#$ proved above, one deduces that $f^*\colon H^1(V,\mathbb{Z}) \to H^1(L,\mathbb{Z})$ is a bijection, which gives enough control to exceed any bound imposed by Audin's conjecture or by Viterbo's theorem if $\mu(i)$ does not vanish and if we iterate that construction a sufficient number of times (see [14] for more detail).

Using the Lagrangian surgery introduced in [14], and developed shortly afterwards by L. Polterovich, it was easy to say exactly in [14] which surfaces can be embedded in the cotangent of any surface (orientable or not), with the sole exception of an eventual local embedding of the Klein bottle, a difficult and classical problem whose solution has recently been explored by various methods, especially the ones of symplectic field theory.

2.1. Methods of symplectic field theory. There are, currently, two promising ways of establishing (some of) the above consequences (I)–(IV). The first one is symplectic field theory. The best results obtained so far are in real dimension 4 (cotangent of surfaces):

Let V be either the 2-sphere or the 2-torus. Then any closed orientable exact Lagrangian submanifold L in T^*V is Hamiltonian isotopic to the zero section.

To prove this, note that by Lalonde–Sikorav [14] and Viterbo [23] above, the degree cannot be zero which means, by the double point formula, that $\chi(L) = \chi(V)$; moreover, in the case $V = S^2$, the same formula implies that the degree is 1 while in the case $V = T^2$, this is Consequence (IV) proved above for tori. Thus L is diffeomorphic to V and is homologous to the zero section. On the other hand, building on a result by Eliashberg–Polterovich [7], Hind (preprint "Lagrangian unknottedness in Stein surfaces" based on [11]) and A. Ivrii [13] showed, using methods of SFT, that such a surface is Lagrangian isotopic to the zero section; since we have proved above that the projection in the torus case induces an isomorphism at the $H^1(\,\cdot\,;\mathbb{R})$-level, one may change the isotopy at each time by translating by the graph of an appropriate closed one-form in order to make the isotopy exact, which proves the statement. See the article by Eliashberg in these Proceedings for more on SFT.

2.2. A natural more algebraic approach. The second promising approach is implicit in the methods of [14]: one very simple idea that inspired the results of that paper is that if the projection $L \to V$ is a covering (without singularities), then the degree must be ± 1. The reason is that, if $|d|$ were larger than 1, the differences $x - y$ between all pairs of distinct points $x, y \in L \cap T^*_q V$ would form an exact Lagrangian submanifold $\mathcal{D}(L)$ of T^*V and the resulting submanifold would not meet the zero section, a contradiction. Unfortunately, this simple argument breaks down when singularities of the projection $L \to V$ occur, because some differences may vanish at a singularity. However, this is a frustrating problem since one should recognize the right pairs. A natural way to do this is to replace the difference of pairs by pseudo-holomorphic strips joining pairs of such points, with one boundary on L and the other on the fiber. What is needed is to update the paper [14] by replacing Gromov's theory

by Floer's theory. Such an approach has been suggested by Fukaya for tori (private communication, Ringberg, 1997) and there is some hope that it will eventually lead to proofs of some of the consequences (II), (III) or (IV).

3. The cluster complex

The most useful algebraic tool for studying Lagrangian submanifolds in general symplectic manifolds is Floer homology. The goal is to assign to a pair L_0, L_1 of Lagrangian submanifolds a homology $FH_*(L_0, L_1)$ invariant under Hamiltonian deformations of any of the L_i (thus it would also assign an invariant to a single L by taking L and any of its images by a Hamiltonian isotopy). Assuming L_0, L_1 closed and meeting each other transversally, the complex is generated over $\mathbb{Q}$ by the finite set $I = L_0 \cap L_1$ and the differential is given by $da = \sum_{b\in I,\lambda} \mathrm{Card}(\mathcal{M}(a, b, \lambda; J))be^{\lambda}$ where λ keeps track of the homotopy class of strips joining a to b (parametrised say by the closed unit disk with two point p_-, p_+ removed, such that the lower boundary be sent to L_0, the upper one to L_1, and so that the map converge to a at p_- and to b at p_+) and where $\mathcal{M}(a, b, \lambda; J)$ is the moduli space of J-holomorphic strips joining a to b, with finite symplectic area, in the class λ, after quotient by the real 1-dimensional group of reparametrizations. The cardinality is taking over $\mathbb{Q}$ and is declared to be zero whenever the expected dimension of $\mathcal{M}(a, b, \lambda; J)$ is different from 0.

It is well known that this scheme does not work in general because d^2 is not always zero. The obstruction occurs when there is real bubbling off either on L_0 or on L_1. The reason is that the way to prove that d^2a vanishes follows the same argument as in ordinary Morse homology: an element in d^2a corresponds to two strips u_1 from a to b, and u_2 from b to c, each one belonging to a moduli space of dimension zero. The J-holomorphic surgery at b removes the singularity at b and exhibits the broken configuration (u_1, u_2) as the boundary of a real one-dimensional moduli space of strips u joining a to c. As this manifold $\mathcal{M}$ is compact, it must have another end: if that end is of the form (u_1', u_2') joining a to c through b', one sees that this cancels out the term ce^{λ} in d^2a. However, unfortunately, $\mathcal{M}$ might have an end of a different nature if its one-parameter family of strips degenerates to a configuration made from one strip joining a to c in class $\lambda - \tau$ and one J-holomorphic disk with boundary on either of the L_i in class τ, and meeting the strip at one of its boundary points on L_i (which, generically, can be assumed to be distinct from a and c). In this case, the resulting broken configuration does not correspond anymore to an element of d^2a and the classical cancellation argument breaks down.

With Octav Cornea, we have recently proposed in [5] a solution to overcome this problem by introducing a broader algebra and larger moduli spaces, large enough so that the above undesirable broken configurations be realised as *interior* points in those larger moduli spaces. In order to carry out this programme, the first step consists in defining, for each of the L_i separately, a new complex, the *cluster complex* of L_i, leading to a well-defined homology assigned to each Lagrangian submanifold; the

second step consists in using these complexes as coefficient rings to define a universal Floer homology, that we called the *Fine Floer homology* of the pair (L_0, L_1). From an algebraic point of view, the cluster complex has similarities with Chekanov's contact homology. From the perspective of the objectives, there are obvious similarities with the Fukaya–Oh–Ohta–Ono [8] approach – they introduced a universal object attached to each Lagrangian submanifold using an A^∞-approach and employed it as a coefficient ring; however our approach is based on a different geometric idea, leading to different moduli spaces and the relations between the cluster and the FOOO settings are still unclear.

Here is a description of the cluster homology, the Fine Floer homologies, and some of their applications.

We shall assume here that all Lagrangian submanifolds are compact, connected, orientable, and relative spin (recall that a Lagrangian submanifold $L \subset (M, \omega)$ is relative spin if the second Stiefel–Whitney class of L admits an extension to $H^2(M; \mathbb{Z}/2)$; a set of Lagrangian submanifolds is relative spin if their second Stiefel–Whitney classes admit a common extension to $H^2(M; \mathbb{Z}/2)$). In the notation L for a Lagrangian submanifold we always implicitly include the choices of an orientation and of a relative spin structure (the same applies for a set of such submanifolds) as described in [8]. The ambient symplectic manifold (M^{2n}, ω) is supposed to be compact or, if not, it should be geometrically bounded, so that no sequence of J-curves with boundary lying on a set of compact Lagrangian submanifolds $L_1, \dots, L_\ell \subset M$ can escape to infinity. In fact, the Lagrangian submanifolds need not all be compact, as long as the above control on sequences of J-curves is ensured.

The cluster complex is associated to a triple formed of (1) a Lagrangian embedding $L^n \hookrightarrow (M, \omega)$, equipped with a choice of an orientation and of a relative spin structure, (2) a generic almost complex structure J on M compatible with the symplectic form ω, and (3) a pair (f, g) with $f\colon L \to \mathbb{R}$ a Morse function and g a Riemannian metric on L so that (f, g) is Morse–Smale. The two conditions implicit in the notation L (i.e. the orientation and the relative spin structure) are needed to orient the clustered moduli spaces – to be roughly described below – in a coherent way.

This complex is denoted by $\mathcal{C}\ell_*(L; J, (f, g))$ and, with $\mathrm{Crit}(f)$ denoting the set of critical points of f, we set

$$\mathcal{C}\ell_*(L; J, (f, g)) = (S\mathbb{Q}\langle s^{-1}\,\mathrm{Crit}(f)\rangle \otimes\ \Lambda)^\wedge_*$$

where $s^{-1}\,\mathrm{Crit}(f)$ indicates that the natural index grading of $\mathrm{Crit}(f)$ is decreased by one unit, SV is the free, graded commutative algebra over the graded vector space V (as usual, the sign commutativity rule is $ab = (-1)^{|a||b|}ba$ for any two elements $a, b \in V$), Λ is the rational group ring of the quotient $\pi_2(M, L)/\sim$ where the equivalence relation $\sim$ is given by $\lambda \sim \tau$ iff $\omega(\lambda) = \omega(\tau)$ and $\mu(\lambda) = \mu(\tau)$, where ω and μ are the area and Maslov classes respectively. We write the elements of Λ in the form of finite sums $\sum_i c_i e^{\lambda_i}$, $c_i \in \mathbb{Q}$. The grading in Λ is given by $|e^\lambda| = -\mu(\lambda)$ for $\lambda \in \pi_2(M, L)/\sim$. With this convention, the grading of the cluster complex is given

by the usual tensor product formula. Thus for $x_i \in \mathrm{Crit}(f)$, we have

$$|x_i| = \mathrm{ind}_f(x_i) - 1, \quad |x_1 \dots x_k e^\lambda| = \sum_{i=1}^{k} |x_i| - \mu(\lambda).$$

Finally, we describe the completion $^\wedge$. An element $m \in \mathcal{C}\ell\,(L; J, (f, g))$ can be written as a possibly infinite sum

$$m = m_0 + m_1 e^{\lambda_1} + \cdots + m_i e^{\lambda_i} + \cdots$$

where m_i are monomials in the elements of $\mathrm{Crit}(f)$ but, if this sum is infinite, then any infinite subsequence with $\omega(\lambda_i)$ bounded above, must have its corresponding word length sequence converging to infinity. Conversely, any formal sum verifying this condition belongs to the cluster complex.

We now give a rough idea of the construction of the cluster differential. The generic data $J, (f, g)$ on L being given, fix an order on the critical points of f. Choose any integer $k \geq 0$, any $x \in \mathrm{Crit}(f)$, any non-decreasing sequence of critical points $x_1, \dots, x_k$, and $\lambda \in \pi_2(M, L)/\sim$, with the constraint that the zero class $\lambda = 0$ is allowed only when k equals 1. The cluster differential

$$d\colon (S\mathbb{Q}\langle s^{-1}\,\mathrm{Crit}(f)\rangle \otimes\ \Lambda)^\wedge_* \to (S\mathbb{Q}\langle s^{-1}\,\mathrm{Crit}(f)\rangle \otimes\ \Lambda)^\wedge_{*-1}$$

is the unique commutative, graded differential algebra extension of

$$dx = \sum_{\substack{\lambda, k \geq 0 \\ x_1, \dots, x_k}} a^x_{x_1,\dots,x_k}(\lambda) x_1 \dots x_k e^\lambda, \tag{1}$$

where $x, x_1, \dots, x_k \in \mathrm{Crit}(f)$ have the property that $(x_1, \dots, x_k)$ respects the fixed order on $\mathrm{Crit}(f)$, $|x| - \sum_i |x_i| + \mu(\lambda) - 1 = 0$ and the coefficients $a^x_{x_1,\dots,x_k}(\lambda)$ count with signs the number of elements in the clustered moduli spaces

$${}^{\nu}\mathcal{M}^x_{x_1,\dots,x_k}(\lambda)$$

(due to the possible presence of multi-sections this number will belong in fact to $\mathbb{Q}$).

A rigorous description of the clustered moduli spaces appears in [5]. The main idea in their definition is simple: consider a one parametric family of J-disks of class λ and assume that the bubbling off of a J-disk of class λ' occurs in this family. The "bubbled configuration" formed by two touching J-disks in classes $\lambda'' = \lambda - \lambda'$ and λ' can of course be viewed as the limit of this bubbling off, but it can also be considered as the limit of a one parametric family of two J-disks in the same classes $\lambda'' = \lambda - \lambda'$ and λ' joined by a negative gradient flowline of f whose length tends to 0. By gluing these two one-parameter moduli spaces at their common limit, the above bubbled configuration becomes an interior point of the larger clustered moduli space.

By pursuing systematically this idea together with the usual description of stable maps (as, for example, in McDuff–Salamon [15]) we obtain moduli spaces of configurations modelled on oriented trees with edges of non-negative length so that each vertex corresponds to a J-disk (or sphere), and each edge corresponds to a negative flow line of f joining incidence points situated on the boundaries of the disks whose corresponding vertices are related by that edge. Moreover, to define ${}^{\nu}\mathcal{M}^{x}_{x_1,\dots,x_k}(\lambda)$, such a configuration is supposed to also carry $k+1$ additional marked points $z, z_1, \dots, z_k$ so that z belongs to the boundary of the root disk (which corresponds to the root vertex of the tree) and the z_i's belong to the boundaries of some of the disks involved so that z is in the unstable manifold of the critical point x and z_i is in the stable manifold of x_i; the sum of the classes of the disks and spheres involved has to be λ. There are, of course, appropriate stability conditions and, to insure a reasonable structure for these moduli spaces, we need to use a system ν of perturbations of the pseudoholomorphic equation. The role of ghost disks (for which the corresponding J-disk is constant) is particularly important as they allow to deal not only with the transversality issues due to multiple coverings but also with the crossing of some of the incidence or marked points.

The dimension of ${}^{\nu}\mathcal{M}^{x}_{x_1,\dots,x_k}(\lambda)$ equals

$$|x| - \sum_{i=1}^{k} |x_i| + \mu(\lambda) - 1. \tag{2}$$

These moduli spaces admit natural compactifications ${}^{\nu}\overline{\mathcal{M}}^{x}_{x_1,\dots,x_k}(\lambda)$. To describe its properties, introduce the notation S for a partially ordered set of critical points (in which repetitions are allowed) which, of course, can be identified with a unique non-decreasing sequence of points. If S', S'' are two such ordered subsets, we will denote by $\langle S' \cup S'' \rangle$ the partially ordered subset made of the elements in $S' \cup S''$. Letting S be the ordered set $\{x_1, \dots, x_k\}$, for those moduli spaces of dimension 1 (which are, in fact, branched 1-dimensional manifolds with rational weights) we have:

$$\partial({}^{\nu}\overline{\mathcal{M}}^{x}_{S}(\lambda)) = \bigcup_{\substack{S=\langle S'\cup S''\rangle \\ y,\ \lambda'+\lambda''=\lambda}} ({}^{\nu}\overline{\mathcal{M}}^{x}_{\langle S',y\rangle}(\lambda')) \times ({}^{\nu}\overline{\mathcal{M}}^{y}_{S''}(\lambda'')). \tag{3}$$

Here ∂ represents the top dimensional stratum of the boundary, the summation is taken over all $y \in \mathrm{Crit}(f)$, all partitions of S into two subsets S', S'', all splittings of λ as sum of two classes λ', λ'' and all the ways to insert y in S' so as to get $\langle S', y\rangle$ (this is relevant if y is already present in S'; the number of these ways is $\ell+1$ where ℓ is the number of appearances of y in S', and corresponds geometrically to the choices of Morse gluings at y). We also assume here that the set S does not contain a repetition of a critical point of odd degree. This ensures that ${}^{\nu}\overline{\mathcal{M}}^{x}_{S}(\lambda)$ admits an orientation and the above formula is verified by taking into account orientations with certain signs affecting the terms on the right hand side, while the orientation on the left side is, of course, the one induced on the boundary.

By Gromov's compactness theorem, only a finite number of the moduli spaces appearing on the right hand side of the last equation are non-empty.

This equation implies that the square of the cluster differential, as defined above, vanishes so that we deduce the first part of the following result:

Theorem 2. *The map d satisfies $d^2 = 0$. The resulting homology $\mathcal{C}\ell\, H_*(L)$ does not depend, up to isomorphism, on the choices of (f, g), J and ν.*

Notice that this statement implies that $\mathcal{C}\ell\, H_*(L) \simeq \mathcal{C}\ell\, H_*(\phi(L))$ for any symplectic diffeomorphism $\phi\colon M \to M$.

Due to the commutative DGA setting, proving the invariance part of this statement is more delicate than just the usual Floer type construction for comparison morphisms. Although the comparison morphism itself between two sets of auxiliary data is defined much as in the classical way, we need a spectral sequence argument to prove that it does induce an isomorphism on homology. Since this spectral sequence plays an important role in the theory, here is its description.

Denote by ε_D the infimum of $\int_{D^2} u^*\omega$ over the set of maps $u\colon (D^2, S^1) \to (M, L)$ which are J_t-holomorphic for some t in a compact set (for instance the set of J_t's in a one-parameter family joining the two auxiliary data J and J') and non-constant. This number is strictly positive and we use it to define the *weight* of a monomial $w(x_1 \dots x_k e^{\lambda}) = k + 2\frac{\omega(\lambda)}{\varepsilon_D}$. Then consider the following *word-area* filtration of the cluster complex $\mathcal{C}\ell\,(L; J, (f, g))$:

$$F^{\ell}\mathcal{C}\ell\,(f) = \mathbb{Q}\langle m = x_1 x_2 \dots x_k e^{\lambda} \mid w(m) \geq \ell\rangle.$$

Notice that the cluster differential preserves this filtration. If $m \in \mathcal{C}\ell\,(L; J, (f, g))$ is a monomial, then we may write $dm = d_0 m + \sum_i m_i$ with d_0 the Morse differential and the m_i are monomials with $w(m_i) \geq w(m) + 1$.

The spectral sequence $E^r(f)$ associated to the filtration $F^{\ell}\mathcal{C}\ell\,(f)$ is the *word-area spectral sequence*. The total vector space of the term $E^1(f)$ is isomorphic to $(S(s^{-1}H_*(L; \mathbb{Q})) \otimes \Lambda)^{\wedge}$ because the 0-order differential in the spectral sequence coincides with the Morse differential. It is this spectral sequence that enables us to establish the invariance of the cluster homology.

Remark 3.1. Note that, if the minimal Maslov number of L is at least 2, one may define a simpler version of the cluster complex defined on $\mathbb{Q}\langle \mathrm{Crit}(f)\rangle$ instead of its graded symmetric algebra, with the same Novikov ring, in which the differential is defined by counting only *linear* cluster trees joining two critical points, i.e. strings of gradient flowlines and J-holomorphic discs starting at x and ending at y. In this case, the word-area spectral sequence boils down to Oh's spectral sequence [18] that was especially useful in recent works of Biran.

Remark 3.2. a. A critical point y of index 0 can *never* appear as end in a 0-dimensional, non-empty moduli space of type

$$^{\nu}\mathcal{M}^{x}_{\dots,y,\dots}(\lambda)$$

(except for usual Morse flow lines). This is because, if there were a negative gradient flowline from a non-constant loop in L to a local minimum, there would be a one-parameter family of these (in our construction all J-spheres that might appear are attached to some non-trivial J-disk which means that we may indeed assume the loop in question to be non-constant). Similarly, for such a moduli space, x cannot be a local maximum.

b. An element in the cluster complex, $\tau \in \mathcal{C}\ell\,(L; J, (f, g))$, is written as a sum $\tau = \sum_\lambda (a(\lambda) + m(\lambda))e^\lambda$ where $a(\lambda) \in \mathbb{Q}$ and $m(\lambda)$ is a sum of words (in the letters consisting of the critical points of f) of length at least one. We call each of the terms $a(\lambda)e^\lambda$ with $a(\lambda) \neq 0$ *a free term* of τ. If there is a critical point x of f whose differential contains at least one free term, we say that the *complex has free terms*. Further, if the Morse index of x above is larger or equal to 1, we say that *the cluster complex has high free terms*. Notice that, due to the fact that $\mu(\lambda)$ is even, if a critical point x verifies $dx = a_0 e^\lambda + \cdots$, $a_0 \neq 0$, then $\mathrm{ind}_f(x)$ is even. Moreover, in view of point a., $\mathrm{ind}_f(x) \neq \dim(L)$.

c. It is not difficult to verify that if the cluster complex is acyclic, i.e. $\mathcal{C}\ell\, H_*(L) = 0$, then the cluster has free terms. If the cluster complex $\mathcal{C}\ell\,(L; J, (f, g))$ has high free terms, then there are, moreover, some J-disks with Maslov index ≤ 0.

Example 3.3. If S^1 is a circle in $\mathbb{C}$ we have

$$\mathcal{C}\ell\, H_*(S^1) = 0.$$

Indeed, take on S^1 the perfect Morse function with one minimum m and one maximum M. There exists one pseudoholomorphic disk passing through m, of Maslov index 2, with a class in Λ that we will denote by λ_0. For the maximum, we have $dM = 0$. The differential of the minimum can be seen to be given by $dm = (1 + M + s)e^{\lambda_0}$ where s is a polynomial in M without constant or linear terms. This implies the claim because in our ring we may then find a series Q so that $Q(1 + M + s) = 1$ which means $d(Qme^{-\lambda_0}) = 1$ (and of course, the cluster homology vanishes identically iff 1 is a boundary).

Example 3.4. In the absence of bubbling (for example if $\omega|_{\pi_2(M,L)} = 0$), then

$$\mathcal{C}\ell\, H_*(L; J, (f, g)) \simeq S((s^{-1}H_*(L; \mathbb{Q})) \otimes \Lambda)^\wedge.$$

This happens because in this case the only component of the cluster differential is provided by the usual Morse differential.

4. Fine Floer homology

The purpose of this paragraph is to introduce the *fine Floer homology*, denoted $I\!F\,H_*(-)$, which was announced earlier in these notes.

4.1. Coefficient ring and moduli spaces. To define the fine Floer complex

$$I\!FC(L_0, L_1, \eta; J, (f_0, g_0), (f_1, g_1))$$

we first recall that the choices of orientations and of a relative spin structure for L_0, L_1 have been made and are included in the notation L_0, L_1. Besides this, we need auxiliary data as follows. First, as before, we need an almost complex structure J, Morse–Smale pairs (f_i, g_i) on L_i and coherent choices of perturbations. We also assume the f_i in generic position with respect to the intersection points $L_0 \cap L_1$ in the sense that these intersection points are included in the unstable manifolds of critical points of index 0 of f_i. We denote by $\Gamma = \{\alpha\colon [0, 1] \to M : \alpha(i) \in L_i, i = 0, 1\}$ the space of continuous paths from L_0 to L_1. Here, η is an element in Γ – its choice means that we fix a basepoint for this space. We denote by Γ_η the connected component of Γ which contains η. We denote by $I(L_0, L_1)$ the intersection points between L_0 and L_1 and we let I_η be those intersection points which, viewed as constant paths, belong to Γ_η. The generators of the fine Floer complex will be precisely the elements of I_η. Up to a shift in degrees, the resulting fine Floer homology will only depend on L_0, L_1, the connected component of η and the choice of orientations and relative spin structures of L_0, L_1.

To continue the construction, note that there are two group morphisms

$$\omega\colon \pi_1\Gamma_\eta \to \mathbb{R}, \quad \mu\colon \pi_1\Gamma_\eta \to \mathbb{Z},$$

the first given by integration of ω and the second, a Maslov index type morphism, obtained in the usual way as in Robbin–Salamon [20].

We now define

$$\mathcal{R} = (S\mathbb{Q}\langle s^{-1}(\mathrm{Crit}(f_0) \cup \mathrm{Crit}(f_1))\rangle \otimes \bar{\Lambda})^\wedge \tag{4}$$

where $\bar{\Lambda}$ is the rational group ring of $\Pi = \mathrm{Im}(\omega \times \mu)$; the completion is as in the case of the cluster complex except that we take into consideration both critical points of f_0 and of f_1.

Notice that there are injective group morphisms $\phi_i : \pi_2(M, L_i)/\sim \to \Pi$ which are obtained by first assuming that η joins the base points in L_0 and L_1 and then viewing a disk with boundary in, say, L_0 as a cylinder whose end on L_1 is constant. Therefore, if we denote by Λ_i the group ring of $\pi_2(M, L_i)/\sim$, we have injective ring morphisms $\phi_i : \Lambda_i \to \bar{\Lambda}$. Thus, $\mathcal{R}$ is isomorphic to the obvious completion of

$$\mathcal{C}\ell\,(L_0; J, (f_0, g_0)) \otimes \mathcal{C}\ell\,(L_1; J, (f_1, g_1)) \otimes_{\Lambda_0 \otimes \Lambda_1} \bar{\Lambda}.$$

4.2. The fine Floer complex. This is the free differential graded module over $\mathcal{R}$ given by

$$I\!FC(L_0, L_1, \eta; J, (f_0, g_0), (f_1, g_1)) = (\mathcal{R} \otimes \mathbb{Q}\langle I_\eta\rangle, d_F).$$

The grading of the elements in I_η is obtained as follows: we consider lifts $\bar{a} \in \tilde{\Gamma}_\eta$ of the points $a \in I_\eta \subset \Gamma_\eta$ where $\tilde{\Gamma}_\eta$ is the regular covering of Γ_η associated to Π (here, as usual, the last inclusion means that we view intersection points as constant paths) and we define $|a| = \mu(\bar{a})$. This grading depends on the choices of the lifts, but different choices produce isomorphic complexes.

We now describe the differential d_F. We order the critical points in $\mathrm{Crit}(f_i)$. The differential d_F verifies the Leibniz formula and for an element $a \in I_\eta$ it is of the form:

$$d_F a = \sum_{\substack{\lambda,\ b,\ k\geq 0,\ l\geq 0 \\ (x_1,\dots,x_k,y_1\dots,y_l)}} w^a_{x_1,\dots,x_k,y_1,\dots,y_l;b}(\lambda)\, x_1 \dots x_k y_1 \dots y_l b e^\lambda$$

where the x_i's belong to $\mathrm{Crit}(f_0)$, the y_j's to $\mathrm{Crit}(f_1)$, they respect the order, $\lambda \in \Pi$, and finally $b \in I_\eta$.

The coefficients $w^a_{x_1,\dots,x_k,y_1,\dots,y_l;b}(\lambda) \in \mathbb{Q}$ count the number of elements in certain 0-dimensional moduli spaces $\mathcal{W}^a_{x_1,\dots,x_k,y_1,\dots,y_l;b}(\lambda)$ (again after perturbation). These moduli spaces are defined in a way similar to the $\mathcal{M}_{\dots}(\lambda)$'s of §3. The starting point consists again of trees as in §3 but the root vertex of the tree no longer corresponds to a J-disk but rather to a J-strip (as in the usual Floer theory) which relates the two intersection points $a, b \in I_\eta$. Except for codimension two phenomena, all of the other vertices correspond to pseudoholomorphic disks with boundaries on one of the L_i's. Moreover, the gradient flows appearing in the construction correspond to one of the two functions f_i. In short, the elements of these moduli spaces are cluster trees on L_0 and L_1 that originate *at finite points* of the root strip. There may be finitely many such clusters attached to the boundary of the strip. These objects are called *cluster-strips*. It is easy to see how to associate a class $\lambda \in \Pi$ to such an object.

For generic choices of J, (f_i, g_i) and after perturbation, the dimension of the moduli space $\mathcal{W}^a_{x_1,\dots,x_k,y_1,\dots,y_l;b}(\lambda)$ is:

$$|a| - |b| - \sum |x_i| - \sum |y_j| + \mu(\lambda) - 1.$$

For one-dimensional moduli spaces, there is a formula analogous to (3). As a consequence, we have:

Theorem 3. *With the notation above, we have $d_F^2 = 0$. The resulting homology is called the fine Floer homology, $I\!F H_*(L_0, L_1, \eta)$. Up to isomorphism (and a possible shift in degrees) it does not depend on the choices made in its construction and if $\phi\colon M \to M$ is a Hamiltonian diffeomorphism, then we have isomorphisms*

$$I\!F H(L_0, L_1, \eta) \simeq I\!F H(\phi(L_0), L_1, \eta')$$

where η' corresponds to η via the Hamiltonian diffeomorphism.

Verifying $d_F^2 = 0$ is less immediate than for the cluster differential because, besides the usual breaking of clusters and of strips, there is a third potential way for

boundary points to emerge: they correspond to some cluster tree attached to a strip at some moving point p which "slides" along the boundary of the strip to one of the ends of the strip. There are two reasons that make these boundary components disappear, one is purely algebraic and is a cancellation resulting from our graded *c*ommutative setting and the other one is analytic and consists in the fact that (as remarked by Oh [16]) the usual gluing argument applies (under generic conditions) to a J-disk passing (transversally) through a and to a itself viewed as a constant strip and produces a non-constant strip with the two ends at a. In contrast with [16], our cancellation argument applies without any hypothesis of symmetry between L_0 and L_1.

4.3. Symmetrization. A particular variant of the construction of the fine Floer homology is useful in applications. To describe it, assume that L_0 equals L_1 (we denote both Lagrangian submanifolds by L), and consider a generic time-dependent Hamiltonian $H_{t\in[0,1]}$, with Hamiltonian flow $\phi_{t\in[0,1]}$, and a generic family of compatible almost complex structures $J_{t\in[0,1]}$. Take as generators of the complex the trajectories I_η^H of ϕ_t starting at time 0 and ending at time 1 on L. We may choose the generic family $J_{t\in[0,1]}$ so that $J_0 = J_1$ (we will denote this almost complex structure by J).

The *symmetric fine Floer complex* appears in this setting by additionally choosing the pair (f_0, g_0) equal to the pair (f_1, g_1) (we denote both pairs by (f, g)). Since we have a differential graded algebra multiplication map:

$$\mathcal{C}\ell\,(L; J, (f, g)) \otimes \mathcal{C}\ell\,(L; J, (f, g)) \to \mathcal{C}\ell\,(L; J, (f, g))$$

and because $J_0 = J_1 = J$, we may replace the ring

$$\mathcal{R} = (\mathcal{C}\ell\,(L_0; J_0, (f_0, g_0)) \otimes \mathcal{C}\ell\,(L_1; J_1, (f_1, g_1)) \otimes \bar{\Lambda})^\wedge$$

which appears naturally in the definition of the fine Floer complex by the ring $\hat{\mathcal{R}} = (\mathcal{C}\ell\,(L; J, (f, g)) \otimes_\Lambda \bar{\Lambda})^\wedge$. To define a differential on

$$\hat{\mathcal{R}} \otimes \mathbb{Q}\langle I_\eta^H \rangle$$

we use moduli spaces consisting of configurations in which the root pseudoholomorphic strip is replaced by a semi-cylinder satisfying the usual (J, H)-Floer type equation, with its two ends coinciding with trajectories γ, γ' and the two side boundaries lying on L.

We denote by $(\hat{I\!F}C(L; H, J, (f, g)), d_{\hat{F}})$ this symmetric fine Floer homology. If no additional notation appears the path η used in this case is just the constant path.

This homology has the same type of invariance properties as the non-symmetric version and, moreover, it is independent of the choice of $(H, J, (f, g))$ as long as it remains generic.

The advantage of this construction is that it relates directly to the cluster complex as we shall see in the following.

4.3.1. A little algebra. Consider a commutative, differential graded algebra of the form $\mathcal{A} = (SV, d)$ with V a rational vector space. Write the elements of the SV-module $SV \otimes V$ in the form

$$x_1 \dots x_k \otimes v = x_1 \dots x_k \bar{v}$$

where $v, x_i \in V$. Define the linear map

$$\alpha \colon SV \to SV \otimes V$$

by letting $\alpha(v) = \bar{v}$, $\alpha(1) = 0$ where 1 is the unit in SV and extending this map by the formula

$$\alpha(ab) = a\alpha(b) + (-1)^{|a||b|} b\alpha(a).$$

Induction on the length of words easily shows that this map is well defined and that the formula above is verified for all homogeneous monomials a, b. Explicitly, we have

$$\alpha(x_1 \dots x_k) = \sum_i (-1)^{\sigma_i} x_1 \dots \hat{x}_i \dots x_k \bar{x}_i$$

where σ_i is the product of the degree of x_i with the sum of the degrees of the x_j, $j > i$. Define the map d on $SV \otimes V$ as the unique (SV, d)-module extension of

$$d\bar{v} = \alpha(dv)$$

which verifies the standard graded Leibniz rule.

One easily checks that d so defined is a differential and that α is a chain map. Denote by

$$\widetilde{\mathcal{A}} = (SV \otimes V, d)$$

the $\mathcal{A}$-differential module constructed in this way.

4.3.2. String-strip symmetrization. We return to our geometric setting. The algebraic construction above appears in the next proposition.

Proposition 4.1. *The symmetric fine Floer homology verifies:*

$$s^{-1}\hat{I\!F} H_*(L) \simeq H_*(\widetilde{\mathcal{C}\ell}\,(L; J, (f, g))).$$

This isomorphism is proved in two steps. First, a chain complex $\mathcal{C}$ is constructed by using, instead of root semi-cylinders, (J, h)-linear clusters: they consist of pairs of critical points of the additional Morse function h related via a linear sequence of negative flow lines of h and J-disks. Of course, there are still f-clusters attached to this linear cluster. This construction is possible even when $f = h$ and in that case the resulting complex is precisely (the suspension of) $\widetilde{\mathcal{C}\ell}\,(L)$. The second step is to define a Piunikin–Salamon–Schwarz [19] map that relates the complexes $\hat{I\!F} C_*(L, H)$ and $\mathcal{C}$ and prove that it induces an isomorphism in homology.

An immediate corollary of this proposition gives the description of the symmetric fine Floer homology if no bubbling is present.

Corollary 4.2. *If* $\omega|_{\pi_2(M,L)} = 0$ *then*

$$\hat{I\!F} H_*(L) \simeq (S(s^{-1}H_*(L;\mathbb{Q})) \otimes \Lambda)^\wedge \otimes H_*(L;\mathbb{Q}).$$

Clearly, if a Lagrangian is displaceable, then both the fine Floer homology and its symmetric version vanish.

5. Applications of cluster homology

We will describe three consequences of the cluster theory developed with Cornea.

5.1. The Gromov–Sikorav problem. As a first consequence, we analyze a plausible conjecture going back to Gromov's original paper [10] on pseudoholomorphic curves, stated orally by Sikorav in the late eighties in the following way: given any compact Lagrangian submanifold of $\mathbb{C}^n$, there is a holomorphic disk passing through each point of L.

Corollary 5.1. *Let* $L \subset M$ *be a compact, orientable, relative spin Lagrangian submanifold of any symplectic manifold* M. *Assume that* $\hat{I\!F} H_*(L) = 0$ (*for example if* L *is displaceable by a Hamiltonian isotopy*). *Then, for any generic almost complex structure* J *compatible with the symplectic form, one of the following holds:*

i. *There are* J*-holomorphic disks with boundary on* L *passing through a dense subset of points of* L.

ii. *The cluster complex* $\mathcal{C}\ell\,(L, J, f)$ *has high free terms for some Morse function* f *with a single local minimum and a single local maximum* (*in particular, there are* J*-disks of non-positive Maslov index*).

Proof. Assume that for any Morse function with a single local minimum and local maximum, the associated cluster complex does not have high free terms. Fix such a function f and denote its minimum by m. By Proposition 4.1, $s^{-1}\hat{I\!F} H_*(L)$ is isomorphic to $H_*(\widetilde{\mathcal{C}\ell}\,(L, J; (f, g)))$, which means that $H_*(\widetilde{\mathcal{C}\ell}\,(L, J; (f, g)))$ vanishes. Notice that if $d\bar{m} \neq 0$, then we also have $dm \neq 0$ in the cluster complex. Assume now that

$$\bar{m} \in \widetilde{\mathcal{C}\ell}\,(L, J; (f, g))$$

is a cycle. Using Remark 3.2, we see that $\bar{m}$ can be a boundary only if $\mathcal{C}\ell\,(-)$ has free terms: indeed, by this remark, the only possible primitive of $\bar{m}$ must have the form $\tau\bar{m}$ where τ is a primitive of the unit 1 in the cluster complex. This means that there is a free term in some dx for some $x \in \mathrm{Crit}(f)$. Once again by Remark 3.2, the index of this x cannot be n and it cannot be strictly between 0 and n by our assumption. Therefore, $x = m$ and $dm \neq 0$.

The fact that dm is different from 0 means that there exists a non-empty moduli space ${}^{\nu}\mathcal{M}^m_{x_1,\ldots,x_k}(\lambda)$ of dimension 0. But for a cluster tree to originate at the minimum

m, the root disk must go through m. As we may use a different function f to place m in any generic point in L, this implies the claim. □

The dichotomy in the statement of the previous corollary can be sometimes resolved by homological restrictions.

Corollary 5.2. *Suppose that L is orientable, relative spin and that $H_{2k}(L;\mathbb{Q}) = 0$ for $2k \notin \{0, \dim(L)\}$. If $\hat{I\!F} H_*(L) = 0$, then L verifies* (i) *of Corollary* 5.1 *above.*

Example 5.3. The homological restriction in the corollary above is serious but, still, there are many examples of such manifolds: $S^1 \times S^{n-1}$ and its connected sums with itself perhaps provide the simplest examples.

Using symmetrization, we can improve these results in the displaceable case by bounding from above the area of the disks detected in terms of the displacing energy. This upper bound and Gromov's compactness theorem then imply:

Corollary 5.4. *Suppose that the relative spin, orientable Lagrangian submanifold L is displaceable by a Hamiltonian isotopy and let $E(L)$ be its Hofer displacement energy. Any ω-tame almost complex structure J has the property that one of the following is true:*

i. *For any point $x \in L$ there exists a J-holomorphic disk of symplectic area at most $E(L)$ whose boundary rests on L and which passes through x.*

ii. *There exists a J-disk of Maslov index at most*

$$2 - \min\{2k \in \mathbb{N}\backslash\{0, \dim(L)\} : H_{2k}(L;\mathbb{Q}) \neq 0\}$$

and of symplectic area at most $E(L)$.

For a Lagrangian submanifold $L \subset (M, \omega)$, define, as in Barraud–Cornea [4], its real, or relative, Gromov radius as the supremum $r(L)$ of the positive constants r so that there is a symplectic embedding of the standard ball $(B(r), \omega_0) \overset{e}{\hookrightarrow} (M, \omega)$ with the property that $e^{-1}(L) = \mathbb{R}^n \cap B(r)$. Define its real Gromov capacity $c_G(L)$ as $\pi r^2(L)/2$.

Corollary 5.5. *If an orientable, relatively spin Lagrangian with $H_{2k}(L;\mathbb{Q}) = 0$ for $2k \notin \{0, \dim(L)\}$ is displaceable, then*

$$E(L) \geq c_G(L).$$

Actually, Barraud–Cornea [4] introduced an even more relative notion of Gromov capacity: if L_0, L_1 are two Lagrangian submanifolds, one may define

$$c_G(L_0, L_1) = \pi r(L_0, L_1)^2/2$$

where $r(L_0, L_1)$ is the supremum of the radii of symplectic balls, disjoint from L_1, whose real parts rest on L_0. They show in [4] that, if L_1 is the Hamiltonian image of L_0, and assuming that we are in a case where real bubbling off does not occur, an analogous energy–capacity inequality holds: $E \geq c_G(L_0, L_1)$ where E is the Hofer energy of the pair (L_0, L_1).

5.2. Constraints on Maslov indices. The cluster complex setting provides straightforward proofs of various constraints regarding Maslov indices of Lagrangian submanifolds. See the section on applications in [5]. However, it has not yet provided a proof of the Audin conjecture, except in dimension 2. Such an application is still premature before the algebraic operations on cluster homology have been well understood.

5.3. Detection of periodic orbits. In the presence of an orientable relative spin pair of Lagrangian submanifolds L, L', we show that, by replacing in the definition of the clustered moduli spaces one (and only one) of the J-disks by a pseudoholomorphic cylinder with one boundary on L and the other boundary on L', one can construct a chain map:

$$\mathrm{cyl} : \mathcal{C}\ell\,(L) \to \mathcal{C}\ell\,(L) \otimes \mathcal{C}\ell\,(L') \otimes \Lambda_{\Phi_0}$$

where Λ_{Φ_0} is an appropriate Novikov ring.

This map induces a morphism in homology whose non-triviality is used to detect the existence of non-constant periodic orbits of Hamiltonian diffeomorphisms that *separate* L from L'. These results, obtained in [5], generalize those in [9]. When L and L' are disjoint sections in a cotangent bundle, the non-triviality is easy to detect. But, in a general symplectic manifold, such a non-triviality could be detected by making use of a specific Hamiltonian H that does have periodic orbits in the prescribed classes, and using the Albers map from the symplectic Floer (or Floer–Novikov) homology of the ambient space (using H) to each of the cluster homologies of L and L'. The gluing of the two half cylinders at each of the orbits of H would then, plausibly, provide a non-trivial realisation of the above morphism, that could then be applied to prove the existence of orbits of any other separating Hamiltonian.

5.4. Concluding remarks on cluster homology. What remains to be done on the cluster theory is: (1) to establish the analysis of its moduli spaces on a solid ground, and (2) make it computable in non-trivial examples. Although (1) has not been entirely written down at the time of submitting these notes, it seems very likely that the transversalities issues fit very well in the Hofer–Wysocki–Zehnder polyfold setting so that, hopefully, (1) will be accomplished shortly after the HWZ approach fully appears in print. A second scheme to solve similar transversality problems in the absolute case has been very recently suggested by Cieliebak–Mohnke and could be likely adapted to the cluster context thanks to the existence of a Donaldson symplectic hypersurface in the complement of any Lagrangian L (established by Auroux–Gayet–Mohsen in [3]) whose role would be to stabilize the holomorphic discs (one would then use the abstract space of non-embedded cluster trees as the new parameter space in defining the dependence of the almost complex structure J). The first step in (2) will be to establish a formula for the cluster homology of the surgery on two Lagrangian submanifolds intersecting transversally. Such a formula requires understanding how to resolve the singularities of holomorphic surfaces with corners at the intersecting points – this was first explored in an appendix of FOOO [8].

Cluster homology may also play a role in the development of the new subject of relative (or Lagrangian) symplectic field theory.

6. The emerging field of real symplectic topology

Real symplectic topology is the study of triples (M, ω, c_M) where (M, ω) is a symplectic manifold and $c_M : M \to M$ is an anti-symplectic involution. It is easy to see that the fixed point set $\mathbb{R}M$ of c_M, called the real part of M, is a Lagrangian submanifold (when it is not empty). It is shown in [24] (see also [8]) that the space $\mathbb{R}\mathcal{J}(M)$ of ω-tame almost complex structures J on M for which c_M is anti-holomorphic is as generic as one could hope: it is both generic for the study of the full space of J-holomorphic curves in M, as well as for the subspace of *real* J-curves, i.e. the space of J-curves that are c_M-invariant.

Note that the results of the preceding sections always assumed that the Lagrangian submanifolds are orientable and relative spin. In real symplectic topology, the Lagrangian submanifold $\mathbb{R}M$ is often not orientable, for instance $\mathbb{R}P^2 \subset \mathbb{C}P^2$. Moreover, the "doubling construction" that assigns a c_M-invariant J-holomorphic 2-sphere to a disk with boundary on L only uses one of the anti-symplectic involutions of the 2-sphere, namely the reflection through the equator (leaving aside the antipodal map). For these reasons, there seems to be no point in studying real symplectic topology solely from the methods defined in the preceding sections.

A very interesting and recent development, due to Welschinger [24], provides a well-defined Gromov–Witten type invariant in real 4-dimensional symplectic manifolds for the space of real rational J-curves (for a generic J in $\mathbb{R}\mathcal{J}(M)$) in a class d passing through the right number ℓ of points in order to cut its dimension down to zero, assuming that these points are invariant under c_M. Denote by δ the number of double points of such a curve. Both ℓ and δ are topological invariants depending only on d. Let $r \leq \ell$ be the number of points belonging to $\mathbb{R}M$. For such a real rational J-curve, let $0 \leq m \leq \delta$, called the *mass*, be the number of its real isolated double points (i.e. those which belong to $\mathbb{R}M$ and which are isolated in $\mathbb{R}M$, being the intersection of complex conjugated branches of the curve). Finally, let $n_d(m)$ be the number of such real curves in class d passing through that generic set of points with m real isolated double points. Then the number $\chi_r^d = \sum_{m=0}^{\delta} (-1)^m n_d(m)$ is independent of both the choice of generic $J \in \mathbb{R}\mathcal{J}(M)$ and the c_M-invariant set of points, as long as the number r remains unchanged. Formally summing over r provides an invariant of the deformation class of (M, ω, c_M). Note that, obviously, χ_r^d is then a lower bound for the number of real rational curves, in particular χ_ℓ^d is a lower bound for the number of real rational curves in class d passing through ℓ real points. These numbers have been computed in various cases, notably by Mikhalkin for toric real surfaces (see his contribution in these proceedings).

These results have been extended to higher dimensions by Welschinger in [25]. Basically, these invariants are obtained by a procedure which has some similarities

with the cluster complex, since they are extracted by gluing together various moduli spaces in an appropriate way. However, they do not point in the direction of a cluster homology, but rather suggest that there might exist some form of real quantum product related to mass. That is to say: the Lagrangian submanifolds occuring as real loci of real symplectic manifolds seem to be special enough so that one could overcome the real bubbling off phenomenon by gluing appropriate moduli spaces and extracting the desired invariants directly from these "clustered" moduli spaces much like in the complex (non-relative) case, without having to introduce a Floer or cluster complex.

Gromov–Witten invariants and moduli spaces of curves

Xiaobo Liu *

Abstract. The purpose of this note is to explain how much information of Gromov–Witten invariants of compact symplectic manifolds are determined by the geometry of moduli spaces of curves. In the case when a manifold has semisimple quantum cohomology, we believe that the information obtained this way might determine all higher genus Gromov–Witten invariants and could be used to study the Virasoro conjecture of Eguchi–Hori–Xiong and S. Katz.

Mathematics Subject Classification (2000). Primary 53D45; Secondary 14N35.

Keywords. Gromov–Witten invariants, quantum cohomology, moduli space of curves, tautological ring.

1. Introduction

Let V be a compact symplectic manifold with an almost complex structure which is compatible with its symplectic structure. Gromov–Witten invariants of V are certain intersection numbers on the moduli spaces of stable pseudo-holomorphic curves in V. Such invariants do not depend on the choice of the almost complex structure and are therefore symplectic invariants. The generating functions of Gromov–Witten invariants satisfy many interesting partial differential equations. A large class of such equations come from the study of the moduli spaces of stable curves $\overline{\mathcal{M}}_{g,k}$ which were introduced by Deligne and Mumford in [7]. There are natural geometric ways to construct cohomology classes on $\overline{\mathcal{M}}_{g,k}$. These classes generate a ring called the tautological ring. There is a canonical way to produce differential equations for generating functions of Gromov–Witten invariants from relations in the tautological ring of $\overline{\mathcal{M}}_{g,k}$. Such equations hold for the Gromov–Witten theory of all compact symplectic manifolds, and are therefore called universal equations. These equations can be used to compute Gromov–Witten invariants and study other properties of Gromov–Witten theory like the Virasoro conjecture of Eguchi–Hori–Xiong and S. Katz. The Virasoro conjecture predicts that the generating functions of Gromov–Witten invariants of smooth projective varieties are annihilated by an infinite sequence of differential operators which form a half branch of the Virasoro algebra. This is a generalization of Witten's conjecture, which was proved by Kontsevich, that the generating function of intersection numbers on $\overline{\mathcal{M}}_{g,k}$ is a τ-function of the KdV hierarchy. Moreover

*Research was partially supported by NSF grant DMS-0505835.

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

universal equations also hold for generating functions of intersection numbers on moduli spaces of spin curves. These equations can be used to study the generalized Witten conjecture which predicts that such generating functions are τ-functions of Gelfand–Dickey hierarchies.

On the other hand, it is a highly non-trivial problem to find explicit relations in the tautological ring of $\overline{\mathcal{M}}_{g,k}$, especially when the genus g is high. Knowledge of Gromov–Witten invariants of compact symplectic manifolds can be used to study this problem. We believe that relations in tautological rings are manifested in the properties of Gromov–Witten invariants of various compact symplectic manifolds. In a certain sense, one may think that Gromov–Witten theory of each compact symplectic manifold V gives a representation of the tautological ring of $\overline{\mathcal{M}}_{g,k}$. A good understanding of Gromov–Witten invariants of a class of manifolds might be sufficient to determine many relations in tautological rings.

In this expository article we will explain how much we know about universal equations and how much information can be obtained from such equations.

2. Tautological relations and universal equations

Let V^{2d} be a compact symplectic manifold with symplectic form ω and almost complex structure J such that the bilinear form $\omega(\cdot, J\cdot)$ defines an Riemannian metric on V. For simplicity, we assume that $H^{\text{odd}}(V;\mathbb{C}) = 0$. For each $A \in H_2(V;\mathbb{Z})$ and $g, k \in \mathbb{Z}_{\geq 0}$, let $\overline{\mathcal{M}}_{g,k}(V, A)$ be the moduli space of stable maps whose elements are of the form $(C; x_1, \ldots, x_k; f)$ where C is a genus-g complex curve with at most nodal singularities, $x_1, \ldots, x_k \in C$ are distinct smooth points which are called marked points, and f is a pseudo-holomorphic map from C to V such that $f_*[C] = A$ and f is stable in the sense that there is no infinitesimal deformation of f without moving marked points and their images. For each $i \in \{1, 2, \ldots, k\}$, let $\text{ev}_i : \overline{\mathcal{M}}_{g,k}(V, A) \longrightarrow V$ be the evaluation map defined by

$$\text{ev}_i(C; x_1, \ldots, x_k; f) := f(x_i)$$

and let $E_i \longrightarrow \overline{\mathcal{M}}_{g,k}(V, A)$ be the tautological line bundle whose geometric fiber over $(C; x_1, \ldots, x_k; f)$ is given by $T^*_{x_i}C$. For any $\gamma_1, \ldots \gamma_k \in H^*(V;\mathbb{C})$ and $n_1, \ldots, n_k \in \mathbb{Z}_{\geq 0}$, the associated Gromov–Witten invariant is defined to be

$$\langle \tau_{n_1}(\gamma_1) \ldots \tau_{n_k}(\gamma_k) \rangle_{g,A} := \int_{[\overline{\mathcal{M}}_{g,k}(V,A)]^{\text{virt}}} \bigcup_{i=1}^{k} (c_1(E_i)^{n_i} \cup \text{ev}_i^*(\gamma_i)),$$

where $[\overline{\mathcal{M}}_{g,k}(V, A)]^{\text{virt}}$ is the virtual fundamental class of degree

$$2\{(d-3)(1-g) + c_1(V)(A) + k\}$$

(cf. [30], [31], and [3]).

To define the generating functions, we need to fix a basis $\{\gamma_1, \dots, \gamma_N\}$ of $H^*(V; \mathbb{C})$ with γ_1 equal to the identity of the cohomology ring of V. For each symbol $\tau_n(\gamma_\alpha)$ we associate a parameter t_n^α. The collection of all such parameters is denoted by

$$t = (t_n^\alpha \mid n \in \mathbb{Z}_{\geq 0},\ \alpha = 1, \dots, N).$$

We can think of these parameters as coordinates on an infinite dimensional vector space called the *big phase space*. The subspace $\{t \mid t_n^\alpha = 0 \text{ if } n > 0\}$ is called the *small phase space*. Note that the small phase space can be canonically identified with $H^*(V; \mathbb{C})$. We also need the Novikov ring which is the completion of the multiplicative ring generated by monomials $q^A := d_1^{a_1} \dots d_r^{a_r}$ over the ring of rational numbers, where $\{d_1, \dots, d_r\}$ is a fixed basis of $H_2(V; \mathbb{Z})$ and $A = \sum_{i=1}^r a_i d_i$. The generating function of genus-g Gromov–Witten invariants is then defined by

$$F_g(t) := \sum_{k \geq 0} \frac{1}{k!} \sum_{\substack{\alpha_1, \dots, \alpha_k \\ n_1, \dots, n_k}} t_{n_1}^{\alpha_1} \dots t_{n_k}^{\alpha_k} \sum_{A \in H_2(V;\, Z)} q^A \langle \tau_{n_1}(\gamma_{\alpha_1}) \dots \tau_{n_k}(\gamma_{\alpha_k}) \rangle_{g, A}.$$

The function F_g is understood as a formal power series of t with values in the Novikov ring.

For $k,\ g \geq 0$, define a k-tensor $\langle\!\langle \underbrace{\cdots}_{k} \rangle\!\rangle_g$ to be the k-th covariant derivative of F_g with respect to the trivial connection on the big phase space. More precisely,

$$\langle\!\langle \mathcal{W}_1 \dots \mathcal{W}_k \rangle\!\rangle_g := \sum_{m_1, \alpha_1, \dots, m_k, \alpha_k} f^1_{m_1, \alpha_1} \dots f^k_{m_k, \alpha_k} \frac{\partial^k}{\partial t_{m_1}^{\alpha_1} \dots \partial t_{m_k}^{\alpha_k}} F_g \tag{1}$$

for vector fields $\mathcal{W}_i = \sum_{m,\alpha} f^i_{m,\alpha} \frac{\partial}{\partial t_m^\alpha}$ where $f^i_{m,\alpha}$ are functions on the big phase space. This tensor is called the *k-point* (*correlation*) *function*. We will identify $\frac{\partial}{\partial t_n^\alpha}$ with $\tau_n(\gamma_\alpha)$ and set $\tau_0(\gamma_\alpha) = \gamma_\alpha$ and $\tau_n(\gamma_\alpha) = 0$ if $n < 0$. We call γ_α a *primary vector field*, and $\tau_n(\gamma_\alpha)$ a *descendant vector field* with descendant level n. We use τ_+ and τ_- to denote the operator which shift the level of descendants, i.e.

$$\tau_\pm\Big(\sum_{n,\alpha} f_{n,\alpha} \tau_n(\gamma_\alpha)\Big) = \sum_{n,\alpha} f_{n,\alpha} \tau_{n\pm 1}(\gamma_\alpha)$$

where $f_{n,\alpha}$ are functions on the big phase space. Let

$$\eta_{\alpha\beta} = \int_V \gamma_\alpha \cup \gamma_\beta$$

be the intersection form on $H^*(V, \mathbb{C})$. We will use $\eta = (\eta_{\alpha\beta})$ and $\eta^{-1} = (\eta^{\alpha\beta})$ to lower and raise indices. For example,

$$\gamma^\alpha := \eta^{\alpha\beta} \gamma_\beta.$$

Here we are using the summation convention that repeated indices (in this formula, β) should be summed over their entire ranges.

When V is a point, the moduli space $\overline{\mathcal{M}}_{g,k}(\{\mathrm{pt}\}, 0)$ is exactly the moduli space of genus-g stable curves with k-marked points constructed by Deligne and Mumford [7]. This space is usually denoted by $\overline{\mathcal{M}}_{g,k}$. Let ψ_i be the first Chern class of the tautological line bundle E_i over $\overline{\mathcal{M}}_{g,k}$. These classes are called ψ-classes. There are natural forgetful maps $\overline{\mathcal{M}}_{g,k+n} \longrightarrow \overline{\mathcal{M}}_{g,k}$ which forgets the last n marked points of a stable curve. There are also two types of natural gluing maps between moduli spaces of stable curves. The first type is $\overline{\mathcal{M}}_{g_1,k_1+1} \times \overline{\mathcal{M}}_{g_2,k_2+1} \longrightarrow \overline{\mathcal{M}}_{g_1+g_2,k_1+k_2}$ which glues the last marked points of two stable curves to form a new stable curve. The second type is $\overline{\mathcal{M}}_{g,k+2} \longrightarrow \overline{\mathcal{M}}_{g+1,k}$ which glues the last two marked points on a stable curve to form a new stable curve. The tautological ring of $\overline{\mathcal{M}}_{g,k}$, denoted by $R^*(\overline{\mathcal{M}}_{g,k})$, is the smallest $\mathbb{Q}$-subalgebra of the Chow ring of $\overline{\mathcal{M}}_{g,k}$ which contains all ψ-classes and is closed under the push-forward of forgetting maps and gluing maps. There is also a natural stratification of $\overline{\mathcal{M}}_{g,k}$ which is labeled by dual graphs of stable curves. The dual graph G of a stable curve C is defined in the following way: The vertices of G are irreducible components of C labeled by their genera. Two vertices are connected by an edge if the corresponding irreducible components intersects at a node of C. Therefore edges of G are one to one correspondent to nodes of C. Finally each marked point of C gives a tail of G emanating from a vertex whose corresponding irreducible component of C contains this marked point. The set of all genus-g stable curves with k marked points whose dual graph is isomorphic to G is denoted by $\mathcal{M}_{g,k}(G)$. The closure of this space, i.e. $\overline{\mathcal{M}}_{g,k}(G)$, gives a class in the tautological ring $R^*(\overline{\mathcal{M}}_{g,k})$. Such classes are called boundary classes. We will call any relation among powers of ψ-classes and boundary classes a *tautological relation*.

There is a natural map

$$\mathrm{St}\colon \overline{\mathcal{M}}_{g,k}(V, A) \longrightarrow \overline{\mathcal{M}}_{g,k}$$

which forgets the map f in $(C; x_1, \ldots, x_k; f) \in \overline{\mathcal{M}}_{g,k}(V, A)$ and stabilizes

$$(C; x_1, \ldots, x_k)$$

by squeezing unstable components to points. A tautological relation on $\overline{\mathcal{M}}_{g,k}$ can be pulled back to $\overline{\mathcal{M}}_{g,k}(V, A)$ which in turn gives relations between various Gromov–Witten invariants of V. Such relations can be described by partial differential equations for $F_0, \ldots, F_g$. Equations obtained in this way hold for all compact symplectic manifolds and therefore are called *universal equations*. It is very convenient to write universal equations as equations for tensors $\langle\!\langle \cdots \rangle\!\rangle_g$.

There is a canonical way to translate tautological relations to universal equations. A boundary class $\overline{\mathcal{M}}_{g,k}(G)$ in a tautological relation corresponds to a product of correlation functions in the universal equation according to the following rules: Each

tail of G is assigned an arbitrary vector field $\mathcal{W}_i$ on the big phase space. Each edge of G is assigned a pair of primary vector fields γ_α and γ^α, one for each half edge. Each genus-h vertex of G is assigned a correlation function of the form

$$\langle\!\langle \mathcal{W}_{i_1} \dots \mathcal{W}_{i_m}\ \gamma_{\alpha_1} \dots \gamma_{\alpha_n}\ \gamma^{\beta_1} \dots \gamma^{\beta_p} \rangle\!\rangle_h$$

if the corresponding tails and half edges are connected to this vertex. Then the boundary class $\overline{\mathcal{M}}_{g,k}(G)$ is assigned the product of all correlation functions associated with all vertices of G. The coefficient of this function in the universal equation should be the coefficient of $\overline{\mathcal{M}}_{g,k}(G)$ in the tautological relation divided by the number of elements in the automorphism group of G. To interpret ψ-classes in a tautological relation, an operator T was introduced in [33] which is defined by

$$T(\mathcal{W}) := \tau_+(\mathcal{W}) - \langle\!\langle \mathcal{W}\, \gamma^\alpha \rangle\!\rangle_0 \gamma_\alpha$$

for any vector field $\mathcal{W}$. If $\psi_i^{n_i}$ is involved in a tautological relation, then in the corresponding universal equation, $\mathcal{W}_i$ should be replaced by $T^{n_i}(\mathcal{W}_i)$. The reason for this is that the cohomology class $c_1(E_i) - St^*(\psi_i)$ on $\overline{\mathcal{M}}_{g,k}(V, A)$ is represented by a cycle consisting of elements $(C; x_1, \dots, x_k; f)$ where C has a genus-0 component with only one marked point, the i-th marked point, and only one node connecting this genus-0 component to another component of C (cf. [17] and [28]).

The simplest tautological relation is $\psi_1 = 0$ on $\overline{\mathcal{M}}_{0,3}$ since $\dim \overline{\mathcal{M}}_{0,3} = 0$. This relation can be translated into the universal equation

$$\langle\!\langle T(\mathcal{W}_1)\ \mathcal{W}_2\ \mathcal{W}_3 \rangle\!\rangle_0 = 0$$

for arbitrary vector fields $\mathcal{W}_1$, $\mathcal{W}_2$, $\mathcal{W}_3$. This equation is called the genus-0 topological recursion relation. It was observed in [44] that derivatives of this equation gives the generalized WDVV equation:

$$\langle\!\langle \mathcal{W}_1\ \mathcal{W}_2\ \gamma^\alpha \rangle\!\rangle_0 \langle\!\langle \gamma_\alpha\ \mathcal{W}_3\ \mathcal{W}_4 \rangle\!\rangle_0 = \langle\!\langle \mathcal{W}_1\ \mathcal{W}_3\ \gamma^\alpha \rangle\!\rangle_0 \langle\!\langle \gamma_\alpha\ \mathcal{W}_2\ \mathcal{W}_4 \rangle\!\rangle_0$$

for arbitrary vector fields $\mathcal{W}_1, \dots, \mathcal{W}_4$. Because of this equation, we can define an associative product

$$\mathcal{W}_1 \circ \mathcal{W}_2 := \langle\!\langle \mathcal{W}_1\ \mathcal{W}_2\ \gamma^\alpha \rangle\!\rangle_0 \gamma_\alpha \tag{2}$$

for any vector fields $\mathcal{W}_1$ and $\mathcal{W}_2$ on the big phase space. This product is called the *quantum product on the big phase space* (cf. [33]). When restricted to the tangent bundle of the small phase space, this product is exactly the product for the quantum cohomology of V. Unlike the quantum product on the small phase space which has an identity element γ_1, the quantum product on the big phase space does not have an identity. Let

$$\mathcal{S} := -\sum_{m,\alpha} \tilde{t}_m^\alpha \tau_{m-1}(\gamma_\alpha)$$

be the *string vector field*, where $\tilde{t}_m^\alpha := t_m^\alpha - \delta_{m,1}\delta_{\alpha,1}$. The *string equation* has the form

$$\langle\!\langle \mathcal{S} \rangle\!\rangle_g = \frac{1}{2}\delta_{g,0}\eta_{\alpha\beta}t_0^\alpha t_0^\beta$$

for $g \geq 0$. By the second derivative of the genus-0 string equation, we can rewrite the operator T as

$$T(\mathcal{W}) = \tau_+(\mathcal{W}) - \mathcal{S} \circ \tau_+(\mathcal{W}).$$

Therefore T measures the difference between $\mathcal{S}$ and the identity of the quantum product on the big phase space, which actually does not exist by our definition of the quantum product. This gives an algebraic interpretation for the operator T.

Universal equations are very powerful for a class of manifolds for which the quantum product defined by equation (2) is semisimple in the following sense: Define the *Euler vector field* on the big phase space by

$$\mathcal{X} := -\sum_{m,\alpha}(m + b_\alpha - b_1 - 1)\,\tilde{t}_m^\alpha\,\tau_m(\gamma_\alpha) - \sum_{m,\alpha,\beta} C_\alpha^\beta \tilde{t}_m^\alpha\,\tau_{m-1}(\gamma_\beta),$$

where (C_α^β) is the matrix of multiplication by $c_1(V)$ in the ordinary cohomology ring of V with respect to the basis $\{\gamma_1, \ldots \gamma_N\}$ and $b_\alpha = \frac{1}{2}(\dim(\gamma_\alpha) - d + 1)$ for a compact symplectic manifold V of dimension $2d$. In case that V is a smooth projective variety, we can choose $\gamma_\alpha \in H^{p_\alpha,q_\alpha}(V)$ and b_α should be modified as $b_\alpha = p_\alpha - \frac{1}{2}(d-1)$. This modification is necessary for formulating the Virasoro conjecture below. The Euler vector field satisfies the following *quasi-homogeneity equation*

$$\langle\!\langle \mathcal{X} \rangle\!\rangle_g = (3-d)(1-g)F_g + \frac{1}{2}\delta_{g,0}\sum_{\alpha,\beta} C_{\alpha\beta}t_0^\alpha t_0^\beta - \frac{1}{24}\delta_{g,1}\int_V c_1(V) \cup c_{d-1}(V).$$

The quantum multiplication by $\mathcal{X}$ is an endomorphism on the vector space spanned by primary vector fields on the big phase space. We say that V has *semisimple* quantum cohomology if this endomorphism has distinct eigenvalues at generic points. Since our definition of quantum product on the big phase space coincides with usual quantum product when restricted to the small phase space, and the restriction of $\mathcal{X}$ to the small phase space also coincides with the Euler vector field for usual quantum cohomology, this definition of semisimplicity is a generalization of the semisimple condition used by Dubrovin in [10]. Under the semisimplicity assumption, there exists vector fields $\mathcal{E}_1, \ldots, \mathcal{E}_N$ on the big phase space which are linear combinations of primary vector fields such that

$$\mathcal{X} \circ \mathcal{E}_i = u_i\mathcal{E}_i, \quad \mathcal{E}_i \circ \mathcal{E}_j = \delta_{ij}\mathcal{E}_i$$

for every i and j where u_i are functions on the big phase space (cf. [36]). These vector fields are called *idempotents* of the quantum product on the big phase space. When restricted to the small phase space, $(u_1, \ldots, u_N)$ is precisely the *canonical coordinate system* for the semisimple Frobenius structure studied in [10]. On the big

phase space these functions are not sufficient to give a nice coordinate system. The idempotents will play the role of the canonical coordinate system. We refer to [36] for more properties of the idempotents on the big phase space.

It is well known that the quantum cohomology on the small phase space defines a Frobenius manifold structure (cf. [10]). However the quantum product on the big phase space defined be equation (2) does not give an infinite dimensional Frobenius manifold structure. To obtain a Frobenius structure on the big phase space, we should modify the definition of the quantum product in the following way: For any vector fields $\mathcal{W}_1$ and $\mathcal{W}_2$ on the big phase space define

$$\mathcal{W} \diamond \mathcal{V} := \sum_{k=0}^{\infty} \langle\!\langle \tau_-^k(\mathcal{W})\ \tau_-^k(\mathcal{V})\ \gamma^\alpha \rangle\!\rangle_0\ T^k(\gamma_\alpha).$$

This product is commutative and associative. The associativity follows from the fact that $\langle\!\langle \{\tau_-^k T^l(\gamma_\alpha)\}\ \mathcal{W}\ \mathcal{V} \rangle\!\rangle_0 = 0$ if $k \neq l$. Moreover for any primary vector fields $\mathcal{W}$ and $\mathcal{V}$,

$$T^k(\mathcal{W}) \diamond T^l(\mathcal{V}) = \delta_{kl}\ T^k(\mathcal{W} \circ \mathcal{V}).$$

This product has an identity

$$\hat{\mathcal{I}} := \sum_{k=0}^{\infty} \langle\!\langle \mathcal{I}\, \mathcal{I} \gamma^\alpha \rangle\!\rangle_0 T^k(\gamma_\alpha) = \sum_{k=0}^{\infty} T^k(\mathcal{I} \circ \mathcal{I}).$$

Define inner product on the big phase space by

$$(\mathcal{W},\ \mathcal{V}) := \sum_{k=0}^{\infty} \langle\!\langle \mathcal{I}\ \tau_-^k(\mathcal{W})\ \tau_-^k(\mathcal{V}) \rangle\!\rangle_0.$$

This is a symmetric non-degenerate bilinear form on the big phase space. Moreover,

$$(T^m(\gamma_\alpha),\ T^n(\gamma_\beta)) = \delta_{mn}\eta_{\alpha\beta}$$

for any $m, n \in \mathbb{Z}_{\geq 0}$ and $1 \leq \alpha, \beta \leq N$. The product "$\diamond$" is compatible with this inner product in the sense that

$$(\mathcal{W}_1 \diamond \mathcal{W}_2,\ \mathcal{W}_3) = (\mathcal{W}_1,\ \mathcal{W}_2 \diamond \mathcal{W}_3)$$

for all vector fields $\mathcal{W}_1, \mathcal{W}_2, \mathcal{W}_3$ and therefore define a Frobenius algebra structure on tangent spaces of the big phase space. Note that if the quantum product "$\circ$" is semisimple in the above sense and $\mathcal{E}_1, \ldots, \mathcal{E}_N$ are the idempotents of "$\circ$", then vector fields

$$\{T^n(\mathcal{E}_i) \mid n \in \mathbb{Z}_{\geq 0},\ i = 1, \ldots, N\}$$

are idempotents for "$\diamond$" and give a frame for the tangent bundle of the big phase space. This also justifies the notion of semisimplicity introduced above. We also note that

this frame is not commutative with respect to the Lie bracket and therefore does not come from coordinate vector fields for any coordinate system on the big phase space. Since the product "$\circ$" is much easier to use than the product "$\diamond$", we will not use the product "$\diamond$" in this paper.

In [27] and [42], the WDVV equation has been used to compute genus-0 Gromov–Witten invariants. Higher genus analogues of genus-0 universal equations can also be used to compute higher genus Gromov–Witten invariants. Lets first see what happens for genus-1 and genus-2 cases.

The genus-1 analogue of the genus-0 topological recursion relation is the following

$$\langle\!\langle T(\mathcal{W})\rangle\!\rangle_1 = A_0(\mathcal{W}) := \frac{1}{24}\langle\!\langle\, \mathcal{W}\, \gamma^\alpha\, \gamma_\alpha \rangle\!\rangle_0.$$

This equation is translated from the following tautological relation on $\overline{\mathcal{M}}_{1,1}$ (cf. [8]):

$$\psi_1 = \frac{1}{12}\{\text{boundary stratum of } \overline{\mathcal{M}}_{1,1}\}.$$

The genus-1 analogue of the WDVV equation is the following equation discovered by Getzler [16]: For any vector fields $\mathcal{W}_1, \ldots, \mathcal{W}_4$,

$$\begin{aligned}\sum_{\sigma\in S_4} \Big\{ & 4\langle\!\langle \{\mathcal{W}_{\sigma(1)} \circ \mathcal{W}_{\sigma(2)} \circ \mathcal{W}_{\sigma(3)}\}\, \mathcal{W}_{\sigma(4)} \rangle\!\rangle_1 \\ & - 3\langle\!\langle \{\mathcal{W}_{\sigma(1)} \circ \mathcal{W}_{\sigma(2)}\}\, \{\mathcal{W}_{\sigma(3)} \circ \mathcal{W}_{\sigma(4)}\} \rangle\!\rangle_1 \\ & + \langle\!\langle \{\mathcal{W}_{\sigma(1)} \circ \mathcal{W}_{\sigma(2)}\}\, \mathcal{W}_{\sigma(3)}\, \mathcal{W}_{\sigma(4)}\, \gamma^\alpha \rangle\!\rangle_0 \langle\!\langle \gamma_\alpha \rangle\!\rangle_1 \\ & -2\langle\!\langle \mathcal{W}_{\sigma(1)}\, \mathcal{W}_{\sigma(2)}\, \mathcal{W}_{\sigma(3)}\, \gamma^\alpha \rangle\!\rangle_0 \langle\!\langle \{\gamma_\alpha \circ \mathcal{W}_{\sigma(4)}\} \rangle\!\rangle_1 \Big\} = B_0(\mathcal{W}_1, \mathcal{W}_2, \mathcal{W}_3, \mathcal{W}_4)\end{aligned}$$

where B_0 is a symmetric 4-tensor which consists of 3 terms involving only genus-0 data (see, for example, [36] for the precise form of B_0 where we used notation G_0 for this tensor). This equation corresponds to a tautological relation on $\overline{\mathcal{M}}_{1,4}$.

Let F_1^s be the restriction of F_1 to the small phase space. Using the genus-1 topological recursion relation, Dijkgraaf and Witten [9] obtained a formula, called the *genus*-1 *constitutive relation*, for computing F_1 from F_1^s. In [11], Dubrovin and Zhang observed that if the quantum cohomology of V is semisimple, then in the canonical coordinate system $(u_1, \ldots, u_N)$ on the small phase space, Getzler's equation gives all second order partial derivatives $\frac{\partial^2 F_1^s}{\partial u_i \partial u_j}$ in terms of genus-0 data. They then use the quasi-homogeneity equation to obtain a formula for all first order derivatives of F_1^s. This formula determines F_1^s in terms of genus-0 functions up to an additive constant. It was observed in [36] that one can solve Getzler's equation on the big phase using idempotents $\mathcal{E}_1, \ldots, \mathcal{E}_N$ and obtain

$$\langle\!\langle\, \mathcal{E}_i \rangle\!\rangle_1 = \frac{1}{24}\Big\{ \langle\!\langle\, \tau_-(\mathcal{L}_0)\, \gamma_\alpha\, \gamma^\alpha\, \mathcal{E}_i \rangle\!\rangle_0 - \sum_j u_j\, B_0(\mathcal{E}_j, \mathcal{E}_j, \mathcal{E}_j, \mathcal{E}_i) \Big\}$$

where $\mathcal{L}_0 := -\mathcal{X} - (b_1 + 1)T(\mathcal{S})$. Let ∇ be the trivial connection on the big phase space which is uniquely characterized by the requirement that all vector fields $\tau_n(\gamma_\alpha)$ are parallel. Then $\nabla_{\mathcal{E}_i}\tau_-(\mathcal{L}_0) = 0$. Moreover, second order derivatives of the string equation imply that $A_0(\mathcal{S})$ is a constant. So the above equation can be written in the following form:

Theorem 2.1 ([36]). *For manifolds with semisimple quantum cohomology,*

$$\mathcal{E}_i F_1 = \frac{1}{24}\Big\{\mathcal{E}_i\ A_0\,(\tau_-(\mathcal{L}_0) + \mathcal{S}) - \sum_j u_j\, B_0(\mathcal{E}_j, \mathcal{E}_j, \mathcal{E}_j, \mathcal{E}_i)\Big\}$$

for $i = 1, \ldots, N$.

Together with the genus-1 topological recursion relation, this equation gives all the first order derivatives of F_1 and therefore completely determines F_1 up to a constant. We also note that when restricted to the small phase space, this equation is equivalent to the equation obtained in [11].

The genus-2 analogue of the topological recursion relation is

$$\langle\!\langle T^2(\mathcal{W})\rangle\!\rangle_2 = A_1(\mathcal{W})$$

where A_1 is a 1-tensor which consists of 5 terms involving only genus-0 and genus-1 data (see, for example, [33] for the precise form of A_1). We call this equation Mumford equation since it corresponds to a tautological relation on $\overline{\mathcal{M}}_{2,1}$ of the form

$$\psi_1^2 = \text{linear combinations of boundary strata of } \overline{\mathcal{M}}_{2,1},$$

which was proved in [40]. Mumford's tautological relation was first translated to a universal equation by Getzler [17] following some observations by Faber.

The genus-2 analogue of the WDVV equation is the following equation due to Belorousski and Pandharipande [4]: For arbitrary vector fields $\mathcal{W}_1$, $\mathcal{W}_2$, and $\mathcal{W}_3$ on the big phase space we have

$$\begin{aligned}
&2\langle\!\langle\{\mathcal{W}_1 \circ \mathcal{W}_2 \circ \mathcal{W}_3\}\rangle\!\rangle_2 - 2\langle\!\langle \mathcal{W}_1\, \mathcal{W}_2\, \mathcal{W}_3\, \gamma^\alpha\rangle\!\rangle_0 \langle\!\langle T(\gamma_\alpha)\rangle\!\rangle_2 \\
&\qquad + \frac{1}{2}\sum_{\sigma\in S_3} \langle\!\langle \mathcal{W}_{\sigma(1)}\, T(\mathcal{W}_{\sigma(2)} \circ \mathcal{W}_{\sigma(3)})\rangle\!\rangle_2 - \langle\!\langle T(\mathcal{W}_{\sigma(1)})\,\{\mathcal{W}_{\sigma(2)} \circ \mathcal{W}_{\sigma(3)}\}\rangle\!\rangle_2 \\
&\quad = B_1(\mathcal{W}_1, \mathcal{W}_2, \mathcal{W}_3),
\end{aligned}$$

where B_1 is a symmetric 3-tensor which consists of 16 terms involving only genus-0 and genus-1 data (see, for example, [33] for the precise form of B_1 where we used the notation B for this tensor). This equation corresponds to a tautological relation on $\overline{\mathcal{M}}_{2,3}$. There is also another genus-2 equation due to Getzler [17] which corresponds to a tautological relation on $\overline{\mathcal{M}}_{2,2}$. It was proved in [33] and [35] that Getzler's genus-2 equation can be derived from Mumford equation and Belorousski-Pandharipande equation. So we will not give the precise form of this equation. Note

that all genus-2 universal equations involve gravitational descendants and can not be reduced to equations on the small phase space. This is the main reason for introducing the quantum product on the big phase space. In [37], we proved that in the semisimple case F_2 can be solved from the above genus-2 universal equations and obtained

Theorem 2.2 ([37]). *For manifolds with semisimple quantum cohomology,*

$$F_2 = \frac{1}{6}\Big\{ A_1\left(2\,\tau_-^2(\mathcal{L}_0) + 3\,\tau_-(\mathcal{S})\right) - \sum_{i=1}^{N} u_i B_1(\mathcal{E}_i, \mathcal{E}_i, \mathcal{E}_i)\Big\}.$$

This formula is very similar to the solution of genus-1 equations if we ignore the vector field $\mathcal{E}_i$ in the formula in Theorem 2.1.

For genus bigger than 2, we do not have enough information about universal equations due to the lack of understanding of the tautological rings of moduli spaces of stable curves. So far the only non-trivial universal equation with genus bigger than 2 is the following genus-3 analogue of the topological recursion relation proved by Kimura and the author in [25]: For any vector field $\mathcal{W}$ on the big phase space

$$\langle\!\langle T^3(\mathcal{W})\rangle\!\rangle_3 = A_2(\mathcal{W})$$

where A_2 is a tensor which consists of 29 terms involving only data of genus less than or equal to 2. (See [25] for the precise form of this tensor. An equivalent formula was derived in [2] using the invariance conjecture which has not yet been proved.) This equation corresponds to a tautological relation on $\overline{\mathcal{M}}_{3,1}$ of the form

$$\psi_1^3 = \text{linear combinations of boundary strata of } \overline{\mathcal{M}}_{3,1}.$$

There is a conjecture by Getzler [17] that any degree g monomial of ψ-classes on $\overline{\mathcal{M}}_{g,k}$ should be supported on the boundary of $\overline{\mathcal{M}}_{g,k}$. This conjecture was proved by Ionel [22]. Faber and Pandharipande [15] further proved that degree g monomials of ψ-classes on $\overline{\mathcal{M}}_{g,k}$ are equal to some tautological classes on the boundary of $\overline{\mathcal{M}}_{g,k}$. Note that tautological rings also contain push-forward classes of powers of ψ-classes, i.e. the so called κ-classes, which do not appear in the definition of Gromov–Witten invariants. These results do not yet guarantee the existence of corresponding universal equations. Nevertheless, as mentioned in [33], we do expect that the following conjecture should be true.

Conjecture 2.3. For all $g \geq 1$, there is a universal equation of the form

$$\langle\!\langle T^g(\mathcal{W})\rangle\!\rangle_g = A_{g-1}(\mathcal{W})$$

where A_{g-1} is a tensor which only involve data of genus less than or equal to $g-1$.

Such equations should be the genus-g analogue of the topological recursion relation. Based on our experience from genus-1 and genus-2, we also expect that there

should be a genus-g analogue of the WDVV equation whose lower genus part should be a symmetric tensor, written as B_{g-1}, which only involves data of genus less than or equal to $g-1$. However, at this stage, we even do not have a good prediction for the top genus part of this equation for $g \geq 3$. Despite of these difficulties we believe that the following conjecture should be true.

Conjecture 2.4. For manifolds with semisimple quantum cohomology, F_g can be solved explicitly from universal equations for $g \geq 2$.

Based on Theorems 2.1 and 2.2, we may even speculate that the form of F_g obtained by solving universal equations should be

$$F_g = A_{g-1}\big(a_g\, \tau_-^g(\mathcal{L}_0) + b_g\, \tau_-^{g-1}(\mathcal{S})\big) - c_g \sum_{i=1}^{N} u_i\, B_{g-1}(\mathcal{E}_i, \ldots, \mathcal{E}_i)$$

where a_g, b_g, c_g are some constants depending only on g.

One might also expect that there exist universal equations of the form

$$\langle\!\langle T^{n_1}(\mathcal{W}_1) \ldots T^{n_k}(\mathcal{W}_k)\rangle\!\rangle_g = \text{an expression involving at most genus-}(g-1)\text{ data} \quad (3)$$

for $n_1 + \cdots + n_k = g$. This statement is somewhat stronger than Getzler's conjecture on the tautological ring of $\overline{\mathcal{M}}_{g,k}$. Since there are only finitely many strata on $\overline{\mathcal{M}}_{g,k}$ with a fixed degree, one can explicitly write out the right-hand side of equation (3) with certain undetermined coefficients. It might be possible that in many cases these coefficients can be fixed by known Gromov–Witten theory. For example, to obtain the genus-3 topological recursion relation in [25], we only need the Gromov–Witten theory of a point and $\mathbb{CP}^1$. However, coefficients obtained in this way are quite mysterious. It would be very interesting to give a better explanation to such coefficients.

3. The Virasoro conjecture

In [14] Eguchi, Hori and Xiong constructed a sequence of differential operators on the big phase space. With a slight modification proposed by S. Katz (cf. [6]), these operators satisfy the Virasoro bracket relation when the underlying manifold is a smooth projective variety and therefore form a half branch of the Virasoro algebra. They conjectured that these operators annihilate the generating function of the Gromov–Witten invariants for all smooth projective varieties. This conjecture is now known as the *Virasoro conjecture*. It is a far-reaching generalization of a conjecture of Witten, which was proved by Kontsevich, that the generating function of intersection numbers of ψ-classes on $\overline{\mathcal{M}}_{g,k}$ is a τ-function of the KdV hierarchy (cf. [45], [26], and [45]). In [13], Dubrovin and Zhang proved that if the quantum cohomology of a projective variety V is semisimple, then higher genus Gromov–Witten invariants of V are determined by genus-0 invariants and the Virasoro conjecture. For manifolds with

semisimple quantum cohomology, Givental [19] has conjectured a form of higher genus generating functions in terms of genus-0 data and the τ-function in Witten's conjecture and showed that his conjectural formula satisfies the Virasoro constraints (cf. [20]). Consequently, Givental's conjecture is equivalent to the Virasoro conjecture for projective varieties with semisimple quantum cohomology. In the case that the underlying manifold has a torus action with isolated fixed points and also has semisimple quantum cohomology, Givental has a scheme to reduce his conjecture to the so-called *R-conjecture* on the fundamental solutions to the flat section equations of a one-parameter family of connections on the small phase space defined using quantum product. Note that localization techniques played a crucial role in this scheme. An outline for the proof of the R-conjecture for projective spaces were given in [20]. The R-conjecture has been verified for flag manifolds in [24] and for Grassmannians in [5]. Also using localization techniques, Okounkov and Pandharipande [41] proved the Virasoro conjecture for algebraic curves. In this paper we will focus on the approach to the Virasoro conjecture using universal equations instead of localization techniques. Since universal equations hold for all compact symplectic manifolds, this approach should apply to a larger class of manifolds. In particular, there is no need to assume the existence of torus actions on the manifolds. In [39], Tian and the author proved the following theorem using genus-0 topological recursion relation (see also [12], [18], [34], [21] for alternative proofs.):

Theorem 3.1 ([39]). *The genus-*0 *Virasoro conjecture holds for all compact symplectic manifolds.*

The genus-1 Virasoro conjecture for manifolds with semisimple quantum cohomology was proved by Dubrovin and Zhang [12] (see also [32] and [36]). The genus-2 analogue of this result was proved in [37] using Theorem 2.2.

Theorem 3.2 ([37]). *The genus-*2 *Virasoro conjecture holds for manifolds with semisimple quantum cohomology.*

This theorem implies in particular that Givental's conjectural formula is correct in the genus-2 case. An alternative approach to the genus-2 Virasoro conjecture for manifolds with semisimple quantum cohomology is to show that Givental's formula satisfies known genus-2 universal equations and then use the result in [33] that known genus-2 universal equations uniquely determine F_2 in the semisimple case. Givental's formula was constructed using actions of twisted loop groups on a product of copies of the τ-function in Witten's conjecture. The invariance of the genus-2 Mumford's relation under the action of Lie algebras of twisted loop groups was discussed in [29]. It was also claimed that the genus-2 equations of Getzler and Belorousski-Pandharipande are invariant in the same sense. In [32] and [33], the author proved that the genus-1 and genus-2 Virasoro conjecture for all smooth projective varieties can be reduced to an SL(2) symmetry for Gromov–Witten invariants. We will give the precise statement of this result later. Below we explain in more detail the relations between universal equations and the Virasoro conjecture.

The following operators were introduced in [33] as a convenient tool in the study of the Virasoro conjecture: For any vector field $\mathcal{W} = \sum_{m,\alpha} f_{m,\alpha}\tau_m(\gamma_\alpha)$ on the big phase space, define

$$G(\mathcal{W}) := \sum_{m,\alpha,\beta} (m + b_\alpha) f_{m,\alpha}\tau_m(\gamma_\alpha), \quad C(\mathcal{W}) := \sum_{m,\alpha,\beta} f_{m,\alpha} C_\alpha^\beta \tau_m(\gamma_\beta),$$

and

$$R(\mathcal{W}) := (GT + C)(\mathcal{W}).$$

Starting from the string vector field $\mathcal{S}$, we can apply the operator R recursively to obtain a sequence of vector fields on the big phase space:

$$\mathcal{L}_n := -R^{n+1}(S)$$

for $n \geq -1$. It was proved in [33] that this sequence of vector fields satisfy the Virasoro bracket relation:

$$[\mathcal{L}_m, \mathcal{L}_n] = (m - n)\mathcal{L}_{m+n}.$$

These vector fields are not exactly the Virasoro operators given in [14] which are second order differential operators. However the Virasoro conjecture can be rephrased using these vector fields in the following way. First, second order derivatives of the genus-0 Virasoro conjecture can be reinterpreted as

$$\mathcal{L}_n \circ \mathcal{W} = -\mathcal{X}^{n+1} \circ \mathcal{W} \tag{4}$$

for any vector field $\mathcal{W}$ and $n \geq 0$, where $\mathcal{W}^k$ is defined to be the quantum product of k copies of $\mathcal{W}$. This equation follows from the associativity of the quantum product and the following property of the operator R (cf. [33]):

$$R(\mathcal{V}) \circ \mathcal{W} = \mathcal{X} \circ \mathcal{V} \circ \mathcal{W}$$

for any vector fields $\mathcal{W}$ and $\mathcal{V}$. Using this property a proof for genus-0 Virasoro conjecture was obtained in [34] which is much simpler than the original proof in [39].

To interpret higher genus Virasoro conjecture, we also need the following operators:

$$Q_0 := \tau_-, \quad Q_1 := Q := G + C\tau_-, \quad Q_k := Q(Q-1)\dots(Q-k+1)\tau_+^{k-1}$$

for $k \geq 1$. These operators were used in [34] to simplify the proof of the genus-0 Virasoro conjecture. Define second order differential operators

$$W_n := \sum_{i=1}^{n} \{Q_i(\gamma^\alpha)\} \{Q_{n-i}\tau_+ Q(\gamma_\alpha)\}$$

for $n \geq 1$. Note that $Q_i(\gamma^\alpha)$ and $Q_{n-i}\tau_+ Q(\gamma_\alpha)$ are parallel vector fields with respect to the trivial connection ∇ on the big phase space. Therefore they commute with each

other as first order differential operators. Then *Virasoro conjecture* for $g \geq 1$ can be formulated as

$$\left\{\mathcal{L}_n + \frac{1}{2}\lambda^2 W_n + \frac{1}{2}(W_n F_0)\right\} e^{\sum_{g=1}^{\infty} \lambda^{2g-2} F_g} = 0$$

for $n \geq -1$. Here $(W_n F_0)$ means the multiplication by the genus-0 function $W_n F_0$. The Virasoro conjecture for $g \geq 2$ can also be formulated as

$$\left\{\mathcal{L}_n + \frac{1}{2}\lambda^2 e^{-F_1}\, W_n\, e^{F_1}\right\} e^{\sum_{g=2}^{\infty} \lambda^{2g-2} F_g} = 0$$

for $n \geq -1$. Here we understand $W_n = 0$ for $n \leq 0$. In this formulation, $e^{-F_1}\, W_n\, e^{F_1}$ is understood as the composition of three operators acting on the space of functions.

The genus-g L_{-1}-constraint is simply the string equation which holds for all compact symplectic manifolds

$$\langle\!\langle \mathcal{L}_{-1} \rangle\!\rangle_g = -\frac{1}{2}\delta_{g,0}\eta_{\alpha\beta} t_0^\alpha t_0^\beta.$$

The genus-g L_0-constraint has the following form

$$\langle\!\langle \mathcal{L}_0 \rangle\!\rangle_g = -\frac{1}{2}\delta_{g,0} C_{\alpha\beta} t_0^\alpha t_0^\beta + \frac{1}{24}\delta_{g,1}\left\{\int_V c_1(V) \cup c_{d-1}(V) - \frac{3-d}{2}\chi(V)\right\}.$$

This constraint follows from the quasi-homogeneity equation and the *dilaton equation*

$$\langle\!\langle T(\mathcal{S}) \rangle\!\rangle_g = (2g-2)F_g + \frac{1}{24}\chi(V)\delta_{g,1}$$

where $\chi(V)$ is the Euler characteristic number of V. These equations also hold for all compact symplectic manifolds.

For $g \geq 1$ and $n \geq 1$, the genus-g L_n-constraint in the Virasoro conjecture can be formulated as:

$$\begin{aligned}\langle\!\langle \mathcal{L}_n \rangle\!\rangle_g = -\frac{1}{2}\sum_{i=1}^{n}\Big\{&\langle\!\langle Q_i(\gamma^\alpha)\ \{Q_{n-i}\tau_+ Q(\gamma_\alpha)\}\rangle\!\rangle_{g-1} \\ &+ \sum_{h=1}^{g-1} \langle\!\langle Q_i(\gamma^\alpha)\rangle\!\rangle_h \langle\!\langle \{Q_{n-i}\tau_+ Q(\gamma_\alpha)\}\rangle\!\rangle_{g-h}\Big\}.\end{aligned}$$

Note that the right-hand side of this formula only involves data of genus less than g.

For any compact symplectic manifold V, we can use universal equations to obtain recursion relations among $\langle\!\langle \mathcal{L}_n \rangle\!\rangle_g$ for $g = 1, 2$. In genus-1 case, we have (cf. [32])

$$\langle\!\langle \mathcal{L}_n \rangle\!\rangle_1 + \frac{n+1}{2}(\mathcal{S} \circ \mathcal{L}_{n-1})\langle\!\langle \mathcal{L}_1 \rangle\!\rangle_1 \equiv 0 \mod \{\text{genus 0 data}\}.$$

In genus-2 case, we have (cf. [33])

$$\langle\!\langle \mathcal{L}_n \rangle\!\rangle_2 + \frac{n+1}{2(n-1)} T(\mathcal{S} \circ \mathcal{L}_0) \langle\!\langle \mathcal{L}_{n-1} \rangle\!\rangle_2 \equiv 0 \mod \{\text{genus} \leq 1 \text{ data}\}.$$

The right-hand sides of these two equations are explicit functions only involving lower genus data (See [32] and [33] for the precise forms). As a consequence of these two formulas, we have the next result.

Theorem 3.3 ([32], [33]). *For any compact symplectic manifold, $\langle\!\langle \mathcal{L}_n \rangle\!\rangle_g$ can be computed from $\langle\!\langle \mathcal{L}_1 \rangle\!\rangle_g$ and lower genus data for all $n \geq 2$ and $g = 1, 2$.*

In case that the manifold is a projective variety we can further verify the following:

Theorem 3.4 ([32], [33]). *For any smooth projective variety, the genus-*1 *and genus-*2 *Virasoro conjecture follows from the L_1-constraint.*

Note that the first 3 Virasoro operators (as well as vector fields $\mathcal{L}_{-1}$, $\mathcal{L}_0$ and $\mathcal{L}_1$) form a 3-dimensional subalgebra which is isomorphic to SL(2). Since the L_{-1} and L_0 constraints are satisfied for all compact symplectic manifolds, the proof of the above theorem can be interpreted as saying that for genus-1 and genus-2 cases universal equations upgrade an SL(2) symmetry for Gromov–Witten invariants to the Virasoro conjecture. We believe that this should also be true for higher genus cases:

Conjecture 3.5. For all compact symplectic manifolds V, $\langle\!\langle \mathcal{L}_n \rangle\!\rangle_g$ can be computed from $\langle\!\langle \mathcal{L}_1 \rangle\!\rangle_g$ and lower genus data for $n \geq 2$ and $g \geq 1$. In case that V is a smooth projective variety the Virasoro conjecture follows from universal equations and the L_1- constraint.

Note that the above two theorems do not need semisimplicity. In case that the quantum cohomology is semisimple, we can actually recover the action of $\mathcal{L}_1$ on F_g from the action of $\mathcal{L}_n$ on F_g for $n \geq 2$ due to algebraic relations among these vector fields (cf. [32] and [33] for details). This is the reason that the genus-1 and genus-2 Virasoro conjecture hold for manifolds with semisimple quantum cohomology. In fact, one can actually use the formulas in Theorems 2.1 and 2.2 to prove the Virasoro conjecture in these cases (cf. [36] and [37] for details). Based on these results, it is reasonable to believe that the following conjecture should be true.

Conjecture 3.6. For all smooth projective varieties with semisimple quantum cohomology, the Virasoro conjecture follows from universal equations.

We also note that besides vector fields $\mathcal{L}_n$, $n \geq -1$, there are also other natural vector fields on the big phase space which satisfy the Virasoro bracket relation. For example, if we define $\overline{\mathcal{X}}^k := \mathcal{S} \circ \mathcal{X}^k$, then these vector fields satisfy the bracket relation

$$[\overline{\mathcal{X}}^m, \overline{\mathcal{X}}^k] = (k-m)\overline{\mathcal{X}}^{m+k-1}$$

for all $m, k \geq 0$ (cf. [33]). Here $\mathcal{X}^0$ is understood to be the string vector field $\mathcal{S}$. The relation between these vector fields and the Virasoro conjecture is explained in equation (4) and in more detail in [33].

Another sequence of vector fields is $T^n(\mathcal{X})$, $n \geq 0$, which satisfy the relation

$$[T^k(\mathcal{X}),\ T^m(\mathcal{X})] = (m-k)T^{m+k}(\mathcal{X})$$

for all $m, k \geq 0$. This relation follows from the following properties of the covariant differentiation

$$\nabla_{\mathcal{W}}\mathcal{X} = -Q(\mathcal{W}) + (b_1+1)\mathcal{W}, \quad \nabla_{\mathcal{V}}\, T^k(\mathcal{W}) = T^k(\nabla_{\mathcal{V}}\mathcal{W}) - T^{k-1}(V \circ W)$$

for all vector fields $\mathcal{V}$ and $\mathcal{W}$, as well as the following properties for operators T and Q

$$T^k Q T^m - T^m Q T^k = (m-k)T^{m+k}$$

for $m, k > 0$, and

$$(QT^k - T^k Q)(\mathcal{W}) = k\, T^k(\mathcal{W}) + T^{k-1}(\mathcal{X} \circ \mathcal{W})$$

for $k > 0$ and any vector field $\mathcal{W}$. The relation between vector fields $T^n(\mathcal{X})$ and the Virasoro conjecture is not clear at this moment.

4. Universal equations and spin curves

Universal equations also arise in the study of intersection theory on moduli spaces of spin curves. As mentioned above, the generating function for intersection numbers on the moduli spaces of stable curves is a τ-function of KdV hierarchy by Kontsevich–Witten theorem. In [46], Witten also proposed an algebraic geometric way to produce a τ-function for more general Gelfand–Dickey hierarchies by considering intersection numbers on the moduli spaces of spin curves. Assume that $r \geq 2$ is an integer and $\boldsymbol{m} = (m_1, \ldots, m_k)$ is a collection of integers with $0 \leq m_i \leq r-2$. When r is prime, an r-spin structure of type $\boldsymbol{m}$ over a smooth stable curve $(C; x_1, \ldots, x_k)$ is a line bundle $L \longrightarrow C$ together with an isomorphism $L^{\otimes r} \longrightarrow \omega\big(-\sum_{i=1}^k m_i x_i\big)$ where ω is the canonical line bundle over C. For degree reasons such a line bundle exists only if $\big(2g-2-\sum_{i=1}^k m_i\big)/r \in \mathbb{Z}$ where g is the genus of C. If r is not prime, then all d-th roots of $\omega\big(-\sum_{i=1}^k m_i x_i\big)$ should be considered for all d which divides r. If C is not smooth the definition of an r-spin structure is more involved (cf. [23] for details). A stable curve with an r-spin structure is called an r-spin curve. Let $\bar{\mathcal{M}}_{g,k}^{1/r}(\boldsymbol{m})$ be the moduli space of all genus-g r-spin curves of type $\boldsymbol{m}$ and with k-marked points. Let Ψ_i be the first Chern class of the line bundle over $\bar{\mathcal{M}}_{g,k}^{1/r}(\boldsymbol{m})$ whose geometric fiber over each r-spin curve is given by $T_{x_i}^* C$.

Let $e_0, \ldots, e_{r-2}$ be some abstract symbols. Define

$$\langle \tau_{n_1}(e_{m_1}) \ldots \tau_{n_k}(e_{m_k}) \rangle_{g,r} := r^{1-g} \int_{\overline{\mathcal{M}}_{g,k}^{1/r}(\boldsymbol{m})} c_{g,n}^{1/r}(\boldsymbol{m}) \cup \Psi_1^{n_1} \cup \cdots \cup \Psi_k^{n_k}$$

where $c_{g,n}^{1/r}(\boldsymbol{m})$ is a rational cohomology class on $\overline{\mathcal{M}}_{g,n}^{1/r}(\boldsymbol{m})$ of degree

$$\frac{2}{r}\Big\{(r-2)(g-1) + \sum_{i=1}^{n} m_i\Big\}.$$

The Poincaré dual of $c_{g,n}^{1/r}(\boldsymbol{m})$ corresponds to the virtual fundamental class in the Gromov–Witten theory. The genus-g generating function $\Phi_{g,r}$ for such numbers is then a function of parameters t_n^m with $0 \le m \le r-2$ and $n \in \mathbb{Z}_{\ge 0}$. Let $\Phi_r = \sum_{g=0}^{\infty} \Phi_{g,r}$. The *generalized Witten conjecture* predicts that $\exp(\Phi_r)$ is a τ-function of r-th KdV hierarchy (also called the Gelfand–Dickey hierarchy). More precisely, consider a differential operator

$$L = D^r - \sum_{i=0}^{r-2} u_i(x)\ D^i, \quad \text{where } D := \frac{\sqrt{-1}}{\sqrt{r}} \frac{\partial}{\partial x}.$$

An r-th root of L is a pseudo-differential operator of the form

$$L^{1/r} = D + \sum_{i>0} w_i(x) D^{-i}$$

whose r-th power is L and w_i are differential polynomials in $u_0, \ldots u_{r-2}$. Assume that L also depends on infinitely many parameters t_n^m with $0 \le m \le r-2$ and $n \ge 0$. The variable x is usually identified with t_0^0. We say that L satisfies the *r-th KdV hierarchy* if

$$\sqrt{-1}\ \frac{\partial L}{\partial t_n^m} = \frac{k_{n,m}}{\sqrt{r}} \big[\big(L^{n+\frac{m+1}{r}}\big)_+,\ L \big] \tag{5}$$

for all m and n, where

$$k_{n,m} = \frac{(-1)^n r^{n+1}}{(m+1)(r+m+1)\ldots(nr+m+1)}$$

and $\big(L^{n+\frac{m+1}{r}}\big)_+$ is a differential operator obtained by discarding all negatives powers of D in $L^{n+\frac{m+1}{r}}$. The *generalized Witten conjecture* says that there exists an operator L which satisfies the r-th KdV hierarchy such that

$$\frac{\partial^2 \Phi_r}{\partial t_0^0\, \partial t_n^m} = -k_{n,m} \operatorname{Res} \big(L^{n+\frac{m+1}{r}}\big) \tag{6}$$

for all m and n. Here "Res" means taking the coefficient of D^{-1}.

In some sense the generating functions $\Phi_{g,r}$ behaves like the generating function F_g for Gromov–Witten invariants of a fictitious manifold of rational dimension $2(r-2)/r$ and with the first Chern class equal to 0. Each abstract symbol e_m plays the role of a cohomology class of this fictitious manifold with rational degree $2m/r$. One can use the bilinear form defined by $(e_i,\ e_j) := \delta_{i+j,r-2}$ as a substitute for the Poincaré pairing. In this way, all structures of Gromov–Witten invariants mentioned in previous sections can make sense for intersection numbers on the moduli spaces of spin curves. In particular, $\Phi_{g,r}$ also satisfies the string equation. Together with the initial condition $\Phi(0) = 0$, the generalized Witten conjecture and the string equation completely determine the intersection numbers $\langle \tau_{n_1}(e_{m_1}) \dots \tau_{n_k}(e_{m_k}) \rangle_{g,r}$. It is also well known that the generalized Witten conjecture and the string equation are equivalent to Virasoro constraints formulated in a similar way (See for example [1]). There is also a canonical map $\overline{\mathcal{M}}^{1/r}_{g,k}(\boldsymbol{m}) \longrightarrow \overline{\mathcal{M}}_{g,k}$ which forgets spin structures on underlying stable curves. Therefore the functions $\Phi_{g,r}$ also satisfy universal equations for Gromov–Witten invariants which are obtained from tautological relations on $\overline{\mathcal{M}}_{g,k}$ (cf. [23]). In particular, a proof for the Virasoro conjecture only using universal equations also gives a proof to the generalized Witten conjecture.

On the other hand, if we assume that the generalized Witten's conjecture is true, we should also get a lot of information for universal equations for Gromov–Witten invariants. For this purpose it is desirable to write equations (5) and (6) in a form closer to universal equations. Analogous to Gromov–Witten theory, we define $\langle\!\langle\, \mathcal{W}_1 \ \dots \ \mathcal{W}_k \,\rangle\!\rangle_g$ and $\langle\!\langle\, \mathcal{W}_1 \ \dots \ \mathcal{W}_k \,\rangle\!\rangle$ as in equation (1) with F_g replaced by $\Phi_{g,r}$ and Φ_r respectively. We also define the grading operator G as a linear operator on the space of vector fields on the big phase space by

$$G(\tau_n(e_m)) := (n + b_m)\, \tau_n(e_m), \quad \text{with } b_m := \frac{m+1}{r}.$$

For any vector field $\mathcal{W}$ on the big phase space define

$$\tilde{T}(\mathcal{W}) := \tau_+(\mathcal{W}) - \sum_{m=0}^{r-2} \langle\!\langle\, \mathcal{W}\, e_m \,\rangle\!\rangle\, e_{r-2-m} \quad \text{and} \quad \tilde{R}(\mathcal{W}) := G\, \tilde{T}(\mathcal{W}).$$

The difference of operator $\tilde{T}$ and the operator T is that the coefficient of e_{r-2-m}, i.e. $\langle\!\langle\, \mathcal{W}\, e_m \,\rangle\!\rangle$, contains information for all genera, not only genus-0. Note that we think of $c_1 = 0$ for the theory of spin curves, so $\tilde{R}$ is a direct analogue of R with T replaced by $\tilde{T}$. In particular, we have

$$\tilde{R}(\tau_n(e_m)) = \left(n + 1 + \frac{m+1}{r}\right) \tau_{n+1}(e_m) - \sum_{j=0}^{r-2} \frac{r-1-j}{r} \langle\!\langle\, \tau_n(e_m)\, e_j \,\rangle\!\rangle\, e_{r-2-j}.$$

For any vector field $\mathcal{W}$ on the big phase space and $0 \le m \le r-2$, define

$$\begin{aligned}\Omega_m(\mathcal{W}) := {} & \langle\!\langle \tilde{R}(\mathcal{W})\, e_0\, e_m \rangle\!\rangle - \sum_{i=0}^{r-2} b_i^2 b_{r-2-i} \langle\!\langle \mathcal{W}\, e_0\, e_m\, e_i\, e_{r-2-i} \rangle\!\rangle \\ & - \sum_{i=0}^{r-2} \frac{b_{r-2-i}+b_m}{2}\ \langle\!\langle \mathcal{W}\, e_0\, e_i \rangle\!\rangle \langle\!\langle e_{r-2-i}\, e_m \rangle\!\rangle \\ & - \sum_{i=0}^{r-2} \frac{b_{r-2-i}+b_0}{2}\ \langle\!\langle \mathcal{W}\, e_m\, e_i \rangle\!\rangle \langle\!\langle e_{r-2-i}\, e_0 \rangle\!\rangle . \end{aligned} \tag{7}$$

For each r, the generalized Witten conjecture can be reformulated in the form

$$\Omega_m(\mathcal{W}) = \cdots \tag{8}$$

for all vector field $\mathcal{W}$, where the right-hand side of this equation is an expression each term of which involves only $\mathcal{W}$ and at least 6 primary vector fields. For example, when $r = 2$, Witten's formulation of his KdV conjecture in [44] is equivalent to

$$\Omega_0(\mathcal{W}) = 0 \tag{9}$$

for all vector field $\mathcal{W}$. Shadrin [43] shows that the generalized Witten conjecture for $r = 3$ also implies a formula which is equivalent to equation (9). In [38], it is proved that the generalized Witten conjecture for $r = 3$ also implies that

$$\Omega_1(\mathcal{W}) = \frac{1}{108}\left\{ -\langle\!\langle \mathcal{W}\, e_0^2 \rangle\!\rangle \langle\!\langle e_0^4 \rangle\!\rangle - \langle\!\langle \mathcal{W}\, e_0^3 \rangle\!\rangle \langle\!\langle e_0^3 \rangle\!\rangle + \langle\!\langle \mathcal{W}\, e_0^4 \rangle\!\rangle \langle\!\langle e_0^2 \rangle\!\rangle \right\}$$

for all vector field $\mathcal{W}$. In fact, this equation and equation (9) together are equivalent to the generalized Witten conjecture for $r = 3$. In this formula and the formula below e_i^k does not mean the quantum power of e_i. It simply means e_i repeating k times.

It seems quite hard to give a general formula for the right-hand side of equation (8) for all r, even for the special case $m = 0$. Equation (9) only holds for $r = 2$ and $r = 3$. It does not hold when $r > 3$. For example, when $r = 4$, we have

$$\Omega_0(\mathcal{W}) = \frac{1}{192}\left\{ \langle\!\langle \mathcal{W}\, e_0^2 \rangle\!\rangle \langle\!\langle e_0^4 \rangle\!\rangle + \langle\!\langle \mathcal{W}\, e_0^3 \rangle\!\rangle \langle\!\langle e_0^3 \rangle\!\rangle - \langle\!\langle \mathcal{W}\, e_0^4 \rangle\!\rangle \langle\!\langle e_0^2 \rangle\!\rangle \right\}$$

as a consequence of the generalized Witten conjecture (cf. [38]). However, from all examples computed in [38], we expect that at the origin of the big phase space $\Omega_m(\mathcal{W}) = 0$ for all $r \ge 2$ and all vector fields $\mathcal{W}$ on the big phase space. Combining with the string equation, the equation $\Omega_0(\mathcal{W}) = 0$ at the origin gives the following recursion formula for intersection numbers:

$$\left(n+1+\frac{m+2}{r}\right)\langle \tau_n(e_m) \rangle = \sum_{j=0}^{r-2} \frac{(j+1)^2(r-1-j)}{r^3} \langle \tau_{n-1}(e_m)\, e_j\, e_{r-2-j} \rangle$$

for all r, m and n. This formula has been checked for $r \leq 7$ in [38] using the generalized Witten conjecture. In particular, we used this formula computed $\langle \tau_n(e_m) \rangle_{3,r}$. The results match with the computations using the genus-3 topological recursion relation in [25].

Starting from any vector field $\mathcal{W}$ on the big phase space, the above equations obtained from the generalized Witten conjecture are recursion relations involving $\tilde{R}(\mathcal{W})$. One can also write them as recursion relations involving $R(\mathcal{W})$ in more complicated forms. In comparison, universal equations obtained from tautological relations are recursion relations involving $T(\mathcal{W})$. In this sense the recursion relations from the generalized Witten conjecture are closer to the Virasoro constraints rather than universal equations. It would be interesting to find out relations between these two types of recursion relations. In [44], Witten showed how to check the compatibility of the equation (9) for $r = 2$ and the topological recursion relations of genus-0 and genus-1. He employed the constitutive relations which were obtained in [9] using genus-0 and genus-1 topological recursion relations. So far there is no analogue for the constitutive relations when the genus is bigger than one. This makes it harder to check the compatibility even for the case when $r = 2$ if the genus is bigger than 1. We believe that it is very important to understand the relations between the generalized Witten conjecture (or τ-functions of Gelfand–Dickey hierarchies) and universal equations of Gromov–Witten invariants. Such relations should be crucial in understanding the structures of the complicated systems of universal equations.

Extremal metrics and stabilities on polarized manifolds

Toshiki Mabuchi*

Abstract. The Hitchin–Kobayashi correspondence for vector bundles, established by Donaldson, Kobayashi, Lübke, Uhlenbeck and Yau, states that an indecomposable holomorphic vector bundle over a compact Kähler manifold is stable in the sense of Takemoto–Mumford if and only if the vector bundle admits a Hermitian-Einstein metric. Its manifold analogue known as Yau's conjecture, which originated from Calabi's conjecture, asks whether "stability" and "existence of extremal metrics" for polarized manifolds are equivalent. In this note the recent progress of this subject, by Donaldson, Tian and our group, together with its relationship to algebraic geometry will be discussed.

Mathematics Subject Classification (2000). Primary 32Q15; Secondary 53C21.

Keywords. Asymptotic Bergman kernel, balanced metrics, Calabi's conjecture, Catlin–Lu–Tian–Zelditch's theorem, Chow–Mumford stable, extremal Kähler metrics, Futaki's character, GIT (geometric invariant theory), geometry of Kähler potentials, Gieseker's stability for surfaces of general type, Hilbert–Mumford stable, Hitchin–Kobayashi correspondence, Kähler–Einstein metrics, K-energy, K-stable, Matsushima's obstruction, stability theorems by Donaldson and Tian, Takemoto–Mumford stable, Yau's conjecture.

1. Introduction

Let M be a compact complex connected manifold. As an introduction to our subject we recall the following well-known conjecture of Calabi [5]:

Conjecture. (i) If $c_1(M)_{\mathbb{R}} < 0$, then M admits a unique Kähler–Einstein metric ω such that $\mathrm{Ric}(\omega) = -\omega$.

(ii) If $c_1(M)_{\mathbb{R}} = 0$, then each Kähler class on M admits a unique Kähler–Einstein metric ω such that $\mathrm{Ric}(\omega) = 0$.

(iii) For $c_1(M)_{\mathbb{R}} > 0$, find a suitable condition for M to admit a Kähler–Einstein metric ω such that $\mathrm{Ric}(\omega) = \omega$.

Based on the pioneering works of Calabi [6], [7] and Aubin [1], a complete affirmative answer to (i) and (ii) was given by Yau [49] by solving systematically certain complex Monge–Ampère equations. However for (iii), sufficient conditions are known only partially by Siu [41], Nadel [37], Tian [42], [44], Tian and Yau [46], Wang and Zhu [52], where some necessary conditions were formulated as obstructions by

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

Futaki [18] and Matsushima [34] (see also Lichnerowicz [23]). It is (iii) that mainly motivates our studies of stabilities and extremal metrics, while an analysis of destabilizing phenomena caused by the non-existence of Kähler–Einstein metrics allows us to obtain very nice by-products, such as Nadel's vanishing theorem [37] via the use of multiplier ideal sheaves.

2. Stability for manifolds in algebraic geometry

In Mumford's GIT [36], moduli spaces of algebraic varieties are constructed via the theory of invariants, where varieties are described by numerical data modulo actions of reductive algebraic groups. Then, roughly speaking, stable points are those away from very bad points in moduli spaces. For a precise definition consider a representation of a reductive algebraic group G on a complex vector space W. Let $w \in W$. We denote by G_w the isotropy subgroup of G at w.

Definition 2.1. A point $w \in W$ is said to be *stable* (resp. *properly stable*) if the orbit $G \cdot w$ is closed in W (resp. $G \cdot w$ is closed in W with $|G_w| < \infty$).

For moduli spaces of polarized varieties the Chow–Mumford stability and the Hilbert–Mumford stability are known. In what follows, by a polarized manifold (M, L), we mean a very ample holomorphic line bundle L over a nonsingular projective algebraic variety M defined over $\mathbb{C}$, where the arguments in this section have nothing to do with the nonsingularity of M. Now for a polarized manifold (M, L) put $n := \dim M$ and let m be a positive integer. Then associated to the complete linear system $|L^m|$ we have the Kodaira embedding

$$\iota_m : M \hookrightarrow \mathbb{P}^*(V_m),$$

where $\mathbb{P}^*(V_m)$ denotes the set of all hyperplanes in $V_m := H^0(M, \mathcal{O}(L^m))$ through the origin. Let d_m be the degree of $\iota_m(M)$ in the projective space $\mathbb{P}^*(V_m)$. Put $G_m := \mathrm{SL}_{\mathbb{C}}(V_m)$ and $W_m := \{S^{d_m}(V_m)\}^{\otimes n+1}$, where $S^{d_m}(V_m)$ is the d_m-th symmetric tensor product of the space V_m. Take an element $M_m \neq 0$ in W_m^* such that the associated element $[M_m]$ in $\mathbb{P}^*(W_m)$ is the Chow point of the irreducible reduced algebraic cycle $\iota_m(M)$ on $\mathbb{P}^*(V_m)$. For the natural action of G_m on W_m^* we now apply Definition 2.1 to $G = G_m$ and $W = W_m$:

Definition 2.2. (a) (M, L^m) is said to be *Chow–Mumford stable* (resp. *Chow–Mumford properly stable*) if M_m in W_m^* is stable (resp. properly stable).

(b) (M, L) is said to be *asymptotically Chow–Mumford stable* (resp. *asymptotically Chow–Mumford properly stable*) if, for $m \gg 1$, (M, L^m) is Chow–Mumford stable (resp. Chow–Mumford properly stable).

Let m and k be positive integers. Then the kernel $I_{m,k}$ of the natural homomorphism of $S^k(V_m)$ to $V_{mk} := H^0(M, \mathcal{O}(L^{mk}))$ is the homogeneous ideal of degree k

defining M in $\mathbb{P}^*(V_m)$. Put $N_{mk} := \dim V_{mk}$ and $\gamma_{m,k} := \dim I_{m,k}$. Then $\wedge^{\gamma_{m,k}} I_{m,k}$ is a complex line in the vector space $W_{m,k} := \wedge^{\gamma_{m,k}}(S^k(V_m))$. Take an element $w_{m,k} \neq 0$ in $\wedge^{\gamma_{m,k}} I_{m,k}$. For the natural action of $G_m := \mathrm{SL}_{\mathbb{C}}(V_m)$ on $W_{m,k}$ we apply Definition 2.1 to $G = G_m$ and $W = W_{m,k}$:

Definition 2.3. (a) (M, L^m) is said to be *Hilbert–Mumford stable* (resp. *Hilbert–Mumford properly stable*) if $w_{\ell,k} \in W_{\ell,k}$ is stable (resp. properly stable).

(b) (M, L) is said to be *asymptotically Hilbert–Mumford stable* (resp. *asymptotically Hilbert–Mumford properly stable*) if, for all $m \gg 1$, (M, L^m) is Hilbert–Mumford stable (resp. Hilbert–Mumford properly stable).

A result of Fogarty [17] shows that if (M, L^m) is Chow–Mumford stable, then (M, L^m) is also Hilbert–Mumford stable. Though the converse has been unknown, the relationship between these two stabilities is now becoming clear (cf. [33]).

Stability for manifolds is an important subject in moduli theories of algebraic geometry. Recall, for instance, the following famous result of Mumford [35]:

Fact 1. *If L is an ample line bundle of degree $d \geq 2g + 1$ over a compact Riemann surface C of genus $g \geq 1$, then (C, L) is Chow–Mumford properly stable.*

For the pluri-canonical bundles $K_M^{\otimes m}$ on $M, m \gg 1$, using the asymptotic Hilbert–Mumford stability, Gieseker [20] generalized this result to the case where M is a surface of general type. For higher dimensions a stability result by Viehweg [48] is known in the case where the canonical bundle K_M is semipositive. However, for both the results of Gieseker and of Viehweg the proof of stability is fairly complicated, while the underlying manifold (or orbifold) admits a Kähler–Einstein metric.

3. The Hitchin–Kobayashi correspondence and its manifold analogue

For a holomorphic vector bundle E over an n-dimensional compact Kähler manifold (M, ω) we say that E is *Takemoto–Mumford stable* if

$$\frac{\int_M c_1(\mathcal{S})\omega^{n-1}}{\mathrm{rk}(\mathcal{S})} < \frac{\int_M c_1(E)\omega^{n-1}}{\mathrm{rk}(E)}$$

for every coherent subsheaf $\mathcal{S}$ of $\mathcal{O}(E)$ satisfying $0 < \mathrm{rk}(\mathcal{S}) < \mathrm{rk}(E)$. Recall the following Hitchin–Kobayashi correspondence for vector bundles:

Fact 2. *An indecomposable holomorphic vector bundle E over M is Takemoto–Mumford stable if and only if E admits a Hermitian-Einstein metric.*

This fact was established in 1980s by Donaldson [13], Kobayashi [22], Lübke [25], Uhlenbeck and Yau [47]. As a manifold analogue of this conjecture we can naturally ask whether the following conjecture (known as Yau's conjecture) is true:

Conjecture. The polarization class of (M, L) admits a Kähler metric of constant scalar curvature (or more generally an extremal Kähler metric) if and only if (M, L) is asymptotically stable in a certain sense of GIT.

For the "only if" part of this conjecture, the first breakthrough was made by Tian [45]. By introducing the concept of K-stability, he gave an answer to the "only if" part for Kähler–Einstein manifolds, and showed that some Fano manifolds without nontrivial holomorphic vector fields admit no Kähler–Einstein metrics. A remarkable progress was made by Donaldson [14] who showed the Chow–Mumford stability for a polarized Kähler manifold (M, ω) of constant scalar curvature essentially when the connected linear algebraic part H of the group $\mathrm{Aut}(M)$ of holomorphic automorphisms of M is semisimple. In the present paper we shall show how Donaldson's work is generalized to extremal Kähler cases without any assumption on H (see also [31], [32]). The relationship between this generalization and a recent result by Chen and Tian [12] will be treated elsewhere.

4. The asymptotic Bergman kernel

For a polarized manifold (M, L) take a Hermitian metric h for L such that $\omega := c_1(L; h)$ is a Kähler form. Define a Hermitian pairing on $V_m := H^0(M, \mathcal{O}(L^m))$ by

$$\langle \sigma_1, \sigma_2 \rangle_{L^2} := \int_M (\sigma_1, \sigma_2)_h \, \omega^n, \quad \sigma_1, \sigma_2 \in V_m,$$

where $(\ ,\ )_h$ denotes the pointwise Hermitian pairing by h^m for sections for L^m. For an orthonormal basis $\{\sigma_1, \sigma_2, \ldots, \sigma_{N_m}\}$ of V_m we put

$$B_{m,\omega} := \frac{n!}{m^n}(|\sigma_1|_h^2 + |\sigma_2|_h^2 + \cdots + |\sigma_{N_m}|_h^2), \tag{1}$$

where $|\sigma|_h^2 := (\sigma, \sigma)_h$ for $\sigma \in V_m$. This $B_{m,\omega}$ is called the m-th *Bergman kernel* for (M, ω) (cf. Tian [43], Zelditch [50], Catlin [4]), where we consider the asymptotic behavior of $B_{m,\omega}$ as $m \to \infty$. Note that $B_{m,\omega}$ depends only on (m, ω) and is independent of the choice of both h and the orthonormal basis for V_m. Next, for

$$D := \{\ell \in L^* ;\ |\ell|_h < 1\}$$

the boundary $X := \partial D = \{\ell \in L^*; |\ell|_h = 1\}$ over M is an S^1-bundle. Let $\mathrm{pr}\colon X \to M$ be the natural projection. We now consider the Szegö kernel

$$S_\omega := S_\omega(x, y)$$

for the projection of $L^2(X)$ onto the Hardy space $L^2(X) \cap \Gamma(D, \mathcal{O})$ of boundary values of holomorphic functions on D. Then for each positive integer m the corresponding

m-th Bergman kernel $B_{m,\omega}$ for the Kähler manifold (M, ω) is characterized as the Fourier coefficient

$$\mathrm{pr}^* B_{m,\omega} := \frac{n!}{m^n} \int_{S^1} e^{-im\theta} S_\omega(e^{i\theta}x, x)\, d\theta.$$

Now the Bergman kernel is defined not only for positive integers m but also for complex numbers ξ as follows. To see the situation, we first consider the case where M is a single point. Then in place of $S_\omega(e^{i\theta}x, x)$ consider a smooth function $S = S(\theta)$ on $S^1 := \mathbb{R}/2\pi\mathbb{Z}$ for simplicity. The associated Fourier coefficient B_m is

$$B_m = \int_{S^1} e^{-im\theta} S(\theta)\, d\theta$$

for each integer $m \neq 0$. Then for open intervals $I_1 := (-3\pi/4, 3\pi/4)$ and $I_2 = (\pi/4, 7\pi/4)$ in $\mathbb{R}$ we choose the open cover

$$S^1 = U_1 \cup U_2$$

where $U_1 := I_1 \bmod 2\pi$ and $U_2 := I_2 \bmod 2\pi$. By choosing a partition of unity subordinate to this open cover we write

$$\rho_1(\theta) + \rho_2(\theta) = 1, \quad \theta \in S^1,$$

where $\rho_\alpha \in C^\infty(S^1)_\mathbb{R}$, $\alpha = 1, 2$, are functions ≥ 0 satisfying $\mathrm{Supp}(\rho_\alpha) \subset U_\alpha$. For the coordinate $\tilde{\theta}$ for $\mathbb{R}$, writing $\tilde{\theta} \bmod 2\pi$ as θ, define $\tilde{\rho}_\alpha \in C^\infty(\mathbb{R})_\mathbb{R}$, $\alpha = 1, 2$, by

$$\tilde{\rho}_\alpha(\tilde{\theta}) = \begin{cases} \rho_\alpha(\theta), & \tilde{\theta} \in I_\alpha \\ 0, & \tilde{\theta} \notin I_\alpha. \end{cases}$$

Then the Fourier transform $\mathcal{F}(S) = \mathcal{F}(S)(\xi)$ of S is an entire function in $\xi \in \mathbb{C}$ defined as the integral

$$\mathcal{F}(S)(\xi) = \int_\mathbb{R} e^{-i\xi\theta}\{\rho_1(\tilde{\theta}) + \rho_2(\tilde{\theta})\}S(\tilde{\theta})\, d\tilde{\theta}, \quad \xi \in \mathbb{C},$$

satisfying $\mathcal{F}(S)(m) = B_m$ for all integers m. Though $\mathcal{F}(S)$ may depend on the choice of the partition of unity, its restriction to $\mathbb{Z}$ is unique. This situation is easily understood for instance by the fact the functions $\mathcal{F}(S)(\xi)$ and $\mathcal{F}(S)(\xi) + \sin(\pi\xi)$ in ξ coincide on $\mathbb{Z}$.

Now the above process of generalization from the Fourier series to the Fourier transform is valid also for the case where the base space M is nontrivial. Actually, we define an entire function $B_{\xi,\omega}$ in $\xi \in \mathbb{C}$ by

$$\mathrm{pr}^* B_{\xi,\omega} := \frac{n!}{\xi^n} \int_\mathbb{R} e^{-i\xi\tilde{\theta}}\{\rho_1(\tilde{\theta}) + \rho_2(\tilde{\theta})\}S_\omega(e^{i\tilde{\theta}}x, x)\, d\tilde{\theta}.$$

By setting $q := \xi^{-1}$ we study the asymptotic behavior of $B_{\xi,\omega}$ as $q \to 0$ along the positive real line $\{q > 0\}$. Let σ_ω denote the scalar curvature of the Kähler manifold (M, ω). Then as in discrete cases by Tian [43], Zelditch [50], Catlin [4], the asymptotic expansion of $B_{\xi,\omega}$ in q yields

$$B_{\xi,\omega} = 1 + a_1(\omega)q + a_2(\omega)q^2 + \cdots, \quad 0 \le q \ll 1, \tag{2}$$

where $a_1(\omega) = \sigma_\omega/2$ by a result of Lu [24]. For more details of the expansion in discrete cases see also Hirachi [21].

5. Balanced metrics

Choose a Hermitian metric h for L such that $\omega := c_1(L; h)$ is a Kähler form. Then ω is called an m-th *balanced metric* (cf. [51], [26]) for (M, L) if $B_{m,\omega}$ is a constant function $(= C_m)$ on M. First put $q := 1/m$. By integrating (1) and (2) on the Kähler manifold (M, ω) we see that C_m is written as

$$C_m := \frac{n!}{m^n c_1(L)^n[M]} N_m = 1 + \frac{n}{2}\frac{c_1(M)c_1(L)^{n-1}[M]}{c_1(L)^n[M]} q + O(q^2), \quad 0 \le q \ll 1,$$

where the left-hand side is the Hilbert polynomial $P(m)$ for (M, L) divided by $m^n c_1(L)^n[M]/n!$. Hence it is easy to define C_ξ by setting

$$C_\xi = \frac{n!P(\xi)}{\xi^n c_1(L)^n[M]}, \quad \xi \in \mathbb{C}^*. \tag{3}$$

Now put $q := 1/\xi$. Define the modified Bergman kernel $\beta_{q,\omega}$ by

$$\beta_{q,\omega} := 2\xi\left(1 + \frac{2q}{3}\Delta_\omega\right)(B_{\xi,\omega} - C_\xi) = \sigma_\omega - \bar{\sigma}_\omega + O(q), \tag{4}$$

where the average $\bar{\sigma}_\omega$ of the scalar curvature σ_ω is $nc_1(M)c_1(L)^{n-1}[M]/c_1(L)^n[M]$ independent of the choice of ω in $c_1(L)_{\mathbb{R}}$. Then, for $\xi = m$, ω is an m-th balanced metric for (M, L) if and only if $\beta_{q,\omega}$ vanishes everywhere on M. Recall the following result by Zhang [51] (cf. [26]; see also [30]):

Fact 3. *(M, L^m) is Chow–Mumford stable if and only if (M, L) admits an m-th balanced metric.*

Consider the maximal connected linear algebraic subgroup H of $\mathrm{Aut}(M)$, so that the identity component of $\mathrm{Aut}(M)/H$ is an Abelian variety. Let us now choose an algebraic torus $T \cong (\mathbb{C}^*)^r$ in the connected component $Z^{\mathbb{C}}$ of the center of the reductive part $R(H)$ for H in the Chevalley decomposition

$$H = R(H) \ltimes H_u,$$

where H_u is the unipotent radical of H. Replacing L by its suitable positive multiple, we may assume that the H-action on M is lifted to a bundle action on L covering the H-action on M. For each character $\chi \in \mathrm{Hom}(T, \mathbb{C}^*)$ we set

$$W\chi := \{\sigma \in V_m\,;\ \sigma \cdot g = \chi(g)\sigma \text{ for all } g \in T\},$$

where $V_m \times T \ni (\sigma, g) \mapsto \sigma \cdot g$ is the right T-action on $V_m = H^0(M, \mathcal{O}(L^m))$ induced by the left H-action on L. Now we have characters $\chi_k \in \mathrm{Hom}(T, \mathbb{C}^*)$, $k = 1, 2, \ldots, r_m$, such that the vector space V_m is expressible as a direct sum

$$V_m = \bigoplus_{k=1}^{r_m} W\chi_k.$$

For the maximal compact torus T_c in T we may assume that both h and ω are T_c-invariant. Put $\mathbb{J}_m := \{1, 2, \ldots, N_m\}$, where $N_m := \dim V_m$. Choose an orthonormal basis $\{\sigma_1, \sigma_2, \ldots, \sigma_{N_m}\}$ for V_m such that all σ_j, $j \in \mathbb{J}_m$, belong to the union $\bigcup_{k=1}^{r_m} W\chi_k$. Hence there exists a map $\kappa : \mathbb{J}_m \to \{1, 2, \ldots, r_m\}$ satisfying

$$\sigma_j \in W\chi_{\kappa(j)}, \quad j \in \mathbb{J}_m.$$

Put $\mathfrak{t}_{\mathbb{R}} := i\mathfrak{t}_c$ for the Lie algebra $\mathfrak{t}_c$ of T_c where $i := \sqrt{-1}$. For each $\mathcal{Y} \in \mathfrak{t}_{\mathbb{R}}$, by setting $g := \exp(\mathcal{Y}/2)$, we put $h_g := h \cdot g$ for the natural T-action on the space of Hermitian metrics on L. Define the m-th weighted Bergman kernel $B_{m,\omega,\mathcal{Y}}$, twisted by $\mathcal{Y}$, for (M, ω) by setting

$$B_{m,\omega,\mathcal{Y}} := \frac{n!}{m^n} \sum_{j=1}^{N_m} |\sigma_j|^2_{h_g} = g^* \left\{ \frac{n!}{m^n} \sum_{j=1}^{N_m} \frac{|\sigma_j|^2_h}{|\chi_{\kappa(j)}(g)|^2} \right\}.$$

Then ω is called an *m-th T-balanced metric* on (M, L) if $B_{m,\omega,\mathcal{Y}}$ is a constant function $(= C_{m,\mathcal{Y}})$ on M for some $\mathcal{Y} \in \mathfrak{t}$. Consider the natural action of the group

$$G_m := \bigoplus_{k=1}^{r_m} \mathrm{SL}_{\mathbb{C}}(W\chi_k)$$

acting on $V_m = \bigoplus_{k=1}^{r_m} W\chi_k$ diagonally (factor by factor). We say that (M, L^m) is *Chow–Mumford T-stable* if the orbit $G_m \cdot M_m$ is closed in W_m^*. Note that (cf. [30])

Fact 4. *If M admits an m-th T-balanced metric on (M, L), then (M, L^m) is Chow–Mumford T-stable.*

We shall now extend $\{B_{m,\omega,\mathcal{Y}}\,;\ m = 1, 2, \ldots\}$ to $\{B_{\xi,\omega,\mathcal{Y}}\,;\ \xi \in \mathbb{C}\}$ in such a way that $B_{m,\omega,\mathcal{Y}}$ coincides with $B_{\xi,\omega,\mathcal{Y}|\xi=m}$ for all positive integers m. By the definition of $B_{m,\omega,\mathcal{Y}}$ (see also [30], p. 578) the equality $B_{m,\omega,\mathcal{Y}} = B_{m,\omega}(h_g/h)^m$ always holds. Hence we put

$$B_{\xi,\omega,\mathcal{Y}} := B_{\xi,\omega} \cdot (h_g/h)^{\xi} = B_{\xi,\omega} \exp\{\xi \log(h_g/h)\}, \quad \xi \in \mathbb{C}. \tag{5}$$

Once $B_{\xi,\omega,\mathcal{Y}}$ is defined, we can also define $C_{\xi,\mathcal{Y}}$, $\xi \in \mathbb{C}$ in such a way that $C_{m,\mathcal{Y}}$ coincides with $C_{\xi,\mathcal{Y}_{|\xi=m}}$. Actually, we put

$$C_{\xi,\mathcal{Y}} := \int_M \frac{B_{\xi,\omega,\mathcal{Y}}}{c_1(L)^n[M]}\, g^*\omega^n. \tag{6}$$

6. A simple heuristic proof of Donaldson's theorem

In this section we shall show that a heuristic application of the implicit function theorem simplifies the proof of Donaldson's theorem [14]. Fix a Kähler metric ω_0 in $c_1(L)_{\mathbb{R}}$ of constant scalar curvature. Assume that the group H in the previous section is trivial. For each Kähler metric ω in $c_1(L)_{\mathbb{R}}$ we can associate a unique real-valued smooth function φ on M such that

$$\omega = \omega_0 + \sqrt{-1}\partial\bar{\partial}\varphi$$

with normalization condition $\int_M \varphi\, \omega_0^n = 0$. For an arbitrary nonnegative integer k and a real number α satisfying $0 < \alpha < 1$, we more generally consider the case where $\varphi \in C^{k+4,\alpha}(M)_{\mathbb{R}}$, so that ω is a $C^{k+2,\alpha}$ Kähler metric on M. The Fréchet derivative $D_\omega\sigma_\omega$ at $\omega = \omega_0$ of the scalar curvature function $\omega \mapsto \sigma_\omega$ is given by

$$\left\{(D_\omega\sigma_\omega)(\sqrt{-1}\partial\bar{\partial}\varphi)\right\}_{|\omega=\omega_0} = \lim_{\varepsilon\to 0} \frac{\sigma_{\omega_0+\sqrt{-1}\varepsilon\partial\bar{\partial}\varphi} - \sigma_{\omega_0}}{\varepsilon} = L_{\omega_0}\varphi,$$

where $L_{\omega_0}\colon C^{k+4,\alpha}(M)_{\mathbb{R}} \to C^{k,\alpha}(M)_{\mathbb{R}}$ is the Lichnerowicz operator for the Kähler metric ω_0 (cf. [23], [14]). Then by (4) the Fréchet derivative $D_\omega\beta_{q,\omega}$ of $\beta_{q,\omega}$ with respect to ω at $(q, \omega) = (0, \omega_0)$ is written as

$$\left\{(D_\omega\beta_{q,\omega})(\sqrt{-1}\,\partial\bar{\partial}\varphi)\right\}_{|(q,\omega)=(0,\omega_0)} = \left\{(D_\omega\sigma_\omega)(\sqrt{-1}\,\partial\bar{\partial}\varphi)\right\}_{|\omega=\omega_0} = L_{\omega_0}\varphi,$$

where L_{ω_0} is an invertible operator by the triviality of H. By setting $q := 1/\xi$, we move q in the half line $\mathbb{R}_{\geq 0} := \{0\} \cup \{1/\xi\,;\, \xi > 0\}$. Replacing q by q^2 if necessary, we apply the implicit function theorem to the map $(q, \omega) \mapsto \beta_{q,\omega}$. (The required regularity for this map is rather delicate: By using [3], Theorem 1.5 and §2.c, we can write both $B_{\xi,\omega}$ and its ω-derivatives as integrals similar to (18) in [50]. Then the estimate of the remainder term in the asymptotic expansion for $B_{m,\omega}$ in [50], Theorem 1, is valid also for the asymptotic expansion of $B_{\xi,\omega}$ and its ω-derivatives. However, for continuity of $\beta_{q,\omega}$ and its ω-derivative, more delicate estimates are necessary. Related to Nash–Moser's process, this will be treated elsewhere.) Then we have openness of the solutions for the one-parameter family of equations

$$\beta_{q,\omega} = 0, \quad q \geq 0, \tag{7}$$

i.e., there exists a one-parameter family of $C^{k+2,\alpha}$ solutions $\omega = \omega(q)$, $0 \leq q < \varepsilon$, for (7) with $\omega(0) = \omega_0$, where ε is sufficiently small. Hence by Fact 3 in Section 5, (M, L^m) is Chow–Mumford stable for all integers $m > 1/\varepsilon$. □

7. The case where M admits symmetries

In this section we consider a polarized manifold (M, L) with an extremal Kähler metric ω_0 in $c_1(L)_{\mathbb{R}}$. Then following Section 6, a result on stability in [32] will be discussed. Let $\mathcal{V}$ be the associated extremal Kähler vector field on M. Assume that H is possibly of positive dimension. Then the identity component K of the isometry group of (M, ω_0) is a maximal compact subgroup in H. Let $\mathfrak{z}$ be the Lie algebra of the identity component Z of the center of K.

Step 1. We assume that the algebraic torus T in Section 5 is the complexification $Z^{\mathbb{C}}$ of Z in H, so that the Lie algebra $\mathfrak{t}$ of T coincides with the Lie algebra $\mathfrak{z}^{\mathbb{C}}$ of $Z^{\mathbb{C}}$. Let $q \in \mathbb{R}_{\geq 0}$, where we set $q = 1/\xi$ for the part $0 < \xi \in \mathbb{R}$. Take an element $\mathcal{W}$ in the Lie algebra $\mathfrak{z}$. Let ω be a Kähler metric in the class $c_1(L)_{\mathbb{R}}$. Then by setting $\mathcal{Y} := iq^2(\mathcal{V} + \mathcal{W})$ for $i := \sqrt{-1}$, we can now consider the following modified weighted Bergman kernel

$$\beta_{q,\omega,\mathcal{W}} := 2\xi\left(1 + \frac{2q}{3}\Delta_\omega\right)(B_{\xi,\omega,\mathcal{Y}} - C_{\xi,\mathcal{Y}}), \quad \xi \in \mathbb{C}^*,$$

where we used (5) and (6) in defining $B_{\xi,\omega,\mathcal{Y}}$ and $C_{\xi,\mathcal{Y}}$. For the Kähler manifold (M, ω), consider the Hamiltonian function $\hat{\sigma}_\omega \in C^\infty(M)_{\mathbb{R}}$ for $\mathcal{V}$ characterized by

$$\mathcal{V} \lrcorner \omega = \bar{\partial}\hat{\sigma}_\omega \quad \text{and} \quad \int_M \sigma_\omega\, \omega^n = \int_M \hat{\sigma}_\omega\, \omega^n.$$

For each $\mathcal{Z} \in \mathfrak{z}$ the associated Hamiltonian function $f_{\mathcal{Z},\omega} \in C^\infty(M)_{\mathbb{R}}$ is uniquely characterized by the identities $\mathcal{Z} \lrcorner \omega = \bar{\partial} f_{\mathcal{Z},\omega}$ and $\int_M f_{\mathcal{Z},\omega}\, \omega^n = 0$. Note that $\mathcal{V} \in \mathfrak{z}$. Then also in this case, as in (4), we obtain

$$\beta_{q,\omega,\mathcal{W}} = \sigma_\omega - \hat{\sigma}_\omega - f_{\mathcal{W},\omega} + O(q). \tag{8}$$

Choose an arbitrary nonnegative integer ℓ with a real number $0 < \alpha < 1$. For the space $\mathcal{F}_\ell$ of all K-invariant functions $f \in C^{\ell,\alpha}(M)_{\mathbb{R}}$ satisfying $\int_M f\omega_0^n = 0$, by setting $\mathcal{N} := \operatorname{Ker} L_{\omega_0} \cap \mathcal{F}_\ell$, we have the identification

$$\theta : \mathfrak{z} \cong \mathcal{N}, \quad \mathcal{Z} \leftrightarrow \theta(\mathcal{Z}) := f_{\mathcal{Z},\omega_0},$$

where $\mathcal{N}$ is independent of the choice of ℓ. Then the vector space $\mathcal{F}_\ell$ is written as a direct sum $\mathcal{N} \oplus \mathcal{N}_\ell^\perp$, where $\mathcal{N}_\ell^\perp$ is the space of all functions f in $\mathcal{F}_\ell$ such that $\int_M f\nu\omega_0^n = 0$ for all $\nu \in \mathcal{N}$. For an arbitrary integer $k \geq 0$, we make a small perturbation of ω_0 by varying ω in the space $\{\omega_0 + \sqrt{-1}\,\partial\bar{\partial}\varphi\,;\ \varphi \in \mathcal{N}_{k+4}^\perp\}$. Since ω_0 is an extremal Kähler metric, we see from (8) that $\beta_{q,\omega,\mathcal{W}}$ vanishes at $(q, \omega, \mathcal{W}) = (0, \omega_0, 0)$, i.e.,

$$\beta_{0,\omega_0,0} = 0 \quad \text{on } M.$$

Again from (8) we see that the Fréchet derivatives $D_\omega \beta_{q,\omega,\mathcal{W}}$ and $D_{\mathcal{W}} \beta_{q,\omega,\mathcal{W}}$ of $\beta_{q,\omega,\mathcal{W}}$ at $(q, \omega, \mathcal{Y}) = (0, \omega_0, 0)$ are

$$\begin{cases} \{(D_\omega \beta_{q,\omega,\mathcal{W}})(\sqrt{-1}\,\partial\bar{\partial}\varphi)\}_{|(q,\omega,\mathcal{W})=(0,\omega_0,0)} = L_{\omega_0}\varphi, & \varphi \in \mathcal{N}_{k+4}^{\perp}, \\ (D_{\mathcal{W}} \beta_{q,\omega,\mathcal{W}})_{|(q,\omega,\mathcal{W})=(0,\omega_0,0)} = -\theta, & \text{on } \mathcal{N}. \end{cases}$$

Since $L_{\omega_0} : \mathcal{N}_{k+4}^{\perp} \to \mathcal{N}_k^{\perp}$ is invertible and since θ is an isomorphism, the implicit function theorem is now applicable to the map: $(q, \omega, \mathcal{W}) \mapsto \beta_{q,\omega,\mathcal{W}}$. Then for some $0 < \varepsilon \ll 1$ we can write

$$\omega = \omega(q) \quad \text{and} \quad \mathcal{W} = \mathcal{W}(q), \quad 0 \le q \le \varepsilon,$$

solving the one-parameter family of equations

$$\beta_{q,\omega,\mathcal{W}} = 0, \quad q \ge 0,$$

in $(\omega, \mathcal{W})$. Hence by setting $\mathcal{Y}(q) := iq^2(\mathcal{V} + \mathcal{W}(q))$ for $q = 1/m$, the m-th weighted Bergman kernel $B_{m,\omega(q),\mathcal{Y}(q)}$ is constant on M for all $m > 1/\varepsilon$. Then by Fact 4 in Section 5, (M, L^m) is Chow–Mumford T-stable for all $m > 1/\varepsilon$.

Step 2. Though we assumed that T coincides with $Z^{\mathbb{C}}$ in the first step, it is better to choose T as small as possible. Then for a sufficiently small positive real number ε, the algebraic torus T in $Z^{\mathbb{C}}$ generated by

$$\bigcup_{1/\varepsilon < m \in \mathbb{Z}} \{\mathcal{V} + \mathcal{W}(q), i\mathcal{V} + i\mathcal{W}(q)\}$$

is a good choice, where $q = 1/m$ and $i := \sqrt{-1}$.

8. Concluding remarks

For the conjecture in Section 3 the "if" part is known to be a difficult problem and it is of particular interest. Assuming that a polarized manifold (M, L) is asymptotically Chow–Mumford stable, we are asked whether there exist Kähler metrics of constant scalar curvature in $c_1(L)_{\mathbb{R}}$. For simplicity, we consider the case where H is trivial. Then by Fact 3 the equation

$$\beta_{q,\omega} = 0 \tag{9}$$

has solutions $(q, \omega) = (1/m, \omega_m)$, $m \gg 1$, while each ω_m is an m-th balanced metric for (M, L). Moreover, the triviality of H implies that ω_m is the only m-th balanced metric for (M, L). Then we are led to study the graph

$$\mathcal{E} := \{(q, \omega)\,;\ \beta_{q,\omega} = 0\}$$

in $\mathbb{C} \times \mathcal{K}$, where $\mathcal{K}$ is the space of all Kähler metrics in the class $c_1(L)_{\mathbb{R}}$. Let $\mathcal{H}$, $\mathcal{M}$ be the sets of all Hermitian metrics for L, V_m, respectively. Consider the Fréchet derivative $D_\omega \beta_{q,\omega}$ at $(q, \omega) = (1/m, \omega_m) \in \mathcal{E}$, where $m \gg 1$. With the same setting of differentiability as in Section 6, the Fréchet derivative will be shown to be invertible.

Let us give a rough idea how the invertibility can be proved. It suffices to show that the operator $D_\omega B_{m,\omega}$ is invertible at $\omega = \omega_m$. Choose a Hermitian metric h_m for L such that $c_1(L; h_m) = \omega_m$. Put $\Psi := \{\psi \in C^\infty(M)_{\mathbb{R}}\,;\, \int_M \psi \omega_m^n = 0\}$. Let $\varphi \in \Psi$. Then the $\mathbb{R}$-orbit in $\mathcal{H}$ through h_m written in the form

$$h_{\varphi;t} := e^{-t\varphi} h_m, \quad t \in \mathbb{R}, \tag{10}$$

projects to the $\mathbb{R}$-orbit $\omega_{\varphi,t} := \omega_m + \sqrt{-1}\, t\, \partial\bar{\partial}\varphi$, $t \in \mathbb{R}$, in $\mathcal{K}$ through ω_m. Note also that every Hermitian metric h for L induces a Hermitian pairing $\langle\ ,\ \rangle_{L^2}$ which will be denoted by $(V_m, \tilde{h})$ (cf. Section 4). Choose an orthonormal basis $\{\sigma_1, \sigma_2, \ldots, \sigma_{N_m}\}$ for $(V_m, \tilde{h}_m)$. Let Φ be the space of all $\varphi \in \Psi$ such that

$$(d/dt)(\tilde{h}_{\varphi,t})_{|t=0} = 0 \quad \text{on } V_m.$$

In other words, if $\varphi \in \Phi$ then the basis $\{\sigma_1, \sigma_2, \ldots, \sigma_{N_m}\}$ infinitesimally remains to be an orthonormal basis for $(V_m, \tilde{h}_{\varphi,t})$ at $t = 0$ with t perturbed a little. Since

$$B_{m,\omega} := |\sigma_1|_h^2 + |\sigma_2|_h^2 + \cdots + |\sigma_{N_m}|_h^2$$

is obtained from the contraction of $\Sigma := \sigma_1\bar{\sigma}_1 + \sigma_2\bar{\sigma}_2 + \cdots + \sigma_{N_m}\bar{\sigma}_{N_m}$ by h^m, and since Σ is fixed by the infinitesimal action $(d/dt)(h_{\varphi,t})$ at $t = 0$ in (10), we obtain

$$(d/dt)(B_{m,\omega_{\varphi,t}})_{|t=0} = (d/dt)(h^m_{\varphi,t})_{|t=0} = -m\varphi. \tag{11}$$

Let $\mathbb{H}$ denote the set of all Hermitian metrics on the vector space V_m. Then we have a natural projection $\pi : \Psi \to T_{\tilde{h}_m}\mathbb{H}$ defined by

$$(d/dt)(h_{\varphi,t})_{|t=0} \mapsto (d/dt)(\tilde{h}_{\varphi,t})_{|t=0}.$$

In view of $\dim \mathbb{H} < +\infty$, it is now easy to see that this map is surjective. Since the kernel of this map is Φ, we obtain

$$\Psi/\Phi \cong T_{\tilde{h}_m}\mathbb{H}. \tag{12}$$

Finally by (11) and (12), the uniqueness of the m-th balanced metric (by $H = \{1\}$) implies the required invertibility of the Fréchet derivative (see also Donaldson [16]). □

Now we can apply the implicit function theorem to obtain an open neighborhood U of $1/m$ in $\mathbb{C}$ such that, for each $\xi \in U$, there exists a unique Kähler metric $\omega(\xi)$ in $c_1(L)_{\mathbb{R}}$ satisfying $\beta_{\xi,\omega(\xi)} = 0$.

Assuming non-existence of Kähler metrics of constant scalar curvature, we have some possibility that, by an argument as in Nadel, destabilizing objects are obtained by studying the behavior of the solutions along the boundary point of $\mathcal{E}$.

Finally, there are many interesting topics, which are related to ours, such as the geometry of Kähler potentials [10], [9], [38], [40] (see also [28]). The uniqueness of extremal Kähler metrics modulo the action of holomorphic automorphisms in compact cases is recently given in [12] (cf. [2], [14]). New obstructions to semistability of manifolds or to the existence of extremal metrics are done by [19], [29], [12]. The concept of K-stability, introduced by Tian [45] and reformulated by Donaldson [15], is deeply related to the Hilbert–Mumford stability criterion, and various kinds of works are actively done related to algebraic geometry.

Tropical geometry and its applications

Grigory Mikhalkin*

Abstract. From a formal perspective tropical geometry can be viewed as a branch of geometry manipulating with certain piecewise-linear objects that take over the rôle of classical algebraic varieties. This talk outlines some basic notions of this area and surveys some of its applications for the problems in classical (real and complex) geometry.

Mathematics Subject Classification (2000). 14A99, 14H50, 14N10, 52B20.

Keywords. Tropical geometry, amoebas, patchworking, enumerative geometry.

1. Introduction

From a geometric point of view tropical geometry describes worst possible degenerations of the complex structure on an n-fold X. Such degenerations cause X to collapse onto an n-dimensional (over $\mathbb{R}$, i.e. $\left(\frac{\dim X}{2}\right)$-dimensional) base B which is a piecewise-linear polyhedral complex, see e.g. [13] for a conjectural picture in the special case of Calabi–Yau n-folds.

According to an idea of Kontsevich such degenerations can be useful, in particular, for computations of the Gromov–Witten invariants of X as holomorphic curves degenerate to graphs $\Gamma \subset B$. A similar picture appeared in the work of Fukaya (see e.g. [5]) where graphs come as degenerations of holomorphic membranes.

Tropical geometry formalizes the base B as an ambient variety so that the graphs Γ become curves in B. Some problems in complex and real geometry then may be reduced to problems of tropical geometry which are often much easier to solve, thanks to the piecewise-linear nature of the subject. Local considerations in tropical geometry correspond to some standard models in classical geometry while the combinatorial tropical structure encodes the way to glue these models together. In this sense it may be viewed as an extension of the Viro patchworking [32].

This talk takes a geometric point of view on tropical geometry and surveys its basic notions as well as some of its applications to classical algebro-geometrical problems. The author is indebted to Ya. Eliashberg, M. Kontsevich, A. Losev, B. Sturmfels and O. Viro for many useful conversations on tropical geometry.

of Mathematicians, Madrid, Spain, 2006

2. Tropical algebra

2.1. Tropical vs. classical arithmetics. The term *tropical semirings* was reputedly invented by a group of French computer scientists to commemorate their Brazilian colleague Imre Simon. For our purposes we use just one of these semirings, the tropical semifield $\mathbb{T} = \mathbb{R} \cup \{-\infty\}$ equipped with the operations of addition and multiplication defined by

$$\text{“}a + b\text{”} = \max\{a, b\}, \quad \text{“}ab\text{”} = a + b.$$

We use the quotation marks to distinguish the tropical operations from the classical addition and multiplication on $\mathbb{R}\cup\{-\infty\}$. It is easy to check that the tropical operations are commutative, associative and satisfy the distribution law.

There is no tropical subtraction as the operation “ $+$ ” is idempotent, but we have the tropical division $\text{“}\frac{a}{b}\text{”} = a - b$, $b \neq -\infty$. This makes $\mathbb{T}$ an idempotent semifield. Its additive zero is $0_{\mathbb{T}} = -\infty$, its multiplicative unit is $1_{\mathbb{T}} = 0$.

Remark 2.1. A classical example of a semifield is the semifield $\mathbb{R}_{\geq 0}$ of nonnegative numbers with classical addition and multiplication. We have the map $\log_t : \mathbb{R}_{\geq 0} \to \mathbb{T}$ between semifields $\mathbb{R}_{\geq 0}$ for any $t > 1$. The larger t, the closer is the map $\log_t$ to a homomorphism. More specifically, $\log_t$ is an isomorphism up to the error of $\log_t(2)$ while $\lim_{t\to+\infty} \log_t 2 = 0$. Indeed, we have $\log_t(ab) = \text{“}\log_t(a)\log_t(b)\text{”}$ and

$$\text{“}\log_t(a) + \log_t(b)\text{”} \leq \log_t(a + b) \leq \text{“}\log_t(a) + \log_t(b)\text{”} + \log_t 2$$

by elementary considerations. Thus $\mathbb{T}$ can be considered as the $t \to +\infty$ limit semifield of a family of (mutually isomorphic) semifields $\mathbb{R} \cup \{-\infty\}$ equipped with arithmetic operations induced from $\mathbb{R}_{\geq 0}$ by $\log_t$. In this sense $\mathbb{T}$ is considered to be the result of *dequantization* of classical arithmetics by Maslov et al., see e.g. [15] or [33] for a geometric version of this dequantization.

Remark 2.2. The semifield $\mathbb{T}$ is closely related to non-Archimedean fields K with (real) valuations $\mathrm{val} : K \to \mathbb{T}$. Indeed, val is a valuation if for any $z, w \in K$ we have $\mathrm{val}(z + w) \leq \text{“}\mathrm{val}(z) + \mathrm{val}(w)\text{”}$, $\mathrm{val}(zw) = \text{“}\mathrm{val}(z)\,\mathrm{val}(w)\text{”}$ and $\mathrm{val}^{-1}(-\infty) = 0$. In this sense val is a sub-homomorphism. This non-Archimedean point of view on tropical geometry is taken e.g. in [4], [25], [29] and [30].

2.2. Polynomials, regular and rational functions. There is no subtraction in the semifield $\mathbb{T}$, but we do not need it to form polynomials. A tropical polynomial is a tropical sum of monomials. For a polynomial f in n variables we get $f : \mathbb{T}^n \to \mathbb{R}$,

$$f(x) = \text{“}\sum_j a_j x^j\text{”} = \max(a_j + \langle j, x\rangle), \tag{1}$$

where $x = (x_1, \ldots, x_n) \in \mathbb{T}^n$, $j = (j_1, \ldots, j_n) \in \mathbb{Z}^n$, $x^j = x_1^{j_1} \ldots x_n^{j_n}$, $\langle j, x\rangle = j_1x_1 \ldots j_nx_n$ and $a_j \in \mathbb{T}$.

Remark 2.3. Not all monomials in f are essential. It may happen that for some element j' we have $a_{j'} + \langle j', x\rangle \le a_j + \langle j, x\rangle$ for any $j \ne j'$. Then for any $b_{j'} \le a_j$ we have "$\sum_j a_j x^j$" = "$b_{j'} + \sum_{j\ne j'} a_j x^j$" = "$\sum_{j\ne j'} a_j x^j$". Thus the presentation of a function f as a tropical polynomial is not, in general, unique. Nevertheless, it is very close to being unique.

Note that (1) defines the Legendre transform of a (partially-defined) function on $\mathbb{R}^n$, $-a\colon j \mapsto -a_j$. The function $-a$ is defined only on a finite set, namely the set J which consists of the powers of the monomials in f. We can use involutivity of the Legendre transform to recover the coefficients a_j from the function f. Take the Legendre transform L_f of f and set $\bar a_j = -L_f(j)$, $j \in \mathbb{Z}^n$. It is easy to see that if f were a tropical polynomial then $a_j = -\infty = 0_{\mathbb{T}}$ for all but finitely many $j \in \mathbb{Z}^n$. Furthermore, if the function $-a$ is convex (i.e. if it is a restriction of a convex function on $\mathbb{R}^n$) then $\bar a_j = a_j$. Thus every function $f\colon \mathbb{T}^n \to \mathbb{T}$ obtained from a tropical polynomial has a "maximal" presentation as a tropical polynomial (clearly, $\bar a_j \ge a_j$).

Once we have polynomials we may form rational functions as the tropical quotients, i.e. the differences of two polynomials. The tropical quotient of two monomials is called a $\mathbb{Z}$-*affine* function. Clearly a $\mathbb{Z}$-affine function is an affine-linear function $\mathbb{R}^n \to \mathbb{R}$ with an integer slope.

A rational function $h = "\frac{f}{g}"$ is defined for every $x \in \mathbb{T}^n$ such that $g(x) \ne -\infty$. At such x h is called *finite* (more precisely, h is called finite at $x \in \mathbb{T}^n$ if it *can be presented* as "$\frac{f}{g}$" with $g(x) \ne -\infty$). A rational function h is called *regular* at $x \in \mathbb{T}^n$ if it is finite at x and there exist a $\mathbb{Z}$-affine function ϕ finite at x, an open neighborhood $U \ni x$ and a tropical polynomial $p\colon \mathbb{T}^n \to \mathbb{T}$ such that $h(y) = p(y) + \phi(y)$ for all $y \in U$. (Here we consider the Euclidean topology on $\mathbb{T}^n = [-\infty, +\infty)^n$.)

All functions $U \to \mathbb{T}$ that are restrictions of rational functions on $\mathbb{T}^n$ that are regular at every point of U form a semiring $\mathcal{O}(U)$. Constant functions give a natural embedding $\mathbb{T} \subset \mathcal{O}(U)$ and thus $\mathcal{O}(U)$ is a *tropical algebra*. In this way we get a sheaf $\mathcal{O}$ of tropical algebras on $\mathbb{T}^n$ called *the structure sheaf*.

3. Geometry: tropical varieties

3.1. Hypersurfaces. To every tropical polynomial f one may associate its hypersurface $V_f \subset \mathbb{T}^n$ that, by definition, consists of all points x where "$\frac{1_{\mathbb{T}}}{f}$" is not regular. This is a piecewise-linear object in $\mathbb{T}^n$.

Example 3.1. Figures 1 and 2 depict some hypersurfaces in $\mathbb{T}^2$ (i.e. planar curves).

The left-hand side of Figure 1 is given by the polynomial "$1 + 0x + 0y$". It is a line in the tropical plane $\mathbb{T}^2$. The right-hand side of Figure 1 is given by the polynomial "$10 + 5.5x + 0x^2 + 8.5y + 6.5y^2 + 4.5xy$", it is a conic. The line and the conic here intersect at two distinct points.

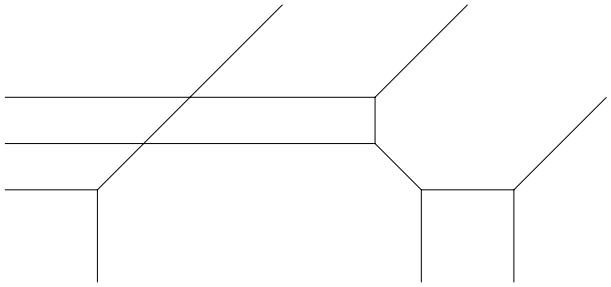

Figure 1. Tropical line and conic.

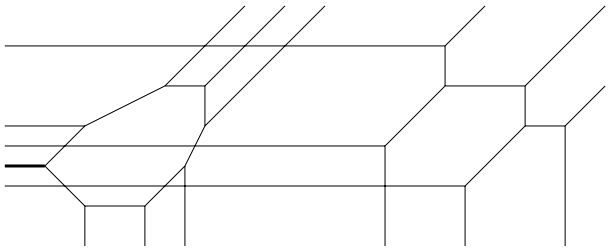

Figure 2. Two tropical cubic curves.

The left-hand side of Figure 2 is given by the polynomial

$$\text{“}5 + 4x + 2.25x^2 + 0x^3 + 4y + 2.5xy + 1x^2y + 3y^2 + 1.5xy^2 + 1.5y^3\text{”}. \quad (2)$$

The right-hand side is given by the polynomial

$$\text{“}17.5 + 12.25x + 7x^2 + 0x^3 + 16.75y + 12xy + 5.5x^2y + 15.5y^2 + 10xy^2 + 13y^3\text{”}.$$

It is easy to see that a tropical hypersurface V_f is a union of convex $(n-1)$-dimensional polyhedra called the facets of V_f. Each facet has *integer slope*, i.e. is parallel to a hyperplane in $\mathbb{R}^n$ defined over $\mathbb{Z}$. For every facet P there exist two monomials $a_{j_1}x^{j_1}$ and $a_{j_2}x^{j_2}$ of f that are equal along P and such that they are greater than any other monomial of f in the (relative) interior of P. The greatest common divisor of the components of the vector $j_2 - j_1$ is called *the weight* of P. E.g. the horizontal edge in Figure 2 adjacent to the leftmost vertex has weight 2 while all other edges have weight 1.

The intersection of any pair of facets is the face of both facets. Furthermore, at every $(n-2)$-dimensional face Q we have the following *balancing property*.

Property 3.2. *Let $P_1, \dots, P_l$ be the facets adjacent to Q and let v_j be the integer covectors whose kernels are parallel to P_j and whose gcd is equal to the weight of P_j.*

In addition we require that the orientation of $v_1, \dots, v_l$ is consistent with a choice of direction around Q. Then we have

$$\sum_{j=1}^{l} v_j = 0.$$

3.2. Integer polyhedral complexes. This balancing property may also be generalized to some piecewise-linear polyhedral complexes X of arbitrary codimension in $\mathbb{T}^n$. A *integer convex polyhedron* in $\mathbb{T}^n$ is the set defined by a finite number of inequalities of the type

$$\langle j, x\rangle \le c,$$

where $x \in \mathbb{T}^n$, $j \in \mathbb{Z}^n$ and $c \in \mathbb{R}$. Here the expression $\langle j, x\rangle$ stands for the scalar product. It may happen that $\langle j, x\rangle$ is an indeterminacy (for some $x \in \mathbb{T} \setminus \mathbb{T}^\times$), we include such x into the polygon. Equivalently, an integer convex polyhedron in $\mathbb{T}^n$ is the closure of a convex polyhedron (bounded or unbounded) in $\mathbb{R}^n$ such that the slopes of all its faces (including the polyhedron itself) are integers. The dimension of an integer convex polyhedron is its topological dimension.

An integer piecewise-linear polyhedral complex X of dimension k in $\mathbb{T}^n$ is the union of a finite collection of integer convex polyhedra of dimension k called *the facets of X* such that the intersection $\bigcap_{j=1}^{l} P_j$ of any finite number of facets is the common face of P_j. We may equip the facets of X with natural numbers called the weights.

The complex X is called balanced if the following property holds.

Property 3.3. *Let Q be a face of dimension $k-1$ and $P_1, \dots, P_l$ be the facets adjacent to Q. The affine-linear space containing Q defines a linear projection $\lambda\colon \mathbb{R}^n \to \mathbb{R}^{n-k+1}$. The image $q = \lambda(Q)$ is a point while the images of $p_j = \lambda(P_j)$ are intervals in $\mathbb{R}^{n-k+1}$ adjacent to q. Let $v_j \in \mathbb{Z}^n$ be the primitive integer vector parallel to p_j in the direction outgoing from q multiplied by the weight of P_j. We have*

$$\sum_{j=1}^{l} v_j = 0.$$

It is easy to see that if $k = n-1$ then Properties 3.2 and 3.3 are equivalent.

3.3. Contractions. Let $f\colon \mathbb{T}^n \to \mathbb{T}$ be a polynomial. We define its *full graph*

$$\Gamma_f \subset \mathbb{T}^n \times \mathbb{T}$$

to be the hypersurface defined by "$y + f(x)$". Note that Γ_f can be obtained from the set-theoretical graph of f by attaching the intervals $[(x, -\infty), (x, f(x))]$ for all x from the hypersurface V_f (i.e. those x where "$\frac{0}{f}$" is not regular), cf. Figure 3 for the full graphs of "$x + 0$" and "$x^2 + x + 1$".

Thus, unlike the classical situation, the full graph of a map is different from the domain of the map. We define the *principal contraction*

$$\delta_f : \Gamma_f \to \mathbb{T}^n \tag{3}$$

associated to f to be the projection onto $\mathbb{T}^n$.

To get a general contraction one iterates this procedure. Suppose that a contraction $\gamma : V \to \mathbb{T}^n$ is already defined. We have $V \subset \mathbb{T}^N$.

If $g : V \to \mathbb{T}$ is a regular function (in N variables) then we can define the full graph $\Gamma_g \subset V \times \mathbb{T}$ as the union of the set-theoretical graph of g with all intervals $[(x, -\infty), (x, g(x))]$ such that "$\frac{0}{g}$" is not regular at x (i.e. at a neighborhood of x in V). The map $\delta_g : \Gamma_g \to V$ is the projection onto V.

The map δ_g is called a principal contraction to V. A general contraction is a composition of principal contractions.

Furthermore, one may associate *the weights* to the new facets of Γ_g by setting them equal to the *orders* of the pole of "$\frac{0}{g}$". Here we say that the order of a pole of a rational function is at least n at x if it can be locally presented as a tropical product of n rational functions that are not regular at x. Then we define the order of the pole to be the largest n with this property.

Definition 3.4. The *order of zero* of g at x is the order of the pole of "$\frac{0}{g}$" at x.

This definition is consistent with the definition of tropical hypersurfaces.

The facets of Γ_g contained in the set-theoretical graph of g inherit their weights from the weights of the corresponding facets of V.

Remark 3.5. Contractions may be used to define counterparts of Zariski open sets in tropical geometry. We define the complements of tautological embeddings $\mathbb{T}^k \to \mathbb{T}^n$, $k \leq n$, to be Zariski open.

To define the principal open set corresponding to a polynomial f we consider the contraction $\delta_f : \Gamma_f \to \mathbb{T}^n$ and take

$$D_f = \Gamma_f \cap (\mathbb{T}^n \times \mathbb{T}^\times).$$

This together with the map $\delta_f|_{D_f}$ is the principal open set associated to f.

Example 3.6. The principal open set associated to "$x + a$" $D_{"x+a"} \to \mathbb{T}$ of "$x + a$", $a \in \mathbb{T}^\times$, can be interpreted as the result of puncturing $\mathbb{T}$ at a finite point $a \subset \mathbb{T}$. Figure 3 depicts $D_{"x+0"}$ and $D_{"x^2+x+1"}$. The corresponding maps are projections onto the x-axis.

Proposition 3.7. *If $\delta : \mathbb{T}^N \supset V \to \mathbb{T}^n$ is a contraction then $V \subset \mathbb{T}^N$ satisfies Property* 3.3.

Remark 3.8. In fact Proposition 3.7 can be used to define the weights of the facets of V and thus the orders of the zeroes of polynomials on V.

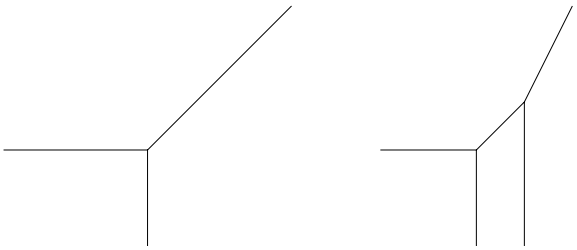

Figure 3. Once and twice punctured affine lines $\mathbb{T}$.

3.4. Tropical varieties and tropical morphisms. A map $\mathbb{R}^N \to \mathbb{R}^M$ is called *integer affine-linear* if it is a composition of a linear map defined over $\mathbb{Z}$ and a translation by an arbitrary vector in $\mathbb{R}^M$. Such a map can be extended to a partially defined map $\mathbb{T}^N \to \mathbb{T}^M$ by taking the closure. Note that integer affine-linear maps leave the class of integer piecewise-linear polyhedral complexes invariant. Furthermore, such maps take facets to facets (at least for some presentation of the image as an integer piecewise-linear polyhedral complex) and respect Property 3.3.

Let X be a topological space together with an atlas $\{U_\alpha\}$, $\phi_\alpha \colon U_\alpha \to \mathbb{T}^n$, $U_\alpha \subset X$.

Definition 3.9. We say that X is a *tropical variety* of dimension n if the following conditions hold.

1. Each ϕ_α is a contraction to an open subset of $\mathbb{T}^n$. More precisely, there is a contraction $\delta_\alpha \colon V_\alpha \to \mathbb{T}^n$, $V_\alpha \subset \mathbb{T}^{N_\alpha}$ and an open embedding $\Phi_\alpha \colon U_\alpha \to V_\alpha$ such that $\phi_\alpha = \delta_\alpha \circ \Phi_\alpha$.
2. The overlapping maps $\Phi_\beta \circ \Phi_\alpha^{-1}$ are induced by the integer affine-linear maps $\mathbb{R}^{N_\alpha} \to \mathbb{R}^{N_\beta}$.
3. For every point $x \in X$ in the interior of a facet of X there exists a chart ϕ_α such that $x \in U_\alpha$ and ϕ_α embeds some neighborhood of x into $\mathbb{T}^n$.
4. There exist a finite covering of X by open sets $W_j \subset X$ such that for every j there exists α such that $W_j \subset U_\alpha$ and the closure of $\Phi_\alpha(W_j)$ in $\mathbb{T}^{N_\alpha}$ is contained in $\Phi_\alpha(U_\alpha)$.

The last condition ensures *completeness* of the tropical structure on X.

A function on a subset W of X is called regular at a point $x \in W$ if it is locally a pull-back of a regular function in a neighborhood of $\Phi_\alpha(x) \in \mathbb{T}^{N_\alpha}$. In this way we get the structure sheaf $\mathcal{O}_X$ of regular functions on X.

A point $x \in X$ is called *finite* if it is mapped to $\mathbb{R}^{N_\alpha} \subset \mathbb{T}^{N_\alpha}$. Note that finiteness does not depend on the choice of a chart. At finite points of x we have the notion of an *integer tangent* vector to X. This comes from tangent vectors to $\Phi_\alpha(U_\alpha)$ at $\Phi_\alpha(x) \in \mathbb{R}^{N_\alpha}$ after identification with the corresponding counterparts for different charts $U_\beta \ni z$ under the differential of the overlapping maps.

Example 3.10. The space $\mathbb{T}^n$ is a n-dimensional tropical variety tautologically. The *projective n-space* $\mathbb{TP}^n$ is defined as the quotient of $\mathbb{T}^{n+1} \setminus (-\infty, \dots, -\infty)$ by the equivalence relation $(x_0, \dots, x_n) \sim (\text{“}\lambda x_0\text{”}, \dots, \text{“}\lambda x_n\text{”}) = (\lambda + x_0, \dots, \lambda + x_n)$, where $\lambda \in \mathbb{T}^\times$.

The space $\mathbb{TP}^n$ is a tropical variety since it admits (as in the classical case) $n+1$ affine charts to $\mathbb{T}^n$ by dividing all coordinates by x_j as long as $x_j \neq -\infty$. This is an example of a compact tropical variety. There is a well-defined notion of a hypersurface of degree d in $\mathbb{TP}^n$. It is given by a homogeneous polynomial of degree d in $n+1$ variables. This polynomial can be translated to an ordinary polynomial in every affine chart of $\mathbb{TP}^n$.

In a similar way, one may construct tropicalizations of other toric varieties. The finite part of all tropical toric varieties is $(\mathbb{T}^\times)^n \approx \mathbb{R}^n$.

Proposition 3.11. *If X and Y are tropical varieties then $X \times Y$ has a natural structure of tropical variety of dimension* $\dim X + \dim Y$.

Definition 3.12. Let $f\colon X \to Y$ be a map between tropical varieties (not necessarily of the same dimension). We say that f is a *linear tropical morphism* if for every $x \in X$ there exist charts $U^X_\alpha \ni x$ and $U^Y_\beta \ni f(x)$ such that $\Phi^Y_\beta \circ f \circ (\Phi^X_\alpha)^{-1}$ is induced by an integer affine-linear map $\mathbb{R}^{N_\alpha} \to \mathbb{R}^{N_\beta}$.

The map f is called a *regular tropical morphism* if $\Phi^Y_\beta \circ f \circ (\Phi^X_\alpha)^{-1}$ is given by N_β rational functions on $\mathbb{T}^{N_\alpha}$ that are regular on $\Phi^X_\alpha(U^X_\alpha)$.

Clearly any linear morphism is a regular morphism. A regular morphism $f\colon X \to Y$ defines a map $\mathcal{O}_Y(U) \to \mathcal{O}_X(f^{-1}(U))$. This map can be interpreted as a homomorphism of tropical algebras (defined over the semifield $\mathbb{T}$).

Proposition 3.13. *If $f\colon X \to Y$ is a linear tropical morphism then its (set-theoretical) graph is a* $(\dim X)$*-dimensional tropical variety.*

3.5. Equivalence of tropical varieties. Different tropical varieties may serve as different models for essentially the same variety. To identify such tropical varieties we globalize the notion of contraction that was so far defined only for $V \subset \mathbb{T}^n$.

Let $f\colon X \to Y$ be a tropical morphism between tropical varieties of the same dimension.

Definition 3.14. The map f is called a *contraction* if for every $y \in Y$ there exist a chart $U^Y_\beta \ni y$ with $\Phi^Y_\beta(U^Y_\beta) \subset V_\beta \subset \mathbb{T}^{N_\beta}$, a contraction $\delta\colon W \to V_\beta$ and an isomorphism of polyhedral complexes

$$h\colon f^{-1}(U^Y_\beta) \approx \delta^{-1}(\Phi^Y_\beta(U_\beta))$$

such that $\Phi^Y_\beta \circ f = \delta \circ h$.

Note that a composition of contractions is again a contraction. A contraction generates an equivalence relation on the class of tropical varieties: tropical manifolds X

and Y are called equivalent if they can be connected by a sequence of contractions or operations inverse to contractions.

Example 3.15. The cubic curve given by (2) and pictured on the left-hand side of Figure 2 is equivalent to the circle S^1 equipped with the tropical structure coming from $\mathbb{R}/4.5\mathbb{Z}$ (as $\mathbb{R} = \mathbb{T}^\times$ is a tropical variety and the translation by 4.5 is a tropical automorphism there is a well-defined tropical structure on the quotient).

In the same time the real number 4.5 is an inner invariant of this cubic curve. It is a tropical counterpart of the J-invariant of elliptic curves.

It is convenient to identify equivalent tropical varieties. This allows to present an arbitrary regular morphism $f\colon X \to Y$ in Definition 3.12 by a linear tropical morphism.

Proposition 3.16. *If $f\colon X \to Y$ is a regular tropical morphism then there exists a contraction $\delta\colon \tilde{X} \to X$ such that $f \circ \delta\colon \tilde{X} \to Y$ is a linear tropical morphism.*

Example 3.17. The map $\mathbb{T} \to \mathbb{T}$ defined by $x \mapsto f(x) = \text{“}x^2 + x + 1\text{”}$ is a regular morphism which is not linear. However, the map $f \circ \delta_f\colon \Gamma_f \to \mathbb{T}$ is a linear morphism as it is given by the projection of the full graph Γ_f onto the vertical axis (cf. the left-hand side of Figure 3).

There is a well-defined notion of a k-form on a tropical variety that is preserved by the tropical equivalence.

Definition 3.18. A k-form on a tropical variety X is an exterior real-valued k-form of the integer tangent vectors at every finite point $x \in X$ such that for every chart U_α this form is induced from a (constant) linear k-form on $\mathbb{R}^{N_\alpha}$.

A k-form ω on X is called globally defined if the following condition holds for every non-finite point $x \in X$. If $x \in U_\alpha$ and $\Phi_\alpha(x) \in \mathbb{T}^{N_\alpha}$ has its jth coordinate $-\infty$ then the form ω in $\mathbb{R}^{N_\alpha}$ vanishes on the kernel of the projection onto the jth coordinate hyperplane.

E.g. the only globally defined k-form on $\mathbb{TP}^n$ is the zero form. But there might be globally defined k-forms on other compact varieties. An easy example is provided by taking X to be a *tropical torus*, the quotient of $\mathbb{R}^n$ by translation from some integer lattice $\Lambda \subset \mathbb{R}^n$ of rank n. Such X is a compact tropical variety while the globally defined k-forms on X are in 1-1 correspondence with constant linear k-forms on $\mathbb{R}^n$.

If $\delta\colon \tilde{X} \to X$ is a contraction then a globally defined k-form must vanish at all vectors in the kernel of $d\delta$, thus there is a 1-1 correspondence between forms on $\tilde{X}$ and X.

4. Tropical intersection theory

4.1. Cycles in X. The notion of an integer piecewise-linear polyhedral complex may be extended to include not only complexes in $\mathbb{T}^n$, but also complexes in an arbitrary

tropical variety X. We say that $B \subset X$ is an integer piecewise-linear polyhedral complex if for every chart $U_\alpha \subset X$ there exists an integer piecewise-linear polyhedral complex $B_\alpha \subset V_\alpha \subset \mathbb{T}^{N_\alpha}$ such that $\Phi_\alpha(B) \subset B_\alpha$.

As the overlapping maps preserve convex polyhedra we have a well-defined notion of a maximal facet on B and thus can consider *weighted* integer piecewise-linear polyhedral complexes in X.

Definition 4.1. A *k-cycle* B in a tropical variety X is a k-dimensional integer piecewise-linear polyhedral complex weighted by integer (possibly negative) numbers that satisfies Property 3.3 in every chart $\Phi_\alpha\colon U_\alpha \to V_\alpha \subset \mathbb{T}^{N_\alpha}$ of X. Accordingly, the codimension of B is $n-k$.

All k-cycles in X form a group by taking unions.

Remark 4.2. In this definition we excluded k-cycles with boundary components. Indeed, by our definition, every k-dimensional convex polyhedron in $\mathbb{T}^n$ is the closure of a convex polyhedron in $\mathbb{R}^n$. Thus we do not have components lying totally in $\mathbb{T}^n \setminus \mathbb{R}^n$. While it is useful also to consider cycles with boundary components, their intersection theory is more elaborate.

Proposition 4.3. *The image $f_*(B) \subset Y$ of a k-cycle B under a linear tropical morphism $f\colon X \to Y$ is a k-cycle.*

In particular, a tropical subvariety is a cycle. An important example is the *fundamental cycle* of the n-dimensional tropical variety X. It is the n-cycle where each facet of X is taken with its own weight.

4.2. Cycle intersections. One very useful feature of tropical varieties is the possibility to intersect cycles there.

Let B_1, B_2 be two cycles of codimension k_1 and k_2 in the same tropical variety X. The goal of this section is to define their *product-intersection* $B_1.B_2$ as a cycle of codimension k_1+k_2 in X.

We start from an easier case when the ambient variety X is $\mathbb{T}^n$. The set-theoretical intersection $B_1 \cap B_2$ is naturally stratified by convex polyhedra that are intersections of the (convex) faces of B_1 and B_2. It might happen that the dimension of some of these polyhedra is greater than $n-(k_1+k_2)$.

Definition 4.4. We define $B_1.B_2$ as the closure of the union of the strata of dimension $n-(k_1+k_2)$ in $B_1 \cap B_2$ equipped with certain weights which we define as follows.

- Suppose that an $(n-(k_1+k_2))$-dimensional stratum $S \subset B_1 \cap B_2$ is the intersection of two facets $F_1 \subset B_1$ and $F_2 \subset B_2$. Let $\Lambda_1, \Lambda_2 \subset \mathbb{Z}^n$ be the subgroups consisting of all integer vectors parallel to F_1 and F_2 respectively. Since by assumption S is of codimension k_1+k_2 the sublattice $\Lambda_1+\Lambda_2 \subset \mathbb{Z}^n$ is of finite index. We set the weight of S equal to the product of this index and the weights of F_1 and F_2.

- Suppose that the $(n-(k_1+k_2))$-stratum $S \subset B_1 \cap B_2$ is the intersection of perhaps smaller-dimensional faces $G_1 \subset B_1$ and $G_2 \subset B_2$. We choose a small vector $\vec{v} \in \mathbb{R}^n$ in the generic (non-rational with non-rational projections) direction and denote by $\tau_v \colon \mathbb{T}^n \to \mathbb{T}^n$ the translation by v (which, clearly, extends from $\mathbb{R}^n$ to $\mathbb{T}^n$). The face G_1 is adjacent to a finite number of facets $F_1^{(\alpha)}$ of B_1 while the face G_2 is adjacent to a finite number of facets $F_2^{(\beta)} \subset B_2$. As v is chosen to be generic the facets $F_1^{(\alpha)}$ and $\tau_v(F_2^{(\beta)})$ intersect transversely along a convex polyhedron parallel to S. Thus the weight of their intersection is already defined. We assign to S the weight equal to the sum of the weights of all such intersections (where the weight equals zero if $F_1^{(\alpha)}$ and $\tau_v(F_2^{(\beta)})$ are disjoint). Proposition 4.5 asserts that this total sum does not depend on the choice of v.

This definition is essentially the same as the definition of *stable intersection* from [25], note also similarities with the *Minkowski weights* from [6].

In the general case one can use in a certain way the contraction charts $\phi_\alpha : U_\alpha \to \mathbb{T}^n$ and the product-intersections $\phi_\alpha(B_1).\phi_\alpha(B_2)$ to define $B_1.B_2$ for an arbitrary tropical variety X.

Proposition 4.5. *The product-intersection $B_1.B_2$ is well defined. It gives an $(n-(k_1+k_2))$-dimensional cycle in X. The operation of taking the product-intersection is commutative and associative.*

4.3. Pull-backs, deformations, linear equivalence. Proposition 4.3 allows us to take the push-forward of a cycle under a linear tropical morphism. Using the product-intersection we can also define a pull-back.

Let $f \colon X \to Y$ be a linear tropical morphism and $B \subset Y$ is a k-cycle. The product $X \times B$ is a $(\dim X + k)$-cycle while the (set-theoretical) graph Γ_f of f is a $(\dim X)$-cycle in $X \times Y$. Their product-intersection $(X \times B).\Gamma_f$ is thus a $(k + \dim X - \dim Y)$-cycle in $X \times Y$. We define the pull-back of B by

$$f^*(B) = \pi^X_*((X \times B).\Gamma_f) \subset X,$$

where $\pi^X \colon X \times Y \to X$ is the projection onto X.

Any cycle $B \subset X \times Y$ can be considered as a family of cycles in X. Indeed, every $y \in Y$ defines a cycle

$$B_y = \pi^X_*(B.(X \times \{y\})) \subset X.$$

Definition 4.6. We call such a family *algebraic* and two cycles that appear in the same family with a connected B results of *deformation* of each other. Two cycles are called *linearly equivalent* if they appear in the same family with $Y = \mathbb{TP}^1$.

Proposition 4.7. *If $B_1, B_2 \subset X$ are two cycles and $B_1', B_2' \subset X$ are results of their deformation then $B_1'.B_2'$ is a result of deformation of $B_1.B_2$.*

The deformations are especially interesting in the case when X is compact as the following proposition shows. Note that a 0-cycle in X (as by our assumption X is covered by a finite collection of charts) is a finite union of points. We define the *degree* of a 0-cycle $B \subset X$ to be the sum of the weights of all points of B.

Proposition 4.8. *The degree of a* 0*-cycle in a compact tropical variety is a deformation invariant.*

We may define the *intersection number* of a collection of cycles of total codimension n as the degree of their product-intersection.

Example 4.9. All hypersurfaces of the same degree in $\mathbb{TP}^n$ (see Example 3.10) can be obtained from each other by deformation. Furthermore, they are linearly equivalent. We have the tropical Bezout theorem: the intersection number of n hypersurfaces of degree $d_1, \dots, d_n$ is equal to $\prod_{j=1}^n d_j$, cf. [31].

We can see the illustration to this theorem in Figures 1 and 2. In Figure 1 we have a line and a conic and they intersect in two distinct points. The weight of each of these intersection points is 1 as the primitive integer vectors parallel to the edges at the points of intersection form a basis of $\mathbb{Z}^2$. In Figure 2 we have two cubics that intersect at eight points. Out of these eight points seven have weight 1 while one, the point of intersection of a horizontal edge with an edge of slope 2, has weight 2. Thus the total intersection number of these two cubics equals 9.

4.4. Intersection with divisors. Taking the product-intersection simplifies in the case when one of the cycles is a (Cartier) divisor.

Definition 4.10. A *divisor* $D \subset X$ is a finite formal linear combination with integer coefficients of $(\dim X - 1)$-cycles given by an open covering $\{U_\alpha\}$ and regular functions $f_\alpha \colon \mathcal{U}_\alpha \to \mathbb{T}$ that defines $D \cap U_\alpha$ as its hypersurface.

Not every cycle of codimension 1 in X is a divisor.

Example 4.11. Let $X \subset \mathbb{T}^3$ be the hypersurface given by "$x+y+z+0$" (see Figure 4). Let $B \subset X$ be the line $\{(t, t, 0) \mid t \in \mathbb{T}\}$. It is a 1-cycle in the 2-dimensional tropical variety X. Yet it cannot be presented as a hypersurface near the point $(0, 0, 0)$ which is the vertex of X.

If $B \subset X$ is a k-cycle and $D \subset X$ is a divisor then in each U_α the product-intersection $D.B$ coincides with the hypersurface defined by f_α on B (i.e. with the points where "$\frac{1_\mathbb{T}}{f_\alpha}$" is not regular weighted by the order of poles of "$\frac{1_\mathbb{T}}{f_\alpha}$").

Similarly, we can define a pull-back of a divisor $D \subset Y$ under a regular morphism $h \colon X \to Y$ by taking the pull-backs of the functions f_α. As the pull-backs $(f_\alpha) \circ h$ are regular on $h^{-1}(U_\alpha)$ they define a divisor $h^*(D) \subset X$.

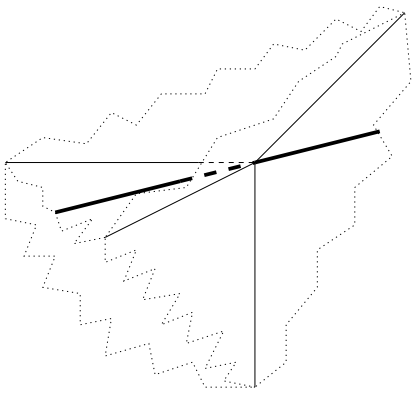

Figure 4. A cycle of codimension 1 which is not a (Cartier) divisor.

5. Tropical curves

5.1. Tropical curves as metric graphs. As in the classical case the easiest varieties to understand are curves. A tropical structure on a curve (which is topologically a graph) can be expressed by introducing a metric. Such presentation is not unlike the presentation of complex curves of negative Euler characteristic with hyperbolic surfaces. For simplicity we restrict our attention to compact tropical curves.

Recall that a *leaf* of a graph is an edge adjacent to a 1-valent vertex. We call an edge which is not a leaf a *finite edge*. Denote the set of all 1-valent vertices by Vert_1.

Definition 5.1 (cf. e.g. [1]). A *metric graph* is a finite graph Γ such that every finite edge has a prescribed positive real length. The length of all leaves is set to be $+\infty$.

This makes $\Gamma \setminus \mathrm{Vert}_1(\Gamma)$ a complete metric space (equipped with an inner metric). We denote the resulting metric by d_Γ. A homeomorphism between metric graphs is an isomorphism if it is an isometry on $\Gamma \setminus \mathrm{Vert}_1(\Gamma)$. Note that a presentation of a topological space as a graph is not unique, at our will we may introduce or erase 2-valent vertices.

Proposition 5.2. *There is a* 1-1 *correspondence between compact tropical curves and metric graphs.*

A primitive integer tangent vector at a point of a tropical curve (in every chart) has the unit length in the corresponding metric.

Proposition 5.3. *A map $f : \Gamma \to \Gamma'$ between tropical curves is a regular morphism if there exists a presentation of Γ as a graph so that for every edge $E \subset \Gamma$ there exists $n(E) \in \mathbb{N} \cup \{0\}$ such that*

$$d_{\Gamma'}(f(x), f(y)) = n(E) d_\Gamma(x, y)$$

for any $x, y \in E$.

Presentation as a metric graph is a convenient way to specify a tropical structure on a curve. The *genus* of a tropical curve Γ is its first Betti number $b_1(\Gamma)$. (This term is justified by Proposition 5.5.)

Example 5.4. Figure 5 depicts all tropical curves of genus 2. Varying the length of the edges we vary the tropical structure on the curve. For the curves in the left and in the right we have three lengths of edges, a, b and c, to vary. The middle curve is an intermediate case when one of these lengths becomes zero.

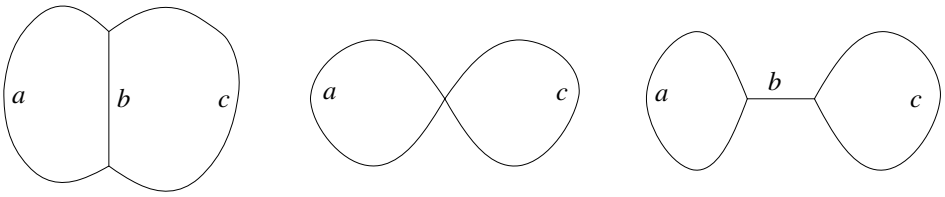

Figure 5. Tropical curves of genus 2.

This shows that the space of tropical curves of genus 2 is 3-dimensional. Furthermore, one may observe that these curves are hyperelliptic as there exists a non-trivial isometry involution for each of the three types in the picture. (The fixed points of this isometry are the midpoints of the edges for the left picture; the midpoint of the edges and the vertex for the center picture; the edge connecting the vertices and the midpoints of the other edges for the right picture.)

5.2. Jacobian varieties and the Riemann–Roch inequality

Proposition 5.5. *All* 1*-forms on a compact tropical curve* Γ *form a real vector space* $\Omega(\Gamma)$ *of dimension* $b_1(\Gamma)$*, i.e. the genus of* Γ.

Note that any 0-cycle on a curve Γ is a divisor in the sense of Definition 4.10. The divisors of degree 0 form a group Div_0 while the divisors of degree d form a homogeneous space Div_d over Div_0. We define the *Picard group* Pic_0 by taking the quotient group of Div_0 by the linear equivalence (see Definition 4.6). Similarly we define Pic_d.

A divisor is called *principal* if it is linearly equivalent to zero. Clearly, the degree of a principal divisor is 0. The classical Mittag-Leffler problem to determine whether a divisor of degree 0 is principal is answered by the Abel–Jacobi theorem. A similar answer exists also in the tropical set-up.

Note that given a 1-form ω and a path $\gamma : [0, 1] \to \Gamma$ there is a well-defined integral $\int_\gamma \omega$. Clearly, the value of this integral depends only on the relative homology class of γ. Let $\Omega^*(\Gamma)$ be the (real) dual vector space to $\Omega(\Gamma)$. Its dimension is equal to the genus g of Γ by Proposition 5.5. Each element $a \in H_1(\Gamma; \mathbb{Z})$ determines a point

of $\Omega^*(\Gamma)$. This point is given by the functional

$$\Lambda(a)\colon \omega \mapsto \int_a \omega.$$

The *Jacobian* of a tropical curve Γ is defined by

$$\mathrm{Jac}(\Gamma) = \Omega^*(\Gamma)/\Lambda(H_1(\Gamma;\mathbb{Z})).$$

The Jacobian is an example of a tropical torus. It is homeomorphic to $(S^1)^g$ and carries the structure of a tropical variety (which depends on the lattice $\Lambda(H_1(\Gamma;\mathbb{Z}))$.

To define the *Abel–Jacobi* map

$$\alpha\colon \mathrm{Pic}_0(\Gamma) \to \mathrm{Jac}(\Gamma) \tag{4}$$

we take any 1-chain C whose boundary is a divisor in the equivalence class $p \in \mathrm{Pic}_0$ and set $\alpha(p)$ to be the functional $\omega \mapsto \int_C \omega$.

Proposition 5.6 (Tropical Abel–Jacobi theorem). *The Abel–Jacobi map* (4) *is a well-defined bijection.*

This gives the structure of a tropical variety on Pic_0 as well as on Pic_d (which is a homogeneous space over Pic_0). We have the tautological map

$$\mathrm{Sym}^d(\Gamma) \to \mathrm{Pic}_d(\Gamma)$$

defined by taking the equivalence class.

As in the classical case this map is especially interesting in the case $d = g - 1$. The image of this map in this case (as well as all its translates in $\mathrm{Pic}_0 = \mathrm{Jac}$) is called the Θ-*divisor*. There is a tropical counterpart of the Riemann theorem stating that the Θ-divisor is given by a θ-function, see [23].

Figure 6 sketches the Θ-divisor in the case of genus 2. In this case it is isomorphic to the curve Γ itself. The Jacobian in Figure 6 is obtained by identifying the opposite sides of the dashed parallelogram.

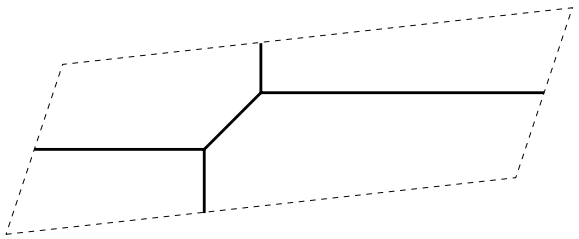

Figure 6. Θ-divisor for genus 2.

The divisor is called *effective* if the weights at all its points are positive. The Riemann–Roch theorem allows to find the dimension of all effective divisors linearly equivalent to a given one. (Alternatively, this number plus one can be interpreted as the dimension of the space of sections of the line bundle corresponding to a given divisor.) Tropically, we have the Riemann–Roch theorem in form of an inequality.

Proposition 5.7 (The tropical Riemann–Roch inequality). *The dimension of the space of effective divisors in the equivalence class $p \in \mathrm{Pic}_d$ is at least $d - g$.*

5.3. The canonical class, regular and superabundant curves in X. We have the Chern classes for compact tropical varieties which are easy to compute (as a tropical variety is already parallelized by the integer affine structure on its facets).

Let X be an n-dimensional compact tropical variety. We have the natural stratification of the faces of X by their dimension. Furthermore, there is the *boundary stratification* of X. We say that a face $F \subset X$ is in the kth boundary stratum if there is a chart $U_\alpha \ni x$ where $\Phi_\alpha(F)$ is contained in an intersection of k out of N_α tropical coordinate hyperplanes of $\mathbb{T}^{N_\alpha}$ and not contained in the intersection of any $(k+1)$ coordinate hyperplanes.

A face in the 0th boundary stratum is called a *finite* face. Clearly a face in the kth boundary stratum has dimension at most $(n-k)$.

The kth Chern class of X is an $(n-k)$-cycle that is the linear combination of all $(n-k)$-dimensional faces of X. Here the strata of boundary codimension k are taken with the weight equal to $(-1)^k$ times some positive number depending only on the local geometry near a point x in the relative interior of F (this weight can be computed inductively from a local presentation of a neighborhood of x by a contraction $\delta\colon V \to \mathbb{T}^n$).

Here we give the computation of weights only in the case of $-c_1$. This is the $(n-1)$-cycle in X that consists of all finite $(n-1)$-faces F taken with the weight equal to the number of adjacent facets to F minus 2 and all $(n-1)$-faces in the 1-boundary stratum taken with the weight -1.

Definition 5.8. The *canonical class* K is the $(n-1)$-cycle in X equal to $-c_1$.

A *parameterized tropical curve* in X is a linear tropical morphism $h\colon \Gamma \to X$. One may use Proposition 5.7 to compute the dimension in which the map h varies (we allow to deform both h and the tropical structure on Γ).

The adjunction formula exists also in the tropical geometry. As in this talk we have not defined tropical vector bundles in general and, in particular, the normal bundles, we state it only in the case when h is an embedding and X is a compact surface. We have

$$h_*([\Gamma]).h_*([\Gamma]) = 2g - 2 - K.h_*([\Gamma]). \tag{5}$$

Here $[\Gamma]$ stands for the fundamental 1-cycle in Γ.

Example 5.9. Consider the compactification of Example 4.11. Let $X \subset \mathbb{TP}^3$ be the closure of the hypersurface $x + y + z + 0$ and $h\colon \mathbb{TP}^1 \to X$ be the linear tropical morphism whose image is the closure of B. The two infinite ends of B contribute $+1$ each to its self-intersection, thus the self-intersection contribution of B at $(0, 0, 0)$ is -1 (see Figure 4)

Proposition 5.10. *The map $h\colon \Gamma \to X$ varies in a family of dimension at least*

$$\mathrm{vdim_h} = K.h_*([\Gamma]) + (n-3)(1-g)$$

if we allow to deform both h and Γ. The number vdim *is called the* virtual dimension *of the deformations of h.*

Definition 5.11. The parameterized curve h is called *regular* if the local dimension of all its deformations is equal to vdim_h. Otherwise, if it is strictly greater than vdim_h, the curve h is called *superabundant*.

E.g. the curve h will necessarily be superabundant if $h(\Gamma)$ contains a loop that is contained in a proper affine-linear subspace of a facet of X.

5.4. Tropical moduli spaces. Let Γ be a compact tropical curve of genus g. Let us choose k distinct points $x_1, \ldots, x_k \in \Gamma$. We call x_j the *marked points*. By replacing Γ with an equivalent tropical curve if needed, we may assume that Γ has exactly k 1-valent vertices which coincide with $x_1, \ldots, x_k$. Such presentation exists unless $g = 0$ and $k < 2$ and it is unique up to isomorphism. Thus we may restrict our attention only to such models.

We denote by $\mathcal{M}_{g,k}$ the space of all tropical curves of genus g with k marked points up to equivalence.

A tropical curve with marked points is determined by its combinatorial type and the lengths of its finite edges. E.g. the tropical curve from Figure 7 is determined by the lengths a and b. The length of the finite edges can be used to enhance $\mathcal{M}_{g,k}$ with

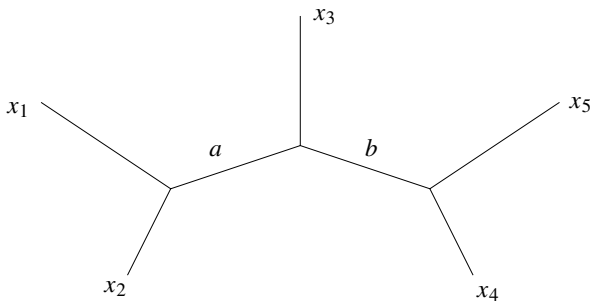

Figure 7. A rational curve with 5 marked points.

a tropical structure. The only problem is that we may only identify the edges within the same combinatorial type of the curve.

One can easily solve this problem if $g = 0$. Let us introduce a global function Z_{x_i,x_j} on $\mathcal{M}_{0,k}$ for any pair of marked points $\{x_i, x_j\}$. We set Z_{x_i,x_j} equal to the total length of finite edges between x_i and x_j. E.g. for the curve $\Gamma \in \mathcal{M}_{0,5}$ from Figure 7 we have $Z_{x_1,x_2}(\Gamma) = 0$, $Z_{x_1,x_3}(\Gamma) = a$ and $Z_{x_1,x_5}(\Gamma) = a + b$.

Proposition 5.12. *The functions Z_{x_i,x_j} define an embedding*

$$\mathcal{M}_{0,k} \subset \mathbb{R}^{\frac{k(k-1)}{2}}.$$

Its image is a tropical subvariety.

Remark 5.13. This embedding is related to the Plücker coordinates on the Grassmannian $G_{2,k}$, see [30] for a tropical version.

Thus we see that $\mathcal{M}_{0,k}$ has a natural structure of a tropical variety. We may compactify $\mathcal{M}_{0,k}$ by allowing the lengths of some (or all) finite edges of Γ to take the value equal to $+\infty$. Such a generalized curve splits into several components: the finite points of each such component are within finite distance from each other.

Proposition 5.14. *The resulting space $\overline{\mathcal{M}}_{0,k}$ is a compact tropical variety.*

This compactification is a tropical counterpart of the Deligne–Mumford compactification.

If $g > 0$ one may use similar arguments to show that $\mathcal{M}_{g,k}$ is a tropical orbifold which can be compactified to a compact tropical orbifold $\overline{\mathcal{M}}_{g,k}$.

5.5. Stable curves in X. As in the classical case we call a parameterized tropical curve $h\colon \Gamma \to X$ in a compact n-dimensional tropical variety X with compact Γ *stable* if there are no infinitesimal automorphisms of h, i.e. if the number of isomorphisms Φ of Γ such that $h = h \circ \Phi$ is finite.

All deformations of a regular stable curve h locally form a tropical variety of dimension $K.h_*([\Gamma]) + (n-3)(1-g)$. Let us fix some class β of stable curves to X that is closed with respect to regular curve deformations. The class β can be given e.g. by prescribing the intersection number with all $(n-1)$-cycles in X.

Denote by $\mathcal{M}^{\beta}_{g,k}(X)$ the space of stable curves of genus g with k marked points in the class. In many cases the space $\mathcal{M}^{\beta}_{g,k}(X)$ can be compactified to a compact tropical variety $\overline{\mathcal{M}}^{\beta}_{g,k}(X)$. This holds for instance if $g = 0$, $X = \mathbb{TP}^n$ and β is formed by curves of degree d. Another instance is if $X = \mathbb{TP}^2$, there are no restrictions on g and β is formed by topological immersions of degree d. These are the two principal cases for our enumerative applications. More generally we may assume that X is any compact toric variety, but then we have to impose the additional constraint on β that it does not contain curves with components lying totally in the boundary divisors of X.

Furthermore, in these cases we have the *evaluation* map

$$\mathrm{ev}_j\colon \overline{\mathcal{M}}^{\beta}_{g,k}(X) \to X,$$

$\mathrm{ev}_j(h) = h(x_j)$ as well as the maps $\mathrm{ft}\colon \overline{\mathcal{M}}^{\beta}_{g,k}(X) \to \overline{\mathcal{M}}_{g,k}$, $\mathrm{ft}(h) = \Gamma$, and the maps $\pi_j\colon \overline{\mathcal{M}}^{\beta}_{g,k}(X) \to \overline{\mathcal{M}}^{\beta}_{g,k-1}(X)$ "forgetting" the marked point x_j. These maps are linear tropical morphisms.

This allows to set up a tropical framework for the Gromov–Witten theory. E.g. given a collection of cycles in X we may take their pull-backs and then take their intersection number in $\overline{\mathcal{M}}^{\beta}_{g,k}(X)$.

Many reasonings in the Gromov–Witten theory can be literally repeated in this tropical set-up. A good example is the WDVV-relation, cf. [7]. As in the classical case the stable curves in $\overline{\mathcal{M}}^{\beta}_{0,k}(X) \setminus \mathcal{M}^{\beta}_{0,k}(X)$ must consist of several components.

Remark 5.15. Moduli spaces of higher-dimensional tropical varieties is a very interesting, but much more difficult subject. Already the tropical K3-surfaces form a very sophisticated geometric object, see [14] and [9].

6. Tropical curves in $\mathbb{R}^n$, their phases and amoebas

Let $V \subset (\mathbb{C}^\times)^n$ be an algebraic variety. Its *amoeba* (see [8]) is the set $\mathcal{A} = \mathrm{Log}(V) \subset \mathbb{R}^n$, where $\mathrm{Log}(z_1, \dots, z_n) = (\log|z_1|, \dots, |z_n|)$. Similarly we may consider the map

$$\mathrm{Log}_t\colon (\mathbb{C}^\times)^n \to \mathbb{R}^n$$

corresponding to taking the logarithm with the base $t > 1$.

Amoebas themselves have proved to be a very useful tool in several areas of mathematics, see e.g. [4], [16], [17], [22], [26], [27]. However, for the purposes of this talk we only use them as an intermediate link between the classical and tropical geometries.

Definition 6.1. The curve $h\colon \Gamma \to \mathbb{R}^n$ is called *classically realizable* if there exist a small regular neighborhood $U \supset B$ in $\mathbb{R}^n$, a retraction $\rho\colon U \to B$, a regular family of holomorphic maps $H_t\colon C_t \to (\mathbb{C}^\times)^n$ for a family of Riemann surfaces C_t defined for all sufficiently large positive $t \gg 1$ and smooth maps $\lambda_t\colon C_t \to \Gamma$ such that

- $h \circ \lambda_t = \rho \circ \mathrm{Log}_t \circ H_t$;
- the genus of C_t coincides with the genus of Γ;
- the number of punctures of C_t coincides with the number of ends of Γ.

The family $H_t\colon C_t \to (\mathbb{C}^\times)^n$ is called an *approximating family* of h.

Proposition 6.2. *If $h\colon \Gamma \to \mathbb{R}^n$ is a tropical curve approximated by H_t then for a sufficiently large t the inverse image $\lambda_t^{-1}(p)$ is a smooth circle for every p inside an edge of Γ while the inverse image $\lambda_t^{-1}(W)$ is diffeomorphic to a sphere with u punctures for a small connected neighborhood W of a vertex of valence u.*

In particular, if Γ is 3-valent then λ_t defines a pair-of-pants decomposition. In turn, this pair-of-pants decomposition determines a point in the boundary of the classical Deligne–Mumford space $\overline{\mathcal{M}}^{\mathbb{C}}_{g,k}$. This point is the limit of the Riemann surfaces C_t.

See [17] for a generalization of the pair-of-pants decomposition for the case of higher-dimensional hypersurfaces .

Remark 6.3. Classical realizability of tropical varieties in $\mathbb{R}^n$ is closely related to their presentation by *non-Archimedean amoebas*, the images of algebraic varieties in $(K^\times)^n$ under the coordinatewise valuations (as defined by Kapranov [10]). Here K is an algebraically closed field with a non-Archimedean valuation $\mathrm{val}\colon K^\times \to \mathbb{R}$. See [29] for an account of what is known on such presentations.

To formulate the realizability theorem in full generality we need to define the *phases* for Γ. We start from their definition in a model case.

Let $\Gamma_k \subset \mathbb{R}^k$ be the tropical curve consisting of $(k+1)$ rays emanating from $0 \in \mathbb{R}^k$ in the directions $(-1,\dots,0),\dots,(0,\dots,-1)$ and $(1,\dots,1)$. The tautological embedding $\Gamma_k \subset \mathbb{R}^k$ is easily realizable. For an approximating family we can take $H_t = L_k \subset (\mathbb{C}^\times)^n \subset \mathbb{CP}^k$, where L_k is a line with $(k+1)$ ends in $(\mathbb{C}^\times)^n$. The choice of L_k up to a multiplication by a point of $(\mathbb{R}_+)^k$ is called the phase of Γ_k.

Locally, near any point $x \in \Gamma$ the map h coincides with the map

$$\Gamma_k \subset \mathbb{R}^k \xrightarrow{A+c} \mathbb{R}^n$$

near $0 \in \Gamma_k$ for a linear map A defined over $\mathbb{Z}$ and $c \in \mathbb{R}^n$, where $(k+1)$ is the valence of x. The linear map A can be exponentiated to a multiplicative linear map $a\colon (\mathbb{C}^\times)^k \to (\mathbb{C}^\times)^n$. The phase σ_U of Γ at a small neighborhood $U \ni x$ is defined to be the equivalence class of $\xi a(L_k) \subset (\mathbb{C}^\times)^n$, $\xi \in (\mathbb{C}^\times)^n$, up to multiplication by an element of $(\mathbb{R}_+)^n$. Two local phases are called *compatible* if they agree on the intersection of the neighborhoods.

We say that H_t approximates Γ *with the local phase* σ_U if $H_t(C_t) \cap \mathrm{Log}_t^{-1}(U)$ converges (in the Hausdorff metric on compacts in $(\mathbb{C}^\times)^n$) to $\xi t^C a(L_k) \in \sigma_U$.

Theorem 1. *Any regular tropical curve $h\colon \Gamma \to \mathbb{R}^n$ equipped with any compatible system of phases is classically realizable.*

Cf. [19] and [28] for the special case $n = 2$ with no restriction on the genus, and [20] and [24] for the special case of genus 0 with no restriction on n. The proof in the general case (though in a somewhat different language) is contained in [2] (cf. also [29]).

Remark 6.4. Regularity is a necessary condition in Theorem 1, it is easy to construct an example of a non-realizable superabundant curve even for a topological immersion of an elliptic curve in $\mathbb{R}^3$, see e.g. [18].

7. Applications

One of the greatest advantages of tropical geometry is that most classical problems become much simpler after their tropicalization (if such a tropicalization exists!). This simplicity comes from the piecewise-linear nature of the tropical objects. Indeed, once we fix the combinatorial type of the data, a tropical problem becomes linear. E.g. if there are finitely many solutions to a problem then in every combinatorial type we will have a unique solution or no solutions at all.

This allows one to find (at least) an algorithmic answer to a tropical problem. Sometimes one can show that the answer to a classical problem and its tropicalization must coincide and obtain the answer to the classical problem in this way. In this last section we list some examples of such problems.

7.1. Complex geometry. Let $g \geq 0$ and $d \geq 1$ be integers. Fix a collection $\mathcal{Z} = \{z_j\}_{j=1}^{3d-1+g}$ of points in $\mathbb{CP}^2$ in general position. There are finitely many holomorphic curves of genus g and degree d passing through $\mathcal{Z}$. Let $N^{\mathbb{C}}_{g,d}$ be their number.

Such set-up can be almost literally repeated in the tropical framework. Fix a collection $\mathcal{X} = \{x_j\}_{j=1}^{3d-1+g}$ of points in $\mathbb{TP}^2$ in general position (see [19]). Again, it can be shown that there are finitely many tropical curves $h\colon \Gamma \to \mathbb{TP}^n$ of genus g and degree d passing through x_j. But in the tropical set-up these curves come with natural positive integer multiplicities $m(h)$ not necessarily equal to 1.

Tropical curves of genus g and degree d that pass through $x_j \in \mathbb{TP}^2$ form a codimension 1 cycle in $\bar{\mathcal{M}}^d_{g,d}(\mathbb{TP}^2)$. We set $m(h)$ to be the weight of their product-intersection at h (in other words this is their local intersection number in h). Let $N^{\mathbb{T}}_{g,d}$ be the number of the tropical curves of degree d and genus g passing through $\mathcal{X}$ counted with multiplicity m.

Theorem 2 ([19]).

$$N^{\mathbb{C}}_{g,d} = N^{\mathbb{T}}_{g,d}.$$

Of course, there are well-known ways to compute $N^{\mathbb{C}}_{g,d}$ (see [12], [3]) as they coincide with the Gromov–Witten invariants of $\mathbb{CP}^2$. Yet Theorem 2 gives another simple and visual way to do it, see [19] for details.

Example 7.1. Figure 8 depicts rational cubic curves in $\mathbb{TP}^2$ passing through a generic configuration $\mathcal{X}$ of 8 points. There are nine curves. Eight of them have multiplicity 1. The remaining one, namely the rightmost in the middle row, has multiplicity 4 (it has

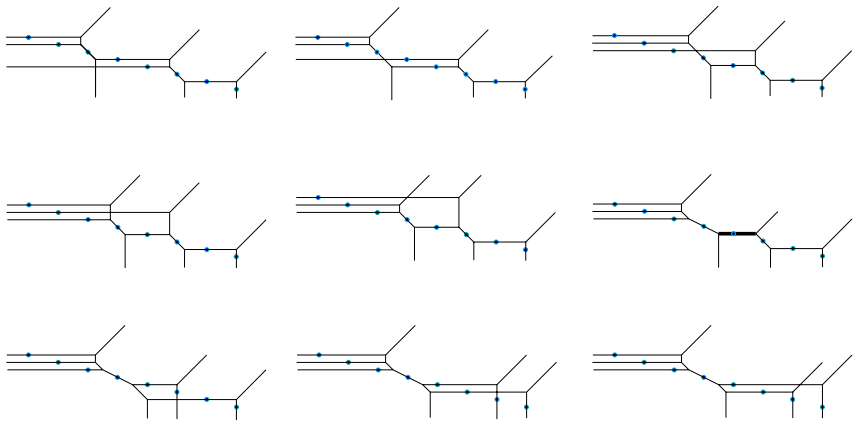

Figure 8. Rational tropical cubics via 8 generic points in the plane.

an edge of weight 2 shown by a bold line in the picture). Thus the total number of tropical curves is 12.

Should we choose a different generic configuration $\mathcal{X}$ the number of tropical curves could be different. But their total number counted with multiplicities is invariant. E.g. there exists a different choice of $\mathcal{X}$ where we have ten tropical curves, nine of multiplicity 1 and one of multiplicity 3. In fact, no other partition of 12 can appear by Example 7.3.

Remark 7.2. In [19] there is also a version of Theorem 2 for other toric surfaces. Note that if the ambient toric surface is not Fano then there is a difference between counting irreducible curves in a given homology class and computing the corresponding Gromov–Witten number (as the latter also has a contribution from curves with some boundary divisors as components). Tropical geometry has the advantage of giving a way to compute the number of irreducible curves directly without having to deal with those extra components.

The same advantage allows to apply tropical geometry for giving an algorithmic answer to another classical problem of complex geometry, namely the computation of Zeuthen's numbers, see [21]. These are the numbers of curves of degree d and genus g that pass through a collection of generic points and tangent to a collection of generic lines in $\mathbb{CP}^2$. Here the total number of points and lines in the configuration is $3d-1+g$. These Zeuthen's numbers also turn out to be equal to the corresponding tropical numbers, and the latter can be computed by a finite (though quite extensive for large genus) algorithm. As far as the author knows such computation in general is not currently accessible by non-tropical techniques.

7.2. Real geometry. The number of real curves of degree d and geometric genus g passing via a collection $\mathcal{Z} = \{z_j\}_{j=1}^{3d-1+g}$ of points in $\mathbb{RP}^2$ depends on $\mathcal{Z}$ even if we choose it to be generic. This is the feature of $\mathbb{R}$ as a non-algebraically closed field. Yet, as it was suggested in [34], one may prescribe a *sign* ± 1 to every such curve so that the sum W_d of these signs becomes invariant in the special case of $g = 0$. The number W_d is called the *Welschinger number*.

If $\mathcal{Z}$ is a generic configuration of $3d - 1$ points in $\mathbb{RP}^2$ then any real rational curve $\mathbb{R}C$ of degree d passing through $\mathcal{Z}$ is a nodal curve, i.e. all singularities of $\mathbb{R}C$ are non-degenerate double points. Over $\mathbb{R}$ there are two types of such nodes: the *hyperbolic* node, corresponding to the intersection of two real branches (given in local coordinates by $x^2 - y^2 = 0$) and the *elliptic* node, corresponding to the intersection of two complex-conjugate branches (given in local coordinates by $x^2 + y^2 = 0$). The sign of $\mathbb{R}C$ is defined as $(-1)^{e(C)}$, where $e(C)$ is the number of elliptic nodes of C.

The Welschinger number also has a tropical counterpart. To a tropical curve $h\colon \Gamma \to \mathbb{TP}^2$ of degree d and genus g passing through a configuration $\mathcal{X}$ of $3d-1+g$ points we associate its *real multiplicity* $m^{\mathbb{R}}(h)$ which is ± 1 or 0. If $h(\Gamma)$ has an edge of even multiplicity then $m^{\mathbb{R}}(h) = 0$. Otherwise we define the local real multiplicity $m_v^{\mathbb{R}}(h)$ for a vertex $v \in \Gamma$ to be $(-1)^{e_v}$, where e_v is the number of integer points in the interior of the lattice triangle such that its sides are perpendicular to the edges adjacent to v and of integer length equal to the weight of that edge. Then we define $m^{\mathbb{R}}(h) = \prod_v m_v^{\mathbb{R}}(h)$. Let $W_{g,d}^{\mathbb{T}}$ be the corresponding tropical number.

Theorem 3 ([19]).

$$W_d = W_{g,d}^{\mathbb{T}}.$$

This theorem is the only currently known way to compute the Welschinger numbers, see [11].

Example 7.3. Let us revisit Example 7.1. The real multiplicities of eight out of the nine curves in Figure 8 is 1 while the real multiplicity of the remaining one is 0. Thus we have $W_3 = 8$. For another choice of a generic configuration of eight points in $\mathbb{TP}^2$ mentioned in Example 7.1 we get nine curves with $m^{\mathbb{R}}(h) = +1$ and one with $m^{\mathbb{R}}(h) = -1$.

Note that we always have $m^{\mathbb{R}}(h) = +1$ if $m(h) = 1$; $m^{\mathbb{R}}(h) = +1$ if $m(h) = 1$ if the multiplicity is 1; and $m^{\mathbb{R}}(h) = 0$ if $m(h)$ is even. Note also that we may never get $m(h) = 2$. Since the sum of the multiplicities has to be 12 and the sum of real multiplicities has to be 8 the partitions $12 = 8 + 4 = 9 + 3$ are the only two possible partitions. In particular, there does not exist a configuration of eight points in $\mathbb{TP}^2$ such that the twelve tropical cubics will all be distinct.

Remark 7.4. There is a 3-dimensional version of the number W_d which is the number of real rational curves in $\mathbb{RP}^3$ of degree d passing through a generic configuration of $2d$ points taken with certain signs, see [35]. These numbers also have tropical counterparts and Theorem 3 extends to the 3-dimensional case providing a way to compute the real geometry numbers, see [20].

As the last application of tropical geometry we would like to mention extending the patchworking [32] to curves in real toric varieties of higher dimensions by using Theorem 1 with real phases.

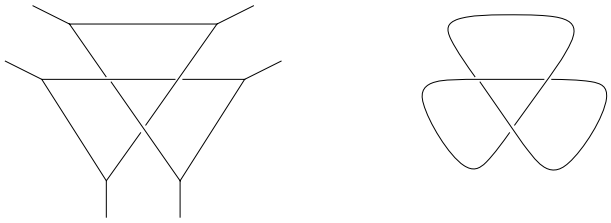

Figure 9. Real algebraic knots from tropical curves in $\mathbb{R}^3$.

Example 7.5. Let $K \subset \mathbb{R}^3$ be a knot presented as an embedded piecewise-linear circle made with k straight intervals. Then there exists an algebraic curve in $(\mathbb{R}^\times)^3$ with a unique closed component in $(\mathbb{R}_+)^3$ isotopic to K such that its complexification has genus 1 and is punctured k times. E.g. a trefoil may be presented by an elliptic curve with 6 punctures in $(\mathbb{C}^\times)^3$, see Figure 9.

To deduce this statement we perturb the broken line K to make the slopes of its intervals rational. Then we add an extra ray at every corner to get a tropical curve $\Gamma \supset K$. Finally we choose real phases for Γ so that the phases of all its bounded edges include the positive quadrant.

Embedded minimal surfaces

William P. Minicozzi II*

Abstract. The study of embedded minimal surfaces in $\mathbb{R}^3$ is a classical problem, dating to the mid 1700s, and many people have made key contributions. We will survey a few recent advances, focusing on joint work with Tobias H. Colding of MIT and Courant Institute, and taking the opportunity to focus on results that have not been highlighted elsewhere.

Mathematics Subject Classification (2000). Primary 53A10; Secondary 53C42.

Keywords. Minimal surfaces, differential geometry, mean curvature.

1. Introduction

An immersed surface Σ in $\mathbb{R}^3$ is said to be *minimal* if it has zero mean curvature and is *embedded* if the immersion is injective. The study of embedded minimal surfaces in $\mathbb{R}^3$ is a classical problem, dating to the mid 1700s, and many people have made key contributions.

Many of the recent results have been surveyed elsewhere and we will take the opportunity to highlight results that have not been as well covered, concentrating on recent joint work with Tobias H. Colding of MIT and the Courant Institute. We will also briefly cover recent important results of W. Meeks and H. Rosenberg and of W. Meeks, J. Perez, and A. Ros. We refer to the following surveys for other perspectives:

- For more on the structure of properly embedded minimal surfaces, see the joint expository article [11] with Tobias H. Colding as well as the surveys [27] of W. Meeks and J. Perez, [35] of J. Perez, [36] of H. Rosenberg, as well as the joint surveys [14], [16], and [17] with Tobias H. Colding.

- For the construction of embedded minimal surfaces, see the surveys [22] of D. Hoffman, M. Weber, and M. Wolf, [23] of N. Kapouleas, and [38] of M. Traizet.

- For properness of minimal surfaces and the Calabi–Yau Conjectures, see the paper [15] as well as the surveys [24] of F. Martin, [16], [17], and [35].

1.1. Embedded minimal surfaces of fixed genus. We have chosen to concentrate on the following central question:

- Can one compactify the space of embedded minimal surfaces of fixed genus?

Roughly speaking, we show in [8] that a sequence of embedded minimal surfaces with fixed genus has a subsequence that converges away from a singular set to a collection of parallel planes. The precise structure of the singular set and of the surfaces near the singular set depends on the topology of the surfaces. Consequently, we consider three separate cases:

1. When the surfaces are disks.
2. When the surfaces are (non-simply connected) planar domains; i.e., the case of genus zero.
3. When the surfaces have a fixed non-zero genus.

The case of disks was completed in [4], [5], [6] and [7] and plays a key role in the other two cases as well; the case of disks was surveyed in [14] and [16]. The other two cases, which were completed in [8], will be one of the focal points of this survey.

A key step in the compactness results for embedded minimal surfaces of fixed genus is a structure result that describes what these surfaces look like. We have chosen to focus on the compactness theorems rather than the underlying structure results, largely because it serves as a unifying theme and allows us to simplify some of the statements. Roughly speaking, two main structure theorems for (non-simply connected) embedded minimal planar domains from [8] are:

- Any such surface *without* small necks can be obtained by gluing together two oppositely-oriented double spiral staircases.
- Any such surface *with* small necks can be decomposed into "pairs of pants" by cutting the surface along a collection of short curves. After the cutting, we are left with graphical pieces that are defined over a disk with either one or two sub-disks removed (a topological disk with two sub-disks removed is called a *pair of pants*).

Both of these structures occur as different extremes in the two-parameter family of minimal surfaces known as the Riemann examples.

1.2. Embedded minimal annuli. The simplest example of a non-simply connected planar domain is of course an annulus. In [10], we obtained a precise description of what an embedded minimal annulus in a ball must look like – roughly speaking, it must look like catenoid. This illustrates a few of the ideas for the general pair of pants decomposition of [8] in a relatively simple setting. This description can be thought of as an effective version of the main theorems of [18] and [13]; i.e., [10] applies to an annulus Σ with $\partial\Sigma \subset \partial B_r(0)$ and as r goes to infinity we recover the results of [18] and [13].

1.3. Properness and removable singularities. The next result that we will highlight is the proof of "properness" in [9]. This properness was used in [7] to analyze a neighborhood of each singular point, showing that an entire neighborhood is foliated by limit planes. This can be viewed as a removable singularity theorem for minimal laminations. The proof of properness in [9] works only in the global case where we have a sequence of embedded minimal disks in a sequence of expanding balls whose radii tend to infinity – the local case is where the disks are in a fixed ball. Perhaps surprisingly, it turned out that properness can fail in the local case: In the local case, we can get limits with non-removable singularities. One local example with non-removable singularities is constructed in [12].

1.4. The global structure of complete embedded minimal surfaces in $\mathbb{R}^3$. As mentioned above, there have been many important recent developments in the field. We will survey two of these where the results of [4]–[8] play a role:

- The uniqueness of the helicoid proven by W. Meeks and H. Rosenberg in [31].
- The curvature bound for embedded minimal planar domains with bounded horizontal flux proven by W. Meeks, J. Perez, and A. Ros in [28].

The uniqueness of the helicoid solved a long-standing problem that was largely considered unapproachable until recently and also has many applications. We will sketch the proof and explain how the lamination theorem and one-sided curvature estimate played a key role.

The curvature bound of [28] was the key step in solving an old conjecture of J. Nittsche and an important step for understanding the moduli space of embedded minimal planar domains. We will explain the result, give an idea why it should be true, and explain how the compactness theorems of [8] play a role in the proof.

We should point out that there is a key distinction between these two results and the other results that we have discussed: these results both use in an essential way that the surfaces are complete and without boundary.

2. Minimal surfaces

An immersed surface $\Sigma \subset \mathbb{R}^3$ is *minimal* if it is a critical point for area, i.e., if it has zero mean curvature. The *mean curvature* is the trace of the second fundamental form A; recall that the eigenvalues of A are called the *principal curvatures*. Our surface Σ will always be embedded and will have a well-defined unit normal $\boldsymbol{n}$. The map

$$\boldsymbol{n}\colon \Sigma \to \mathbb{S}^2 \tag{1}$$

is called the *Gauss map*. Note that A is the differential of the Gauss map.

Observe that if $\Sigma \subset \mathbb{R}^3$ is minimal, then so is every rigid motion of Σ. Furthermore, so is a dilation of Σ, i.e., so is the surface

$$\lambda\,\Sigma = \{\lambda\, x \mid x \in \Sigma\}. \tag{2}$$

This is because dilating Σ by λ dilates the second fundamental form by λ^{-1}.

Note that minimal surfaces are not necessarily area-minimizing. A surface is *stable* if it satisfies the second derivative test; obviously, area-minimizing surfaces are stable.

2.1. Classical minimal surfaces. The simplest example of a minimal surface is a flat plane (where the unit normal is constant and, hence, where $A = 0$).

The only non-trivial rotationally invariant minimal surface is the *catenoid* (discovered in 1776), i.e., the minimal surface in $\mathbb{R}^3$ parametrized by

$$(\cosh s\ \cos t, \cosh s\ \sin t, s) \quad \text{where } s, t \in \mathbb{R}. \tag{3}$$

More precisely, since dilations preserve minimality, there is a one-parameter family of catenoids (modulo rigid motions) given by

$$\lambda\,(\cosh s\ \cos t, \cosh s\ \sin t, s) \quad \text{where } s, t \in \mathbb{R}. \tag{4}$$

The *helicoid* (also discovered in 1776) is the minimal surface Σ in $\mathbb{R}^3$ parametrized by

$$(s\cos t, s\sin t, t) \quad \text{where } s, t \in \mathbb{R}. \tag{5}$$

Note that the helicoid is a "double-spiral staircase", consisting of a straight line in each horizontal plane where these lines rotate at constant speed. It can also be thought of as the union of the "graphs" of the functions θ and $\theta + \pi$ together with the vertical axis. We will make this last characterization more precise later when we introduce the notion of a multi-valued graph.

The catenoid can be thought of as "two planes glued together along a small neck." Surprisingly, by a theorem of F. Lopez and A. Ros, it is impossible to glue together any other *finite* number of planes to get a complete properly embedded minimal planar domain. However, the *Riemann examples* (constructed by Riemann around 1860) give a periodic collection of horizontal planes glued together along small necks. This is actually (modulo rigid motions) a two parameter family of surfaces, where the parameters can roughly be thought of as

- the size of the necks (or injectivity radius), and
- the angle from one to the next.

As the angle goes to zero, the necks get further and further apart and the family degenerates to a collection of catenoids. As the angle goes to $\pi/2$, the necks become virtually on top of each other and the family degenerates to the union of two oppositely oriented helicoids. There are very pretty pictures of this available from David Hoffman's web page:

http://www.msri.org/about/sgp/jim/geom/minimal/library/riemann/index.html

3. Embedded minimal surfaces with fixed genus

As mentioned, we will focus on compactness theorems for a sequence $\Sigma_i \subset \mathbb{R}^3$ of embedded minimal surfaces. There are various notions of weak convergence (e.g., as currents or varifolds). However, for us, the sequence Σ_i converges to a surface Σ_∞ at a point $x \in \Sigma$ if there is a ball $B_r(x)$ so that:

- For every i sufficiently large, $B_r(x) \cap \Sigma_i$ is a (connected) graph over a (subset of) the tangent plane $T_x\Sigma_\infty$ of a function u_i.
- As $i \to \infty$, the functions u_i converge smoothly to a function u_∞ where $B_r(x) \cap \Sigma_\infty$ is the graph of u_∞.

Notice that there are two obvious necessary conditions for the sequence Σ_i to converge in this sense: The curvatures and areas of the sequence must be locally bounded.

It is not hard to see that the lack of a local area bound is not such a serious problem as long as we have embeddedness. Namely, if we have a uniform curvature bound near x, then the components of $B_r(x) \cap \Sigma_i$ are well-approximated by their tangent planes for r small. Embeddedness then implies that all of these tangent planes must be almost parallel. In particular, these components are all graphs over the same plane of functions with a uniform C^1 bound. We can use the Arzela–Ascoli theorem to pass to a subsequence that "converges" to a *collection* of minimal surfaces that do not cross. The strong maximum principle then implies that two of these limit surfaces must be identical if they touch at all, i.e., they are like the leaves of a foliation. This sort of structure is called a *lamination*.

The failure of the curvature bound is a more serious problem and will force us to allow for a singular set where the sequence simply does not converge smoothly. The simplest example of this is a sequence of rescalings $\lambda_i\,\Sigma$ with $\lambda_i \to 0$ of a fixed non-flat complete embedded minimal surface Σ. This scales the curvature by the factor λ_i^{-1} and, thus, will force the curvature to blow up at the origin. For example, a sequence of rescaled catenoids converges with multiplicity two to the punctured plane. The convergence is smooth except at 0 where $|A|^2 \to \infty$. Notice that 0 is a removable singularity for the limit.

It follows from Choi and Schoen, [1], that a similar singular compactness result holds as long as we assume a uniform bound on the total curvature:

> A subsequence converges smoothly with finite multiplicity away from a finite set of singular points; these singular points are then removable singularities for the limit surface.[1]

The situation is more complicated when there is no a priori total curvature bound. For example, if we take a sequence of rescaled helicoids, then the curvature blows up along the entire vertical axis but is bounded away from this axis. Thus we get:

[1] In fact, one can say a good deal more about the convergence and the structure of the limit; see the 1995 paper of A. Ros in the Indiana University Mathematics Journal.

- The intersection of the rescaled helicoids with a ball *away from* the vertical axis gives a collection of graphs over the plane $\{x_3 = 0\}$. As $i \to \infty$, these graphs become flat and horizontal.

- The intersection of the rescaled helicoids with a ball *centered on* the vertical axis gives a double spiral staircase, rotating faster and faster as $i \to \infty$.

In particular, the sequence of rescaled helicoids converges away from the vertical axis to a foliation by flat parallel planes.

Remark 3.1. The same thing happens when one rescales any surface asymptotic to the helicoid – such as the genus one helicoid constructed by D. Hoffman, M. Weber, and M. Wolf in [21].

If we do the same rescaling to a fixed surface in the family of Riemann examples, then we get convergence away from a line to a foliation by horizontal planes. In this case, the line is *not* perpendicular to the planes.

However, unlike the catenoid and helicoid, the Riemann examples are a two-parameter family. By choosing the two parameters appropriately, one can produce sequences of Riemann examples that illustrate both of the two structure theorems:

1. If we take a sequence of Riemann examples where the neck size is fixed and the angles go to $\frac{\pi}{2}$, then the surfaces with angle near $\frac{\pi}{2}$ can be obtained by gluing together two oppositely-oriented double spiral staircases. Each double spiral staircase looks like a helicoid. This sequence of Riemann examples converges to a foliation by parallel planes. The convergence is smooth away from the axes of the two helicoids (these two axes are the singular set where the curvature blows up).
2. Suppose now that we take a sequence of examples where the neck sizes go to zero. In this case, the surfaces can be cut along short curves into collections of graphical pairs of pants. The short curves converge to singular points where the curvature blows up and the graphical pieces converge to flat planes except at these points.

4. [8]: Compactness of embedded minimal surfaces with fixed genus

We turn next to the main compactness results of [8] for embedded minimal surfaces with fixed genus. We will restrict our discussion to the case of planar domains, i.e., when the surfaces have genus zero, to simplify things. In any case, the general case of fixed genus requires only minor changes.

In this section, $\Sigma_i \subset B_{R_i} \subset \mathbb{R}^3$ is a sequence of compact embedded minimal planar domains with $\partial\Sigma_i \subset \partial B_{R_i}$. Moreover, we will assume that $R_i \to \infty$.

The singular set $\mathcal{S}$ is defined to be the set of points where the curvature is blowing up. That is, a point y in $\mathbb{R}^3$ is in $\mathcal{S}$ for a sequence Σ_i if

$$\sup_{B_r(y)\cap\Sigma_i} |A|^2 \to \infty \quad \text{as } i \to \infty \text{ for all } r > 0. \tag{6}$$

It is not hard to see that we can pass to a subsequence so that $\mathcal{S}$ is well-defined and, furthermore, if $x \notin \mathcal{S}$, then there exists $r_x > 0$ so that

$$\sup_i \sup_{B_{r_x}(x)\cap\Sigma_i} |A| < \infty. \tag{7}$$

4.1. The finer structure of $\mathcal{S}$: Where the topology concentrates. Sequences of planar domains which are not simply connected are, after passing to a subsequence, naturally divided into two separate cases depending on whether or not the topology is concentrating at points. To distinguish between these cases, we will say that a sequence of surfaces $\Sigma_i^2 \subset \mathbb{R}^3$ is *uniformly locally simply connected* (or ULSC) if for each $x \in \mathbb{R}^3$, there exists a constant $r_0 > 0$ (depending on x) so that for every surface Σ_i

$$\text{each connected component of } B_{r_0}(x) \cap \Sigma_i \text{ is a disk.} \tag{8}$$

For instance, a sequence of rescaled catenoids where the necks shrink to zero is not ULSC, whereas a sequence of rescaled helicoids is.

Another way of locally distinguishing sequences where the topology does not concentrate from sequences where it does comes from analyzing the singular set. The singular set $\mathcal{S}$ consists of two types of points. The first type is roughly modelled on rescaled helicoids and the second on rescaled catenoids:

- A point y in $\mathbb{R}^3$ is in $\mathcal{S}_{\text{ulsc}}$ if the curvature for the sequence Σ_i blows up at y and the sequence is ULSC in a neighborhood of y.
- A point y in $\mathbb{R}^3$ is in $\mathcal{S}_{\text{neck}}$ if the sequence is not ULSC in any neighborhood of y. In this case, a sequence of closed non-contractible curves $\gamma_i \subset \Sigma_i$ converges to y.

The sets $\mathcal{S}_{\text{neck}}$ and $\mathcal{S}_{\text{ulsc}}$ are obviously disjoint and the curvature blows up at both, so $\mathcal{S}_{\text{neck}} \cup \mathcal{S}_{\text{ulsc}} \subset \mathcal{S}$. An easy argument (proposition $I.0.19$ in [6]) shows that, after passing to a further subsequence, we can assume that

$$\mathcal{S} = \mathcal{S}_{\text{neck}} \cup \mathcal{S}_{\text{ulsc}}. \tag{9}$$

Note that $\mathcal{S}_{\text{neck}} = \emptyset$ is equivalent to that the sequence is ULSC as is the case for sequences of rescaled helicoids. On the other hand, $\mathcal{S}_{\text{ulsc}} = \emptyset$ for sequences of rescaled catenoids. (These definitions of $\mathcal{S}_{\text{ulsc}}$ and $\mathcal{S}_{\text{neck}}$ are specific to the genus zero case that we are focusing on now; the definitions in the fixed genus case can be found in section 1.1 of [8].)

4.2. Compactness away from $\mathcal{S}$. If we combine the local curvature bound (7) away from $\mathcal{S}$ and a variation on the Arzela–Ascoli theorem, we can pass to a subsequence so that the Σ_i's converge away from $\mathcal{S}$ to a limit lamination $\mathcal{L}'$ of $\mathbb{R}^3 \setminus \mathcal{S}$.

The leaves of $\mathcal{L}'$ are smooth, but not necessarily complete, surfaces. To make this precise, we define the closure Γ_{Clos} of a leaf Γ of $\mathcal{L}'$ to be the union of the closures of all bounded (intrinsic) geodesic balls in Γ; that is, we fix a point $x_\Gamma \in \Gamma$ and set

$$\Gamma_{\text{Clos}} = \bigcup_r \overline{\mathcal{B}_r(x_\Gamma)}, \tag{10}$$

where $\overline{\mathcal{B}_r(x_\Gamma)}$ is the closure of $\mathcal{B}_r(x_\Gamma)$ as a subset of $\mathbb{R}^3$.

Clearly, a leaf Γ is complete if and only if $\Gamma_{\text{Clos}} = \Gamma$ and we always have that

$$\Gamma_{\text{Clos}} \setminus \Gamma \subset \mathcal{S}. \tag{11}$$

The incomplete leaves of Γ can be divided into several types, depending on how Γ_{Clos} intersects $\mathcal{S}$:

- Collapsed leaves where $\Gamma_{\text{Clos}} \cap \mathcal{S}_{\text{ulsc}}$ contains a removable singularity for Γ.
- Leaves Γ with $\Gamma_{\text{Clos}} \cap \mathcal{S}_{\text{ulsc}} \neq \emptyset$, but where Γ does not have a removable singularity. This would occur, for example, if Γ spirals infinitely into the collapsed leaf through $\Gamma_{\text{Clos}} \cap \mathcal{S}_{\text{ulsc}}$. (We show in [8] that this does not occur.)
- Leaves Γ where $\Gamma_{\text{Clos}} \setminus \Gamma \subset \mathcal{S}_{\text{neck}}$; these obviously do not occur in the ULSC case.

4.3. Disks. Before discussing the general ULSC case, it is useful to recall the case of disks. One consequence of [4]–[7] is that there are only two *local models* for ULSC sequences of embedded minimal surfaces. That is, locally in a ball in $\mathbb{R}^3$, one of following holds:

- The curvatures are bounded and the surfaces are locally *graphs* over a plane.
- The curvatures blow up and the surfaces are locally *double spiral staircases*.

Both of these cases are illustrated by taking a sequence of rescalings of the helicoid; the first case occurs away from the axis, while the second case occurs on the axis.

Using in part this local description, we were able to prove that any sequence of embedded minimal disks with curvatures blowing up has a subsequence that converges to a foliation by parallel planes. This convergence is away from a Lipschitz curve $\mathcal{S}$ that is transverse to the planes. (See the appendix for the precise statements.)

4.4. Planar domains: the general structure theorems. We will show that every sequence Σ_i has a subsequence that is either ULSC or for which $\mathcal{S}_{\text{ulsc}}$ is empty. This is the next "no mixing" theorem. We will see later that these two different cases give two very different structures.

Theorem 4.1 (No mixing theorem, [8]). *If the Σ_i's are genus zero, then there is a subsequence with either $\mathcal{S}_{\text{ulsc}} = \emptyset$ or $\mathcal{S}_{\text{neck}} = \emptyset$.*

Common for both the ULSC case and the case where $\mathcal{S}_{\text{ulsc}}$ is empty is that the limits are always laminations by flat parallel planes and the singular sets are always closed subsets contained in the union of the planes. This is the content of the next theorem:

Theorem 4.2 (Planar lamination theorem, [8]). *If the Σ_i's are genus zero and*

$$\sup_{B_1 \cap \Sigma_i} |A|^2 \to \infty, \tag{12}$$

then there exists a subsequence Σ_j, a lamination $\mathcal{L} = \{x_3 = t\}_{\{t \in \mathcal{I}\}}$ of $\mathbb{R}^3$ by parallel planes (where $\mathcal{I} \subset \mathbb{R}$ is a closed set), and a closed nonempty set $\mathcal{S}$ in the union of the leaves of $\mathcal{L}$ such that after a rotation of $\mathbb{R}^3$:

(A) *For each $1 > \alpha > 0$, $\Sigma_j \setminus \mathcal{S}$ converges in the C^α-topology to the lamination $\mathcal{L} \setminus \mathcal{S}$.*

(B) *$\sup_{B_r(x) \cap \Sigma_j} |A|^2 \to \infty$ as $j \to \infty$ for all $r > 0$ and $x \in \mathcal{S}$. (The curvatures blow up along $\mathcal{S}$.)*

4.5. Planar domains: the fine structure theorems. We will assume here that the Σ_i's are not disks (recall that the case of disks was dealt with in [4]–[7]). In particular, we will assume that for each i, there exists some $y_i \in \mathbb{R}^3$ and $s_i > 0$ so that

$$\text{some component of } B_{s_i}(y_i) \cap \Sigma_i \text{ is not a disk.} \tag{13}$$

Moreover, if the non-simply connected balls $B_{s_i}(y_i)$ "run off to infinity" (i.e., if each connected component of $B_{R_i'}(0) \cap \Sigma_i$ is a disk for some $R_i' \to \infty$), then the results of [4]–[7] apply. Therefore, after passing to a subsequence, we can assume that the surfaces are uniformly not disks, namely, that there exists some $R > 0$ so that (13) holds with $s_i = R$ and $y_i = 0$ for all i.

In view of Theorem 4.1 and the earlier results for disks, it is natural to first analyze sequences that are ULSC, so where $\mathcal{S}_{\text{neck}} = \emptyset$, and second analyze sequences where $\mathcal{S}_{\text{ulsc}}$ is empty. We will do this next.

4.6. ULSC sequences. Loosely speaking, our next result shows that when the sequence is ULSC (but not simply connected), a subsequence converges to a foliation by parallel planes away from two lines $\mathcal{S}_1$ and $\mathcal{S}_2$. The lines $\mathcal{S}_1$ and $\mathcal{S}_2$ are disjoint and orthogonal to the leaves of the foliation and the two lines are precisely the points where the curvature is blowing up. This is similar to the case of disks, except that we get two singular curves for non-disks as opposed to just one singular curve for disks.

Theorem 4.3 (ULSC compactness, [8]). *Let a sequence Σ_i, limit lamination $\mathcal{L}$, and singular set $\mathcal{S}$ be as in Theorem* 4.2. *Suppose that each Σ_i satisfies* (13) *with $s_i = R > 1$ and $y_i = 0$. If every Σ_i is ULSC and*

$$\sup_{B_1 \cap \Sigma_i} |A|^2 \to \infty, \tag{14}$$

then the limit lamination $\mathcal{L}$ is the foliation $\mathcal{F} = \{x_3 = t\}_t$ and the singular set $\mathcal{S}$ is the union of two disjoint lines $\mathcal{S}_1$ and $\mathcal{S}_2$ such that:

(C_{ulsc}) *Away from $\mathcal{S}_1 \cup \mathcal{S}_2$, each Σ_j consists of exactly two multi-valued graphs spiraling together. Near $\mathcal{S}_1$ and $\mathcal{S}_2$, the pair of multi-valued graphs form double spiral staircases with opposite orientations at $\mathcal{S}_1$ and $\mathcal{S}_2$. Thus, circling only $\mathcal{S}_1$ or only $\mathcal{S}_2$ results in going either up or down, while a path circling both $\mathcal{S}_1$ and $\mathcal{S}_2$ closes up.*

(D_{ulsc}) *$\mathcal{S}_1$ and $\mathcal{S}_2$ are orthogonal to the leaves of the foliation.*

Remark 4.4. See Appendix A for the definition of a multi-valued graph. Roughly speaking a multi-valued graph is locally a graph over a subset of a plane, but fails to be a global graph since the projection to the plane is not one-to-one.

4.7. Sequences that are not ULSC. When the sequence is no longer ULSC, one can get other types of curvature blow-up by considering the family of embedded minimal planar domains known as the Riemann examples. Recall that, modulo translations and rotations, this is a two-parameter family of periodic minimal surfaces, where the parameters can be thought of as the size of the necks and the angle from one fundamental domain to the next.

With these examples in mind, we are now ready to state our second main structure theorem describing the case where $\mathcal{S}_{\text{ulsc}}$ is empty.

Theorem 4.5 ([8]). *Let a sequence Σ_i, limit lamination $\mathcal{L}$, and singular set $\mathcal{S}$ be as in Theorem* 4.2. *If $\mathcal{S}_{\text{ulsc}} = \emptyset$ and*

$$\sup_{B_1 \cap \Sigma_i} |A|^2 \to \infty, \tag{15}$$

then $\mathcal{S} = \mathcal{S}_{\text{neck}}$ by (9) *and*

(C_{neck}) *Each point y in $\mathcal{S}$ comes with a sequence of graphs in Σ_j that converge to the plane $\{x_3 = x_3(y)\}$. The convergence is in the C^∞ topology away from the point y and possibly also one other point in $\{x_3 = x_3(y)\} \cap \mathcal{S}$. If the convergence is away from one point, then these graphs are defined over annuli; if the convergence is away from two points, then the graphs are defined over disks with two subdisks removed.*

4.8. An overview of the proofs: The ULSC case. A key point will be that the results of [4]–[7] for disks will give a sequence of multi-valued graphs in the Σ_j's near each point $x \in \mathcal{S}_{\text{ulsc}}$. Moreover, these multi-valued graphs close up in the limit to give a leaf of $\mathcal{L}'$ which extends smoothly across x. Such a leaf is said to be *collapsed*; in a neighborhood of x, the leaf can be thought of as a limit of double-valued graphs where the upper sheet collapses onto the lower. We show that every collapsed leaf is stable, has at most two points of $\mathcal{S}_{\text{ulsc}}$ in its closure, and these points are removable singularities. These results on collapsed leaves are applied first in the USLC case and then again to get the structure of the ULSC regions of the limit in general, i.e., (C2) and (D) in Theorem C.1.

Roughly speaking, there are two main steps to the proof of Theorem 4.3:

1. Show that each collapsed leaf is in fact a plane punctured at two points of $\mathcal{S}$ and, moreover, the sequence has the structure of a double spiral staircase near both of these points, with opposite orientations at the two points.
2. Show that leaves which are nearby a collapsed leaf of $\mathcal{L}'$ are also planes punctured at two points of $\mathcal{S}$. (We call this "properness".)

4.9. An overview of the proofs: The general structure. Theorem 4.5, as well as Theorem 4.1, are proven by first analyzing sequences of minimal surfaces without any assumptions on the sets $\mathcal{S}_{\text{ulsc}}$ and $\mathcal{S}_{\text{neck}}$. The precise statement of this general theorem is given in Appendix C. We will give an overview of the theorem next.

In this general case, we show that a subsequence converges to a lamination $\mathcal{L}'$ divided into regions where Theorem 4.3 holds and regions where Theorem 4.5 holds. This convergence is in $C^{1,1}$ topology away from the singular set $\mathcal{S}$ where the curvature blows up. Moreover, each point of $\mathcal{S}$ comes with a plane and these planes are essentially contained in $\mathcal{L}'$. The set of heights of the planes is a closed subset $\mathcal{I} \subset \mathbb{R}$ but may not be all of $\mathbb{R}$ as it was in Theorem 4.3 and may not even be connected. The behavior of the sequence is different at the two types of singular points in $\mathcal{S}$ – the set $\mathcal{S}_{\text{neck}}$ of "catenoid points" and the set $\mathcal{S}_{\text{ulsc}}$ of ULSC singular points. We will see that $\mathcal{S}_{\text{ulsc}}$ consists of a union of Lipschitz curves transverse to the lamination $\mathcal{L}$. This structure of $\mathcal{S}_{\text{ulsc}}$ implies that the set of heights in $\mathcal{I}$ which intersect $\mathcal{S}_{\text{ulsc}}$ is a union of intervals; thus this part of the lamination is foliated. In contrast, we will not get any structure of the set of "catenoid points" $\mathcal{S}_{\text{neck}}$. Given a point y in $\mathcal{S}_{\text{neck}}$, we will get a sequence of graphs in Σ_j converging to a plane through y. This convergence will be in the smooth topology away from either one or two singular points, one of which is y. Moreover, this limit plane through y will be a leaf of the lamination $\mathcal{L}$.

The key steps for proving the general structure theorem are the following:

1. Finding a *stable* plane through each point of $\mathcal{S}_{\text{neck}}$. This plane will be a limit of a sequence of stable graphical annuli that lie in the complement of the surfaces.
2. Finding graphs in Σ_j that converge to a plane through each point of $\mathcal{S}_{\text{neck}}$. To do this, we look in regions between consecutive necks and show that in any

such region the surfaces are ULSC. The one-sided curvature estimate will then allow us to show that these regions are graphical.

3. Using (1) and (2) we then analyze the ULSC regions of a limit. That is, we show that if the closure of a leaf in $\mathcal{L}'$ intersects $\mathcal{S}_{\text{ulsc}}$, then it has a neighborhood that is ULSC. This will allow us to use the argument for the proof of Theorem 4.3 to get the same structure for such a neighborhood as we did in case where the entire surfaces where ULSC.

The main point left in Theorem 4.5, which is not included in this general compactness theorem, is to prove that *every* leaf of the lamination $\mathcal{L}$ in Theorem 4.5 is a plane. In contrast, the general compactness theorem gives a plane through each point of $\mathcal{S}_{\text{neck}}$, but does not claim that the leaves of $\mathcal{L}'$ are planar.

Finally, since the no mixing theorem implies that Theorem 4.3 and Theorem 4.5 cover all cases, Theorem 4.2 will be a corollary of these two theorems.

5. The structure of embedded minimal annuli

We turn next to a local structure theorem for embedded minimal annuli that, roughly speaking, shows that they must look like catenoids. Namely, the main theorem of [10] proves that any embedded minimal annulus in a ball (with boundary in the boundary of the ball and) with a small neck can be decomposed by a simple closed geodesic into two graphical sub-annuli. Moreover, there is a sharp bound for the length of this closed geodesic in terms of the separation (or height) between the graphical sub-annuli. This serves to illustrate the "pair of pants" decomposition from [8] in the special case where the embedded minimal planar domain is an annulus.

The precise statement of this decomposition for annuli is:

Theorem 5.1 (Main Theorem, [10]). *There exist $\varepsilon > 0$, $C_1,\ C_2,\ C_3 > 1$ so: If $\Sigma \subset B_R \subset \mathbb{R}^3$ is an embedded minimal annulus with $\partial\Sigma \subset \partial B_R$ and $\pi_1(B_{\varepsilon R} \cap \Sigma) \neq 0$, then there is a simple closed geodesic $\gamma \subset \Sigma$ of length ℓ so that:*

- *The curve γ splits the connected component of $B_{R/C_1} \cap \Sigma$ containing it into annuli Σ^+ and Σ^-, each with $\int |A|^2 \leq 5\,\pi$.*
- *Each of $\Sigma^{\pm} \setminus \mathcal{T}_{C_2\,\ell}(\gamma)$ is a graph with gradient ≤ 1.*
- *$\ell \log(R/\ell) \leq C_3\, h$ where the separation h is given by*

$$h = \min_{x_{\pm} \in \partial B_{R/C_1} \cap \Sigma^{\pm}} |x_+ - x_-|. \tag{16}$$

Here $\mathcal{T}_s(S) \subset \Sigma$ denotes the intrinsic s-tubular neighborhood of a subset $S \subset \Sigma$.

5.1. A sketch of the proof. We will next give a brief sketch of the proof of the decomposition theorem, Theorem 5.1. The starting point is to use the hypothesis $\pi_1(B_{\varepsilon R} \cap \Sigma) \neq 0$ and a barrier argument to find a stable graph Γ_0 that is defined over an annulus and disjoint from Σ. The stable graph Γ_0 will allow us to divide Σ into two pieces, one on each side of Γ_0. To do this, we first fix a simple closed $\tilde{\gamma} \subset B_{\varepsilon R} \cap \Sigma$ that separates the two boundary components of Σ. The curve $\tilde{\gamma}$ is contained in a small extrinsic ball, but there is no a priori reason why it must be short.[2] A barrier argument using a result of Meeks and Yau then gives a stable embedded minimal annulus Γ that separates the two boundary components of Σ and where $\tilde{\gamma}$ is one component of the boundary $\partial\Gamma$ and the other component is in ∂B_R. Finally, Theorem 0.3 of [6] then implies that Γ contains the desired graph Γ_0; this should be compared with the well-known result of D. Fischer-Colbrie in the complete case.

We will see next that each half of Σ, i.e., the part above Γ_0 and the part below Γ_0, is itself a graph away from the boundary of Γ_0. This part of the argument applies more generally to an "annular end" of a minimal surface. We will prove that each half of Σ contains a graph by showing that it must contain large locally graphical pieces and then using embeddedness to see that these pieces must be global graphs (i.e., the projection down is one-to-one). This follows by combining three facts:

(1) The one-sided curvature estimate of [4]–[7] gives a scale-invariant curvature estimate for Σ's in a narrow cone about the graph Γ_0. This requires that we know that each component of Σ in balls away from the origin is a disk; this can be seen from the maximum principle.

(2) Using (1), the gradient estimate gives a narrower cone about Γ_0 where Σ is locally graphical. This is because (1) implies that the surface is well-approximated by its tangent plane and, since it cannot cross Γ_0, it must be almost parallel to Γ_0.

(3) As long as ε is small enough, each half of Σ must intersect any narrow cone about Γ_0. This was actually proven in lemma 3.3 of [9] that gave the existence of low points in a *connected* minimal surface contained on one side of a plane and with interior boundary close to this plane.[3]

Step (3) allows us to find very flat regions in Σ near Γ_0, we can then repeatedly apply the Harnack inequality to build this out into large locally graphical regions that stay inside the narrow cone about Γ_0. These locally graphical regions piece together to give a graph over an annulus; the other possibility would be to form a multi-valued graph, but this is impossible since such a multi-valued graph would be forced to spiral infinitely (since it cannot cross itself and also cannot cross the stable graph Γ_0).

[2]However, the chord arc bounds in the later paper [15] could now be used to bound the length.

[3]The argument for this was by contradiction. Namely, if there were no low points, then we would get a contradiction from the strong maximum principle by first sliding a catenoid up under the surface and then sliding the catenoid horizontally away, eventually separating two boundary components of the surface. Here the strong maximum principle is used to keep the sliding catenoids and the surface disjoint. See, for instance, corollary 1.18 in [2] for a precise statement of the strong maximum principle.

Finally, the last step of the proof is to use a blow up argument to get the precise bounds on the length of the curve γ.

5.2. Complete properly embedded minimal annuli. The decomposition of properly embedded minimal annuli given by Theorem 5.1 can be viewed as a local version of well-known global results of P. Collin, [18], and Colding and the author, [13], on annular ends.

To explain these global results, recall that Σ is said to have *finite topology* if it is homeomorphic to a closed Riemann surface with a finite number of punctures; the genus of Σ is then the genus of this Riemann surface and the number of punctures is the number of ends. It follows that a neighborhood of each puncture corresponds to a properly embedded annular end of Σ. Perhaps surprisingly at first, the more restrictive case is when Σ has more than one end. The reason for this is that a barrier argument gives a stable minimal surface between any pair of ends. Such a stable surface is then asymptotic to a plane (or catenoid), essentially forcing each end to live in a half-space. Using this restriction, P. Collin proved:

Theorem 5.2 (Main theorem, [18]). *Each end of a complete properly embedded minimal surface with finite topology and at least two ends is asymptotic to a plane or catenoid.*

In particular, such a Σ has finite total curvature and, outside some compact set, Σ is given by a finite collection of disjoint graphs over a common plane.

As mentioned above, Collin proved Theorem 5.2 by showing that an embedded annular end that lives in a half-space must have finite total curvature. [13] used the one-sided curvature estimate to strengthen this from a half-space to a strictly larger cone, and in the process give a very different proof of Collin's theorem.

Theorem 5.3 (Main theorem, [13]). *There exists $\varepsilon > 0$ so that any complete properly embedded minimal annular end contained in the cone*

$$\{x_3 \geq -\varepsilon\,(x_1^2 + x_2^2 + x_3^2)^{1/2}\} \tag{17}$$

is asymptotic to a plane or catenoid.

6. Properness and removable singularities for minimal laminations

The compactness theorems of [4]–[8] assume that the surface Σ_i has boundary $\partial\Sigma_i$ in the boundary ∂B_{R_i} of an expanding sequence of balls where R_i goes to infinity. We call this the *global* case, in contrast to the *local* case where the boundaries are in the boundary of a fixed ball ∂B_R.[4]

This distinction between the local and global cases explains why the global compactness theorem for sequences of disks does not imply the compactness theorem for

[4]One can also consider the more restrictive *complete* case where Σ_i is complete without boundary.

ULSC sequences. Namely, even though the ULSC sequence consists *locally* of disks, the compactness result for disks was in the *global* case where the radii go to infinity and hence does not apply.

In order to focus the discussion, we will explain the differences between the global and local cases for disks. The assumption that $R_i \to \infty$ is used in the compactness theorem for disks in two ways:

(1) We show that the limit lamination contains a stable leaf through each singular point. Since $R_i \to \infty$, this stable leaf is complete and, hence, a plane by the Bernstein theorem of D. Fischer-Colbrie and R. Schoen and M. Do Carmo and C. Peng.

(2) We show next that the leaves nearby a singular point must also be planes. It follows that the singular set cannot stop and all of $\mathbb{R}^3$ is foliated by planes in the limit. We call this *properness*.

The use of $R_i \to \infty$ in (1) is not really essential. The leaf would no longer have to be flat in the local case, but it would satisfy uniform estimates by R. Schoen's curvature estimate for stable surfaces, [37] (cf. [3]).

In contrast, it turns out that the use of $R_i \to \infty$ in (2) is essential. Namely, in [14], we constructed a sequence of embedded minimal disks Σ_i in the unit ball B_1 with $\partial\Sigma_i \subset \partial B_1$ where the curvatures blow up only at 0 and

$$\Sigma_i \setminus \{x_3 = 0\} \tag{18}$$

converges to two embedded minimal disks

$$\Sigma^- \subset \{x_3 < 0\}, \tag{19}$$

$$\Sigma^+ \subset \{x_3 > 0\}, \tag{20}$$

each of which spirals into $\{x_3 = 0\}$ and thus is not proper. Thus, in the example from [14], 0 is the first, last, and only point in $\mathcal{S}_{\text{ulsc}}$ and the limit lamination consists of three leaves: Σ^+, Σ^-, and the punctured unit disk $B_1 \cap \{x_3 = 0\} \setminus \{0\}$. This lamination of $B_1 \setminus \{0\}$ cannot be extended smoothly to a lamination of B_1; that is to say, 0 is not a removable singularity. This should be contrasted with the global case where every singular point is a removable singularity for the limit foliation by parallel planes. B. Dean has constructed similar examples where the singular set is an arbitrary finite set of points in the vertical axis; see [20].

6.1. A sketch of the proof of properness for disks. To explain the proof of properness in the global case for disks, we first need to see what could go wrong. Suppose therefore that the origin 0 is a singular point and $\{x_3 = 0\}$ is the corresponding limit plane. It follows from the one-sided curvature estimate that the intersection of each Σ_j with a low cone about $\{x_3 = 0\}$ consists of two multi-valued graphs for j large (the fact that there are exactly two is established in proposition II.1.3 in [7]). There are now two possibilities:

(P) The multi-valued graphs in the complement of the cone close up in the limit to a foliation.

(N-P) These multi-valued graphs converge to a collection of graphs and *at least one* multi-valued graph that spirals infinitely on one side of $\{x_3 = 0\}$.

As we saw above, the second case (N-P) can occur in the local case. We will explain why it cannot happen in the global case.

Suppose therefore that (N-P) holds and the limit contains a multi-valued graph that spirals infinitely down to the plane $\{x_3 = 0\}$; it is the graph of a multi-valued function $u(\rho, \theta)$ defined for all $\rho \geq \mathrm{e}$ and *all* $\theta > 0$. The separation $w(\rho, \theta)$ between consecutive sheets is by definition

$$w(\rho, \theta) = u(\rho, \theta + 2\pi) - u(\rho, \theta). \tag{21}$$

Since the limit is embedded and spirals downward, we must have $w < 0$. We will actually work with the conformally changed functions $\tilde{u}(x + iy) = u(\mathrm{e}^x, y)$ and $\tilde{w}(x + iy) = w(\mathrm{e}^x, y)$ that are defined on the quadrant $\{x > 1,\ y > 0\}$. The key point in the proof of properness is to show that:

(Key) The vertical flux across $\{x = 1\}$ is negative infinity.

Why (Key) *leads to a contradiction*: To see why (Key) leads to a contradiction, we need to recall more about the limit in case (N-P). Namely, we showed in [7] that there must be two multi-valued graphs spiralling together just as occurs for the helicoid. The same argument applies to both multi-valued graphs, so both have unbounded negative flux across $\{x = 1\}$, i.e., over the circle of radius e in the plane. Moreover, we also showed in [7] that these two halves can be joined together by curves in the embedded minimal disk with a uniform bound on the length of the curves. For example, the helicoid contains two infinite valued graphs and these can be connected by horizontal lines. In any case, this leads to a flux contradiction: Stokes' theorem implies that the sum of the fluxes across compact subcurves over the circle of radius e must be bounded by the length of the connecting curves. However, the length of the connecting curves is uniformly bounded and the fluxes across the other curves both go to negative infinity.

The idea of the proof of (Key): In order to keep things simple, we will pretend that u is a harmonic function; this serves to illustrate the main ideas. Since the separation w is locally the difference of two harmonic functions, w is also harmonic; hence, the conformally changed functions $\tilde{u}$ and $\tilde{w}$ are harmonic on the quadrant $\{x > 1,\ y > 0\}$. Note that $\tilde{u}$ is positive and $\tilde{w}$ is negative.

The property (Key) is now roughly equivalent to showing that

$$\int_0^\infty \frac{\partial \tilde{u}}{\partial x}(1, y)\, dy = +\infty. \tag{22}$$

It may be helpful to consider an example; the function $\tilde{u} = \pi/2 - \arctan(y/x)$ is positive, harmonic, and its multi-valued graph is an embedded infinite spiral that

accumulated to the plane $\{x_3 = 0\}$. Furthermore, is is easy to verify (22) in this case:

$$\int_0^\infty \frac{\partial \tilde{u}}{\partial x}(1, y)\, dy = \int_0^\infty \frac{y}{1+y^2}\, dy = +\infty. \tag{23}$$

To prove (22) for a general function $\tilde{u}$, first observe that Stokes' theorem gives

$$\int_1^R \frac{\partial \tilde{u}}{\partial x}(1, y)\, dy + \int_1^R \frac{\partial \tilde{u}}{\partial y}(x, 1)\, dx = \int_{\{x^2+y^2=R^2+1,\, x>1,\, y>1\}} \frac{\partial u}{\partial r}. \tag{24}$$

In [10], we used the lower bound $\tilde{u} \geq 0$ to prove that

$$\int_{\{x^2+y^2=R^2+1,\, x>1,\, y>1\}} \frac{\partial u}{\partial r} \tag{25}$$

is essentially non-negative. The reason for this is that (25) measures the logarithmic rate of growth of the average of $\tilde{u}$ on the semi-circle; if this was negative, the function $\tilde{u}$ would eventually have to become negative.

We then proved the claim (24) in [10] by using a sharp estimate for the decay of $\tilde{w}$ to show that

$$\int_1^\infty \frac{\partial \tilde{u}}{\partial y}(x, 1)\, dx = -\infty. \tag{26}$$

To explain this, observe that $\tilde{w}(x, 1)$ is nothing more than $\tilde{u}(x, 1+2\pi) - \tilde{u}(x, 1)$ and, hence, can be written as

$$\tilde{w}(x, 1) = \int_1^{1+2\pi} \frac{\partial \tilde{u}}{\partial y}(x, y)\, dy. \tag{27}$$

In particular, $\tilde{w}(x, 1) \approx 2\pi\, \frac{\partial \tilde{u}}{\partial y}(x, 1)$. We proved in [10] that the fastest possible decay for $|\tilde{w}(x, 1)|$ is c_1/x and, consequently, we get that

$$\int_1^\infty \tilde{w}(x, 1)\, dx = -\infty. \tag{28}$$

This completes the sketch of the proof. The actual argument in [10] is somewhat more complicated, but similar in flavor.

7. The uniqueness of the helicoid

The helicoid and plane are the only classical examples of properly embedded complete minimal disks in $\mathbb{R}^3$. It turns out that there is a good reason for the scarcity of examples. Namely, using the compactness theorem and one-sided curvature estimate of [4]–[7], W. Meeks and H. Rosenberg proved the uniqueness of the helicoid:

Theorem 7.1 (Main theorem, [31]). *The plane and helicoid are the only complete properly embedded simply-connected minimal surfaces in* $\mathbb{R}^3$.

This uniqueness has many applications, including additional regularity of the singular set $\mathcal{S}$. To set this us, recall that if we take a sequence of rescalings of the helicoid, then the singular set $\mathcal{S}$ for the convergence is the vertical axis perpendicular to the leaves of the foliation. In [25], W. Meeks used this fact together with the uniqueness of the helicoid to prove that the singular set $\mathcal{S}$ in Theorem B.1 is always a straight line perpendicular to the foliation.

There is an analog of Theorem 7.1 in the higher genus case. Namely, any properly embedded minimal surface with finite (non-zero) genus and one end must be asymptotic to a helicoid. Until recently, it was not known whether any such surface exists; however, the construction of the genus one helicoid in [21] suggests that there may be a substantial theory of these.

Remark 7.2. It follows from [15] that any complete embedded minimal surface with finite topology in $\mathbb{R}^3$ is automatically properly embedded. In particular, the hypothesis of properness can be removed from Theorem 7.1.

7.1. A sketch of the proof. We will give a brief overview of the proof by Meeks and Rosenberg for the uniqueness of the helicoid; we refer to the original paper [31] for the details.

The first main step in the proof of Theorem 7.1 is to analyze the asymptotic structure of a non-flat embedded minimal disk Σ, showing that it looks roughly like a helicoid. This is done in [31] by analyzing sequences of rescalings of Σ. This rescaling argument yields a sequence of embedded minimal disks which does not converge in the classical sense (there are no local area bounds). However, the lamination theorem of [4]–[7] gives that a subsequence converges to a foliation by parallel planes away from a Lipschitz curve transverse to these planes. Moreover, the lamination theorem also gives that the intersection of Σ with a cone consists of two asymptotically flat multi-valued graphs. In particular, this foliation is unique, i.e., does not depend on the choice of subsequence. After possibly rotating $\mathbb{R}^3$, we can assume that the limit foliation is by horizontal planes (i.e., level sets of x_3).

The second main step is to show that the height function x_3 together with its harmonic conjugate (which we will denote by x_3^*) give global isothermal coordinates on Σ. This step is crucial since it reduces the problem to analyzing the potential Weierstrass data on the plane. There are two key components to getting these global coordinates, both of independent interest. First, one must show that ∇x_3 does not vanish on Σ – i.e., that the Gauss map misses the north and south poles. Second, one must show that the map (x_3, x_3^*) is proper – i.e., that x_3^* goes to infinity as we go out horizontally. Both of these steps strongly use the asymptotic structure established in the first step.

The third main step is to analyze the Weierstrass data in the conformal coordinates (x_3, x_3^*). In these coordinates, the only unknown is a meromorphic function g that is the stereographic projection of the Gauss map of Σ. Since the Gauss map was already shown to miss the north and south poles, the function g can be written as

$g = e^f$ for an entire holomorphic function f. Meeks and Rosenberg then use a Picard type argument to show that f must be linear. The key in this argument is to analyze the inverse images of horizontal circles in $\mathbb{S}^2$ under the Gauss map $\boldsymbol{n}$, using rescaling arguments and the compactness theory of [4]–[7] to control the number of components. Finally, every linear function f gives rise to a surface in the associate surface family of the helicoid, but the actual helicoid is the only one of these that is embedded.

8. Quasiperiodicity of properly embedded minimal planar domains

We turn next to recent results of W. Meeks, J. Perez, and A. Ros on the structure of *complete* properly embedded minimal planar domains with infinitely many ends in $\mathbb{R}^3$. They have obtained many important results on these surfaces in the series of papers [28]–[30]; we have chosen to focus on the main result of [28].

Many of these structure results are motivated by the two-parameter family of minimal planar domains known as the Riemann examples mentioned earlier.

8.1. A few definitions. To set this up, we first recall a few properties of a complete properly embedded minimal planar domain $M \subset \mathbb{R}^3$.

First, it follows from a barrier argument of Meeks and Yau that one can find a stable embedded annulus between each pair of ends of M; a result of Fischer-Colbrie then implies that this stable surface has finite total curvature, so its ends are asymptotic to planes or half-catenoids. Since M is embedded, these planes or half-catenoids between its ends must all be parallel; this plane is the *limit tangent plane at infinity*.

Using these planes and half-catenoids in this way, Callahan, Frohman, Hoffman, and Meeks showed that the ends of M are ordered by height over this limit tangent plane at infinity. Moreover, a nice argument of Collin, Kusner, Meeks, and Rosenberg in [19] shows that there are at most two *limit ends*; these can only be on the "top" or on the "bottom".

Finally, since the coordinate functions are harmonic on any minimal surface, it follows from Stokes' theorem that the flux of a coordinate function x_i around a closed curve γ depends only on its homology class $[\gamma]$. Recall that the flux of x_i around γ is

$$\int_\gamma \frac{\partial x_i}{\partial n}, \tag{29}$$

where $\frac{\partial x_i}{\partial n}$ is the derivative of x_i in the conormal direction, i.e., the direction tangent to M but normal to γ. Using all three coordinates functions at once gives the *flux* map

$$\text{Flux}\colon [\gamma] \to \mathbb{R}^3. \tag{30}$$

8.2. The curvature estimate of [28]. We can now define $\mathcal{M}$ to be the space of properly embedded minimal planar domains in $\mathbb{R}^3$ with two limit ends, normalized so that every surface $M \in \mathcal{M}$ has horizontal limit tangent plane at infinity and the vertical component of its flux equals one. Here the horizontal flux is the projection of the flux vector to the limit tangent plane at infinity.

The main theorem of [28] is:

Theorem 8.1 (Theorem 5, [28]). *If a sequence $M_i \in \mathcal{M}$ has bounded horizontal flux, then the Gaussian curvature of the sequence is uniformly bounded.*

Remark 8.2. The main result in [29] is that there must always be two limit ends; thus this hypothesis can be removed from Theorem 8.1.

The first important application of the curvature estimates is to describe the geometry of a properly embedded minimal planar domain M with two limit ends:

> Such a surface M has bounded curvature and is conformally a compact Riemann surface punctured in a countable closed subset with two limit points; the spacing between consecutive ends is bounded from below in terms of the bound for the curvature; M is quasiperiodic in the sense that there exists a divergent sequence $V(n) \in \mathbb{R}^3$ such that the translated surfaces $M + V(n)$ converge to a properly embedded minimal surface of genus zero, two limit ends, a horizontal limit tangent plane at infinity and with the same flux as M.

Another particularly interesting consequence of Theorem 8.1 is a solution of an old conjecture of Nitsche:

Theorem 8.3 (Theorem 1, [28]). *Any complete minimal surface which is a union of simple closed curves in horizontal planes must be a catenoid.*

8.3. A heuristic argument for Theorem 8.1. Theorem 8.1 is best illustrated by considering the family of singly-periodic minimal surfaces known as the Riemann examples. After normalizing so the vertical flux is one and rotating so the horizontal flux points in the x_1-direction, there is a 1-parameter family parameterized by the length of the horizontal flux H. As $H \to 0$, this degenerates to a catenoid; when $H \to \infty$, this degenerates to a helicoid.

With this in mind, there is a simple heuristic argument for why such an estimate should hold. Namely, assume that $|A|^2(0) \to \infty$ for a sequence Σ_i and consider two possibilities:

1. The injectivity radius goes to zero.
2. Each Σ_i is uniformly simply connected.

In the first case, we would get short dividing curves in Σ_i; integrating around these would then imply that the flux was going to zero (violating the normalization).

In the second case, the results of Colding and the author in [8] give a limit plane through the origin which, by the uniqueness of the helicoid of Meeks and H. Rosenberg, is locally modelled by the helicoid for large i. As discussed above, this corresponds (roughly, at least) to a great deal of horizontal flux, violating the assumed bound on this.

The actual argument is much more complicated but has at least a similar flavor. One reason for the complications is that the dichotomy (1) or (2) above is more subtle; (1) involves the intrinsic distance while (2) uses the extrinsic distance. This dichotomy can now be made rigorous using the proof of the Calabi–Yau conjectures for embedded minimal surfaces with finite topology in [15]; however, the proof of Theorem 8.1 came before [15], so intrinsic and extrinsic distances were not yet known to be equivalent.

Appendix

A. Multi-valued graphs

We have used two notions of multi-valued graphs – namely, the one used in [4]–[7] and a generalization.

In [4]–[7], we defined multi-valued graphs as multi-sheeted covers of the punctured plane. To be precise, let D_r be the disk in the plane centered at the origin and of radius r and let $\mathcal{P}$ be the universal cover of the punctured plane $\mathbb{C} \setminus \{0\}$ with global polar coordinates (ρ, θ) so $\rho > 0$ and $\theta \in \mathbb{R}$. An N-valued graph of a function u on the annulus $D_s \setminus D_r$ is a single valued graph over

$$\{(\rho, \theta) \mid r \leq \rho \leq s,\ |\theta| \leq N\pi\}. \tag{31}$$

Note that the helicoid is the union of two infinite-valued graphs over the punctured plane together with the vertical axis.

Locally, the above multi-valued graphs give the complete picture for a ULSC sequence. However, the global picture can consist of several different multi-valued graphs glued together. To allow for this, we are forced to consider multi-valued graphs defined over the universal cover of $\mathbb{C} \setminus P$ where P is a discrete subset of the complex plane $\mathbb{C}$. We will see that the bound on the genus implies that P consists of at most two points.

B. The lamination theorem and one-sided curvature estimate

The first theorem that we recall shows that embedded minimal disks are either graphs or are part of double spiral staircases; moreover, a sequence of such disks with curvature blowing up converges to a foliation by parallel planes away from a singular

curve $\mathcal{S}$. This theorem is modelled on rescalings of the helicoid and the precise statement is as follows (we state the version for extrinsic balls; it was extended to intrinsic balls in [11]):

Theorem B.1 (Theorem 0.1 in [7]). *Let $\Sigma_i \subset B_{R_i} = B_{R_i}(0) \subset \mathbb{R}^3$ be a sequence of embedded minimal disks with $\partial\Sigma_i \subset \partial B_{R_i}$ where $R_i \to \infty$. If*

$$\sup_{B_1 \cap \Sigma_i} |A|^2 \to \infty, \tag{32}$$

then there exists a subsequence, Σ_j, and a Lipschitz curve $\mathcal{S}: \mathbb{R} \to \mathbb{R}^3$ such that after a rotation of $\mathbb{R}^3$:

1. *$x_3(\mathcal{S}(t)) = t$. (That is, $\mathcal{S}$ is a graph over the x_3-axis.)*
2. *Each Σ_j consists of exactly two multi-valued graphs away from $\mathcal{S}$ (which spiral together).*
3. *For each $1 > \alpha > 0$, $\Sigma_j \setminus \mathcal{S}$ converges in the C^α-topology to the foliation, $\mathcal{F} = \{x_3 = t\}_t$, of $\mathbb{R}^3$.*
4. *$\sup_{B_r(\mathcal{S}(t)) \cap \Sigma_j} |A|^2 \to \infty$ for all $r > 0$, $t \in \mathbb{R}$. (The curvatures blow up along $\mathcal{S}$),*

The second theorem that we need to recall asserts that every embedded minimal disk lying above a plane, and coming close to the plane near the origin, is a graph. Precisely this is the *intrinsic one-sided curvature estimate* which follows by combining [7] and [11]:

Theorem B.2. *There exists $\varepsilon > 0$, so that if*

$$\Sigma \subset \{x_3 > 0\} \subset \mathbb{R}^3 \tag{33}$$

is an embedded minimal disk with $\mathcal{B}_{2R}(x) \subset \Sigma \setminus \partial\Sigma$ and $|x| < \varepsilon R$, then

$$\sup_{\mathcal{B}_R(x)} |A_\Sigma|^2 \leq R^{-2}. \tag{34}$$

Theorem B.2 is in part used to prove the regularity of the singular set where the curvature is blowing up.

Note that the assumption in Theorem B.1 that the surfaces are disks is crucial and cannot even be replaced by assuming that the sequence is ULSC. To see this, observe that one can choose a one-parameter family of Riemann examples which is ULSC but where the singular set $\mathcal{S}$ is given by a *pair* of vertical lines. Likewise, the assumption in Theorem B.2 that Σ is simply connected is crucial as can be seen from the example of a rescaled catenoid, see (3). Under rescalings the catenoid converges (with multiplicity two) to the flat plane. Thus a neighborhood of the neck can be scaled arbitrarily close to a plane but the curvature along the neck becomes unbounded as it gets closer to the plane. Likewise, by considering the universal cover of the catenoid, one sees that embedded, and not just immersed, is needed in Theorem B.2.

C. The precise statement of the general compactness theorem

The precise statement of the compactness theorem for sequences that are neither necessarily ULSC nor with $\mathcal{S}_{\text{ulsc}} = \emptyset$ is the following:

Theorem C.1 ([8]). *Let $\Sigma_i \subset B_{R_i} = B_{R_i}(0) \subset \mathbb{R}^3$ be a sequence of compact embedded minimal planar domains with $\partial\Sigma_i \subset \partial B_{R_i}$ where $R_i \to \infty$. If*

$$\sup_{B_1 \cap \Sigma_i} |A|^2 \to \infty, \tag{35}$$

then there is a subsequence Σ_j, a closed set $\mathcal{S}$, and a lamination $\mathcal{L}'$ of $\mathbb{R}^3 \setminus \mathcal{S}$ so that:

(A) *For each $1 > \alpha > 0$, $\Sigma_j \setminus \mathcal{S}$ converges in the C^α-topology to the lamination $\mathcal{L}'$.*

(B) $\sup_{B_r(x)\cap\Sigma_j} |A|^2 \to \infty$ *as $j \to \infty$ for all $r > 0$ and $x \in \mathcal{S}$. (The curvatures blow up along $\mathcal{S}$).*

(C1) (C_{neck}) *from Theorem* 4.5 *holds for each point y in $\mathcal{S}_{\text{neck}}$.*

(C2) (C_{ulsc}) *from Theorem* 4.3 *holds locally near $\mathcal{S}_{\text{ulsc}}$. More precisely, each point y in $\mathcal{S}_{\text{ulsc}}$ comes with a sequence of multi-valued graphs in Σ_j that converge to the plane $\{x_3 = x_3(y)\}$. The convergence is in the C^∞ topology away from the point y and possibly also one other point in $\{x_3 = x_3(y)\} \cap \mathcal{S}_{\text{ulsc}}$. These two possibilities correspond to the two types of multi-valued graphs defined in Section A.*

(D) *The set $\mathcal{S}_{\text{ulsc}}$ is a union of Lipschitz curves transverse to the lamination. The leaves intersecting $\mathcal{S}_{\text{ulsc}}$ are planes foliating an open subset of $\mathbb{R}^3$ that does not intersect $\mathcal{S}_{\text{neck}}$. For the set $\mathcal{S}_{\text{neck}}$, we make no claim about the structure.*

(P) *Together* (C1) *and* (C2) *give a sequence of graphs or multi-valued graphs converging to a plane through each point of $\mathcal{S}$. If P is one of these planes, then each leaf of $\mathcal{L}'$ is either disjoint from P or is contained in P.*

Note that Theorem C.1 is a technical tool that is superseded by the stronger compactness theorems in the ULSC and non-ULSC cases, Theorem 4.3 and Theorem 4.5. This is because we will know by the no mixing theorem that either $\mathcal{S}_{\text{neck}} = \emptyset$ or $\mathcal{S}_{\text{ulsc}} = \emptyset$, so that these cover all possible cases.

Floer homology in symplectic geometry and in mirror symmetry

Yong-Geun Oh* and Kenji Fukaya

Abstract. In this article the authors review what the Floer homology is and what it does in symplectic geometry both in the closed string and in the open string context. In the first case, the authors will explain how the chain level Floer theory leads to the C^0 symplectic invariants of Hamiltonian flows and to the study of topological Hamiltonian dynamics. In the second case, the authors explain how Floer's original construction of Lagrangian intersection Floer homology is obstructed in general as soon as one leaves the category of exact Lagrangian submanifolds. They will survey the construction of the Floer complex and describe its obstruction in terms of the filtered A_∞-algebras. This can be promoted to the level of A_∞-category (Fukaya category) of symplectic manifolds. Some applications of this general machinery to the study of the topology of Lagrangian embeddings in relation to symplectic topology and to mirror symmetry are also reviewed.

Mathematics Subject Classification (2000). Primary 53D40; Secondary 14J32.

Keywords. Floer homology, Hamiltonian flows, Lagrangian submanifolds, A_∞-structure, mirror symmetry.

1. Prologue

The Darboux theorem in symplectic geometry manifests *flexibility* of the group of symplectic transformations. On the other hand, the following celebrated theorem of Eliashberg [El1] revealed subtle *rigidity* of symplectic transformations: *The subgroup* $\mathrm{Symp}(M, \omega)$ *consisting of symplectomorphisms is closed in* $\mathrm{Diff}(M)$ *with respect to the* C^0*-topology.*

This demonstrates that the study of symplectic topology is subtle and interesting. Eliashberg's theorem relies on a version of non-squeezing theorem as proven by Gromov [Gr]. Gromov [Gr] uses the machinery of pseudo-holomorphic curves to prove his theorem. There is also a different proof by Ekeland and Hofer [EH] of the classical variational approach to Hamiltonian systems. The interplay between these two facets of symplectic geometry has been the main locomotive in the development of symplectic topology since Floer's pioneering work on his 'semi-infinite' dimensional homology theory, now called the *Floer homology theory*.

*Oh thanks A. Weinstein and late A. Floer for putting everlasting marks on his mathematics. Both authors thank H. Ohta and K. Ono for a fruitful collaboration on the Lagrangian intersection Floer theory where some part of this survey is based on.

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

As in classical mechanics, there are two most important boundary conditions in relation to Hamilton's equation $\dot{x} = X_H(t, x)$ on a general symplectic manifold: one is the *periodic* boundary condition $\gamma(0) = \gamma(1)$, and the other is the *Lagrangian* boundary condition $\gamma(0) \in L_0,\ \gamma(1) \in L_1$ for a given pair (L_0, L_1) of two Lagrangian submanifolds: A submanifold $i : L \hookrightarrow (M, \omega)$ is called Lagrangian if $i^*\omega = 0$ and $\dim L = \frac{1}{2} \dim M$. The latter replaces the *two-point* boundary condition in classical mechanics.

In either of the above two boundary conditions, we have a version of the *least action principle*: a solution of Hamilton's equation corresponds to a critical point of the action functional on a suitable path space with the corresponding boundary condition. For the periodic boundary condition we consider the free loop space

$$\mathcal{L}M = \{\gamma : S^1 \to M\},$$

and for the Lagrangian boundary condition we consider the space of paths connecting

$$\Omega(L_0, L_1) = \{\gamma : [0, 1] \to M \mid \gamma(0) \in L_0,\ \gamma(1) \in L_1\}.$$

Both $\mathcal{L}M$ and $\Omega(L_0, L_1)$ have countable number of connected components. For the case of $\mathcal{L}M$, it has a distinguished component consisting of the contractible loops. On the other hand, for the case of $\Omega(L_0, L_1)$ there is no such distinguished component in general.

Daunting Questions. For a given time dependent Hamiltonian $H = H(t, x)$ on (M, ω), does there exist a solution of the Hamilton equation $\dot{x} = X_H(t, x)$ with the corresponding boundary conditions? If so, how many different ones can exist?

One crucial tool for the study of these questions is the least action principle. Another seemingly trivial but crucial observation is that when $H \equiv 0$ for the closed case and when $L_1 = L_0$ (and $H \equiv 0$) for the open case, there are "many" solutions given by *constant* solutions. It turns out that these two ingredients, combined with Gromov's machinery of pseudo-holomorphic curves, can be utilized to study each of the above questions, culminating in Floer's proof of Arnold's conjecture for the fixed points [Fl2], and for the intersection points of L with its Hamiltonian deformation $\phi_H^1(L)$ [Fl1] for the exact case respectively.

We divide the rest of our exposition into two categories, one in the closed string and the other in the open string context.

2. Floer theory of Hamiltonian fixed points

2.1. Construction. On a symplectic manifold (M, ω), for each given time-periodic Hamiltonian H i.e., H with $H(t, x) = H(t + 1, x)$, there exists an analog $\mathcal{A}_H$ to the classical action functional defined on a suitable covering space of the free loop space.

To exploit the fact that in the vacuum, i.e., when $H \equiv 0$, we have many constant solutions all lying in the distinguished component of the free loop space $\mathcal{L}(M)$,

$$\mathcal{L}_0(M) = \{\gamma\colon [0,1] \to M \mid \gamma(0) = \gamma(1),\ \gamma \text{ contractible}\}$$

one studies the contractible periodic solutions and so the action functional on $\mathcal{L}_0(M)$. The covering space, denoted by $\widetilde{\mathcal{L}}_0(M)$, is realized by the set of suitable equivalence classes $[z, w]$ of the pair (z, w) where $z\colon S^1 \to M$ is a loop and $w\colon D^2 \to M$ is a disc bounding z. Then $\mathcal{A}_H$ is defined by

$$\mathcal{A}_H([z,w]) = -\int w^*\omega - \int_0^1 H(t,\gamma(t))\,dt. \tag{2.1}$$

This reduces to the classical action $\int p\,dq - H\,dt$ if we define the canonical symplectic form as $\omega_0 = \sum_j dq^j \wedge dp_j$ on the phase space $\mathbb{R}^{2n} \cong T^*\mathbb{R}^n$.

To do Morse theory, one needs to introduce a metric on $\Omega(M)$, which is done by introducing an almost complex structure J that is compatible to ω (in that the bilinear form $g_J := \omega(\cdot, J\cdot)$ defines a Riemannian metric on M) and integrating the norm of the tangent vectors of the loop γ. To make the Floer theory a more flexible tool to use, one should allow this J to be time-dependent.

A computation shows that the negative L^2-gradient flow equation of the action functional for the path $u\colon \mathbb{R} \times S^1 \to M$ is the following *nonlinear* first order partial differential equation

$$\frac{\partial u}{\partial \tau} + J\left(\frac{\partial u}{\partial t} - X_H(t,u)\right) = 0. \tag{2.2}$$

The rest points of this gradient flow are the periodic orbits of $\dot{x} = X_H(t,x)$. Note that when $H = 0$, this equation becomes the pseudo-holomorphic equation

$$\overline{\partial}_J(u) = \frac{\partial u}{\partial \tau} + J\frac{\partial u}{\partial t} = 0 \tag{2.3}$$

which has many constant solutions. Following Floer [Fl2], for each given *nondegenerate* H, i.e., one whose time-one map ϕ_H^1 has the linearization with no eigenvalue 1, we consider a vector space $CF(H)$ consisting of *Novikov Floer chains*

Definition 2.1. For each formal sum

$$\beta = \sum_{[z,w] \in \mathrm{Crit}\mathcal{A}_H} a_{[z,w]}[z,w],\ a_{[z,w]} \in \mathbb{Q} \tag{2.4}$$

we define the *support* of β by the set

$$\operatorname{supp}\beta = \{[z,w] \in \operatorname{Crit}\mathcal{A}_H \mid a_{[z,w]} \neq 0 \text{ in } (2.4)\}.$$

We call β a Novikov Floer chain or (simply a Floer chain) if it satisfies the condition

$$\#\{[z,w] \in \operatorname{supp}\beta \mid \mathcal{A}_H([z,w]) \geq \lambda\} < \infty$$

for all $\lambda \in \mathbb{R}$ and define $CF(H)$ to be the set of Novikov Floer chains.

$CF(H)$ can be considered either as a $\mathbb{Q}$-vector space or a module over the Novikov ring Λ_ω of (M, ω). Each Floer chain β as a $\mathbb{Q}$-chain can be regarded as the union of "unstable manifolds" of the generators $[z, w]$ of β, which has a 'peak'. There is the natural Floer boundary map $\partial = \partial_{(H,J)}\colon CF(H) \to CF(H)$ i.e., a linear map satisfying $\partial\partial = 0$. The pair $(CF(H), \partial_{(H,J)})$ is the *Floer complex* and the quotient

$$HF_*(H, J; M) := \ker \partial_{(H,J)} / \operatorname{im} \partial_{(H,J)}$$

is the *Floer homology*. By now the general construction of this Floer homology has been carried out by Fukaya–Ono [FOn], Liu–Tian [LT1], and Ruan [Ru] in its complete generality, after the construction had been previously carried out by Floer [Fl2], Hofer–Salamon [HS] and by Ono [On] in some special cases.

The Floer homology $HF_*(H, J; M)$ also has the ring structure arising from the pants product, which becomes the *quantum product* on $H^*(M)$ in "vacuum", i.e. when $H \equiv 0$. The module $H^*(M) \otimes \Lambda_\omega$ with this ring structure is the *quantum cohomology ring* denoted by $QH^*(M)$. We denote by $a \cdot b$ the quantum product of two quantum cohomology classes a and b.

2.2. Spectral invariants and spectral norm. Knowing the existence of periodic orbits of a given Hamiltonian flow, the next task is to organize the collection of the actions of different periodic orbits and to study their relationships.

We first collect the actions of all possible periodic orbits, *including their quantum contributions*, and define the *action spectrum* of H by

$$\operatorname{Spec}(H) := \{\mathcal{A}_H([z, w]) \in \mathbb{R} \mid [z, w] \in \widetilde{\Omega}_0(M),\ d\mathcal{A}_H([z, w]) = 0\} \tag{2.5}$$

i.e., the set of critical values of $\mathcal{A}_H\colon \widetilde{\mathcal{L}}_0(M) \to \mathbb{R}$. In general this set is a countable subset of $\mathbb{R}$ on which the (spherical) period group Γ_ω acts. Motivated by classical Morse theory and mini-max theory, one would like to consider a sub-collection of critical values that are *homologically essential*: each non-trivial cohomology class gives rise to a mini-max value, which cannot be pushed further down by the gradient flow. One crucial ingredient in the classical mini-max theory is a choice of semi-infinite cycles that are linked under the gradient flow.

Applying this idea in the context of chain level Floer theory, Oh generalized his previous construction [Oh4], [Oh5] to the non-exact case in [Oh8], [Oh10]. We define the *level* of a Floer chain β by the maximum value

$$\lambda_H(\beta) := \max_{[z,w]} \{\mathcal{A}_H([z, w]) \mid [z, w] \in \operatorname{supp} \beta\}. \tag{2.6}$$

Now for each $a \in QH^k(M)$ and a generic J, Oh considers the mini-max values

$$\rho(H, J; a) = \inf_\alpha \{\lambda_H(\alpha) \mid \alpha \in CF_{n-k}(H),\ \partial_{(H,J)}\alpha = 0,\ [\alpha] = a^\flat\} \tag{2.7}$$

where $2n = \dim M$ and proves that this number is independent of J [Oh8]. The common number denoted by $\rho(H; a)$ is called the *spectral invariant* associated to

the Hamiltonian H relative to the class $a \in QH^*(M)$. The collection of the values $\rho(H; a)$ extend to arbitrary smooth Hamiltonian function H, *whether H is nondegenerate or not*, and satisfy the following basic properties.

Theorem 2.2 ([Oh8], [Oh10]). *Let (M, ω) be an arbitrary closed symplectic manifold. For any given quantum cohomology class $0 \neq a \in QH^*(M)$, we have a continuous function denoted by $\rho = \rho(H; a) : C^\infty_m([0, 1]\times M)\times(QH^*(M)\setminus\{0\}) \to \mathbb{R}$ which satisfies the following axioms. Let $H,\ F \in C^\infty_m([0, 1] \times M)$ be smooth Hamiltonian functions and $a \neq 0 \in QH^*(M)$. Then we have:*

1. (Projective invariance) $\rho(H; \lambda a) = \rho(H; a)$ *for any* $0 \neq \lambda \in \mathbb{Q}$.
2. (Normalization) *For a quantum cohomology class a, we have $\rho(\underline{0}; a) = v(a)$ where $\underline{0}$ is the zero function and $v(a)$ is the valuation of a on $QH^*(M)$.*
3. (Symplectic invariance) $\rho(\eta^* H; a) = \rho(H; a)$ *for any* $\eta \in \mathrm{Symp}(M, \omega)$.
4. (Homotopy invariance) *For any $H,\ K$ with $[H] = [K]$, $\rho(H; a) = \rho(K; a)$.*
5. (Multiplicative triangle inequality) $\rho(H\#F; a \cdot b) \leq \rho(H; a) + \rho(F; b)$.
6. (C^0-continuity) $|\rho(H; a) - \rho(F; a)| \leq \|H - F\|$. *In particular, the function $\rho_a : H \mapsto \rho(H; a)$ is C^0-continuous.*
7. (Additive triangle inequality) $\rho(H; a + b) \leq \max\{\rho(H; a), \rho(H; b)\}$.

Under the canonical one-one correspondence between (*smooth*) H (satisfying $\int_M H_t = 0$) and its Hamiltonian path $\phi_H : t \mapsto \phi^t_H$, we denote by $[H]$ the path-homotopy class of the Hamiltonian path $\phi_H : [0, 1] \to \mathrm{Ham}(M, \omega)$; $\phi_H(t) = \phi^t_H$ with fixed end points, and by $\widetilde{\mathrm{Ham}}(M, \omega)$ the set of $[H]$'s which represents the universal covering space of $\mathrm{Ham}(M, \omega)$.

This theorem generalizes the results on the exact case by Viterbo [V2], Oh [Oh4], [Oh5] and Schwarz [Sc] to the non-exact case. The axioms 1 and 7 already hold at the level of *cycles* or for λ_H and follow immediately from its definition. All other axioms are proved in [Oh8] except the homotopy invariance for the *irrational* symplectic manifolds which is proven in [Oh10]. The additive triangle inequality was explicitly used by Entov and Polterovich in their construction of some quasi-morphisms on $\mathrm{Ham}(M, \omega)$ [EnP]. The axiom of homotopy invariance implies that $\rho(\,\cdot; a)$ projects down to $\widetilde{\mathrm{Ham}}(M, \omega)$. It is a consequence of the following spectrality axiom, which is proved for *any* H on *rational* (M, ω) in [Oh8] and just for *nondegenerate* H on *irrational* (M, ω) [Oh10]:

8. (Nondegenerate spectrality) *For nondegenerate H, the mini-max values $\rho(H; a)$ lie in* $\mathrm{Spec}(H)$, *i.e. they are critical values of $\mathcal{A}_H$ for all $a \in QH^*(M) \setminus \{0\}$.*

The following is still an open problem.

Question 2.3. Let (M, ω) be a irrational symplectic manifold, i.e., the period group $\Gamma_\omega = \{\omega(A) \mid A \in \pi_2(M)\}$ be a dense subgroup of $\mathbb{R}$. Does $\rho(H; a)$ still lie in $\mathrm{Spec}(H)$ for all $a \neq 0$ for *degenerate* Hamiltonian H?

It turns out that the invariant $\rho(H; 1)$ can be used to construct a canonical invariant norm on $\mathrm{Ham}(M, \omega)$ of the Viterbo type which is called the *spectral norm*. To describe this construction, we start by reviewing the definition of the Hofer norm $\|\phi\|$ of a Hamiltonian diffeomorphism ϕ.

There are two natural operations on the space of Hamiltonians H: one the *inverse* $H \mapsto \bar{H}$ where $\bar{H}$ is the Hamiltonian generating the inverse flow $(\phi_H^t)^{-1}$ and the *product* $(H, F) \mapsto H \# F$ where $H \# F$ is the one generating the composition flow $\phi_H^t \circ \phi_F^t$. Hofer [H] introduced an invariant norm on $\mathrm{Ham}(M, \omega)$. Hofer also considered its $L^{(1,\infty)}$-version $\|\phi\|$ defined by

$$\|\phi\| = \inf_{H \mapsto \phi} \|H\|; \quad \|H\| = \int_0^1 (\max H_t - \min H_t)\, dt$$

where $H \mapsto \phi$ stands for $\phi = \phi_H^1$. We call $\|H\|$ the $L^{(1,\infty)}$*-norm* of H and $\|\phi\|$ the $L^{(1,\infty)}$ *Hofer norm* of ϕ.

Making use of the spectral invariant $\rho(H; 1)$, Oh defined in [Oh9] a function $\gamma : C_m^\infty([0, 1] \times M) \to \mathbb{R}$ by

$$\gamma(H) = \rho(H; 1) + \rho(\bar{H}; 1)$$

on $C_m^\infty([0, 1] \times M)$, whose definition is more *topological* than $\|H\|$. For example, γ canonically projects down to a function on $\widetilde{\mathrm{Ham}}(M, \omega)$ by the homotopy invariance axiom while $\|H\|$ does not. Obviously $\gamma(H) = \gamma(\bar{H})$. The inequality $\gamma(H) \leq \|H\|$ was also shown in [Oh4], [Oh9] and the inequality $\gamma(H) \geq 0$ follows from the triangle inequality applied to $a = b = 1$ and from the normalization axiom $\rho(\underline{0}; 1) = 0$.

Now we define a non-negative function $\gamma : \mathrm{Ham}(M, \omega) \to \mathbb{R}_+$ by $\gamma(\phi) := \inf_{H \mapsto \phi} \gamma(H)$. Then the following theorem is proved in [Oh9].

Theorem 2.4 ([Oh9]). *Let (M, ω) be any closed symplectic manifold. Then*

$$\gamma : \mathrm{Ham}(M, \omega) \to \mathbb{R}_+$$

defines a (*non-degenerate*) *norm on* $\mathrm{Ham}(M, \omega)$ *which satisfies the following additional properties:*

1. $\gamma(\eta^{-1}\phi\eta) = \gamma(\phi)$ *for any symplectic diffeomorphism* η*;*
2. $\gamma(\phi^{-1}) = \gamma(\phi)$, $\gamma(\phi) \leq \|\phi\|$.

Oh then applied the function $\gamma = \gamma(H)$ to the study of the geodesic property of Hamiltonian flows [Oh7], [Oh9].

Another interesting application of spectral invariants is a new construction of *quasi-morphisms* on $\mathrm{Ham}(M,\omega)$ carried out by Entov and Polterovich [EnP]. Recall that for a closed (M,ω), there exists no non-trivial homomorphism to $\mathbb{R}$ because $\mathrm{Ham}(M,\omega)$ is a simple group [Ba]. However for a certain class of *semi-simple* symplectic manifolds, e.g. for (S^2,ω), $(S^2\times S^2, \omega\oplus\omega)$, $(\mathbb{C}P^n,\omega_{FS})$, Entov and Polterovich [EnP] produced non-trivial quasi-morphisms, exploiting the spectral invariants $\rho(e,\cdot)$ corresponding to a certain idempotent element e of the quantum cohomology ring $QH^*(M)$.

It would be an important problem to unravel what the true meaning of Gromov's pseudo-holomorphic curves or of the Floer homology in general is in regard to the underlying symplectic structure.

3. Towards topological Hamiltonian dynamics

We note that the construction of spectral invariants largely depends on the smoothness (or at least differentiability) of Hamiltonians H because it involves the study of Hamilton's equation $\dot{x} = X_H(t,x)$. If H is smooth there is a one-one correspondence between H and its flow ϕ_H^t. However this correspondence breaks down when H does not have enough regularity, e.g., if H is only continuous or even C^1 *because the fundamental existence and uniqueness theorems of ODE's fail.*

However the final outcome $\rho(H;a)$ still makes sense for and can be extended to a certain natural class of C^0-functions H. Now a natural questions to ask is:

Question 3.1. Can we define the notion of topological Hamiltonian dynamical systems? If so, what is the dynamical meaning of the numbers $\rho(H;a)$ when H is just continuous but not differentiable?

These questions led to the notions of *topological Hamiltonian paths* and *Hamiltonian homeomorphisms* in [OM].

Definition 3.2. A continuous path $\lambda\colon [0,1]\to \mathrm{Homeo}(M)$ with $\lambda(0)=\mathrm{id}$ is called a topological Hamiltonian path if there exists a sequence of smooth Hamiltonians $H_i\colon [0,1]\times M\to\mathbb{R}$ such that

1. H_i converges in the $L^{(1,\infty)}$-topology (or Hofer topology) of Hamiltonians, and
2. $\phi_{H_i}^t\to\lambda(t)$ uniformly converges on $[0,1]$.

We say that the $L^{(1,\infty)}$-limit of any such sequence H_i is a *Hamiltonian* of the topological Hamiltonian flow λ. The following uniqueness result is proved in [Oh12].

Theorem 3.3 ([Oh12]). *Let λ be a topological Hamiltonian path. Suppose that there exist two sequences H_i and H_i' satisfying the conditions in Definition* 3.2. *Then their limits coincide as an $L^{(1,\infty)}$-function.*

The proof of this theorem is a modification of Viterbo's proof [V3] of a similar uniqueness result for the C^0 Hamiltonians, combined with a structure theorem of topological Hamiltonians which is also proven in [Oh12]. An immediate corollary is the following extension of the spectral invariants to the space of topological Hamiltonian paths.

Definition 3.4. Suppose λ is a topological Hamiltonian path and let H_i be the sequence of smooth Hamiltonians that converges in $L^{(1,\infty)}$-topology and whose associated Hamiltonian path ϕ_{H_i} converges to λ uniformly. We define

$$\rho(\lambda; a) = \lim_{i\to\infty} \rho(H_i; a).$$

The uniqueness theorem of topological Hamiltonians and the $L^{(1,\infty)}$ continuity property of ρ imply that this definition is well defined.

Definition 3.5. A homeomorphism h of M is a Hamiltonian homeomorphism if there exists a sequence of smooth Hamiltonians $H_i : [0, 1] \times M \to \mathbb{R}$ such that

1. H_i converges in the $L^{(1,\infty)}$-topology of Hamiltonians, and
2. the Hamiltonian path $\phi_{H_i} : t \mapsto \phi^t_{H_i}$ uniformly converges on $[0, 1]$ in the C^0-topology of Homeo(M), and $\phi^1_{H_i} \to h$.

We denote by Hameo(M, ω) the set of such homeomorphisms.

Motivated by Eliashberg's rigidity theorem we also define the group Sympeo(M, ω) as the subgroup of Homeo(M) consisting of the C^0-limits of symplectic diffeomorphisms. Then Oh and Müller [OM] proved the following theorem.

Theorem 3.6 ([OM]). Hameo(M, ω) *is a path-connected normal subgroup of* Sympeo$_0(M, \omega)$*, the identity component of* Sympeo(M, ω).

One can easily derive that Hameo(M, ω) is a proper subgroup of Sympeo$_0(M, \omega)$ whenever the so-called mass flow homomorphism [Fa] is non-trivial or there exists a symplectic diffeomorphism that has no fixed point, e.g., T^{2n} [OM]. In fact, we conjecture that this is always the case.

Conjecture 3.7. The group Hameo(M, ω) is a proper subgroup of Sympeo$_0(M, \omega)$ for any closed symplectic manifold (M, ω).

A case of particular interest is the case $(M, \omega) = (S^2, \omega)$. In this case, together with the smoothing result proven in [Oh11], the affirmative answer to this conjecture would yield a negative response to the following open question in area preserving dynamical systems. See [Fa] for the basic theorems on the measure preserving homeomorphisms in dimension greater than or equal to 3.

Question 3.8. Is the identity component of the group of area preserving homeomorphisms on S^2 a simple group?

4. Floer theory of Lagrangian intersections

Floer's original definition [Fl1] of the homology $HF(L_0, L_1)$ of Lagrangian submanifolds meets many obstacles when one attempts to generalize his definition beyond the exact cases, i.e. the case

$$L_0 = L, \quad L_1 = \phi(L) \quad \text{with } \pi_2(M, L) = \{0\}.$$

In this exposition we will consider the cases of Lagrangian submanifolds that are not necessarily exact. In the open string case of Lagrangian submanifolds one has to deal with the phenomenon of bubbling-off discs besides bubbling-off spheres. One crucial difference between the former and the latter is that the former is a phenomenon of codimension one while the latter is of codimension two. This difference makes the general Lagrangian intersection Floer theory show a very different perspective compared to the Floer theory of Hamiltonian fixed points. For example, for the intersection case in general, one has to study the theory *in the chain level*, which forces one to consider the chain complexes themselves. Then the meaning of invariance of the resulting objects is much more non-trivial to define compared to that of Gromov–Witten invariants for which one can work in the level of homology.

There is one particular case that Oh singled out in [Oh1] for which the original version of Floer cohomology is well defined and invariant just under the change of almost complex structures and under the Hamiltonian isotopy. This is the case of *monotone* Lagrangian submanifolds with *minimal Maslov number* $\Sigma_L \geq 3$:

Definition 4.1. A Lagrangian submanifold $L \subset (M, \omega)$ is *monotone* if there exists a constant $\lambda \geq 0$ such that $\omega(A) = \lambda\mu(A)$ for all elements $A \in \pi_2(M, L)$. The minimal Maslov number is defined by the integer

$$\Sigma_L = \min\{\mu(\beta) \mid \beta \in \pi_2(M, L),\ \mu(\beta) > 0\}.$$

We will postpone further discussion on this particular case until later in this survey but proceed with describing the general story now.

To obtain the maximal possible generalization of Floer's construction, it is crucial to develop a proper *off-shell* formulation of the relevant Floer moduli spaces.

4.1. Off-shell formulation. We consider the space of paths

$$\Omega = \Omega(L_0, L_1) = \{\ell : [0, 1] \to P \mid \ell(0) \in L_0, \ell(1) \in L_1\}.$$

On this space we are given the *action one-form* α defined by

$$\alpha(\ell)(\xi) = \int_0^1 \omega(\dot{\ell}(t), \xi(t))\, dt$$

for each tangent vector $\xi \in T_\ell\Omega$. From this expression it follows that

$$\text{Zero}(\alpha) = \{\ell_p : [0, 1] \to M \mid p \in L_0 \cap L_1, \quad \ell_p \equiv p\}.$$

Using the Lagrangian property of (L_0, L_1), a straightforward calculation shows that this form is *closed*. Note that $\Omega(L_0, L_1)$ is not connected but has countably many connected components. We will work on a particular fixed connected component of $\Omega(L_0, L_1)$. We pick up a based path $\ell_0 \in \Omega(L_0, L_1)$ and consider the corresponding component $\Omega(L_0, L_1; \ell_0)$, and then define a covering space

$$\pi : \widetilde{\Omega}(L_0, L_1; \ell_0) \to \Omega(L_0, L_1; \ell_0)$$

on which we have a single valued action functional such that $d\mathcal{A} = -\pi^*\alpha$. One can repeat Floer's construction similarly as in the closed case replacing $\mathcal{L}_0(M)$ by the chosen component of the path space $\Omega(L_0, L_1)$. We refer to [FOOO] for the details of this construction. We then denote by $\Pi(L_0, L_1; \ell_0)$ the group of deck transformations. We define the associated Novikov ring $\Lambda(L_0, L_1; \ell_0)$ as a completion of the group ring $\mathbb{Q}[\Pi(L_0, L_1; \ell_0)]$.

Definition 4.2. $\Lambda_k(L_0, L_1; \ell_0)$ denotes the set of all (infinite) sums

$$\sum_{\substack{g \in \Pi(L_0, L_1; \ell_0) \\ \mu(g) = k}} a_g [g]$$

with $a_g \in \mathbb{Q}$ and such that for each $C \in \mathbb{R}$,

$$\#\{g \in \Pi(L_0, L_1; \ell_0) \mid E(g) \leq C,\ a_g \neq 0\} < \infty.$$

We put $\Lambda(L_0, L_1; \ell_0) = \bigoplus_k \Lambda_k(L_0, L_1; \ell_0)$.

We call this graded ring the *Novikov ring* of the pair (L_0, L_1) relative to the path ℓ_0. Note that this ring depends on L and ℓ_0. In relation to mirror symmetry one needs to consider a family of Lagrangian submanifolds and to use a universal form of this ring. The following ring was introduced in [FOOO], which plays an important role in the rigorous formulation of homological mirror symmetry conjecture.

Definition 4.3 (Universal Novikov ring). We define

$$\Lambda_{\text{nov}} = \Big\{ \sum_{i=1}^{\infty} a_i T^{\lambda_i} \ \Big|\ a_i \in \mathbb{Q},\ \lambda_i \in \mathbb{R},\ \lambda_i \leq \lambda_{i+1},\ \lim_{i \to \infty} \lambda_i = \infty \Big\}, \tag{4.1}$$

$$\Lambda_{0,\text{nov}} = \Big\{ \sum_{i=1}^{\infty} a_i T^{\lambda_i} \in \Lambda_{\text{nov}} \ \Big|\ \lambda_i \geq 0 \Big\}. \tag{4.2}$$

In the above definitions of Novikov rings, one can replace $\mathbb{Q}$ by other commutative rings with unit, e.g. $\mathbb{Z}$, $\mathbb{Z}_2$ or $\mathbb{Q}[e]$ with a formal variable e.

There is a natural filtration on these rings by the valuation $v\colon \Lambda_{\text{nov}},\ \Lambda_{0,\text{nov}} \to \mathbb{R}$ defined by

$$v\Big(\sum_{i=1}^{\infty} a_i T^{\lambda_i} \Big) := \lambda_1. \tag{4.3}$$

This is well defined by the definition of the Novikov ring and induces a filtration $F^\lambda\Lambda_{\text{nov}} := v^{-1}([\lambda, \infty))$ on Λ_{nov}. The function $e^{-v}\colon \Lambda_{\text{nov}} \to \mathbb{R}_+$ also provides a natural non-Archimedean norm on Λ_{nov}. We call the induced topology on Λ_{nov} a *non-Archimedean topology*.

We now assume that L_0 intersects L_1 transversely and form the $\mathbb{Q}$-vector space $CF(L_0, L_1)$ over the set $\text{span}_{\mathbb{Q}}\,\text{Crit}\,\mathcal{A}$ similarly as $CF(H)$. Now let $p,\ q \in L_0 \cap L_1$. We denote by $\pi_2(p, q) = \pi_2(p, q; L_0, L_1)$ the set of homotopy classes of smooth maps $u\colon [0, 1] \times [0, 1] \to M$ relative to the boundary

$$u(0, t) \equiv p, \quad u(1, t) = q; \quad u(s, 0) \in L_0, \quad u(s, 1) \in L_1,$$

by $[u] \in \pi_2(p, q)$ the homotopy class of u, and by B a general element in $\pi_2(p, q)$. For given $B \in \pi_2(p, q)$ we denote by $\text{Map}(p, q; B)$ the set of such w's in the class B. Each element $B \in \pi_2(p, q)$ induces a map given by the obvious gluing map $[p, w] \mapsto [q, w \# u]$ for $u \in \text{Map}(p, q; B)$. There is also the natural gluing map

$$\pi_2(p, q) \times \pi_2(q, r) \to \pi_2(p, r)$$

induced by the concatenation $(u_1, u_2) \mapsto u_1 \# u_2$.

4.2. Floer moduli spaces and Floer operators. Now for each given $J = \{J_t\}_{0\le t\le 1}$ and $B \in \pi_2(p, q)$ we define the moduli space $\widetilde{\mathcal{M}}(p, q; B)$ consisting of finite energy solutions of the Cauchy–Riemann equation

$$\begin{cases} \frac{du}{d\tau} + J_t \frac{du}{dt} = 0, \\ u(\tau, 0) \in L_0,\ u(\tau, 1) \in L_1,\ \int u^*\omega < \infty \end{cases}$$

with the asymptotic condition and the homotopy condition

$$u(-\infty, \cdot) \equiv p, \quad u(\infty, \cdot) \equiv q; \quad [u] = B.$$

We then define $\mathcal{M}(p, q; B) = \widetilde{\mathcal{M}}(p, q; B)/\mathbb{R}$ the quotient by the τ-translations and a collection of *rational* numbers $n(p, q; J, B) = \#(\mathcal{M}(p, q; J, B))$ whenever the expected dimension of $\mathcal{M}(p, q; B)$ is zero. Finally we define the Floer 'boundary' map $\partial\colon\ CF(L_0, L_1; \ell_0) \to CF(L_0, L_1; \ell_0)$ by the sum

$$\partial([p, w]) = \sum_{q\in L_0\cap L_1} \sum_{B\in\pi_2(p,q)} n(p, q; J, B)[q, w \# B]. \tag{4.4}$$

When a Hamiltonian isotopy $\{L'_s\}_{0\le s\le 1}$ is given one also considers the non-autonomous version of the Floer equation

$$\begin{cases} \frac{du}{d\tau} + J_{t,\rho(\tau)} \frac{du}{dt} = 0, \\ u(\tau, 0) \in L,\ u(\tau, 1) \in L'_{\rho(\tau)}, \end{cases}$$

as done in [Oh1] where $\rho\colon \mathbb{R} \to [0,1]$ is a smooth function with $\rho(-\infty) = 0$, $\rho(\infty) = 1$ such that ρ' is compactly supported and define the Floer 'chain' map

$$h\colon\ CF^*(L_0, L_0') \to CF^*(L_1, L_1').$$

However unlike the closed case or the exact case, many things go wrong when one asks for the property $\partial \circ \partial = 0$ or $\partial h + h\partial = 0$ especially over the rational coefficients, and even when $HF^*(L, \phi_H^1(L))$ is defined, it is not isomorphic to the classical cohomology $H^*(L)$.

In the next three subsections, we explain how to overcome these troubles and describe the spectral sequence relating $HF^*(L, \phi_H^1(L))$ to $H^*(L)$ when the former is defined. All the results in these subsections are joint work with H. Ohta and K. Ono that appeared in [FOOO], unless otherwise said. We refer to Ohta's article [Ot] for a more detailed survey on the work from [FOOO].

4.3. Orientation. We first recall the following definition from [FOOO].

Definition 4.4. A submanifold $L \subset M$ is called *relatively spin* if it is orientable and there exists a class $st \in H^2(M, \mathbb{Z}_2)$ such that $st|_L = w_2(TL)$ for the Stiefel–Whitney class $w_2(TL)$ of TL. A pair (L_0, L_1) is relatively spin if there exists a class $st \in H^2(M, \mathbb{Z}_2)$ satisfying $st|_{L_i} = w_2(TL_i)$ for each $i = 0,\ 1$.

We fix such a class $st \in H^2(M, \mathbb{Z}_2)$ and a triangulation of M. Denote by $M^{(k)}$ its k-skeleton. There exists a unique rank 2 vector bundle $V(st)$ on $M^{(3)}$ with $w^1(V(st)) = 0,\ w^2(V(st)) = st$. Now suppose that L is relatively spin and $L^{(2)}$ be the 2-skeleton of L. Then $V \oplus TL$ is trivial on the 2-skeleton of L.

Definition 4.5. We define a (M, st)-relative spin structure of L to be a spin structure of the restriction of the vector bundle $V \oplus TL$ to $L^{(2)}$.

The following theorem was proved independently by de Silva [Si] and in [FOOO].

Theorem 4.6. *The moduli space of pseudo-holomorphic discs is orientable if $L \subset (M, \omega)$ is relatively spin Lagrangian submanifold. Furthermore the choice of relative spin structure on L canonically determines an orientation on the moduli space $\mathcal{M}(L; \beta)$ of holomorphic discs for all $\beta \in \pi_2(M, L)$.*

For the orientations on the Floer moduli spaces the following theorem was proved in [FOOO].

Theorem 4.7. *Let $J = \{J_t\}_{0 \le t \le 1}$ and suppose that a pair of Lagrangian submanifolds (L_0, L_1) are (M, st)-relatively spin. Then for any $p, q \in L_0 \cap L_1$ and $B \in \pi_2(p, q)$ the Floer moduli space $\mathcal{M}(p, q; B)$ is orientable. Furthermore a choice of relative spin structures for the pair (L_0, L_1) determines an orientation on $\mathcal{M}(p, q; B)$.*

One can amplify the orientation to the moduli space of pseudo-holomorphic polygons $\mathcal{M}(\mathcal{L}, \vec{p}; B)$, where $\mathcal{L} = (L_0, L_1, \dots, L_k)$ and $\vec{p} = (p_{01}, p_{12}, \dots, p_{k0})$ with $p_{ij} \in L_i \cap L_j$, and extend the construction to the setting of A_∞-category [Fu1]. We refer to [Fu2] for a more detailed discussion on this.

4.4. Obstruction and A_∞-structure. Let (L_0, L_1) be a relatively spin pair with $L_0 \pitchfork L_1$ and fix a (M, st)-relatively spin structure on each L_i. To convey the appearance of obstruction to the boundary property $\partial\partial = 0$ in a coherent way, we assume in this survey, for simplicity, that all the Floer moduli spaces involved in the construction are transverse and so the expected dimension is the same as the actual dimension. For example, this is the case for monotone Lagrangian submanifolds at least for the Floer moduli spaces of dimension 0, 1 and 2. However, we would like to emphasize that we have to use the machinery of *Kuranishi structure* introduced in [FOn] in the level of *chain* to properly treat the transversality problem for the general case, whose detailed study we refer to [FOOO].

We compute $\partial\partial([p, w])$. According to the definition (4.4) of the map ∂ we have the formula for its matrix coefficients

$$\langle \partial\partial[p, w], [r, w \# B]\rangle = \sum_{q\in L_0\cap L_1} \sum_{B=B_1\#B_2\in\pi_2(p,r)} n(p, q; B_1)n(q, r; B_2) \qquad (4.5)$$

where $B_1 \in \pi_2(p, q)$ and $B_2 \in \pi_2(q, r)$. To prove $\partial\partial = 0$, one needs to prove $\langle \partial\partial[p, w], [r, w \# B]\rangle = 0$ for all pairs $[p, w]$, $[r, w \# B]$. On the other hand it follows from the definition that each summand $n(p, q; B_1)n(q, r; B_2)$ is nothing but the number of broken trajectories lying in $\mathcal{M}(p, q; B_1) \# \mathcal{M}(q, r; B_2)$. The way how Floer [Fl1] proved the vanishing of (4.5) under the assumption that

$$L_0 = L,\ L_1 = \phi_H^1(L);\ \pi_2(M, L_i) = 0 \qquad (4.6)$$

is to construct a suitable compactification of the one-dimensional (smooth) moduli space $\mathcal{M}(p, r; B) = \widetilde{\mathcal{M}}(p, r; B)/\mathbb{R}$ in which the broken trajectories of the form $u_1 \# u_2$ comprise *all* the boundary components of the compactified moduli space. By definition, the expected dimension of $\mathcal{M}(p, r; B)$ is one and so the compactified moduli space becomes a compact one-dimensional manifold. Then $\partial\partial = 0$ follows.

As soon as one goes beyond Floer's case (4.6), one must consider the problems of *a priori energy bound* and *bubbling-off discs*. As in the closed case the Novikov ring is introduced to solve the problem of energy bounds. On the other hand, bubbling-off-discs is a new phenomenon which is that of codimension one and can indeed occur in the boundary of the compactification of Floer moduli spaces.

To handle the problem of bubbling-off discs, Fukaya–Oh–Ohta–Ono [FOOO] associated a structure of filtered A_∞-algebra $(C, \mathfrak{m})$ *with non-zero* $\mathfrak{m}_0$*-term* in general to each compact Lagrangian submanifold. The notion of A_∞-structure was first introduced by Stasheff [St]. We refer to [GJ] for an exposition close to ours with different sign conventions. The above mentioned obstruction is closely related to the non-vanishing of $\mathfrak{m}_0$ in this A_∞-structure. A description of this obstruction is now in order.

Let C be a graded R-module where R is the coefficient ring. In our case R will be $\Lambda_{0,\mathrm{nov}}$. We denote by $C[1]$ its suspension defined by $C[1]^k = C^{k+1}$. We denote by $\deg(x) = |x|$ the degree of $x \in C$ before the shift and by $\deg'(x) = |x|'$ that after

the degree shifting, i.e., $|x|' = |x| - 1$. Define the *bar complex* $B(C[1])$ by

$$B_k(C[1]) = (C[1])^{k\otimes}, \quad B(C[1]) = \bigoplus_{k=0}^{\infty} B_k(C[1]).$$

Here $B_0(C[1]) = R$ by definition. We provide the degree of elements of $B(C[1])$ by the rule

$$|x_1 \otimes \cdots \otimes x_k|' := \sum_{i=1}^{k} |x_i|' = \sum_{i=1}^{k} |x_i| - k \tag{4.7}$$

where $|\cdot|'$ is the shifted degree. The ring $B(C[1])$ has the structure of a *graded coalgebra*.

Definition 4.8. The structure of a (strong) A_∞*-algebra* is a sequence of R-module homomorphisms

$$\mathfrak{m}_k \colon B_k(C[1]) \to C[1], \quad k = 1, 2, \ldots,$$

of degree +1 such that the coderivation $d = \sum_{k=1}^{\infty} \widehat{\mathfrak{m}}_k$ satisfies $dd = 0$, which is called the A_∞*-relation*. Here we denote by $\widehat{\mathfrak{m}}_k \colon B(C[1]) \to B(C[1])$ the unique extension of $\mathfrak{m}_k$ as a coderivation on $B(C[1])$. A *filtered* A_∞*-algebra* is an A_∞-algebra with a filtration for which $\mathfrak{m}_k$ are continuous with respect to the induce non-Archimedean topology.

In particular, we have $\mathfrak{m}_1\mathfrak{m}_1 = 0$ and so it defines a complex $(C, \mathfrak{m}_1)$. We define the $\mathfrak{m}_1$-cohomology by

$$H(C, \mathfrak{m}_1) = \ker \mathfrak{m}_1 / \operatorname{im} \mathfrak{m}_1. \tag{4.8}$$

A *weak* A_∞*-algebra* is defined in the same way, except that it also includes

$$\mathfrak{m}_0 \colon R \to B(C[1]).$$

The first two terms of the A_∞-relation for a weak A_∞-algebra are given as

$$\mathfrak{m}_1(\mathfrak{m}_0(1)) = 0 \tag{4.9}$$

$$\mathfrak{m}_1\mathfrak{m}_1(x) + (-1)^{|x|'}\mathfrak{m}_2(x, \mathfrak{m}_0(1)) + \mathfrak{m}_2(\mathfrak{m}_0(1), x) = 0. \tag{4.10}$$

In particular, for the case of weak A_∞-algebras, $\mathfrak{m}_1$ will not necessarily satisfy the boundary property, i.e., $\mathfrak{m}_1\mathfrak{m}_1 \neq 0$ in general.

The way how a weak A_∞-algebra is attached to a Lagrangian submanifold $L \subset (M, \omega)$ arises as an A_∞-deformation of the classical singular cochain complex including the instanton contributions. In particular, when there is no instanton contribution as in the case $\pi_2(M, L) = 0$, it will reduce to an A_∞-deformation of the singular cohomology in the chain level including all possible higher Massey product. One

outstanding circumstance arises in relation to the *quantization* of rational homotopy theory on the cotangent bundle T^*N of a compact manifold N. In this case the authors proved in [FOh] that the A_∞-subcategory 'generated' by such graphs is literally isomorphic to a certain A_∞-category constructed by the Morse theory of *graph flows*.

We now describe the basic A_∞-operators $\mathfrak{m}_k$ in the context of A_∞-algebra of Lagrangian submanifolds. For a given compatible almost complex structure J consider the moduli space of stable maps of genus zero

$$\begin{aligned}&\mathcal{M}_{k+1}(\beta; L)\\ &\quad = \{(w, (z_0, z_1, \dots, z_k)) \mid \overline{\partial}_J w = 0,\ z_i \in \partial D^2, [w] = \beta \text{ in } \pi_2(M, L)\}/\sim,\end{aligned}$$

where $\sim$ is the conformal reparameterization of the disc D^2. The expected dimension of this space is given by

$$n + \mu(\beta) - 3 + (k+1) = n + \mu(\beta) + k - 2. \tag{4.11}$$

Now given k chains

$$[P_1, f_1], \dots, [P_k, f_k] \in C_*(L)$$

of L considered as *currents* on L, we put the cohomological grading $\deg P_i = n - \dim P_i$ and consider the fiber product

$$ev_0 \colon \mathcal{M}_{k+1}(\beta; L) \times_{(ev_1,\dots,ev_k)} (P_1 \times \cdots \times P_k) \to L.$$

A simple calculation shows that the expected dimension of this chain is given by

$$n + \mu(\beta) - 2 + \sum_{j=1}^{k} (\dim P_j + 1 - n)$$

or equivalently we have the expected degree

$$\deg \left[\mathcal{M}_{k+1}(\beta; L) \times_{(ev_1,\dots,ev_k)} (P_1 \times \cdots \times P_k), ev_0\right] = \sum_{j=1}^{n} (\deg P_j - 1) + 2 - \mu(\beta).$$

For each given $\beta \in \pi_2(M, L)$ and $k = 0, \dots$ we define

$$\mathfrak{m}_{k,\beta}(P_1, \dots, P_k) = \left[\mathcal{M}_{k+1}(\beta; L) \times_{(ev_1,\dots,ev_k)} (P_1 \times \cdots \times P_k), ev_0\right]$$

and $\mathfrak{m}_k = \sum_{\beta \in \pi_2(M,L)} \mathfrak{m}_{k,\beta} \cdot q^\beta$ where $q^\beta = T^{\omega(\beta)} e^{\mu(\beta)/2}$ with T, e formal parameters encoding the area and the Maslov index of β. We provide T with degree 0 and e with 2. Now we denote by $C[1]$ the completion of a *suitably chosen countably generated* cochain complex with $\Lambda_{0,\mathrm{nov}}$ as its coefficients with respect to the non-Archimedean topology. Then it follows that the map $\mathfrak{m}_k \colon C[1]^{\otimes k} \to C[1]$ is well defined, has degree 1 and is continuous with respect to the non-Archimedean topology. We extend $\mathfrak{m}_k$ as a coderivation $\widehat{\mathfrak{m}}_k \colon BC[1] \to BC[1]$ where $BC[1]$ is the

completion of the direct sum $\bigoplus_{k=0}^{\infty} B^k C[1]$ and where $B^k C[1]$ itself is the completion of $C[1]^{\otimes k}$. $BC[1]$ has a natural filtration defined similarly as 4.3. Finally we take the sum

$$\hat{d} = \sum_{k=0}^{\infty} \widehat{m}_k : \ BC[1] \to BC[1].$$

A main theorem then is the following coboundary property.

Theorem 4.9. *Let L be an arbitrary compact relatively spin Lagrangian submanifold of an arbitrary tame symplectic manifold (M, ω). The coderivation $\hat{d}$ is a continuous map that satisfies the A_∞-relation $\hat{d}\hat{d} = 0$, and so $(C, \mathfrak{m})$ is a filtered weak A_∞-algebra.*

One might want to consider the homology of this huge complex, but if one naively takes the homology of this complex itself, it will end up with getting a trivial group, which is isomorphic to the ground ring $\Lambda_{0,\mathrm{nov}}$. This is because the A_∞-algebra associated to L in [FOOO] has the (*homotopy*) *unit*: if an A_∞-algebra has a unit, the homology of $\hat{d}$ is isomorphic to its ground ring.

A more geometrically useful homology relevant to the Floer homology is the $\mathfrak{m}_1$-homology (4.8) in this context, which is the Bott–Morse version of the Floer cohomology for the pair (L, L). However in the presence of $\mathfrak{m}_0$, $\mathfrak{m}_1\mathfrak{m}_1 = 0$ no longer holds in general. Motivated by Kontsevich's suggestion [K2], this led Fukaya–Oh–Ohta–Ono to consider deforming Floer's original definition by a bounding chain of the obstruction cycle arising from bubbling-off discs. One can always deform the given (filtered) A_∞-algebra $(C, \mathfrak{m})$ by an element $b \in C[1]^0$ by re-defining the A_∞-operators as

$$\mathfrak{m}_k^b(x_1, \ldots, x_k) = \mathfrak{m}(e^b, x_1, e^b, x_2, e^b, x_3, \ldots, x_k, e^b)$$

and taking the sum $\hat{d}^b = \sum_{k=0}^{\infty} \widehat{\mathfrak{m}}_k^b$. This defines a new weak A_∞-algebra in general. Here we simplify the notation by writing

$$e^b = 1 + b + b \otimes b + \cdots + b \otimes \cdots \otimes b + \cdots .$$

Note that each summand in this infinite sum has degree 0 in $C[1]$ and converges in the non-Archimedean topology if b has positive valuation, i.e., $v(b) > 0$.

Proposition 4.10. *For the A_∞-algebra $(C, \mathfrak{m}_k^b)$, $\mathfrak{m}_0^b = 0$ if and only if b satisfies*

$$\sum_{k=0}^{\infty} \mathfrak{m}_k(b, \ldots, b) = 0. \tag{4.12}$$

This equation is a version of the Maurer–Cartan equation *for the filtered A_∞-algebra.*

Definition 4.11. Let $(C, \mathfrak{m})$ be a filtered weak A_∞-algebra in general and $BC[1]$ be its bar complex. An element $b \in C[1]^0 = C^1$ is called a *bounding cochain* if it satisfies the equation (4.12) and $v(b) > 0$.

In general a given A_∞-algebra may or may not have a solution to (4.12).

Definition 4.12. A filtered weak A_∞-algebra is called *unobstructed* if the equation (4.12) has a solution $b \in C[1]^0 = C^1$ with $v(b) > 0$.

One can define a notion of homotopy equivalence between two bounding cochains as described in [FOOO]. We denote by $\mathcal{M}(L)$ the set of equivalence classes of bounding cochains of L.

Once the A_∞-algebra is attached to each Lagrangian submanifold L, we then construct an A_∞-*bimodule* $C(L, L')$ for the pair by considering operators

$$\mathfrak{n}_{k_1,k_2} \colon C(L, L') \to C(L, L')$$

defined similarly to $\mathfrak{m}_k$: A typical generator of $C(L, L')$ has the form

$$P_{1,1} \otimes \cdots \otimes P_{1,k_1} \otimes [p, w] \otimes P_{2,1} \otimes \cdots \otimes P_{2,k_2}$$

and then the image $\mathfrak{n}_{k_1,k_2}$ thereof is given by

$$\sum_{[q,w']} \left[\left(\mathcal{M}([p, w], [q, w']; P_{1,1}, \ldots, P_{1,k_1}; P_{2,1}, \ldots, P_{2,k_2}), ev_\infty \right) \right] [q, w'].$$

Here $\mathcal{M}([p, w], [q, w']; P_{1,1}, \ldots, P_{1,k_1}; P_{2,1}, \ldots, P_{2,k_2})$ is the Floer moduli space

$$\mathcal{M}([p, w], [q, w']) = \bigcup_{[q,w']=[q,w\#B]} \mathcal{M}(p, q; B)$$

cut-down by intersecting with the given chains $P_{1,i} \subset L$ and $P_{2,j} \subset L'$, and the evaluation map

$$ev_\infty \colon \mathcal{M}([p, w], [q, w']; P_{1,1}, \ldots, P_{1,k_1}; P_{2,1}, \ldots, P_{2,k_2}) \to \mathrm{Crit}\mathcal{A}$$

is defined by $ev_\infty(u) = u(+\infty)$.

Theorem 4.13. *Let (L, L') be an arbitrary relatively spin pair of compact Lagrangian submanifolds. Then the family $\{\mathfrak{n}_{k_1,k_2}\}$ defines a left $(C(L), \mathfrak{m})$ and right $(C(L'), \mathfrak{m}')$ filtered A_∞-bimodule structure on $C(L, L')$.*

In other words, each of the map $\mathfrak{n}_{k_1,k_2}$ extends to a A_∞-bimodule homomorphism $\hat{\mathfrak{n}}_{k_1,k_2}$ and if we take the sum

$$\hat{d} := \sum_{k_1,k_2} \hat{\mathfrak{n}}_{k_1,k_2} \colon C(L, L') \to C(L, L'),$$

$\hat{d}$ satisfies the following coboundary property.

Proposition 4.14. *The map $\hat{d}$ is a continuous map and satisfies $\hat{d}\hat{d} = 0$.*

Again this complex is too big for computational purposes and we would like to consider the Floer homology by restricting the A_∞-bimodule to a much smaller complex, an ordinary Λ_{nov}-module $CF(L, L')$. However Floer's original definition again meets obstruction coming from the obstruction cycles of either L_0, L_1 or of both. We need to deform Floer's 'boundary' map δ using suitable bounding cochains of L, L'. The bimodule $C(L, L')$ is introduced to perform this deformation coherently.

In the case where both L, L' are unobstructed, we can carry out this deformation of $\mathfrak{n}$ by bounding chains $b_1 \in \mathcal{M}(L)$ and $b_2 \in \mathcal{M}(L')$ similarly as $\mathfrak{m}^b$ above. Symbolically we can write the new operator as

$$\delta^{b_1,b_2}(x) = \mathfrak{n}(e^{b_1}, x, e^{b_2}).$$

Theorem 4.15. *For each $b_1 \in \mathcal{M}(L)$ and $b_2 \in \mathcal{M}(L')$, the map δ^{b_1,b_2} defines a continuous map $\delta^{b_1,b_2}\colon CF(L, L') \to CF(L, L')$ that satisfies $\delta^{b_1,b_2}\delta^{b_1,b_2} = 0$.*

This theorem enables us to define the *deformed Floer cohomology*.

Definition 4.16. For each $b \in \mathcal{M}(L)$ and $b' \in \mathcal{M}(L')$, we define the (b, b')-*Floer cohomology* of the pair (L, L') by

$$HF((L, b), (L', b'); \Lambda_{\text{nov}}) = \frac{\ker \delta^{b_1,b_2}}{\text{im } \delta^{b_1,b_2}}.$$

Theorem 4.17. *The above cohomology remains isomorphic under the Hamiltonian isotopy of L, L' and under the homotopy of bounding cochains b, b'.*

We refer to [FOOO] and its revised version for all the details of algebraic language needed to make the statements in the above theorems precise.

4.5. Spectral sequence. The idea of spectral sequence is quite simple to describe. One can follow more or less the standard construction of the spectral sequence on the filtered complex, as e.g. in [Mc]. One trouble to overcome in the construction of the spectral sequence on $(C(L), \delta)$ or $(C(L, L'), \delta)$ is that the general Novikov ring, in particular $\Lambda_{0,\text{nov}}$ is *not* Noetherian and so the standard theorems on Noetherian modules cannot be applied. In addition, the Floer complex is not bounded above which also makes the proof of convergence of the spectral sequence somewhat tricky. We refer to [FOOO] for a complete discussion on the construction of the spectral sequence and the study of their convergences.

However for the case of monotone Lagrangian submanifolds, the Novikov ring becomes a field and the corresponding spectral sequence is much more simplified as originally carried out by Oh [Oh3] by a crude analysis of thick-thin decomposition of Floer moduli spaces as two Lagrangian submanifolds collapse to one. Then the geometric origin of the spectral sequence is the decomposition of the Floer boundary map δ into $\delta = \delta_0 + \delta_1 + \delta_2 + \cdots$ where each δ_i is the contribution coming from the Floer trajectories of a given symplectic area in a way that the corresponding area is

increasing as $i \to \infty$. Here δ_0 is the contribution from the classical cohomology. In general this sequence may not stop at a finite stage but it does for monotone Lagrangian submanifolds. In this regard, we can roughly state the following general theorem:

There exists a spectral sequence whose E^2-term is isomorphic to the singular cohomology $H^*(L)$ and which converges to the Floer cohomology $HF^*(L, L)$.

See [Oh3] and [FOOO] for the details of the monotone case and of the general case respectively. The above decomposition also provides an algorithm to utilize the spectral sequence in examples, especially when the Floer cohomology is known as for the case of Lagrangian submanifolds in $\mathbb{C}^n$. Here are some sample results.

Theorem 4.18 (Theorem II [Oh3]). *Let (M, ω) be a tame symplectic manifold with* $\dim M \geq 4$. *Let L be a compact monotone Lagrangian submanifold of M and ϕ be a Hamiltonian diffeomorphism of (M, ω) such that $L \pitchfork \phi(L)$. Then the following assertions hold:*

1. *If $\Sigma_L \geq n + 2$, $HF^k(L, \phi(L); \mathbb{Z}_2) \cong H^k(L; \mathbb{Z}_2)$ for all $k \mod \Sigma_L$.*
2. *If $\Sigma_L = n + 1$, the same is true for $k \neq 0, n \mod n + 1$.*

Theorem 4.19 (Theorem III [Oh3]).[1] *Let $L \subset \mathbb{C}^n$ be a compact monotone Lagrangian torus. Then we have $\Sigma_L = 2$ provided $1 \leq n \leq 24$.*

A similar consideration, using a more precise form of the spectral sequence from [FOOO], proves

Theorem 4.20. *Suppose that $L \subset \mathbb{C}^n$ is a compact Lagrangian embedding with $H^2(L; \mathbb{Z}_2) = 0$. Then its Maslov class μ_L is not zero.*

The following theorem can be derived from Theorem E [FOOO] which should be useful for the study of intersection properties of special Lagrangian submanifolds on Calabi–Yau manifolds.

Theorem 4.21. *Let M be a Calabi–Yau manifold and L be an unobstructed Lagrangian submanifold with its Maslov class $\mu_L = 0$ in $H^1(L; \mathbb{Z})$. Then we have $HF^i(L; \Lambda_{0,\mathrm{nov}}) \neq 0$ for $i = 0, \dim L$.*

For example, any special Lagrangian homology sphere satisfies all the hypotheses required in this theorem. Using this result combined with some Morse theory argument, Thomas and Yau [TY] proved the following uniqueness result of special Lagrangian homology sphere in its Hamiltonian isotopy class

Theorem 4.22 (Thomas-Yau). *For any Hamiltonian isotopy class of embedded Lagrangian submanifold L with $H^*(L) \cong H^*(S^n)$ there exists at most one smooth special Lagrangian representative.*

Biran [Bi] also used this spectral sequence for the study of geometry of Lagrangian skeletons and polarizations of Kähler manifolds.

[1] *Added in proof.* In the revised version of [FOOO] the dimensional restriction $1 \leq n \leq 24$ was removed following the scheme suggested by Biran [Bi].

5. Displaceable Lagrangian submanifolds

Definition 5.1. We call a compact Lagrangian submanifold $L \subset (M, \omega)$ displaceable if there exists a Hamiltonian isotopy ϕ_H such that $L \cap \phi_H^1(L) = \emptyset$.

One motivating question for studying such Lagrangian submanifolds is the following well-known folklore conjecture in symplectic geometry.

Conjecture 5.2 (Maslov Class Conjecture). Any compact Lagrangian embedding in $\mathbb{C}^n$ has non-zero Maslov class.

Polterovich [P] proved the conjecture in dimension $n = 2$ whose proof uses a loop γ realized by the boundary of Gromov's holomorphic disc constructed in [Gr]. Viterbo proved this conjecture for any Lagrangian torus in $\mathbb{C}^n$ by a different method using the critical point theory on the free loop spaces of $\mathbb{C}^n$ [V1]. Also see Theorem 4.20 in the previous section for L with $H^2(L; \mathbb{Z}_2) \neq 0$.

It follows from the definition that $HF^*(L, \phi_H^1(L)) = 0$ for a displaceable Lagrangian submanifold L *whenever* $HF^*(L, \phi_H^1(L))$ *is defined*. An obvious class of displaceable Lagrangian submanifolds are those in $\mathbb{C}^n$. This simple observation, when combined with the spectral sequence described in the previous section, provides many interesting consequences on the symplectic topology of such Lagrangian submanifolds as illustrated by Theorem 4.18 and 4.19.

Some further amplification of this line of reasoning was made by Biran and Cieliebak [BC] for the study of topology of Lagrangian submanifolds in (complete) *sub-critical Stein manifolds* (V, J) or a symplectic manifold M with such V as a factor. They cooked up some class of Lagrangian submanifolds in such symplectic manifolds with suitable condition on the first Chern class of M under which the Lagrangian submanifolds become monotone and satisfy the hypotheses in Theorem 4.18. Then applying this theorem, they derived restrictions on the topology of such Lagrangian submanifolds, e.g., some *cohomological sphericality* of such Lagrangian submanifolds (see Theorem 1.1 [BC]).

Recently Fukaya [Fu4] gave a new construction of the A_∞-structure described in the previous section as a deformation of the differential graded algebra of the de Rham complex of L associated to a natural solution to the Maurer–Cartan equation of the Batalin–Vilkovisky structure discovered by Chas and Sullivan [CS] on the loop space. In this way, Fukaya combined Gromov's and Polterovich's pseudo-holomorphic curve approach and Viterbo's loop space approach [V1] and proved several new results on the structure of Lagrangian embeddings in $\mathbb{C}^n$. The following are some sample results proven by this method [Fu4]:

1. If L is spin and aspherical in $\mathbb{C}^n$ then a finite cover $\widetilde{L}$ of L is homotopy equivalent to a product $S^1 \times \widetilde{L}'$. Moreover the Maslov index of $[S^1] \times [\text{point}]$ is 2.

2. If $S^1 \times S^{2n}$ is embedded as a Lagrangian submanifold of $\mathbb{C}^{2n+1}$, then the Maslov index of $[S^1] \times [\text{point}]$ is 2.

There is also the symplectic field theory approach to the proof of the first result above for the case of torus $L = T^n$ as Eliashberg explained to the authors [El2]. Eliashberg's scheme has been further detailed by Cieliebak and Mohnke [CM]. The first result for T^n is an affirmative answer to Audin's question [Au] on the minimal Maslov number of the embedded Lagrangian torus in $\mathbb{C}^n$ for general n. Previously this was known only for $n = 2$, [P], [V1], and for monotone Lagrangian tori [Oh3] (see Theorem 4.19).

6. Applications to mirror symmetry

Mirror symmetry discovered in super-string theory attracted much attention from many (algebraic) geometers since it made a remarkable prediction on the relation between the number of rational curves on a Calabi–Yau 3-fold M and the deformation theory of complex structures of another Calabi–Yau manifold $M^\dagger$.

6.1. Homological mirror symmetry. Based on Fukaya's construction of the A_∞-category of symplectic manifolds [Fu1], Kontsevich [K1] proposed a conjecture on the relation between the category $\mathrm{Fuk}(M)$ of (M, ω) and the derived category of coherent sheaves $\mathrm{Coh}(M^\dagger)$ of $M^\dagger$, and extended the mirror conjecture in a more conceptual way. This extended version is called the *homological mirror symmetry*, which is closely related to the D-brane duality studied much in physics. Due to the obstruction phenomenon we described in §3.4, the original construction in [Fu1] requires some clarification of the definition of $\mathrm{Fuk}(M)$. The necessary modification has been completed in [FOOO], [Fu2].

For the rest of this subsection, we will formulate a precise mathematical conjecture of homological mirror symmetry. Let (M, ω) be an integral symplectic manifold, i.e., one with $[\omega] \in H^2(M; \mathbb{Z})$. For such (M, ω), we consider a family of complexified symplectic structures $M_\tau = (M, -\sqrt{-1}\tau\omega)$ parameterized by $\tau \in \mathfrak{h}$ where $\mathfrak{h}$ is the upper half plane. The mirror of this family is expected to be a family of complex manifolds $M_q^\dagger$ parameterized by $q = e^{\sqrt{-1}\tau} \in D^2 \setminus \{0\}$, the punctured disc. Suitably 'formalizing' this family at 0, we obtain a scheme $\mathfrak{M}^\dagger$ defined over the ring $\mathbb{Q}[[q]][q^{-1}]$. We identify $\mathbb{Q}[[q]][q^{-1}]$ with a sub-ring of the universal Novikov ring Λ_{nov} defined in Subsection 4.1. The ext group $\mathrm{Ext}(\mathcal{E}_0, \mathcal{E}_1)$ between the coherent sheaves $\mathcal{E}_i$ on $\mathfrak{M}^\dagger$ is a module over $\mathbb{Q}[[q]][q^{-1}]$.

We consider the quadruple $\mathcal{L} = (L, s, d, [b])$, which we call a *Lagrangian brane*, that satisfies the following data:

1. L a Lagrangian submanifold of M such that the Maslov index of L is zero and $[\omega] \in H^2(M, L; \mathbb{Z})$. We also enhance L with flat complex line bundle on it.
2. s is a spin structure of L.
3. d is a grading in the sense of [K1], [Se1].
4. $[b] \in \mathcal{M}(L)$ is a bounding cochain described in Subsection 4.4.

Conjecture 6.1. To each Lagrangian brane $\mathcal{L}$ as above, we can associate an object $\mathcal{E}(\mathcal{L})$ of the derived category of coherent sheaves on the scheme $\mathfrak{M}^\dagger$ so that the following holds:

1. There exists a canonical isomorphism

$$HF(\mathcal{L}_1, \mathcal{L}_2) \cong \mathrm{Ext}(\mathcal{E}(\mathcal{L}_1), \mathcal{E}(\mathcal{L}_2)) \otimes_{\mathbb{Q}[[q]][q^{-1}]} \Lambda_{\mathrm{nov}}.$$

2. The isomorphism in 1. is functorial: namely the product of Floer cohomology is mapped to the Yoneda product of the Ext group by the isomorphism in 1.

The correct Floer cohomology $HF(\mathcal{L}_1, \mathcal{L}_2)$ used in this formulation of the conjecture is given in [FOOO] (see §3.4 for a brief description). The spin structure in $\mathcal{L}$ is needed to define orientations on the various moduli spaces involved in the definition of Floer cohomology, and the grading d is used to define an absolute integer grading on $HF(\mathcal{L}_1, \mathcal{L}_2)$. We refer the reader to [FOOO] §1.4, [Fu3] for the details of construction and for more references.

We now provide some evidences for this conjecture. A conjecture of this kind was first made by Kontsevich in [K1] for the case of an elliptic curve M, which is further explored by Polischchuk–Zaslow [PZ], and by Fukaya in [Fu3] for the case when M is a torus (and so $M^\dagger$ is also a torus) and $L \subset M$ is an affine sub-torus. In fact, in these cases one can use the convergent power series for the formal power series or the Novikov ring. Kontsevich–Soibelman [KS] gave an alternative proof, based on the adiabatic degeneration result of the authors [FOh], for the case where L is an etalé covering of the base torus of the Lagrangian torus fibration $M = T^{2n} \to T^n$. Seidel proved Conjecture 5.1 for the quartic surface M [Se2].

6.2. Toric Fano and Landau–Ginzburg correspondence. So far we have discussed the case of Calabi–Yau manifolds (or a symplectic manifold (M, ω) with $c_1(M) = 0$). The other important case that physicists studied much is the case of toric Fano manifolds, which physicists call the correspondence between the σ-model and the Landau–Ginzburg model. Referring readers to [Ho] and [HV] for detailed physical description of this correspondence, we briefly describe an application of the machinery developed in [FOOO] for an explicit calculation of Floer cohomology of Lagrangian torus orbits of toric Fano manifolds. We will focus on the correspondence of the A-model of a toric Fano manifold and the B-model of Landau–Ginzburg model of its mirror. We refer to [HIV] for the other side of the correspondence between the toric Fano B-model and the Landau–Ginzburg A-model.

According to [FOOO] the obstruction cycles of the filtered A_∞-algebra associated to a Lagrangian submanifold is closely related to $\mathfrak{m}_0$. This $\mathfrak{m}_0$ is defined by a collection of the (co)chains $[\mathcal{M}_1(\beta), ev_0]$ for all $\beta \in \pi_2(M, L)$. More precisely, we have

$$\mathfrak{m}_0(1) = \sum_{\beta \in \pi_2(M,L)} [\mathcal{M}_1(\beta), ev_0] \cdot T^{\omega(\beta)} q^{\mu(\beta)/2} \in C^*(L) \otimes \Lambda_{0,\mathrm{nov}}. \tag{6.1}$$

This is the sum of all genus zero instanton contributions with one marked point.

On the other hand, based on a B-model calculations, Hori [Ho], Hori–Vafa [HV] proposed some correspondence between the instanton contributions of the A-model of toric Fano manifolds and the Landau–Ginzburg potential of the B-model of its mirror. This correspondence was made precise by Cho and Oh [CO]. A description of this correspondence is now in order. First they proved the following

Theorem 6.2. $[\mathcal{M}_1(\beta), ev_0] = [L]$ *as a chain, for every* $\beta \in \pi_2(M, L)$ *with* $\mu(\beta) = 2$ *and so* $\mathfrak{m}_0(1) = \lambda[L]$ *for some* $\lambda \in \Lambda_{0,\mathrm{nov}}$.

It had been previously observed in Addenda of [Oh1] for the monotone case that Floer cohomology $HF^*(L, L)$ is defined even when the minimal Maslov number $\Sigma_L = 2$. Using the same argument Cho and Oh proved that $HF^*(L, L; \Lambda_{0,\mathrm{nov}})$ is well defined for the torus fibers of toric Fano manifolds *without deforming* Floer's 'boundary' map, at least for the *convex* case. We believe this convexity condition can be removed. More specifically, they proved $\mathfrak{m}_1\mathfrak{m}_1 = 0$. This is because in (4.10) the last two terms cancel each other *if* $\mathfrak{m}_0(1) = \lambda e$ *is a multiple of the unit* $e = [L]$ and then (4.9) implies that $\mathfrak{m}_0(1)$ is a $\mathfrak{m}_1$-cycle. We refer the reader to the revision of [FOOO] for a further discussion on this case, in which any filtered A_∞-algebra deformable to such a case is called *weakly unobstructed*.

In fact, Cho and Oh obtained the explicit formula

$$\mathfrak{m}_0(1) = \sum_{i=1}^{N} h^{v_j} e^{\sqrt{-1}\langle v, v_j\rangle} T^{\omega(\beta_j)}[L] \cdot q \tag{6.2}$$

after including flat line bundles attached to L and computing precise formulae for the area $\omega(\beta_j)$'s. Here $h^{v_j} = e^{\sqrt{-1}\langle v, v_j\rangle}$ is the holonomy of the flat line bundle and $\omega(\beta_j)$ was calculated explicitly in [CO]. Denote by $v = (v_1, \ldots, v_N)$ the holonomy vector of the line bundle appearing in the description of linear σ-model [HV].

On the other hand, the Landau–Ginzburg potential is given by the formula

$$\sum_{i=1}^{N} \exp(-y_i - \langle \Theta, v_i\rangle) =: W(\Theta)$$

for the mirror of the given toric manifold (see [HV] for example).

Theorem 6.3 ([CO]). *Let* $A \in \mathfrak{t}^*$ *and denote* $\Theta = A - \sqrt{-1}v$. *We denote by* $\mathfrak{m}^\Theta$ *the* A_∞*-operators associated to the torus fiber* $T_A = \pi^{-1}(A)$ *coupled with the flat line bundle whose holonomy vector is given by* $v \in (S^1)^N$ *over the toric fibration* $\pi : X \to \mathfrak{t}^*$. *Under the substitution of* $T^{2\pi} = e^{-1}$ *and ignoring the harmless grading parameter* q, *we have the exact correspondences*

$$\mathfrak{m}_0^\Theta \longleftrightarrow W(\Theta), \tag{6.3}$$

$$\mathfrak{m}_1^\Theta(pt) \longleftrightarrow dW(\Theta) = \sum_{j=1}^{n} \frac{\partial W}{\partial \Theta_j}(\Theta) d\Theta_j \tag{6.4}$$

under the mirror map given in [HV].

Combined with a theorem from [CO] which states that $HF^*(\mathcal{L}, \mathcal{L}) \cong H^*(L; \mathbb{C}) \otimes \Lambda_{0,\mathrm{nov}}$ whenever $\mathfrak{m}_1^{\Theta}(pt) = 0$, this theorem confirms the prediction made by Hori [Ho], Hori–Vafa [HV] about the Floer cohomology of Lagrangian torus fibers. This theorem has been further enhanced by Cho [Cho] who relates the higher derivatives of W with the higher Massey products $\mathfrak{m}_k^{\Theta}$. For example, Cho proved that the natural product structure on $HF^*(L, L)$ is not isomorphic to the cohomology ring $H^*(T^n) \otimes \Lambda_{0,\mathrm{nov}}$ but isomorphic to the Clifford algebra associated to the quadratic form given by the Hessian of the potential W under the mirror map. This was also predicted by physicists (see [Ho]).

Properly embedded minimal surfaces with finite topology

Antonio Ros*

Abstract. We present a synthesis of the situation as it now stands about the various moduli spaces of properly embedded minimal surfaces of finite topology in flat 3-manifolds. This family includes the case of minimal surfaces with finite total curvature in $\mathbb{R}^3$ as well as singly, doubly and triply periodic minimal surfaces.

Mathematics Subject Classification (2000). Primary 53A10; Secondary 53C42.

Keywords. Minimal surfaces, flux, least area.

1. Introduction

In these notes we will consider minimal surfaces Σ of finite topology which are properly embedded in $\mathbb{R}^3$ or in a complete flat 3-manifold $M = \mathbb{R}^3/\mathcal{G}$. For most of purposes, up to passing to a finite covering, we can assume that Σ is orientable and $\mathcal{G}$ is a cyclic group of rank 1, 2 or 3, which correspond to the singly, doubly and triply periodic cases, respectively. In the singly periodic case, $\mathcal{G}$ is generated by a screw motion (which in particular could be a translation). In the other cases, $\mathcal{G}$ consisting only on translations and M is either a flat 2-torus times $\mathbb{R}$, $T^2 \times \mathbb{R}$, or a flat 3-torus T^3.

We will focus on uniqueness and classification results. We will also emphasize those ideas and techniques which are (or could be) useful to understand the structure of moduli spaces of minimal surfaces. Although we have a large number of results in this area, several important questions about these moduli spaces remain unanswered.

There is also an interesting theory for the family of properly embedded minimal surfaces of finite genus and infinitely many ends, see for instance Meeks, Pérez and Ros [33] for structure results and Hauswirth and Pacard [13] for some recent examples. However we will not consider this situation in this paper. It is worth noticing that Colding and Minicozzi have proved that complete minimal surfaces of finite topology embedded in $\mathbb{R}^3$ are necessarily proper [3]. The same result holds in flat 3-manifolds, see [51].

Most of the surfaces we will consider have finite total curvature. They form an important and natural subclass. We refer the reader to the texts Pérez and Ros [50] and Hoffman and Karcher [15] and references therein, for more details about these surfaces.

2. Geometry of the ends

An important achievement of the last years has been the complete understanding of the asymptotic geometry of these surfaces: the ends approximate simple model surfaces like the plane, the Catenoid or the Helicoid. Hoffman and Meeks [17] and Collin [5] showed that each end of a properly embedded minimal surface in Σ in $\mathbb{R}^3$ with finite topology and more than one end is asymptotic to either a plane or a Catenoid and the ends are all parallel (henceforth we will assume that these ends are horizontal). If Σ has just one end, then Meeks and Rosenberg [38] prove that Σ approaches to a Helicoid. The proof depends on recent results concerning limits of embedded minimal surfaces without curvature bounds, see Colding and Minicozzi [4], [40] and references therein.

In the periodic case, the geometry of the surface at infinity has been determined by Meeks and Rosenberg [35], [36], see Table 1 (note that when M is a 3-torus, we are just considering compact minimal surfaces). Assuming $M = \mathbb{R}^3/S_\theta$, where S_θ denotes a screw motion of angle θ and vertical axis, each end is asymptotic either to a plane (when $\theta \neq 0$, the plane must be horizontal), or to a flat vertical annulus like in the Scherk surface, see Figure 1 (this kind of end occurs only if θ is rational), or to the end of a vertical Helicoid.

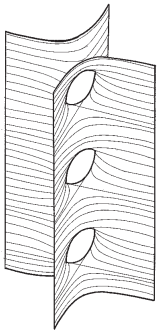

Figure 1. The singly periodic Scherk surface (seeing as a surface in the quotient space) has genus zero and four ends asymptotic to half-cylinders. It is a 1-parameter family of surfaces (the parameter is given by the angle between two consecutive wings).

If $M = T^2 \times \mathbb{R}$, then Σ has an even number of top (resp. bottom) ends and all of them are of Scherk type. The top ends are all parallel and the same holds for the bottom ones. Moreover, in case the top ends are not parallel to the bottom ends, then all the ends are vertical.

The above description of the ends has strong consequences on the geometry and the conformal structure of the minimal surface: Σ is conformally equivalent to a closed Riemann surface $\overline{\Sigma}$ with a finite number of punctures and the surface Σ can be described, by means of the Weierstrass representation, in terms of meromorphic data on the compactified surface $\overline{\Sigma}$.

Table 1. The admissible behaviour of the ends of a nonflat finite topology minimal surface. All the cases, but the first one, have finite total curvature. In the singly periodic case, all the ends of a given surface must be of the same type. The non-periodic helicoidal end is asymptotic to the Helicoid in $\mathbb{R}^3$, while the singly periodic one is asymptotic to that surface in $\mathbb{R}^3/S_\theta$.

periodicity	kind of ends
non-periodic	one helicoidal end
non-periodic	planar or catenoidal (more than one end)
singly-periodic	planar, helicoidal or Scherk ends
doubly-periodic	Scherk type

3. Minimal surfaces with finite topology in $\mathbb{R}^3$

Given integers $k \geq 0$ and $r \geq 1$, let $\mathcal{M}(k, r)$ be the moduli space of minimal surfaces $\Sigma \subset \mathbb{R}^3$ of genus k and r horizontal ends, properly embedded in $\mathbb{R}^3$. The simplest examples in this family can be characterized in terms of its topology.

Theorem 3.1. *The only properly embedded minimal surfaces of finite topology and genus zero in $\mathbb{R}^3$ are the Plane, the Catenoid and the Helicoid.*

If the surface has more than one end, the above result was proved by López and Ros [26]. In the one ended case this is a recent result of Meeks and Rosenberg [38]. The uniqueness of the Helicoid was a long standing problem which has been solved by using results of Colding and Minicozzi [4], [40].

Theorem 3.2. *The unique properly embedded minimal surface of finite topology in $\mathbb{R}^3$ with two ends is the Catenoid.*

Observe that in this characterization we prescribe only the number of ends, but not the genus. It was proved by Schoen [60] using the Alexandrov reflexion technique. A result in the same spirit has been obtained recently by Meeks and Wolf [39]: they prove that the singly periodic Scherk surface is characterized as the unique properly embedded minimal surface in $\mathbb{R}^3/T$ with four ends of Scherk type.

The first examples of higher genus where obtained by Costa [7] and Hoffman and Meeks [16] in the eighties. They constructed surfaces $\Sigma(k)$ of genus $k \geq 2$, two catenoidal ends and a middle planar end. The picture of the surface can be described as follows: each horizontal plane, other that $x_3 = 0$, meets the surface in a Jordan curve and $\Sigma \cap \{x_3 = 0\}$ consists on an equiangular system of $k + 1$ straight lines, see Figure 2.

These examples can be characterized as the ones of maximal symmetry in term of the genus of the surface.

Theorem 3.3. *Let Σ be a properly embedded minimal surface $\mathbb{R}^3$ with finite topology and positive genus. Then the symmetry group of Σ satisfies $|\mathrm{Sym}(\Sigma)| \leq$*

4(genus(Σ)+1). *Moreover, the equality holds if and only if* Σ *is one of the three-ended surfaces* $\Sigma(k)$ *constructed by Costa, Hoffman and Meeks.*

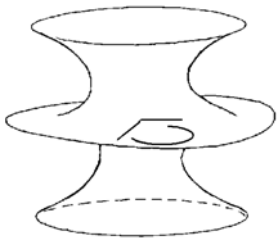

Figure 2. The Costa surface has genus one and three ends: the middle one is planar and the other are of catenoidal type. The surface has two vertical mirror planes and two horizontal reflection axes contained in the surface, but not in the mirror planes.

In the case Σ has three ends, the uniqueness in Theorem 3.3 was proved by Meeks and Hoffman [16]: the assumptions allows us to determine the symmetry group $\mathcal{G}$, the conformal structure of the surface, its picture in $\mathbb{R}^3$, up to a $\mathcal{G}$-invariant isotopy, and, finally, its Weierstrass data. This analysis has been used in several situations to produce new examples or to classify minimal surfaces with prescribed symmetry, see §1 in [1] for a general description of the method and concrete applications (in the final step we meet the so called *periods problem* which can be completely solved only in some cases). If the number of ends r is larger than 3, then the same kind of analysis shows that $r = 4$, $x_3 = 0$ is a mirror plane of the surface, $\Sigma \cap \{x_3 = 0\}$ consists of $k + 1$ Jordan curves with pairwise disjoint interior and $\Sigma \cap \{x_3 \geq 0\}$ is a surface of genus zero, 2 ends and $k + 1$ boundary components like in Figure 3, see Ros [54]. Finally we can prove that this surface does not exists by using the *vertical*

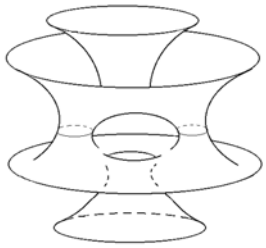

Figure 3. In $\mathbb{R}^3$, there are not properly embedded minimal surfaces of genus one, finitely many horizontal ends and an horizontal mirror plane. This can be shown by using the vertical flux deformation argument.

flux deformation argument, see [54] and Section 5 below. In fact, the surfaces exist as immersed surfaces, but they are not embedded. If $r = 1$, then the end is helicoidal and, therefore, the order of the symmetry group is at most 4. So this case is discarded.

The surface $\Sigma(k)$ admits a 1-parameter deformation by means of embedded minimal surfaces $\Sigma(k,t)$, $t \in \mathbb{R}$, with $\Sigma(k,0) = \Sigma(k)$ and three catenoidal ends for $t \neq 0$. Its symmetry group is generated by k vertical reflexion planes in equiangular position, see Hoffman and Karcher [15].

Costa [8] classified minimal tori with three punctures. This is the only positive genus case where the moduli space is completely known. The proof depends on the properties of elliptic functions.

Theorem 3.4. *Any properly embedded minimal surface in* $\mathbb{R}^3$ *with genus* 1 *and three ends lies in the family above,* $\mathcal{M}(1,3) = \{\Sigma(1,t)\}$.

For genus larger than 1, the above surfaces can be characterized in terms of its symmetries. The following classification theorem by Martin and Weber [30] extends previous results in [15], [25].

Theorem 3.5. *Let* Σ *be a properly embedded minimal surface in* $\mathbb{R}^3$ *with three ends and genus* $k \geq 2$. *If* $|\operatorname{Sym}(\Sigma)| \geq 2(k+1)$, *then* Σ *is one the of surfaces* $\Sigma(k,t)$.

A central and basic open problem concerning finite topology minimal surfaces in $\mathbb{R}^3$ is the following one, see Hoffman and Meeks [16].

Conjecture. The moduli space $\mathcal{M}(k,r)$ is empty for $r > k+2$.

In the case $k = 0$, this is has been proved in [26]. For higher genus, Meeks, Pérez and Ros [34] have proved that, given k, $\mathcal{M}(k,r)$ is empty for r large enough.

In the one-ended case, Hoffman, Weber and Wolf [18] have constructed a properly embedded minimal surface of genus one and one helicoidal end. No characterization of this example is known at the present. Meeks and Rosenberg [38] have proposed the following question (which they proved for $k = 0$).

Conjecture. For each $k = 0, 1, \ldots$, there is a unique properly embedded minimal surface in $\mathbb{R}^3$ of genus k and one end.

There is a large number of examples constructed by *desingularization*, see for instance Kapouleas [21] and Traizet [61] for the non-periodic case and Traizet and Weber [62], [64] for the periodic one.

There is another group of ideas (depending on conformal geometry tools as flat structures, Teichmüller theory, extremal length, …) which is well-adapted to prove existence, nonexistence and deformability results for minimal surfaces with prescribed symmetric-isotopy class, when the fundamental region of the surface is a disc bounded by mirror lines. The method has been developed by Weber and Wolf [65], [66], [67]. For instance, it can be shown by this method that a genus three surface, with the same symmetries than the Costa surface, and in the symmetric isotopy class of the surface in Figure 4 cannot be realized by a minimal surface, see [30].

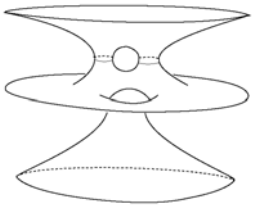

Figure 4. There are no properly embedded minimal surfaces with genus three, three ends, the same symmetries than the Costa surface and belonging to the symmetric-isotopy class of this figure. This can be shown by using flat structures and extremal length arguments.

4. The periodic case

There are a large number of examples of periodic minimal surfaces. As we are interested in those surfaces which have been characterized in some way, we will mention only a few of them.

Meeks [31] has classified the moduli space of minimal Klein bottles with a handle in flat 3-tori. These surfaces have (absolute) total curvature equal to 4π and correspond to the largest Euler characteristic among nonflat closed minimal surfaces in tori.

Theorem 4.1. *The space of closed minimal surfaces Σ in flat 3-tori with total curvature 4π (or, equivalently nonorientable surfaces with $\chi(\Sigma) = -2$) is parametrized by the family of antipodally invariant sets X in the 2-sphere with $\#(X) = 8$. Each X produces two surfaces, one and its conjugate. The surfaces Σ are all embedded.*

The next simplest situation to be understood is the genus 3 case, which contains in particular the orientable double covering of the Meeks surfaces above. There are genus 3 minimal surfaces, like the Schoen Gyroid [59], which cannot be obtained in this way. The following is a basic open question.

Problem. Give an explicit description of the moduli space of closed minimal surfaces of genus 3 in flat 3-tori.

Classical triply periodic minimal surfaces have a large symmetry group. Interestingly, several important examples have been constructed by crystallographers, see for instance Schoen [59], Fischer and Koch [11] and Lord and Mackay [27]. Many of these examples deserve a more exhaustive mathematical treatment, see Karcher [23] and Huff [19] for some results in this direction. To fix that idea, we focus now in a concrete question. Fischer and Koch [11] (see also Kawasaki [24]) have classified all the closed spatial polygons $\Gamma \subset \mathbb{R}^3$ which produce embedded triply periodic minimal surfaces by means of the following routine:

1) Construct a discoidal patch Δ by solving the Plateau problem for the boundary Γ.
2) After reflecting the patch Δ with respect to the edges of Γ, and so on, we get an embedded triply periodic minimal surface.

Most of the polygons Γ project monotonically onto a convex polygon in a plane. As a well-known consequence of the maximum principle, each of these Γ bound a unique minimal surface Δ. Therefore we deduce a number of uniqueness results for triply periodic minimal surfaces in terms of symmetry and topology. Eleven families of surfaces can be characterized in this way, see Fisher and Koch [11]. However there are four of these polygons, the ones named S, Y, $C(S)$ and $C(Y)$, which do not satisfy the convexity condition above, and so, the existence and uniqueness question remains to be clarified. In fact the surfaces Y and $C(S)$ can be realized, at least, by the D and P Schwarz surfaces, respectively (to do that we need to take on D and P patches larger than the usual ones) but other realizations cannot not be discarded at the moment.

Among noncompact periodic minimal surfaces which can be characterized in terms of its topology and symmetry, we have the following theorem, concerning a singly periodic version of Costa, Hoffman and Meeks surfaces, which combines existence results of Callahan, Hoffman and Meeks [1] with a uniqueness property by Martín and Rodriguez [29], [28].

Theorem 4.2. *Let $\Sigma \subset \mathbb{R}^3/S_\theta$ be a properly embedded minimal surface of genus $k \geq 2$ and two planar ends. Then $|\operatorname{Sym}(\Sigma)| \leq 4(k+1)$. Moreover, if the equality holds, then k is odd, $(k+1)\theta \in 4\pi\,\mathbb{Z}$ and Σ is one of the (translation invariant) surfaces constructed by Callahan, Hoffman and Meeks.*

It would be interesting and very useful to have a complete list of properly embedded minimal surfaces in flat three manifolds with small total curvature, or more generally, minimal surfaces with small total curvature modulo symmetries. As a first step, we propose the following more concrete question.

Problem. Classify properly embedded minimal surfaces in flat 3-manifolds with (absolute) total curvature smaller than or equal to 4π.

We have ten different types of compact flat 3-manifolds (some of them admit minimal surfaces of total curvature 2π).

5. Vertical flux

According to the *Weierstrass representation*, an orientable minimal surface in $\mathbb{R}^3$ can be represented by the data (Σ, g, ω), where Σ is a Riemann surface, g is a meromorphic map on Σ which corresponds (up to stereographic projection) to the Gauss map of the surface and ω is an holomorphic 1-form vanishing just at the poles of g (and the order of the zero being double of the order of the pole). The minimal surface is recovered as the immersion $\psi\colon \Sigma \to \mathbb{R}^3$ given by

$$\psi = \Re \int \left(\frac{1}{2}(1-g^2), \frac{i}{2}(1+g^2), g\right)\omega. \tag{1}$$

In order the immersion to be globally well-defined, we require that the real part of the periods of the above integral vanish. More generally, if the surface is periodic, the real part of the periods of (1) must be compatible with the prescribed periodicity. Several aspects of the geometry of the minimal surface are reflected in its Weierstrass representation.

If C is a closed curve on Σ, the *flux along the curve* is defined as the integral of the unit conormal vector, see Figure 5. This corresponds with the imaginary part of the periods of (1).

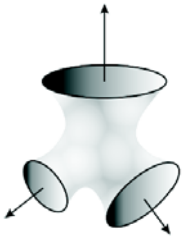

Figure 5. Flux of a minimal surface along its boundary components.

Among the simplest deformations of a minimal surface by minimal surfaces we have the *associated family*, given by $\Sigma_\theta = (\Sigma, g, e^{i\theta}\omega)$, $0 \leq \theta < 2\pi$, and the *vertical flux deformation* $\Sigma_\lambda = (\Sigma, \lambda g, \frac{1}{\lambda}\omega)$, $\lambda > 0$. In the first one the Gauss map and the induced metric are preserved. This deformation is globally well-defined if and only if all fluxes vanish. The second deformation fixes the third coordinate of the immersion and transforms the normal direction in a simple conformal way. It gives globally well-defined immersions if and only if the flux of any curve on Σ is vertical. An important difference between both deformations is that the first one consists on a compact family of surfaces while the second one is noncompact. After reparametrization and change of scale in $\mathbb{R}^3$, the part of the surface around a point where g has a zero converges, when λ goes to infinity, to the surface given by the Weierstrass data $(\mathbb{C}, z^n, a\,dz)$, $a \in \mathbb{C}^*$, which is not embedded. In a neighborhood of an end of the surface given by a punctured disc $0 < |z| < \varepsilon$ with meromorphic g and ω and $g(0) = 0$, Σ_λ converges to the minimal surface $(\mathbb{C}^*, z^n, a\,z^m dz)$, $a \in \mathbb{C}^*$. It can be checked easily that the only surfaces of this type which are embedded are the (vertical) Catenoid and the Helicoid. These surfaces correspond to the cases $n = 1, m = -2, a = 1$ and $m = n - 1, a = i$, respectively. Planar, catenoidal and helicoidal ends with vertical normal directions transform by the λ-deformation into ends of the same type (note that the flux at this ends is always vertical). Under suitable global assumptions this deformation gives strong restrictions on the geometry and the topology of minimal surfaces all of whose fluxes are vertical, see works of López, Pérez and Ros [26], [47], [54], [44]. In particular we have the following result.

Theorem 5.1. *A nonflat properly embedded minimal surface $\Sigma \subset \mathbb{R}^3$ of finite topology, horizontal ends and vertical flux is either a Catenoid or an Helicoid.*

As a minimal surface in the hypothesis of Theorem 3.1 has necessarily vertical flux, this theorem follows from the result above.

Now we explain briefly the proof of Theorem 5.1. First observe that the deformation Σ_λ, $\lambda > 0$, is well defined. It follows easily from the maximum principle for minimal surfaces that, if we start with an embedded nonflat triply-periodic minimal surface and we deform it continuously by triply-periodic minimal surfaces, embeddedness is preserved along the deformation. For general properly embedded minimal surfaces this fact is not generally true and it depends of the behaviour of the deformation at infinity. The maximum principle at infinity [37] and the behaviour of the vertical flux deformation at the ends allows to conclude that the surfaces Σ_λ are all embedded. Taking λ going to zero and infinity we conclude that no point on Σ has vertical normal vector. In the same way, we deduce that Σ has no planar ends and we obtain directly that Σ is homeomorphic either to a plane or a annulus. Now the theorem follows from [43], [38].

Some uniqueness results for singly periodic embedded minimal surfaces of finite topology, can be obtained by the arguments above:

i) there are not genus one minimal surfaces in $\mathbb{R}^3/S_\theta$, $\theta \neq 0$, with finitely many horizontal planar ends, see [47], and

ii) the only genus zero minimal surface in $\mathbb{R}^3/T$ with finitely many helicoidal ends is the Helicoid, [44].

Table 2. The surfaces in the first column are characterized as the unique embedded minimal surfaces satisfying the restrictions in the other columns. The last three results follow from the vertical flux deformation argument. The genus must be computed in the quotient surface.

surface	periodicity	genus	ends
Helicoid	none	0	one end
Catenoid	none	whatever	two ends
Catenoid	none	0	more than one
Helicoid	translation	0	helicoidal
none	screw $\theta \neq 0$	1	planar

6. Compactness and limit configurations

Consider a sequence $\{\Sigma_n\} \subset \mathcal{M}(k, r)$, where $\Sigma_n \subset \mathbb{R}^3$ is a properly embedded minimal surface of genus k and $r \geq 2$ horizontal ends. As the Gauss map $g_n \colon \overline{\Sigma}_n \to \overline{\mathbb{C}}$ is a meromorphic map of fixed degree, it converges up to a subsequence, to a family of nonconstant meromorphic maps $g_{\infty,1} \colon \overline{\Sigma}_{\infty,1} \to \overline{\mathbb{C}}, \ldots, g_{\infty,m} \colon \overline{\Sigma}_{\infty,m} \to \overline{\mathbb{C}}$, defined

over closed Riemann surfaces with $\text{degree}(g_{\infty,1})+\cdots+\text{degree}(g_{\infty,m}) = \text{degree}(g_n)$. For large n, one can see inside Σ_n large pieces of the surfaces $\overline{\Sigma}_{\infty,s}$ joined by regions with almost constant g_n.

A more careful analysis, see Ros [53], shows that each one of these meromorphic maps $g_{\infty,s}$ is the Gauss map of a properly embedded minimal surface $\Sigma_{\infty,s} \subset \mathbb{R}^3$ with horizontal ends, and that suitably chosen homothetic images of Σ_n converge to the different $\Sigma_{\infty,s}$. Moreover the regions joining these surfaces consist of *unbounded pieces* Ω_i, $i = 1, \ldots, r$ satisfying the following properties:

a) Each Ω_i contains exactly one end of Σ_n. So, the unbounded pieces are naturally ordered by their levels in $\mathbb{R}^3$,

b) the projection of Ω_i over the plane $\{x_3 = 0\}$ is one-to-one, and

c) the boundary of Ω_i consists of several convex Jordan curves in horizontal planes.

Therefore, for large n, the surface Σ_n looks like the one in Figure 6. As an example, the three-ended surfaces $\Sigma(k, t)$ described in §3 converge, when t goes to infinity, to a Catenoid between the level 1 and 2 and $k + 1$ Catenoids between levels 2 and 3.

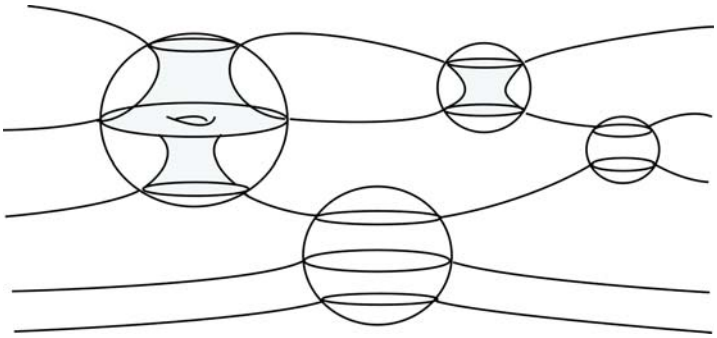

Figure 6. A sequence of minimal surfaces with fixed finite topology converges, up to a subsequence, to a union of surfaces with smaller topology joined by unbounded domains at different levels.

Working at the right scale, the limit can be seen as a horizontal plane of finite multiplicity with a finite number of marked points at different levels. Traizet [63] associates to this figure a number of horizontal forces (which correspond to rescaled limits of the fluxes of Σ_n). This *limit configuration* must be balanced in a natural sense.

We say that the moduli space $\mathcal{M}(k, r)$ is *compact (in the strong sense)* if any sequence $\{\Sigma_n\} \subset \mathcal{M}(k, r)$ converges (up to a subsequence) to a limit which consists of a single surface $\Sigma_\infty \in \mathcal{M}(k, r)$. In particular the moduli spaces $\mathcal{M}(k, 3)$, $k \geq 1$, are noncompact. The following theorem have been obtained by Ros [53] (for $r \geq 5$) and Traizet [63].

Theorem 6.1. *The moduli spaces* $\mathcal{M}(1, r)$, $r \geq 4$ *are compact* (*in the strong sense*).

In fact the compactness result can be extended (in a conditional but useful way) to higher genus. The space $\mathcal{M}(k, r)$ is compact for $r \geq g + 3$, assuming that the Hoffman–Meeks conjecture is true for genus smaller than k. This compactness can be seen as a first step in the proof of this conjecture. Thus Hoffman–Meeks conjecture will follow from the following one.

Conjecture. The moduli space $\mathcal{M}(k, r)$ is either empty or noncompact.

The compactness result in Ros [53] depends of the non existence of the piece described in Figure 7 in a limit of surfaces Σ_n with fixed topology. This piece consists

Figure 7. A sequence of minimal surfaces with fixed finite topology in $\mathbb{R}^3$ cannot converge to a limit which contains that piece, because the vertical flux argument gives a contradiction.

on an unbounded domain with just two catenoidal ends forming on it, one of positive and the other of negative logarithmic growth. The nonexistence of this piece is shown by using the vertical flux deformation argument.

The compactness theorem of Traizet [63] follows from the nonexistence in the limit of the surfaces Σ_n of a subsurface like the one in Figure 8. It is formed by

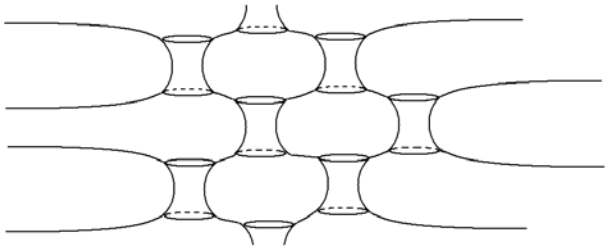

Figure 8. This picture cannot appear in a limit of a sequence of minimal surfaces in $\mathcal{M}(k, r)$. Otherwise, the limit configuration will be unbalanced.

several unbounded pieces at consecutive levels. Each one of this pieces is connected with the nearest ones by exactly two Catenoids forming. The top and the bottom unbounded pieces connect with the remaining part of the surface just by a catenoidal end forming. The reason why this piece cannot exist is because it is unbalanced.

The above ideas can be extended to the periodic case although the results have been explicitly stated only in some cases. Consider, for instance, a sequence $\{\Sigma_n\}$ of

genus one minimal surfaces with r horizontal planar ends, properly embedded in the flat three manifold $\mathbb{R}^3/T_n$, where T_n is a non-horizontal vector. It can be shown that the third coordinate has no critical points on $\overline{\Sigma}_n$ and so, each horizontal level curve is a Jordan curve (which might pass through one of the ends) and the Gauss map omits the vertical directions.

Up to a subsequence and suitable choice of scaling, $\{\Sigma_n\}$ converges either to a minimal surface $\Sigma_\infty \subset \mathbb{R}^3/T_\infty$ with the same topology than Σ_n or to a union of genus zero surfaces. Using the uniqueness results stated in Section 3 and further analysis, we can see that Σ_n approach to either r vertical Catenoids forming or to 2 vertical Helicoids forming, [32], see Figures 9 and 10. The second option is a simple example of the so called *parking garage* structure.

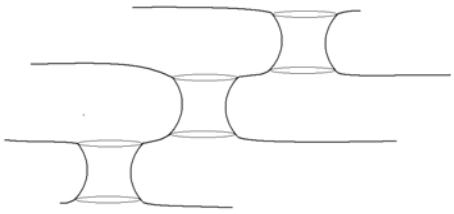

Figure 9. The Catenoid forming limit.

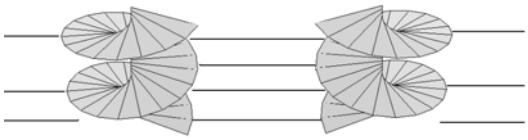

Figure 10. The Helicoid forming figure.

7. Smoothness of moduli spaces

Now we want to understand the structure of the moduli space $\mathcal{M}(k,r)$, $r \geq 2$, of finite topology minimal surfaces in $\mathbb{R}^3$ at its nonsingular points.

By expository reasons, we will consider in this section not $\mathcal{M}(k,r)$ but the subspace $\mathcal{M}'(k,r)$ of surfaces whose end logarithmic growths are all different (thus embeddedness is preserved by natural deformations in this space). Infinitesimal deformations of Σ in $\mathcal{M}'(k,r)$ are represented by *Jacobi functions*. These are smooth solutions $u\colon \Sigma \to \mathbb{R}$ of the equation $\Delta u + |\sigma|^2 u = 0$, where Δ is the Laplacian of the induced metric and $|\sigma|^2$ is the square length of the second fundamental form of the immersion. The functions u have at most logarithmic singularities at the ends of Σ,

which correspond to the fact that the growing of the catenoidal ends changes along the deformation. Denote by $\mathcal{J}(\Sigma)$ the space of these Jacobi functions. Using linear elliptic theory, it can be shown that $\dim \mathcal{J}(\Sigma) \geq r+3$, Pérez and Ros [48]. Moreover the subspace of nondegenerate surfaces $\mathcal{M}^*(k,r) = \{\Sigma \in \mathcal{M}'(k,r) : \dim \mathcal{J}(\Sigma) = r+3\}$ is a real analytic manifold, whose tangent space at a point Σ coincides with $\mathcal{J}(\Sigma)$. On this manifold we have the following additional structure: let $f\colon \mathcal{M}(k,r) \to \mathbb{R}^{2r}$ be the map which associates to a surface Σ the logarithmic growth of the asymptotic Catenoid and the *height of its neck* for each one of its ends. Then f induces a Lagrangian immersion of $\mathcal{M}^*(k,r)$ (modulo horizontal translations) in $\mathbb{R}^{2r-2}$, see [48]. We have been also able to compute the second fundamental form of this immersion, see Pérez and Ros [49].

If $\mathcal{B}(\Sigma)$ denotes the space of bounded Jacobi functions on Σ, then $\mathcal{B}(\Sigma)$ contains, at least the linear functions of the Gauss map (which correspond to the infinitesimal translations) and the function $\det(N, p, e_3)$, N, p and e_3 being the normal vector, the position vector and the vertical direction, respectively. This Jacobi function corresponds to the infinitesimal rotation of the surface around the vertical axis. It can be shown that if the above functions are the unique functions in $\mathcal{B}(\Sigma)$, then the surface is nondegenerate.

An interesting, and somewhat intriguing, fact is that bounded Jacobi functions in $\mathcal{B}(\Sigma)$ can be represented by branched conformal minimal immersions from $\overline{\Sigma} - B$ into $\mathbb{R}^3$, B being the ramification divisor of the Gauss map of Σ, whose Gauss map is the same than the one of Σ and whose ends have a bounded coordinate function, see Montiel and Ros [41] and Ejiri and Kotani [10]. Using this representation, Nayatani [42] has shown that the Costa, Hoffman and Meeks surfaces $\Sigma(k)$ are nondegenerate, for $k \leq 37$.

The local structure around a nondegenerate surface has been also considered in the periodic case and either planar or Scherk type ends [45], [14]. It would be interesting to clarify the nondegeneration condition and the smoothness properties of the moduli space of minimal surfaces in the case of helicoidal ends, both periodic and non-periodic.

Let $\mathcal{M}$ be the space of genus 3 embedded minimal surfaces in flat 3-tori. Then we can prove that there are some degenerate surfaces in $\mathcal{M}$, arguing as follows: assuming that any surface is nondegenerate, the subset $\mathcal{M}'$ of surfaces in $\mathcal{M}$ obtained as two sheeted coverings of non-orientable minimal surfaces of Euler characteristic -2 described in Theorem 4.1 is a union of connected components of $\mathcal{M}$. However, this is impossible as it is known that the Schwarz minimal surface $P \in \mathcal{M}'$, can be deformed to the Schoen Gyroid $G \in \mathcal{M} - \mathcal{M}'$.

An important open problem is to decide if a (generic) surface in $\mathcal{M}'(k,r)$ is nondegenerate. A related question is to give practical criteria which guarantee that a surface is nondegenerate. As an example, Montiel and Ros [41] proved that if all the branch values of the Gauss map (on the compactified surface $\overline{\Sigma}$) lie on a great circle, then the only bounded Jacobi functions are the linear functions of the Gauss map. In this way, we can prove the nondegeneracion of some surfaces, like finite coverings

of singly and doubly periodic Scherk surfaces, Riemann examples and Saddle towers constructed by Karcher [22].

8. Classification results

In this section we describe a strategy which has been used several times to classify surfaces in a moduli space. The first result of this type was proved by Meeks, Pérez and Ros [32] who classified genus zero properly embedded minimal surfaces in $\mathbb{R}^3$ with infinite symmetries. One of the key results in this classification is contained in the following theorem, see Figure 11.

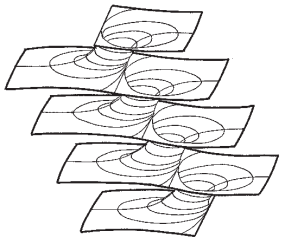

Figure 11. The Riemann minimal example.

Theorem 8.1. *A minimal surface Σ of genus 1 and r planar horizontal ends properly embedded in $\mathbb{R}^3/T$, T being a non horizontal vector, is a finite covering of one of the Riemann minimal examples.*

We will use this result to explain briefly how the method works. Consider the moduli space $\mathcal{M}$ of surfaces described in the theorem (r is fixed). As described in Section 6, any horizontal section C (whose level does not coincide with the level of an end) of a surface in $\mathcal{M}$ is a Jordan curve. The flux along C cannot be vertical, as the vertical flux deformation give a contradiction. Normalize the surfaces so that the third coordinate of the flux vector of C is 2π and define *the horizontal flux map* $F\colon \mathcal{M} \to \mathbb{R}^2 - \{0\}$ as the horizontal component of the flux along C (note that the flux of a curve around a planar end is zero and therefore the flux vector does not depend of the level we use to compute it). The following property follows from the results in Section 6.

I) *The map F is proper.*

In fact, the Catenoid forming picture has almost vertical flux which means that $F(\Sigma)$ converges to 0. In the Helicoid forming case the flux vector is almost horizontal and so $F(\Sigma)$ goes to ∞.

Denote by $\mathcal{R}$ the subspace of $\mathcal{M}$ formed by the coverings of the Riemann surfaces. The results in Section 7 imply that $\mathcal{R}$ is a smooth 2-dimensional manifold and moreover,

II) *$\mathcal{R}$ is an open an closed subset of $\mathcal{M}$, and $F\colon \mathcal{R} \to \mathbb{R}^2 - \{0\}$ is a diffeomorphism.*

We want to prove that F is an open map. This fact would follow, via the implicit function theorem, if we know that the surfaces in $\mathcal{M}$ are nondegenerate. However we do not have this property a priori. Instead we use the following complex variable theorem.

Theorem 8.2. *Let $f\colon \{z \in \mathbb{C}^m\colon |z| < \varepsilon\} \to \mathbb{C}^m$ be a holomorphic map with $f(0) = 0$. If 0 is an isolated point in $f^{-1}(0)$, then f is open around the origin.*

In our context we consider the space of *Weierstrass data* $\mathcal{W}$ which is a m-dimensional complex manifold. We also consider the *Period map* which consists on, both, the real and the imaginary parts of the periods which appear in the Weierstrass representation along a certain basis of the homology of the Riemann surface. A crucial point is that in this way we find a holomorphic map $P\colon \mathcal{W} \to \mathbb{C}^m$ between manifolds of the same dimension. This is a strong restriction which limitates the range of application of the whole method to problems where the involved surfaces are essentially (may be modulo symmetries) of genus zero.

In order a point Σ in $\mathcal{W}$ to define an immersed minimal surface, the real part of $P(\Sigma)$ must be zero. The imaginary part corresponds to the fluxes along the homology base and in our case this fluxes reduce to $F(\Sigma)$. Given a surface $\Sigma_0 \in \mathcal{M}$, the analytic subset $\mathcal{S} = \{\Sigma \in \mathcal{W} : P(\Sigma) = P(\Sigma_0)\}$ coincides, locally around Σ_0, with $\{\Sigma \in \mathcal{M} : F(\Sigma) = F(\Sigma_0)\}$ which is compact. After that we can deduce that Σ_0 is an isolated surface in $\mathcal{S}$, and then, using Theorem 8.2, we get that

III) *The map F is open.*

The final step is to prove that for some value of $\mathbb{R}^2 - \{0\}$ the pullback image of F consists only of Riemann examples. To do that we use an implicit function argument at the degenerate point of $\mathcal{W}$ given by the r Catenoids forming limit. Is can be shown that P extends holomorphically at that boundary point and has nonzero Jacobian. This proves that

IV) *Given $\Sigma \in \mathcal{M}$, if the length of $F(\Sigma)$ is small enough, then Σ is one of the Riemann examples.*

In Table 3 we have collected the different situations where the above strategy has been successfully applied. The first column contains the surfaces whose uniqueness have been shown. Lazard–Holly and Meeks [20] proved that the doubly periodic Scherk surface is the only genus zero minimal surface in $T^2 \times \mathbb{R}$. Pérez and Traizet [51] have proved recently that the Saddle towers constructed by Karcher [22] are the only examples of genus in $\mathbb{R}^3/T$ other than the Helicoid, and Rodriguez, Pérez and Traizet [46] characterized a 3-dimensional family of standard examples constructed by Karcher [22] and Meeks and Rosenberg [35], as the unique double periodic minimal surfaces of genus one and parallel Scherk type ends. Finally Meeks and Wolf [39]

Table 3. The (families of) surfaces in the first column have been characterized as the unique among surfaces satisfying the restrictions of the other columns. The topology we consider is the one of the quotient surface.

surfaces	periodicity	genus	ends
Riemann	singly	1	planar
Scherk	doubly	0	whatever
Saddle towers	single translation	0	Scherk
Standard examples	doubly	1	parallel Scherk
Scherk	single translation	whatever	four Scherk

have proved that the singly periodic Scherk surface is the unique surface in $\mathbb{R}^3/T$ with four Scherk ends. The proofs of these results follow formally the same steps than the one of the Riemann examples case, but the concrete arguments are more involved and several additional problems appear. In particular, the proof of the last result depends on a different group of ideas developed around the notion of orthodisks in Riemann surface theory. The following is a very natural problem which contains several of the results above.

Problem ([51]). Classify complete genus zero surfaces (of finite topology) embedded in complete flat 3-manifolds.

We remark that there exists a large family of genus zero surfaces with helicoidal ends in $\mathbb{R}^3/S_\theta$. These are called *twisted saddle towers* and were constructed by Karcher [22]. These surfaces are obtained as twisted deformations of the surfaces characterized in [51]. Other flat 3-manifolds may have genus zero minimal surfaces with ends of Scherk type.

9. Least area surfaces

Of course, the most natural class of minimal surfaces is the one of area minimizing surfaces. Although the plane is the unique least area surface in $\mathbb{R}^3$, there are nonplanar least area surfaces if we prescribe suitable symmetries. The complete description of area minimizing surfaces among surfaces satisfying a natural constraint, like to belong to a given symmetric isotopy class, is natural question. As a first goal, we propose the following more precise problem.

Problem. Classify area minimizing surfaces, modulo 2, in complete flat 3-manifolds.

Table 4. $\mathbb{Z}_2$-least area surfaces in the flat 3-manifolds obtained as a quotient of $\mathbb{R}^3$ by a translations group.

3-manifold	least area surfaces (mod 2)
$\mathbb{R}^3$	plane
$\mathbb{R}^3/T$	planar and 2π-Helicoid
$T^2 \times \mathbb{R}$, T^2 rectangular	planar and 2π-Scherk
$T^2 \times \mathbb{R}$, $T^2 \neq$ rectangular	planar
T^3	2-tori and $\chi(\Sigma) = -2$ (?)

It can be seen that any solution of this problem is either (a quotient of a) plane or an one-sided surface. In Table 4 we have listed the solutions of the problem for the quotients of $\mathbb{R}^3$ by translation groups. The result has been proved by Ros [55] and follows from the classification of complete stable surfaces in these 3-manifolds. The 2-sided case was solved by do Carmo and Peng [9], Fisher-Colbrie and Schoen [12] and Pogorelov [52], but the 1-sided remained open; for previous related results see Ross and Schoen [57], [58]. We prove that a complete stable minimal surface in $\mathbb{R}^3/T$ (resp. $T^2 \times \mathbb{R}$) is either planar or the nonorientable Helicoid (resp. Scherk surface) of total curvature 2π. We also prove that these surfaces are, both, area minimizing (mod 2). In the case of flat 3-tori, we prove that any stable nonflat closed minimal surface is a nonorientable surface with Euler characteristic equal to -2. Some surfaces of this topology are stable, like P and D Schwarz surfaces, see [56], but some other are unstable. However it is natural to hope that area minimizing surfaces in a flat 3-torus are flat 2-tori.

Applications of loop group factorization to geometric soliton equations

Chuu-Lian Terng*

Abstract. The 1-d Schrödinger flow on S^2, the Gauss–Codazzi equation for flat Lagrangian submanifolds in $\mathbb{R}^{2n}$, and the space-time monopole equation are all examples of geometric soliton equations. The linear systems with a spectral parameter (Lax pair) associated to these equations satisfy the reality condition associated to $\mathrm{SU}(n)$. In this article, we explain the method developed jointly with K. Uhlenbeck that uses various loop group factorizations to construct inverse scattering transforms, Bäcklund transformations, and solutions to Cauchy problems for these equations.

Mathematics Subject Classification (2000). 35Q55, 37K15, 37K35, 53C07.

Keywords. Soliton equations, space-time monopole equation, inverse scattering, Bäcklund transformations.

1. Introduction

A Hamiltonian system in $2n$-dimension is called *completely integrable* if it has n independent commuting Hamiltonians. By the Arnold–Liouville Theorem, such systems have *action-angle* variables that linearize the flow. The concept of completely integrability has been extended to soliton equations. These equation can be linearized using "scattering data", allowing one to use the Inverse Scattering method to solve the Cauchy problem with rapidly decaying initial data. Two model examples are the Korteweg–de Vries equation (KdV) and the non-linear Schrödinger equation (NLS). Soliton equations often arise naturally in differential geometry too. For example, the Gauss–Codazzi equations for surfaces in $\mathbb{R}^3$ with Gaussian curvature -1, isothermic surfaces in $\mathbb{R}^3$ [11], isometric immersions of space forms in space forms [15], [25], [24], Egoroff metrics, and flat Lagrangian submanifolds in $\mathbb{C}^n$ and $\mathbb{C}P^n$ [26], and the space-time monopole equation are soliton equations.

One of the key properties of a soliton equation is the existence of a Lax pair. A PDE for maps $q\colon \mathbb{R}^n \to \mathbb{R}^m$ admits a *Lax pair* if there exists a family of $\mathcal{G}$-connections θ_λ on $\mathbb{R}^n$, given in terms of q, such that the condition for θ_λ to be flat for all λ in an open subset of $\mathbb{C}$ is that q satisfy the PDE. The parameter λ is called the *spectral parameter*. For a solution q decaying at spatial infinity, we often can find a

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

normalization so that there exists a unique parallel frame E_λ of θ_λ. Usually E_λ has two types of singularities for $\lambda \in \mathbb{C}P^1$; one type is a jump across a contour and the other type is a pole. We call the jump singularities of E_λ the *continuous scattering data for* q and the poles and residues of E_λ the *discrete scattering data for* q. The *scattering transform* maps a solution q to its scattering data S. A key feature of soliton PDEs is that the induced equations on the scattering data is linear, so it is easy to write down the scattering data of a solution at time t for a given initial data. The inverse scattering transform reconstructs q from the scattering data, i.e., it reconstructs E_λ from prescribed singularities. This is done for KdV in [17], for NLS in [36], [14], and for the n-wave equation in [36], [4], [5]. As a consequence, the Cauchy problem for these soliton equations can be solved via the inverse scattering transform.

The proof of the existence of the inverse scattering transform for soliton equations involves hard analysis and is difficult ([4]). However, if the Lax pair satisfies the $\mathrm{SU}(n)$-reality condition, then the frame $E_\lambda(x)$ has only one jumping circle plus pole singularities in the λ-sphere for each x, so the continuous scattering data is a loop into $\mathrm{SL}(n,\mathbb{C})$ for each x. In this case, we can use Pressley–Segal loop group factorization to construct the inverse scattering transform for the continuous scattering data (cf. [27]).

Bäcklund transformations (BTs) for surfaces in $\mathbb{R}^3$ with $K = -1$ arose from the study of line congruences in classical differential geometry. It associates to each surface in $\mathbb{R}^3$ with $K = -1$ a family of compatible systems of ordinary differential equations (ODEs) so that solutions of these ODE systems give rise to a family of new surfaces in $\mathbb{R}^3$ with $K = -1$. One can use line and sphere congruences to construct Bäcklund type transformations for many geometric problems in differential geometry (cf. [24]). Bäcklund transformations for soliton equations produce a new solution from a given one by adding discrete scattering data. These transformations can be obtained in a unified way from the following type of factorization: Let Γ_1, Γ_2 be disjoint subsets of S^2, and $g_i\colon S^2 \setminus \Gamma_i \to \mathrm{GL}(n,\mathbb{C})$ holomorphic for $i = 1, 2$. Factor $g_1 g_2 = \tilde{g}_2 \tilde{g}_1$ such that $\tilde{g}_i$ is holomorphic on $S^2 \setminus \Gamma_i$. This factorization can always be done when g_1 is rational and g_i satisfy the $\mathrm{SU}(n)$-reality condition, so global Bäcklund transformations exist for flows in the $\mathrm{SU}(n)$-hierarchy and for the space-time monopole equation with gauge group $\mathrm{SU}(n)$. Moreover, if the initial data q_0 has continuous scattering data S and discrete scattering data $\triangle$, then we can first use Pressley–Segal loop group factorization to construct a solution q whose scattering data is S, and then apply BTs to q to construct the solution $\tilde{q}$ with scattering data $S \cup \triangle$.

This paper is organized as follows: In Section 2, we outline the construction of the ZS-AKNS hierarchy of soliton equations associated to a complex simple Lie algebra $\mathcal{G}$, and review certain invariant submanifolds and restricted flows associated to involutions of $\mathcal{G}$. We give examples of PDEs in submanifold geometry that are soliton equations in Section 3. In Section 4, we give a brief review of Lax pairs associated to the space-time monopole equations. The direct scattering for soliton equations in the $\mathrm{SU}(n)$-hierarchy is given in Section 5, and direct scattering for space monopole equation is in Section 6. We use Pressley–Segal loop group factorization

to construct the inverse scattering transform for flows in the SU(n)-hierarchy and for the space-time monopole equation in Section 7 and 8 respectively. In Section 9, we use the Birkhoff factorization to construct local solutions for flows in the SU(n)-hierarchy. Finally, we discuss the constructions of Bäcklund transformations, pure solitons, and solutions with both continuous and discrete scattering data for flows in the SU(n)-hierarchy and for the space-time monopole equations in the last two sections.

Acknowledgment. The author thanks her long-time collaborator and good friend Karen Uhlenbeck. Much of this article concerns our joint project on the differential geometric aspects of soliton equations.

2. Soliton equations associated to simple Lie algebras

The method of constructing a hierarchy of $n \times n$ soliton flows developed by Zakharov–Shabat [39] and Ablowitz–Kaup–Newell–Segur [1] works equally well if we replace the algebra of $n \times n$ matrices by a semi-simple, complex Lie algebra $\mathcal{G}$ (cf. [18], [23], [27]).

The G-hierarchy. Let G be a complex, simple Lie group, $\mathcal{G}$ its Lie algebra, $\langle\ ,\ \rangle$ a non-degenerate, ad-invariant bilinear form on $\mathcal{G}$, $\mathcal{A}$ a maximal abelian subalgebra of $\mathcal{G}$, and $\mathcal{A}^\perp = \{\xi \in \mathcal{G} \mid \langle \xi, \mathcal{A}\rangle = 0\}$. Let $\mathcal{S}(\mathbb{R}, \mathcal{A}^\perp)$ denote the space of rapidly decaying maps from $\mathbb{R}$ to $\mathcal{A}^\perp$. Fix a regular element $a \in \mathcal{A}$ (i.e., the centralizer $\mathcal{G}_a = \mathcal{A}$). Then there is a unique family of $\mathcal{G}$-valued maps $Q_{b,j}(u)$ parametrized by $b \in \mathcal{A}$ and positive integer j satisfying the following recursive formula,

$$(Q_{b,j}(u))_x + [u, Q_{b,j}(u)] = [Q_{b,j+1}(u), a], \quad Q_{b,0}(u) = b, \tag{1}$$

and $\sum_{j=0}^{\infty} Q_{b,j}(u)\lambda^{-j}$ is conjugate to b as an asymptotic expansion at $\lambda = \infty$. In fact, $Q_{b,j}(u)$ is a polynomial in $u, \partial_x u, \ldots, \partial_x^{j-1} u$ (cf., [23], [27]). For $b \in \mathcal{A}$ and a positive integer j, the (b, j)-*flow* is the following evolution equation on $\mathcal{S}(\mathbb{R}, \mathcal{A}^\perp)$:

$$u_t = (Q_{b,j}(u))_x + [u, Q_{b,j}(u)] = [Q_{b,j+1}(u), a]. \tag{2}$$

The G-*hierarchy* is the collection of these (b, j)-flows.

The recursive formula (1) implies that u is a solution of the (b, j)-flow (2) if and only if

$$\theta_\lambda = (a\lambda + u)\, dx + (b\lambda^j + Q_{b,1}(u)\lambda^{j-1} + \cdots + Q_{b,j}(u))\, dt \tag{3}$$

is a flat $\mathcal{G}$-valued connection 1-form on the (x, t) plane for all $\lambda \in \mathbb{C}$. Here θ_λ is (left) flat, i.e., $d\theta_\lambda + \theta_\lambda \wedge \theta_\lambda = 0$. In other words, θ_λ is a Lax pair for the (b, j)-flow (2). Also θ_λ is flat is equivalent to

$$[\partial_x + a\lambda + u,\ \partial_t + b\lambda^j + Q_{b,1}(u)\lambda^{j-1} + \cdots + Q_{b,j}(u)] = 0.$$

The U-hierarchy. Let τ be an involution of G such that its differential at the identity e (still denoted by τ) is a conjugate linear involution on the complex Lie algebra $\mathcal{G}$, and U the fixed point set of τ. The Lie algebra $\mathcal{U}$ of U is a real form of $\mathcal{G}$. If $a, b \in \mathcal{U}$, then the (b, j)-flow in the G-hierarchy leaves $\mathcal{S}(\mathbb{R}, \mathcal{A}^\perp \cap \mathcal{U})$-invariant (cf. [27]). The restriction of the flow (2) to $\mathcal{S}(\mathbb{R}, \mathcal{A}^\perp \cap \mathcal{U})$ is the (b, j)-flow in the *U-hierarchy*. Since $Q_{b,j}(u)$ lies in $\mathcal{U}$, the Lax pair θ_λ defined by (3) is a $\mathcal{G}$-valued 1-form satisfying the *U-reality condition*:

$$\tau(\theta_{\bar\lambda}) = \theta_\lambda. \tag{4}$$

The U/K-hierarchy. Suppose U is the real form defined by the involution τ of G, and σ an involution of G such that $d\sigma_e$ is complex linear and $\sigma\tau = \tau\sigma$. Let K be the fixed point set of σ in U, $\mathcal{U}$ and $\mathcal{K}$ the Lie algebras of U and K respectively, and $\mathcal{P}$ the -1-eigenspace of $d\sigma_e$ on $\mathcal{U}$. Then U/K is a symmetric space, and $\mathcal{U} = \mathcal{K} + \mathcal{P}$. Let $\mathcal{A}$ be a maximal abelian subalgebra in $\mathcal{P}$. If $a, b \in \mathcal{A}$ and u in $\mathcal{A}^\perp \cap \mathcal{K}$, then the (b, j)-flow in the U-hierarchy leaves $\mathcal{S}(\mathbb{R}, \mathcal{A}^\perp \cap \mathcal{K})$ invariant if j is odd, and is normal to $\mathcal{S}(\mathbb{R}, \mathcal{A}^\perp \cap \mathcal{K})$ if j is even. The restriction of odd flows in the U-hierarchy to $\mathcal{S}(\mathbb{R}, \mathcal{A}^\perp \cap \mathcal{K})$ is called the *U/K-hierarchy*. Moreover, θ_λ satisfies the *U/K-reality condition*

$$\tau(\theta_{\bar\lambda}) = \theta_\lambda, \quad \sigma(\theta_\lambda) = \theta_{-\lambda}.$$

Example 2.1. SL$(2, \mathbb{C})$-*hierarchy* (cf. [2]). Let $a = b = \operatorname{diag}(i, -i)$ and $\mathcal{A} = \mathbb{C}a$. Then

$$\mathcal{A}^\perp = \left\{ \begin{pmatrix} 0 & q \\ r & 0 \end{pmatrix} \mid q, r \in \mathbb{C} \right\},$$

$$Q_{a,1}(u) = u = \begin{pmatrix} 0 & q \\ r & 0 \end{pmatrix}, \quad Q_{a,2}(u) = \frac{i}{2} \begin{pmatrix} qr & \partial_x q \\ -\partial_x r & -qr \end{pmatrix},$$

$$Q_{a,3} = \frac{i}{4} \begin{pmatrix} q\partial_x r - r\partial_x q - \partial_x^2 q + 2q^2 r \\ -\partial_x^2 r + 2qr^2 - q\partial_x r + r\partial_x q \end{pmatrix}, \ldots.$$

The (a, j)-flows, $j = 1, 2, 3$, in the SL$(2, \mathbb{C})$-hierarchy are:

$$\begin{aligned} &\partial_t q = \partial_x q, && \partial_t r = \partial_x r, \\ &\partial_t q = \frac{i}{2}(\partial_x^2 q - 2q^2 r), && \partial_t r = -\frac{i}{2}(\partial_x^2 r - 2qr^2), \\ &\partial_t q = \frac{1}{4}(-\partial_x^3 q + 6qr\partial_x q), && \partial_t r = \frac{1}{4}(-\partial_x^3 r + 6qr\partial_x r). \end{aligned}$$

Let τ be the involution of $sl(2, \mathbb{C})$ defined by $\tau(\xi) = -\bar\xi^t$. Then the fixed point set of τ is the real form $\mathcal{U} = su(2)$ and

$$\mathcal{A}^\perp \cap \mathcal{U} = \left\{ \begin{pmatrix} 0 & q \\ -\bar q & 0 \end{pmatrix} \mid q \in \mathbb{R} \right\}.$$

So the SU(2)-hierarchy is the restriction of the SL(2, $\mathbb{C}$)-hierarchy to the subspace $r = -\bar{q}$. The second flow in the SU(2)-hierarchy is the NLS $\partial_t q = \frac{i}{2}(\partial_x^2 q + 2|q|^2 q)$.

Let $\sigma(\xi) = -(\xi^t)$. Then $\sigma\tau = \tau\sigma$ and the corresponding symmetric space is SU(2)/ SO(2). Note that $u \in \mathcal{S}(\mathbb{R}, \mathcal{A}^\perp \cap \mathcal{K})$ means $q = -r$ is real. The third flow in the SU(2)/ SO(2)-hierarchy is the mKdV equation $q_t = -\frac{1}{4}(q_{xxx} + 6q^2 q_x)$.

The U-system. Let $\mathcal{U}$ be the real form of $\mathcal{G}$ defined by the involution τ, $\mathcal{A}$ a maximal abelian subalgebra of $\mathcal{U}$, and $a_1, \ldots, a_n$ a basis of $\mathcal{A}$. The U-system is the following PDE for $v\colon \mathbb{R}^n \to \mathcal{A}^\perp$:

$$[a_j, \partial_{x_i} v] - [a_i, \partial_{x_j} v] + [[a_i, v], [a_j, v]] = 0, \quad i \neq j. \tag{5}$$

It has a Lax pair

$$\theta_\lambda = \sum_{i=1}^{n} (a_i \lambda + [a_i, v])\, dx_i. \tag{6}$$

This Lax pair satisfies the *U-reality condition* $\theta_\lambda = \tau(\theta_{\bar{\lambda}})$.

The U/K-system. Let $\tau, \sigma, U, K, \mathcal{P}, \mathcal{A}$ be as in the U/K-hierarchy, and $a_1, \ldots, a_n$ a basis of $\mathcal{A}$. The U/K-system is the restriction of (5) to the space of $v\colon \mathbb{R}^n \to \mathcal{A}^\perp \cap \mathcal{P}$. Since $a_i \in \mathcal{P}$ and $[a_i, v] \in \mathcal{K}$, its Lax pair $\theta_\lambda = \sum_{i=1}^n (a_i\lambda + [a_i, v])\, dx_i$ satisfies the *U/K-reality condition*.

The frame of a Lax pair. Suppose we are given a family of flat $\mathcal{G}$-valued connections $\theta_\lambda = \sum_{i=1}^n P_i(x, \lambda) dx_i$ on $\mathbb{R}^n$. Then we call $E(x, \lambda)$ *a frame* of θ_λ if $E^{-1}\partial_{x_i} E = P_i$ for all $1 \leq i \leq n$.

Proposition 2.2. *Let G, τ, σ, U and K be as above, and E_λ the frame of θ_λ such that $E_\lambda(0) = \mathrm{I}$.*

1. *If θ_λ satisfies the U-reality condition, then E_λ satisfies the U-reality condition $\tau(E_{\bar{\lambda}}) = E_\lambda$,*

2. *If θ_λ satisfies the U/K-reality condition, then E_λ satisfies the U/K-reality condition $\tau(E_{\bar{\lambda}}) = E_\lambda$, $\sigma(E_\lambda) = E_{-\lambda}$.*

3. Soliton equations in submanifold geometry

Since the Gauss–Codazzi equations for submanifolds in space forms are equivalent to the flatness of certain connections, it is not surprising that many PDEs in submanifold geometry turns out to be soliton equations. We give some examples below:

Example 3.1 (Vortex filament equation, Schrödinger flow on S^2, and the NLS). In 1906, da Rios modeled the movement of a thin vortex in a viscous fluid by the motion of a curve propagating in $\mathbb{R}^3$ by

$$\partial_t \gamma = \partial_x \gamma \times \partial_x^2 \gamma. \tag{7}$$

If γ is a solution of (7), then

$$\partial_t \langle \partial_x \gamma, \partial_x \gamma \rangle = 2\langle \partial_x \partial_t \gamma, \partial_x \gamma \rangle = 2\langle \partial_x (\partial_x \gamma \times \partial_x^2 \gamma), \partial_x \gamma \rangle = 0.$$

So (7) preserves arc-length. Hence we may assume that a solution $\gamma(x, t)$ of (7) satisfying $\|\partial_x \gamma\| = 1$. It is known that there exists a parallel normal frame $(v_1, v_2)(\cdot, t)$ for each curve $\gamma(\cdot, t)$ such that $q = k_1 + ik_2$ is a solution of the NLS, where k_1 and k_2 are the principal curvatures of γ along v_1 and v_2 respectively.

Let $\mathcal{E}$ denote the energy functional on the space of paths on S^2, and J the complex structure on S^2 (if we view $S^2 \subset \mathbb{R}^3$, then $J_u(v) = u \times v$). The Schrödinger flow on S^2 is

$$u_t = J_u(\nabla \mathcal{E}(u)) = u \times u_{xx}.$$

If γ is a solution of (7), then $u = \gamma_x$ is a solution of the Schrödinger flow on S^2 ([14], [28]).

Example 3.2 (Isothermic surfaces in $\mathbb{R}^3$). A parametrized surface $f(x, y) \in \mathbb{R}^3$ is *isothermal* if (x, y) is a conformal line of curvature coordinate system, i.e., the two fundamental forms are of the form

$$\mathrm{I} = e^{2u}(dx_1^2 + dx_2^2), \quad \mathrm{II} = e^u(r_1 dx_1^2 + r_2 dx_2^2).$$

The Gauss–Codazzi equation is the $\frac{O(4,1)}{O(3)\times O(1,1)}$-system (cf. [11], [10], [9]).

Example 3.3 (Local isometric immersions of $N^n(c)$ in $N^{2n}(c)$, [25]). Let $N^m(c)$ denote the n-dimensional space form of constant sectional curvature c. The normal bundle of a submanifold M in $N^m(c)$ is *flat* if its induced normal connection is flat, and is *non-degenerate* if the dimension of $\{A_v \mid v \in \nu(M)_p\}$ is equal to $\operatorname{codim}(M)$. Here A_v is the shape operator along normal vector v. It is proved in [25] that if M^n is a submanifold of $N^{2n}(c)$ with constant sectional curvature c and its normal bundle $\nu(M)$ is flat and non-degenerate, then there exists a local orthogonal coordinate system $(x_1, \ldots, x_n)$ on M and parallel normal frame $e_{n+1}, \ldots, e_{2n}$ such that

$$\mathrm{I} = \sum_{i=1}^n b_i^2 dx_i^2, \quad \mathrm{II} = \sum_{j=1}^n a_{ji} b_i dx_i^2 e_{n+j}. \tag{8}$$

Moreover, the Levi-Civita connection 1-form for I is $w = \delta F - F^t \delta$, where $F = (f_{ij})$, $f_{ij} = \frac{\partial_{x_j} b_i}{b_j}$ if $i \neq j$, $f_{ii} = 0$ for all $1 \leq i \leq n$, and $\delta = \operatorname{diag}(dx_1, \ldots, dx_n)$. The Gauss–Codazzi equation for the local isometric immersion becomes an equation for F, which is the $\frac{O(2n)}{O(n)\times O(n)}$-system if $c = 0$, the $\frac{O(2n+1)}{O(n+1)\times O(n)}$-system if $c = 1$, and the $\frac{O(2n,1)}{O(n)\times O(n,1)}$-system if $c = -1$.

Example 3.4 (Egoroff metrics and the $\frac{U(n)}{O(n)}$-system). A local orthogonal system $(x_1, \ldots, x_n)$ of $\mathbb{R}^n$ is *Egoroff* if the flat Euclidean metric ds^2 written in this coordinate system is of the form

$$ds^2 = \sum_{j=1}^{n} \partial_{x_i}\phi \, dx_i^2$$

for some smooth function ϕ. Then $F = (f_{ij})$ is a solution of the $\frac{U(n)}{O(n)}$-system, where $f_{ij} = \frac{\partial_{x_i}\partial_{x_j}\phi}{2\sqrt{\partial_{x_i}\phi\partial_{x_j}\phi}}$ if $i \neq j$ and $f_{ii} = 0$ for $1 \leq i \leq n$. Conversely, given a solution $F = (f_{ij})\colon \mathbb{R}^n \to V_n$ of the $\frac{U(n)}{O(n)}$-system, the first order system

$$\partial_{x_j} b_i = f_{ij} b_j, \quad i \neq j \tag{9}$$

is solvable for $b_1, \ldots, b_n$, and solutions are locally defined and depend on n functions of one variable. Moreover, since $f_{ij} = f_{ji}$, $\sum_{i=1}^{n} b_i^2 dx_i$ is closed, hence locally there exists a smooth function ϕ such that $b_i^2 = \partial_{x_i}\phi$ for $1 \leq i \leq n$.

Although we can construct global solutions F for the $U(n)/O(n)$-system, it is not clear whether there exist global solutions b_i of (9) such that $b_i > 0$ and the metric $ds^2 = \sum_{i=1}^{n} b_i^2$ is complete. This is also the case for isometric immersions of $N^n(c)$ in $N^{2n}(c)$ and for the next example.

Example 3.5 (Flat Lagrangian submanifolds in $\mathbb{R}^{2n}$). As seen in Example 3.3, the Gauss–Codazzi equation for local isometric immersions of $\mathbb{R}^n$ into $\mathbb{R}^{2n}$ with flat and non-degenerate normal bundle is the $\frac{O(2n)}{O(n)\times O(n)}$-system. These immersions are Lagrangian if and only if F is symmetric and F is a solution of the $\frac{U(n)}{O(n)}$-system.

4. The space-time monopole equation

For flows in the SU(n)-hierarchy, we have been using left flat connections $\theta = \sum_{i=1}^{n} A_i dx_i$, i.e., $d\theta + \theta \wedge \theta = 0$ or equivalently, $[\partial_{x_i} + A_i, \partial_{x_j} + A_j] = 0$ for all $i \neq j$. But for space-time monopole equations, it is more customary to use right flat connections, i.e., $d\theta - \theta \wedge \theta = 0$, or equivalently, $[\partial_{x_i} - A_i, \partial_{x_j} - A_j] = 0$ for all $i \neq j$.

The curvature of a $su(n)$-valued connection 1-form $A = \sum_{i=1}^{4} A_i(x) dx_i$ is $F_A = \sum_{i<j} F_{ij}\, dx_i \wedge dx_j$. where

$$F_{ij} = [\partial_{x_i} - A_i, \partial_{x_j} - A_j] = \partial_{x_j} A_i - \partial_{x_i} A_j + [A_i, A_j].$$

The connection A is anti self-dual Yang–Mills (ASDYM) if

$$F_A = - * F_A,$$

where $*$ is the Hodge star operator with respect to the metric $dx_1^2+dx_2^2-dx_3^2-dx_4^2$.

Set $z = x_1 + ix_2$, $w = x_3 + ix_4$, $\nabla_z = \frac{1}{2}(\nabla_1 - i\nabla_2) = \frac{\partial}{\partial z} - A_z$, $\nabla_{\bar z} = \frac{1}{2}(\nabla_1 + i\nabla_2) = \frac{\partial}{\partial \bar z} - A_{\bar z}$, and $\nabla_w, \nabla_{\bar w}$ similarly. Since $A_i \in u(n)$, $A_{\bar z} = -A_z^*$ and $A_{\bar w} = -A_w^*$. Then (cf. [8], [21]) A is ASDYM if and only if

$$[\nabla_{\bar w} + \mu\nabla_z,\ \nabla_w + \mu^{-1}\nabla_{\bar z}] = 0. \tag{10}$$

holds for all $\mu \in \mathbb{C} \setminus \{0\}$.

If we assume that the ASDYM connection A is independent of x_4, and set $x = x_1$, $x_2 = y$, and $x_3 = t$, then $A_w = \frac{1}{2}(A_t - i\phi)$ and $A_{\bar w} = \frac{1}{2}(A_t + i\phi)$, where $\phi = A_{x_4}$ is the Higgs field, $A = A_t\,dt + A_z\,dz + A_{\bar z}\,d\bar z$ is a connection 1-form on $\mathbb{R}^{2,1}$. Then (A, ϕ) satisfies the *space-time monopole equation*

$$D_A\phi = *F_A,$$

where $*$ is the Hodge star operator with respect to the metric $dx^2 + dy^2 - dt^2$. It has a Lax pair induced from (10):

$$\left[\frac{1}{2}\nabla_t - \frac{i\phi}{2} + \mu\nabla_z,\ \ \frac{1}{2}\nabla_t + \frac{i\phi}{2} + \mu^{-1}\nabla_{\bar z}\right] = 0. \tag{11}$$

Set

$$D_1(\mu) = \frac{1}{2}\nabla_t - \frac{i\phi}{2} + \mu\nabla_z, \quad D_2(\mu) = \frac{1}{2}\nabla_t + \frac{i\phi}{2} + \mu^{-1}\nabla_{\bar z},$$
$$\begin{cases} P_1(\mu) = D_1(\mu) - D_2(\mu) = \frac{\mu-\mu^{-1}}{2}\nabla_x - i\frac{\mu+\mu^{-1}}{2}\nabla_y - i\phi, \\ P_2(\mu) = D_1(\mu) + D_2(\mu) = \nabla_t + \mu\nabla_z + \mu^{-1}\nabla_{\bar z}. \end{cases}$$

So (11) is equivalent to

$$\left[\frac{\mu-\mu^{-1}}{2}\nabla_x - \frac{i(\mu+\mu^{-1})}{2}\nabla_y - i\phi,\ \nabla_t + \mu\nabla_z + \mu^{-1}\nabla_{\bar z}\right] = 0. \tag{12}$$

Note that the first operator is a linear operator in space variables. This is the Lax pair we use to construct monopoles with continuous scattering data.

We need an equivalent form of the Lax pair to construct soliton monopoles. First we make a change of coordinates and spectral parameter:

$$\xi = \frac{t+x}{2}, \quad \eta = \frac{t-x}{2}, \quad \mu = \frac{\tau - i}{\tau + i}.$$

A direct computation shows that

$$L_1 = (\tau+i)D_1(\mu) + (\tau-i)D_2(\mu) = \tau\nabla_\xi - \nabla_y + \phi,$$
$$L_2 = \frac{1}{i}((\tau+i)D_1(\mu) - (\tau-i)D_2(\mu)) = \tau(\nabla_y + \phi) - \nabla_\eta,$$

so $[\tau\nabla_\xi - \nabla_y + \phi,\ \tau(\nabla_y + \phi) - \nabla_\eta] = 0$. Change spectral parameter again by $\lambda = \tau^{-1}$ to get

$$[\lambda(\nabla_y - \phi) - \nabla_\xi,\ \lambda\nabla_\eta - \nabla_y - \phi] = 0. \tag{13}$$

This is the Lax pair we use to construct Bäcklund transformations and solitons for the monopole equation. So we have

Proposition 4.1. *The following statements are equivalent for* (A, ϕ)*:*

1. (A, ϕ) *is a solution of the space-time monopole equation,*
2. (11) *holds for all* $\mu \in \mathbb{C} \setminus \{0\}$*,*
3. (12) *holds* $\mu \in \mathbb{C} \setminus \{0\}$*,*
4. (13) *holds for all* $\lambda \in \mathbb{C}$*,*
5. *there exists* $E_\mu(x, y, t)$ *such that*

$$\begin{cases} \left(\frac{\mu-\mu^{-1}}{2}\,\partial_x - \frac{i(\mu+\mu^{-1})}{2}\,\partial_y\right)E_\mu = \left(\frac{\mu-\mu^{-1}}{2}\,A_x - \frac{i(\mu+\mu^{-1})}{2}\,A_y + i\phi\right)E_\mu, \\ (\partial_t + \mu\partial_z + \mu^{-1}\partial_{\bar z})E_\mu = (A_t + \mu A_z + \mu^{-1}A_{\bar z})E_\mu, \\ E^*_{\bar\mu^{-1}}E_\mu = \mathrm{I}, \end{cases} \tag{14}$$

6. *there exists* $\psi_\lambda(x, y, t)$ *such that*

$$\begin{cases} (\lambda\partial_y - \partial_\xi)\psi_\lambda = (\lambda(A_y + \phi) - A_\xi)\psi_\lambda, \\ (\lambda\partial_\eta - \partial_y)\psi_\lambda = (\lambda A_\eta - A_y + \phi)\psi_\lambda, \\ \psi^*_{\bar\lambda}\psi_\lambda = \mathrm{I}, \end{cases} \tag{15}$$

7. $E_\mu(x, y, t)$ *is a solution of* (14) *if and only if*

$$\psi_\lambda(x, y, t) = E_{\frac{1-i\lambda}{1+i\lambda}}(x, y, t)$$

is a solution of (15)*.*

We call solutions of (14) and (15) *frames* of the monopole (A, ϕ). But frames are not unique. In fact, if ψ_λ is a solution of (15) and ϕ_λ satisfies

$$(\lambda\partial_y - \partial_\xi)\phi_\lambda = (\lambda\partial_\eta - \partial_y)\phi_\lambda = 0, \quad \phi^*_{\bar\lambda}\phi_\lambda = \mathrm{I}, \tag{16}$$

then $\psi_\lambda\phi_\lambda$ is also a solution of (15). Moreover, given any meromorphic map $h\colon \mathbb{C} \to \mathrm{GL}(n, \mathbb{C})$ that satisfies $h(\bar\lambda)^* h(\lambda) = \mathrm{I}$, then $\phi_\lambda(x, y, t) = h(y + \lambda\xi + \lambda^{-1}\eta)$ is a solution of (16). However, if (A, ϕ) is rapidly decaying in spatial variables, then we can choose normalizations (boundary conditions at infinity) so that there is a unique frame satisfying the normalization.

5. Direct scattering for flows in the SU(n)-hierarchy

Let $V_n = \{(\xi_{ij}) \in su(n) \mid \xi_{ii} = 0 \ \forall\ 1 \le i \le n\}$. The phase space of evolution equations in the SU(n)-hierarchy is the set $\mathcal{S}(\mathbb{R}, V_n)$ of all smooth $u\colon \mathbb{R} \to V_n$ that are rapidly decaying.

Recall that u is a solution of the (b, j)-flow in the SU(n)-hierarchy if and only if

$$\begin{cases} \psi_\lambda^{-1}\partial_x\psi_\lambda = a\lambda + u, \\ \psi_\lambda^{-1}\partial_t\psi_\lambda = b\lambda^j + Q_{b,1}(u)\lambda^{j-1} + \cdots + Q_{b,j}(u), \\ \psi_{\bar\lambda}^{*}\psi_\lambda = \mathrm{I} \end{cases} \tag{17}$$

is solvable. Since u decays in x, it is natural to study solutions of the first linear operator in (17) of the form $e^{a\lambda x}m(x,\lambda)$. The direct scattering refers to the study of singularities of $m(x,\lambda)$ in spectral parameter λ. This was done by Beals and Coifman:

Theorem 5.1 ([4]). *If $u \in \mathcal{S}(\mathbb{R}, V_n)$, then there exist a bounded discrete subset $\triangle_u$ of $\mathbb{C}\setminus\mathbb{R}$ and a smooth map $m\colon \mathbb{R}\times\mathbb{C}\setminus(\mathbb{R}\cup\triangle_u) \to \mathrm{GL}(n,\mathbb{C})$ such that*

1. *$\psi(x,\lambda) = e^{a\lambda x}m(x,\lambda)$ satisfies $d_x\psi = \psi(a\lambda + u)$,*

(i) *$m(x,\bar\lambda)^* m(x,\lambda) = \mathrm{I}$ and $\lim_{x\to-\infty} m(x,\lambda) = \mathrm{I}$,*

(ii) *$m(x,\lambda)$ is holomorphic for $\lambda \in \mathbb{C}\setminus(\mathbb{R}\cup\triangle_u)$, has poles at points in $\triangle_u$, and $m_\pm(x,r) = \lim_{s\to 0^\pm} m(x, r+is)$ is smooth,*

(iii) *m has an asymptotic expansion at $\lambda = \infty$:*

$$m(x,\lambda) \sim \mathrm{I} + m_1(x)\lambda^{-1} + m_2(x)\lambda^{-2} + \cdots .$$

Moreover,

1. *there is an open dense subset $\mathcal{S}_0(\mathbb{R}, V_n)$ of $\mathcal{S}(\mathbb{R}, V_n)$ such that $\triangle_u$ is a finite set for $u \in \mathcal{S}_0(\mathbb{R}, V_n)$,*
2. *if the L^1-norm of u is less than 1, then $m(x,\lambda)$ is holomorphic in $\lambda \in \mathbb{C}\setminus\mathbb{R}$, i.e., $\triangle_u$ is empty,*
3. *set $S(x,r) = m_+(x,r)m_-(x,r)^{-1}$, then $S^* = S$ and $S(x,r) - \mathrm{I}$ is rapidly decaying in r.*

The function m in the above theorem is called the *reduced wave function for the operator* $d_x + a\lambda + u$, the poles and residues of m are called the *discrete scattering data*, and the jump S is called the *continuous scattering data* of $d_x + a\lambda + u$.

Theorem 5.2 ([4], [5]). *Let u be a solution of the (b, j)-flow (2) in the* SU(n)*-hierarchy such that $u(\cdot,t) \in \mathcal{S}(\mathbb{R}, V_n)$, $m(\cdot,t,\cdot)$ and $S(\cdot,t,\cdot)$ the reduced wave function and the continuous scattering data for $d_x + a\lambda + u(\cdot,t)$ respectively for each t. Set $\psi(x,t,\lambda) = e^{a\lambda x + b\lambda^j t}m(x,t,\lambda)$. Then:*

1. *ψ is a solution of* (17)*,*
2. $\begin{cases}\partial_x S = [S, ar], \\ \partial_t S = [S, br^j].\end{cases}$
   In particular one has $S(x,t,r) = e^{-(arx+br^j t)}s_0(r)e^{arx+br^j t}$ *for some mapping* $s_0 : \mathbb{R} \to \mathrm{GL}(n,\mathbb{C})$ *such that* $s_0^* = s_0$ *and* $s_0 - \mathrm{I}$ *is rapidly decaying.*
3. *If* $u(\cdot, 0)$ *has only continuous scattering data, then so has* $u(\cdot, t)$*.*
4. *If the reduced wave function* $m(\cdot, 0, \lambda)$ *has a pole at* $\lambda = \alpha$*, then so has* $m(\cdot, t, \lambda)$ *for all* t*.*
5. $u = [a, m_1]$*, where* m_1 *is the coefficient of* λ^{-1} *in the asymptotic expansion of* $m(\cdot, \cdot, \lambda)$ *at* $\lambda = \infty$*.*

6. Direct scattering for the space-time monopole equation

The linear system associated to the Lax pair (12) for the monopole equation is (14). The first operator $P_1(\mu)$ is a linear operator in spatial variables only. Given a rapidly decaying initial data (A, ϕ) on $\mathbb{R}^2$, the scattering data for the operator $P_1(\mu)$ is the singularity data of the solution E_μ for $P_1(\mu)E_\mu = 0$ satisfying certain boundary condition.

Definition 6.1. A rapidly decaying spatial pair $(A, \phi) : \mathbb{R}^2 \to \bigoplus_{i=1}^4 su(n)$ is said to have only *continuous scattering data* if there exists $E_\mu : \mathbb{R}^2 \to \mathrm{GL}(n,\mathbb{C})$ defined on $\mathcal{O}_\varepsilon^\pm = \{\mu \in \mathbb{C} \mid 1 < |\mu|^{\pm 1} < 1 + \varepsilon\}$ for some $\varepsilon > 0$ such that

1. $\begin{cases} P_1(\mu)E_\mu = \left(\frac{\mu-\mu^{-1}}{2}\nabla_x - \frac{i(\mu+\mu^{-1})}{2}\nabla_y - i\phi\right)E_\mu = 0, \\ E_\mu(\infty) = \mathrm{I}, \quad E_{\bar{u}^{-1}} = (E_\mu^*)^{-1}, \end{cases}$
2. $\mu \mapsto E_\mu(x,t)$ are holomorphic in $\mu \in \mathcal{O}_\varepsilon^\pm$,
3. the limits $\lim_{\mu \in \mathcal{O}^\pm, \mu \to e^{i\theta}} E_\mu = S_\theta^\pm$ exist.

It follows from the reality condition that $S_\theta^- = (S_\theta^+)^{*^{-1}}$. We call the non-negative Hermitian matrix

$$S_\theta = (S_\theta^-)^{-1}S_\theta^+ = (S_\theta^+)^* S_\theta^+$$

the *scattering matrix* or the *continuous scattering data*.

Let $W^{2,1}$ denote the space of maps f whose partial derivatives up to second order are in L^1.

Theorem 6.2 ([32], [16], [13]). *Assume that* (A, ϕ) *is a rapidly decaying spatial data and* (A, ϕ) *is small in* $W^{2,1}$*. Then the continuous scattering matrix* S_θ *exists,* $\mathrm{I} - S_\theta$ *decays for each* θ*, and the scattering matrix* S_θ *satisfies*

(a) $\mathrm{I} - S_\theta$ *is small in* L^∞,

(b) $S_\theta^* = S_\theta \geq 0$,

(c) $\big(-\sin\theta\frac{\partial}{\partial x} + \cos\theta\frac{\partial}{\partial y}\big)S_\theta = 0$.

Theorem 6.3 ([32], [16], [13]). *If* (A, ϕ) *is a smooth solution of the space-time monopole equation in* $\mathbb{R}^2 \times (T_1, T_2)$ *and decays in spatial variables, and has a smooth continuous scattering data. Then*

$$0 = \left(\frac{\partial}{\partial t} + \cos\theta\frac{\partial}{\partial x} + \sin\theta\frac{\partial}{\partial y}\right) S_\theta.$$

Moreover, two gauge equivalent solutions give rise to the same scattering data.

Corollary 6.4. *Let* (A, ϕ) *be as in Theorem* 6.3. *Then there is a unique* $s_0 \colon \mathbb{R} \times S^1 \to \mathrm{GL}(n, \mathbb{C})$ *such that* $s_0^* = s_0$, $s_0(r, e^{i\theta})$ *is rapidly decaying in* $r \in \mathbb{R}$, *and the continuous scattering data for* $(A(\,\cdot\,,\,\cdot\,,t), \phi(\,\cdot\,,\,\cdot\,,t))$ *is*

$$S_\theta(x, y, t) = s_0(x\cos\theta + y\sin\theta - t, e^{i\theta}).$$

7. Inverse scattering for the SU(n)-hierarchy via loop group factorizations

Given $u \in \mathcal{S}(\mathbb{R}, V_n)$, the scattering data for the operator $L_u = d_x + a\lambda + u$ is the singularities of the reduced wave function, which contains two parts, the continuous (jumping line) and the discrete (poles) scattering data. The inverse scattering, which constructs u from the scattering data of L_u, was done in [39], [4].

By Theorem 5.1, the scattering data only depends on $f(\lambda) = m(0, 0, \lambda)$, where m is the reduced wave function. We identify the image of the scattering transform for those u's with only continuous scattering data as a homogeneous space, and then use Pressley–Segal loop group factorization to construct the inverse scattering transform ([27]).

Let $\mathcal{D}_-$ denote the group of smooth $f \colon \mathbb{R} \to \mathrm{GL}(n, \mathbb{C})$ such that

(i) f is the boundary value of a holomorphic map in $\mathbb{C}_+ = \{\lambda \in \mathbb{C} \mid \mathrm{Im}(\lambda) > 0\}$,

(ii) f has the same asymptotic expansion at $r = \pm\infty$,

(iii) decompose $f(r) = p(r)v(r)$ with $p(r)$ upper triangular and $v(r)$ unitary, then $p - \mathrm{I}$ is rapidly decaying.

Suppose u is a solution of the (b, j)-flow (2) in the SU(n)-hierarchy with only continuous scattering data, and $m(x, t, \lambda)$ the reduced wave function for u. Then

$m(x,t,\cdot) \in \mathcal{D}_-$. Set $f(\lambda) = m(0,0,\lambda)$. Since $\psi(x,t,\lambda) = e^{a\lambda x + b\lambda^j t} m(x,t,\lambda)$ satisfies (17),

$$E(x,t,\lambda) = f(\lambda)^{-1} e^{(a\lambda x + a\lambda^2 t)} m(x,t,\lambda), \tag{18}$$

is a solution of (17) with $E(0,0,\lambda) = \mathrm{I}$. Because the right hand side of (18) is holomorphic in $\mathbb{C}_+$, $E(x,t,\lambda)$ is holomorphic in $\lambda \in \mathbb{C}_+$. Proposition 2.2 implies that E satisfies the $U(n)$-reality condition $E(x,t,\bar{\lambda})^* E(x,t,\lambda) = \mathrm{I}$. So by the reflection principal $E(x,t,\lambda)$ is holomorphic for all $\lambda \in \mathbb{C}$.

Set $e_{a,1}(x)(\lambda) = e^{a\lambda x}$, $e_{b,j}(t) = e^{b\lambda^j t}$, $E(x,t)(\lambda) = E(x,t,\lambda)$, and $m(x,t)(\lambda) = m(x,t,\lambda)$. Then we can rewrite (18) as

$$f^{-1} e_{a,1}(x) e_{b,j}(t) = E(x,t) m(x,t)^{-1}. \tag{19}$$

Here $f, m(x,t) \in \mathcal{D}_-$, and $e_{a,1}(x)e_{b,j}(t)$ and $E(x,t)$ holomorphic in $\mathbb{C}$ and satisfy the $U(n)$-reality condition. To construct the inverse scattering is to construct m from f. In other words, given $f \in \mathcal{D}_-$, we want to find a method to factor $f^{-1} e_{a,1}(x) e_{b,j}(t)$ as $E(x,t)m^{-1}(x,t)$ such that $E(x,t)$ satisfies the $U(n)$-reality condition and is holomorphic in $\mathbb{C}$ and $m(x,t) \in \mathcal{D}_-$ for all (x,t). We need Pressley–Segal loop group factorization [22] given below to do this factorization.

Let $S^2 \setminus S^1 = \mathbb{C} \cup \{\infty\} = \Omega_+ \cup \Omega_-$, where $\Omega_+ = \{\mu \in \mathbb{C} \mid |\mu| < 1\}$ and $\Omega_- = \{\lambda \in S^2 \mid |\mu| > 1\}$. Let $\Lambda(\mathrm{SL}(n,\mathbb{C}))$ denote the group of smooth loops $g\colon S^1 \to \mathrm{SL}(n,\mathbb{C})$, and $\Lambda_+(\mathrm{SL}(n,\mathbb{C}))$ the subgroup of $g \in \Lambda(\mathrm{SL}(n,\mathbb{C}))$ such that g can be extended to a holomorphic map on Ω_+ and $g(-1)$ is upper triangular with real diagonal entries. Let $\Lambda(\mathrm{SU}(n))$ denote the loops in $\mathrm{SU}(n)$. The Pressley–Segal factorization is the analogue of the Iwasawa decomposition of $\mathrm{SL}(n,\mathbb{C})$ for loop groups:

Theorem 7.1 (Pressley–Segal Factorization Theorem [22]). *The multiplication map from $\Lambda(\mathrm{SU}(n)) \times \Lambda_+(\mathrm{SL}(n,\mathbb{C}))$ to $\Lambda(\mathrm{SL}(n,\mathbb{C}))$ is a bijection. In particular, given $f \in \Lambda(\mathrm{SL}(n,\mathbb{C}))$, there exist unique $g \in \Lambda(\mathrm{SU}(n))$ and $h_+ \in \Lambda_+(\mathrm{SL}(n,\mathbb{C}))$ such that $f = gh_+$.*

If we change the spectral parameter λ by the linear fractional transformation $\mu = \frac{1+i\lambda}{1-i\lambda}$, then we can see that $\mathcal{D}_-$ is isomorphic to a subgroup of $\Lambda_+(\mathrm{SL}(n,\mathbb{C}))$. In fact, we have

Proposition 7.2 ([27]). *Given a map $g\colon S^1 \to \mathrm{GL}(n,\mathbb{C})$, let $\Phi(g)\colon \mathbb{R} \to \mathrm{GL}(n,\mathbb{C})$ be the map defined by $\Phi(g)(r) = g\left(\frac{1+ir}{1-ir}\right)$. Then:*

1. *g is smooth if and only if $\Phi(g)$ is smooth and has the same asymptotic expansion at $r = \pm\infty$.*

2. *$j_\infty(g - \mathrm{I})_{-1} = 0$ (the infinite jet of $g - \mathrm{I}$ at $\mu = -1$) if and only if $\Phi(g) - \mathrm{I}$ is rapidly decaying.*

3. *Suppose g extends holomorphically to $|\mu| < 1$, and define g on $|\mu| > 1$ by $g(\mu) = (g(\bar{\mu}^{-1})^*)^{-1}$. Then $f(\lambda) = g\left(\frac{1+i\lambda}{1-i\lambda}\right)$ is holomorphic in $\lambda \in \mathbb{C} \setminus \mathbb{R}$ and satisfies the reality condition $f(\bar{\lambda})^* f(\lambda) = \mathrm{I}$.*

Corollary 7.3. *$\mathcal{D}_-$ is isomorphic to the subgroup of $g \in \Lambda_+(\mathrm{SL}(n,\mathbb{C}))$ such that $j_\infty(h - \mathrm{I})_{-1} = 0$ where $g = hv$ with h upper triangular and v unitary.*

Now we go back to the problem of factorizing $f^{-1}e_{a,1}(x)$. By Proposition 7.2, $\Phi^{-1}(f^{-1}e_{a,1}(x))$ does not belong to $\Lambda(\mathrm{SL}(n,\mathbb{C}))$. So we can not use Theorem 7.1 to do the factorization directly. However, if we write $f = pv$ with p upper triangular and v unitary, then by definition of $\mathcal{D}_-$, $p - \mathrm{I}$ is rapidly decaying. This implies that $\Phi^{-1}(e_{a,1}^{-1}(x)p^{-1}e_{a,1}(x))$ lies in $\Lambda(\mathrm{SL}(n,\mathbb{C}))$. Apply the Pressley–Segal loop group factorization to get

$$e_{a,1}^{-1}(x)p^{-1}e_{a,1}(x) = B(x)m(x)^{-1}$$

such that $\Phi^{-1}(B(x)) \in \Lambda(\mathrm{SU}(n))$ and $\Phi^{-1}(m(x)) \in \Lambda_+(\mathrm{SL}(n,\mathbb{C}))$. Since $p(\lambda)$, $e_{a,1}(x)(\lambda)$, and $m(x)(\lambda)$ are smooth for $\lambda \in \mathbb{R}$ and can be extended holomorphically to $\lambda \in \mathbb{C}_+$, so is $B(x)(\lambda)$. But $B(x)(\lambda)$ is unitary for $\lambda \in \mathbb{R}$ implies that $B(x)(\lambda)$ can be extended holomorphically across the real axis in the λ-plane by defining $B(x)(\lambda) = (B(x)(\bar{\lambda})^*)^{-1}$. Hence $\lambda \mapsto B(x)(\lambda)$ is holomorphic for all $\lambda \in \mathbb{C}$. Therefore

$$\begin{aligned} f^{-1}e_{a,1}(x) = v^{-1}p^{-1}e_{a,1}(x) &= v^{-1}e_{a,1}(x)(e_{a,1}^{-1}(x)p^{-1}e_{a,1}(x)) \\ &= v^{-1}e_{a,1}(x)B(x)m(x)^{-1} = E(x)m(x)^{-1}. \end{aligned}$$

But $E(x)(\lambda) = v^{-1}(\lambda)e^{a\lambda x}B(x)(\lambda)$ is holomorphic for $\lambda \in \mathbb{C}$.

Since $E(x,\lambda) = f^{-1}(\lambda)e^{a\lambda x}m(x,\lambda)$,

$$E^{-1}\partial_x E = m^{-1}\partial_x m + m^{-1}a\lambda m.$$

Use the asymptotic expansion at $\lambda = \infty$ to conclude that $E^{-1}\partial_x E$ must be a degree one polynomial in λ. So if $m_1(x)$ is the coefficient of λ^{-1} in the asymptotic expansion of $m(x,\lambda)$ at $\lambda = \infty$, then

$$E^{-1}\partial_x E = a\lambda + u_f, \quad \text{where } u_f = [a, m_1].$$

Note that the scattering data of $d_x + a\lambda + u_f$ is $e^{-a\lambda x}f_+f_-^{-1}e^{a\lambda x}$. However, the map $\mathcal{F}(f) = u_f$ is not one to one. In fact, $u_{f_1} = u_{f_2}$ if and only if there is $h \in \mathcal{D}_-$ such that $h(r)$ is diagonal for all $r \in \mathbb{R}$. These give a rough idea of how the following results are obtained.

Theorem 7.4 ([27]). *Assume a, b are diagonal matrices in $su(n)$, and a has distinct eigenvalues. If $f \in \mathcal{D}_-$, then there exist $E(x,t,\lambda)$ and $m(x,t,\lambda)$ such that*

1. $f^{-1}e_{a,1}(x)e_{b,j}(t) = E(x,t,\cdot)m(x,t,\cdot)^{-1}$,
2. *E is holomorphic for $\lambda \in \mathbb{C}$, $E(x,t,\bar{\lambda})^*E(x,t,\lambda) = \mathrm{I}$, and $m(x,t,\cdot) \in \mathcal{D}_-$,*

3. *$u_f = [a, m_1]$ is a solution of the (b, j)-flow equation* (2) *in the* $\mathrm{SU}(n)$*-hierarchy, and E is the frame for the Lax pair associated to u with initial condition $E(0, \lambda) = \mathrm{I}$, where $m_1(x, t)$ is the coefficient of λ^{-1} in the asymptotic expansion of $m(x, t, \lambda)$ at $\lambda = \infty$,*

4. *$u_f(x, t)$ is defined for all $(x, t) \in \mathbb{R}^2$ and is rapidly decaying in x for each t,*

5. *if f also satisfies the* $\mathrm{SU}(n)/\mathrm{SO}(n)$*-reality condition, then u_f is a solution of the (b, j)-flow in the* $\mathrm{SU}(n)/\mathrm{SO}(n)$*-hierarchy.*

Theorem 7.5 ([27]). *Let $\mathcal{S}^c(\mathbb{R}, V_n)$ denote the space of all $u \in \mathcal{S}(\mathbb{R}, V_n)$ such that $L_u = d_x + a\lambda + u$ has only continuous scattering data, and $\mathcal{D}_-(A)$ denotes the subgroup of $f \in \mathcal{D}_-$ such that $f(r)$ is diagonal for all $r \in \mathbb{R}$, and $\mathcal{F} : \mathcal{S}^c(\mathbb{R}, V_n) \to \mathcal{D}_-/\mathcal{D}_-(A)$ defined by $\mathcal{F}(u) = [m(0, \cdot)]$, where $m(x, \lambda)$ is the reduced wave function of $L_u = d_x + a\lambda + u$. Then $\mathcal{F}$ is a bijection, and $\mathcal{F}^{-1}([f]) = [a, m_1]$, where m_1 is the coefficient of λ^{-1} in the asymptotic expansion of m at $\lambda = \infty$.*

Theorem 7.6 ([27]). *Let $L^\tau_+(\mathrm{SL}(n, \mathbb{C}))$ denote the group of holomorphic maps $f : \mathbb{C} \to \mathrm{GL}(n, \mathbb{C})$ that satisfy the* $\mathrm{SU}(n)$*-reality condition, and $\mathcal{D}_+(A)$ the subgroup of $L^\tau_+(\mathrm{SL}(n, \mathbb{C}))$ generated by $\{e_{b,j}(t) \mid b \in su(n)$ diagonal, $j \geq 1$ integer$\}$. Then $\mathcal{D}_+(A)$ acts on $\mathcal{D}_-/\mathcal{D}_-(A)$ by $e_{a,j}(t) * [f] = [m(t)]$, where $m(t)$ is obtained by factoring $f^{-1}e_{b,j}(t) = E(t)m(t)^{-1}$ such that $E(t) \in L^\tau_+(\mathrm{SL}(n, \mathbb{C}))$ and $m(t) \in \mathcal{D}_-$. Moreover, the (b, j)-flow in the* $\mathrm{SU}(n)$*-hierarchy corresponds to the action of $e_{b,j}(t)$ on $\mathcal{D}_-/\mathcal{D}_-(A)$ under the isomorphism $\mathcal{F}$.*

Theorem 7.7 ([27]). *Let $a_1, a_2, \ldots, a_n$ be linearly independent diagonal matrices in $u(n)$, and $f \in \mathcal{D}_-$. Then we can factor*

$$f^{-1}e_{a_1,1}(x_1) \ldots e_{a_n,1}(x_n) = E(x)m(x)^{-1}$$

such that $E(x) \in L^\tau_+(\mathrm{GL}(n, \mathbb{C}))$ and $m(x) \in \mathcal{D}_-$. Moreover,

1. *$v = m_1^\perp$ is a solution of the $U(n)$-system, where $m_1(x)$ is the coefficient of λ^{-1} in the asymptotic expansion of $m(x)(\lambda)$ at $\lambda = \infty$ and $\xi^\perp = \xi - \sum_{i=1}^n \xi_{ii} e_{ii}$,*

2. *if $f \in \mathcal{D}_-$ satisfies the $\frac{U(n)}{O(n)}$-reality condition, then $v = (m_1)^\perp$ is a solution of the $\frac{U(n)}{O(n)}$-system.*

In other words, the $U(n)$-system is the system obtained by putting together the $(a_1, 1)$-, …, $(a_n, 1)$-flow in the $U(n)$-hierarchy.

8. The inverse scattering for monopole equations

The scattering data of the linear operator

$$P_1(\mu) = \mu\nabla_z - \mu^{-1}\nabla_{\bar{z}} - i\phi$$

on the $z = x + iy$ plane for the rapidly decaying spatial pair (A, ϕ) is a smooth map $s_0 : \mathbb{R}^1 \times S^1 \to \mathrm{GL}(n, \mathbb{C})$. The inverse scattering for $P_1(\mu)$, which constructs $(A, \phi) : \mathbb{R}^2 \to \oplus^4 su(n)$ from s_0, was done in [32], [16]. In this section, we give a brief review of the construction of the inverse scattering transform for $P_1(\mu)$ via Pressley–Segal loop group factorization given in [13].

Theorem 8.1 ([13]). *Suppose $s : \mathbb{R} \times S^1 \to \mathrm{GL}(n, \mathbb{C})$ is smooth such that $s^* = s \geq 0$ and $s(r, e^{i\theta}) - \mathrm{I}$ is rapidly decaying for $r \in \mathbb{R}$. Define*

$$S(x, y, t, e^{i\theta}) = s(x \cos\theta + y \sin\theta - t, e^{i\theta}).$$

Then there exists a smooth $E : \mathbb{R}^{2,1} \times (\mathbb{C} \setminus S^1) \to \mathrm{GL}(n, \mathbb{C})$ such that

1. *$E^*_{\bar{\mu}^{-1}} E_\mu = \mathrm{I}$, where $E_\mu = E(\ldots, \mu)$,*
2. *$((\partial_t + \mu\partial_z)E_\mu)E_\mu^{-1} = B_0 + \mu B_1$ and $((\partial_t + \mu^{-1}\partial_{\bar{z}})E_\mu)E_\mu^{-1} = -(B_0^* + \mu^{-1}B_1^*)$ for some $B_0, B_1 : \mathbb{R}^{2,1} \to sl(n, \mathbb{C})$,*
3. *if we set $A_z = \frac{1}{2}B_1$, $A_t = \frac{1}{2}(B_0 - B_0^*)$, $\phi = \frac{i}{2}(B_0 + B_0^*)$, then (A, ϕ) is a solution of the space-time monopole equation decaying rapidly in the spatial variables,*
4. *the scattering data for $(A(\cdot, \cdot, t), \phi(\cdot, \cdot, t))$ is $S(\cdot, \cdot, t, \cdot)$.*

Here is a sketch of the proof: Set $S_\mu = S(\ldots, \mu)$ for $|\mu| = 1$. Write $S_\mu = P_\mu^2$ with $P_\mu^* = P_\mu$. By Pressley–Segal Factorization Theorem 7.1 we can factor $P_\mu = U_\mu E_\mu^+$ with $U_\cdot$ a loop in $\mathrm{SU}(n)$ and E_μ^+ extends holomorphically to $|\mu| < 1$. Define $E_\mu^- = ((E^+_{\bar{\mu}^{-1}})^*)^{-1}$ for $|\mu| > 1$. Then $S_\mu = (E_\mu^-)^{-1}E_\mu^+$. The rest of the theorem can be proved using the fact that $(-\sin\theta\ \partial_x + \cos\theta\ \partial_y)S = 0$ and $(\cos\theta\ \partial_x + \sin\theta\ \partial_y - \partial_t)S = 0$.

Corollary 8.2 ([13]). *Suppose (A_0, ϕ_0) is a rapidly decaying spatial pair with only continuous scattering data. Then there is a global solution (A, ϕ) of the space-time monopole equation decaying rapidly in the spatial variables such that the scattering data of $(A(\cdot, \cdot, 0), \phi(\cdot, \cdot, 0))$ and (A_0, ϕ_0) are the same. Moreover, any two such solutions are gauge equivalent.*

Corollary 8.3. *There is a bijective correspondence between the space of solutions of the space-time monopole equation with only continuous scattering data modulo the gauge group, and the group of maps $f : \mathbb{R} \to \Lambda^\tau_+(\mathrm{SL}(n, \mathbb{C}))$ such that $(f^* f)(r)(e^{i\theta}) - \mathrm{I}$ is rapidly decaying in $r \in \mathbb{R}$.*

9. Birkhoff factorization and local solutions

The factorization (19)

$$f^{-1}(\lambda)e^{a\lambda x + b\lambda^j t} = E(x, t, \lambda)m(x, t, \lambda)^{-1}$$

is for $f, m(x,t,\cdot)$ in $\mathcal{D}_-$ and E holomorphic in $\lambda \in \mathbb{C}$ and satisfies the $U(n)$-reality condition. However if f is holomorphic at $\lambda = \infty$, then we can use the Birkhoff factorization to get E and m such that E is holomorphic in $\mathbb{C}$ and m is holomorphic at $\lambda = \infty$. Moreover, it can be shown easily that E is the frame of a solution of the (b, j)-flow with $E(0,0,\lambda) = \mathrm{I}$. Since the Birkhoff factorization only works on an open dense subset of loops, solutions constructed this way are local solutions defined in a neighborhood of $(0,0)$.

Let $\varepsilon > 0$, and $\mathcal{O}_\varepsilon = \{\lambda \mid |\lambda| > \frac{1}{\varepsilon}\}$ an open neighborhood of ∞ in $S^2 = \mathbb{C} \cup \{\infty\}$. Then $S^2 = C \cup \mathcal{O}_\varepsilon$. Let $L^\tau(\mathrm{SL}(n,\mathbb{C}))$ denote the group of holomorphic maps f from $C \cap \mathcal{O}_\infty$ to $\mathrm{SL}(n,\mathbb{C})$ satisfying the $\mathrm{SU}(n)$-reality condition $f(\bar{\lambda})^* f(\lambda) = \mathrm{I}$, $L^\tau_+(\mathrm{SL}(n,\mathbb{C}))$ the subgroup of $f \in L^\tau(\mathrm{SL}(n,\mathbb{C}))$ that extend holomorphically to $\mathbb{C}$, and $L^\tau_-(\mathrm{SL}(n,\mathbb{C}))$ the subgroup of $f \in L^\tau(\mathrm{SL}(n,\mathbb{C}))$ that extend holomorphically to $\mathcal{O}_\varepsilon$ and satisfying $f(\infty) = I$.

Theorem 9.1 (Birkhoff Factorization Theorem (cf. [22])). *The multiplication map $L^\tau_+(\mathrm{SL}(n,\mathbb{C})) \times L^\tau_-(\mathrm{SL}(n,\mathbb{C})) \to L^\tau(\mathrm{SL}(n,\mathbb{C}))$ is injective and the image is an open dense subset of $L^\tau(\mathrm{SL}(n,\mathbb{C}))$.*

Let a, b be diagonal matrices in $su(n)$ such that a is regular. Then $e_{a,1}(x)e_{b,j}(t) \in L^\tau_+(\mathrm{SL}(n,\mathbb{C}))$. Given $f \in L^\tau_-(\mathrm{SL}(n,\mathbb{C}))$, by the Birkhoff factorization there exists $\delta > 0$ such that

$$f^{-1}e_{a,1}(x)e_{b,j}(t) = E(x,t)m(x,t)^{-1}$$

with $E(x,t) \in L^\tau_+(\mathrm{SL}(n,\mathbb{C}))$ and $m(x,t) \in L^\tau_-(\mathrm{SL}(n,\mathbb{C}))$ for all $(x,t) \in B_\delta(0)$. Here $B_\delta(0)$ is the ball of radius δ centered at $(0,0)$. Then

$$\begin{cases} E^{-1}\partial_x E = m^{-1}m_x + m^{-1}a\lambda m, \\ E^{-1}\partial_t E = m^{-1}m_x + m^{-1}b\lambda^j m. \end{cases}$$

Since m is holomorphic at $\lambda = \infty$ and $m(x,t)(\infty) = \mathrm{I}$, $E^{-1}\partial_x E$ and $E^{-1}\partial_t E$ must be a polynomial of degree 1 and j in λ respectively. Hence E must be a frame of a solution of the (b, j)-flow in the $\mathrm{SU}(n)$-hierarchy. So we have

Theorem 9.2 ([27]). *If $f \in L^\tau_-(\mathrm{SL}(n,\mathbb{C}))$, then there exist an open neighborhood $\mathcal{O}$ of $(0,0)$, $E(x,t) \in L^\tau_+(\mathrm{SL}(n,\mathbb{C}))$, and $m(x,t) \in L^\tau_-(\mathrm{SL}(n,\mathbb{C}))$ such that $f^{-1}e_{a,1}(x)e_{b,j}(t) = E(x,t)m(x,t)^{-1}$ for all $(x,t) \in \mathcal{O}$. Moreover,*

1. *$u = [a, m_1]$ is a solution of the (b, j)-flow in the $\mathrm{SU}(n)$-hierarchy, where $m_1(x,t)$ is the coefficient of λ^{-1} the expansion of $m(x,t)(\lambda)$ at $\lambda = \infty$, (we will use $f * 0$ to denote u),*
2. *E is the frame of the Lax pair of u such that $E(0)(\lambda) = \mathrm{I}$,*
3. *if f satisfies the $\mathrm{SU}(n)/\mathrm{SO}(n)$-reality condition, then $u = [a, m_1]$ is a solution of the (b, j)-flow in the $\mathrm{SU}(n)/\mathrm{SO}(n)$-hierarchy.*

Note that for $f \in \mathcal{D}_-$, Theorem 7.4 gives a global solution u_f of the (b, j)-flow on $\mathcal{S}(\mathbb{R}, V_n)$ in the $\mathrm{SU}(n)$-hierarchy. But for $f \in L^\tau_-(\mathrm{SL}(n,\mathbb{C}))$, the above theorem only gives a local solution of the (b, j)-flow in general.

Theorem 9.3 ([27]). *If $f \in L^\tau_-(\mathrm{GL}(n,\mathbb{C}))$, then there exist an open neighborhood $\mathcal{O}$ of 0 in $\mathbb{R}^n$, $E(x) \in L^\tau_+(\mathrm{GL}(n,\mathbb{C}))$ and $m(x) \in L^\tau_-(\mathrm{GL}(n,\mathbb{C}))$ for $x \in \mathcal{O}$ such that $f^{-1}e_{a_1,1}(x_1)\dots e_{a_n,1}(x_n) = E(x)m(x)^{-1}$. Moreover,*

1. *$v = m_1^\perp$ is a solution of the $U(n)$-system, where $m_1(x)$ is the coefficient of λ^{-1} in the expansion of $m(x)(\lambda)$ at $\lambda = \infty$ and $m_1^\perp = m_1 - \sum_i (m_1)_{ii}e_{ii}$, (we will use $f * 0$ to denote v),*
2. *E is the frame of the Lax pair (6) of v such that $E(0)(\lambda) = \mathrm{I}$,*
3. *If f also satisfies the $U(n)/O(n)$-reality condition, then $v = f*0$ is a solution of the $U(n)/O(n)$-system.*

10. Bäcklund transformations for the $U(n)$-hierarchy

In general, the solution $f * 0$ constructed in Theorem 9.2 has singularities. But if f is rational, then $f * 0$ is a global solution of the (b, j)-flow in the $\mathrm{SU}(n)$-hierarchy, and can be computed explicitly. These are the soliton solutions. Moreover, if f is rational with only one simple pole and E is a frame of a solution u, then the Birkhoff factorization $fE = \tilde{E}\tilde{f}$ can be carried out by an explicit algebraic algorithm so that $\tilde{E}$ is a frame of the new solution. These give Bäcklund transformations for the (b, j)-flow.

If $\alpha \in \mathbb{C} \setminus \mathbb{R}$ and π is a Hermitian projection of $\mathbb{C}^n$, then the map

$$g_{\alpha,\pi}(\lambda) = \mathrm{I} + \frac{\alpha - \overline{\alpha}}{\lambda - \alpha}\,\pi$$

satisfies the $U(n)$-reality condition. So $g_{\alpha,\pi} \in L^\tau_-(\mathrm{GL}(n,\mathbb{C}))$.

The following theorem is a key ingredient for constructing Bäcklund transformations for the (b, j)-flow in the $\mathrm{SU}(n)$-hierarchy.

Theorem 10.1 ([29]). *Given $f \in L^\tau_+(\mathrm{SL}(n,\mathbb{C}))$ and $g_{\alpha,\pi}$, let $\tilde{\pi}$ be the Hermitian projection of $\mathbb{C}^n$ onto $f(\alpha)^{-1}(\mathrm{Im}\,\pi)$. Then $g_{\alpha,\pi}f = \tilde{f}g_{\alpha,\tilde{\pi}}$ and $\tilde{f} \in L^\tau_+(\mathrm{SL}(n,\mathbb{C})$.*

Proof. Set $\tilde{f}(\lambda) = g_{\alpha,\pi}(\lambda)f(\lambda)g_{\alpha,\tilde{\pi}}(\lambda)^{-1} = (\mathrm{I} + \frac{\alpha-\overline{\alpha}}{\lambda-\alpha}\pi^\perp)f(\lambda)(\mathrm{I} + \frac{\overline{\alpha}-\alpha}{\lambda-\overline{\alpha}}\tilde{\pi}^\perp)$. Note that $\tilde{f}$ is holomorphic for $\lambda \in \mathbb{C} \setminus \{\alpha, \overline{\alpha}\}$. But

$$\mathrm{Res}(\tilde{f}, \alpha) = (\alpha - \overline{\alpha})\pi^\perp f(\alpha)\tilde{\pi}, \quad \mathrm{Res}(\tilde{f}, \overline{\alpha}) = (\overline{\alpha} - \alpha)\pi f(\overline{\alpha})\tilde{\pi}^\perp.$$

By definition $f(\alpha)(\mathrm{Im}\,\tilde{\pi}) = \mathrm{Im}\,\pi$, so $\tilde{f}$ is holomorphic at $\lambda = \alpha$. Set $V = \mathrm{Im}\,\pi$ and $\tilde{V} = \mathrm{Im}\,\tilde{\pi}$. Since f satisfies the reality condition, we have

$$(f(\overline{\alpha})(\tilde{V}^\perp), V) = (\tilde{V}^\perp, f(\overline{\alpha})^*(V)) = (\tilde{V}^\perp, f(\alpha)^{-1}(V)) = (\tilde{V}^\perp, \tilde{V}) = 0.$$

This implies that $\operatorname{Res}(\tilde{f}, \overline{\alpha}) = 0$, hence $\tilde{f}$ is holomorphic in $\mathbb{C}$. □

The proof of the above theorem in fact gives the following more general result:

Theorem 10.2 ([12]). *Let $\mathcal{O}$ be an open subset of $\mathbb{C}$ that is invariant under complex conjugation, and $f: \mathcal{O} \to \mathrm{SL}(n, \mathbb{C})$ a meromorphic map satisfying the $U(n)$-reality condition. Let $\alpha \in \mathbb{C} \setminus \mathbb{R}$, and π a Hermitian projection of $\mathbb{C}^n$. Suppose f is holomorphic and non-singular at $\lambda = \alpha$. Let $\tilde{\pi}$ denote the Hermitian projection of $\mathbb{C}^n$ onto $f(\alpha)^{-1}(\operatorname{Im}\pi)$. Then $g_{\alpha,\pi} f = \tilde{f} g_{\alpha,\tilde{\pi}}$, and $\tilde{f}$ is holomorphic and non-degenerate at $\lambda = \alpha$ and satisfies the $U(n)$-reality condition.*

Theorem 10.3 (Bäcklund transformation for the (b, j)-flow, [29]). *Suppose u is a solution of the (b, j)-flow* (2) *in the* $\mathrm{SU}(n)$*-hierarchy, and $E(x, t, \lambda)$ is the frame for the Lax pair of u such that E is holomorphic for $\lambda \in \mathbb{C}$ and $E(0, 0, \lambda) = \mathrm{I}$. Given $\alpha \in \mathbb{C} \setminus \mathbb{R}$ and a Hermitian projection π of $\mathbb{C}^n$, set $\tilde{\pi}(x, t)$ to be the Hermitian projection of $E(x, t, \alpha)^{-1}(\operatorname{Im}\pi)$, $\tilde{E} = g_{\alpha,\pi} E g_{\alpha,\tilde{\pi}}^{-1}$, and $\tilde{u} = u + (\alpha - \overline{\alpha})[a, \tilde{\pi}]$. Then*

1. *$\tilde{u}$ is again a solution of* (2)*, and $\tilde{E}$ is the frame of $\tilde{u}$,*
2. *if u is smooth for all $(x, t) \in \mathbb{R}^2$, then so is $\tilde{u}$,*
3. *if $u(x, t)$ is rapidly decaying in x for all t, then so is $g_{\alpha,\pi} * u$.*

Let $\mathcal{D}_-^r$ denote the group of rational maps $g: S^2 \to \mathrm{GL}(n, \mathbb{C})$ that satisfy the $U(n)$-reality condition and $g(\infty) = \mathrm{I}$. Uhlenbeck proved in [30] that $\mathcal{D}_-^r$ is generated by the set $\{g_{\alpha,\pi} \mid \alpha \in \mathbb{C} \setminus \mathbb{R},\ \pi \text{ is a Hermitian projection of } \mathbb{C}^n\}$.

A *pure soliton* for the (b, j)-flow is a solution that is rapidly decaying in the spatial variable, has no continuous scattering data and has finitely many discrete scattering data, so its reduced wave function $m(x, \lambda)$ is rational in λ. Or equivalently, its reduced wave function m lies in the group $\mathcal{D}_-^r$.

Corollary 10.4 ([29]). *The group $\mathcal{D}_-^r$ acts on the space of solutions of the (b, j)-flow in the* $\mathrm{SU}(n)$*-hierarchy. In fact, if $g = g_{\alpha_1,\pi_1} \dots g_{\alpha_k,\pi_k}$, then $g * u = g_{\alpha_1,\pi_1} * (\cdots * (g_{\alpha_k,\pi_k} * u) \cdots)$.*

Corollary 10.5 ([27]). *Let $E_0(x, t, \lambda) = e^{a\lambda x + b\lambda^j t}$ (E_0 is the frame for the vacuum solution $u = 0$ of the (b, j)-flow). If we apply BT (Theorem* 10.3*) to E_0 repeatedly, then we obtain all pure soliton solutions of the (b, j)-flow, i.e., solutions with continuous scattering data $S = \mathrm{I}$ and finitely many discrete scattering data.*

Theorem 10.6 ([27]). *Let u be the global solution of the (b, j)-flow* (2) *in the* $\mathrm{SU}(n)$*-hierarchy constructed in Theorem* 7.4 *with only continuous scattering data, and E its frame. If we apply BT (Theorem* 10.3*) repeatedly to E, then we obtain solutions of the (b, j)-flow that have both continuous and finite discrete scattering data. Conversely, any solution u of the (b, j)-flow in the* $\mathrm{SU}(n)$*-hierarchy that has continuous scattering data and finite discrete scattering data can be constructed this way.*

Theorem 10.7 (Bäcklund transformation for the $U(n)$-system, [29]). *Suppose v is a solution of the $U(n)$-system, and $E(x,\lambda)$ is the frame for the Lax pair of v such that E is holomorphic for $\lambda \in \mathbb{C}$ and $E(0,\lambda) = \mathrm{I}$. Given $\alpha \in \mathbb{C} \setminus \mathbb{R}$ and a Hermitian projection π of $\mathbb{C}^n$, set $\tilde{\pi}(x)$ to be the Hermitian projection of $E(x,\alpha)^{-1}(\operatorname{Im}\pi)$, $\tilde{E} = g_{\alpha,\pi} E g_{\alpha,\tilde{\pi}}^{-1}$, and $\tilde{v} = v + (\alpha - \overline{\alpha})\tilde{\pi}^{\perp}$, where $\xi^{\perp} = \xi - \sum_{i=1}^{n} \xi_{ii} e_{ii}$. Then*

1. *$\tilde{v}$ is again a solution of the $U(n)$-system, and $\tilde{E}$ is a frame of the Lax pair of $\tilde{v}$,*
2. *if v is smooth for all $x \in \mathbb{R}^n$, then so is $\tilde{v}$.*

The group $\mathcal{D}_-^r$ acts on the space of solutions of the $U(n)$-system such that $g_{\alpha,\pi} * v = \tilde{v}$, where $\tilde{v}$ is given in the above theorem.

It is easy to see that if u is a solution of the $\frac{U(n)}{O(n)}$-system, $s \in \mathbb{R}$, and $\overline{\pi} = \pi$, then $g_{is,\pi}$ satisfies the $U(n)/O(n)$-reality condition and $g_{is,\pi} * u$ is also a solution of the $\frac{U(n)}{O(n)}$-system. In general,

Corollary 10.8 ([29]). *If $g \in \mathcal{D}_-^r$ satisfies the $\frac{U(n)}{O(n)}$-reality condition and v is a solution of the $\frac{U(n)}{O(n)}$-system, then $g * v$ is again a solution of the $\frac{U(n)}{O(n)}$-system.*

11. Bäcklund transformations for the space-time monopole equation

We use Lax pair (13) to construct soliton solutions and Bäcklund transformations for the monopole equation. Since the spectral parameter λ in (13) is related to the spectral parameter μ in (12) by $\mu = \frac{1-i\lambda}{1+i\lambda}$, the continuous scattering data for (13) is the jump across the real axis, and the discrete scattering data is given by the poles in $\mathbb{C} \setminus \mathbb{R}$ and their residues.

Definition 11.1. A monopole (A, ϕ) rapidly decaying in the spatial variable is a *k-soliton* if there is a gauge equivalent monopole with a frame (solution of (15)) ψ_λ that is rational in λ with k poles, $\psi_\infty = \mathrm{I}$, and $\lim_{\|(x,y)\|\to\infty} \psi_\lambda(x, y, t, \lambda) = h(\lambda)$ is independent of t.

We identify the set of all rank k Hermitian projections of $\mathbb{C}^n$ as the complex Grassmannian $\mathrm{Gr}(k, \mathbb{C}^n)$ by $\pi \mapsto \operatorname{Im}\pi$.

Theorem 11.2 ([33]). *Let $\alpha \in \mathbb{C} \setminus \mathbb{R}$, $\pi_0 \colon S^2 \to \mathrm{Gr}(k, \mathbb{C}^n)$ a holomorphic map, $\xi = \frac{1}{2}(t + x)$, $\eta = \frac{1}{2}(t - x)$, $\pi(x, y, t) = \pi_0(y + \alpha\xi + \alpha^{-1}\eta)$, and*

$$g_{\alpha,\pi}(x, y, t) = \mathrm{I} + \frac{\alpha - \overline{\alpha}}{\lambda - \alpha}\, \pi(x, y, t).$$

Then $g_{\alpha,\pi}$ is a 1-soliton monopole frame. Moreover, all 1-soliton frames are of this form up to gauge equivalence.

The following theorem is a consequence of Theorem 10.2 and the fact that $\lambda\partial_y - \partial_\xi$ and $\lambda\partial_\eta - \partial_y$ are derivations.

Theorem 11.3 (BT for monopoles, [12]). *Suppose $\alpha \in \mathbb{C} \setminus \mathbb{R}$ is a constant, and ψ is a frame of the monopole solution (A, ϕ) (i.e., solution of* (15)*), and $\psi(x, y, t, \tau)$ is holomorphic and non-degenerate at $\tau = \alpha$. Let $g_{\alpha,\pi}$ be a 1-soliton monopole frame, $\tilde{\pi}(x, y, t)$ the Hermitian projection of $\mathbb{C}^n$ onto $\psi(x, y, t, \alpha)(\operatorname{Im}\pi(x, y, t))$, and $\tilde{\psi} = g_{\alpha,\tilde{\pi}}\psi g_{\alpha,\pi}^{-1}$. Then*

1. *$\tilde{\psi}$ is holomorphic and non-degenerate at $\tau = \alpha$,*
2. *$\psi_1 = g_{\alpha,\tilde{\pi}}\psi = \tilde{\psi} g_{\alpha,\pi}$ is a frame for* (15) *with $\tilde{A}$, $\tilde{\phi}$ given by*

$$\begin{cases} \tilde{A}_\eta = A_\eta, \\ \tilde{A}_\xi = (1 - \frac{\bar{a}}{\alpha})(\partial_\xi\tilde{\pi})h + h^{-1}A_\xi h, \\ \tilde{A}_y + \tilde{\phi} = A_y + \phi, \\ \tilde{A}_y - \tilde{\phi} = (1 - \frac{\bar{\alpha}}{\alpha})(\partial_y\tilde{\pi})h + h^{-1}(A_y - \phi)h, \end{cases}$$

   where $h = \tilde{\pi} + \frac{\alpha}{\bar{\alpha}}\,\tilde{\pi}^\perp$,

3. *$(\tilde{A}, \tilde{\phi})$ is a solution of the space-time monopole equation.*

If we apply Theorem 11.3 to a 1-soliton k-times, then we get a $(k + 1)$-soliton whose frame has $(k + 1)$ distinct simple poles. Moreover, we have

Corollary 11.4. *Suppose (A, ϕ) is a solution of the space-time monopole equation with only continuous scattering data and E is its frame constructed in Theorem* 8.1. *If we apply Theorem* 11.3 *to E repeatedly, then we obtain a monopole whose frame has both continuous scattering data and finitely many distinct simple poles.*

Note that a BT for flows in the SU(n)-hierarchy adds to a given solution, a soliton with scattering pole at α, regardless of whether the given solution already has a scattering pole at α or not. But this is not the case for the monopole equation, so BTs produce soliton monopole frames with distinct simple poles only. Ward and his group ([35], [19], [3], [20]) take limits of soliton monopole frames with 2 and 3 distinct poles to construct 2- and 3-soliton monopoles with a double and a triple pole at i that are time dependent. Dai and Terng used BT (Theorem 11.3) and a systematic limiting method to construct rational monopole frames with arbitrary poles and multiplicities:

Theorem 11.5 ([12]). *Given $\alpha_i \in \mathbb{C} \setminus \mathbb{R}$ and positive integers n_i for $1 \le i \le k$, there are soliton monopole frames that are rational and have poles at $\alpha_1, \ldots, \alpha_k$ with multiplicities $n_1, \ldots, n_k$.*

Below is a more general Bäcklund transformation that adds a multiplicity k pole at $\lambda = \alpha$ to a given monopole frame.

Theorem 11.6 ([12]). *Suppose ψ is a monopole frame that is holomorphic and non-degenerate at $\lambda = \alpha$ and ϕ is a soliton (rational) monopole frame with a single pole at $\lambda = \alpha$ with multiplicity k. Then there exist unique $\tilde{\phi}$, $\tilde{\psi}$ such that $\psi_1 = \tilde{\phi}\psi = \tilde{\psi}\phi$ is a monopole frame, $\tilde{\phi}$ is rational with a single pole at $\lambda = \alpha$ with multiplicity k, and $\tilde{\psi}$ is holomorphic and non-degenerate at $\lambda = \alpha$. We use $\phi * \psi$ to denote ψ_1.*

Theorem 11.7 ([13]). *If ψ is a monopole frame with both continuous scattering data and finitely many poles, then there exist unique monopole frames ψ_c and ϕ such that ψ_c has only continuous scattering data, ϕ has only discrete scattering data, and $\psi = \phi * \psi_c$.*

Finiteness of arithmetic Kleinian reflection groups

Ian Agol*

Abstract. We prove that there are only finitely many arithmetic Kleinian maximal reflection groups.

Mathematics Subject Classification (2000). Primary 30F40; Secondary 57M.

Keywords. Kleinian group, reflection group.

1. Introduction

A Kleinian reflection group Γ is a discrete group generated by reflections in the faces of hyperbolic polyhedron $P \subset \mathbb{H}^3$. We may assume that the dihedral angles of P are of the form π/n, $n \geq 2$, in which case P forms a fundamental domain for the action of Γ on $\mathbb{H}^3$. If P has finite volume, then $\mathbb{H}^3/\Gamma = \mathcal{O}$ is a hyperbolic orbifold of finite volume, which is obtained by "mirroring" the faces of P. Andreev gave a combinatorial characterization of hyperbolic reflection groups in 3-dimensions, in terms of the topological type of P and the dihedral angles assigned to the edges of P [1]. A reflection group Γ is maximal if there is no reflection group Γ' such that $\Gamma < \Gamma'$. We shall defer the definition of arithmetic groups until later, but a theorem of Margulis implies that Γ is arithmetic if and only if $[\mathrm{Comm}(\Gamma) : \Gamma] = \infty$, where $\mathrm{Comm}(\Gamma) = \{g \in \mathrm{Isom}(\mathbb{H}^3) \mid [\Gamma : g^{-1}\Gamma g \cap \Gamma] < \infty\}$ [14]. The main theorem of this paper is that there are only finitely many arithmetic Kleinian groups which are maximal reflection groups.

The argument generalizes an argument of Long–MacLachlan–Reid [12], which implies that there are only finitely many arithmetic minimal hyperbolic 2-orbifolds with bounded genus. Their argument is in fact a generalization of an argument of Zograf [26], who reproved that there are only finitely many congruence groups Γ commensurable with $\mathrm{PSL}(2, \mathbb{Z})$ such that $\mathbb{H}^2/\Gamma$ has genus 0 (this was proven originally by Dennin [4], [5], and was known as Rademacher's conjecture). The key ingredient of their argument is a theorem of Vigneras [20] (based on work of Gelbart–Jacquet [7] and Jacquet–Langlands [10]), which implies that a congruence arithmetic Fuchsian group has $\lambda_1 \geq \frac{3}{16}$ (and which has a generalization to higher dimensions [3]). The other key ingredient is an estimate of Zograf [27], which implies that for a hyperbolic 2-orbifold $\mathcal{O}$, $\lambda_1(\mathcal{O})\mathrm{Vol}(\mathcal{O})$ is bounded linearly by the genus of $\mathcal{O}$. Zograf's argument

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

is based on a sequence of improvements of a result of Szëgo (who did this for planar domains)[18], by Hersch (for S^2) [9], Yang–Yau (for orientable surfaces) [25], and Li–Yau (for non-orientable surfaces and manifolds of a fixed conformal type) [11]. We observe that the Li–Yau argument (sharpened by El Soufi–Ilias [6]) generalizes to orbifolds, and we then apply this to arithmetic Kleinian reflection groups.

In the concluding section, we consider how one might generalize this result to higher dimensions to prove

Conjecture 1.1. There are only finitely many maximal arithmetic reflection groups in $\mathrm{Isom}(\mathbb{H}^n)$, $n > 1$.

2. Conformal volume of orbifolds

Conformal volume was first defined by Li–Yau, partially motivated by generalizing results on surfaces due to Yang–Yau, Hersch, and Szëgo. We generalize this notion to orbifolds. Let $(\mathcal{O}, g)$ be a compact Riemannian orbifold, possibly with boundary. Let $|\mathcal{O}|$ denote the underlying topological space. Denote the volume form by dv_g, and $\mathrm{Vol}(\mathcal{O}, g)$ its volume. Let $\mathrm{Möb}(\mathbb{S}^n)$ denote the conformal transformations of $\mathbb{S}^n$. It is well known that $\mathrm{Möb}(\mathbb{S}^n) = \mathrm{Isom}(\mathbb{H}^{n+1})$. $|\mathcal{O}|$ has a codimension zero dense open subset which is a Riemannian manifold. We will say that a map $\varphi\colon |\mathcal{O}_1| \to |\mathcal{O}_2|$ is *PC* if it is a continuous map which is piecewise conformal on the open submanifold of $|\mathcal{O}_1|$ which maps to the manifold part of $|\mathcal{O}_2|$. Clearly, if $\varphi\colon |\mathcal{O}| \to \mathbb{S}^n$ is PC, and $\mu \in \mathrm{Möb}(\mathbb{S}^n)$, then $\mu \circ \varphi$ is also PC. Let *can* denote the canonical round metric on $\mathbb{S}^n$.

Definition 2.1. For a piecewise smooth map $\varphi\colon |\mathcal{O}| \to (\mathbb{S}^n, can)$, define

$$V_c(n, \varphi) = \sup_{\mu \in \mathrm{Möb}(\mathbb{S}^n)} \mathrm{Vol}(\mathcal{O}, (\mu \circ \varphi)^*(can)).$$

If there exists a PC map $\varphi\colon |\mathcal{O}| \to \mathbb{S}^n$, then we also define

$$V_c(n, \mathcal{O}) = \inf_{\varphi\colon \mathcal{O} \to \mathbb{S}^n \text{ PC}} V_c(n, \varphi).$$

$V_c(n, \mathcal{O})$ is denoted the (n-dimensional) *conformal volume* of $\mathcal{O}$.

Remark. For our application, it would suffice to define a PC map to be Lipschitz and *a.e.* conformal. It seems likely that our definition of conformal volume coincides with that of Li–Yau for manifolds, but we have not checked this (it would suffice to show that a PC map can be approximated by conformal maps).

If there exists a piecewise isometric map $\varphi\colon (|\mathcal{O}|, g) \to \mathbb{E}^n$ for some n, then clearly $V_c(n, \mathcal{O})$ is well-defined, since $\mathbb{E}^n$ has a conformal embedding into $\mathbb{S}^n$. For an orbifold $(\mathcal{O}, g)$, to prove that $V_c(n, \mathcal{O})$ is well-defined, one need only check that $(|\mathcal{O}|, g)$ embeds piecewise isometrically into some compact Riemannian manifold, in which case the Nash isometric embedding theorem implies that $(|\mathcal{O}|, g)$ embeds

piecewise isometrically into $\mathbb{E}^n$, for some n. We will only apply conformal volume to orbifolds which will obviously have a PC map to $\mathbb{S}^n$, for some n. We record basic facts about conformal volume which were recorded in [11], and which carry over to our notion of conformal volume for orbifolds.

Fact 1. If $\mathcal{O}$ admits a degree d PC map onto another orbifold $\mathcal{P}$, then

$$V_c(n, \mathcal{O}) \leq |d| V_c(n, \mathcal{P}).$$

Fact 2. Since $\mathbb{S}^n \hookrightarrow \mathbb{S}^{n+1}$ embeds isometrically, it is clear that $V_c(n, \mathcal{O}) \geq V_c(n+1, \mathcal{O})$. Define the conformal volume $V_c(\mathcal{O}) = \lim_{n\to\infty} V_c(n, \mathcal{O})$.

Fact 3. If $\mathcal{O}$ is of dimension m, and $\varphi\colon |\mathcal{O}| \to \mathbb{S}^n$ is a PC map, then

$$V_c(n, \varphi) \geq V_c(n, \mathbb{S}^m) = \mathrm{Vol}(\mathbb{S}^m).$$

The same argument as in Li–Yau works here: "blow up" about a smooth manifold point of $\varphi(|\mathcal{O}|)$ so that the image Hausdorff limits to a geodesic sphere of dimension m.

Fact 4. If $\mathcal{O}$ is an embedded suborbifold of the orbifold $\mathcal{P}$, and $\varphi\colon |\mathcal{P}| \to \mathbb{S}^n$ is PC, then $V_c(n, \varphi) \geq V_c(n, \varphi|_{|\mathcal{O}|})$. Thus, $V_c(n, \mathcal{P}) \geq V_c(n, \mathcal{O})$.

3. Finite subgroups of O(3)

Lemma 3.1. *Let $G < \mathrm{O}(3)$ be a finite subgroup. Then there exists a group G', $G \leq G' < \mathrm{O}(3)$, which is generated by reflections such that $[G' : G] \leq 4$.*

Proof. This follows from a case-by-case analysis of spherical 2-orbifolds. We will use Conway's notation for spherical orbifolds (see *e.g.* ch. 13 [19]).

Case $(*)$, $(*p, p)$ or $(*p, q, r)$: These orbifold groups are generated by reflections.

Case (p, p) or (p, q, r): These 2-fold cover $(*p, p)$ or $(*p, q, r)$ respectively.

Case $(n*)$: This 2-fold covers $(*n, 2, 2)$.

Case $(2 * m)$: This 2-fold covers $(*2m, 2, 2)$.

Case $(3 * 2)$: This 2-fold covers $(*4, 3, 2)$.

Case $(n|\circ)$: This 2-fold covers $(2n*) \xrightarrow{2:1} (*2n, 2, 2)$ (this includes the case $n = 1$, *i.e.* $(1|\circ) = \mathbb{RP}^2$).

This exhausts all possible spherical orbifolds, and we see that in each case the orbifold fundamental group is of index ≤ 4 in a reflection group (all but the last case have index ≤ 2). □

Question. Given a dimension n, is there a constant $C(n)$ such that any finite subgroup of $\mathrm{O}(n)$ is of index $\leq C(n)$ in a reflection group? If so, then one should be able to prove Conjecture 7.1. We suspect the answer to this question is no, which is why we have not been able to generalize the proof in this section to higher dimensions.

4. Eigenvalue bounds

We observe that the argument of Thm. 2.2 [6] generalizes to our context of orbifolds (their theorem sharpens Cor. 3, Sect. 2 of [11]). If $(\mathcal{O}, g)$ is a Riemannian orbifold with piecewise smooth boundary, then $\lambda_1(\mathcal{O}, g)$ is the first non-zero eigenvalue of Δ_g on $\mathcal{O}$ with Neumann boundary conditions.

Theorem 4.1 ([6]). *Let $(\mathcal{O}, g)$ be a compact Riemannian orbifold of dimension m, possibly with boundary. If $\varphi\colon |\mathcal{O}| \to \mathbb{S}^n$ is a PC map,*

$$\lambda_1(\mathcal{O}, g)\mathrm{Vol}(\mathcal{O}, g)^{\frac{2}{m}} \leq m V_c(n, \varphi)^{\frac{2}{m}}.$$

Proof. Let $\boldsymbol{X} = (X_1, \ldots, X_{n+1})$ be the coordinate functions on $\mathbb{S}^n \subset \mathbb{R}^{n+1}$. Then $\sum_{i=1}^{n+1} X_i^2 = 1$, restricted to $\mathbb{S}^n$.

Lemma 4.2. *There exists $\mu \in \mathrm{M\ddot{o}b}(\mathbb{S}^n)$ such that $\int_{\mathcal{O}} \boldsymbol{X} \circ \mu \circ \varphi \, dv_g = \mathbf{0}$.*

Proof. Let $\boldsymbol{x} \in \mathbb{S}^n$. For $0 \leq t < 1$, $t\boldsymbol{x} \in \mathbb{H}^{n+1}$, let $\mu_{t\boldsymbol{x}} \in \mathrm{M\ddot{o}b}(\mathbb{S}^n) = \mathrm{Isom}(\mathbb{H}^{n+1})$ be the hyperbolic translation along the ray $\mathbb{R}\boldsymbol{x}$ taking $\mathbf{0}$ to $t\boldsymbol{x}$ (thus, $\mu_{0\mathbf{x}} = \mu_{\mathbf{0}} = \mathrm{Id}$). Let $H(t\boldsymbol{x}) = \frac{1}{\mathrm{Vol}(\mathcal{O},g)} \int_{\mathcal{O}} \boldsymbol{X} \circ \mu_{t\boldsymbol{x}} \circ \varphi \, dv_g$. We may think of H as defining a function $H\colon \mathbb{H}^{n+1} \to \mathbb{H}^{n+1}$, which gives the center of mass of the measure coming from $\varphi_* dv_g$, where we take the point $-t\boldsymbol{x}$ to be the origin of the sphere $\mathbb{S}^n = \partial\mathbb{H}^{n+1}$ by the conformal map $\mu_{t\boldsymbol{x}}$. As $t \to 1$, all of the mass of $\mu_{t\mathbf{x}} \circ \varphi(\mathcal{O})$ becomes concentrated at $\boldsymbol{x}$, and we see that H extends to a continuous function $H\colon B^{n+1} \to B^{n+1}$ (where $B^{n+1} = \mathbb{H}^{n+1} \cup \mathbb{S}^n$) such that $H_{|\mathbb{S}^n} = \mathrm{Id}_{|\mathbb{S}^n}$. Thus, H is onto, so there exists $\boldsymbol{y} \in \mathbb{H}^{n+1}$ such that $H(\boldsymbol{y}) = \mathbf{0}$, and we take $\mu = \mu_{\boldsymbol{y}}$. □

Now replace φ with $\mu \circ \varphi$, noting that this is still a PC map. Then $X_i \circ \varphi$ may be used as test functions in the Rayleigh–Ritz quotient, since they are Lipschitz functions which are L^2 orthogonal to the constant function. Thus,

$$\lambda_1(\mathcal{O}) \int_{\mathcal{O}} |X_i \circ \varphi|^2 \, dv_g \leq \int_{\mathcal{O}} |\nabla X_i \circ \varphi|^2 \, dv_g.$$

Summing, we see that

$$\begin{aligned}
\lambda_1(\mathcal{O}) \int_{\mathcal{O}} \sum_{i=1}^{n+1} |X_i \circ \varphi|^2 \, dv_g &= \lambda_1(\mathcal{O})\mathrm{Vol}(\mathcal{O}, g) \\
&\leq m \int_{\mathcal{O}} \frac{1}{m} \sum_{i=1}^{n+1} |\nabla X_i \circ \varphi|^2 \, dv_g \\
&\leq m \left(\int_{\mathcal{O}} \left(\frac{1}{m} \sum_{i=1}^{n+1} |\nabla X_i \circ \varphi|^2 \right)^{\frac{m}{2}} dv_g \right)^{\frac{2}{m}} \mathrm{Vol}(\mathcal{O}, g)^{1-\frac{2}{m}},
\end{aligned}$$

where the last inequality is Hölder's inequality. Now we use the fact that φ is PC to see that $\varphi^* can = \frac{1}{m}\sum_{i=1}^{n+1} |\nabla X_i \circ \varphi|^2$ *a.e.*, and thus

$$\int_{\mathcal{O}} \Big(\frac{1}{m}\sum_{i=1}^{n+1} |\nabla X_i \circ \varphi|^2\Big)^{\frac{m}{2}} dv_g \leq \mathrm{Vol}(\mathcal{O}, \varphi^* can).$$

Finally, we obtain the desired inequality putting these inequalities together. □

5. Congruence arithmetic hyperbolic 3-orbifolds

We need to know some properties of arithmetic hyperbolic 3-orbifolds. For background and notation, see Maclachlan–Reid [13].

Let $k \subset \mathbb{C}$ be a number field with only one complex place, and let A be a quaternion algebra over k. Let $\rho\colon A \to M(2,\mathbb{C})$ be a k-embedding, $P\colon \mathrm{GL}(2,\mathbb{C}) \to \mathrm{PGL}(2,\mathbb{C})$. Let $\mathcal{E} \subset A$ be either a maximal order or an Eichler order, and let $N(\mathcal{E}) \subset A^*$ be the normalizer of $\mathcal{E}$ in A. Let Γ be an arithmetic Kleinian group, such that $\Gamma = P\rho G$, $G \subset A^*$. Then there exists an order $\mathcal{E} \subset A$ which is either a maximal order or an Eichler order such that $G \subset N(\mathcal{E})$ (see thm. 11.4.3 [13]). In particular, if Γ is a maximal arithmetic Kleinian group, then $\Gamma = P\rho N(\mathcal{E})$, for some order $\mathcal{E}$.

An ideal I in A is a complete R_k-lattice. The left order of I is $\mathcal{O}_l(I) = \{a \in A \mid aI \subset I\}$, and the right order is $\mathcal{O}_r(I) = \{a \in A \mid Ia \subset I\}$. The ideal I is 2-*sided* if $\mathcal{O}_l(I) = \mathcal{O}_r(I)$. The ideal is *integral* if I lies in both $\mathcal{O}_l(I)$ and in $\mathcal{O}_r(I)$ (*i.e.* $I^2 \subseteq I$ is multiplicatively closed). If $\mathcal{O}$ is a maximal order in A, and I is a 2-sided integral ideal in $\mathcal{O}$ such that $\mathcal{O} = \mathcal{O}_l(I) = \mathcal{O}_r(I)$, then the *principal congruence subgroup* of $\mathcal{O}^1$ is

$$\mathcal{O}^1(I) = \mathcal{O}^1 \cap (1 + I).$$

Thus, $\mathcal{O}^1(I)$ is the kernel of the map $\mathcal{O}^1 \to \mathcal{O}/I$, which is therefore of finite index in $\mathcal{O}^1$, since $\mathcal{O}/I$ is finite. A discrete group $G \subset A$ is *congruence* if it contains a principal congruence subgroup, and $\Gamma < \mathrm{PGL}(2,\mathbb{C})$ is congruence if $\Gamma = P\rho G$, for some $G < A$ congruence.

Lemma 5.1 (Long–MacLachlan–Reid [12]). *A maximal arithmetic Kleinian group is congruence.*

Proof. Let $\Gamma \subset \mathrm{PGL}(2,\mathbb{C})$ be a maximal arithmetic Kleinian group. Then $\Gamma = P\rho N(\mathcal{E})$, for some order $\mathcal{E}$ of square-free level. If $\mathcal{E}$ is a maximal order, then $\mathcal{E}^1$ is a congruence subgroup for the trivial ideal $I = \mathcal{E}$. If $\mathcal{E} = \mathcal{O}_1 \cap \mathcal{O}_2$, where $\mathcal{O}_i$ are maximal orders (so that $\mathcal{E}$ is an Eichler order), then choose $\alpha \in R_k - \{0\}$ such that $I = \alpha\mathcal{O}_1 \subset \mathcal{O}_2$. Then $\mathcal{O}_l(I) = \mathcal{O}_r(I) = \mathcal{O}_1$, and $I^2 = \alpha^2\mathcal{O}_1 \subset \alpha\mathcal{O}_1 = I$. Also, clearly $1 + I \subset \mathcal{O}_1 \cap \mathcal{O}_2$. Thus, $\mathcal{O}^1(I) = \mathcal{O}_1^1 \cap (1 + I) \subset \mathcal{O}_1 \cap \mathcal{O}_2$. Thus, $\mathcal{O}^1(I) \subset \mathcal{E}^1$, and we see that $\mathcal{E}^1$ is a principal congruence subgroup. □

A fundamental theorem of Vigneras, making use of work of Jacquet–Langlands [10] and Gelbart–Jacquet [7], generalizes a result of Selberg for $\mathrm{PSL}(2,\mathbb{Z})$. For a hyperbolic orbifold $\mathcal{O}$, let $\lambda_1(\mathcal{O})$ be the minimal non-zero eigenvalue of the Laplacian Δ on $\mathcal{O}$.

Theorem 5.2 ([20], [3]). *Let $\mathcal{O} = \mathbb{H}^3/\Gamma$, where Γ is an arithmetic congruence subgroup. Then $\lambda_1(\mathcal{O}) \geq \frac{3}{4}$.*

It is conjectured that under the hypotheses of the above theorem, $\lambda_1(\mathcal{O}) \geq 1$, which is known as (a special case of) the *generalized Ramanujan conjecture* [3].

6. Finiteness of arithmetic Kleinian maximal reflection groups

We put together the results from the previous sections to prove our main theorem.

Theorem 6.1. *There are only finitely many arithmetic maximal reflection groups in* $\mathrm{Isom}(\mathbb{H}^3)$.

Proof. Suppose that Γ is an arithmetic maximal reflection group. That is, there is no group $\Gamma' < \mathrm{Isom}(\mathbb{H}^3)$, with $\Gamma < \Gamma'$, such that Γ' is generated by reflections. Then there exists $\Gamma \leq \Gamma_0 < \mathrm{Isom}(\mathbb{H}^3)$, such that Γ_0 is a maximal Kleinian group. Γ is generated by reflections in a finite volume polyhedron P.

Lemma 6.2 (Vinberg [21]). *Γ is a normal subgroup of Γ_0. Moreover, there is a finite subgroup $\Theta < \Gamma_0$ such that $\Theta \to \Gamma_0/\Gamma$ is an isomorphism, and Θ preserves the polyhedron P.*

Proof. This follows from the fact that the set of reflections in Γ_0 is conjugacy invariant, and therefore the group generated by reflections is normal in Γ_0. Since Γ is a maximal reflection group, this subgroup must be Γ. The polyhedron P is a fundamental domain of Γ, and if there is an element $\gamma \in \Gamma_0$ such that $\mathrm{int(P)} \cap \gamma(\mathrm{int(P)}) \neq \emptyset$, then $\gamma(P) = P$. Otherwise, there would be a geodesic plane V containing a face of P, such that $V \cap \mathrm{int(P)} \neq \emptyset$. The reflection $r_V \in \Gamma$ in the plane V would be conjugate to a reflection $r_{\gamma(V)} = \gamma r_V \gamma^{-1}$, which is not in Γ since $r_{\gamma(V)}(\mathrm{int(P)}) \cap \mathrm{int(P)} \neq \emptyset$, which implies that Γ is not a maximal reflection group, a contradiction. Let Θ be the subgroup of Γ_0 such that $\Theta(P) = P$. Clearly Θ is finite, since P is finite volume and has finitely many faces. If $\gamma_0 \in \Gamma_0$, let $\gamma \in \Gamma$ be such that $\gamma_0(\mathrm{int(P)}) \cap \gamma(\mathrm{int(P)}) \neq \emptyset$. Then $\gamma^{-1}\gamma_0(P) = P$, so $\gamma_0 \in \gamma\Theta$. Thus, $\Theta \to \Gamma_0/\Gamma$ is an isomorphism. □

Let $\mathcal{O} = \mathbb{H}^3/\Gamma_0$, and Θ is the finite group coming from the previous lemma.

Lemma 6.3. $\lambda_1(\mathcal{O}) = \lambda_1(P/\Theta)$.

Proof. Let f be an eigenfunction on P/Θ with eigenvalue $\lambda_1(P/\Theta)$. Since f has Neumann boundary conditions, its level sets in P/Θ are orthogonal to $\partial P/\Theta$. Let $\tilde{f}$

be the preimage of f under the map $P \to P/\Theta$, so that $\tilde{f}$ is invariant under the action of Θ. Extend $\tilde{f}$ to a function $\tilde{F}$ on $\mathbb{H}^3$, by the action of Γ (and therefore invariant under the action of Γ_0). By the reflection principle, $\tilde{F}$ is a smooth function, so it descends to an eigenfunction F of Δ on $\mathcal{O}$ with eigenvalue $\lambda_1(P/\Theta)$. Conversely, if F is an eigenfunction of Δ on $\mathcal{O}$ with eigenvalue $\lambda_1(\mathcal{O})$, then $F_{|P/\Theta}$ gives an eigenfunction on P/Θ with Neumann boundary conditions, since the level sets of $\tilde{F}$ must be invariant under reflections, and therefore perpendicular to the faces of P. □

Consider $\mathbb{H}^3 \subset \mathbb{S}^3$ embedded conformally as the upper half space of $\mathbb{S}^3$, so that $\mathrm{Isom}(\mathbb{H}^3)$ acts conformally on $\mathbb{S}^3$. Normalize so that Θ acts isometrically on $\mathbb{S}^3$, which we may do by a result of Wilker [24]. Clearly, $V_c(n, \mathcal{O}) = V_c(n, P/\Theta)$, since $|\mathcal{O}| = |P/\Theta|$. Then the orbifold $P/\Theta \subset \mathbb{S}^3/\Theta$ is a conformal embedding, so by Fact 4, $V_c(3, P/\Theta) \leq V_c(3, \mathbb{S}^3/\Theta)$. The group Θ embeds in a finite reflection group $\Theta' \subset \mathrm{O}(3)$ such that $[\Theta' : \Theta] \leq 4$. Then by Fact 1, $V_c(3, \mathbb{S}^3/\Theta) \leq 4V_c(3, \mathbb{S}^3/\Theta')$. Now, there is a polyhedron $Q \subset \mathbb{S}^3$ with geodesic faces which is the fundamental domain for Θ'. Clearly $V_c(3, Q) = V_c(3, \mathbb{S}^3/\Theta')$. By Facts 2 and 4, $V_c(3, Q) = \mathrm{Vol}(\mathbb{S}^3, \mathit{can}) = 2\pi^2$. Thus, we have $V_c(\mathcal{O}) \leq 8\pi^2$.

Now we apply the eigenvalue estimates

$$\frac{3}{4}\mathrm{Vol}(\mathcal{O})^{\frac{2}{3}} \leq \lambda_1(\mathcal{O})\mathrm{Vol}(\mathcal{O})^{\frac{2}{3}} \leq 3V_c(\mathbb{H}^3/\Gamma_0)^{\frac{2}{3}} \leq 3(8\pi^2)^{\frac{2}{3}}.$$

Thus we obtain $\mathrm{Vol}(\mathcal{O}) \leq 64\pi^2$. Since volumes of arithmetic hyperbolic orbifolds are discrete, and Γ_0 is uniquely determined by Γ, we conclude that there are only finitely many arithmetic maximal reflection groups. □

7. Conclusion

From the main theorem, we conclude that given an arithmetic reflection group $\Gamma < \mathrm{Isom}(\mathbb{H}^3)$, it must lie in one of finitely many maximal reflection groups (up to conjugacy). If Γ is a reflection group in a polyhedron P for which all the dihedral angles are $\pi/2$ or all are $\pi/3$, then there are infinitely many co-finite volume reflection subgroups of Γ. Thus we see that there are commensurability classes of arithmetic groups for which there are infinitely many reflection groups in the commensurability class, and thus in our finiteness result, the maximality assumption is crucial. It is an interesting project to try to identify all arithmetic maximal reflection groups, and to classify their reflection subgroups of finite covolume.

For the non-compact examples, one may apply volume formulae to estimate the maximal discriminant of a quadratic imaginary number field k for which $\mathrm{PGL}(2, k)$ contains a reflection group. Humbert first computed the covolumes of Bianchi groups, and a generalization due to Borel implies that for a non-compact arithmetic Kleinian

group, the minimal covolume μ satisfies

$$\mu \geq \frac{|\Delta_k|^{\frac{3}{2}}\zeta_k(2)}{16\pi^2 h_k},$$

where h_k is the class number of the number field k. The Brauer–Siegel theorem gives an estimate of h_k for a number field and implies for a quadratic imaginary number field k that

$$|\Delta_k|\zeta_k(2) \geq \frac{h_k(2\pi)^2}{2w},$$

where w is the order of the group of roots of unity in k. If $k \neq \mathbb{Q}(i), \mathbb{Q}(\sqrt{-3})$, then $w = 2$ (see the proof of theorem 11.7.2 [13]). Thus, we have

$$64\pi^2 \geq \mu \geq \frac{1}{16}|\Delta_k|^{\frac{1}{2}}.$$

Thus $|\Delta_k| < 2^{20}\pi^4 = 1.02 \times 10^8$. Hatcher has computed orbifold structures of some of the Bianchi groups of small discriminant, and from his pictures one may deduce that $\mathrm{PGL}(2, R_k)$ is commensurable with a reflection group for

$$\begin{aligned}\Delta_k = &-3,\ -4,\ -7,\ -8,\ -11,\ -15,\ -19,\ -20,\\ &-24,\ -39,\ -40,\ -52,\ -55,\ -56,\ -68,\ -84,\end{aligned}$$

where k is a quadratic imaginary number field [8]. In principle, it ought to be possible to compute all arithmetic reflection groups, but clearly even in the non-compact case, the volume estimates we obtain do not make this computation feasible. To classify non-compact Kleinian arithmetic groups, it may require the infusion of some more number theory. Arithmetic restrictions have been found on reflection groups containing the Bianchi groups by Vinberg [23] and Blume-Nienhaus [2]. If these results could be extended to all maximal non-compact arithmetic groups, then one may be able to give a complete classification. The classification of compact arithmetic maximal reflection groups, although in principle decidable, is probably not feasible at this stage.

It is clear that for a finite volume polyhedron $P \subset \mathbb{H}^n$, $V_c(n, P) = \mathrm{Vol}(\mathbb{S}^n)$, so

$$\lambda_1(P)\mathrm{Vol}(P)^{\frac{2}{n}} < n\mathrm{Vol}(\mathbb{S}^n)^{\frac{2}{n}}.$$

Thus in n dimensions, there are finitely many reflection groups $\Gamma < \mathrm{Isom}(\mathbb{H}^n)$ which have a lower bound on $\lambda_1(\mathbb{H}^n/\Gamma)$. It would be interesting if one could generalize the arguments of the main theorem to higher dimensions. It is known by work of Prokhorov that there cannot be any reflection groups in dimension > 996 [17] (Vinberg showed that compact reflection groups cannot exist in dimension > 30 [22]). Vinberg also gave a characterization of arithmetic reflection groups, in terms of a totally real field of definition K and an integrality condition [21]. Nikulin has shown that there

exists a constant N_0 such that the set of arithmetic groups in $\mathrm{Isom}(\mathbb{H}^n)$ generated by reflections with $n > 16$ and $[K : \mathbb{Q}] > N_0$ is empty [16]. It was proved in a previous paper by Nikulin that the set of maximal arithmetic groups generated by reflections in $\mathrm{Isom}(\mathbb{H}^n)$ with a fixed degree $[K : \mathbb{Q}]$ is finite [15]. Thus, to generalize the main argument of this paper, one would have to bound the conformal volume of a minimal arithmetic n-orbifold containing a reflection suborbifold up to dimensions $n \leq 16$. By the characterization of maximal arithmetic groups in $\mathrm{Isom}(\mathbb{H}^n)$, it should follow that they are congruence. By a result of Burger–Sarnak, if $\Gamma < \mathrm{Isom}(\mathbb{H}^n)$ is a congruence arithmetic reflection group with $n > 2$, then $\lambda_1(\mathbb{H}^n/\Gamma) > \frac{2n-3}{4}$ (Cor. 1.3 [3], and the fact that reflection groups are defined by quadratic forms). Every maximal arithmetic group covered by a reflection group will embed conformally in an elliptic n-orbifold. So to prove the following conjecture for $n \leq 16$:

Conjecture 7.1. There is a function $K(n)$, such that if $\mathcal{O}$ is an elliptic n-orbifold, then $V_c(\mathcal{O}) \leq K(n)$.

Non-positive curvature and complexity for finitely presented groups

Martin R. Bridson*

Abstract. A universe of finitely presented groups is sketched and explained, leading to a discussion of the fundamental role that manifestations of non-positive curvature play in group theory. The geometry of the word problem and associated filling invariants are discussed. The subgroup structure of direct products of hyperbolic groups is analysed and a process for encoding diverse phenomena into finitely presented subdirect products is explained. Such an encoding is used to solve problems of Grothendieck concerning profinite completions and representations of groups. In each context, explicit groups are crafted to solve problems of a geometric nature.

Mathematics Subject Classification (2000). Primary 20F65; Secondary 20F67.

Keywords. Geometric group theory, finitely presented groups, non-positive curvature, Dehn functions, filling invariants, decision problems.

Introduction

When viewed through the eyes of a topologist, a finite group-presentation $\Gamma = \langle \mathcal{A} \mid \mathcal{R} \rangle$ is a concise description of a compact, connected, 2-dimensional CW-complex K with one vertex: the generators $a \in \mathcal{A}$ index the (oriented) 1-cells and the defining relations $r \in \mathcal{R}$ describe the loops along which the boundaries of the 2-cells are attached. Γ emerges as the group of deck transformations of the universal cover $\tilde{K}$ and the Cayley graph $\mathcal{C}_{\mathcal{A}}(\Gamma)$ is the 1-skeleton of $\tilde{K}$.

Thus we meet the two main strands of geometric group theory, intertwined as they often are. In the first and most classical strand, one studies actions of groups on metric and topological spaces in order to elucidate the structure of the space and the group. The quality of the insights that one obtains varies with the quality of the action: one may prefer discrete cocompact actions by isometries on spaces with fine geometric structure, but according to context one must vary the conditions on the action, sometimes weakening admission criteria to obtain a more diverse class of groups, sometimes demanding more structure to narrow the focus and study groups and spaces of exceptional character.

This first strand mingles with the second, wherein one regards finitely generated groups as geometric objects in their own right [62], equipped with *word metrics*: given a finite generating set S for a group Γ one defines $d_S(\gamma_1, \gamma_2)$ to be the length of

*This work was supported in part by an EPSRC Advanced Fellowship.

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

the shortest word in the free group on S that is equal to $\gamma_1^{-1}\gamma_2$ in Γ. In other words, d_S is the restriction to the vertex set of the standard length metric on the Cayley graph of Γ. The word metric and Cayley graph depend on the choice of generating set, but their quasi-isometry type does not. Thus one is particularly interested in properties of groups and spaces that are invariant under quasi-isometry. When dealing with such invariants, one is free to replace Γ by any space that is quasi-isometric to it, such as the universal cover of a closed Riemannian manifold with fundamental group Γ, where the tools of analysis can be brought to bear.

The techniques of geometric group theory merge into the more combinatorial techniques that held sway in the study of finitely presented groups for most of the twentieth century. At the heart of combinatorial group theory lie the fundamental decision problems first articulated by Max Dehn [50] – the word, conjugacy and isomorphism problems. These continue to play an important role in geometric group theory and provide a unifying theme for the ideas presented here, serving as fundamental measures of the complexity of groups.

In this article and the accompanying lecture I shall discuss two topics that account for much of my work: manifestations of non-positive curvature in group theory, and the geometry of the word problem and associated filling invariants. I shall also explore the subgroup structure of direct products of hyperbolic groups. It transpires that a huge range of phenomena can be encoded into the finitely presented subgroups of such direct products. Fritz Grunewald and I used such an encoding to solve problems of Grothendieck concerning profinite completions and representations of groups; this is explained in Section 6. Throughout the discussion, the reader will find that a prominent role is played by explicit groups crafted to solve problems of a geometric nature.

Acknowledgements. It is a pleasure to thank my coauthors, past and present, for their ideas and companionship. It is also a pleasure to acknowledge the great intellectual debt that I owe to Mikhael Gromov.

1. The universe of finitely presented groups

The picture of the universe of groups that I am about to sketch[1] is shaded by personal taste and the needs of today but nevertheless I claim that it has intrinsic merit. The point of attempting such a sketch is that it forces one to consider how different classes of groups that arise in disparate settings are related; it challenges one to locate given groups in relation to others and to explain how different classes intersect; and it helps to tease out why certain classes are worthy of particular attention. One asks what theorems hold where, and how various measures of complexity (decision problems, subgroup structure, finiteness properties, ...) vary and decay as one moves around the universe. One finds oneself reflecting on how problems from elsewhere in mathematics can be encoded in groups of one type but not another, and one starts to wonder

[1] I thank Tim Riley for his skillful rendering of my hand-drawing.

how such problems might be transported to a more hospitable region of the universe where one has stricter definitions and better theorems to mount an attack.

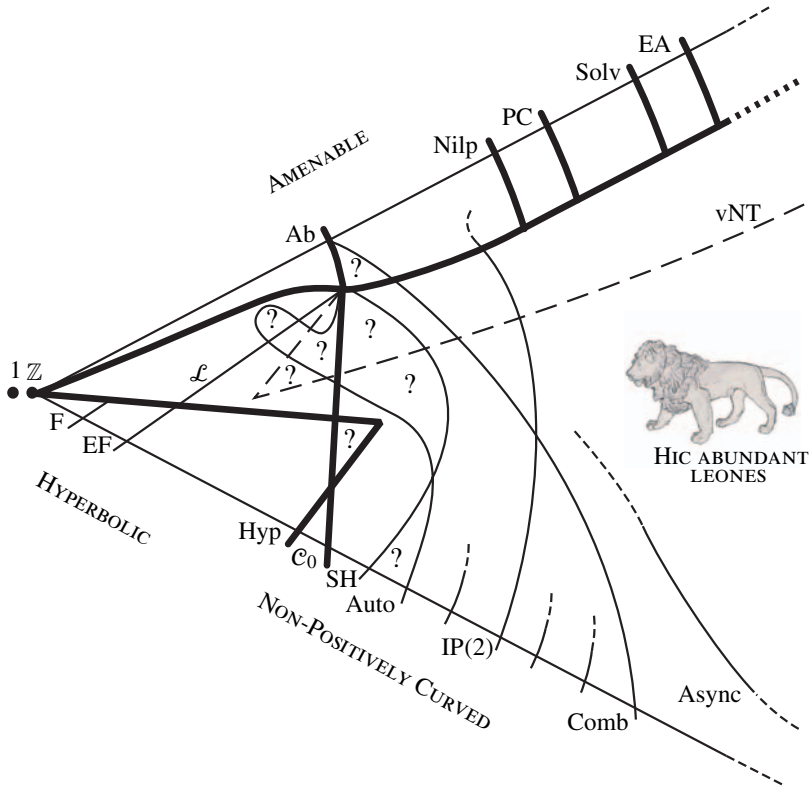

Figure 1. The universe of finitely presented groups.

When approaching group theory from the viewpoint of large-scale geometry, it is natural to blur the distinction between commensurable groups. Thus our universe begins with a single (large and interesting) point labelled 1 representing the finite groups. The simplest infinite group is surely $\mathbb{Z}$, so we have a second point representing the virtually cyclic groups. Here the universe divides. If one wants to retain the safety of commutativity and amenability, one can proceed from $\mathbb{Z}$ to the virtually abelian groups. As one slowly relinquishes commutativity and control over growth and constructibility, one passes through the progressively larger classes of (virtually-) nilpotent, polycyclic, solvable and elementary amenable groups, which are marked in the region bounded by a thick line enclosing the amenable groups.

Thinking more freely, instead of taking direct products one might proceed from $\mathbb{Z}$ by taking free products, moving into the class F of virtually free[2] groups, with their tree-like Cayley graphs. As one proceeds away from F, the infinite curvature of tree-

[2]F contains only one commensurability class besides $\mathbb{Z}$, but is drawn larger for effect.

ness gives way to the strictly negative curvature of hyperbolic groups Hyp, then the increasingly weak forms of non-positive curvature that define the classes discussed in the sections that follow: $\mathcal{C}_0$, the groups that act properly and cocompactly by isometries on CAT(0) spaces; SH, the semihyperbolic groups of [2]; the automatic groups Auto of [55]; and the combable and asynchronously combable groups Comb and Async. The line marked IP(2) encloses the groups that satisfy a quadratic isoperimetric inequality (4.3). The thickness of the line delimiting $\mathcal{C}_0$ expresses the view that these groups deserve particular attention.

The *von Neumann–Tits line* (vNT) separates the groups that contain non-abelian free groups from those that do not. For each group below the line, one asks whether its finitely generated subgroups satisfy a *Tits alternative*: if non-amenable, they should contain a non-abelian free group. One also asks what type of amenable subgroups can arise, cf. (2.3).

In contrast to the other amenable groups, virtually abelian groups are indisputably "non-positively curved". Several classes of non-positively curved groups serve as natural envelopes uniting free and free-abelian groups. These include the right-angled Artin groups, cocompact groups of isometries of CAT(0) cube complexes, and limit groups (marked $\mathcal{L}$). The case for placing the class EF $\subset \mathcal{L}$ of *elementarily free groups* immediately next to F is discussed in (1.2). The fundamental group Σ_g of any closed surface of genus $g \geq 2$ is in EF, lending substance to the tradition in combinatorial group theory that, among non-free groups, it is the Σ_g that resemble free groups most closely (cf. 1.8).

1.1. Accuracy and completeness. Adapting to today's foci, and so as not to crowd the diagram, I have omitted many natural classes of groups, even non-positively curved groups. In particular, I have not subdivided $\mathcal{C}_0$ according to subclasses of CAT(0) spaces such as CAT(-1) spaces, spaces with isolated flats, or the classes mentioned above in connection with $\mathbb{Z}^n$; these all enjoy important additional properties and have a rich hoard of examples.

The hints at subdivision in Comb are intended to suggest the various subclasses defined by varying the degree of control one demands over the geometry and linguistic complexity of the combing, cf. (3.2). A question mark in a region of intersection indicates that it is unknown if that region is empty. The question mark at the amenable end of Comb asks, more generally, which amenable groups are combable. Likewise, the vague manner in which the boundary of IP(2) ends reflects a lack of knowledge about which amenable groups have quadratic Dehn functions (4.3). The extent of Async is also unknown, though we know it contains many solvable groups and the fundamental groups of compact 3-manifolds (3.5).

1.2. Limits and ultralimits. From a geometric perspective (as well as others) the virtually nilpotent groups have an indisputable claim to the ground next to abelian groups: they are exactly the groups of polynomial growth, as Gromov proved in the landmark paper [63]. A key idea in that paper is to construct a space on which a

group Γ of polynomial growth acts by taking the limit in the Gromov–Hausdorff topology of a subsequence of the pointed metric spaces $X_n = (\Gamma, \frac{1}{n}d)$, where d is a fixed word metric on Γ (the identity serves as a basepoint).

To circumvent the failure of the sequence $X_n = (\Gamma, \frac{1}{n}d)$ to converge in the non-nilpotent case, one fixes a non-principal ultrafilter and takes an *ultralimit* to obtain an *asymptotic cone* $\mathrm{Cone}_\omega\Gamma$. Such cones have been intensively studied in recent years, particularly in connection with quasi-isometric rigidity, e.g. [73]. Their geometry and algebraic topology encode a good deal of information about Γ (see [64], [83], [54]). If Γ is a non-abelian free group, then $\mathrm{Cone}_\omega\Gamma$ is an everywhere-branching $\mathbb{R}$-tree (regardless of the choice of ω). The class of finitely generated groups that share this property consists precisely of the non-elementary *hyperbolic groups*. This is just one of the ways in which hyperbolic groups appear as the most commanding generalisation of a free group.

1.3. Next to the free groups: limit groups. Continuing with the idea of taking limits, one might ask which finitely generated groups arise as Gromov–Hausdorff limits of free groups [47]. More precisely[3], given Γ, one asks if there exists a finite generating set S for Γ and a sequence of finite generating sets S_n for a fixed free group F with bijections $S_n \to S$ making the ball of radius $\rho \in \mathbb{N}$ about the identity in the Cayley graph $\mathcal{C}_{S_n}(F)$ isomorphic (as a marked graph) to that in $\mathcal{C}_S(\Gamma)$ whenever $n \geq N(\rho)$.

The groups that arise in this way are the *limit groups* $\mathcal{L}$, which are non-positively curved in every reasonable sense [1]. The fundamental importance of this class has been greatly illuminated in recent years by the work of Zlil Sela and others (see Subsection 5.3). A fascinating aspect of their study is that the same class of groups emerges from a range of different definitions that make precise the idea of an *approximately free group*. In terms of first order logic, $\mathcal{L}$ consists of those finitely generated groups that have the same existential theory as a free group [82], while $\mathrm{EF} \subset \mathcal{L}$ consists of those that have the same elementary theory.

1.4. Beware of the lions: encoding. Constructions such as the Higman Embedding Theorem [68] show that one can encode the workings of an arbitrary Turing machine into a finite group-presentation. The groups that one obtains from such constructions will typically not belong to any of our marked classes but rather will lie in the region where the fierce lion is shown defying the groups that submit to the control of our definitions. One should therefore regard the lion as a warning that it is reckless to base a conjecture about arbitrary finitely presented groups on evidence gained along the coasts of the universe.

1.5. Embracing the lions: subdirect products. It is not satisfactory to content oneself with the study of groups in our marked classes alone. In particular one wants to attack problems from elsewhere in mathematics by exploiting the ability

[3]The corresponding topology on marked groups is often called the Grigorchuk topology [60].

to encode arbitrary recursive phenomena into finite group-presentations. In order to do so without leaving the safety of the regions where one has definitions and theorems, one has to find a way of encoding arbitrary presentations into the structure of groups in the labelled classes (the closer to the origin 1 the better). Such encodings exist in remarkable generality, provided one is prepared to accept passing to finitely presented subgroups in the given class. This is the theme of Section 5 below, where I explain and exploit the fact that finitely presented subgroups of direct products of hyperbolic groups (but not limit groups) can be made extremely complicated. Section 6 shows how such an encoding can be used to solve problems of interest elsewhere in mathematics.

1.6. Special groups. One might begin an open-minded search for groups of special interest by asking what sort of actions are admitted by an arbitrary finitely presented group. As one tries to improve the quality of the space or action, obstructions emerge and special groups are singled out. For example, when one knows that every finitely presented group is the fundamental group of a closed symplectic 4-manifold and a closed complex manifold, it is natural to ask which groups are fundamental groups of compact Kähler manifolds, or of 3-manifolds, and to pay special attention to such groups, classifying them if possible. It is also stimulating to try to locate them in our map of the universe.

1.7. Classifying spaces. Other special classes emerge as one tries to improve on the construction of $K = K(\mathcal{A}, \mathcal{R})$ in the opening paragraph, making it more highly-connected and looking for a classifying space. *Higher finiteness properties* emerge and conditions that ensure the existence of a compact $K(\Gamma, 1)$ come into focus, such as the existence of a 1-relator or small-cancellation presentation. Complete non-positively curved spaces serve as classifying spaces but these are not always of the minimum possible dimension [25], [18]. This discrepancy fits into a large body of work in which different notions of dimension measure the cost of choosing between algebraic, topological and geometric models for a group.

Of the classes in figure 1, hyperbolic, polycyclic and $\mathcal{C}_0$ groups all act properly and cocompactly on contractible, finite-dimensional complexes but certain groups in Solv, IP(2) and Async do not. Members of the classes other than Solv, IP(2) and EA have classifying spaces with only finitely many cells in each dimension.

1.8. The first groups and their automorphisms. The view that $\mathbb{Z}^n$, F_n and Σ_g are the most basic of infinite groups begins a rich vein of ideas concerning the automorphisms of these groups. At the level of individual automorphisms, classical facts about integer matrices are paralleled by the *Nielsen–Thurston theory* of surface automorphisms and, for free groups, the *train-track technology* of Bestvina, Feighn and Handel [10], [11].

The analogies between the outer automorphism groups $\mathrm{GL}(n, \mathbb{Z})$, $\mathrm{Out}(F_n)$ and $\mathrm{Mod}_g \cong \mathrm{Out}(\Sigma_g)$ (the mapping class group) go far beyond the observation that

$\mathrm{GL}(2,\mathbb{Z}) \cong \mathrm{Out}(F_2) \cong \mathrm{Mod}_1$. Indeed much of the work on mapping class groups and automorphisms of free groups is premised on such analogies [9], [91], [44]. Karen Vogtmann has been particularly influential in promoting this idea.

2. CAT(0) spaces and their isometries

The theory of CAT(0) spaces has had a huge impact in recent years, not only in geometric group theory but also in the study of low-dimensional manifolds and rigidity phenomena in geometry. (This influence, which owes much to the work of Gromov, is easy to discern in the proceedings of recent ICMs including this one.) My purpose here is not to survey this field but rather to highlight some features of the basic theory with an eye on their quasi-fication in the next section. My book with André Haefliger [35] provides a thorough introduction to the subject.

2.1. CAT(0) spaces. Following A.D. Alexandrov, one defines non-positive curvature in the context of length spaces X by means of the *CAT*(0) *inequality*, which requires that small triangles in X be no fatter than their comparison triangles in the Euclidean plane. Thus one compares triangles $\Delta = \Delta(x_1, x_2, x_3)$ consisting of three points $x_1, x_2, x_3 \in X$ and three geodesic segments $[x_i, x_j]$ to triangles $\overline{\Delta}(\bar{x}_1, \bar{x}_2, \bar{x}_3) \subset \mathbb{E}^2$ with $d(\bar{x}_i, \bar{x}_j) = d(x_i, x_j)$. A point $\bar{p}$ on the line segment $[\bar{x}_i, \bar{x}_j]$ is called a *comparison point* for $p \in [x_i, x_j]$ if $d(x_i, p) = d(\bar{x}_i, \bar{p})$.

A geodesic space is said to be a CAT(0) *space* if for all triangles Δ in that space, $d(p, q) \leq d(\bar{p}, \bar{q})$ for all comparison points $\bar{p}, \bar{q} \in \overline{\Delta}$. And a metric space X is defined to be *non-positively curved* if every point of X has a neighbourhood that, when equipped with the induced metric, is a CAT(0) space. Similarly, one defines the notion of a CAT(-1) space by taking comparison triangles in the hyperbolic plane, and one defines a space to be negatively curved (in the sense of A. D. Alexandrov) if it is locally CAT(-1).

Because the CAT(0) condition encapsulates the essence of non-positive curvature so well, non-positively curved metric spaces satisfy many of the elegant features inherent in the theory of Riemannian manifolds of non-positive sectional curvature. At the heart of the theory lie local-to-global phenomena that spring from the fact that the metric on a CAT(0) space X is convex: if $c_1, c_2 \colon [0, 1] \to X$ are geodesics, then for all $t \in [0, 1]$

$$d(c_1(t),\, c_2(t)) \leq (1-t)\, d(c_1(0),\, c_2(0)) + t d(c_1(1),\, c_2(1)). \tag{2.1}$$

This inequality implies that there is a unique geodesic segment joining each pair of points in X and that X is contractible. The most important example of a local-to-global phenomenon is the Cartan–Hadamard Theorem: *If a complete, simply-connected metric space is non-positively curved, then it is* CAT(0) *space.* (See Chapter II.4 of [35] for a more general result and references.)

It follows from this theorem that compact non-positively curved spaces have contractible universal covers and hence provide classifying spaces. The usefulness of this observation is greatly enhanced by two facts. First, Gromov's *link condition* ([35], p. 206) enables one to reduce the question of whether a polyhedral complex supports a metric of non-positive curvature to a question about the geometry of links in that complex; this allows arguments that proceed by induction on the dimension of the complex, and if the cells are sufficiently regular (e.g. cubes) it can lead to purely combinatorial criteria for the existence of metrics of non-positive curvature. Secondly, gluing theorems ([35], II.11) allow one to preserve non-positive curvature while combining spaces according to group-theoretic constructions that one wishes to perform at the level of π_1, such as amalgamated free products $\Gamma_1 *_{\mathbb{Z}} \Gamma_2$.

2.2. Splitting theorems. A rich vein of ideas begins with Alexandrov's observation that, when considering a triangle Δ in a complete CAT(0) space X, if one gets any non-trivial equality in the CAT(0) inequality, then Δ spans an isometrically embedded triangular Euclidean disc in X. This observation leads one quickly to the fact that any pair of geodesic lines $\mathbb{R} \to X$ a bounded distance apart must bound a flat strip in X, and thence to a Product Decomposition Theorem:

Let $c\colon \mathbb{R} \to X$ be a geodesic line and let P be the set of geodesic lines c' contained in a bounded neighborhood of $c(\mathbb{R})$. Let $c'_0 \in c'(\mathbb{R})$ be the unique point closest to $c(0)$ and let $X^0_c = \{c'_0 \mid c' \in P\}$. Then $\bigcup\{c'(\mathbb{R}) \mid c' \in P\}$ is isometric to $X^0_c \times \mathbb{R}$.

This places severe restrictions on the way groups can act on CAT(0) spaces.

Proposition 2.1. *If Γ acts properly and cocompactly by isometries on a* CAT(0) *space and $\gamma \in \Gamma$ has infinite order, then the centralizer $C_\Gamma(\gamma)$ has a subgroup of finite index that splits as a direct product $C_0 = N \times \langle\gamma\rangle$.*

To prove this, one considers the union $\mathrm{Min}(\gamma)$ of the geodesic lines in X that are left invariant by γ. The Product Decomposition Theorem gives a splitting $\mathrm{Min}(\gamma) = \mathrm{Y}_0 \times \mathbb{R}$. The centralizer $C_\Gamma(\gamma)$ preserves $\mathrm{Min}(\gamma)$ and its splitting, acting by translations on the second factor. $C_\Gamma(\gamma)$ is finitely generated (3.3), so the image of $C_\Gamma(\gamma) \to \mathrm{Isom}(\mathbb{R})$ is isomorphic to $\mathbb{Z}^r$ for some r. Projecting onto a direct factor of $\mathbb{Z}^r$ gives an epimorphism ϕ from a subgroup of finite index $C_0 \subset C_\Gamma(\gamma)$ to $\langle\gamma\rangle$. Hence $C_0 = \ker\phi \times \langle\gamma\rangle$. A similar argument proves:

If a finitely generated group Γ acts by isometries on a CAT(0) *space* (*the action need not be proper*) *and a central subgroup $A \cong \mathbb{Z}^n$ acts freely by hyperbolic isometries, then Γ has a subgroup of finite index that contains A as a direct factor.*

These results give us our first glimpse of the fact that centralizers play an important role in non-positively groups. Many groups that lie in SH and Auto are seen not to lie in $\mathcal{C}_0$ because their centralizers do not virtually split; examples include mapping class groups [77] and central extensions of hyperbolic groups [79]. Such central extensions are defined by bounded cocycles and hence are quasi-isometric to the corresponding direct products. It follows that $\mathcal{C}_0$ is not closed under quasi-isometry.

More elaborate arguments akin to the one sketched above allow one to generalize splitting theorems proved in the Riemannian setting by D. Gromoll and J. Wolf [61] and B. Lawson and S. Yau [74] (see [35], pp. 239-253).

Theorem 2.2. *If a group $\Gamma = \Gamma_1 \times \Gamma_2$ with trivial centre acts properly and cocompactly by isometries on a* CAT(0) *space in which geodesics can be extended locally, then Γ_1 and Γ_2 also admit such actions.*

Theorem 2.3. *If Γ acts properly and cocompactly by isometries on a* CAT(0) *space X, then every solvable subgroup $S \subset \Gamma$ is finitely generated and virtually abelian. Moreover, S leaves invariant an isometrically embedded copy of Euclidean space $\mathbb{E}^n \hookrightarrow X$ on which is acts cocompactly.*

A refinement of the last part of this theorem can be used to identify constraints on the *length functions* $\gamma \mapsto \min_x d(x, \gamma.x)$ associated to semisimple actions on CAT(0) spaces. Such constraints serve as obstructions to the existence of actions both absolutely and in certain dimensions [18], [25], [57].

2.3. Subgroups in $\mathcal{C}_0$. As one pursues an understanding of the groups that act properly and cocompactly by isometries on CAT(0) spaces one finds increasingly subtle obstructions to the existence of metrics of non-positive curvature on aspherical spaces. In order to get at the heart of this subtlety one wants to bypass the obstructions to semisimple actions. One way of doing this is to focus on the finitely presented subgroups of fundamental groups of compact non-positively curved spaces. It transpires that such subgroups form a much more diverse class than the fundamental groups themselves – see [35], III.Γ.5, [29] and Section 5.

In very low dimensions, finitely presented subgroups are well-behaved [29]. *If Γ is the fundamental group of a compact non-positively curved manifold of dimension ≤ 3 (allowing boundary) then so too is each of its finitely generated subgroups.*

A similar result holds for complexes of dimension ≤ 2, except that one has to impose the hypothesis that the subgroups are finitely presented. In higher dimensions all manner of additional obstructions emerge: higher finiteness conditions, the complexity of decision problems, the structure of centralizers, *etc.* The subtlety of the situation is illustrated by the following construction [29].

Theorem 2.4. *There exist pairs of closed aspherical manifolds $N^n \hookrightarrow M^{n+1}$ with the following properties: M supports a metric of non-positive sectional curvature; $\pi_1 N \hookrightarrow \pi_1 M$ is a quasi-isometric embedding; the centralizers of all finite subsets in $\pi_1 N$ are fundamental groups of closed aspherical manifolds and have solvable word and conjugacy problems; but $\pi_1 N$ is not semihyperbolic, and hence N does not support a metric of non-positive curvature.*

One sees that $\pi_1 N$ is not semihyperbolic by examining the complexity of the word problem in centralizers: although $\pi_1 N$ satisfies a polynomial isoperimetric inequality, the centralizers of certain elements do not.

2.4. Complexes of group. An important instance of the local-to-global effect of non-positive curvature is the *Developability Theorem* for non-positively curved complexes of groups. This was inspired by Gromov and proved by Haefliger, who placed it in the more general setting of groupoids of local isometries [35], p. 584.

Complexes of groups were introduced by Haefliger to describe groups actions on 1-connected polyhedral complexes in terms of suitable local data on the quotient. If a complex of groups arises from such an action then it is said to be *developable*. In contrast to the 1-dimensional situation (graphs of groups), complexes of groups are not developable in general. But, crucially, they are if they satisfy a (local) *non-positive curvature condition* [35]. A full account of the theory is given in the final chapters of our book [35]. In recent years, this theory has played an important role in the construction of group actions.

3. Non-positively curved groups

In this section I'll describe the manifestations of non-positive curvature in group theory that arise from the following strategy. One starts by identifying a *robust feature* of CAT(0) spaces that encapsulates much of their large-scale geometry. Then, given a group Γ with generators $\mathcal{A}$ acting properly and cocompactly by isometries on a CAT(0) space X with basepoint p, one tries to articulate what remains of this feature when it is pulled-back to the Cayley graph $\mathcal{C}_{\mathcal{A}}(\Gamma)$ via the Γ-equivariant quasi-isometry sending the edge $[1, a]$ ($a \in \mathcal{A}$) to the geodesic $[p, a.p]$. One wants to define a group to be non-positively curved if it satisfies the resulting condition. The condition should be strong enough to facilitate a range of theorems analogous to what one knows about the prototypical groups of isometries, but one wants to avoid unnecessary hypotheses.

3.1. Hyperbolic groups. Let me recall how such a strategy is implemented in the hyperbolic case. The prototypical hyperbolic group is a group Γ that acts properly and cocompactly by isometries on a CAT(-1) space X. By comparing geodesic triangles $\Delta = \Delta(x, y, z)$ in X to triangles $\overline{\Delta} \subset \mathbb{H}^2$, one sees that there is a universal constant δ such that the distance from any point $q \in [x, y]$ to $[x, z] \cup [z, y]$ is at most δ. Moreover, quasigeodesics in CAT(-1) spaces stay uniformly close to geodesics, so (λ, ε)-quasigeodesic triangles in X are uniformly thin in the same sense (with a different δ). The quasi-isometry $\mathcal{C}_{\mathcal{A}}(\Gamma) \to X$ sends geodesic triangles in $\mathcal{C}_{\mathcal{A}}(\Gamma)$ to (λ, ε)-quasigeodesic triangles in X, where λ and ε depend on $\mathcal{A}$ and p. Therefore geodesic triangles in $\mathcal{C}_{\mathcal{A}}(\Gamma)$ are also uniformly thin. One takes this to be the defining property of a hyperbolic group.

Gromov's great insight is that because the thin triangles condition (which has many reformulations [35], p. 407) encapsulates so much of the essence of the large-scale geometry of CAT(-1) spaces, the groups whose Cayley graphs satisfy this condition share almost all of the properties enjoyed by the groups of isometries that were their prototypes. For example, every hyperbolic group Γ acts properly and cocompactly

on a contractible cell complex, has only finitely many conjugacy classes of finite subgroups, and contains no copy of $\mathbb{Z}^2$. Hyperbolic groups also enjoy a great deal of algorithmic structure. They are precisely the groups with linear Dehn functions. Their conjugacy problems can be solved in less than quadratic time, and conjugacy for finite subsets can also be determined efficiently [36]. Strikingly, the *translation lengths* $\tau(\gamma) = \lim d(1, \gamma^n)/n$ of elements of infinite order are rational numbers with bounded denominators [65], [51]. And given a finite generating set $\mathcal{A}$, the set of geodesic words for Γ is a *regular language*, i.e. there is a finite state automaton that recognises which words label geodesics in $\mathcal{C}_{\mathcal{A}}(\Gamma)$.

3.2. The pantheon of non-positively curved groups. The behaviour of geodesics described in (2.1) explains much of the global geometry of CAT(0) spaces, so we apply our strategy to this condition. For the prototype of Γ acting on X, the geodesics $[p, \gamma.p]$ pull-back to quasi-geodesics σ_γ connecting 1 to γ in $\mathcal{C}_{\mathcal{A}}(\Gamma)$. There is no loss of generality in assuming that σ_γ is an edge-path. By identifying σ_γ with the word in the generators $\mathcal{A}^{\pm 1}$ that labels it, we get a map $\sigma : \gamma \mapsto \sigma_\gamma$ to the free monoid $(\mathcal{A} \cup \mathcal{A}^{-1})^*$, where the image $\sigma(\Gamma)$ can be studied as a *formal language*. Following Bill Thurston [55], one calls σ a *combing*.

The convexity of the metric on X (2.1) implies that there exists a constant $k > 0$ such that for all $\gamma, \gamma' \in \Gamma$,

$$d(\sigma_\gamma(t),\ \sigma_{\gamma'}(t)) \leq k\, d(\gamma, \gamma') \tag{3.1}$$

for all $t \leq \max\{|\sigma_\gamma|,\ |\sigma_{\gamma'}|\}$. This is called the *fellow-traveller property*. A group that admits a combing (normal form) with this property is said to be *combable*.

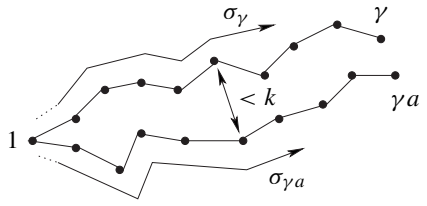

Figure 2. The fellow-traveller property.

All hyperbolic groups Γ are combable: one can take σ_γ to be any geodesic from 1 to γ but it is better to be systematic, choosing the first word in the dictionary-ordering obtained by ordering the generating set. If one adopts this systematic choice, then $\sigma(\Gamma)$ will be a *regular language*. With this in mind, ought one to include regularity as part of the definition of a non-positively curved group?

Requiring $\sigma(\Gamma)$ to be regular leads to the theory of *automatic groups*, which sprang from conversations between Bill Thurston and Jim Cannon on the algorithmic properties of Kleinian groups [46] and grew into a rich theory with large classes of

natural examples. It is described in detail in the book by Epstein *et al.* [55]. Automatic groups lend themselves well to practical computation.

If $\sigma(\Gamma)$ is a regular language, it follows from the fellow-traveller property that the paths σ_γ are quasi-geodesics with uniform constants. But in the absence of regularity it is unclear if one eliminates groups by imposing conditions on the length of σ_γ. This question is related to the complexity of the word problem for combable groups: a diagrammatic argument [21] shows that if one has a function $L\colon \mathbb{N} \to \mathbb{N}$ bounding the length of combing lines, $|\sigma_\gamma| \leq L(d(1,\gamma))$, then the Dehn function of Γ satisfies $\delta_\Gamma(n) \preccurlyeq n\,L(n)$; in particular, if the combing lines are quasi-geodesics then the group satisfies a quadratic isoperimetric inequality.

Another dilemma arises from the observation that although the convexity of $t \mapsto d(c_1(t), c_2(t))$ in the CAT(0) setting follows easily from the special case $c_1(0) = c_2(0)$, the analogous statement for groups is false. Thus it is unclear whether every group Γ that admits a combing with the fellow-traveller property must admit a combing σ with the stronger property

$$d(a.\sigma_{a^{-1}\gamma a'}(t),\ \sigma_\gamma(t)) \leq k \tag{3.2}$$

for all $a, a' \in \mathcal{A}$ and $\gamma \in \Gamma$. Groups that admit such combings are said to be *bicombable* [90]. If, in addition, the combing lines are quasi-geodesics (with uniform constants) then, following Alonso–Bridson [2], one says the group is *semihyperbolic*; this is the smallest of the classes we are discussing that includes $\mathcal{C}_0$.

This completes my brief sketch of how the classes Comb, Auto and SH marked in figure 1 present themselves for study. But are these classes distinct? Geometric group theory in the 1990s was marred by the absence of examples to distinguish between them but this situation was now been resolved [26].

Theorem 3.1. *There exist combable groups that are neither bicombable nor automatic.*

Once one knows that combable groups need not be automatic, it is natural to ask what classes or groups are incorporated if one places weaker constraints on the linguistic complexity of the formal language $\sigma(\Gamma) \subseteq (\mathcal{A} \cup \mathcal{A}^{-1})^*$. Among full abstract families of languages the regular, context-free and indexed languages form a hierarchy Reg $\subset$ CF $\subset$ Ind. If $\sigma(\Gamma)$ lies in a family $\mathcal{F}$, one calls σ an $\mathcal{F}$-combing.

Theorem 3.2 ([26]). *There exist* Ind*-combable groups that are not automatic; some of these have quadratic Dehn functions, others have cubic ones.*

A fascinating aspect of the struggle to understand different manifestations of non-positive curvature concerns the *free-by-cyclic groups* $F_n \rtimes \mathbb{Z}$. One feels these groups ought to conform to the expectations of non-positive curvature, yet they remain enigmatic. Since free-group automorphisms are more complicated than surface automorphisms, free-by-cyclic groups are more complicated than the fundamental groups $\Sigma_g \times \mathbb{Z}$ of 3-manifolds that fibre over the circle. We know that $F_n \rtimes_\phi \mathbb{Z}$ need not be

automatic [17] but we do not know for which ϕ it is; nor when it lies in $\mathcal{C}_0$. Daniel Groves and I used the train-track technology of [10], [11] to prove that all $F_n \rtimes \mathbb{Z}$ lie in IP(2), but this is highly non-trivial.

3.3. Subgroups. We saw in (2.2) that centralizers of groups in SH do not virtually split as they do in $\mathcal{C}_0$. However, SH is closed under passage to centralizers of finite subsets. Theorem 2.2 extends to SH. As for Theorem 2.3, one can prove that any polycyclic subgroup P of $\Gamma \in \mathrm{SH}$ must be virtually abelian and that $P \hookrightarrow \Gamma$ must be a quasi-isometric embedding, but it is unknown if abelian subgroups must be finitely generated. The positive part of this statement ultimately derives from the fact that translation numbers $\tau(\gamma) = \lim d(1, \gamma^n)/n$ are positive for elements of infinite order, while the negative part derives from the fact that, unlike in Hyp and $\mathcal{C}_0$, one does not know if the set of these numbers is discrete. These results are proved in [2] and [90] using ideas from [59].

In combable groups, the control over centralizers is lost [26].

3.4. The conjugacy and isomorphism problems. If two rectifiable loops c_0, c_1 in a compact, non-positively curved space X are freely homotopic, they are homotopic through loops c_t of length $l(c_t) \leq \max\{l(c_0),\ l(c_1)\}$. Accordingly, there is a constant $k > 0$ so that any conjugacy between words u_0, u_1 in the generators of $\pi_1 X$ can be realized by a sequence of moves $u_t \mapsto a_t u_t a_t^{-1}$ where a_t is a generator and $d(1,\ u_t) \leq K \max\{|u_0|,\ |u_1|\}$; see [35], p. 445. This control carries over to SH and bicombable groups, where it yields a solution to the conjugacy problem. But control is lost as one weakens the link to CAT(0) spaces [27].

Theorem 3.3. *The conjugacy problem is unsolvable in certain combable groups.*

Zlil Sela [88] solved the isomorphism problem for torsion-free hyperbolic groups. His solution was recently extended to a large class of relatively hyperbolic groups by F. Dahmani and D. Groves [48]. When combined with the topological rigidity theorem of T. Farrell and L. Jones [56], Sela's result implies that the homeomorphism problem is solvable among closed n-manifolds, $n \geq 5$, that admit a metric of negative curvature. The results of Farrell and Jones remain valid for non-positively curved manifolds and there is therefore considerable interest in the isomorphism problem in SH, $\mathcal{C}_0$ and the subclass consisting of the fundamental groups of such manifolds. These problems remain open, but beyond SH decidability is lost:

Theorem 3.4 ([27]). *The isomorphism problem is unsolvable among combable groups.*

To prove this one seeks a recursive sequence $\langle A \mid R_n \rangle$ of presentations of combable groups such that there is no algorithm that decides which are isomorphic. Starting with a hyperbolic group H in which there is no algorithm to decide when maps $\phi_n \colon F_r \to H$ are epic, one extends ϕ_n to a homomorphism $\hat{\phi}_n \colon F_{2r} \to H$ and defines $\langle A \mid R_n \rangle$ to be a certain presentation of $\Gamma *_{\Sigma(n)} \Gamma$, where $\Gamma = (\mathbb{Z}_2 * H) \times F_{2r}$ and $\Sigma(n) = \{(\hat{\phi}_n(x), x) \mid x \in F_{2r}\}$ is quasi-isometrically embedded.

3.5. Asynchronous combings and 3-manifolds. As one moves further from the CAT(0) setting and weakens the convexity condition on the metric, combings arise that only satisfy a weakened form of the fellow-traveller property (3.1): the paths σ_γ remain close only after *monotone reparameterization*.

Little of the strength of non-positive curvature remains in this definition but it does embrace a much larger class of groups, e.g. [22], [55]. Moreover, the amount of convexity retained is enough to provide a reasonable solution to the word problem and to ensure that these groups have classifying spaces with only finitely many cells in each dimension. Epstein *et al.* examined what happens when one requires $\sigma(\Gamma)$ to be regular. Bob Gilman [32] and I explored larger families of languages.

Epstein and Thurston [55] proved that the fundamental group of a compact 3-manifold M is automatic if and only if it satisfies a quadratic isoperimetric inequality (which excludes connected summands that are torus bundles over the circle with infinite holonomy). Gilman and I, building on [22], sharpened the negative part of their theorem and proved that by using indexed languages one can construct combings that encode the coarse geometry of any cocompact 3-manifold. (This result relies on the fact that 3-manifolds are geometrizable.)

Theorem 3.5. *The fundamental group of every compact* 3*-manifold M is asynchronously* Ind*-combable, but in some cases $\pi_1 M$ is not asynchronously* CF*-combable.*

4. Word problems and filling invariants

4.1. Dehn functions. The word problem for finitely presented groups has been at the heart of combinatorial group theory since its inception. When one attacks the word problem for a finitely presented group $\Gamma = \langle \mathcal{A} \mid \mathcal{R} \rangle$ directly, one's chances of success depend heavily on the *Dehn function* $\delta_\Gamma \colon \mathbb{N} \to \mathbb{N}$. Given a word w in the kernel of the map from the free group $F(\mathcal{A})$ to Γ, one defines

$$\mathrm{Area}(w) := \min\left\{N \mid w \overset{\text{free}}{=} \prod_{i=1}^{N} x_i^{-1} r_i x_i \text{ some } x_i \in F(\mathcal{A}),\ r_i \in \mathcal{R}^{\pm 1}\right\} \qquad (4.1)$$

and

$$\delta_\Gamma(n) := \max\{\mathrm{Area}(w) \mid w =_\Gamma 1,\ |w| \le n\}.$$

The subscript on δ_Γ is somewhat misleading since different finite presentations of the same group will in general yield different Dehn functions. This ambiguity is tolerated because it is tightly controlled: if the groups defined by two finite presentations are isomorphic, or just quasi-isometric, the corresponding Dehn functions are $\simeq$ equivalent in the following sense: *given two monotone functions $f, g \colon [0,\infty) \to [0,\infty)$, one writes $f \preccurlyeq g$ if there exists a constant $C > 0$ such that $f(l) \le C\, g(Cl + C) + Cl + C$ for all $l \ge 0$, and $f \simeq g$ if $f \preccurlyeq g$ and $g \preccurlyeq f$; and one extends this relations to include functions $\mathbb{N} \to [0,\infty)$.*

If $\delta_\Gamma(n) \preccurlyeq n^d$, one says that Γ satisfies a *polynomial isoperimetric inequality* of degree d. See [30] for references and basic facts about Dehn functions.

The first step from word problems to filling problems is provided by *van Kampen's Lemma* [70], which states that $\mathrm{Area}(w)$ is equal to the least number of 2-cells in any *van Kampen diagram* for w. Such a diagram describes a combinatorial *filling* (i.e. null-homotopy) for the loop labelled w in the 1-skeleton of the 2-complex $K = K(\mathcal{A}, \mathcal{R})$ described in the first paragraph of the introduction.

Suppose $\Gamma = \langle \mathcal{A} \mid \mathcal{R} \rangle$ acts properly and cocompactly by isometries on a Riemannian manifold X. Fix $p \in X$. If X is simply connected, the quasi-isometry $\gamma \mapsto \gamma.p$ extends to a Γ-equivariant map $\phi\colon \widetilde{K} \to X$. An edge-loop σ in $\mathcal{C}_{\mathcal{A}}(\Gamma) = \widetilde{K}^{(1)}$ defines a piecewise-geodesic loop $\phi \circ \sigma$ in X, and a van Kampen diagram that describes a filling of σ defines a singular disc in X with boundary $\phi \circ \sigma$. Conversely, any rectifiable loop c in X can be approximated by a word-like loop $\phi \circ \sigma$ whose length is linearly bounded by that of c and (more delicately) disc-fillings $g\colon \mathbb{D}^2 \to X$ with $g|_{\partial D} = c$ give rise to van Kampen diagrams for σ.

This line of thought, initiated by Gromov, suggests that the large-scale behaviour of Riemannian filling-discs – quantified by features such as area, radius, diameter *etc.* – should be translated to the setting of van Kampen diagrams. Then, in the spirit of van Kampen's Lemma, these features can be used to measure the complexity of the word problem in Γ. The following implementation of this strategy was described by Gromov and presented in detail in [30] (also [45]).

Let M be a compact Riemannian manifold with universal cover $\widetilde{M}$. Define the filling area $\mathrm{FArea}(c)$ of a rectifiable loop $c\colon S^1 \to \widetilde{M}$ to be the infimum of the areas of all Lipschitz maps $g\colon \mathbb{D} \to X$ where $\mathbb{D}$ is the standard 2-disc and $g|_{\partial D}$ is a monotone reparameterization of c. Consider

$$\mathrm{Fill}_M(l) := \sup\{\, \mathrm{FArea}(c) \mid c\colon S^1 \to \widetilde{M},\ \mathrm{length}(c) \leq l\},$$

the *genus zero, 2-dimensional, isoperimetric function* of M.

Theorem 4.1 (Filling Theorem). $\mathrm{Fill}_M(l) \simeq \delta_{\pi_1 M}(l)$.

A similar statement holds for isoperimetric functions of more general compact spaces with upper curvature bounds. Similar theorems also hold with *area* replaced by other invariants of the geometry of filling-discs. Among these, the most actively studied is intrinsic diameter (i.e. diameter measured in the induced length metric on the disc); in this case, FArea and the Dehn function are replaced by (intrinsic) *isodiametric functions*. When translated into algebra, bounds on intrinsic diameter correspond to bounds on the length of the conjugating words x_i in (4.1).

Results giving lower bounds on intrinsic diameter often proceed via extrinsic diameter, i.e. diameter measured in the metric on the ambient space. It was only recently that Tim Riley and I constructed the first compact manifolds for which the isodiametric functions corresponding to the choice intrinsic-versus-extrinsic have distinct asymptotic behaviour [43]. This extends a considerable body of work relating different aspects of the geometry of filling discs [64], [84].

4.2. The isoperimetric spectrum. A major theme in geometric group theory in the 1990s and into this century has been the struggle to determine which $\simeq$ classes of functions arise as Dehn functions. (I shall say little about the complementary challenge of calculating the Dehn functions of groups of special interest.)

The development of our knowledge can be charted by how the set

$$\mathrm{IP} = \{\rho \in [1,\infty) \mid f(n) = n^\rho \text{ is } \simeq \text{a Dehn function}\}$$

came to be understood. This set is called the *isoperimetric spectrum*. I should emphasize that it is far from the case that all Dehn functions are of the form n^α: there are non-polynomial Dehn functions such as $n^\alpha \log n$, as well as examples of small presentations with huge Dehn functions, e.g. faster than any iterated exponential (see 4.4). If Γ has unsolvable word problem, $\delta_\Gamma(n)$ will grow faster than any recursive function (indeed this serves as a definition of such groups).

The class of groups with linear Dehn functions coincides with the class of hyperbolic groups. The non-hyperbolic groups in $\mathcal{C}_0$ and Auto have quadratic Dehn functions. Certain combable groups have cubic Dehn functions (3.2), as does the 3-dimensional Heisenberg group. In about 1992, sequences of groups $(\Gamma_d)_{d\in\mathbb{N}}$ such that the Dehn function of Γ_d is polynomial of degree d were discovered by Gromov [64], Baumslag–Miller–Short [7], and Bridson–Pittet [42]. The literature now contains such sequences with all manner of additional properties. An example of a group whose Dehn function is polynomial of degree $d+1$ is $\mathbb{Z}^d \rtimes_\phi \mathbb{Z}$, where $\phi \in \mathrm{GL}(d,\mathbb{Z})$ has 1's on the diagonal and superdiagonal and zeroes elsewhere.

A result of Gromov [65], reproved by many people, states that if the Dehn function of a group is sub-quadratic (i.e. $\delta_\Gamma(n) = o(n^2)$) then $\delta_\Gamma(n) \simeq n$. Thus $\mathrm{IP} \cap (1,2)$ is empty. This begs the question of what other gaps there may be in IP, and whether there are any non-integral exponents at all. I settled this last question by constructing the *abc groups* of [20], formed by taking three torus bundles over the circle (different dimensions) and amalgamating their fundamental groups along central cyclic subgroups. Indiscrete families of exponents were first constructed in [86]. Noel Brady and I [15] completed the understanding of the coarse structure of IP by constructing a dense set of exponents in $[2,\infty)$.

Theorem 4.2. *The closure of* IP *is* $\{1\} \cup [2,\infty)$.

We proved this by associating to each pair of positive integers $p \geq q$ an aspherical 2-complex whose fundamental group

$$G_{p,q} \;=\; \langle a,b,s,t \mid [a,b]=1,\ sa^q s^{-1} = a^p b,\ ta^q t^{-1} = a^p b^{-1}\rangle,$$

has Dehn function $\simeq n^{2\log_2(2p/q)}$. These complexes are obtained by attaching a pair of annuli to a torus in a manner that ensures the existence of a family of discs in the universal cover that display a certain *snowflake geometry*. With Max Forester and Ravi Shankar [16], we developed a more sophisticated version of the snowflake

construction that yields a much larger class of isoperimetric exponents, showing in particular that $[2, \infty) \cap \mathbb{Q} \subseteq \mathrm{IP}$.

Once one knows that IP is not a discrete set, one assumes that it will follow the general pattern of group theory by exhibiting all plausible levels of complexity. This expectation is realized in a remarkable piece of work by M. Sapir, J.-C. Birget and E. Rips [86] who give a comprehensive description of Dehn functions $\delta_\Gamma(n) \succcurlyeq n^4$ by encoding the time functions of Turing machines. (The fine structure of $\mathrm{IP} \cap (2, 4)$ has yet to be determined.) In a subsequent work with A. Yu. Ol'shanskii [19] the same authors prove that the word problem for Γ is in NP if and only if Γ is a subgroup of a finitely presented group with polynomial Dehn function.

4.3. Groups with quadratic Dehn functions. The structure of IP provides us with two classes of groups that demand special attention – the groups with linear Dehn functions (which we know to be the hyperbolic groups) and the groups with quadratic Dehn functions. It is far from clear what to expect from groups in this second class. They have simply-connected asymptotic cones [80] but so do many (not all [23]) other groups with polynomial Dehn functions. It is unknown if they all have a solvable conjugacy problem. IP(2) contains many nilpotent groups N that are not virtually abelian and certain non-nilpotent polycyclic groups [53]. It is unknown if it contains any solvable groups that are not virtually polycyclic. Thurston proposed that $\mathrm{SL}(n, \mathbb{Z})$, $n \geq 4$, should be in IP(2) but this has yet to be confirmed. V. Guba [67] proved that Richard Thompson's group (which is torsion-free, of type FP_∞, and infinite dimensional) lies in IP(2). Groves and I proved the same for groups of the form $F_n \rtimes \mathbb{Z}$ [33].

4.4. Applications to the geometry and topology of manifolds. The dictionary of equivalence illustrated by the Filling Theorem translates information about Dehn functions into statements about the geometry of manifolds. But there are also less obvious mechanisms that allow one to gain geometric and topological information from an understanding of the nature of Dehn functions.

The *Andrews–Curtis conjecture* is one of the famous open problems of low-dimensional topology. It is related to the Zeeman conjecture and the smooth 4-dimensional Poincaré conjecture [72]. It asserts that one can reduce any *balanced presentation* $\langle a_1, \ldots, a_n \mid r_1, \ldots, r_n \rangle$ of the trivial group to the presentation $\langle a_1, \ldots, a_n \mid a_1, \ldots, a_n \rangle$ by a sequence of certain elementary moves. The main construction of [31] associates a balanced presentation P_w to each word w in the generators of a group B satisfying a deletion condition. P_w presents the trivial group if and only if $w = 1$ in B. Moreover, if P_w presents $\{1\}$ then it satisfies the Andrews–Curtis conjecture *but* the number of elementary moves required to trivialise it is bounded below by $\log \mathrm{Area}^*_B(w)$.

One gets dramatic lower bounds by taking $B = \langle a, t \mid [tat^{-1},\ a] = a^{r-1} \rangle$, since $\delta_B(n) \simeq \Delta_r \lfloor \log_2 n \rfloor$ where $\Delta_r(m)$ is defined by $\Delta_r(1) := r$ and $\Delta_r(m+1) := r^{\Delta_r(m)}$. In this case P_w has 4 generators and relations of total length $2(10 + |w| + r)$.

In a remarkable series of papers, A. Nabutovsky and S. Weinberger [78] use Dehn functions to explore the sub-level sets of functionals such as diameter on moduli spaces of metrics for closed manifolds M^n, $n \geq 5$. The constructions in [31] allow one to extend parts of their work to dimension 4.

4.5. Higher-dimensional isoperimetric inequalities. In the Riemannian context, having considered the isoperimetric problem for discs filling loops, it is natural to explore fillings of higher-dimensional spheres. In particular one wants to understand the isoperimetric function that bounds the volume of optimal ball-fillings. Correspondingly, one defines the *k-th order Dehn function* $\delta^{(k)}$ of a finitely presented group Γ that has a classifying space X with a compact $(k+1)$-skeleton $X^{(k+1)}$. Such functions were introduced by Gromov [64]. Roughly speaking $\delta^{(k)}(l)$ bounds the number of $(k+1)$-cells required to fill any singular k-sphere in $X^{(k)}$ comprised of at most l k-cells. The algebraic foundations of the subject were worked out carefully by Alonso *et al.* [3] and interpreted more topologically in [24]. From an algebraic point of view, $\delta^{(k)}(l)$ provides the least upper bound on the number of summands required to express an element $[f] \in \pi_k(X^{(k)})$ as a Γ-linear combination of the attaching maps of the $(k+1)$-cells of X. The $\simeq$ equivalence class of $\delta^{(k)}$ is an invariant of quasi-isometry.

In each dimension k one has the *isoperimetric spectrum*

$$\mathrm{IP}^{(k)} = \{\alpha \in [1,\infty) \mid f(x) = x^\alpha \text{ is } \simeq \text{ a } k\text{-th order Dehn function}\}.$$

Until recently, our knowledge even for $\mathrm{IP}^{(2)}$ was remarkably sparse, but my recent work with Brady, Forester and Shankar [16] remedies this. *We prove that if P is an irreducible non-negative integer matrix with Perron–Frobenius eigenvalue $\lambda > 1$, and r is an integer greater than every row sum in P, then for every $k \geq 2$ there is a group $\Gamma = \Sigma^{k-1} G_{r,P}$ with a compact $(k+1)$-dimensional classifying space such that $\delta^{(k)}(x) \simeq x^{2\log_\lambda(r)}$.* It follows from this and a related result in [16] that $\mathrm{IP}^{(k)}$ is dense in the range $[1+1/k, \infty)$. Indeed the case of 1×1 matrices alone leads to:

Theorem 4.3. $\mathbb{Q} \cap [1+\frac{1}{k}, \infty) \subset \mathrm{IP}^{(k)}$.

The exponent $1+1/k$ arises for $\mathbb{Z}^{k+1}$. Comparing with $\mathrm{IP} = \mathrm{IP}^{(1)}$, it is tempting to speculate that $\overline{\mathrm{IP}}^{(k)} = \{1\} \cup [1+1/k, \infty)$ but there are reasons to doubt this. One suspects that the fine structure of $\mathrm{IP}^{(k)}$ is similar to that of $\mathrm{IP}^{(1)}$.

The group $G_{r,P}$ is the fundamental group of an aspherical 2-complex $X_{r,P}$ assembled from a finite collection of annuli and tori; the rational number r encodes the multiplicities of the attaching maps while the matrix P encodes a prescription for the number and orientation of the tubes connecting each pair of tori. Least-area discs in $\widetilde{X}_{r,P}$ exhibit a more subtle form of the *snowflake geometry* from [15]. When r is an integer, certain families of these discs admit a precise scaling by a factor of r. One stacks scaled copies of them to form embedded 3-balls in the universal covering of the mapping torus associated to a certain 2-letter HNN extension $\Sigma G_{r,P}$ of $G_{r,P}$. These balls provide a lower bound on $\delta^{(2)}$ of $\Sigma G_{r,P}$; this proves to be sharp. The balls inherit the scaling property, so one can iterate.

The calculation of $\delta^{(k)}$ for $\Sigma^{(k-1)}G_{r,P}$ involves an induction on dimension. In order to make this work smoothly, one must bound not only the isoperimetric behaviour of disc-fillings for spheres but also the isoperimetric behaviour of *other pairs of compact manifolds* $(M, \partial M)$ mapping to the complexes in question. The topological approach to $\delta^{(k)}$ taken in [24] is well-adapted to such generalizations.

The *homological filling invariants* of the groups $\Sigma^{(k-1)}G_{r,P}$ exhibit a similar range of behaviour. Such invariants provide upper bounds on the size of (cellular) $(k+1)$-chains needed to fill k-cycles in the universal covering of a classifying space with finite $(k+1)$-skeleton; size is measured using the ℓ_1-norm associated to the cellular basis. These invariants are easier to work with than their homotopical counterparts and relate well to the Riemannian setting – see [64] and [55], Chapter 10.

5. Subdirect products of hyperbolic groups

The results in this section highlight a dichotomy in the behaviour of the finitely presented subgroups of direct products of hyperbolic groups: in general the structure of such subgroups can be fiendishly complicated; but for free groups and limit groups, these subgroups are remarkably controlled.

5.1. Encoding wildness. E. Rips [85] found a simple algorithm that associates to a finite presentation $\mathcal{Q}$ a short exact sequence $1 \to N \to H \to Q \to 1$, where Q is the group that $\mathcal{Q}$ presents, N is a 2-generator group, and H is a 2-dimensional hyperbolic group. To get H from $\mathcal{Q}$, one adds two new generators a_1, a_2, replaces the relations $r = 1$ of $\mathcal{Q}$ by relations $r = U_r(a_1, a_2)$ and adds a new relation $x_i^{-\varepsilon} a_j x_i^{\varepsilon} = V_{i,j,\varepsilon}(a_1, a_2)$ for each generator x_i in $\mathcal{Q}$ and $j = 1, 2$, $\varepsilon = \pm 1$; the words U_r and $V_{i,j,\varepsilon}$ are chosen to satisfy a small-cancellation condition. This construction depends on the specific presentation $\mathcal{Q}$, not just the group Q.

The flexibility of the Rips construction is such that (at the expense of increasing the number of generators of N) one can arrange for H to have additional properties such as being the fundamental group of a compact negatively curved 2-complex [93], [35], p. 225, or residually finite [94]. Thus one can encode all of the complexity of finite group-presentations (the lions of figure 1) into the finitely generated subgroups of such H. But such constructions say nothing about finitely presented subgroups because, by a theorem of R. Bieri [14], N is not finitely presentable if Q is infinite. The following theorem from [6] obviates this difficulty.

Theorem 5.1 (1-2-3 Theorem). *Suppose that* $1 \to N \to \Gamma \to Q \xrightarrow{p} 1$ *is exact. If* N *is finitely generated,* Γ *is finitely presented and* Q *is of type* F_3*, then the fibre-product* $P := \{(\gamma_1, \gamma_2) \mid p(\gamma_1) = p(\gamma_2)\} \subseteq \Gamma \times \Gamma$ *is finitely presented.*

The name of this theorem comes from the fact that the groups N, Γ, Q are assumed to be of type F_1, F_2 and F_3 respectively. (Recall that a group G is of type F_k if there exists a $K(G, 1)$ with compact k-skeleton.) The F_3 hypothesis says π_2 of a

presentation 2-complex for Q is finitely generated as a $\mathbb{Z}Q$-module. This allows one to control the relations among the generators of $N \times N$ (cf. [4]).

By combining the Rips construction and the 1-2-3 *Theorem, one can encode the complexities of arbitrary finitely presented groups directly into the structure of finitely presented subgroups of direct products of hyperbolic groups.*

An application of this principle is described it the next section. Several other applications are given in [6], one of which was refined in [40] to prove that *there exist* 2*-dimensional hyperbolic groups* Γ *such that there is no algorithm to decide isomorphism among the finitely presented subgroups of* $\Gamma \times \Gamma \times \Gamma$.

5.2. Subdirect products of surface groups. John Stallings [89] and Robert Bieri [13] showed that among the kernels of maps from direct products of free groups to abelian groups one finds a range of finiteness properties; in particular there exist finitely presented subgroups of $F_2 \times F_2 \times F_2$ whose third homology is not finitely generated and finitely presented subgroups S of a direct product of n free groups that are of type F_{n-1} with $H_n(S, \mathbb{Z})$ not finitely generated. Thus one senses that the wild behaviour observed above may continue among subdirect products of free groups, and indeed it does for finitely generated subgroups [76].

But Gilbert Baumslag and Jim Roseblade proved that the only finitely presented subgroups S of a direct product of *two* free groups are the obvious ones: such S are free or have a subgroup of finite index that is the product of its intersections with the factors. Howie, Miller, Short and I [39] discovered an analogous phenomenon in higher dimensions, cf. (5.3).

If a subgroup S *of a direct product of* n *free and surface groups is of type*[4] F_n *then* S *has a subgroup of finite index that is a direct product of free and surface groups.*

The case of surface groups is important because of its implications concerning *the fundamental groups of compact Kähler manifolds*. The work of Delzant and Gromov [52] shows that if such a group Γ is torsion-free and has sufficient multi-ended splittings, then there is an exact sequence $1 \to \mathbb{Z}^n \to \Gamma_0 \to S \to 1$, where S is a subdirect product of surface groups and $\Gamma_0 \subset \Gamma$ has finite index. Motivated by this, one would like to understand *all* finitely presented subdirect products of surface groups. In [41] Miller and I proved the following theorem and a weaker version (involving nilpotent quotients) for products of arbitrarily many surfaces.

Theorem 5.2. *If* S *is a finitely presented subgroup of a direct product of at most three surface groups, then either* S *is virtually a product of free and surface groups* (*the case where* S *is of type* F_3) *or else* S *is virtually the kernel of a map from a product of surface groups to an abelian group* (*the Stallings–Bieri situation*).

One hopes that a complete classification of the finitely presented subdirect products of free and surface groups may be within reach. What we have already proved shows

[4] It is enough that finite-index subgroups of S have $H_i(-, \mathbb{Z})$ finitely generated for $i \leq n$.

that *the conjugacy and membership problems are solvable for all finitely presented subgroups of direct products of surface groups.* This would not remain true if one were to replace surface groups by arbitrary 2-dimensional hyperbolic groups or Kleinian groups. Likewise, the splitting phenomenon for subgroups of type F_n does not extend to these classes. But it is does extend to limit groups.

5.3. Limit groups again. A finitely generated group L is *fully residually free* if for each finite subset $X \subset L$ there is a homomorphism to a finitely generated free group $\psi_X \colon L \to F$ that is injective on X. It is difficult to prove that such L are finitely presented but it is then easy to deduce that these are the limit groups defined in (1.2). The term *limit group* was coined by Sela to connote that these are the groups that occur as limits of stable sequences $\phi_n \colon G \to F$, where G is an arbitrary finitely generated group and *stable* means that for each $g \in G$ either $I_g = \{n \in \mathbb{N} : \phi_n(g) = 1\}$ or $J_g = \{n \in \mathbb{N} : \phi_n(g) \neq 1\}$ is finite; the *limit* is the quotient of G by $\{g \mid |I_g| = \infty\}$.

Such sequences arise when one studies $\mathrm{Hom}(G, F)$. A homomorphism $\phi \colon G \to F$ gives an action of G on the tree that is the Cayley graph of F, and it is profitable to examine sequences (ϕ_n) in the space of G-actions on $\mathbb{R}$-trees. By bringing to bear much of what is known about such spaces, Sela ([87] *et seq.*) obtains a finite parameterization of $\mathrm{Hom}(G, F)$ and a hierarchical decomposition of limit groups. His description of the *elementarily free groups* $\mathrm{EF} \subset \mathcal{L}$ solves a famous problem of A. Tarski. Similar results were obtained in a parallel project by O. Kharlampovich and A. Myasnikov [71] *et seq.* For an introduction to limit groups, see [10].

Jim Howie and I [37], [38] and H. Wilton [92] have been using Sela's work to explore the subgroup structure of limit groups and their direct products. The similarities with surface groups include:

Theorem 5.3 ([37]). *If $G_1, \ldots, G_n$ are elementarily free and $\Gamma \subset G_1 \times \cdots \times G_n$ is of type $\mathrm{FP_n}$, then there are finitely presented subgroups $H_i \subset G_i$ such that Γ is isomorphic to a finite-index subgroup of $H_1 \times \cdots \times H_n$.*

It is likely that this can be extended from EF to $\mathcal{L}$ as conjectured by Sela.

6. Two questions of Grothendieck

In this section I shall outline my solution with Fritz Grunewald to two problems concerning profinite completions and representations of groups that were posed by Alexander Grothendieck in 1970 [66]. The proof exemplifies two general points that I made earlier: the importance of being able to craft groups with specific properties, and the usefulness of the encodings into subdirect products.

6.1. Profinite completions. The profinite completion of a group Γ is the inverse limit of the directed system of finite quotients of Γ; it is denoted by $\hat{\Gamma}$. If Γ is residually finite, the natural map $\Gamma \to \hat{\Gamma}$ is injective. In [66] Grothendieck related the representation theory of a finitely generated group to its profinite completion:

if $A \neq 0$ is a commutative ring and $u\colon \Gamma_1 \to \Gamma_2$ is a homomorphism of finitely generated groups, then $\hat{u}\colon \hat{\Gamma}_1 \to \hat{\Gamma}_2$ is an isomorphism if and only the restriction functor $u_A^*\colon \mathrm{Rep}_A(\Gamma_2) \to \mathrm{Rep}_A(\Gamma_1)$ is an equivalence of categories, where $\mathrm{Rep}_A(\Gamma)$ is the category of finitely presented A-modules with a Γ-action.

Grothendieck investigated under what circumstances $\hat{u}\colon \hat{\Gamma}_1 \to \hat{\Gamma}_2$ being an isomorphism implies that u is an isomorphism. This led him to pose the following problem: *Let Γ_1 and Γ_2 be finitely presented, residually finite groups and let $u\colon \Gamma_1 \to \Gamma_2$ be a homomorphism such that $\hat{u}\colon \hat{\Gamma}_1 \to \hat{\Gamma}_2$ is an isomorphism of profinite groups. Does it follow that u is an isomorphism from Γ_1 onto Γ_2?*

A negative solution to the corresponding problem for finitely generated groups was given by Platonov and Tavgen [81]. But there is an emphasis on finite presentability in Grothendieck's problem because of his original motivation for studying profinite completions: he wanted to understand the extent to which the topological fundamental group of a complex projective variety determines the algebraic fundamental group, and *vice versa*. In the Spring of 2003 Fritz Grunewald and I settled Grothendieck's question in the negative.

Theorem 6.1. *There exist residually finite, 2-dimensional, hyperbolic groups H and finitely presented subgroups $P \subseteq \Gamma := H \times H$ of infinite index, such that P is not abstractly isomorphic to Γ, but $u\colon P \hookrightarrow \Gamma$ induces an isomorphism $\hat{u}\colon \hat{P} \to \hat{\Gamma}$.*

The first ingredient in the proof is the following distillation of arguments of Platonov and Tavgen [81]. *Let $1 \to N \to H \to Q \to 1$ be a short exact sequence of groups with fibre product $u\colon P \hookrightarrow H \times H$. If Q is superperfect*[5] *and has no finite quotients, and H is finitely generated, then $\hat{u}\colon \hat{P} \to \hat{H} \times \hat{H}$ is an isomorphism.*

One applies this criterion to the output of an algorithm obtained by combining D. Wise's refinement [94] of the Rips construction with the 1-2-3 Theorem [6]:

There is an algorithm that associates to any finite aspherical presentation $\mathcal{Q}$ a short exact sequence $1 \to N \to H \to Q \to 1$ and a finite presentation for the fibre product $P \subset H \times H$, where H is hyperbolic and residually finite.

To complete the proof, one needs suitable input presentations $\mathcal{Q}$. A simple calculation in homology shows that if a perfect group has a balanced presentation then it is superperfect. Thus it suffices to construct balanced, aspherical presentations of infinite groups with no non-trivial finite quotients. The following example was constructed in [34]; earlier examples are due to G. Higman [69]. Let $p \geq 2$.

$$\langle a_1, a_2, \hat{a}_1, \hat{a}_2 \mid a_1^{-1}a_2^p a_1 a_2^{-p-1},\ \hat{a}_1^{-1}\hat{a}_2^p \hat{a}_1 \hat{a}_2^{-p-1},\ a_1^{-1}[\hat{a}_2, \hat{a}_1^{-1}\hat{a}_2\hat{a}_1],\ \hat{a}_1^{-1}[a_2, a_1^{-1}a_2 a_1]\rangle.$$

At the expense of complicating the construction of the *Grothendieck pair* $P \hookrightarrow \Gamma \times \Gamma$, one can replace the requirement that the input presentation $\mathcal{Q}$ be aspherical by the

[5] $H_1(Q, \mathbb{Z}) = H_2(Q, \mathbb{Z}) = 0$.

hypothesis that Q be of type F_3. This allows one to associate a Grothendieck pair to any group of type F_3; for if $\mathcal{G}$ is a class (such as F_3) closed under the formation of HNN extensions and amalgamated free products along free groups, one can embed any group $G \in \mathcal{G}$ into a $\overline{G} \in \mathcal{G}$ that has no finite quotients [28].

6.2. Grothendieck's Tannaka duality groups. In the same paper [66] as he raised the problem described above, Grothendieck described an idea for reconstructing a residually finite group from the tensor product structure of its representation category $\mathrm{Rep}_A(\Gamma)$. He encoded this structure into a Tannaka duality group: if $\mathrm{Mod}(A)$ is the category of all finitely generated A-modules and $\mathcal{F}\colon \mathrm{Rep}_A(\Gamma) \to \mathrm{Mod}(A)$ is the forgetful functor, Grothendieck defines $\mathrm{cl}_A(\Gamma)$ to be the group of natural self-transformations of the functor $\mathcal{F}$ that are compatible with the tensor product $\otimes_A$. And he poses the following problem: *If Γ is a finitely presented, residually finite group, is the natural monomorphism from Γ to $\mathrm{cl}_A(\Gamma)$ an isomorphism for every non-zero commutative ring A, or at least some suitable commutative ring $A \neq 0$?*

Theorem 6.2 ([34]). *If P is one of the groups constructed in Theorem* 6.1*, then P is of infinite index in $\mathrm{cl}_A(P)$ for every commutative ring $A \neq 0$.*

Previously, Alex Lubotzky [75] had exhibited finitely presented, residually finite groups Γ such that $\Gamma \to \mathrm{cl}_A(\Gamma)$ is not surjective when $A = \mathbb{Z}$.

Link homology and categorification

Mikhail Khovanov

Abstract. This is a short survey of algebro-combinatorial link homology theories which have the Jones polynomial and other link polynomials as their Euler characteristics.

Mathematics Subject Classification (2000). 57M25, 57Q45.

Keywords. Link homology, quantum link invariants, matrix factorizations.

1. Introduction

The discovery of the Jones polynomial by V. Jones [J] and quantum groups by V. Drinfeld and M. Jimbo led to an explosive development of quantum topology. The newly found topological invariants were christened "quantum invariants"; for knots and links they often take the form of polynomials. By late 80s to early 90s it was realized that each complex simple Lie algebra $\mathfrak{g}$ gives rise to a gaggle of quantum invariants. To a link L in $\mathbb{R}^3$ with each component colored by an irreducible representation of $\mathfrak{g}$ there is assigned an invariant $P(L, \mathfrak{g})$ taking values in the ring of Laurent polynomials $\mathbb{Z}[q, q^{-1}]$ (sometimes fractional powers of q are necessary). Polynomials $P(L, \mathfrak{g})$ have a representation-theoretical description, via intertwiners between tensor products of irreducible representations of the quantum group $U_q(\mathfrak{g})$, the latter a Hopf algebra deformation of the universal enveloping algebra of $\mathfrak{g}$. These invariants by no means exhaust all quantum invariants of knots and links; various modifications and generalizations include finite type (Vassiliev) invariants, invariants associated with quantum deformations of Lie superalgebras, etc.

Quantum $\mathfrak{sl}(n)$ link polynomials, when each component of L is colored by the fundamental n-dimensional representation, can be conveniently encapsulated into a single 2-variable polynomial $P(L)$, known as the HOMFLY or HOMFLY-PT polynomial [HOMFLY], [PT].

The skein relation

$$\lambda P(L_1) - \lambda^{-1} P(L_2) = (q - q^{-1}) P(L_3)$$

for any three links L_1, L_2, L_3 that differ as shown below and the value of P on the unknot, uniquely determines the HOMFLY-PT invariant, which lies in the ring $\mathbb{Z}[\lambda^{\pm 1}, (q - q^{-1})^{\pm 1}]$ (in the original papers a single variable was used instead of

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

$q - q^{-1}$, making P a genuine Laurent polynomial in two variables).

L_1 L_2 L_3

Specializing $\lambda = q^n$, for $n \geq 0$, leads to a link polynomial invariant $P_n(L) \in \mathbb{Z}[q, q^{-1}]$, normalized so that $P_n(\text{unknot}) = q^{n-1} + q^{n-3} + \cdots + q^{1-n}$ for $n > 0$ and $P_0(\text{unknot}) = 1$.

$P_0(L)$ and $P_2(L)$ are the Alexander and Jones polynomials of L, respectively, while $P_1(L)$ is a trivial invariant. For $n > 0$, the polynomial $P_n(L)$ can be interpreted via the representation theory of quantum $\mathfrak{sl}(n)$, and $P_0(L)$ – via that of the quantum Lie superalgebra $U_q(\mathfrak{gl}(1|1))$.

The miracle that emerged in the past few years is that these polynomials are Euler characteristics of link homology theories:

- The Jones polynomial $P_2(L)$ is the Euler characteristic of a bigraded link homology theory $\mathcal{H}(L)$, discovered in [K1].
- The Alexander polynomial $P_0(L)$ is the Euler characteristic of a bigraded knot homology theory, discovered by P. Ozsváth, Z. Szabó [OS1] and J. Rasmussen [R1].
- The polynomial $P_3(L)$ is the Euler characteristic of a link homology theory $\mathrm{H}(L)$, defined in [K2].
- For each $n \geq 1$, Lev Rozansky and the author constructed a bigraded link homology theory $\mathrm{H}_n(L)$ with $P_n(L)$ as the Euler characteristic, see [KR1].
- The entire HOMFLY-PT polynomial is the Euler characteristic of a triply-graded link homology theory [KR2], [K6] (for a possible alternative approach via string theory see [GSV]).

Ideally, a link homology theory should be a monoidal functor $\mathcal{F}$ from the category LCob of link cobordisms to a tensor triangulated category T (for instance, T could be the category of complexes of R-modules, up to chain homotopies, for a commutative ring R). Objects of LCob are oriented links in $\mathbb{R}^3$, morphisms from L_0 to L_1 are isotopy classes (rel boundary) of oriented surfaces S smoothly and properly embedded in $\mathbb{R}^3 \times [0, 1]$ such that $L_0 \sqcup (-L_1)$ is the boundary of S and $L_i \subset \mathbb{R}^3 \times \{i\}, i = 0, 1$. In many known examples, $\mathcal{F}$ is a projective functor: the map $\mathcal{F}(S)\colon \mathcal{F}(L_0) \longrightarrow \mathcal{F}(L_1)$ is well defined up to overall multiplication by invertible central elements of T (e.g. by ± 1 for homology theory $\mathcal{H}$).

No a priori reason why quantum link invariants should lift to link homology theories is known and the general framework for lifting quantum invariants to homology

theories remains a mystery. We call such a lift a *categorification* of the invariant. The term categorification was coined by L. Crane and I. Frenkel [CF] in the context of lifting an n-dimensional TQFT to an $(n+1)$-dimensional one ($n = 2, 3$ are the main interesting cases).

Let us also point out that the Casson invariant (a degree two finite-type invariant of 3-manifolds) is the Euler characteristic of instanton Floer homology, that the Seiberg–Witten and Ozsváth–Szabó 3-manifold homology theories categorify degree one finite-type invariants of 3-manifolds (the order of $H_1(M, \mathbb{Z})$ when the first homology of the 3-manifold M is finite and, more generally, the Alexander polynomial of M), that equivariant knot signatures are Euler characteristics of $\mathbb{Z}/4\mathbb{Z}$-graded link homologies (O. Collin, B. Steer [CS], W. Li), and that there exist ideas on how to categorify the 2-variable Kauffman polynomial [GW], the colored Jones polynomial, and quantum invariants of links colored by arbitrary fundamental representations $\Lambda^i V$ of $\mathfrak{sl}(n)$ [KR1].

2. A categorification of the Jones polynomial

In the late nineties the author discovered a homology theory $\mathcal{H}(L)$ of links which is bigraded,

$$\mathcal{H}(L) = \bigoplus_{i,j\in\mathbb{Z}} \mathcal{H}^{i,j}(L),$$

and has the Jones polynomial as the Euler characteristic,

$$P_2(L) = \sum_{i,j\in\mathbb{Z}} (-1)^i q^j \operatorname{rk}(\mathcal{H}^{i,j}(L)).$$

The construction of $\mathcal{H}$ categorifies the Kauffman bracket description of the Jones polynomial. Starting from a plane projection D of L we build homology groups $\mathcal{H}(D)$ inductively on the number of crossings of the projection via long exact sequences

and then check that $\mathcal{H}(D)$ are invariants of L alone. Homology of the empty link is $\mathbb{Z}$, homology of the unknot is $\mathcal{A} = \mathbb{Z}[X]/(X^2)$, which should be thought of as the integral cohomology ring of the 2-sphere. Homology of the k-component unlink is $\mathcal{A}^{\otimes k}$. The obvious cobordisms between unlinks turn $\mathcal{A}$ into a commutative Frobenius ring, with the trace map $\operatorname{tr}(1) = 0$, $\operatorname{tr}(X) = 1$ (in any full-fledged link homology theory homology of the unknot is a commutative Frobenius algebra over homology of the empty link). $\mathcal{H}(D)$ is the homology of a complex $\mathcal{C}(D)$ constructed in an elementary way from direct sums of tensor powers of $\mathcal{A}$ and the structure maps of this Frobenius ring.

Theorem 2.1. *There exists a combinatorially defined bigraded homology theory $\mathcal{H}(L)$ of oriented links in $\mathbb{R}^3$. The groups $\mathcal{H}^{i,j}(L)$ are finitely-generated and their Euler characteristic is the Jones polynomial. The theory is functorial: to an oriented cobordism S between links L_0 and L_1 it assigns a homomorphism of groups*

$$\mathcal{H}(S)\colon \mathcal{H}(L_0) \longrightarrow \mathcal{H}(L_1),$$

well defined up to overall minus sign and of bidegree $(0, -\chi(S))$, where $\chi(S)$ is the Euler characteristic of the surface S.

That $\pm\mathcal{H}(S)$ is well defined was proved in [Ja] and [K4] in two different ways.

The homology theory $\mathcal{H}$ is manifestly combinatorial and programs computing it were written by D. Bar-Natan, A. Shumakovitch and J. Green. The earliest program [BN1] led to the conjecture that ranks of the homology groups of alternating links are determined by the Jones polynomial and the signature. This conjecture was proved by E.-S. Lee [L1]. For arbitrary knots and links, the structure of $\mathcal{H}$ is more complicated than that of the Jones polynomial; right now we do not even have a guess at what the rational homology groups of arbitrary (n, m)-torus knots are.

We next list several interesting applications of $\mathcal{H}$ and related developments.

1) J. Rasmussen used $\mathcal{H}$ and its deformation studied by E. S. Lee [L2] to give a combinatorial proof of the Milnor conjecture that the slice genus of the (p, q)-torus knot is $\frac{(p-1)(q-1)}{2}$ and of its generalization to all positive knots [R2]. This can also be used to show that certain knots are topologically but not smoothly slice without having to invoke Donaldson or Seiberg–Witten gauge theories. Originally, the Milnor conjecture was proved by P. Kronheimer and T. Mrowka via the Donaldson theory [KM].

2) Lenhard Ng [N] obtained an upper bound on the Thurston–Bennequin number of a Legendrian link from its homology $\mathcal{H}(L)$. This bound is sharp on alternating knots and on all but one or two knots with at most 10 crossings.

3) A. Shumakovitch [S] showed that over the 2-element field homology decomposes: $\mathcal{H}(L, \mathbb{F}_2) \cong \widetilde{\mathcal{H}}(L, \mathbb{F}_2) \otimes \mathbb{F}_2[X]/(X^2)$, where $\widetilde{\mathcal{H}}(L, \mathbb{F}_2)$ is the reduced homology of L with coefficients in $\mathbb{F}_2$. P. Ozsváth and Z. Szabó [OS2] discovered a spectral sequence with the E^2-term $\widetilde{\mathcal{H}}(L, \mathbb{F}_2)$ that converges to the Ozsváth–Szabó homology of the double branched cover of L[1].

4) P. Seidel and I. Smith defined a $\mathbb{Z}$-graded homology theory of links via Lagrangian intersection Floer homology of a certain quiver variety [SS]. Their theory is similar to $\mathcal{H}$ in many respects, and, conjecturally, isomorphic to $\mathcal{H}$ after the bigrading in the latter is collapsed to a single grading.

3. Extensions to tangles

The quantum group $U_q(\mathfrak{sl}(2))$ controls the extension of the Jones polynomial to an invariant of tangles, the latter a functor from the category of tangles to the category

of $U_q(\mathfrak{sl}(2))$ representations. To a tangle T with n bottom and m top endpoints (an (m, n)-tangle) there is assigned an intertwiner

$$f(T)\colon V^{\otimes n} \longrightarrow V^{\otimes m}$$

between tensor powers of the fundamental representation V of $U_q(\mathfrak{sl}(2))$.

A categorification of the invariant $f(T)$ was suggested in [BFK]. We considered the category

$$\mathcal{O}^n = \bigoplus_{0\le k\le n} \mathcal{O}^{k,n-k},$$

the direct sum of parabolic subcategories $\mathcal{O}^{k,n-k}$ of a regular block of the highest weight category for $\mathfrak{sl}(n)$. The category $\mathcal{O}^{k,n-k}$ is equivalent to the category of perverse sheaves on the Grassmannian of k-planes in $\mathbb{C}^n$, smooth with respect to the Schubert stratification. The Grothendieck group of $\mathcal{O}^n$ is naturally isomorphic (after tensoring with $\mathbb{C}$) to $V^{\otimes n}$, considered as a representation of $U_{q=1}(\mathfrak{sl}(2))$, and derived Zuckerman functors in $D^b(\mathcal{O}^n)$ lift the action of $\mathfrak{sl}(2)$ on $V^{\otimes n}$. We showed that projective functors in $\mathcal{O}^n$ categorify the action of the Temperley–Lieb algebra on $V^{\otimes n}$ and conjectured how to extend this to arbitrary tangles, by assigning to a tangle T a functor $\mathcal{F}(T)$ between derived categories $D^b(\mathcal{O}^n)$ and $D^b(\mathcal{O}^m)$.

Our conjectures were proved by C. Stroppel [St], who worked with the graded versions $\mathcal{O}^n_{gr}$ of these categories, associated a functor $\mathcal{F}(T)$ between derived categories $D^b(\mathcal{O}^n_{gr})$ and $D^b(\mathcal{O}^m_{gr})$ to each (m, n)-tangle T and a natural transformation $\mathcal{F}(S)\colon \mathcal{F}(T_0) \longrightarrow \mathcal{F}(T_1)$ to a tangle cobordism S between tangles T_0 and T_1. The whole construction is a 2-functor from the 2-category of tangle cobordisms to the 2-category whose objects are $\mathbb{C}$-linear triangulated categories, 1-morphisms are exact functors and 2-morphisms are natural transformations of functors, up to rescalings by invertible complex numbers. When the tangle is a link L, this theory produces bigraded homology groups, conjecturally isomorphic to $\mathcal{H}(L) \otimes \mathbb{C}$.

The braid group action on $V^{\otimes n}$ lifts to a braid group action on the derived category $D^b(\mathcal{O}^n_{gr})$. Restricting to the subcategory $D^b(\mathcal{O}^{1,n-1}_{gr})$ results in a categorification of the Burau representation, previously studied in [KS].

For a more economical extension of the Jones polynomial to tangles, we restrict to even tangles (when the number of endpoints on each of the two boundary planes is even) and to the subspace of $U_q(\mathfrak{sl}(2))$-invariants

$$\mathrm{Inv}(n) = \mathrm{Hom}_{U_q(\mathfrak{sl}(2))}(\mathbb{C}, V^{\otimes 2n})$$

in $V^{\otimes 2n}$. The invariant of a $(2m, 2n)$-tangle is a linear map

$$f_{\mathrm{inv}}(T)\colon \mathrm{Inv}(n) \longrightarrow \mathrm{Inv}(m)$$

between these subspaces.

A categorification of $f_{\mathrm{inv}}(T)$ was found in [K3], [K4]. We defined a graded ring H^n and established an isomorphism

$$K(H^n\text{-mod}) \otimes \mathbb{C} \cong \mathrm{Inv}(n)$$

between the Grothendieck group (tensored with $\mathbb{C}$) of the category of graded finitely-generated H^n-modules and the space of invariants in $V^{\otimes 2n}$. To an even tangle T we assigned an exact functor $\mathcal{T}$ between the derived categories of H^n-mod (this functor induces the map $f_{\mathrm{inv}}(T)$ on the Grothendieck groups) and to a tangle cobordism – a natural transformation of functors. This results in a 2-functor from the 2-category of cobordisms between even tangles to the 2-category of natural transformation between exact functors in triangulated categories. Restricting to links, we recover homology groups $\mathcal{H}(L)$. This approach is more elementary than that via category $\mathcal{O}$, and should carry the same amount of information.

The space of invariants $\mathrm{Inv}(n)$ is a subspace of $V^{\otimes 2n}(0)$, the weight zero subspace of $V^{\otimes 2n}$. A categorification of this inclusion relates rings H^n and parabolic categories $\mathcal{O}^{n,n}$. The latter category is equivalent to the category of finite-dimensional modules over a $\mathbb{C}$-algebra $A_{n,n}$, explicitly described by T. Braden [B]. There exists an idempotent e in $A_{n,n}$ such that $eA_{n,n}e \cong H^n \otimes \mathbb{C}$. This idempotent picks out all self-dual indecomposable projectives in $A_{n,n}$.

Rings H^n can also be used to categorify certain level two representations of $U_q(\mathfrak{sl}(m))$, see [HK].

For a more geometric and refined approach to invariants of tangles and tangle cobordisms we refer the reader to Bar-Natan [BN2]. Some of his generalizations of link homology can be thought of as G-equivariant versions of $\mathcal{H}$, for various compact subgroups G of SU(2), see [K5] for speculations in this direction and for an interpretation of the Rasmussen invariant via the SU(2)-equivariant version of $\mathcal{H}$.

4. $\mathfrak{sl}(n)$ link homology and matrix factorizations

Theorem 4.1. *For each $n > 0$ there exists a homology theory which associates bigraded homology groups*

$$\mathrm{H}_n(L) \cong \bigoplus_{i,j\in\mathbb{Z}} \mathrm{H}_n^{i,j}(L)$$

to every oriented link in $\mathbb{R}^3$. The Euler characteristic of H_n is the polynomial invariant P_n,

$$P_n(L) = \sum_{i,j\in\mathbb{Z}} (-1)^i q^j \dim_{\mathbb{Q}}(\mathrm{H}_n^{i,j}(L)).$$

The homology groups $\mathrm{H}_n^{i,j}(L)$ are finite-dimensional $\mathbb{Q}$-vector spaces, and, for a fixed L, only finitely many of them are non-zero. This homology is functorial: an oriented link cobordism S between L_0 and L_1 induces a homomorphism

$$\mathrm{H}_n(S)\colon \mathrm{H}_n(L_0) \longrightarrow \mathrm{H}_n(L_1),$$

well defined up to overall rescaling by nonzero rationals.

The groups $\mathrm{H}_n(L)$ are constructed in [KR1], where we start with a presentation for $P_n(L)$ as an alternating sum

$$P_n(L) = \sum_{\Gamma} \pm q^{\alpha(\Gamma)} P_n(\Gamma). \tag{1}$$

Here we choose a generic plane projection D of L with m crossings, and form the sum over 2^m planar trivalent graphs Γ which are given by replacing each crossing of D by one of the two planar pictures on the right

Each such planar graph Γ has a well-defined invariant $P_n(\Gamma) \in \mathbb{Z}[q, q^{-1}]$, with all the coefficients being nonnegative integers. Weights $\alpha(\Gamma)$ are given by a simple rule. The edges are of two types: regular oriented edges and "wide" unoriented edges as on the rightmost picture above.

We then define single-graded homology groups $\mathrm{H}_n(\Gamma)$ which have the graded dimension $P_n(\Gamma)$ and satisfy certain naturality conditions allowing us to build a complex out of $\mathrm{H}_n(\Gamma)$, over all modifications Γ of the link diagram D. The complex is a categorification of the right hand side of the equation (1); its homology groups $\mathrm{H}_n(D)$ depend on L only and satisfy the properties listed in Theorem 4.1.

Our definition of $\mathrm{H}_n(\Gamma)$ is based on matrix factorizations. Let $R = \mathbb{Q}[x_1, \ldots, x_k]$. A matrix factorization M of a polynomial $f \in R$ consists of a pair of free R-modules and a pair of R-module maps

$$M^0 \xrightarrow{d} M^1 \xrightarrow{d} M^0$$

such that $d^2 = f \cdot \mathrm{Id}$. The polynomial f is called the *potential* of M. A matrix factorization can be thought of as a two-periodic generalized complex; the square of the differential in not zero, but a fixed multiple of the identity operator. Matrix factorizations were introduced by D. Eisenbud [E] to study homological properties of hypersurface singularities, and later made an appearance in string theory, as boundary conditions in Landau–Ginzburg models [KL]. The tensor product $M \otimes_R N$ of matrix factorizations with potentials f, g is a matrix factorization with potential $f + g$.

To each Γ we associate a collection of matrix factorizations $M_1, \ldots, M_m$, one for each crossing of D, with potentials $f_1, \ldots, f_m$ that add up to zero: $f_1 + f_2 + \cdots + f_m = 0$. The tensor product $M_1 \otimes M_2 \otimes \cdots \otimes M_m$ is a two-periodic complex (since the square of the differential is now zero). Finally, $\mathrm{H}_n(\Gamma)$ is defined as the cohomology of this complex; it inherits a natural $\mathbb{Z}$-grading from that of the polynomial algebra R.

The homology theory H_n is trivial when $n = 1$, while $\mathrm{H}_2(L) \cong \mathcal{H}(L) \otimes \mathbb{Q}$. The theory H_3 should be closely related to the homology theory constructed earlier in [K2]

(the two theories have the same Euler characteristic; the one in [K2] is defined over $\mathbb{Z}$ and not just over $\mathbb{Q}$).

J. Rasmussen [R3] determined homology groups $\mathrm{H}_n(L)$ for all 2-bridge knots L and a few other knots (with a mild technical restriction $n > 4$). Little else is known about homology groups $\mathrm{H}_n(L)$ for $n > 2$.

A Lagrangian intersection Floer homology counterpart of H_n was discovered by C. Manolescu [M]. His theory $\mathcal{H}_{(n)symp}(L)$ is singly-graded, but defined over $\mathbb{Z}$. Manolescu conjectured that $\mathcal{H}_{(n)symp}$, after tensoring with $\mathbb{Q}$, becomes isomorphic to H_n, with the bigrading of the latter folded into a single grading.

5. Triply-graded link homology and beyond

It turns out that the entire HOMFLY-PT polynomial, and not just its one-variable specializations, admits a categorification. The original construction via degenerate matrix factorizations with a parameter [KR2] was later recast in the language of Hochschild homology for bimodules over polynomial algebras [K6]. We represent a link L as the closure of a braid σ with m strands. To σ we assign a certain complex $F(\sigma)$ of graded bimodules over the polynomial algebra R in $m-1$ generators. Taking the Hochschild homology over R of each term in the complex produces a complex of bigraded vector spaces

$$\cdots \longrightarrow \mathrm{HH}(R, F^j(\sigma)) \longrightarrow \mathrm{HH}(R, F^{j+1}(\sigma)) \longrightarrow \cdots$$

The cohomology groups $\mathrm{H}(\sigma)$ of this complex are triply-graded and depend on L only (a convenient grading normalization was pointed out by H. Wu [W]). The Euler characteristic of $\mathrm{H}(L)$ is the HOMFLY-PT polynomial $P(L)$, normalized so that $P(\text{unknot}) = 1$.

This homology theory suffers from two problems. First, the definition requires choosing a braid representative of a knot, rather than just a plane projection. Second, it is not possible to assign maps $\mathrm{H}(S)$ to all link cobordisms S so as to turn H into a functor from LCob to the category of (triply-graded) vector spaces (simply because homology of the unknot is one-dimensional, while that of an unlink is infinite-dimensional). We conjecture that the theory can be redefined on k-component links for all $k > 1$ so as to assign finite-dimensional homology groups $\widetilde{\mathrm{H}}(L)$ to all oriented links L, and not just to knots. The Euler characteristic of $\widetilde{\mathrm{H}}(L)$ will still be the HOMFLY-PT polynomial, but rescaled so as to be a Laurent polynomial in λ and q rather than a rational function. The theory should extend to a projective functor from the category of *connected* link cobordisms to the category of triply-graded vector spaces.

Further extension of $\widetilde{\mathrm{H}}$ to all link cobordisms should only require a minor modification, where one assigns the algebra $\mathbb{Q}[a]$ to the empty link, the differential graded algebra

$$\mathbb{Q}\langle y_1, \ldots, y_n\rangle \otimes \mathbb{Q}[a], \quad y_i y_j + y_j y_i = 0, \quad [y_i, a] = 0, \quad d(y_i) = a, \quad d(a) = 0$$

to a k-component unlink, and suitably resolves each $\widetilde{\mathrm{H}}(L)$, viewed as a $\mathbb{Q}[a]$ module with the trivial action of a, into a complex of free $\mathbb{Q}[a]$-modules.

Understanding $\widetilde{\mathrm{H}}$ could be an important step towards an algebraic description of knot Floer homology, since we expect $\widetilde{\mathrm{H}}$ to degenerate (possibly via a spectral sequence) into knot Floer homology of Ozsváth–Szabó and Rasmussen [OS1], [R1], which categorifies the Alexander polynomial.

An algebraic description of knot and link Floer homology, if someday found and combined with the combinatorial construction [OS3] of Ozsváth–Szabó 3-manifold homology of surgeries on a knot from a filtered version of knot Floer homology (and a generalization of their construction to links), could lead to a combinatorial definition of Ozsváth–Szabó and Seiberg–Witten 3-manifold homology and, eventually, to an algebraic formulation of gauge-theoretical invariants of 4-manifolds.

In conclusion, we mention two other difficult open problems.

I. Categorify polynomial invariants $P(L, \mathfrak{g})$ of knots and links associated to arbitrary complex simple Lie algebras $\mathfrak{g}$ and their irreducible representations.

II. Categorify the Witten–Reshetikhin–Turaev invariants of 3-manifolds.

Curve complexes, surfaces and 3-manifolds

Yair N. Minsky*

Abstract. A survey of the role of the complex of curves in recent work on 3-manifolds and mapping class groups.

Mathematics Subject Classification (2000). Primary 57M50; Secondary 30F40, 30F60.

Keywords. Kleinian groups, mapping class group, complex of curves.

1. Disjoint curves in surfaces

The complex of curves, a combinatorial object associated to a surface, has been of interest recently in low-dimensional topology and geometry. In the study of mapping class groups of surfaces, it has shed some light on *relative hyperbolicity* properties, and more generally on the coarse geometry of these groups, and of the Teichmüller spaces (parameter spaces of Riemann surfaces) on which they act. In the setting of hyperbolic 3-manifolds, the complex of curves has been used in the classification theory, particularly the solution of Thurston's Ending Lamination Conjecture, and generally in the attempt to relate more concretely the topology of a 3-manifold to its geometric structure. This paper will attempt to survey some of these developments. Of necessity we will focus on those aspects with which the author is most familiar, thus leaving out a lot of interesting topology and geometry.

We will begin with a leisurely discussion of the natural ways in which simple closed curves (i.e. embedded circles), and particularly the relation of disjointness, occur in low-dimensional topology. After this, in § 2 we will lay out the basic definitions and theorems about curve complexes. In § 3 we will describe work with H. Masur on the inductive structure of curve complexes and its relation to the geometry of mapping class groups. In § 4 we will go into more detail about mapping class groups and outline some recent work with J. Behrstock on their asymptotic cones and the Brock–Farb rank conjecture. In § 5 we will describe work with J. Brock and R. Canary on Thurston's Ending Lamination Conjecture. In § 6 we will lay out some thoughts on the hyperbolic geometry of Heegaard splittings, an area in which our knowledge is still rather incomplete.

*The author is grateful to the NSF for support of this research.

of Mathematicians, Madrid, Spain, 2006

Surfaces and mapping class groups. The first interesting thing one can do with a homotopically essential simple closed curve in a surface is to cut along it, and then glue back. If before gluing back by the identity, the complementary surface is given one full twist in a neighborhood of the curve, the resulting self-map is not homotopic to the identity, and is called a Dehn twist.

The group of orientation preserving homeomorphisms of an oriented surface S to itself, taken modulo isotopy, is called the *mapping class group* of S, or $\mathcal{MCG}(S)$. Dehn twists give rise to infinite cyclic subgroups of $\mathcal{MCG}(S)$, and two disjoint non-homotopic simple curves give rise to commuting Dehn twists.

More generally, let Δ denote a system of disjoint, essential, pairwise non-homotopic simple closed curves (necessarily a finite number, if S is compact). The stabilizer of Δ (up to homotopy) in $\mathcal{MCG}(S)$ is denoted $\mathrm{Stab}(\Delta)$, and we have a short exact sequence

$$0 \to \mathbb{Z}^n \to \mathrm{Stab}(\Delta) \to \mathcal{MCG}'(S \setminus \Delta) \to 0 \tag{1}$$

where $\mathbb{Z}^n$ is the group of Dehn twists generated by elements of Δ and $\mathcal{MCG}'(S \setminus \Delta)$ is the finite-index subgroup of $\mathcal{MCG}(S \setminus \Delta)$ whose elements permute the boundary in such a way that it can still be glued back to obtain Δ in S.

A mapping class that preserves a system of disjoint essential simple closed curves is called *reducible*. Thurston classified the nontrivial conjugacy classes in $\mathcal{MCG}(S)$ as reducible, finite-order, and *pseudo Anosov* [49], [43]. A pseudo-Anosov mapping class does not preserve any finite set of closed curves. Instead, it preserves a pair of *measured geodesic laminations* (see §2), and any closed curve tends, under forward iteration, to one of these and under backward iteration to the other.

The kernel in (1) is an example of an abelian subgroup of $\mathcal{MCG}(S)$. Birman–Lubotzky–McCarthy [13] used Thurston's classification theorem to classify all abelian (and solvable) subgroups of $\mathcal{MCG}(S)$. In particular they showed that the maximal rank of an abelian subgroup is equal to the maximal cardinality of a disjoint system of curves Δ. The pure Dehn-twist group appearing in (1) is not the only way of obtaining a maximal rank abelian group, however – for example if Δ divides S into 3-holed spheres and 1-holed tori, and a Dehn twist is chosen on each component of Δ and a pseudo-Anosov is chosen on each 1-holed torus component, then these elements generate a maximal rank abelian group.

When studying the "coarse" geometry of $\mathcal{MCG}(S)$, i.e. its large-scale geometry when viewed as a metric space by means of its Cayley graph, these maximal abelian subgroups turn out to be quite important. They are quasi-isometrically embedded (see §4 for definitions) by Mosher [105] in the punctured case and Farb–Lubotzky–Minsky [48] in general (See also Theorem 4.1). On the other hand Brock and Farb asked whether these subgroups represent the largest n for which $\mathbb{Z}^n$ is quasi-isometrically embedded in $\mathcal{MCG}(S)$ (not necessarily as a subgroup). This was answered affirmatively by Hamenstädt [58] and by Behrstock–Minsky [8]. The techniques that go into the latter proof are part of what concerns us in this paper.

Hyperbolic geometry. In a complete hyperbolic surface S, each nontrivial homotopy class is represented by a unique geodesic (if it is not homotopic into a cusp). If Δ is a maximal set of disjoint essential simple closed curves, not homotopic to each other or the cusps, then they are realized as a disjoint set of simple geodesics which cut S into 3-holed spheres. It turns out that a hyperbolic 3-holed sphere is determined uniquely by its boundary lengths and all possible lengths can occur. Once lengths are selected for the components of Δ the hyperbolic metric of S is almost determined, except for the gluings of the boundaries back together, for which there is an additional real parameter for each one. This gives *Fenchel–Nielsen coordinates* for the Teichmüller space of S,

$$\mathcal{T}(S) \cong \mathbb{R}_+^{\Delta} \times \mathbb{R}^{\Delta}.$$

The Teichmüller space of S is the set of all hyperbolic metrics on S, up to isometries homotopic to the identity (see e.g. [131], [72], [51]).

On the other hand, the Collar Lemma (see e.g. [78], [38]) asserts that a closed geodesic in S has a regular neighborhood whose radius goes to infinity as the curve's length goes to 0. In particular any sufficiently short geodesic has no self-intersections, and two sufficiently short geodesics cannot cross each other. That suggests a division of $\mathcal{T}(S)$ into *thin regions*, where some curve is shorter than a certain threshold, and *thick regions* where no curves are very short. The intersection pattern of the thin regions is prescribed exactly by the disjointness relation among simple closed curves.

In three dimensional hyperbolic geometry, the generalization of the collar lemma is the "Margulis Lemma" (Kazhdan–Margulis [77]), or Jørgensen's inequality [76] (see also Brooks–Matelski [37], Thurston [131]). In particular sufficiently short closed geodesics have a standard solid torus neighborhood sometimes called a Margulis tube. If for example we consider a hyperbolic structure on $N = S \times \mathbb{R}$, work of Thurston and Bonahon [130], [19] showed that if a geodesic is sufficiently short it must be homotopic to a *simple curve* in S, and Otal [108], [109] showed that any number of sufficiently short curves must be *unknotted and unlinked* – that is, isotopic in N to a collection of disjoint simple level curves with respect to the product structure. See Souto [124] for a generalization of this to the setting of any embedded surface in a hyperbolic 3-manifold.

These sort of results are obtained using *pleated surfaces* (or sometimes *simplicial hyperbolic surfaces*). A pleated surface in a hyperbolic 3-manifold N is a map $f\colon S \to N$ where S is a surface, the pullback path-metric from N gives a complete hyperbolic metric on S, and moreover f is totally geodesic on the complement of a system of simple geodesic lines called a *lamination*. Thurston introduced these tools into hyperbolic geometry, and their great advantage is that (a) their presence greatly constrains the geometry of the 3-manifold in terms of the well-understood geometry of hyperbolic surfaces, and (b) they are plentiful. In fact if $f\colon S \to N$ is a π_1-injective map and Δ is a collection of disjoint, essential, nonhomotopic simple closed curves in S whose f-images are not homotopic to cusps, then there exists a pleated map homotopic to f which carries Δ to its geodesic representatives.

This again gives a geometric interpretation to the disjointness relation for simple curves. Indeed, the Gauss–Bonnet theorem implies that the diameter of a hyperbolic surface is bounded, outside of the thin collars, in terms of its topology. In our 3-manifold setting this means that the geodesic representatives of disjoint curves on S are "close modulo thin parts". Thus the pattern of Margulis tubes in a hyperbolic 3-manifold is closely related to patterns of disjoint curves.

Heegaard splittings. Any closed oriented 3-manifold can be expressed, in infinitely many ways, as a union of two handlebodies glued along their boundaries (a handlebody is a 3-ball with 1-handles attached, or a regular neighborhood of a 1-complex embedded in $\mathbb{R}^3$. For example, consider regular neighborhoods of the 1-skeletons of a triangulation and its dual). This is known as a Heegaard splitting. The non-uniqueness of Heegaard splittings means that it is difficult, although not impossible, to extract meaningful topological information from them. The literature on Heegaard splittings is by now extensive, and our discussion will not come close to being comprehensive. For more information the reader is directed to Birman [14], Scharlemann [116] and Zieschang [133].

Given a surface S, an identification of S with the boundary of a handlebody is determined (up to isotopy) by specifying a maximal set Δ of disjoint nonhomotopic simple curves which are to be the boundaries of essential disks, or *meridians*. (Actually it suffices to choose Δ so that its complement consists of a single genus 0 subsurface). The combination of two such sets for the two handlebodies is called a Heegaard diagram. This is a finite amount of information, but we are faced with the fact that there is no natural choice for this diagram among all possible ones for a given splitting.

A splitting is called *reducible* if there is a curve which is a meridian in both sides. The two disks thus bounded form a sphere, which either bounds a ball, in which case the genus of the splitting can be reduced, or is essential, in which case the manifold can be reduced to a connected sum of manifolds with lower-genus splittings. Haken [56] showed conversely that if a manifold is a connected sum and S is a Heegaard surface, then there exists a sphere that meets S in exactly one meridian. That is, a splitting of a reducible manifold is a reducible splitting. In an irreducible manifold, a splitting of minimal genus is irreducible. However irreducible splittings do not have to be of minimal genus.

Casson–Gordon [44] introduced the notion of *weak reducibility:* A splitting is weakly reducible if it contains two *disjoint* meridians (note that reducible implies weakly reducible, as two equal meridians can be made disjoint). They showed that a weakly reducible splitting is either reducible, or contains a 2-sided incompressible surface (an incompressible surface is a π_1-injectively embedded surface of positive genus; manifolds which admit 2-sided incompressible surfaces are called *Haken*, and are in many ways easier to study.) Thus an irreducible non-Haken manifold has a *strongly irreducible* (i.e. not weakly reducible) splitting. For Haken manifolds, extensions of the arguments of Casson–Gordon by Scharlemann–Thompson (see [117] and [115])

lead to a decomposition along incompressible surfaces into strongly irreducible Heegaard splittings-with-boundary, known as a *generalized Heegaard splitting*. This has become a widely applied and sophisticated theory.

Hempel [69] showed that a splitting of a manifold that is Seifert-fibred or contains an essential torus must have the *disjoint curve property*: There exist meridians m_1, m_2 from the two sides, and a curve γ so that both m_1 and m_2 are disjoint from γ. (Note that reducibility and weak-reducibility are special cases of this property).

At this point, the properties of splittings and their meridians come into contact with Thurston's geometrization conjecture. After decomposing along essential spheres and tori, a 3-manifold should fall into pieces admitting one of the eight 3-dimensional geometries – Euclidean, hyperbolic, spherical, or the five non-isotropic fibred geometries (see Scott [122]). Our discussion so far implies that manifolds that break up non-trivially have reducible splittings (by Haken) or splittings with the disjoint curve property (by Hempel).

Irreducible splittings for the non-hyperbolic pieces are now very well understood, through the work of Waldhausen [132], Bonahon–Otal [20], Moriah [103], Boileau–Rost–Zieschang and Boileau–Collins–Zieschang [17], [15], Frohman–Hass [50], Boileau–Otal [16], Moriah–Schultens [104] and Cooper–Scharlemann [46]. In all these cases splittings have the disjoint curve property.

A splitting without the disjoint curve property should therefore yield a hyperbolic manifold (modulo the geometrization conjecture, whose proof by Perelman is, as of this writing, edging ever closer to formal acceptance). Hempel brought the notions of reducibility, weak reducibility, and the disjoint curve property together as particular values of a *distance function on splittings*, which we will discuss further in §6. The main question that we will discuss in §6 is: how do we translate information in the Heegaard diagram into geometric data for a hyperbolic manifold?

2. Curve complexes

In view of the foregoing discussion, one is naturally led to consider a combinatorial object which captures the disjointness relation among simple closed curves (up to homotopy) on a surface. Actually when Harvey introduced the complex of curves in [63], [64] he was motivated by analogy, in the setting of $\mathcal{MCG}(S)$, with Bruhat–Tits buildings for Lie groups. We will now give some precise definitions, which are somewhat more tedious than one would hope because of the need to deal with a few special cases.

2.1. Definitions. Let $S = S_{g,b}$ be an orientable compact surface with genus g and b boundary components. An *essential simple curve* in S will, for us, be an embedded circle in S which is homotopically non-trivial, and not homotopic into ∂S (non-peripheral).

Let $\mathcal{C}(S)$ denote the simplicial complex whose vertices are homotopy classes of essential simple curves on S, and whose k-simplices are, except in a few sporadic cases described below, defined to be $(k+1)$-tuples of distinct vertices $[\alpha_0, \ldots, \alpha_k]$ whose representatives can be chosen to be pairwise disjoint. One may check that, when S has negative Euler characteristic, that there are at most $\xi(S) \equiv 3g - 3 + b$ such curves, and so $\dim \mathcal{C}(S) = \xi(S) - 1$. Although $\mathcal{C}(S)$ is finite dimensional, it is not locally finite, and this complexity accounts for much of the interest in studying and applying it. We let $\mathcal{C}_k(S)$ denote the k-skeleton of $\mathcal{C}(S)$.

Sporadic cases. For $S_{0,b}$ with $b \leq 3$ the complex is empty (although the annulus $S_{0,2}$ will later play an important role in a different way). For the tori $S_{1,0}$ and $S_{1,1}$, and for the 4-holed sphere $S_{0,4}$, the above definition gives a 0-dimensional complex. It turns out to be useful to add edges according to the rule that $[vw]$ is an edge if v and w have representatives that intersect once (in the case of the tori) or twice (in the case of the sphere). This forms our definition of $\mathcal{C}(S)$ for these cases.

Examples. For $S_{1,0}$ and $S_{1,1}$, simple curves are identified by their slopes in homology, i.e. $\mathcal{C}_0(S) \cong \mathbb{Q} \cup \{\infty\}$. Edges correspond to edges of the *Farey triangulation* of the disk, that is $\left[\frac{p}{q}, \frac{r}{s}\right]$ is an edge iff $|ps - qr| = 1$ (with fractions in lowest terms). See Figure 1. $\mathcal{C}(S_{0,4})$ is also isomorphic to $S_{1,1}$, with the isomorphism obtained from the fact that $S_{1,0}$ or $S_{1,1}$ modulo the hyperelliptic involution, and punctured at the fixed points, is $S_{0,4}$.

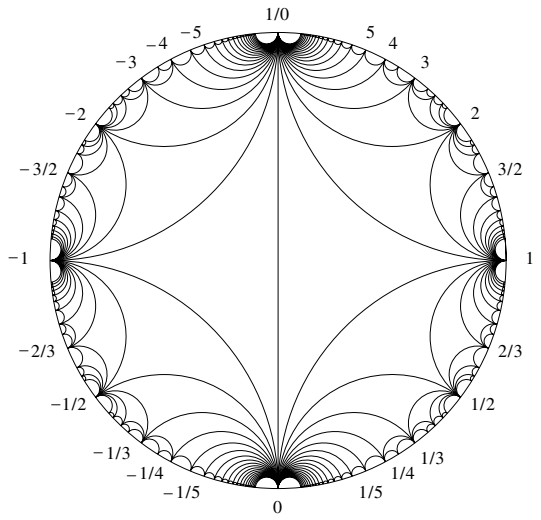

Figure 1. The Farey triangulation is the curve complex of $S_{1,0}$, $S_{1,1}$ and $S_{0,4}$.

For $S = S_{0,5}$ and $S_{1,2}$ (the case $\xi(S) = 2$), $\mathcal{C}(S)$ is again a graph, and in fact the two are isomorphic (again via the hyperelliptic involution). The link of a vertex $v \in \mathcal{C}(S_{0,5})$ is $\mathcal{C}_0(S_{0,4}) = \mathbb{Q} \cup \{\infty\}$.

Mapping class group action. $\mathcal{MCG}(S)$ acts naturally on $\mathcal{C}(S)$ and since homeomorphisms preserve disjointness it acts by simplicial automorphisms, and the quotient is easily seen to be finite (the set of vertices $[\alpha]$ of $\mathcal{C}(S)/\mathcal{MCG}(S)$, for example, is indexed by the topological type of $S \setminus \alpha$). The action is far from proper, as the large stabilizer in (1) indicates (we now recognize Δ as a simplex in $\mathcal{C}(S)$).

Nevertheless the simplicial structure of $\mathcal{C}(S)$ records all of the structure of $\mathcal{MCG}(S)$ in the following sense:

Theorem 2.1 (Ivanov [75], Luo [86], Korkmaz [82]). *The map $\mathcal{MCG}(S) \to \mathrm{Aut}(S)$ is an isomorphism in all cases except for $S_{1,2}$, where it is injective with index 2 image.*

(Ivanov proved this for genus at least 2. Luo and Korkmaz proved the remaining cases, with Luo's proof giving a unified argument.)

Hatcher–Thurston [67] defined a closely related complex and used it to give a presentation for $\mathcal{MCG}(S)$. Harer [61], [60] computed the homotopy type of $\mathcal{C}(S)$ and related complexes, and used it to study the homology of $\mathcal{MCG}(S)$. Hatcher [65] gave simplified proofs of contractibility for related complexes of arcs in a punctured surface.

2.2. Geometric structure. As the local structure of $\mathcal{C}(S)$ is rather intricate, it turns out that something can be gained by attempting to ignore it. First let us view $\mathcal{C}(S)$ as a metric space by making each simplex standard Euclidean with sidelength 1, say, and taking the path metric (a theorem of Bridson [24] assures us that this makes it into a complete geodesic metric space). It will sometimes be simpler to consider the path metric just on the 1-skeleton $\mathcal{C}_1(S)$. These two metric spaces are quasi-isometric, and we will be interested in coarse features such as quasi-geodesics, quasi-isometric type, etc.

Hyperbolicity. With Masur in [94], we proved the following theorem:

Theorem 2.2. *In all nontrivial cases $\mathcal{C}(S)$ is an infinite diameter δ-hyperbolic metric space.*

The usual definition of δ-hyperbolic, due to Rips, Gromov and Cannon, is equivalent for complete path metric spaces to the *δ-thin triangles property:* each leg of a geodesic triangle is contained in a δ-neighborhood of the other two legs.

Examples. Typical examples to keep in mind are metric trees, classical hyperbolic spaces, and Cayley graphs of fundamental groups of closed negatively curved manifolds. $\mathbb{R}^n$ and $\mathbb{Z}^n$ are not δ-hyperbolic when $n > 1$, and in fact any group that contains a $\mathbb{Z}^2$ subgroup does not have a δ-hyperbolic Cayley graph. Note, this includes $\mathcal{MCG}(S)$ for non-sporadic S.

The proof of Theorem 2.2 involved the construction of a family of paths in $\mathcal{C}(S)$ using geodesics in the Teichmüller space of S. If to each point along a Teichmüller

geodesic we associate the set of shortest curves in the associated metric, we obtain a "quasi-path" in $\mathcal{C}(S)$. Properties of quadratic differentials and their foliations were used to construct a "quasi-retraction" from $\mathcal{C}(S)$ to such a path, which has certain strong contraction properties that imply that $\mathcal{C}(S)$ is hyperbolic, and the paths are quasi-geodesics.

See Bowditch [22] for a considerable simplification of this proof, which in particular provides explicit upper bounds for δ, logarithmic in $\xi(S)$.

Laminations and boundary. A δ-hyperbolic space has a natural boundary at infinity, whose points are equivalence classes of "fellow-traveling" quasigeodesic rays. Klarreich's theorem describes this boundary, and relates it to Thurston's theory of geodesic laminations on surfaces.

Fix a complete, finite-area hyperbolic metric on $\mathrm{int}(S)$. A geodesic lamination on a complete hyperbolic surface is a closed set which is a disjoint union of complete simple geodesics. For example, a closed geodesic loop is a lamination, and a sequence of such loops whose lengths increase without bound will have a subsequence that converges on compact sets to a geodesic lamination, in the Hausdorff topology. Thurston used this notion to complete the set of geodesic loops in S. (His construction involved additional structure – he considers laminations equipped with *transverse measures* – but we will ignore this point here).

We note also that different choices of hyperbolic structures give rise to canonically homeomorphic representations of the space of geodesic laminations, so we may consider this as an intrinsic topological object (see Hatcher [66]).

Of interest to us will be the set of *filling* laminations, which we denote $\mathcal{EL}(S)$. A lamination is filling if it intersects every simple closed geodesic. $\mathcal{EL}(S)$ comes with a natural topology (which is somewhat coarser than the topology of Hausdorff convergence, and involves the transverse measures).

Example. For $S_{1,1}$ and $S_{0,4}$ we have seen that $\mathcal{C}_0(S)$ can be identified with $\mathbb{Q} \cup \{\infty\}$. The set of all laminations is the circle $\mathbb{R} \cup \infty$, with irrational slopes corresponding to filling laminations.

Klarreich's theorem states the following:

Theorem 2.3 (Klarreich [79]). *The boundary of $\mathcal{C}(S)$ is naturally homeormorphic to $\mathcal{EL}(S)$.*

The proof uses the same Teichmüller-geodesic paths used in the proof of hyperbolicity. A Teichmüller ray has a "foliation at infinity" whose length shrinks exponentially as one travels along the ray. These foliations correspond to the laminations in $\mathcal{EL}(S)$ (see Levitt [85] for the general correspondence between foliations and laminations). An alternate proof was found by Hamenstädt [59], using the machinery of train-tracks.

The topological structure of $\mathcal{EL}(S)$ is still somewhat mysterious. It is not known for example if it is disconnected, except in the case $\xi = 1$ where it is the set of irrationals in $\mathbb{R}$ (this question was first raised by P. Storm).

3. Nested structure

The coarse information given by the hyperbolicity theorem is hard to use by itself. With Masur in [95], we refine the coarse approach by applying it to the link structure of $\mathcal{C}(S)$. The link of a simplex in $\mathcal{C}(S)$ is closely related to the curve complex of a subsurface of S, and hence the idea here is to use coarse geometry in an inductive way, looking successively at finer levels of structure.

Subsurfaces and partitions. Let W be an essential subsurface of S, and suppose first that $\xi(W) > 1$. It is evident that $\mathcal{C}(W)$ is a subcomplex of $\mathcal{C}(S)$, contained in the link of the simplex $[\partial W]$. The remaining cases, namely when W is an annulus, one-holed torus and four-holed sphere, cause a certain amount of extra trouble. For $W = S_{1,1}$ and $W = S_{0,4}$, for example, all the vertices of $\mathcal{C}(W)$ are vertices of $\mathcal{C}(S)$, but the edges are not edges of $\mathcal{C}(S)$, due to the special definition of $\mathcal{C}(W)$ in that case. When W is an annulus, $\mathcal{C}(W)$ is empty but we will want something that will correspond to the Dehn twist group around W. (If $W = S_{0,3}$ then $\mathcal{C}(W) = \emptyset$ also, and we will be happy with that).

So, let us make the following new definitions. Let W be a surface with nonempty boundary. Let $\mathcal{A}(W)$ be the complex whose vertices are essential curves (i.e. vertices of $\mathcal{C}(W)$) and properly embedded essential arcs. Except when W is an annulus, we consider these things up to isotopy rel boundary, and "essential" for arcs means not isotopic into the boundary. For an annulus we take the isotopies to have fixed endpoints. Simplices are sets of arcs and curves that have representatives with disjoint interiors. This makes $\mathcal{A}$ infinite dimensional for an annulus, but it is still quasi-isometric to $\mathbb{Z}$. For $\xi(W) > 1$, we note that $\mathcal{C}(W)$ embeds in $\mathcal{A}(W)$ and this embedding is a quasi-isometry (when $\xi(W) = 1$ there is a quasi-isometry which is not quite an embedding).

If Δ is a simplex of $\mathcal{C}(S)$, let $\sigma(\Delta)$ be the union of components of $S \setminus \Delta$ which are not 3-holed spheres, together with annuli whose cores are components of Δ. This is called the "partition" of Δ. We let $lk^*(\Delta)$ denote the join of $\mathcal{A}(W_i)$ over all components $W_i \in \sigma(\Delta)$.

We think of $lk^*(\Delta)$ as an "extended link" for Δ. The actual link of Δ is the join of the complexes for components of $S \setminus \Delta$ of $\xi > 1$, and the 0-skeletons of the complexes for $\xi = 1$ components. The annular factors are not visible in the link; they can be detected in the neighborhood of radius 2, however.

Basic geometric properties. There is a small number of geometric properties of $\mathcal{C}(S)$ which connect global geometry to geometry in the extended links lk^*, and are responsible for most of the rest of our analysis. In outline they are the following:

1. *Hyperbolicity at all levels.* By Theorem 2.2 $\mathcal{C}(S)$ is hyperbolic, and furthermore for every simplex Δ, $lk^*(\Delta)$ is the join of the hyperbolic complexes associated to the components of $\sigma(\Delta)$.

2. *Subsurface projection bounds.* There is a natural projection from $\mathcal{C}(S)$ minus a neighborhood of $[\partial W]$ to $\mathcal{A}(W)$, where W is an essential subsurface. A geodesic in $\mathcal{C}_1(S)$ which stays out of this neighborhood has uniformly bounded projection image.
3. *Hierarchy paths and rigidity.* There is a distinguished family of quasigeodesic paths in the graph of markings on S (see below) which are controlled in a strong way by the subsurface projections of their endpoints.

Subsurface projections. For any essential $W \subset S$ there is a useful map

$$\pi_W : \mathcal{C}(S) \to \mathcal{A}(W) \cup \{\emptyset\}.$$

Namely, given a point $x \in \mathcal{C}(S)$, let δ be the simplex whose interior contains x. There is a unique cover of S to which W lifts homeomorphically, and this cover has a natural compactification $\overline{W}$ that identifies it with W (inherited from the natural compactification of the universal cover of S). Each component of δ lifts to a system of curves and/or arcs in $\overline{W}$, and the essential ones define vertices of $\mathcal{A}(W)$. The union over all vertices of δ gives a (possibly empty) simplex in $\mathcal{A}(W)$, and barycentric coordinates of x in δ push forward to define a unique point in this simplex, which is $\pi_W(x)$. Note that $\pi_W(x) = \emptyset$ only if δ has no essential intersections with W. (See also Ivanov [74] for a version of π_W).

One can think of this map as analogous to visual projection from $X \setminus \{x\}$ to the unit sphere around x, for a reasonably nice space X.

Link projection bounds. In [95], we proved the following theorem:

Theorem 3.1. *Let $W \subset S$ be an essential surface. let g be a geodesic in the 1-skeleton of $\mathcal{C}(S)$ all of whose vertices intersect W essentially. Then*

$$\operatorname{diam}_{\mathcal{A}(W)}(g) \leq B$$

where B depends only on the topological type of S.

A motivational analogy for this theorem may be found in the setting of CAT(0) complexes. (CAT(0) refers to non-positive curvature in the sense of comparison geometry, and in particular implies uniqueness of geodesics between points. See e.g. [25].) Let v be a point in a piecewise Euclidean CAT(0) complex X, and let $l(v)$ be its link, which we may identify with the unit "sphere" around v. There is a well-defined projection of $X \setminus \{v\}$ to $l(v)$, via geodesic segments from points in X to v, and the diameter $d_v(Y)$ of the projection of $Y \subset X \setminus \{v\}$ is the "visual diameter of Y". If g is a geodesic segment that avoids v then the cone of g onto v is an embedded triangle, and it follows that $d_{l(v)}(g) < \pi$. Conversely if $d_{l(v)}(g) \geq \pi$ it follows that g must pass through v.

The reason that this theorem holds in the curve complex, in spite of there not being a CAT(0) metric, is roughly the following: Let g be the geodesic and imagine that g

is extended to an infinite ray $\widehat{g}$, still with all vertices crossing W essentially (this is always possible in one direction or the other). Klarreich's theorem implies that $\widehat{g}$ converges to a filling lamination λ. The lift of λ to $\widehat{W}$ gives a point (or really simplex) in $\mathcal{A}(W)$, and since the vertices of $\widehat{g}$ converge to λ in a geometric sense, eventually their projections to $\mathcal{A}(W)$ are within bounded distance of the projection of λ. Thus $\operatorname{diam}_{\mathcal{A}(W)}(\widehat{g}) < \infty$.

Now to obtain the bound of Theorem 3.1, we need a uniform version of the above argument. This requires a more delicate analysis using some of the same machinery used to prove the hyperbolicity theorem.

Theorem 3.1 is the first step in a finer inductive study of the geometry of $\mathcal{MCG}(S)$. In order to describe this, we need to introduce some more terminology.

Markings and hierarchies. A convenient way to study the geometry of $\mathcal{MCG}(S)$ is to look at its action on the *marking graph* $\mathcal{M}(S)$. A marking μ of S is given by the following data: A maximal simplex of $\mathcal{C}(S)$, called base(μ), and a collection of *transversal curves* trans(μ), where each base curve α is equipped with one transversal curve t_α, which intersects α. t_α is disjoint from all other base curves, and α and t_α either intersect exactly once, or twice with opposite orientations (their regular neighborhood is then, respectively, $S_{1,1}$ or $S_{0,4}$). It is easy to see that $\mathcal{MCG}(S)$ acts on these markings with finite quotient and finite stabilizers. Moreover one can easily write down a simple finite list of "elementary moves" $\mu \to \nu$ such that the graph $\mathcal{M}(S)$ whose vertices are markings and whose edges are elementary moves is connected. Hence $\mathcal{M}(S)$, with the natural metric in which every edge has unit length, is quasi-isometric to $\mathcal{MCG}(S)$, which acts on it properly, cocompactly and isometrically.

In [95], we study a class of paths in $\mathcal{M}(S)$ which arise from an iterated construction in $\mathcal{C}(S)$ which we call a "hierarchy of geodesics".

Let us begin with an example (the same one treated extensively in [101]). If $S = S_{0,5}$ then $\mathcal{C}(S)$ is a graph, and a marking consists of two base curves and two transversals. Let μ and ν be two markings. Let $v_0, v_1, \ldots, v_N$ be the vertices of a geodesic in $\mathcal{C}_1(S)$ joining $v_0 \in \text{base}(\mu)$ to $v_N \in \text{base}(\nu)$. For $0 < i < N$ we note that v_i cuts S into $W_i \cong S_{0,4}$ and a three-holed sphere. Both v_{i-1} and v_{i+1} are vertices in $\mathcal{C}(W_i)$, and we may join them by a geodesic $v_{i-1} = u_0, \ldots, u_k = v_{i+1}$ in $\mathcal{C}_1(W_i)$. This gives us a sequence

$$[v_i, u_0], \ldots, [v_i, u_k]$$

of edges, or pants decompositions of S, with each step corresponding to a simple curve-replacement move. At the beginning we similarly join the second vertex of base(μ) to v_1 in W_0, and likewise at the end with base(ν). The result of this is a sequence of pants decompositions of S joining μ to ν, and separated by simple moves. Now consider an interior point u_j of the $\mathcal{C}(W_i)$-geodesic built over v_i. u_{j-1} and u_{j+1} intersect u_j, and they give two points in $\mathcal{A}(u_j)$, the annulus complex. We can join one to the other by a geodesic in $\mathcal{A}(u_j)$, which amounts to a sequence of Dehn twists. Something slightly subtle happens at the endpoints of the $\mathcal{C}(W_i)$-geodesics, which the

reader is invited to investigate. This procedure extends all the pants decompositions we built into markings, which can be traversed in a sequence of elementary moves from μ to ν.

In general something similar happens – starting with a geodesic in $\mathcal{C}_1(S)$ we inductively add geodesics in the extended links of the simplices traversed. (Actually we work with sequences of simplices called "tight geodesics", but we will ignore this technicality here). The final output of this procedure is not exactly a sequence of markings; this is because, when the process fills in two or more disjoint subsurfaces, the geodesics in those subsurfaces can be traversed in either order. That is, we are dealing with the unavoidable appearance of product regions in $\mathcal{M}(S)$. However the structure can be resolved (non-uniquely) into a sequence of markings connected by elementary moves. We call these *hierarchy paths*. The following theorem summarizes the properties of hierarchies and their paths established in [95]:

Theorem 3.2. *For any pair of points $\mu, \nu \in \mathcal{M}(S)$ there is a hierarchy and a family of hierarchy paths with the following properties.*

- Efficiency. *Hierarchy paths are quasigeodesics in $\mathcal{M}(S)$, with uniform constants.*
- Monotonicity. *For any essential $W \subseteq S$ and a hierarchy path β, $\pi_W \circ \beta$ traverses quasi-monotonically a bounded neighborhood of a geodesic between $\pi_W(\mu)$ and $\pi_W(\nu)$.*
- Forced traversals. *There is a constant B depending only on the topology of S such that if, for $W \subset S$, we have $d_W(\mu, \nu) > B$, then W appears in any hierarchy for μ and ν, and in particular any hierarchy path must have a subpath in which all the markings contain $[\partial W]$.*
- Partial ordering and stability. *There is a partial order defined among subsurfaces which appear in a hierarchy, such that any two subsurfaces which intersect essentially are ordered. If $W < Z$ in this order for a hierarchy from μ to ν then ∂W appears before ∂Z in any hierarchy path from μ to ν. If also $d_W(\mu, \nu)$ and $d_Z(\mu, \nu)$ are larger than a certain a priori constant, then this partial ordering is consistent over all hierarchies from μ to ν, and moreover for any ν' for which Z appears in a hierarchy from μ to ν', W is forced to appear as well.*

(We have abbreviated $d_{\mathcal{A}(W)}(\pi_W(\mu), \pi_W(\nu))$ as $d_W(\mu, \nu)$, and will continue to do this.) The Forced Traversals property is essentially a generalization of Theorem 3.1.

Distance formula. The partial ordering and monotonicity properties mean that the length of a hierarchy path is, roughly, the sum of the projection distances of its endpoints in all subsurfaces which it traverses. Moreover the forced traversals property implies that those subsurfaces traversed account for all subsurfaces in which these projection distances are sufficiently large. Any competing path from μ to ν is forced

to make up the same distances at some point, and this is the basic reason for the quasi-geodesic property of hierarchy paths. This argument also gives rise to the following Distance Formula, which plays an important role later on.

Theorem 3.3. *If $\mu, \nu \in \mathcal{M}(S)$,*

$$d_{\mathcal{M}(S)}(\mu, \nu) \approx \sum_{Y \subseteq S} \{d_Y(\mu, \nu)\}_K . \tag{2}$$

Some explanations are in order here: We define the expression $\{N\}_K$ to be N if $N > K$ and 0 otherwise – hence K functions as a "threshold" below which contributions are ignored. The constant K used depends only on the topological type of S, and the expression $f \approx g$ means $g/a - b < f < ag + b$ where $a > 1, b > 0$ are also a priori constants. Note that, if $W \subset S$ is an essential surface and $\mu \in \mathcal{M}(S)$ is a marking, then $\pi_W(\mu) \in \mathcal{A}(W)$ is always defined (up to finitely many choices), since some part of μ, possibly only a transversal curve, must intersect W essentially.

So this theorem is saying that, after throwing away the low-level "noise", only finitely many subsurfaces $W \subseteq S$ remain, and the projection distances in these account for the distance between μ and ν. Note also that the sum includes a term for $Y = S$, i.e. distance in the curve complex itself.

Geodesics in Teichmüller space. Just as Teichmüller geodesics play a role in the proof of hyperbolicity for $\mathcal{C}(S)$, the geometry of $\mathcal{C}(S)$ and its nested structure gives us some added understanding of Teichmüller geodesics. Rafi [112], [111] analyzed the extent to which the long-term behavior of a Teichmüller geodesic mirrors the combinatorial structure of a hierarchy, and also develops in [110] a distance formula in $\mathcal{T}(S)$ analogous to Theorem 3.3. See also Rees [113] for a related but independent study of Teichmüller geodesics.

4. Coarse geometry of $\mathcal{MCG}(S)$

The study of coarse geometric properties of abstract groups, by means of their Cayley graphs (or equivalently their word metric), can be traced back to the theorem of Milnor and Švarc [98], [128] on growth rates of groups, to Gromov's work [53] on groups of polynomial growth, and the introduction by Gromov [54] and Cannon [41], [42] of hyperbolic groups. This field is now enormous and we will not attempt to survey it. Some good general references are Gromov [55], [54] and Bridson–Haefliger [25].

We will be interested in examining phenomena of hyperbolicity, undistorted (quasi-isometrically embedded) subgroups, geometric rank, and asymptotic cones, as they relate to $\mathcal{MCG}(S)$. $\mathcal{MCG}(S)$ is not hyperbolic, but as we have already seen it is hyperbolic in a relative sense, through its action on the hyperbolic space $\mathcal{C}(S)$. Before we proceed let us record some of the usual definitions.

A map $f\colon X \to Y$ between metric spaces is *coarse Lipschitz* if a uniform inequality holds of the form

$$d(f(x), f(x')) \leq ad(x, x') + b$$

for all $x, x' \in X$. It is *coarsely bilipschitz*, or a *quasi-isometric embedding*, if the opposite inequality

$$d(x, x') \leq ad(f(x), f(x')) + b$$

holds as well. Finally we say that $f\colon X \to Y$ is a *quasi-isometry* if it is coarsely bilipschitz, and in addition there is an upper bound on $d(y, f(X))$ for all $y \in Y$.

We assume from now on that generators for $\mathcal{MCG}(S)$ are fixed, giving $\mathcal{MCG}(S)$ a word metric, which (as remarked in § 3) is quasi-isometric to $\mathcal{M}(S)$.

Quasi-isometrically embedded subgroups. One almost immediate consequence of the Distance Formula is this theorem:

Theorem 4.1. *Let Δ be a simplex in $\mathcal{C}(S)$. The subgroup* Stab(Δ) *is quasi-isometrically embedded in $\mathcal{MCG}(S)$. Moreover, there is a coarse-Lipschitz retraction $\mathcal{MCG}(S) \to$* Stab(Δ). *Finally,* Stab(Δ) *is quasi-isometric to a product*

$$\prod_{W \in \sigma(\Delta)} \mathcal{MCG}(W)$$

where $\sigma(\Delta)$ refers to the partition of S defined by Δ, as in § 3.

(For annular components of $\sigma(\Delta)$, we interpret $\mathcal{MCG}(W)$ to be the Dehn twist group of W).

The constants of the quasi-isometry and retraction depend on the choice of Δ. A uniform statement is obtained by fixing Δ and considering all left-cosets of Stab(Δ). More geometrically, and more in keeping with our approach, we consider the marking graph $\mathcal{M}(S)$, and within it the subsets $Q(\Delta)$ which consist of all markings whose base contains the simplex Δ. This subset is clearly quasi-isometric to Stab(Δ) and its left cosets. With this notation, what we produce is a coarse-Lipschitz retraction $\mathcal{M}(S) \to Q(\Delta)$, and a quasi-isometry

$$Q(\Delta) \cong \prod_{W \in \sigma(\Delta)} \mathcal{M}(W). \tag{3}$$

Where now the constants depend only on the topological type of S, and not on the choice of Δ. For an annulus W, $\mathcal{M}(W)$ is just $\mathcal{A}(W)$, which we recall is quasiisometric to $\mathbb{Z}$.

Example. If $S = S_{0,5}$ and $\Delta = [\delta_0, \delta_1]$ is an edge, then $Q(\Delta)$ is quasi-isometric to $\mathbb{Z}^2$ (and stabilized by the $\mathbb{Z}^2$ subgroup of Dehn twists about δ_0 and δ_1). If Δ is a vertex then $Q(\Delta)$ is quasi-isometric to $\mathbb{Z} \times \mathrm{SL}_2(\mathbb{Z})$, with the second factor corresponding to $\mathcal{M}(S_{0,4})$. Compare to the short exact sequence (1).

The quasi-isometric embedding part of the statement is a reflection of the fact that in the distance formula for two elements of $Q(\Delta)$, the only contributions come from terms that have no essential intersection with Δ, i.e. those that contribute also to the product over $\sigma(\Delta)$. See also Hamenstädt [57] for a proof of a similar statement using train-track technology.

The coarse retraction to $Q(\Delta)$ is built, inductively, using the subsurface projections described in the previous section. See Behrstock [7] for details. We call this retraction $\pi_{Q(\Delta)}$. The composition of $\pi_{Q(\Delta)}$ with projection to any of the factors $\mathcal{M}(W)$ of the product in (3) is called $\pi_{\mathcal{M}(W)}$, and it is well defined up to bounded ambiguity.

Asymptotic cones. Another way to quantify our coarse understanding of the group is to consider its *asymptotic cones*, which are rescaling limits of the group, in a certain sense. They were used implicitly by Gromov in [53], and introduced explicitly in Van den Dries–Wilkie [47]. In order to define the limit one resorts to the mechanism of *ultrafilters*, which can be briefly described as follows.

Let $X = (X, d)$ be a metric space, fix a sequence $s_n \to \infty$, and consider the metric spaces $(X_n, d_n) \equiv (X, \frac{1}{s_n} d)$, namely $X$with metric scaled down by $1/s_n$. We want, essentially, to consider the set of all "limiting pictures" of X_n, as $n \to \infty$. An *ultrafilter* is a way of organizing the natural numbers so as to pick out a convergent subsequence for every sequence of points in a compact space. More precisely, let ω be a *finitely additive probability measure* on $\mathbb{N}$, which is defined on every subset, and takes on only values of 0 and 1. Further, we assume ω is *non-principal*, meaning it is 0 on finite subsets. Existence of such measures is a nice exercise in using Zorn's lemma. If p_n is a sequence in a Hausdorff space T, we declare the ω-limit to be $\lim_\omega p_n = p$ if, for every neighborhood U of p, $\omega\{j : x_j \in U\} = 1$.

With this definition we find that *every* sequence in a compact space has a unique ω-limit. Now returning to X_n, we consider all sequences $\boldsymbol{x} = (x_n \in X_n)$. A pseudo-distance can be defined by

$$d_\omega(\boldsymbol{x}, \boldsymbol{y}) = \lim_\omega d_n(x_n, y_n)$$

which gives a point in $[0, \infty]$. Fixing a basepoint sequence $\boldsymbol{x}_0$ we can restrict to the subset $\{\boldsymbol{x} : d_\omega(\boldsymbol{x}_0, \boldsymbol{x}) < \infty\}$ and identify pairs $\boldsymbol{x} \sim \boldsymbol{y}$ whenever $d_\omega(\boldsymbol{x}, \boldsymbol{y}) = 0$. This gives a metric space, known as an asymptotic cone for X.

Note that this construction depends on the choice of scaling constants, ultrafilter ω, and basepoints. In our setting X will be $\mathcal{M}(S)$ (or equivalently $\mathcal{MCG}(S)$), and the basepoint will not matter because the space is (coarsely) homogeneous. The scaling constants and ultrafilter will be assumed fixed. We denote the asymptotic cone of $\mathcal{M}(S)$ by $\mathcal{M}^\omega(S)$.

Examples. The asymptotic cone of $\mathbb{Z}^n$ is always $\mathbb{R}^n$. The symptotic cone of a δ-hyperbolic space is an $\mathbb{R}$-tree, that is, a geodesic metric space in which any two points are joined by a unique embedded path. $\mathcal{MCG}(S_{1,1})$ and $\mathcal{MCG}(S_{0,4})$ are both commensurable with $\mathrm{SL}_2(\mathbb{Z})$, and hence with the free group F_2 whose Cayley graph

is a tree. Hence their asymptotic cones are $\mathbb{R}$-trees as well. (Note that these $\mathbb{R}$-trees have dense, and uncountable, branching).

A quasi-isometric embedding gives rise, after taking asymptotic cones, to a bilipschitz embedding. This allows us to replace coarse statements with topological statements, which is part of what makes asymptotic cones useful.

A sequence of subsets $Q(\Delta_i)$ of $\mathcal{M}(S)$ gives rise to an ω-limit which we denote by $\mathcal{Q}^\omega(\mathbf{\Delta}) \subset \mathcal{M}^\omega(S)$ (where $\mathbf{\Delta}$ denotes the sequence (Δ_i)). Theorem 4.1, or rather the quasi-isometry (3), immediately tells us that $\mathcal{Q}^\omega(\mathbf{\Delta})$ is a bilipschitz-embedded product of lower-complexity asymptotic cones, admitting a Lipschitz retraction from $\mathcal{M}^\omega(S)$.

This retraction and some related constructions are instrumental in studying separation and dimension properties of the asymptotic cone, as is done in Behrstock [7] and Behrstock–Minsky [8]. The main theorem of [8] is the following:

Theorem 4.2. $\widehat{\dim}\, \mathcal{M}^\omega(S) = \xi(S)$.

Here $\widehat{\dim}$ denotes the maximal topological dimension over all locally compact subsets of $\mathcal{M}^\omega(S)$.

A direct consequence of this is a proof of the "rank conjecture" of Brock–Farb [30], which states that $\xi(S)$ is the maximal rank of a quasi-isometrically embedded flat in $\mathcal{M}^\omega(S)$. Independently, Hamenstädt [58] proved this theorem by somewhat different means, establishing in particular a homological version of the dimension theorem. The main idea of our proof is to study certain families of separating sets, which we describe in more detail below.

Separation properties of the asymptotic cone. In Behrstock [7] it was shown that every point of $\mathcal{M}^\omega(S)$ is a cut point. An extension and refinement of Behrstock's construction leads to the following statement. First, let $r(W) = \xi(W)$ if W is a connected non-annular essential subsurface of S, $r(W) = 1$ if W is an essential annulus, and define it over disjoint unions to be additive. It is not hard to see that Theorem 4.2 for essential (but not necessarily connected) subsurfaces W in S should state that $\widehat{\dim}\, \mathcal{M}^\omega(W) = r(W)$, where $\mathcal{M}^\omega(W)$ is the product of $\mathcal{M}^\omega(W_i)$ over the components. (When W is an annulus in particular, note that $\mathcal{M}^\omega(W)$ is $\mathcal{A}^\omega(W) = \mathbb{R}$, hence the definition $r = 1$ in that case).

Theorem 4.3. *There is a family $\mathcal{L}$ of closed subsets of $\mathcal{M}^\omega(S)$ with the following properties:*

- *Each $L \in \mathcal{L}$ is either a single point, or is bilipschitz equivalent to $\mathcal{M}^\omega(W)$ for a (possibly disconnected) subsurface $W \subset S$ with $r(W) < r(S)$.*
- *For any $x, y \in \mathcal{M}^\omega(S)$ there exists $L \in \mathcal{L}$ which separates x from y.*

We call $\mathcal{L}$ "separators" of $\mathcal{M}^\omega(S)$. The case that $L \in \mathcal{L}$ is a single point is Behrstock's cut point theorem, and the theorem on topological dimension can be obtained

by induction (in a locally compact space, the existence of a family of separators like this with dimensions at most $n-1$ implies a dimension upper bound of n for the whole space. The lower bound is easy).

The idea of the proof is to find "rank 1 directions" in the cone, and establish the separators as "transverse sets" for these directions. Let us consider the special case of $S = S_{0,5}$, let $\boldsymbol{\delta} = (\delta_n)$ be a sequence of simple closed curves in S, and let $\mathcal{Q}^\omega(\boldsymbol{\delta})$ be the ω-limit of $Q_n(\delta_n)$. We know from Theorem 4.1 that $\mathcal{Q}^\omega(\boldsymbol{\delta})$ can be identified with $\mathbb{R} \times T$, where $\mathbb{R}$ is $\mathcal{M}^\omega(\delta)$, the asymptotic cone of the sequence of twist complexes $\mathcal{A}(\delta_n)$, and T is $\mathcal{M}^\omega(S \setminus \boldsymbol{\delta})$, the asymptotic cone of $\mathcal{M}(S \setminus \delta_n)$, which is an $\mathbb{R}$-tree since $S \setminus \delta_n \cong S_{0,4}$.

A separator associated to this picture is a subset of $\mathcal{Q}^\omega(\boldsymbol{\delta})$ of the form $\{s\} \times T$, which certainly separates $\mathcal{Q}^\omega(\boldsymbol{\delta})$, and has $\widehat{\dim} = 1$ since it is an $\mathbb{R}$-tree. To show that it has global separation properties we consider the map

$$\pi_{\boldsymbol{\delta}} \colon \mathcal{M}^\omega(S) \to \mathcal{M}^\omega(\boldsymbol{\delta}) = \mathbb{R}$$

which is the rescaled ω-limit of the projection maps from $\mathcal{M}(S)$ to $\mathcal{A}(\delta_n)$. This is certainly a Lipschitz map, and restricted to $\mathcal{Q}^\omega(\boldsymbol{\delta})$ becomes projection to the first factor. Globally, it has the following useful property:

Lemma 4.4. *$\pi_{\boldsymbol{\delta}}$ is locally constant in the complement of $\mathcal{Q}^\omega(\boldsymbol{\delta})$.*

To understand why this holds, consider a point $\boldsymbol{x} \in \mathcal{M}^\omega(S) \setminus \mathcal{Q}^\omega(\boldsymbol{\delta})$. $\boldsymbol{x}$ is a sequence (or rather an equivalence class of sequences) of markings (x_n) whose distance from $Q(\delta_n)$ is growing linearly (with respect to the scale constants s_n). Using the distance formula (Theorem 3.3), one can show that $d(x_n, Q(\delta_n))$ is estimated by

$$\sum_{Y \cap \delta_n \neq \emptyset} \{d_{\mathcal{A}(Y)}(x_n, \delta_n)\}_K \tag{4}$$

which is therefore growing linearly as well. The domains in the sum (4) are partially ordered by their appearance in any hierarchy from δ_n to x_n (see Theorem 3.2). Now if y_n is given where $d_{\mathcal{M}(S)}(x_n, y_n)$ is a (sufficiently small) fraction of s_n, then the stability property in Theorem 3.2 implies that most of these domains are forced to appear in the hierarchy from δ_n to y_n as well.

In particular, the boundaries of these domains cross δ_n, and with this one can then show that $\pi_{\delta_n}(x_n)$ and $\pi_{\delta_n}(y_n)$ are a bounded distance apart. In the rescaling limit, we conclude that there is a neighborhood of $\boldsymbol{x}$ on which $\pi_{\boldsymbol{\delta}}$ is constant.

Once this lemma is established, we see immediately that the complement of $L_s = \{s\} \times T$ in $\mathcal{M}^\omega(S)$ is a union of three disjoint open sets: $\pi_{\boldsymbol{\delta}}^{-1}((-\infty, s))$, $\pi_{\boldsymbol{\delta}}^{-1}((s, \infty))$, and $\pi_{\boldsymbol{\delta}}^{-1}(s) \setminus L_s$. This gives the desired separation property.

In the general setting, the tricky question is what should take the place of the $\mathbb{R}$ factor in $\mathcal{Q}^\omega(\boldsymbol{\delta})$. One might for example take a sequence $\boldsymbol{W} = (W_n)$ and look at the product decomposition

$$\mathcal{Q}^\omega(\partial \boldsymbol{W}) \cong \mathcal{M}^\omega(\boldsymbol{W}) \times \mathcal{M}^\omega(\boldsymbol{W}^c)$$

(where $\boldsymbol{W}^c = (W_n^c)$, and W_n^c denotes all the pieces except W_n in the partition $\sigma(\partial W_n)$.) There is a projection $\mathcal{M}^\omega(S) \to \mathcal{M}^\omega(\boldsymbol{W})$, but it does *not* have the required locally constant properties.

Instead we identify a certain decomposition of $\mathcal{M}^\omega(\boldsymbol{W})$ into $\mathbb{R}$-trees, and for each such tree F we consider the set

$$\mathcal{P}_F = F \times \mathcal{M}^\omega(\boldsymbol{W}^c) \subset \mathcal{Q}^\omega(\partial \boldsymbol{W}).$$

F now plays the role of the $\mathbb{R}$ factor in the example – there is a map $\mathcal{M}^\omega(S) \to F$ which is locally constant outside $\mathcal{P}_F$, and is projection to the first factor within $\mathcal{P}_F$. The sets $\{s\} \times \mathcal{M}^\omega(\boldsymbol{W}^c)$ are our separators.

This family of product regions and retractions gives a tractable structure for analyzing $\mathcal{M}^\omega(S)$. There is a reasonable hope that these techniques can lead to a good understanding of bilipschitz flats in $\mathcal{M}^\omega(S)$ and hence quasiflats in $\mathcal{M}(S)$, and more generally to a global understanding of the topology of the asymptotic cone. In particular we are hopeful, at the time of this writing, that this should yield another approach to showing the *quasi-isometric rigidity of* $\mathcal{MCG}(S)$. (This is the property that the group of quasi-isometries of $\mathcal{MCG}(S)$ is, up to bounded error, the same as the left-action of $\mathcal{MCG}(S)$ on itself). We note that Hamenstädt has announced a proof of quasi-isometric rigidity using her technique of analyzing train-track splitting sequences, which has a somewhat different flavor.

5. Hyperbolic geometry and ending laminations

The complex of curves, and the machinery of hierarchies, play an important role in the solution of Thurston's Ending Lamination Conjecture, a classification conjecture for the deformation space of a Kleinian group. We will give a brief description of this conjecture and its connection to the complex of curves; for more details see the expository article [102].

If G is a torsion-free, finitely generated group we may consider the set $AH(G)$ of (conjugacy classes of) discrete, faithful representations of G into $\mathrm{PSL}_2(\mathbb{C})$, the isometry group of hyperbolic 3-space $\mathbb{H}^3$. Equivalently $AH(G)$ is the set of marked hyperbolic 3-manifolds with fundamental group G. Let $N_\rho = \mathbb{H}^3/\rho(G)$ for $\rho \in AH(G)$.

Mostow/Prasad rigidity states that, if $AH(G)$ contains an element with finite volume, then in fact $AH(G)$ is a singleton – there is a unique hyperbolic manifold in the corresponding homotopy class. In the infinite volume case, there is a rich deformation theory, in which the dominant theme is that the geometry of a hyperbolic 3-manifold is controlled by its *ends*, which are in turn described by deformation theory of surfaces.

Let us sketch this structure briefly in rough historical order, focusing first on the case that G is $\pi_1(S)$, for a closed surface S (more about the general case below).

Fuchsian groups. If ρ takes values in $\mathrm{PSL}_2(\mathbb{R})$ then it leaves invariant the circle $\mathbb{R} \cup \infty$ in the Riemann sphere, and its convex hull the hyperbolic plane $\mathbb{H}^2 \subset \mathbb{H}^3$. The quotient is diffeomorphic to $S \times \mathbb{R}$, with a well-known warped product metric.

Kleinian groups. Poincaré perturbed Fuchsian groups in $\mathrm{PSL}_2(\mathbb{C})$ to obtain groups that are still topologically (in fact quasiconformally) conjugate to Fuchsian groups. In particular their quotients are still $S \times \mathbb{R}$. The circle becomes a Jordan curve, now defined as the *limit set* of ρ.

QC deformation theory. Bers and Ahlfors [2], [9] showed how to parameterize the entire quasiconformal deformation space of a Fuchsian group as $\mathcal{T}(S) \times \mathcal{T}(S)$. The idea is that the two sides of the limit set, modulo the group, give two Riemann surfaces, and conversely (the hard part) these Riemann surfaces can be arbitrarily prescribed using the Measureable Riemann Mapping Theorem.

Degenerations. Bers, Greenberg, Kra, Maskit, Marden and Sullivan [10], [12], [52, 83], [91], [89], [87], [88], [127] studied spaces of quasiconformal deformations, and particularly limits in which cusps are formed, and more exotic "degenerate groups" occur. The action on the Riemann sphere is no longer conjugate to the Fuchsian action (in particular the limit set is no longer a Jordan curve) but the quotient of $\mathbb{H}^3$ is still $S \times \mathbb{R}$ (this was initially known only in the case where the degeneration only involved cusp formation, i.e. the *geometrically finite* case).

Geometric tameness. Thurston proposed the notion of a geometrically tame group, whose convex core is swept out by pleated surfaces (see § 1). The convex core is the quotient of the hyperbolic convex hull of the limit set, and is also the smallest convex submanifold of N_ρ carrying the fundamental group. Geometrically finite manifolds have convex hulls of finite volume. He showed that if ρ is geometrically tame then N_ρ is still homeomorphic to $S \times \mathbb{R}$, and established tameness for certain limits of quasiconformal deformations. He defined the notion of *ending laminations* which, for the degenerate ends, take the place of the Riemann surfaces of Ahlfors–Bers.

Tameness for surface groups. Bonahon [19] established tameness for *all* surface groups $\rho \in AH(\pi_1(S))$, and more generally for all groups that have no free-product decomposition.

So far the description of $\rho \in AH(\pi_1(S))$ is that N_ρ is diffeomorphic to $S \times \mathbb{R}$, has two ends (corresponding to the two ends of $\mathbb{R}$), each of which has either a "Riemann surface at infinity" which describes its asymptotic structure, or an "ending lamination" which we describe now. (We are oversimplifying – when cusps are present we should cut along them and obtain a larger collection of ends).

In language amenable to our curve-complex discussion, we can define the ending laminations as follows: If one end of N_ρ is degenerate, it is filled by a sequence of pleated surfaces homotopic to $S \times \{0\}$. Each such surface contains simple curves of uniformly bounded length, and these must go to infinity in $\mathcal{C}(S)$. They converge to a point in $\partial\mathcal{C}(S) = \mathcal{EL}(S)$ (this is by no means obvious and is a major ingredient in the work of both Thurston and Bonahon).

Thurston's Ending Lamination Conjecture is then the following statement:

Theorem 5.1 (Brock–Canary–Minsky [99], [29], [28]). *A hyperbolic* 3*-manifold with finitely-generated fundamental group is uniquely determined by its topological type and its list of end invariants.*

This theorem gives a complete classification of the deformation space of a Kleinian group, and this has a number of consequences. For example, it is an ingredient of the proof of the Bers–Sullivan–Thurston Density Conjecture, which states that the geometrically finite (or equivalently structurally stable) representations are dense in the deformation space of any group. (This proof, whose outline was in place since the work of Thurston and Bonahon, required for its completion also the work of Kleineidam–Souto [80], Lecuire [84], Kim–Lecuire–Ohshika [71], and Namazi–Souto. An alternate treatment was given by Rees [114]. A completely different, rather surprising proof which works at least in the incompressible-boundary case was given by Bromberg [33] and Brock–Bromberg [27], before Theorem 5.1 was established.)

On the other hand, the Ending Lamination Conjecture does not give us a complete understanding of the geometry and topology of Kleinian deformation spaces. In fact this structure turns out to be considerably more complex than originally suspected, and perhaps too complex for any neat description. See e.g. Anderson–Canary–McCullough [3], Bromberg [34], Bromberg–Holt [36], Ito [73], McMullen [97].

A little about the proof. We begin by attempting to understand the *bounded-length curves* in N_ρ – that is to locate the homotopy classes in S of those curves whose geodesic representatives in N_ρ satisfy some fixed length bound. As above, many such curves exist because of the presence of pleated surfaces.

The structure of $\mathcal{C}(S)$ comes in naturally here because, as observed in the introduction, if $[vw]$ is an edge in $\mathcal{C}(S)$ then there is a pleated surface mapping v and w simultaneously to geodesics. Thus we study the *length function*

$$\ell_\rho \colon v \mapsto \ell(\rho(v))$$

on $\mathcal{C}(S)$, associating to each vertex the length of the corresponding closed geodesic in N_ρ. The ending laminations are accumulation points, on the boundary at infinity $\partial\mathcal{C}(S) \cong \mathcal{EL}(S)$, of the set $\{\ell_\rho \le L_0\}$ where L_0 is a fixed constant depending on the topology of S. The initial geometric result linking the geometry of N_ρ with that of $\mathcal{C}(S)$ is

Theorem 5.2 ([100]). *The sublevel set*

$$\{v \in \mathcal{C}(S) : \ell_\rho(v) \le L\}$$

is quasiconvex for $L \ge L_0$.

This gives some kind of very rough control, but as in the discussion of the mapping class group, we need to somehow refine this by looking at the link structure of

the complex. This is accomplished in [99], where we show that, for any essential subsurface $W \subset S$, the projection

$$\pi_{\mathcal{A}(W)}(\{v : \ell_\rho(v) \leq L\}) \tag{5}$$

is also quasiconvex. In the end, this refined control leads to a theorem about hierarchies. We extend the notion of a finite hierarchy to an infinite one whose "endpoints" are filling laminations, and establish a statement of this type:

Theorem 5.3 ([99]). *Given an end-invariant pair (ν_-, ν_+) in a surface S, there exists a hierarchy of geodesics H in $\mathcal{C}(S)$ connecting ν_- to ν_+, such that, if $\rho \in AH(\pi_1(S))$ has end invariants $\nu_\pm$ then*

1. *All the vertices that appear in H have uniformly bounded ρ-length.*
2. *All sufficiently ρ-short curves do appear in H, and the geometry of their Margulis tubes can be estimated from the data in H.*
3. *The order in which the Margulis tubes are arranged in N_ρ is consistent with the order of hierarchy paths of H.*

By "sufficiently" and "uniformly", we refer to bounds that depend only on the topological type of S, and not on ρ or $(\nu_\pm)$.

In order to prove this theorem, we study the map $\Pi\colon \mathcal{M}(S) \to \mathcal{M}(S)$ which maps a marking μ to a marking of minimal length in a pleated surface that maps base(μ) to its geodesic representative in N_ρ. In fact this map plays an important role in the proof of Theorem 5.2 and its generalization (5). Its "shadow" in the complex of curves, for example, is a map from $\mathcal{C}(S)$ to $\{v \in \mathcal{C}(S) : \ell_\rho(v) \leq L\}$ which we show is coarsely Lipschitz and coarsely the identity on its target – i.e. a coarse Lipschitz retraction. In a δ-hyperbolic space, the image of such a map is quasi-convex, and furthermore has the stability property that any geodesic with endpoints in $\{\ell_\rho(v) \leq L\}$ must be mapped uniformly close to itself.

A generalization of this argument shows, for any μ in a hierarchy path associated to H, that

$$d_{\mathcal{A}(W)}(\mu, \Pi(\mu))$$

is uniformly bounded, for *any* essential W. The distance formula of Theorem 3.3 now shows that μ and $\Pi(\mu)$ are a uniform distance apart in $\mathcal{M}(S)$, and in particular it follows that the length of base(μ) in N_ρ is uniformly bounded. These *a priori* bounds are the main step, and make the proof of the rest of the theorem possible.

Theorem 5.3 enables us to build a *combinatorial model* M_ν for the geometry of N_ρ, which depends only on the end invariants themselves, and show (in [29]) that M_ν and N_ρ are bilipschitz homeomorphic. Hence two N_ρ's with the same end invariants are bilipschitz equivalent to each other, and Sullivan's rigidity theorem [126] then implies that they are isometric.

The structure of the model, very roughly, is this: M_ν, which we identify topologically with $S \times \mathbb{R}$, contains a union $\mathcal{U}$ of level solid tori, i.e. regular neighborhoods of

curves of the form $\gamma \times \{t\}$. Each of these solid tori is given the geometry of a Margulis tube. The complement of $\mathcal{U}$ is broken up into "blocks", each of which falls into a finite number of topological types $F \times [-1, 1]$ and a compact set of geometric shapes. The tubes and the boundaries of the block surfaces F all correspond to vertices in the hierarchy. (We are oversimplifying a bit by not describing the cases where there are cusps, or where the convex core is not the whole manifold). See [101] for a detailed exposition of this construction when $S = S_{0,5}$.

The general case. Most of the geometry discussed above applies to any π_1-injectively immersed surface in a hyperbolic 3-manifold, by considering the appropriate cover. In particular, a general hyperbolic N with finitely-generated fundamental group has a *compact core* $K \subset N$ (Scott [121], McCullough [96]) whose inclusion is a homotopy-equivalence, and when ∂K is incompressible we can apply the same technique to understand the *ends* of N, i.e. the components of $N \setminus K$.

When K has compressible boundary the situation is more delicate, but a collection of, by now, well-known techniques, together with the resolution by Agol [1] and Calegari–Gabai [39] of Marden's Tameness Conjecture, allow us again to extend the arguments.

The Tameness Conjecture (now theorem) states that N is homeomorphic to the interior of K, or equivalently K can be chosen so that $N \setminus K \cong \partial K \times \mathbb{R}$. (This was not obvious in the incompressible boundary case either, but was established by the work of Thurston and Bonahon [130], [19]).

Canary [40] showed that the end of a tame hyperbolic 3-manifold is isometric to an *incompressible* end of a 3-manifold with *pinched negative curvature*. This is done by means of lifting to an appropriately chosen branched cover. Working in this branched cover we can apply the techniques that worked in the incompressible boundary case to obtain again a bilipschitz model for the ends.

One disadvantage of this technique is that *uniformity* of the model no longer holds. Whereas in the case of $S \times \mathbb{R}$ the quality of our estimates depended only on the topological type of S, in general even the topology of the branched cover construction depends on the geometry, via the choice of branching locus. Outside some compact set our model does have uniform quality, but there is no uniform control on the size of this compact set, and hence no uniform overall model. This issue plays a role in the next section as well.

Our proof in the compressible-boundary case [28] has still, alas, not appeared. However, accounts (with alternative proofs) are available by Bowditch [23] and Rees [114]. Namazi [106] has also written down some of the tools needed to attack the compressible case.

6. Heegaard splittings

By Mostow's theorem, the geometry of a closed hyperbolic 3-manifold is uniquely determined by its topology. There does not, however, presently exist an effective general way of describing the geometry from topological data. Let us examine a specific version of this question, namely how the data of a Heegaard splitting give us geometric (and for that matter, topological) information.

The genus, of course, is the first interesting piece of data, and in particular Heegaard splittings of minimal genus (called the *Heegaard genus*) should be of interest. The genus clearly bounds from above the rank of the fundamental group, but no general bound exists in the opposite direction. Boileau–Zieschang [18] first gave examples with rank 2 and genus 3. Irreducible examples giving arbitrarily large difference between genus and rank have been found by Schultens–Weidmann [120] – these examples are all graph manifolds. There are no hyperbolic examples with rank smaller than genus, and one may speculate that they are equal, or more conservatively that rank gives some explicit upper bound on genus in the hyperbolic setting. Some partial results in this direction are due to Namazi-Souto [107] and Souto [125]. Bachman–Cooper–White [4] have shown that the Heegaard genus gives an upper bound for the injectivity radius at any point in a hyperbolic 3-manifold. Their methods involve "sweepouts" a la Pitts–Rubinstein, and should have further applications (see also Souto [125]). There are many related questions, e.g. behavior of tunnel number for knot complements, which we will not touch here. Instead we will concentrate on fixing a genus and obtaining geometric information from the complexity of the gluing map between the two handlebodies.

Let H_+ and H_- denote the pair of handlebodies of a Heegard splitting of a 3-manifold M, with $S = \partial H_+ = \partial H_-$. This defines two *meridian sets*, $\mathcal{D}_+$ and $\mathcal{D}_-$ in $\mathcal{C}(S)$, namely those simple curves that are the boundaries of essential disks in H_+ and H_- respectively. In turn, $\mathcal{D}_\pm$ determine the pair (M, S) uniquely. Note that $\mathcal{D}_\pm$ contain all possible Heegaard diagrams for the splitting.

Hempel distance. Hempel [68] pointed out that the quantity

$$d(M, S) = d_{\mathcal{C}(S)}(\mathcal{D}_+, \mathcal{D}_-),$$

called "Heegaard distance" or "Hempel distance" (where $d_{\mathcal{C}(S)}$ denotes minimal distance between the two sets), is a useful indication of complexity which generalizes the notions of weak and strong reducibility we mentioned in the introduction. Indeed it is not hard to see that the definitions from the introduction translate this way:

- $d(M, S) = 0$ iff the splitting is reducible;
- $d(M, S) \leq 1$ iff the splitting is weakly reducible;
- $d(M, S) \leq 2$ iff the splitting has the disjoint curve property;
- $d(M, S) \geq 2$ iff the splitting is strongly irreducible.

Moreover Hempel showed that there are splittings with arbitrarily large distance. As mentioned in the introduction (see also Thompson [129]), Hempel showed that if M is Seifert fibred or has an essential torus then $d(M, S) \leq 2$. One can also check that $d(M, S) \leq 2$ for all remaining geometrizable non-hyperbolic cases, and Hempel therefore conjectured that

$$d(M, S) \geq 3 \quad \Longrightarrow \quad M \text{ is hyperbolic.}$$

Perelman's work on Thurston's geometrization conjecture, once accepted, implies that this conjecture holds.

Schleimer [119] proved that, if M is fixed, then there are at most finitely many (isotopy classes of) Heegaard surfaces with $d(M, S) > 2$. This is a sort of rigidity property for high-distance splittings, and suggests that they should convey topological information.

Hartshorn [62] obtained upper bounds on Hempel distance in the presence of incompressible surfaces, using ideas of Kobayashi [81]. Bachman–Schleimer [5], [6] obtain related results for knots and surface bundles. Scharlemann–Tomova [118] have obtained distance bounds from the interaction of pairs of splittings in a manifold.

However, one soon observes that $d(M, S)$ by itself is far from being an accurate measure of complexity. For example, for fixed g one can find hyperbolic manifolds, of arbitrarily high volume, which have a (minimal) genus g splitting of distance 1 (see Souto [123]).

One should really look at a more refined comparison of $\mathcal{D}_+$ and $\mathcal{D}_-$, much as in § 5 we looked at hierarchies connecting end invariants rather than plain geodesics in $\mathcal{C}(S)$ connecting them.

If $\mathcal{P}_+$ is the set of pants decompositions of S composed of meridian curves in H_+ (and similarly $\mathcal{P}_-$) we could for example consider the combinatorial distance $d(\mathcal{P}_+, \mathcal{P}_-)$, by which we mean the distance in the "graph of pants decompositions" as in [26]. This distance, by a triangulation argument, gives an upper bound for the hyperbolic volume. Brock–Souto [31] have formulated a slightly different combinatorial distance (enlarging $\mathcal{P}_\pm$ to include more pants decompositions) which gives both upper and lower bounds.

Geometric models for handlebodies. One is naturally led from Heegaard splittings into the related problem of describing hyperbolic structures on a *single* handlebody. If one were to have a recipe for handlebodies one could attempt to glue them together and obtain models for Heegaard splittings. Namazi carried this out in [106] for a special family of splittings.

A partial answer was provided by the Ending Lamination construction, namely a geometric model for the end of the manifold. As mentioned above, this model was lacking in uniformity. In other words the work of [28] partitions a hyperbolic handlebody N into a compact handlebody K and an end E homeomorphic to $\partial K \times (0, \infty)$.

We provide a bilipschitz model for E of uniform quality, but give no information at all about the geometry of K.

What sort of geometric pictures do we expect to find? Let us describe a motivating list of examples, drawn from work of Namazi and Brock–Souto. When we say a subset of a manifold has *bounded geometry* here, we mean that, within the family of examples in question, it is drawn from a compact set of possibilities.

Capped-off products. One can construct hyperbolic handlebodies H for which there is a decomposition $H = E \cup K$, with K a compact handlebody with bounded geometry and E bilipschitz-equivalent to an end of an $S \times \mathbb{R}$. Indeed, Namazi [106] exhibited a family of such manifolds whose end invariants satisfy a *bounded combinatorics* condition, and which furthermore satisfy a lower bound on injectivity radius.

Small 1*-handles.* There are hyperbolic handlebodies H which admit a decomposition $H = E \cup B \cup K_1 \cup K_2$, where K_1 and K_2 are handlebodies of lower genus, each K_i is bilipschitz equivalent to the convex hull of a "capped off product" as above, B is a 1-handle of bounded geometry joining K_1 to K_2, and E is bilipschitz equivalent to an end of an $S \times \mathbb{R}$, and is attached along its bottom boundary to the handlebody $K_1 \cup B \cup K_2$.

Brock–Souto show that this (with variations in the number and arrangement of the pieces and 1-handles) is the structure of a general hyperbolic handlebody with a uniform lower bound on injectivity radius

Incompressible I-bundles. After representing a (closed) handlebody as $F \times [-1, 1]$ where F is a compact surface with boundary, let γ be a copy of $\partial F \times \{0\}$ pushed slightly into the interior H. One can find a hyperbolic structure on $H \setminus \gamma$ which makes the components of γ into cusps, and then after a geometric step known as "Dehn filling" obtain a hyperbolic structure on H where γ is extremely short. This can be done so that the geometry of H, outside the Margulis tubes of γ, is essentially that of a surface group with cusps based on F, and hence is described by a model manifold of the type used for the Ending Lamination Conjecture.

Tubes with 1*-handles* One can start with a finite number of Margulis tubes (solid tori), and join them with 1-handles of bounded geometry.

These examples can be combined – for example the tubes with 1-handles can serve as a core to which a standard product end is added, and the product structure example can be attached to something else using a 1-handle, or a peripheral annulus. This can be done geometrically via the Klein–Maskit combination theorem [90], the Ahlfors–Bers deformation theory [11], and variations on Thurston's Dehn filling construction (see Bonahon–Otal [21], Bromberg [32], [35], Comar [45], Hodgson–Kerckhoff [70]).

We expect that any handlebody will have a decomposition into pieces of this type. An interesting challenge is to *predict* from the topological data what pieces actually occur. In other words, starting with a pair $(\mathcal{D}, \mu)$ where $\mathcal{D}$ is a meridian set and μ an end invariant on S, we would like to give such a decomposition, whose structure and the shape of the pieces (e.g. boundary structure of the Margulis tubes, and end invariants of the I-bundle pieces) can be read off from the input data.

Geometry of $\mathcal{D}$. A first step toward the goal of providing uniform geometric models is to understand the structure of $\mathcal{D}$ and how it embeds in $\mathcal{C}(S)$. With Masur in [92] we proved

Theorem 6.1. *$\mathcal{D}$ is a quasi-convex subset of $\mathcal{C}(S)$.*

This is analogous to Theorem 5.2 on quasiconvexity of the bounded-curve set in the incompressible setting.

The next step might be to analyze projections of $\mathcal{D}$ into subsurfaces. Very roughly, one expects surfaces $W \subset S$ in which $d_W(\mathcal{D}, \mu)$ is very large to play a role in the hyperbolic geometry associated to the end invariant μ – much as subsurfaces where $d_W(\nu_+, \nu_+)$ is large played a role in the geometry of surface groups with end invariants ν_+ and ν_-. For the purpose of understanding when this happens, those W for which $\operatorname{diam}_W(\mathcal{D})$ is bounded are somewhat easier to analyze. Masur–Schleimer have studied the structure of $\mathcal{D}$ quite extensively in [93], and have shown in particular that

Theorem 6.2 (Masur–Schleimer). *Let S be the boundary of a handlebody H. If W is an essential subsurface of S then $\operatorname{diam}_W(\mathcal{D})$ is bounded by a number depending on the genus of S, unless*

1. *there is a meridian in the complement of W,*
2. *there is a meridian in W but not in its complement,*
3. *there is an essential I-bundle B in H with W a component of its horizontal boundary, and at least one vertical annulus of B lying in S.*

In cases 1 *and* 3, *$\pi_W(\mathcal{D})$ is all of $\mathcal{A}(W)$ up to bounded gaps. In case* 2, *$\pi_W(\mathcal{D})$ is within a bounded neighborhood of $\mathcal{D} \cap \mathcal{C}(W)$.*

This is part of a larger analysis in which, in particular, they show that the Hempel distance of a splitting can be estimated algorithmically.

There is an interplay between this classification of subsurfaces and the geometric examples we listed above. To understand case 3, for example, note that in a product $F \times [-1, 1]$, where F is a surface with boundary, there are essential disks of the form $a \times [-1, 1]$ where a is any essential arc in F. Hence (supposing $F \times [-1, 1]$ to be embedded in the handlebody H as in part (3)) we see that $\pi_{F\times\{1\}}(\mathcal{D})$ gives all arcs of $\mathcal{A}(F)$. This corresponds to the "incompressible I-bundle" case in the list of geometric examples, and we expect in this case that the projections of μ to $F \times \{\pm 1\}$ should act as end invariants for this incompressible surface group within H.

With these results as a starting point, one can hope that there is a model based, in a way analogous to hierarchies, on the shortest path from a marking μ to the meridian set $\mathcal{D}$. The parts of the path far from $\mathcal{D}$ should give a portion of the model analogous to the compressible products in the example list, whereas near $\mathcal{D}$ the construction would need to give rise to a system of 1-handles and incompressible I-bundles. A successful version of this would give us uniform bilipschitz models for handlebodies,

and via some deformation and gluing could enable us to build models for closed hyperbolic 3-manifolds as well. One would also like to apply our understanding of $\mathcal{D}$ directly to the combinatorics of a Heegaard splitting, that is to the relative positioning of a pair $(\mathcal{D}_+, \mathcal{D}_-)$.

$\mathbb{A}^1$-algebraic topology

Fabien Morel

Abstract. We present some recent results in $\mathbb{A}^1$-*algebraic topology*, which means both in $\mathbb{A}^1$-homotopy theory of schemes and its relationship with algebraic geometry. This refers to the classical relationship between homotopy theory and (differential) topology. We explain several examples of "motivic" versions of classical results: the theory of the Brouwer degree, the classification of $\mathbb{A}^1$-coverings through the $\mathbb{A}^1$-fundamental group, the Hurewicz Theorem and the $\mathbb{A}^1$-homotopy of algebraic spheres, and the $\mathbb{A}^1$-homotopy classification of vector bundles. We also give some applications and perspectives.

Mathematics Subject Classification (2000). 14F05, 19E15, 55P.

Keywords. $\mathbb{A}^1$-homotopy theory, Milnor K-theory, Witt groups.

1. The Brouwer degree

Let $n \geq 1$ be an integer and let X be a pointed topological space. We shall denote by $\pi_n(X)$ the n-th homotopy group of X. A basic fact in homotopy theory is:

Theorem 1.1. *Let $n \geq 1$, $d \geq 1$ be integers and denote by S^n the n-dimensional sphere.*

1) *If $d < n$ then $\pi_d(S^n) = 0$;*

2) *If $d = n$ then $\pi_n(S^n) = \mathbb{Z}$.*

A classical proof uses the Hurewicz Theorem and the computation of the integral singular homology of the sphere. Half of this paper is devoted to explain the analogue of these results in $\mathbb{A}^1$-homotopy theory [54], [38].

For our purpose we also recall a more geometric proof of 2) inspired by the definition of Brouwer's degree. Any continuous map $S^n \to S^n$ is homotopic to a $\mathcal{C}^\infty$-differentiable map $f\colon S^n \to S^n$. By Sard's theorem, f has at least one regular value $x \in S^n$, so that $f^{-1}(x)$ is a finite set of points in S^n and for each $y \in f^{-1}(x)$, the differential $df_y\colon T_y(S^n) \to T_x(S^n)$ of f at y is an isomorphism. The "sign" $\varepsilon_y(f)$ at y is $+1$ if df_y preserves the orientation and -1 else. The integer $\delta(f) := \sum_{y \mapsto x} \varepsilon_y(f)$ is the *Brouwer degree* of f and only depends on the homotopy class of f.

Now choose a small enough open n-ball $\mathcal{B}$ around x such that $f^{-1}(\mathcal{B})$ is a disjoint union of an open n-balls $\mathcal{B}_y$ around each y's. The quotient space $S^n/(S^n - \bigcup \mathcal{B}_y)$ is

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

homeomorphic to the wedge of spheres $\vee_y S^n$ and the quotient map $S^n \to S^n/(S^n - \mathcal{B})$ is a homotopy equivalence. The induced commutative square

$$\begin{array}{ccc} S^n & \xrightarrow{\quad f \quad} & S^n \\ \downarrow & & \downarrow \wr \\ \vee_y S^n = S^n/(S^n - \bigcup \mathcal{B}_y) & \xrightarrow[\vee_y f_y]{} & S^n/(S^n - \mathcal{B}) \end{array} \tag{1.1}$$

expresses the homotopy class of f as the sum of the homotopy classes of the f_y's, each of which being the one point compactification of the differential map df_y. This proves that the degree homomorphism $\pi_n(S^n) \to \mathbb{Z}$ is injective, thus an isomorphism.

We illustrate the algebraic situation by a simple close example. Let k be a field, let $f \in k(T)$ be a rational fraction and denote still by $f\colon \mathbb{P}^1 \to \mathbb{P}^1$ the k-morphism from the projective line to itself corresponding to f. Assume, for simplicity, that f admits a regular value x in the following strong sense (which is not the generic one): x is a rational point in $\mathbb{A}^1 \subset \mathbb{P}^1$ such that f is étale over x, such that the finite étale k-scheme $f^{-1}(x)$ consists of finitely many rational points $y \in \mathbb{A}^1$ (none being ∞), and that the differentials $\frac{df}{dt}(y)$ are each units α_y. Observe that $\mathbb{P}^1 - \{x\}$ is isomorphic to the affine line $\mathbb{A}^1$ and thus the quotient morphism $\mathbb{P}^1 \to \mathbb{P}^1/\mathbb{A}^1 := T$ a "weak $\mathbb{A}^1$-equivalence". The commutative diagram (in some category of spaces over k, see below)

$$\begin{array}{ccc} \mathbb{P}^1 & \xrightarrow{\quad f \quad} & \mathbb{P}^1 \\ \downarrow & & \downarrow \wr \\ \vee_y T = \mathbb{P}^1/(\mathbb{P}^1 - f^{-1}(x)) & \xrightarrow[\vee \hat{\alpha}_y]{} & T \end{array}$$

analogous to (1.1), also expresses f, up to $\mathbb{A}^1$-weak homotopy, as the sum of the classes of the morphisms $\hat{\alpha}_y\colon T \to T$ induced by the multiplication by α_y. The idea is that in algebraic geometry the analogue of the "sign" of a unit $u \in k^\times$, or the $\mathbb{A}^1$-homotopy class of $\hat{u}$, is its class in $k^\times/(k^\times)^2$. The set $k^\times/(k^\times)^2$ should also be considered as the set of *orientations* of the affine line over k. We observe that $\hat{u}$ is $\mathbb{A}^1$-equivalent to the "1-point compactification" of the multiplication by $u\colon \mathbb{P}^1 \to \mathbb{P}^1$, $[x, y] \mapsto [ux, y]$. If $u = v^2$, the latter is $[x, y] \mapsto [ux, y] = [vx, v^{-1}y]$ which is given by the action of the matrix $\left(\begin{smallmatrix} v & 0 \\ 0 & v^{-1} \end{smallmatrix}\right)$ of $\mathrm{SL}_2(k)$ and thus, being a product of elementary matrices, is $\mathbb{A}^1$-homotopic to the identity.

Using the same procedure as in topology, we have "expressed" the $\mathbb{A}^1$-homotopy class of f as a sum of units modulo the squares and the Brouwer degree of a morphism $\mathbb{P}^1 \to \mathbb{P}^1$ in the $\mathbb{A}^1$-homotopy category $\mathsf{H}(k)$ over k should have this flavor. Denote by $GW(k)$ the Grothendieck–Witt ring of non-degenerate symmetric bilinear forms over k, that is to say the group completion of the monoid – for the direct sum – of isomorphism classes of such forms over k, see [27]. It is a quotient of the free abelian

group on units $k^\times$. We will find that the algebraic Brouwer degree over k takes it values in $GW(k)$ by constructing for $n \geq 2$ an isomorphism

$$\mathrm{Hom}_{\mathsf{H}(k)}((\mathbb{P}^1)^{\wedge n}, (\mathbb{P}^1)^{\wedge n}) \cong \mathrm{Hom}_{\mathsf{H}_\bullet(k)}((\mathbb{P}^1)^{\wedge n}, (\mathbb{P}^1)^{\wedge n}) \cong GW(k)$$

where $\mathsf{H}_\bullet(k)$ is the pointed $\mathbb{A}^1$-homotopy category over k and $\wedge$ denotes the smash-product [54], [38]. For $n = 1$ the epimorphism $\mathrm{Hom}_{\mathsf{H}_\bullet(k)}(\mathbb{P}^1, \mathbb{P}^1) \to GW(k)$ has a kernel isomorphic to the subgroup of squares $(k^\times)^2$.

The ring $GW(k)$ is actually the cartesian product of $\mathbb{Z}$ and $W(k)$ (the Witt ring of isomorphism classes of anisotropic forms) over $\mathbb{Z}/2$, fitting into the cartesian square

$$\begin{array}{ccc} GW(k) & \longrightarrow & \mathbb{Z} \\ \downarrow & & \downarrow \\ W(k) & \longrightarrow & \mathbb{Z}/2\,. \end{array}$$

The possibility of defining the Brouwer degree with values[1] in $GW(k)$ and the above cartesian square emphasizes one of our constant intuition in this paper and should be kept in mind: from the degree point of view, the (top horizontal) rank homomorphism corresponds to "taking care of the topology of the complex points" and the projection $GW(k) \to W(k)$ corresponds to "taking care of the topology of the real points". Indeed, given a real embedding $k \to \mathbb{R}$, with associated signature $W(k) \to \mathbb{Z}$, the signature of the degree of f is the degree of the associated map $f(\mathbb{R})\colon \mathbb{P}^1(\mathbb{R}) \to \mathbb{P}^1(\mathbb{R})$. This idea of taking care of these two topological intuitions at the same time is essential in the present work.

We do not pretend to be exhaustive in such a short paper; we have mostly emphasized the progress in unstable $\mathbb{A}^1$-homotopy theory and we will almost not address stable $\mathbb{A}^1$-homotopy theory.

Notations. We fix a base field k of any characteristic; Sm_k will denote the category of smooth quasi-projective k-schemes. Given a presheaf of sets on Sm_k, that is to say a functor $F\colon (\mathsf{Sm}_k)^{\mathrm{op}} \to \mathsf{Sets}$, and an essentially smooth k-algebra A, which means that A is the filtering union of its sub-k-algebras A_α which are smooth and finite type over k, we set $F(A) := \mathrm{colimit}_\alpha F(\mathrm{Spec}(A_\alpha))$. For instance, for each point $x \in X \in \mathsf{Sm}_k$ the local ring $\mathcal{O}_{X,x}$ of X at x as well as its henselization $\mathcal{O}^h_{X,x}$ are essentially smooth k-algebras.

Some history and acknowledgements. This work has its origin in my discussions and collaboration with V. Voevodsky [38]; I thank him very much for these discussions.

I thank J. Lannes for his influence and interest on my first proof of the Milnor conjecture on quadratic forms in [29], relying on Voevodsky's results and on the use of the Adams spectral sequence based on mod. 2 motivic cohomology. Since then I considerably simplified the topological argument in [33].

[1] Barge and Lannes have defined and studied a related degree from the set of naive $\mathbb{A}^1$-homotopy classes of k-morphisms $\mathbb{P}^1 \to \mathbb{P}^1$ to $GW(k)$, unpublished.

I also want to warmly thank M. Hopkins and M. Levine for their constant interest in this work -as well as related works-, for discussions and comments which helped me very much to simplify and improve some parts, and also for some nice collaborations on and around this subject during the past years.

Finally, I want to thank very much the Mathematics Institute as well as my colleagues of the University of Munich for their welcome.

2. A quick recollection on $\mathbb{A}^1$-homotopy

A convenient category of spaces. We will always consider that Sm_k is endowed with the Nisnevich topology [40], [38]. We simply recall the following characterization for a presheaf of sets on Sm_k to be a sheaf in this topology.

Proposition 2.1 ([38]). *A functor $F\colon (\mathsf{Sm}_k)^{\mathrm{op}} \to \mathsf{Sets}$ is a sheaf in the Nisnevich topology if and only if for any cartesian square in Sm_k of the form*

$$\begin{array}{ccc} W & \subset & V \\ \downarrow & & \downarrow \\ U & \subset & X \end{array} \tag{2.1}$$

where U is an open subscheme in X, the morphism $f\colon V \to X$ is étale and the induced morphism $(f^{-1}(X-U))_{\mathrm{red}} \to (X-U)_{\mathrm{red}}$ is an isomorphism, the map

$$F(X) \to F(U) \times_{F(W)} F(V)$$

is a bijection.

Squares like (2.1) are call *distinguished squares*. We denote by $\Delta^{\mathrm{op}}\mathsf{Shv}_k$ the category of simplicial sheaves of sets over Sm_k (in the Nisnevich topology); these objects will be just called "spaces" (this is slightly different from [54] where "space" only means a sheaf of sets, with no simplicial structure). This category contains the category Sm_k as the full subcategory of representable sheaves.

$\mathbb{A}^1$-weak equivalence and $\mathbb{A}^1$-homotopy category. Recall that a *simplicial weak equivalence* is a morphism of spaces $f\colon \mathcal{X} \to \mathcal{Y}$ such that each of its stalks

$$\mathcal{X}(\mathcal{O}^h_{X,x}) \to \mathcal{Y}(\mathcal{O}^h_{X,x})$$

at $x \in X \in \mathsf{Sm}_k$ is a weak equivalence of simplicial sets. Inverting these morphisms in $\Delta^{\mathrm{op}}\mathsf{Shv}_k$ yields the classical *simplicial homotopy category of sheaves* [10], [21]. The notion of $\mathbb{A}^1$-*weak equivalence* is generated in some natural way by that of simplicial weak equivalences and the projections $\mathcal{X} \times \mathbb{A}^1 \to \mathcal{X}$ for any space $\mathcal{X}$. Inverting the class of $\mathbb{A}^1$-weak equivalence yields now the $\mathbb{A}^1$-homotopy category $\mathsf{H}(k)$ [54], [38]. We denote by $\mathsf{H}_\bullet(k)$ the $\mathbb{A}^1$-homotopy category of pointed spaces.

The smash product with the simplicial circle S^1 induces the simplicial suspension functor $\Sigma\colon \mathsf{H}_\bullet(k) \to \mathsf{H}_\bullet(k)$, $\mathcal{X} \mapsto \Sigma(\mathcal{X})$. For a pointed morphism $f\colon \mathcal{X} \to \mathcal{Y}$ we may define the $\mathbb{A}^1$-homotopy fiber $\Gamma(f)$ together with an $\mathbb{A}^1$-fibration sequence $\Gamma(f) \to \mathcal{X} \to \mathcal{Y}$, which moreover induces for any other pointed space $\mathcal{Z}$ a long homotopy exact sequence (of pointed sets, groups, abelian groups as usual)

$$\begin{aligned}\cdots \to \mathrm{Hom}_{\mathsf{H}_\bullet(k)}(\Sigma(\mathcal{Z}), \mathcal{X}) \to \mathrm{Hom}_{\mathsf{H}_\bullet(k)}(\Sigma(\mathcal{Z}), \mathcal{Y}) \to \mathrm{Hom}_{\mathsf{H}_\bullet(k)}(\mathcal{Z}, \Gamma(f))\\ \to \mathrm{Hom}_{\mathsf{H}_\bullet(k)}(\mathcal{Z}, \mathcal{X}) \to \mathrm{Hom}_{\mathsf{H}_\bullet(k)}(\mathcal{Z}, \mathcal{Y}).\end{aligned}$$

In a dual way a distinguished square like (2.1) above is $\mathbb{A}^1$-homotopy cocartesian and induces corresponding Mayer–Vietoris type long exact sequences by mapping its vertices to $\mathcal{Z}$.

The geometric ideas on the Brouwer degree recalled in the introduction lead in general (for $d > n$) to the interpretation, due to Pontryagin, of the stable homotopy groups of spheres in terms of *parallelized cobordism groups*, and even more generally to the *Thom–Pontryagin construction* used by Thom to compute most of the cobordism rings. Recall that given a closed embedding $i\colon Z \hookrightarrow X$ between differentiable manifolds (with Z compact for simplicity) and a *tubular neighborhood* $Z \subset U \subset X$ of Z in X there is a pointed continuous map (indeed homeomorphism)

$$X/(X - U) \to Th(\nu_i) \tag{2.2}$$

to the Thom space (the one point compactification of the total space $E(\nu_i) \cong U$ of the normal bundle ν_i) which is independent up to pointed homotopy of the choices of the tubular neighborhood.

The choice of the topology on Sm_k (see [38]) was very much inspired by the this Thom–Pontryagin construction and the definition of the $\mathbb{A}^1$-homotopy category of smooth schemes over a base in [54], [38] allows to construct, for any closed immersion $i\colon Z \to X$ between smooth k-schemes, a pointed $\mathbb{A}^1$-weak equivalence $X/(X - Z) \to Th(\nu_i)$ [38], although no tubular neighborhood is available in general in algebraic geometry. In that case we get an $\mathbb{A}^1$-cofibration sequence

$$(X - Z) \to X \to Th(\nu_i).$$

Let $\mathcal{X}$ be a space. We let $\pi_0^{\mathbb{A}^1}(\mathcal{X})$ denote the associated sheaf (of sets) on Sm_k to the presheaf $U \mapsto \mathrm{Hom}_{\mathsf{H}(k)}(U, \mathcal{X})$. If moreover $\mathcal{X}$ is pointed, and $n \geq 1$ we denote by $\pi_n^{\mathbb{A}^1}(\mathcal{X})$ the sheaf on Sm_k associated to the presheaf $U \mapsto \mathrm{Hom}_{\mathsf{H}_\bullet(k)}(\Sigma^n(U_+), \mathcal{X})$ (where U_+ means U together with a base point added outside), a sheaf of groups for $n = 1$, of abelian groups for $n \geq 2$.

It is also very useful for the intuition to recall from [38] the existence of the topological realization functors. When $\rho\colon k \to \mathbb{C}$ (resp. $k \to \mathbb{R}$) is a complex (resp. real) embedding there is a canonical functor $\mathsf{H}(k) \to \mathsf{H}$ to the usual homotopy category of C.W.-complexes, induced by sending $X \in \mathsf{Sm}_k$ to the set of complex points $X(\mathbb{C})$ (resp. real points $X(\mathbb{R})$) with its classical topology.

3. $\mathbb{A}^1$-homotopy and $\mathbb{A}^1$-homology: the basic theorems

We recall that everywhere in this paper the topology to be understood is the Nisnevich topology.

Strictly $\mathbb{A}^1$-invariant sheaves

Definition 3.1. 1) A presheaf of sets M on Sm_k is said to be $\mathbb{A}^1$-*invariant* if for any $X \in \mathsf{Sm}_k$, the map $M(X) \to M(X \times \mathbb{A}^1)$ induced by the projection $X \times \mathbb{A}^1 \to X$, is a bijection.

2) A sheaf of groups M is said to be *strongly* $\mathbb{A}^1$-*invariant* if for any $X \in \mathsf{Sm}_k$ and any $i \in \{0, 1\}$ the map $H^i(X; M) \to H^i(X \times \mathbb{A}^1; M)$ induced by the projection $X \times \mathbb{A}^1$, is a bijection.

3) A sheaf of abelian groups M is said to be *strictly* $\mathbb{A}^1$-*invariant* if for any $X \in \mathsf{Sm}_k$ and any $i \in \mathbb{N}$ the map $H^i(X; M) \to H^i(X \times \mathbb{A}^1; M)$ induced by the projection $X \times \mathbb{A}^1$ is a bijection.

These notions, except 2), appear in Voevodsky's study of cohomological properties of presheaves with transfers [55] and were extensively studied in [34] over a general base, though very few is known except when the base is a field. Hopefully, given a sheaf of abelian groups the *a priori* different properties 2) and 3) coincide.

Theorem 3.2 ([36]). *A sheaf of abelian groups which is strongly* $\mathbb{A}^1$-*invariant is strictly* $\mathbb{A}^1$-*invariant.*

This result can be used to simplify some of the proofs of [55]. Let us denote by Ab_k the abelian category of sheaves of abelian groups on Sm_k. Another easy application is that the full sub-category $\mathsf{Ab}_k^{\mathbb{A}^1} \subset \mathsf{Ab}_k$, consisting of strictly $\mathbb{A}^1$-invariant sheaves, is an abelian category for which the inclusion functor is exact. From Theorem 3.3 below, these strictly $\mathbb{A}^1$-invariant sheaves and their cohomology play in $\mathbb{A}^1$-algebraic topology the role played in classical algebraic topology by the abelian groups and the singular cohomology with coefficients in those.

The constant sheaf $\mathbb{Z}$, the sheaf represented by an abelian variety over k are examples of strictly $\mathbb{A}^1$-invariant sheaves, in fact the higher cohomology groups, $H^i_{Nis}(X; -)$, $i > 0$, for these sheaves automatically vanish. Another well known example is the multiplicative group $\mathbb{G}_m = \mathbb{A}^1 - \{0\}$. More elaborated examples were produced by Voevodsky over a perfect field: for each $\mathbb{A}^1$-homotopy invariant presheaf with transfers F its associated sheaf F_{Nis} a strictly $\mathbb{A}^1$-invariant sheaf [55]. In particular if F itself is an $\mathbb{A}^1$-homotopy invariant sheaf with transfers, it is strictly $\mathbb{A}^1$-invariant. By [12] these sheaves are very closely related to Rost's cycle modules [46], which also produce strictly $\mathbb{A}^1$-invariant sheaves, like the unramified Milnor K-theory sheaves introduced in [19]. There are other types of strictly $\mathbb{A}^1$-invariant sheaves given for instance by the unramified Witt groups $\underline{\mathbf{W}}$ as constructed in [42], or [36], as well as their subsheaves of unramified power of the fundamental ideal $\underline{\mathbf{I}}^n$ used in [33].

$\mathbb{A}^1$-homotopy sheaves

Theorem 3.3 ([36]). *Let $\mathcal{X}$ be a pointed space. Then the sheaf $\pi_1^{\mathbb{A}^1}(\mathcal{X})$ is strongly $\mathbb{A}^1$-invariant, and the sheaves $\pi_n^{\mathbb{A}^1}$, for $n \geq 2$, are strictly $\mathbb{A}^1$-invariant.*

Curiously enough, we are unable to prove that the sheaf $\pi_0^{\mathbb{A}^1}(\mathcal{X})$ is $\mathbb{A}^1$-invariant, though it is true in all the cases we can compute.

Remark 3.4. One of the main tool used in the proof of the Theorem 3.3 is the presentation Lemma of Gabber [14] as formalized in [11]. Then a "non-abelian" variant of [11] and ideas from [46] lead to the result. In fact one can give a quite concrete description of a sheaf of groups which is strongly $\mathbb{A}^1$-invariant [36].

A pointed space $\mathcal{X}$ such that the sheaves $\pi_i^{\mathbb{A}^1}(\mathcal{X})$ vanish for $i \leq n$ will be called n-$\mathbb{A}^1$-connected. In case $n = 0$ we simply say $\mathbb{A}^1$-connected.

Corollary 3.5 (Unstable $\mathbb{A}^1$-connectivity theorem). *Let $\mathcal{X}$ be a pointed space and n be an integer ≥ 0 such that $\mathcal{X}$ is* simplicially *n-connected. Then it is n-$\mathbb{A}^1$-connected.*

This result was only known in the case $n = 0$ in [38], over a general base. As a consequence, the simplicial suspension of an $(n-1)$-$\mathbb{A}^1$-connected pointed space is n-$\mathbb{A}^1$-connected.

The main example of a simplicially n-connected space is the $(n+1)$-th simplicial suspension of a pointed space.

For n and i two natural numbers we set $S^n(i) = (S^1)^{\wedge(n)} \wedge (\mathbb{G}_m)^{\wedge i}$ where $\wedge$ denotes the smash-product. Observe that these are actually mapped to spheres (up to homotopy) through any topological realization functors (real or complex). Note also the following isomorphisms in $\mathsf{H}_\bullet(k)$: $\mathbb{A}^n - \{0\} \cong S^{(n-1)}(n)$ and $(\mathbb{P}^1)^{\wedge n} \cong S^1 \wedge (\mathbb{A}^n - \{0\}) \cong S^n(n)$.

From the previous Corollary $S^n(i)$ is $(n-1)$-$\mathbb{A}^1$-connected. Actually we will see below that it is exactly $(n-1)$-$\mathbb{A}^1$-connected, as $\pi_n^{\mathbb{A}^1}(S^n(i))$ is always non trivial. The $\mathbb{A}^1$-connectivity corresponds to the connectivity of the space of real points.

$\mathbb{A}^1$-fundamental group and universal $\mathbb{A}^1$-covering.

An $\mathbb{A}^1$-trivial cofibration $\mathcal{A} \to \mathcal{B}$ is a monomorphism between spaces which is also an $\mathbb{A}^1$-weak equivalence. The following definition is the obvious analogue of the definition of a covering in topology:

Definition 3.6. An $\mathbb{A}^1$-covering $\mathcal{Y} \to \mathcal{X}$ is a morphism of spaces which has the unique right lifting property with respect to $\mathbb{A}^1$-trivial cofibrations. This means that given any commutative square of spaces

$$\begin{array}{ccc} \mathcal{A} & \longrightarrow & \mathcal{Y} \\ \downarrow & & \downarrow \\ \mathcal{B} & \longrightarrow & \mathcal{X} \end{array}$$

in which $\mathcal{A} \to \mathcal{B}$ is an $\mathbb{A}^1$-trivial cofibration, there exists one and exactly one morphism $\mathcal{B} \to \mathcal{Y}$ which makes the whole diagram commutative.

Example 3.7. 1) Any finite étale covering $Y \to X$ between smooth k-varieties, in characteristic 0, is an $\mathbb{A}^1$-covering. Any Galois étale covering $Y \to X$ with Galois group of order prime to the characteristic of k is an $\mathbb{A}^1$-covering.

2) Any $\mathbb{G}_m$-torsor $\mathcal{Y} \to \mathcal{X}$ is an $\mathbb{A}^1$-covering. Remember to think about the real points! A $\mathbb{G}_m$-torsor gives (up to homotopy) a $\mathbb{Z}/2$-covering.

Theorem 3.8. *Any pointed $\mathbb{A}^1$-connected space $\mathcal{X}$ admits a universal pointed $\mathbb{A}^1$-covering $\tilde{\mathcal{X}} \to \mathcal{X}$ in the category of pointed coverings of $\mathcal{X}$. The fiber of this universal $\mathbb{A}^1$-covering at the base point is isomorphic to $\pi_1^{\mathbb{A}^1}(\mathcal{X})$ and $\tilde{\mathcal{X}} \to \mathcal{X}$ is (up to canonical isomorphism) the unique pointed $\mathbb{A}^1$-covering with $\tilde{\mathcal{X}}$ being 1-$\mathbb{A}^1$-connected.*

Remark 3.9. A pointed $\mathbb{A}^1$-connected smooth k-scheme (X, x) admits no non-trivial étale pointed covering. Thus the $\pi_1^{\mathbb{A}^1}$ is in some sense orthogonal to the étale one and gives a more combinatorial information, as shown by the example of the $\mathbb{P}^n$'s below. On the other hand the pointed étale coverings always come from the $\pi_0^{\mathbb{A}^1}$: for instance an abelian variety X is discreet, in the sense that $\pi_0^{\mathbb{A}^1}(X) = X$, and have huge étale π_1. We did not try to further study the $\mathbb{A}^1$-fundamental groupoid which cares about both aspects, the combinatorial and the étale.

Lemma 3.10. *Let $n \geq 2$. The canonical $\mathbb{G}_m$-torsor*

$$(\mathbb{A}^{n+1} - \{0\}) \to \mathbb{P}^n$$

is the universal covering of $\mathbb{P}^n$. As a consequence the morphism $\pi_1^{\mathbb{A}^1}(\mathbb{P}^n) \to \mathbb{G}_m$ is an isomorphism.

Indeed, $\mathbb{A}^{n+1} - \{0\}$ is 1-$\mathbb{A}^1$-connected. For $n = 1$ the problem is that $\mathbb{A}^2 - \{0\}$ is no longer 1-$\mathbb{A}^1$-connected. See the next section for more information.

$\mathbb{A}^1$-derived category, $\mathbb{A}^1$-homology and Hurewicz Theorem. Let us denote by $\mathbb{Z}(\mathcal{X})$ the free abelian sheaf generated by a space $\mathcal{X}$ and by $C_*(\mathcal{X})$ its the associated chain complex; if moreover $\mathcal{X}$ is pointed, let us denote by $\mathbb{Z}_\bullet(\mathcal{X}) = \mathbb{Z}(\mathcal{X})/\mathbb{Z}$ and $\tilde{C}_*(\mathcal{X}) = C_*(\mathcal{X})/\mathbb{Z}$ the reduced versions obtained by collapsing the base point to 0.

We may perform in the derived category of chain complexes in Ab_k exactly the same process as for spaces and define the class of $\mathbb{A}^1$-weak equivalences, rather $\mathbb{A}^1$-quasi isomorphisms; these are generated by quasi-isomorphisms and collapsing $\mathbb{Z}_\bullet(\mathbb{A}^1)$ to 0. Formally inverting these morphisms yields the *$\mathbb{A}^1$-derived category* $\mathsf{D}_{\mathbb{A}^1}(k)$ of k [34]. The functor $\mathcal{X} \mapsto C_*(\mathcal{X})$ obviously induces a functor $\mathsf{H}(k) \to \mathsf{D}_{\mathbb{A}^1}(k)$ which admits a right adjoint given by the usual Eilenberg–MacLane functor $K : \mathsf{D}_{\mathbb{A}^1}(k) \to \mathsf{H}(k)$.

As for spaces, one may define $\mathbb{A}^1$-homology sheaves of a chain complex C_*. An abelian version of Theorem 3.3 implies that for any complex C_* these $\mathbb{A}^1$-homology sheaves are strictly $\mathbb{A}^1$-invariant [36], [34].

Definition 3.11. For a space $\mathcal{X}$ and for each integer $n \in \mathbb{Z}$, we let $\mathbb{H}_n^{\mathbb{A}^1}(X)$ denote the n-th $\mathbb{A}^1$-homology sheaf of $C_*(\mathcal{X})$ and call $\mathbb{H}_*^{\mathbb{A}^1}(\mathcal{X})$ the $\mathbb{A}^1$-homology of $\mathcal{X}$ (with integral coefficients). In case $\mathcal{X}$ is pointed, we let $\tilde{\mathbb{H}}_*^{\mathbb{A}^1}(\mathcal{X})$ denote the reduced version obtained by collapsing the base point to 0.

Observe that these $\mathbb{A}^1$-homology sheaves are strictly $\mathbb{A}^1$-invariant and that $\mathbb{H}_i^{\mathbb{A}^1}(\mathcal{X}) = 0$ for $i < 0$ by the abelian analogue of Corollary 3.5. As a consequence for a space $\mathcal{X}$ the sheaf $\mathbb{H}_0^{\mathbb{A}^1}(\mathcal{X})$ is the *free strictly* $\mathbb{A}^1$*-invariant sheaf* generated by $\mathcal{X}$. These sheaves play a fundamental role in $\mathbb{A}^1$-algebraic topology. For instance we have suspension isomorphisms $\tilde{\mathbb{H}}_*^{\mathbb{A}^1}(S^n(i)) \cong \tilde{\mathbb{H}}_{*-n}^{\mathbb{A}^1}((\mathbb{G}_m)^{\wedge i})$ for our spheres $S^n(i)$. In particular the first *a priori* non trivial sheaf is $\tilde{\mathbb{H}}_n^{\mathbb{A}^1}(S^n(i)) \cong \tilde{\mathbb{H}}_0^{\mathbb{A}^1}((\mathbb{G}_m)^{\wedge i})$. We will compute these sheaves in the next section in terms of Milnor–Witt K-theory.

The computation of the higher $\mathbb{A}^1$-homology sheaves is at the moment highly non trivial and mysterious[2].

Remark 3.12. There exists a natural morphism of sheaves $\mathbb{H}_n^{\mathbb{A}^1}(X;\mathbb{Z}) \to \mathbb{H}_n^S(X)$ where the right hand side denotes Suslin–Voevodsky singular homology sheaves [52], [55]. In general, this is not an isomorphism. More generally let $\mathsf{DM}(k)$ be Voevodsky's triangulated category of motives [56]. Then there exists a canonical functor of "adding transfers"

$$\mathsf{D}_{\mathbb{A}^1}(k) \to \mathsf{DM}(k).$$

It is not an equivalence. One explanation is given by the (pointed) algebraic Hopf map:

$$\eta\colon \mathbb{A}^2 - \{0\} \to \mathbb{P}^1.$$

The associated morphism on $\mathbb{H}_1^{\mathbb{A}^1}$ defines a morphism[3]:

$$\eta\colon \tilde{\mathbb{H}}_0^{\mathbb{A}^1}(\mathbb{G}_m) \otimes_{\mathbb{A}^1} \tilde{\mathbb{H}}_0^{\mathbb{A}^1}(\mathbb{G}_m) \cong \mathbb{H}_1^{\mathbb{A}^1}(\mathbb{A}^2 - \{0\}) \to \mathbb{H}_1^{\mathbb{A}^1}(\mathbb{P}^1) \cong \tilde{\mathbb{H}}_0^{\mathbb{A}^1}(\mathbb{G}_m).$$

The latter is never nilpotent (use the same argument as in the proof of Theorem 4.7). On the other hand, the computation of the motive of $\mathbb{P}^2$, which is the cone of η, shows that $\mathbb{P}^1 \to \mathbb{P}^2$ admits a retraction in $\mathsf{DM}(k)$ and thus that the image of η in $\mathsf{DM}(k)$ is the zero morphism.

Theorem 3.13 (Hurewicz Theorem, [36]). *Let $\mathcal{X}$ be a pointed $\mathbb{A}^1$-connected space. Then the Hurewicz morphism*

$$\pi_1^{\mathbb{A}^1}(\mathcal{X}) \to \mathbb{H}_1^{\mathbb{A}^1}(\mathcal{X})$$

[2] We do not know any example which does not use the Bloch–Kato conjecture.

[3] Here for sheaves M and N, we denote by $M \otimes_{\mathbb{A}^1} N$ the $\mathbb{H}_0^{\mathbb{A}^1}$ of the sheaf $M \otimes N$, and call it the $\mathbb{A}^1$-tensor product.

is the universal morphism from $\pi_1^{\mathbb{A}^1}(\mathcal{X})$ *to a strictly* $\mathbb{A}^1$*-invariant sheaf*[4]*. If moreover* $\mathcal{X}$ *is* $(n-1)$*-connected for some* $n \geq 2$ *then the Hurewicz morphism*

$$\pi_i^{\mathbb{A}^1}(\mathcal{X}) \to \mathbb{H}_i^{\mathbb{A}^1}(\mathcal{X})$$

is an isomorphism for $i \leq n$ *and an epimorphism for* $i = (n+1)$.

We now may partly realize our program of proving the analogue of Theorem 1.1. Given a sphere $S^n(i)$ with $n \geq 2$, we have $\pi_m^{\mathbb{A}^1}(S^n(i)) = 0$ for $m < n$ and

$$\pi_n^{\mathbb{A}^1}(S^n(i)) \cong \tilde{\mathbb{H}}_0^{\mathbb{A}^1}((\mathbb{G}_m)^{\wedge n}) \cong \tilde{\mathbb{H}}_0^{\mathbb{A}^1}(\mathbb{G}_m)^{\otimes_{\mathbb{A}^1}(n)}.$$

In the next section we will describe those sheaves.

Remark 3.14. Of course, the Hurewicz Theorem has a lot of classical consequences. We do not mention them here, see [36].

4. $\mathbb{A}^1$-homotopy and $\mathbb{A}^1$-homology: computations involving Milnor–Witt K-theory

Milnor–Witt K-theory of fields. The following definition was obtained in collaboration with Mike Hopkins.

Definition 4.1. Let F be a commutative field. The Milnor–Witt K-theory $K_*^{MW}(F)$ of F is the graded associative ring generated by the symbols $[u]$, for each unit $u \in F^\times$, of degree $+1$, and η of degree -1 subject to the following relations:

(1) (Steinberg relation) For each $a \in F^\times - \{1\}$, one has $[a].[1-a] = 0$.

(2) For each pair $(a,b) \in (F^\times)^2$ one has $[ab] = [a] + [b] + \eta.[a].[b]$.

(3) For each $a \in F^\times$, one has $[a].\eta = \eta.[a]$.

(4) One has $\eta^2.[-1] + 2\eta = 0$.

This Milnor–Witt K-theory groups were introduced by the author in a different complicated way. The previous one, is very simple and natural (but maybe the 4-th relation which will be explained below): all the relations easily come from natural $\mathbb{A}^1$-homotopies, see Theorem 4.8.

The quotient $K_*^{MW}(F)/\eta$ of the Milnor–Witt K-theory of F by η is the *Milnor K-theory* $K_*^M(F)$ of F as defined in [26]; indeed after η is killed, the symbol $[a]$ becomes additive and there is only the Steinberg relation.

For any unit $a \in F^\times$, set $\langle a \rangle = \eta[a] + 1 \in K_0^{MW}(F)$. One can show that $[1] = 0$, $\langle 1 \rangle = 1$ and $\langle ab \rangle = \langle a \rangle \langle b \rangle$. Set $\varepsilon := -\langle -1 \rangle$ and $h = 1 + \langle -1 \rangle$. Observe that $h = \eta.[-1] + 2$ and the fourth relation can be written $\eta\varepsilon = \eta$ or equivalently $\eta \,.\, h = 0$.

[4] it is not yet known whether this is the abelianization nor an epimorphism

This η will be interpreted below in term of the algebraic Hopf map (see also Remark 3.12 above). Observe that the relation $\eta^2.[-1] + 2\eta = 0$ is compatible with the complex points (where $[-1] = 0$ and stably $2.\eta = 0$) and the real points (where $[-1] = -1$, $\eta = 2$ and $-2^2 + 2 \times 2 = 0$).

It is natural to call the quotient ring $K^{MW}_*(F)/h$ the *Witt K-theory* of F and to denote it by $K^W_*(F)$. The mod 2-Milnor K-theory $k_*(F) := K^M_*(F)/2$ is thus also the mod η Witt K-theory $K^W_*(F)/\eta = K^{MW}_*(F)/(h, \eta)$.

It is not hard to check that $K^{MW}_0(F)$ admits the following presentation as an abelian group: a generator $\langle u\rangle$ for each unit of $F^\times$ and the relations of the form: $\langle u(v^2)\rangle = \langle u\rangle$, $\langle u\rangle + \langle v\rangle = \langle u + v\rangle + \langle (u + v)uv\rangle$ if $(u + v) \neq 0$ and $\langle u\rangle + \langle -u\rangle = 1 + \langle -1\rangle$. Moreover one checks that the morphism $\eta^n : K^{MW}_0(F) \to K^{MW}_{-n}(F)$ induces an isomorphism $K^W_0(F) \cong K^{MW}_{-n}(F)$ for $n > 0$. Thus in particular $K^{MW}_*(F)[\eta^{-1}] \to K^W_0(F)[\eta, \eta^{-1}]$ is an isomorphism.

Remark 4.2. In the above presentation of $K^{MW}_0(F)$ one recognizes the presentation of the Grothendieck–Witt ring $GW(F)$, see [47] in the case of characteristic $\neq 2$ and [27] in the general case. The element h becomes the hyperbolic plane. The quotient group (actually a ring) $K^W_0(F) = GW(F)/h$ is exactly the Witt ring $W(F)$ of F.

Let us define the *fundamental ideal* $I(F)$ of $K^W_0(F)$ to be the kernel of the mod 2 rank homomorphism $K^W_0(F) \to \mathbb{Z}/2$. Set $I^*(F) = \bigoplus_{n\in\mathbb{Z}} I^n(F)$ (with the convention $I^n(F) = K^W_0(F)$ for $n \leq 0$). We observe that the obvious correspondence $[u] \mapsto \langle u\rangle - 1 \in I(F)$ induces an (epi)morphism

$$S_F : K^W_*(F) \to I^*(F)$$

where η acts through the inclusions $I^n(F) \subset I^{n-1}(F)$. Killing η in this morphism yields the Milnor morphism [26]:

$$s_F : k_*(F) \to i^*(F) \tag{4.1}$$

where $i^*(F)$ denotes $\oplus I^n(F)/I^{(n+1)}(F)$.

Theorem 4.3 ([32]). *For any field F of characteristic $\neq 2$ the homomorphism*

$$S_F : K^W_*(F) \to I^*(F)$$

is an isomorphism.

This statement cannot be trivial as it implies the Milnor conjecture on quadratic forms that morphism (4.1) is an isomorphism. This statement is a reformulation of [1] and thus uses the proof of the Milnor conjecture on mod 2 Galois cohomology by Voevodsky [57], [41].

As a consequence we obtained in [32] that the commutative square of graded rings,

$$\begin{array}{ccc} K^{MW}_*(F) & \longrightarrow & K^M_*(F) \\ \downarrow & & \downarrow \\ K^W_*(F) & \longrightarrow & k_*(F) \end{array} \tag{4.2}$$

is cartesian (for a field of characteristic $\neq 2$).

Remark 4.4. 1) Using Kato's proof [20] of the analogue of the Milnor conjecture in characteristic 2, we can also show the previous result holds in characteristic 2.

2) The fiber products of the form $I^n(F) \times_{i^n(F)} K^M_n(F)$ where considered in [5] in characteristic not 2.

For $n \geq 1$ we simply set

$$\mathbb{Z}_{\mathbb{A}^1}(n) := \tilde{\mathbb{H}}^{\mathbb{A}^1}_0((\mathbb{G}_m)^{\wedge n})$$

for the free (reduced) strictly $\mathbb{A}^1$-invariant sheaf on $(\mathbb{G}_m)^{\wedge n}$. The Hopf morphism $\eta\colon \mathbb{A}^2 - \{0\} \to \mathbb{P}^1$ induces on $\tilde{\mathbb{H}}^{\mathbb{A}^1}_1$ a morphism of the form $\eta\colon \mathbb{Z}_{\mathbb{A}^1}(2) \to \mathbb{Z}_{\mathbb{A}^1}(1)$. Observe that $\tilde{\mathbb{H}}^{\mathbb{A}^1}_0((\mathbb{G}_m)^{\wedge 0}) = \mathbb{H}^{\mathbb{A}^1}_0(\mathrm{Spec}(k)) = \mathbb{Z}$ but that we did not set $\mathbb{Z}_{\mathbb{A}^1}(0) = \mathbb{Z}$. We will in fact extend this family of sheaves $\mathbb{Z}_{\mathbb{A}^1}(n)_{n\geq 1}$ to integers $n \leq 0$ using a construction of Voevodsky.

Given a presheaf of pointed sets M one defines the *pointed $\mathbb{G}_m$-loop space* M_{-1} on M so that for $X \in \mathsf{Sm}_k$, $M_{-1}(X)$ is the "Kernel" of the restriction through the unit section $M(X \times \mathbb{G}_m) \to M(X)$. If M is a sheaf of abelian groups, so is M_{-1}. We may iterate this construction to get M_n for $n < 0$; we set, for $n \leq 0$

$$\mathbb{Z}_{\mathbb{A}^1}(n) = \mathbb{Z}_{\mathbb{A}^1}(1)_{n-1}.$$

The canonical morphism $\mathbb{Z} \to \mathbb{Z}_{\mathbb{A}^1}(0)$ is far from being an isomorphism. The tensor product (and internal Hom) defines natural pairings $\mathbb{Z}_{\mathbb{A}^1}(n) \otimes \mathbb{Z}_{\mathbb{A}^1}(m) \to \mathbb{Z}_{\mathbb{A}^1}(n+m)$ for any integers $(n, m) \in \mathbb{Z}^2$. The element η becomes now an element $\eta \in \mathbb{Z}_{\mathbb{A}^1}(-1)(k)$. Any unit $u \in F^\times$ in a separable field extension $F|k$, viewed as an element in $\mathbb{G}_m(F)$ defines an element $[u] \in \mathbb{Z}_{\mathbb{A}^1}(1)(F)$.

The following result own very much to the definition of the Milnor–Witt K-theory found with Hopkins:

Theorem 4.5 ([28]). *For any separable field extension $F|k$, the symbols $[u] \in \mathbb{Z}_{\mathbb{A}^1}(1)(F)$, for any $u \in F^\times$, and $\eta \in \mathbb{Z}_{\mathbb{A}^1}(-1)(F)$, satisfy the* 4 *relations of Definition* 4.1 *in the graded ring $\mathbb{Z}_{\mathbb{A}^1}(*)(F)$. We thus obtain a canonical homomorphism of graded rings*

$$\Theta_*(F)\colon K^{MW}_*(F) \to \mathbb{Z}_{\mathbb{A}^1}(*)(F).$$

The Steinberg relation (1) is a consequence of the following nice result of P. Hu and I. Kriz [17]. Consider the canonical closed immersion $\mathbb{A}^1 - \{0, 1\} \hookrightarrow \mathbb{G}_m \times \mathbb{G}_m$, $x \mapsto (x, 1-x)$. Then its (unreduced) suspension $\tilde{\Sigma}^1(\mathbb{A}^1 - \{0, 1\}) \to \Sigma^1(\mathbb{G}_m \times \mathbb{G}_m)$ composed with $\Sigma^1(\mathbb{G}_m \times \mathbb{G}_m) \to \Sigma^1(\mathbb{G}_m \wedge \mathbb{G}_m)$ is trivial in $\mathsf{H}_\bullet(k)$. Applying $\mathbb{H}_1^{\mathbb{A}^1}$ yields the Steinberg relation.

The last 3 relations are consequences of the following fact: let $\mu\colon \mathbb{G}_m \times \mathbb{G}_m \to \mathbb{G}_m$ denote the product morphism of the group scheme $\mathbb{G}_m$, then the induced morphism on $\mathbb{H}_1^{\mathbb{A}^1}$, $\mathbb{Z}_{\mathbb{A}^1}(1) \oplus \mathbb{Z}_{\mathbb{A}^1}(1) \oplus \mathbb{Z}_{\mathbb{A}^1}(2) \to \mathbb{Z}_{\mathbb{A}^1}(1)$ is of the form $\mathrm{Id}_{\mathbb{Z}_{\mathbb{A}^1}(1)} \oplus \mathrm{Id}_{\mathbb{Z}_{\mathbb{A}^1}(1)} \oplus \eta$. The relation (2) follows clearly form this fact. The relations (3) and (4) follow from the commutativity of μ. □

Unramified Milnor–Witt K-theory and the main computation. We next define for each $n \in \mathbb{Z}$ an explicit sheaf $\underline{\mathbf{K}}_n^{MW}$ called the sheaf of *unramified Milnor–Witt K-theory* in weight n. To do this, let us give some recollection. For the Milnor K-theory [26], for any discrete valuation v on a field F, with valuation ring $\mathcal{O}_v \subset F$, residue field $\kappa(v)$, one can define a unique homomorphism (of graded groups)

$$\partial_v\colon K_*^M(F) \to K_{*-1}^M(\kappa(v))$$

called "residue" homomorphism, such that

$$\partial_v(\{\pi\}\{u_2\}\dots\{u_n\}) = \{\overline{u_2}\}\dots\{\overline{u_n}\}$$

for any uniformizing element π (of v) and units $u_i \in \mathcal{O}_v^\times$, and where $\bar{u}$ denotes the image of $u \in \mathcal{O}_v \cap F^\times$ in $\kappa(v)$.

In the same way, given a uniformizing element π, one can define a residue morphism

$$\partial_v^\pi\colon K_*^{MW}(F) \to K_{*-1}^{MW}(\kappa(v))$$

satisfying the formula:

$$\partial_v^\pi([\pi].[u_2]\dots[u_n]) = [\overline{u_2}]\dots[\overline{u_n}].$$

However, one important feature is that in the case of Milnor K-theory, these residues do not depend on the choice of π, only on the valuation, but in the case of Milnor–Witt K-theory, they do depend on the choice of π: for $u \in \mathcal{O}^\times$, as one has $\partial_v^\pi([u.\pi]) = \partial_v^\pi([\pi]) + \eta.[\bar{u}] = 1 + \eta.[\bar{u}]$.

To make this residue homomorphism "canonical" (see [5], [6], [48] for instance), one defines for a field κ and a one dimensional κ-vector space L, twisted Milnor–Witt K-theory groups: $K_*^{MW}(\kappa; L) = K_*^{MW}(\kappa) \otimes_{\mathbb{Z}[\kappa^\times]} \mathbb{Z}[L - \{0\}]$, where the group ring $\mathbb{Z}[\kappa^\times]$ acts through $u \mapsto \langle u\rangle$ on $K_*^{MW}(\kappa)$ and through multiplication on $\mathbb{Z}[L - \{0\}]$. The canonical residue homomorphism is of the following form

$$\partial_v\colon K_*^{MW}(F) \to K_{*-1}^{MW}(\kappa(v); m_v/(m_v)^2)$$

with $\partial_v([\pi].[u_2]\dots[u_n]) = [\overline{u_2}]\dots[\overline{u_n}]\otimes\overline{\pi}$, where $m_v/(m_v)^2$ is the cotangent space at v (a one dimensional $\kappa(v)$-vector space).

Using these residue homomorphisms, one may define for any smooth k-scheme $X \in \mathsf{Sm}_k$, irreducible say, with function field K, and any $n \in \mathbb{Z}$, the group $\underline{\mathbf{K}}^{MW}(X)$ of unramified Milnor–Witt K-theory in weight n as the kernel of the (locally finite) sum of the residues at points x of codimension 1, viewed as discrete valuations on K:

$$K_n^{MW}(K) \xrightarrow{\Sigma_x \partial_x} \bigoplus_{x \in X^{(1)}} K_{n-1}^{MW}(\kappa(x); m_x/(m_x)^2)$$

and extends this to a sheaf $X \mapsto \underline{\mathbf{K}}_n^{MW}(X)$.

Example 4.6. 1) In [18] Kato considered first the sheaves of unramified Milnor K-theory $\underline{\mathbf{K}}_n^M$ defined exactly in the same way on the Zariski site of X. It was turned into a strictly $\mathbb{A}^1$-invariant sheaf (on Sm_k) by Rost in [46].

2) One may also define unramified Witt K-theory $\underline{\mathbf{K}}_n^W$, unramified mod 2 Milnor K-theory $\underline{\mathbf{k}}_n$ in the same way, etc.

These types of cohomology theories easily give the non nilpotence of η:

Theorem 4.7. *Let $n \geq 1$ and $i \geq 1$ be natural numbers. The n-th suspension in $\mathsf{H}_\bullet(k)$*

$$\Sigma^n(\eta^i)\colon S^{n+1}(i+1) \to S^{n+1}(1)$$

of the i-th iteration of the Hopf map $\eta\colon S^1(2) \to S^1(1)$, is never trivial. Thus the algebraic Hopf map is not stably nilpotent.

This is trivial if one has a real embedding as $\eta(\mathbb{R})$ is the degree 2 map. In general, one uses the cohomology theory $H^*(-; \underline{\mathbf{K}}_*^{MW}[\eta^{-1}])$, in which η induces an isomorphism. To conclude remember that $K_*^{MW}(k)[\eta^{-1}] = K_0^W(k)[\eta, \eta^{-1}]$ and that $K_0^W(k)$ is never 0 (for k algebraically closed it is $\mathbb{Z}/2$).

We can now state our main computational result. Any strictly $\mathbb{A}^1$-invariant sheaf M has residue homomorphisms (see [34] for instance) and one proves that the homomorphism of Theorem 4.8

$$\Theta_*(F)\colon K_*^{MW}(F) \to \mathbb{Z}_{\mathbb{A}^1}(*)(F)$$

is compatible with residues. Thus (by [33, A.1] it induces a morphism of sheaves

$$\Theta_*\colon \underline{\mathbf{K}}_*^{MW} \to \mathbb{Z}_{\mathbb{A}^1}(*). \tag{4.3}$$

Theorem 4.8 ([28]). *The above morphism* (4.3) *is an isomorphism.*

We observe that the product $\mathbb{G}_m \wedge \underline{\mathbf{K}}_n^{MW} \to \underline{\mathbf{K}}_1^{MW} \wedge \underline{\mathbf{K}}_n^{MW} \to \underline{\mathbf{K}}_{n+1}^{MW}$ induces an isomorphism $\underline{\mathbf{K}}_n^{MW} \cong (\underline{\mathbf{K}}_{n+1}^{MW})_{-1}$. We deduce the existence for each $n > 0$, each $i > 0$, of a canonical $\mathsf{H}_\bullet(k)$-morphism

$$S^n(i) \to K(\underline{\mathbf{K}}_i^{MW}, n). \tag{4.4}$$

Some consequences and applications. The previous result and the Hurewicz Theorem imply:

Theorem 4.9. *For any $n \geq 2$, any $i > 0$:*

1) *The morphism* (4.4) *induces an isomorphism*

$$\pi_n^{\mathbb{A}^1}(S^n(i)) \cong \underline{\mathbf{K}}_i^{MW}.$$

2) *For any $m \in \mathbb{N}$, any $j \in \mathbb{N}$, the previous isomorphism induces canonical isomorphisms*

$$\mathrm{Hom}_{\mathsf{H}(k)}(S^m(j), S^n(i)) \cong \begin{cases} 0 & \text{if } m < n, \\ K_{i-j}^{MW}(k) & \text{if } m = n. \end{cases}$$

In case $i = 0, \pi_n^{\mathbb{A}^1}(S^n) = \mathbb{Z}$ and $\mathrm{Hom}_{\mathsf{H}(k)}(S^m(j), S^n) = \begin{cases} 0 \text{ if } m < n \quad \text{or } j \neq 0, \\ \mathbb{Z} \text{ if } m = n \quad \text{and } j = 0. \end{cases}$

In general, for $n = 1$ the question is much harder, and in fact unknown. We only know $\pi_1^{\mathbb{A}^1}(S^1(i))$ in the cases $i = 0, 1, 2$. For $i = 0$, $\pi_1^{\mathbb{A}^1}(S^1(i))(S^1) = \mathbb{Z}$.

For $i = 2$, as $\mathrm{SL}_2 \to \mathbb{A}^2 - \{0\} \cong S^1(2)$ is an $\mathbb{A}^1$-weak equivalence, the sphere $S^1(2)$ is an h-space and (by Hurewicz Theorem and Theorem 3.2) $\pi_1^{\mathbb{A}^1}(S^1(2)) = \mathbb{H}_1^{\mathbb{A}^1}(S^1(2)) = \underline{\mathbf{K}}_2^{MW}$. In fact the universal $\mathbb{A}^1$-covering given by Theorem 3.8 admits a group structure and we thus get an extension of sheaves of groups (in fact in the Zariski topology as well)

$$0 \to \underline{\mathbf{K}}_2^{MW} \to \widetilde{\mathrm{SL}}_2 \to \mathrm{SL}_2 \to 1.$$

This is a central extension which also arises in the following way. Let $B(\mathrm{SL}_2)$ denote the simplicial classifying space of SL_2. Then the canonical cohomology class $\Sigma(\mathrm{SL}_2) \cong S^2(2) \to K(\underline{\mathbf{K}}_2^{MW}, 2)$ can be uniquely extended to a $\mathsf{H}_\bullet(k)$-morphism:

$$B(\mathrm{SL}_2) \to K(\underline{\mathbf{K}}_2^{MW}, 2)$$

because the quotient $B(\mathrm{SL}_2)/\Sigma(\mathrm{SL}_2)$ is 3-$\mathbb{A}^1$-connected. It is well-known that such an element in $H^2(B(\mathrm{SL}_2); \underline{\mathbf{K}}_2^{MW})$ corresponds to a central extension of sheaves as above. It is the universal $\mathbb{A}^1$-covering for SL_2.

Remark 4.10. 1) In view of [13] it should be interesting to determine the possible $\pi_1^{\mathbb{A}^1}$ of linear algebraic groups.

2) A. Suslin has computed in [49] the group $H_2(\mathrm{SL}_2(k))$ for most field k and found exactly $\underline{\mathbf{K}}_2^{MW}(k) = I^2(k) \times_{i^2(k)} K_2^M(k)$. This computation has clearly influenced our work.

To understand $\pi_1^{\mathbb{A}^1}(\mathbb{P}^1)$ we use the $\mathbb{A}^1$-fibration sequence

$$\mathbb{A}^2 - \{0\} \to \mathbb{P}^1 \to \mathbb{P}^\infty \tag{4.5}$$

which, using the long exact sequence of $\mathbb{A}^1$-homotopy sheaves, gives a short exact sequence of the form:

$$1 \to \underline{\mathbf{K}}_2^{MW} \to \pi_1^{\mathbb{A}^1}(\mathbb{P}^1) \to \mathbb{G}_m \to 1$$

because $\underline{\mathbf{K}}_2^{MW} = \pi_1^{\mathbb{A}^1}(\mathbb{A}^2 - \{0\})$ and because $\mathbb{P}^\infty \cong B(\mathbb{G}_m)$ has only non-trivial $\pi_1^{\mathbb{A}^1}$ equal to $\mathbb{G}_m$. This extension of (sheaves of) groups can be completely explicited [36]. In particular $\pi_1^{\mathbb{A}^1}(\mathbb{P}^1)$ is non abelian!

The Brouwer degree. Now we can deduce as particular case of Theorem 4.9 what we announced in the introduction.

Corollary 4.11. *For any $n \geq 2$, any $i > 0$, the degree morphism induced by the morphism* (4.4)

$$\mathrm{Hom}_{\mathsf{H}(k)}(S^n(i), S^n(i)) \to K_0^{MW}(k)$$

is an isomorphism. As a consequence, the endomorphism ring of the $\mathbb{P}^1$-sphere spectrum $\mathbb{S}^0$, which by definition is

$$\pi_0^{\mathbb{A}^1}(\mathbb{S}^0) = \mathrm{colim}_{n\to\infty} \mathrm{Hom}_{\mathsf{H}(k)}(S^n(n), S^n(n)),$$

is isomorphic to the Grothendieck–Witt ring $GW(k) = K_0^{MW}(k)$ of k (see [31]*,* [30] *for the case of a perfect field of characteristic $\neq 2$).*

When $n = 1$, $i = 1$, $S^1(1) \cong \mathbb{P}^1$, using the $\mathbb{A}^1$-fibration sequence (4.5) one may entirely describe $\mathrm{Hom}_{\mathsf{H}(k)}(\mathbb{P}^1, \mathbb{P}^1)$ [36]. One may check the morphism $\mathbb{P}^1 \to K(\underline{\mathbf{K}}_1^{MW}, 1)$ induces a degree morphism $\mathrm{Hom}_{\mathsf{H}_\bullet(k)}(\mathbb{P}^1, \mathbb{P}^1) \to K_0^{MW}(k)$, which coincides with the one sketched in the introduction, for an actual morphism $\mathbb{P}^1 \to \mathbb{P}^1$ which has a regular value. However it is not an isomorphism in general: its kernel is isomorphic to the subgroup of squares $(k^\times)^2$ in $k^\times$.

Remark 4.12. 1) *Transfers.* It is well know that, given a finite separable field extension $k \subset L$ together with a primitive element $x \in L$ (which generates $L|k$), one can define a transfer morphism in $\mathsf{H}_\bullet(k)$ of the form

$$tr_x : \mathbb{P}^1 \to \mathbb{P}^1 \wedge (\mathrm{Spec}(L)_+).$$

This follows from the Purity Theorem of [38] (or the Thom–Pontryagin construction) applied to the closed immersion $\mathrm{Spec}(L) \to \mathbb{P}^1$ determined by x. Using our computations and methods, we have been able to show that the induced morphism on $\mathbb{H}_1^{\mathbb{A}^1}$ does not depend on the choice of x. As a consequence we obtain that for any strictly $\mathbb{A}^1$-invariant sheaf M the strictly $\mathbb{A}^1$-invariant sheaf M_{-1} has canonical transfers morphisms for finite separable extensions between separable extensions of k. This can be used to simplify the construction of transfers in Milnor K-theory [18], [7].

Beware however that this notion of transfers for finite extension is slightly more general than Voevodsky's notion. The sheaf M_{-1} is automatically a sheaf of modules

over $\underline{\mathbf{K}}_0^{MW}$. Given a finite separable extension $k \subset L$ as above, the composition $M_{-1}(k) \to M_{-1}(L) \xrightarrow{\mathrm{tr}} M_{-1}(k)$ is precisely the multiplication by the class of L in $K_0^{MW}(k)$ (which is its Euler characteristic by the remark below). In characteristic $\neq 2$, this is (up to an invertible element) the trace form of $L|k$ in the Grothendieck–Witt group. In the case of Voevodsky's structure this composition is just the multiplication by $[L : k] \in \mathbb{N}$.

2) Using the previous computations as well as the classical ideas on Atiyah duality [2] and [16] in $\mathbb{A}^1$-algebraic topology[5] one may define for any morphism f (in fact in $\mathsf{H}(k)$) from a smooth projective k-variety X to itself a Lefschetz number $\lambda(f) \in K_0^{MW}(k)$ which satisfies all the usual properties (like the Lefschetz fixed point formula). In particular the Euler characteristic of X lies in $K_0^{MW}(k)$.

3) In view of the cartesian diagram (4.2) and our philosophy, the part coming from the Milnor K-theory is the one compatible with the intuition coming from the topology of complex points (or motives), and the part coming from the Witt K-theory is the one compatible with the intuition on the topology of real points. For any $X \in \mathsf{Sm}_k$ the graded ring $\bigoplus_n H^n(X; \underline{\mathbf{K}}_n^{MW})$ maps surjectively to the Chow ring $CH^*(X) = \bigoplus_n H^n(X; \underline{\mathbf{K}}_n^M)$ and to the graded ring $\bigoplus_n H^n(X; \underline{\mathbf{K}}_n^W)$ (however it does not inject into the product in general: one has a Mayer–Vietoris type long exact sequence). Given a real embedding there exists a morphism of rings $\bigoplus_n H^n(X; \underline{\mathbf{K}}_n^W) \to H^*(X(\mathbb{R}); \mathbb{Z})$. Note that it is known that the Chow ring only maps to $H^*(X(\mathbb{R}); \mathbb{Z}/2)$.

5. Some results on classifying spaces in $\mathbb{A}^1$-homotopy theory

Serre's splitting principle and $\mathbb{H}_0^{\mathbb{A}^1}$ of some classifying spaces. The Serre's splitting principle was stated in [15] only in terms of étale cohomology groups §24 or in terms of Witt groups §29, but we may easily generalize it to our situation.

Let us briefly recall from [53] and also [38] the notion of *geometric classifying space* $B_{gm}(G)$ for a linear algebraic group G. Choose a closed immersion of k-groups $\rho\colon G \subset \mathbb{G}L_n$. For each $r > 0$, denote by $U_r \subset \mathbb{A}^{rn}$ the open subset where G acts freely (in the étale topology) in the direct sum of r copies of the representation ρ. $B_{gm}(G)$ is then the union over r of the quotient k-varieties U_r/G, which are smooth k-varieties. We proved in [38] that for G a finite group of order prime to $\mathrm{char}(k)$ and X a smooth k-variety:

$$\mathrm{Hom}_{\mathsf{H}(k)}(X, B_{gm}(G)) \cong H^1_{\text{ét}}(X; G).$$

For n an integer, denote by $m = [\frac{n}{2}]$ and by $(\mathbb{Z}/2)^m \subset \Sigma_n$ the natural embedding. The following result is a variation on the Splitting principle [15, §24] (using the fact

[5] These ideas are also present in much more elaborated form in Voevodsky formalism of cross-functors [59], see also [3].

that strictly $\mathbb{A}^1$-invariant sheaves have also residues [34] as well as [15, Appendix C, A letter from B. Totaro to J.-P. Serre]):

Theorem 5.1 (Serre's splitting principle). *For any strictly $\mathbb{A}^1$-invariant sheaf M the restriction map*

$$H^0(B_{gm}(\Sigma_n); M) \to H^0(B_{gm}((\mathbb{Z}/2)^m); M)$$

is injective.

Corollary 5.2. *The homomorphism*

$$\mathbb{H}_0^{\mathbb{A}^1}(B_{gm}((\mathbb{Z}/2)^m) \to \mathbb{H}_0^{\mathbb{A}^1}(B_{gm}(\Sigma_n))$$

is an epimorphism.

We observe that $B_{gm}((\mathbb{Z}/2)^m)$ is $\mathbb{A}^1$-equivalent to a point in characteristic 2, see [38]. In that case we get $\mathbb{H}_0^{\mathbb{A}^1}(B_{gm}(\Sigma_n)) = \mathbb{Z}$.

In characteristic $\neq 2$, one has an exact sequence $\tilde{\mathbb{H}}_0^{\mathbb{A}^1}(\mathbb{G}_m) \to \tilde{\mathbb{H}}_0^{\mathbb{A}^1}(\mathbb{G}_m) \to \tilde{\mathbb{H}}_0^{\mathbb{A}^1}(B_{gm}(\mathbb{Z}/2)) \to 0$ where the left morphism is induced by the squaring map (this comes from the fact that $B_{gm}(\mathbb{Z}/2)$ is the union of the quotients $(\mathbb{A}^n - \{0\})/(\mathbb{Z}/2)$). Thus $\tilde{\mathbb{H}}_0^{\mathbb{A}^1}(B_{gm}(\mathbb{Z}/2)) = \underline{\mathbf{K}}_1^{MW}/h = \underline{\mathbf{K}}_1^W$ and $\mathbb{H}_0^{\mathbb{A}^1}(B_{gm}(\mathbb{Z}/2)) = \mathbb{Z} \oplus \underline{\mathbf{K}}_1^W$.

Now the $\mathbb{A}^1$-tensor product $\underline{\mathbf{K}}_n^W \otimes_{\mathbb{A}^1} \underline{\mathbf{K}}_m^W$ is $\underline{\mathbf{K}}_{n+m}^W$. Using this we may compute $\mathbb{H}_0^{\mathbb{A}^1}(B_{gm}((\mathbb{Z}/2)^m))$ by the Künneth formula and as the morphism of Theorem 5.1 is invariant under the action of Σ_m we get in characteristic $\neq 2$ an epimorphism of sheaves

$$\bigoplus_{i\in\{0,\dots,m\}} \underline{\mathbf{K}}_i^W \twoheadrightarrow \mathbb{H}_0^{\mathbb{A}^1}(B_{gm}(\Sigma_n)). \tag{5.1}$$

Theorem 5.3. *In characteristic $\neq 2$ the epimorphism* (5.1) *is an isomorphism.*

The method is to construct refined Stiefel–Whitney classes $W_i\colon K_0^{MW}(F) \to K_i^W(F)$ lifting the usual ones w_i in $k_i(F)$ using the same method as in [26, §3]. The composition $\mathbb{H}_0^{\mathbb{A}^1}(B_{gm}(\Sigma_n)) \to \mathbb{H}_0^{\mathbb{A}^1}(B_{gm}(O_n)) \xrightarrow{\oplus W_i} \bigoplus_{i\in\{0,\dots,m\}} \underline{\mathbf{K}}_i^W$ is the required left inverse.

Remark 5.4. 1) This result implies the Baratt–Priddy–Quillen Theorem in dimension 0 (at least in characteristic $\neq 2$), stating that the morphism induced by the stable transfers

$$\amalg_{n\in\mathbb{N}} B_{gm}(\Sigma_n) \to Q_{\mathbb{P}^1}\mathbb{S}^0$$

where $Q_{\mathbb{P}^1}\mathbb{S}^0$ means the colimit of the iterated $\mathbb{P}^1$-loop spaces[6], is an $\mathbb{A}^1$-stable group completion[7], see [37].

[6] $\operatorname{colim}_n R\underline{\mathrm{Hom}}_\bullet((\mathbb{P}^1)^{\wedge n}, (\mathbb{P}^1)^{\wedge n})$

[7] Voevodsky proved that it is not the usual group completion.

2) The same computation holds for Suslin singular homology [52] of $B_{gm}(\Sigma_n)$: one gets in characteristic $\neq 2$: $\mathbb{H}_0^S(B_{gm}(\Sigma_n)) = \bigoplus_{i\in\{0,\dots,m\}} \underline{\mathbf{k}}_i$.

3) Using the refined Stiefel–Whitney classes W_i considered previously and [15] we can also compute in characteristic $\neq 2$: $\mathbb{H}_0^{\mathbb{A}^1}(B_{gm}(O_n)) = \oplus_{i\in\{0,\dots,n\}} \underline{\mathbf{K}}_i^W$ and $\mathbb{H}_0^S(B_{gm}(O_n)) = \oplus_{i\in\{0,\dots,n\}} \underline{\mathbf{k}}_i$. We observe as a consequence that the natural map (of sets)

$$H^1_{\text{ét}}(k;\, O_n) \to \mathbb{H}_0^{\mathbb{A}^1}(B_{gm}(O_n))(k)$$

is injective (but is not if one consider the Suslin $\mathbb{H}_0^S$ instead !). It is a natural question to ask for which algebraic k-groups the analogous map is injective. It is wrong for finite groups in general (but the abelian ones). It could be however true for a general class of algebraic groups G, in connection with a conjecture of Serre addressing the injectivity of the extension map $H^1_{\text{ét}}(k; G) \to H^1_{\text{ét}}(L_1; G) \times H^1_{\text{ét}}(L_2; G)$ when the finite field extensions L_1 and L_2 have coprime degrees over k.

$\mathbb{A}^1$-homotopy classification of algebraic vector bundles. Lindel has proven in [25] that for any n and for any smooth affine k-scheme X the projection $X \times \mathbb{A}^1 \to X$ induces a bijection

$$H^1_{Zar}(X; \mathbb{G}L_n) \to H^1_{Zar}(X \times \mathbb{A}^1; \mathbb{G}L_n)$$

(after the fundamental cases obtained by Quillen [45] and Suslin [50] on the Serre problem). As a consequence if one denotes by $\mathbb{G}r_n$ the "infinite Grassmanian of n-plans" the natural map $\mathrm{Hom}_k(X; \mathbb{G}r_n) \to H^1_{Zar}(X; \mathbb{G}L_n)$ which to a morphism assigns the pull-back of the universal rank n bundle, induces a map $\pi(X; \mathbb{G}r_r) \to H^1_{Zar}(X; \mathbb{G}L_n)$ (where the source means the set of morphisms modulo naive $\mathbb{A}^1$-homotopies); it is moreover easy to show this map is a bijection.

Theorem 5.5 ([35]). *For any integer $n \geq 3$ and any affine smooth k-scheme X the obvious map*

$$H^1_{Zar}(X; \mathbb{G}L_n) \cong \pi(X; \mathbb{G}r_r) \to \mathrm{Hom}_{\mathsf{H}(k)}(X, \mathbb{G}r_r)$$

is a bijection.

For $n = 1$ this is well-known [38]. The proof of this result relies on the works of Quillen, Suslin, Lindel cited above and also on the works of Suslin [51] and Vorst [60] on the generalized Serre problem for the general linear group. In these latter works n has to be assumed $\neq 2$. We conjecture however that the statement of the previous theorem should remain true also for $n = 2$.

One then observes that one has an $\mathbb{A}^1$-fibration sequence of pointed spaces:

$$\mathbb{A}^n - \{0\} \to \mathbb{G}r_{n-1} \to \mathbb{G}r_n \tag{5.2}$$

because the simplicial classifying space $B(\mathbb{G}L_m)$ is $\mathbb{A}^1$-equivalent to $\mathbb{G}r_m$, for any m, and because $\mathbb{G}L_n/\mathbb{G}L_{n-1} \to \mathbb{A}^n - \{0\}$ is an $\mathbb{A}^1$-weak equivalence. From Theorem 4.9

we know that the space $\mathbb{A}^n - \{0\}$ is $(n-2)$-connected and that there exists a canonical isomorphism of sheaves: $\pi_{n-1}^{\mathbb{A}^1}(\mathbb{A}^n - \{0\}) \cong \underline{\mathbf{K}}_n^{MW}$.

Euler class and Stably free vector bundles. For a given smooth affine k-scheme X and an integer $n \geq 4$ we may now study the map:

$$H^1_{Zar}(X; \mathbb{G}L_{n-1}) \to H^1_{Zar}(X; \mathbb{G}L_n)$$

of adding the trivial line bundle following the classical method of obstruction theory in homotopy theory:

Theorem 5.6 (Theory of Euler class, [35]). *Assume $n \geq 4$. Let X be a smooth affine k-scheme, together with an oriented algebraic vector bundle ξ of rank n (this means a vector bundle of rank n and a trivialization of $\Lambda^n(\xi)$). Define its Euler class*

$$e(\xi) \in H^n(X; \underline{\mathbf{K}}_n^{MW}) = H^n(X; \pi_{n-1}^{\mathbb{A}^1}(\mathbb{A}^n - \{0\}))$$

to be the obstruction class obtained from Theorem 5.5 *and the $\mathbb{A}^1$-fibration sequence* (5.2). *If dimension $X \leq n$ we have the following equivalence:*

$$\xi \textit{ split off a trivial line bundle} \Leftrightarrow e(\xi) = 0 \in H^n(X; \underline{\mathbf{K}}_n^{MW}).$$

Remark 5.7. 1) In case $\mathrm{char}(k) \neq 2$, the group $H^n(X; \underline{\mathbf{K}}_n^{MW})$ coincides with the oriented Chow group $\widetilde{CH}^n(X)$ as defined in [5] and our Euler class coincides also with the one defined in *loc. cit.* There is an epimorphism from the Euler class group of Nori [8] to ours but we do not know whether this is an isomorphism. We observe that in [8] an analogous result is proven, and our result implies the result in [8]. If $\mathrm{char}(k) \neq 2$, in [5] the case of rank $n = 2$ was settled by some other method.

2) If ξ is an algebraic vector bundle of rank n over X, let $\lambda_\xi = \Lambda^n(\xi) \in \mathrm{Pic}(X)$ denotes its first Chern class. The obstruction class $e(\xi)$ obtained by the $\mathbb{A}^1$-fibration sequence (5.2) lives now in the corresponding cohomology group $H^n(X; \underline{\mathbf{K}}_n^{MW}(\lambda_\xi))$ obtained by twisting the sheaf $\underline{\mathbf{K}}_n^{MW}$ by λ_ξ.

3) The obvious morphism

$$H^n(X; \underline{\mathbf{K}}_n^{MW}) \to H^n(X; \underline{\mathbf{K}}_n^{M}) = CH^n(X)$$

maps the Euler class to the top Chern class $c_n(\xi)$. When k is algebraically closed and $\dim(X) \leq n$, this homomorphism is an isomorphism. This case of the Theory is due to Murthy [39].

4) Given a real embedding of the base field $k \to \mathbb{R}$, the canonical morphism from Remark 4.12 3): $H^n(X; \underline{\mathbf{K}}_n^{MW}) \to H^n(X(\mathbb{R}); \mathbb{Z})$ maps the Euler class $e(\xi)$ to the Euler class of the real vector bundle $\xi(\mathbb{R})$.

The long exact sequence in homotopy for the $\mathbb{A}^1$-fibration sequence (5.2) (applied to $(n+1)$) also gives the following theorem (compare [9]):

Theorem 5.8 (Stably free vector bundles, [35]). *Assume $n \geq 3$. Let X be a smooth affine k-scheme. The canonical map*

$$\mathrm{Hom}_{\mathsf{H}(k)}(X, \mathbb{A}^{n+1} - \{0\}) \,/\, \mathrm{Hom}_{\mathsf{H}(k)}(X, \mathbb{G}L_{n+1}) \to \mathrm{Hom}_{\mathsf{H}(k)}(X, \mathbb{G}r_n)$$

is injective and its image $\Psi_n(X) \subset H^1_{Zar}(X; \mathbb{G}L_n) = \mathrm{Hom}_{\mathsf{H}(k)}(X, \mathbb{G}r_n)$ consists exactly of the set of isomorphism classes of algebraic vector bundles of rank n over X such that $\xi \oplus \theta^1$ is trivial.

Moreover if the dimension of X is $\leq n$, the natural map

$$\mathrm{Hom}_{\mathsf{H}(k)}(X, \mathbb{A}^{n+1} - \{0\}) \to H^n(X; \underline{\mathbf{K}}^{MW}_{n+1})$$

is a bijection and the natural action of $\mathrm{Hom}_{\mathsf{H}(k)}(X, \mathbb{G}L_{n+1})$ factors trough the determinant as an action of $\mathcal{O}(X)^\times$. In that case, we get a bijection

$$H^n(X; \underline{\mathbf{K}}^{MW}_{n+1})/\mathcal{O}(X)^\times \cong \Psi_n(X).$$

Remark 5.9. Using Popescu's approximation result [43] it is possible, with some care, to extend the results of this paragraph to affine regular schemes defined over a field k.

6. Miscellaneous

Proofs of the Milnor conjecture on quadratic forms. Using Voevodsky's result [57] we have produced two proofs of the Milnor conjecture on quadratic forms asserting that for a field F of characteristic $\neq 2$ the Milnor epimorphism $s_F : k_*(F) \to i^*(F)$ is an isomorphism.

The first one is only sketched in [29], however it is very striking in the context of $\mathbb{A}^1$-algebraic topology. We consider the Adams spectral sequence based on mod 2 motivic cohomology "converging" to $\pi_*^{\mathbb{A}^1}(\mathbb{S}^0)$. Using an unpublished work of Voevodsky on the computation of the mod 2 motivic Steenrod algebra we showed that $E_2^{s,u} = \mathrm{Ext}^s_{\mathcal{A}_k}(H^*(k; \mathbb{Z}/2(*)), H^*(k; \mathbb{Z}/2(*))[s+u])$ and could compute enough. First $E_2^{s,u}$ vanishes for $u < 0$ which is compatible with the $\mathbb{A}^1$-connectivity result 3.5, which implies $\pi_u^{\mathbb{A}^1}(\mathbb{S}^0) = 0$ for $u < 0$. More striking is the computation of the column $E_2^{s,0}$ converging to $\pi_0^{\mathbb{A}^1}(\mathbb{S}^0) = GW(k)$ (in characteristic $\neq 2$). We found that $E_2^{0,0} = \mathbb{Z}/2$ and that for $s > 0$

$$E^{s,0} = \mathbb{Z}/2 \oplus k_s(k).$$

This is exactly the predicted form of the associated graded ring for $GW(k)$ by the Milnor conjecture. The terms $\mathbb{Z}/2$ are detected (in the bar complex) by the tensor powers of the Bockstein $\beta^{\otimes s}$ and the mod 2 Milnor K-theory terms are detected by the tensor powers of the $\mathbb{S}q^2$-operation[8] of Voevodsky $(\mathbb{S}q^2)^{\otimes s}$. The proof of the Milnor

[8] This relationship is explained again by "taking" the real points: the operation $\mathbb{S}q^2$ "induces" the Bockstein operation on mod 2 singular cohomology of real points

conjecture then amounts to showing that the Adams spectral sequence degenerates from the $E_2^{*,*}$-term on the column $u = 0$.

The degenerescence was obtained by a careful study of the column $E_2^{*,1}$ from which the potential differentials start to reach $E_2^{*,0}$, using the Milnor conjecture on mod 2 Galois cohomology of fields of characteristic 2 established by Voevodsky in [57]. The idea was to observe that the groups $E_2^{*,1}$ are enough "divisible" by some suitable mod 2-Milnor K-theory groups. We realized recently in [33] that this argument could be made much simpler and that everything amounts to proving some "$\mathbb{P}^1$-cellularity" of the sheaves $\underline{\mathbf{k}}_n$ in the $\mathbb{A}^1$-derived category, which again is given by the main result of [57].

Global properties of the stable $\mathbb{A}^1$-homotopy category. We have unfortunately no room available to discuss much recent developments in the global properties of the stable $\mathbb{A}^1$-homotopy category. Let us just mention briefly: our work (in preparation) on the rational stable homotopy category and its close relationship with Voevodsky's category of rational mixed motives. The slice filtration and motivic Atiyah–Hirzebruch's type spectral sequence approach due to Voevodsky (see [58] for instance); we must also mention Levine's recent work in this direction, for instance [22]. There is also a work in preparation by Hopkins and the author starting from the Thom spectrum $M\mathbb{G}L$, where is proven that the "homotopical quotient" $M\mathbb{G}L/(x_1, \dots, x_n, \dots)$ obtained by killing the generators of the Lazard ring is, in characteristic 0, the motivic cohomology spectrum of Voevodsky. This gives an Atiyah–Hirzebruch spectral sequence for $M\mathbb{G}L$ (and also K-theory) and gives an other (purely homotopical) proof of the general degree formula of [24], [23].

We must mention Voevodsky's formalism of cross functors [59] and Ayoub's work [3] in which is established the analogue of the theory of vanishing cycles in the context of Voevodsky's triangulated category of motives.

From $\mathbb{A}^1$-homotopy to algebraic geometry? We conclude this paper by an observation. All the tools and notions concerning the classical approach to surgery in classical differential topology seem now available in $\mathbb{A}^1$-algebraic topology: degree, homology, fundamental groups, cobordism groups [24], [23], Poincaré complexes, classification of vector bundles, etc. We also have natural candidates of surgery groups using Balmer's Witt groups [4] of some triangulated category of $\pi_1^{\mathbb{A}^1}$-modules. Why not then dreaming about a surgery approach also for smooth projective k-varieties? Of course there is no obvious analogues for surgery. There is also a major new difficulty: we have observed that even the simplest varieties like the projective spaces are never simply connected. This fact obstructs any hope of "h-cobordism" theorem[9], but now we also understand the reason: the $\mathbb{A}^1$-fundamental group of a pointed projective smooth k-scheme is almost never trivial. A major advance would then be to find the analogue of the "s-cobordism" theorem, the generalization of the h-cobordism theorem in the presence of π_1.

[9] Marc Levine indeed produced a counter-example

Development in symplectic Floer theory

Kaoru Ono*

Abstract. In the middle of the 1980s, Floer initiated a new theory, which is now called the Floer theory. Since then the theory has been developed in various ways. In this article we report some recent progress in Floer theory in symplectic geometry. For example, we give an outline of a proof of the flux conjecture, which states that the Hamiltonian diffeomorphism group is C^1-closed in the group of symplectomorphisms for closed symplectic manifolds. We also give a brief survey on the obstruction–deformation theory for Floer theory of Lagrangian submanifolds and explain some of its applications.

Mathematics Subject Classification (2000). Primary 53D40; Secondary 53D35.

Keywords. Symplectic manifold, Hamiltonian systems, Lagrangian submanifolds, Floer cohomology, A_∞-structure.

1. Introduction

In [9]–[14], Andreas Floer initiated "$\frac{\infty}{2}$-dimensional" (co)homology theory, which is now called Floer theory. He invented this theory to prove Arnold's conjecture for fixed points of Hamiltonian diffeomorphism and, under certain assumptions, its analogue for Lagrangian intersections. Roughly speaking, the conjecture states that there is a non-trivial topological lower bound for the number of fixed points of a Hamiltonian diffeomorphism. It is one of his conjectures which stimulated recent developments in symplectic geometry. This theory was soon adapted in Donaldson theory and he constructed the instanton homology theory. A lot of work has been done since and Floer theory has been developed in various directions. In this article, we will describe some recent development of Floer theory in symplectic geometry.

In these decades, symplectic geometry has been much developed. In particular, Gromov revealed many significant phenomena based on his theory of pseudo-holomorphic curves [18] and revolutionized the study in this area. Hamiltonian dynamics is one of main sources of symplectic geometry. The existence of periodic trajectories is a basic problem and there are many works on this subject up to now. In fact, the existence of periodic trajectories reflects so-called symplectic rigidity phenomena. Since trajectories of a Hamiltonian system are characterized by the least action principle, the variational method can be applied to the existence of periodic

of Mathematicians, Madrid, Spain, 2006

trajectories. Namely, closed trajectories are critical points of the action functional associated to the Hamiltonian system. Floer combined the variational framework with the theory of pseudo-holomorphic curves to construct an analogue of Morse theory for the action functional.

In the first part of this article, we discuss Floer theory for Hamiltonian systems and present some applications including the flux conjecture. In the second part, we discuss Floer theory for Lagrangian submanifolds. In general, Floer cohomology may not be defined for a pair of Lagrangian submanifolds. We briefly describe the obstruction to defining Floer cohomology as well as the filtered A_∞-algebra associated to a Lagrangian submanifold. We also present some applications, e.g., Lagrangian intersections, non-triviality of the Maslov class, etc. Although there will be some overlaps with Y. G. Oh's contribution to this proceedings, we will try to put different emphases on the theory in this lecture.

2. Floer theory for symplectomorphisms

2.1. Review on the construction. In this section, we briefly review the construction of Floer cohomology for symplectomorphisms, especially Hamiltonian diffeomorphisms, which was initiated in [14] and developed in e.g., [21], [36], [16], [29]. Let (M, ω) be a symplectic manifold. In this article, we assume that M is compact without boundary for simplicity. Denote by X_h the Hamiltonian vector field of h defined by

$$i(X_h)\omega = dh.$$

For $H = \{h_t\}_{t\in\mathbb{R}}$, we integrate the time-dependent vector field X_{h_t} to obtain the one-parameter family $\{\varphi_t^H\}$ of diffeomorphisms. We call such $\{\varphi_t^H\}$ a time-dependent Hamiltonian flow. A diffeomorphism φ of M is called a Hamiltonian diffeomorphism, when φ is the time-one map of $\{\varphi_t^H\}$ for some H. We may assume that $h_{t+1} = h_t$. Denote by $\mathrm{Ham}(M, \omega)$ resp. $\mathrm{Symp}(M, \omega)$ the group of Hamiltonian diffeomorphisms resp. the group of symplectomorphisms which are diffeomorphisms preserving ω. Clearly, $\mathrm{Ham}(M, \omega) \subset \mathrm{Symp}(M, \omega)$. Hamiltonian diffeomorphisms are fundamental in symplectic geometry and enjoy some distinguished properties, e.g., existence of fixed points (see Arnold's conjecture below), simplicity [1], existence of a biinvariant distance on (the universal covering group of) $\mathrm{Ham}(M, \omega)$, called Hofer's distance, etc. Now we recall the following:

Conjecture 2.1 (Arnold's conjecture). For $\varphi \in \mathrm{Ham}(M, \omega)$ there are as many fixed points of φ as the smallest number of critical points of smooth functions on M, namely,

$$\#\,\mathrm{Fix}(\varphi) \geq \min\{\#\mathrm{Crit}(f) \mid f \in C^\infty(M)\}.$$

If all the fixed points of φ are non-degenerate, i.e. 1 is not an eigenvalue of $d\varphi$ at any

fixed point, then

$$\#\,\mathrm{Fix}(\varphi) \geq \min\{\#\mathrm{Crit}(f) \mid f \text{ is a Morse function on } M\}.$$

This conjecture has been verified for closed oriented surfaces, the torus, complex projective spaces, etc. A weaker version of the conjecture is formulated by replacing the lower bounds with the cup-length and the sum of Betti numbers, respectively. We call it homological Arnold conjecture.

Let φ be a symplectomorphism of (M, ω) such that all fixed points are non-degenerate. Following [6], we introduce the twisted loop space

$$\mathcal{P}_\varphi = \{\sigma : [0, 1] \to M \mid \varphi(\sigma(1)) = \sigma(0)\},$$

and define a closed 1-form, in a formal sense, on $\mathcal{P}_\varphi$ by

$$\alpha_\varphi(\xi) = \int_0^1 \omega(\xi, \dot{\sigma})\, dt \quad \text{for } \xi \in T_\sigma \mathcal{P}_\varphi.$$

Clearly, fixed points of φ are in one-to-one correspondence with zeros of α_φ. We take the smallest covering space $\pi : \widetilde{\mathcal{P}}_\varphi \to \mathcal{P}_\varphi$ such that (1) $\pi^*\alpha_\varphi$ is exact, i.e., there exists a primitive function $\mathcal{A}_\varphi$ for α_φ, and (2) the integer valued Maslov index μ is well defined on $\mathrm{Crit}(\mathcal{A}_\varphi) = \pi^{-1}(\mathrm{Zero}(\alpha_\varphi))$. From now on we call such a covering space the Floer covering space. Pick an almost complex structure $J = \{J_t\}$ compatible with ω such that $\varphi_* J_1 = J_0$. Then the gradient of $\mathcal{A}_\varphi$ is formally written as

$$\mathrm{grad}\, \mathcal{A}_\varphi(\sigma) = -J\dot{\sigma},$$

and gradient flow lines are regarded as solutions of the following equation

$$\frac{\partial u}{\partial \tau} + J_t(u)\frac{\partial u}{\partial t} = 0$$

for

$$u = u(\tau, t) : \mathbb{R} \times [0, 1] \to M \quad \text{such that } \varphi(u(\tau, 1)) = u(\tau, 0).$$

We set

$$CF^*(\varphi, J) = \Big\{ \sum_i a_i \tilde{\sigma}_i \mid a_i \in \mathbb{Q},\ \tilde{\sigma}_i \in \mathrm{Crit}(\mathcal{A}_\varphi) \text{ satisfy the following condition:}$$
$$\#\{i \mid a_i \neq 0,\ \mathcal{A}_\varphi(\tilde{\gamma}_i) < c\} \text{ is finite for any } c \in \mathbb{R}\Big\}.$$

The grading is given by the Maslov index μ on $\mathrm{Crit}(\mathcal{A}_\varphi)$. The coboundary operator $\delta = \delta^{\varphi, J}$ is defined by counting gradient flow lines connecting the critical points $\tilde{\sigma}^\pm$ of $\mathcal{A}_\varphi$ such that $\mu(\tilde{\sigma}^+) - \mu(\tilde{\sigma}^-) = 1$. Note that the covering transformation group $G_{M,\varphi}$ of $\pi : \widetilde{\mathcal{P}}_\varphi \to \mathcal{P}_\varphi$ naturally acts on the Floer complex. In fact, this action

extends to the so-called Novikov ring associated to $\varphi \in \mathrm{Symp}(M, \omega)$, which is a certain completion of the group ring of $G_{M,\varphi}$. To make this construction rigorous, we need to study compactness properties, transversality, etc. for the moduli space of solutions of the J-holomorphic curve equation above. We can achieve these points as in [16], [29], see also [28], [41], [45] based on the notion of stable maps [23], [24]. The resulting cohomology is the Floer cohomology $HF^*(\varphi, J)$, which is a module over the Novikov ring associated to $\varphi \in \mathrm{Symp}(M, \omega)$. We also find that Floer cohomology is invariant under Hamiltonian deformations of φ. In the case that M is 2-dimensional, Seidel noticed that the Floer cohomology is invariant under a class of deformations which contains all Hamiltonian deformations [43].

When $\varphi \in \mathrm{Symp}_0(M, \omega)$, i.e., there is a path φ_t, $0 \le t \le 1$, such that $\varphi_0 = \mathrm{id}$ and $\varphi_1 = \varphi$, we can formulate the Floer theory on the loop space LM of M rather than the twisted loop space $\mathcal{P}_\varphi$. (From now on, we call φ_t with $\varphi_0 = \mathrm{id}$ a based path.) Namely, we identify them by

$$\sigma(t) \in \mathcal{P}_\varphi \mapsto \gamma(t) = (\varphi_t)^{-1}(\sigma(t)) \in LM.$$

In particular, when $\varphi \in \mathrm{Ham}(M, \omega)$ we choose a based path φ_t in $\mathrm{Ham}(M, \omega)$. Denote by H the time-dependent Hamiltonian function which generates φ_t. Then fixed points of φ are in one-to-one correspondence with 1-periodic orbits of the time-dependent flow φ_t, which are characterized as zeros of the following closed 1-form α_H on the loop space LM of M:

$$\alpha_H(\xi) = \int_0^1 \omega(\xi(t), \dot{\gamma}(t) - X_{H_t}(\gamma(t)))\, dt,$$

where $\gamma \in LM$ and $\xi \in T_\gamma LM$, i.e., a section of $\gamma^* TM$. Write $J_t' = (\varphi_t)_* J_t$. (Note that $J_0' = J_1'$.) Then gradient flow lines are solutions of the following equation:

$$\frac{\partial u}{\partial \tau} + J'(u)\left(\frac{\partial u}{\partial t} - X_{H_t}(u)\right) = 0,$$

for $u = u(\tau, t) \colon \mathbb{R} \times S^1 \to M$. Denote by $p \colon \tilde{L}M \to LM$ the Floer covering space of LM and by $\mathcal{A}_H \colon \tilde{L}M \to \mathbb{R}$ the action functional, i.e., $d\mathcal{A}_H = p^* \alpha_H$. Consider the graded module generated by the critical points of $\mathcal{A}_H$ with the grading given by μ, which is known as the Conley–Zehnder index in this setting. Then take its completion with respect to the filtration $\{\tilde{\gamma} \in \mathrm{Crit}(\mathcal{A}_H) \mid \mathcal{A}_H(\tilde{\gamma}) > c\}$ for $c \in \mathbb{R}$. We denote it by $CF^*(H)$. The coboundary operator $\delta = \delta^{H,J}$ is defined by counting the number of connecting orbits joining critical points. In this case Floer cohomology can be computed as follows:

$$HF^*(H, J) \cong H^{*+n}(M; \mathbb{Q}) \otimes \Lambda_\omega,$$

where Λ_ω is the Novikov ring of (M, ω).

As a corollary we have the following result ([16], [29]).

Theorem 2.2. *If $\varphi \in \mathrm{Ham}(M, \omega)$ has only non-degenerate fixed points then*

$$\#\,\mathrm{Fix}(\varphi) \geq \sum_k \mathrm{rank}\ H^k(M; \mathbb{Q}).$$

More precisely, we can find that the number of fixed points which correspond to contractible 1-periodic orbits of any based Hamiltonian path is at least the sum of Betti numbers in this theorem. As a consequence, we also find that there always exists a contractible 1-periodic orbit for any time-dependent periodic Hamiltonian system. For a based path $\{\psi_t\}$ in $\mathrm{Symp}_0(M, \omega)$ we can define the Floer cohomology, which we may call the Floer–Novikov cohomology, in a way similar to the case of Hamiltonian diffeomorphisms. Under the $\pm$-monotonicity assumption we have a similar computation for $\varphi \in \mathrm{Symp}_0(M, \omega)$ using Novikov cohomology of the flux of φ_t in place of the ordinary cohomology of M, see [27].

2.2. Application to the flux conjecture. The flux of a based path $\{\phi_t\}_{0\leq t\leq 1}$ in $\mathrm{Symp}_0(M, \omega)$ is defined to be

$$\widetilde{\mathrm{Flux}}(\phi_t) = \int_0^1 [i(X_t)\omega]\, dt \in H^1(M; \mathbb{R}),$$

where X_t is the family of symplectic vector fields generating ϕ_t. The flux depends only on the homotopy class of paths with fixed end points $\phi_0 = \mathrm{id}$ and ϕ_1, and induces a homomorphism from the universal covering group $\widetilde{\mathrm{Symp}}_0(M, \omega)$ of $\mathrm{Symp}_0(M, \omega)$ to $H^1(M; \mathbb{R})$. Denote by Γ_ω, which is called the flux group, the image of $\mathrm{Ker}\left(\widetilde{\mathrm{Symp}}_0(M; \omega) \to \mathrm{Symp}_0(M; \mathbb{R})\right) \cong \pi_1(\mathrm{Symp}_0(M; \mathbb{R}))$ under $\widetilde{\mathrm{Flux}}$. It is known that the path ϕ_t above can be homotoped to a path in $\mathrm{Ham}(M; \omega)$ keeping the end points fixed if and only if $\widetilde{\mathrm{Flux}}(\phi_t) = 0$. $\widetilde{\mathrm{Flux}}$ descends to a homomorphism $\mathrm{Flux}\colon \mathrm{Symp}_0(M; \omega) \to H^1(M; \mathbb{R})/\Gamma_\omega$. The group $\mathrm{Ham}(M; \mathbb{R})$ is also known to be the kernel of this homomorphism, see [1]. Hence, it is a basic question in order to understand $\mathrm{Ham}(M, \omega) \subset \mathrm{Symp}_0(M, \omega)$ how Γ_ω is embedded in $H^1(M; \mathbb{R})$.

Conjecture 2.3 (Flux conjecture). Γ_ω is discrete in $H^1(M; \mathbb{R})$.

This conjecture is equivalent to that $\mathrm{Ham}(M, \omega)$ is C^1-closed in $\mathrm{Symp}_0(M, \omega)$. There are various cases in which the flux conjecture is verified. For example, if $[\omega] \in H^1(M; \mathbb{Q})$ the conjecture clearly holds. A less trivial case is that (M, ω) is of Lefschetz type, i.e., $\wedge[\omega]^{n-1}\colon H^1(M; \mathbb{R}) \to H^{2n-1}(M; \mathbb{R})$ is an isomorphism. It was Lalonde, McDuff and Polterovich [25], [26] who noticed that the affirmative answer to the homological Arnold conjecture can be used to prove the flux conjecture. Among other things, they proved the following:

Theorem 2.4. *If $c_1(M)\colon \pi_2(M) \to \mathbb{Z}$ is trivial or its minimal positive value (the minimal Chern number) is at least $2n = \dim_{\mathbb{R}} M$, then the flux conjecture holds.*

Theorem 2.5. *The rank of the flux group Γ_ω is at most the first Betti number $b_1(M)$ of M. In particular, the flux conjecture holds if $b_1(M) = 1$.*

Remark 2.6. Note that Theorem 2.5 follows from the flux conjecture.

We give an outline of the proof of the flux conjecture. First of all, we collect some notation and fundamental properties of the Floer–Novikov cohomology. For any based path $\{\psi_t\}$ in $\mathrm{Symp}_0(M, \omega)$, we can deform it by a homotopy so that $i(X_t)\omega$ does not depend on t and is equal to $\theta = \widetilde{\mathrm{Flux}}(\psi_t)$. Here X_t is the family of symplectic vector fields generating ψ_t. Denote by $\pi : \overline{M} \to M$ the covering space of M associated to the homomorphism $I_\theta : \pi_1(M) \to \mathbb{R}$ obtained by integrating θ along loops. Then there exists $\widetilde{H} = \{\tilde{h}_t\}$, a smooth family of smooth functions on $\overline{M}$ such that $\pi^* i(X_t)\omega = d\tilde{h}_t$. Denote by $\tilde{L}^\theta M$ the Floer covering space of LM for $\{\psi_t\}$ which depends only on its flux θ, and by $G_{\omega,\theta}$ its covering transformation group. Then we can perform the Floer construction for $\mathcal{A}_{\widetilde{H}} : \tilde{L}^\theta M \to \mathbb{R}$ and obtain the cochain complex $(CFN^*(\widetilde{H}, J), \delta = \delta^{\widetilde{H},J})$. The group $G_{\omega,\theta}$ naturally acts on this complex. Moreover, the action extends to the Novikov completion $\Lambda_{\omega,\theta}$ of the group ring of $G_{\omega,\theta}$. Denote by $HFN^*(\{\psi_t\})$ the resulting cohomology, which is the Floer–Novikov cohomology of $\{\psi_t\}$ and which is a finitely generated module over $\Lambda_{\omega,\theta}$.

We collect its fundamental properties as follows.

Theorem 2.7. *For based paths $\{\psi_t^{(1)}\}$ and $\{\psi_t^{(2)}\}$ with $\widetilde{\mathrm{Flux}}(\{\psi_t^{(1)}\}) = \widetilde{\mathrm{Flux}}(\{\psi_t^{(2)}\})$ we have a natural isomorphism*

$$HFN^*(\{\psi_t^{(1)}\}) \cong HFN^*(\{\psi_t^{(2)}\}).$$

Theorem 2.8. *If $\widetilde{\mathrm{Flux}}(\{\psi_t\})$ is sufficiently small we have*

$$HFN^*(\{\psi_t\}) \cong HN^{*+n}(\theta) \otimes_{\overline{\Lambda}_\theta} \Lambda_{\omega,\theta}.$$

Here $HN^*(\theta)$ is the Novikov cohomology of θ and $\overline{\Lambda}_\theta$ is its coefficient ring.

Secondly, we note that the Floer construction can be performed with coefficients in a local system as in the ordinary cohomology theory, see e.g., [38], [39]. In particular, when the flux vanishes, i.e. $\{\psi_t\}$ is a Hamiltonian path, we obtain the Floer cohomology for based Hamiltonian paths with coefficients in a local system. Let $L \to M$ be a local system or a flat vector bundle. We denote by $HFN^*(\{\psi_t\}; L)$ the Floer–Novikov cohomology of $\{\psi_t\}$ with coefficients in L. Then Theorems 2.7 and 2.8 holds with coefficients in L. We state them for reference.

Theorem 2.9. *Let $L \to M$ be a flat vector bundle. For based paths $\{\psi_t^{(1)}\}$ and $\{\psi_t^{(2)}\}$ with $\widetilde{\mathrm{Flux}}(\{\psi_t^{(1)}\}) = \widetilde{\mathrm{Flux}}(\{\psi_t^{(2)}\})$ we have a natural isomorphism*

$$HFN^*(\{\psi_t^{(1)}\}; L) \cong HFN^*(\{\psi_t^{(2)}\}; L).$$

Theorem 2.10. *If* $\widetilde{\mathrm{Flux}}(\{\psi_t\})$ *is sufficiently small we have*

$$HFN^*(\{\psi_t\}; L) \cong HN^{*+n}(\theta; L) \otimes_{\bar{\Lambda}_\theta} \Lambda_{\omega,\theta}$$

for any flat vector bundle L. *Here* $HN^*(\theta; L)$ *is the Novikov cohomology of* θ *with coefficients in* L.

Based on the above preparation, we give an outline of the proof of the flux conjecture. Let $U \subset H^1(M; \mathbb{R})$ be a neighborhood of the origin consisting of $\theta \in U$, which is represented by a sufficiently C^1-small closed 1-form such that Theorems 2.8 and 2.10 holds for the flux $[\theta]$. We may assume that U is symmetric with respect to the origin. It is enough to show the following.

Claim. $\Gamma_\omega \cap U = \{0\}$.

If it is false, there is a based loop $\{\psi_t\}$ in $\mathrm{Symp}_0(M, \omega)$ such that $\theta = \widetilde{\mathrm{Flux}}(\{\psi_t\})$ belongs to $(\Gamma_\omega \cap U) \setminus \{0\}$. Denote by $\{\psi_t^{-\theta}\}$ the based symplectic isotopy generated by the vector field $X_{-\theta}$ which is the symplectic dual of $-\theta$. Then $\{\psi'_t = \psi_t^{-\theta} \circ \psi_t\}$ is a based symplectic isotopy, the flux of which vanishes. Hence, we can deform $\{\psi'_t\}$ up to homotopy keeping end points fixed to a Hamiltonian path $\{\phi_t\}$. Thus we obtain a based Hamiltonian path $\{\phi_t\}$ and a based symplectic path $\{\psi_t^{-\theta}\}$ with $\psi_1^{-\theta} = \phi_1$. Since $\psi_t^\theta = (\psi_t^{-\theta})^{-1}$, $\Phi_t = \phi_t \circ \psi_t^\theta$ is a based loop in $\mathrm{Symp}_0(M, \omega)$, which induces an isomorphism $\Phi\colon \gamma(t) \in LM \mapsto \Phi_t(\gamma(t)) \in LM$. It is clear that Φ restricts to one-to-one correspondence between 1-periodic orbits of $\{\phi_t^{-\theta}\}$ and 1-periodic orbits of $\{\phi_t\}$. Note that the former are constant loops at zeros of θ, since we assumed that θ is sufficiently C^1-small. On the other hand, Theorem 2.2 guarantees the existence of contractible 1-periodic orbits of $\{\phi_t\}$ as we noted there. Hence, Φ preserves the component of LM consisting of contractible loops. We have the following:

Lemma 2.11. $\Phi^*\alpha_{\{\phi_t\}} = \alpha_{\{\psi_t^{-\theta}\}}$.

As a consequence, we find that $\Phi\colon LM \to LM$ admits a lift $\tilde{\Phi}\colon \tilde{L}^{-\theta}M \to \tilde{L}^0 M$. Note also that Φ_t preserves the homotopy class of almost complex structures compatible with ω, hence $c_1(M)(u) = c_1(M)[\Phi_\#(u)]$. Here $u\colon S^1 \times S^1 \to M$ and $\Phi_\#(u)(s,t) = \Phi_t(u(s,t))$. Therefore $\tilde{\Phi}$ induces an isomorphism between the Floer–Novikov cohomology of $\{\psi_t^{-\theta}\}$ and the Floer cohomology of $\{\phi_t\}$. (Φ also induces an isomorphism between the moduli spaces of gradient trajectories in the sense of Kuranishi structures, after choosing almost compatible structures appropriately.) We can also see that $\tilde{\Phi}$ induces an isomorphism between the Novikov rings $\Lambda_{\omega,-\theta}$ and $\Lambda_\omega = \Lambda_{\omega,0}$. Namely, we find

Proposition 2.12. *Let* $L \to M$ *be an arbitrary flat vector bundle. Then there exists* $c \in \mathbb{Z}$ *such that*

$$\tilde{\Phi}_*\colon HFN^*(\{\psi_t^{-\theta}\}; L) \cong HF^{*+c}(\{\phi_t\}; L).$$

Since $-\theta$ is sufficiently C^1-small, Theorem 2.10 implies that

$$HFN^*(\{\psi_t^{-\theta}\}; L) \cong HN^{*+n}(-\theta; L) \otimes_{\bar{\Lambda}_{-\theta}} \Lambda_{\omega,-\theta}.$$

On the other hand, we have

$$HF^*(\{\phi_t\}; L) \cong H^{*+n}(M; L) \otimes \Lambda_\omega.$$

Now we choose $L \to M$ as the flat real line bundle $L_{\varepsilon\theta}$ associated to $\ell \in \pi_1(M) \mapsto \exp(\varepsilon \int \ell^*\theta) \in \mathbb{R}^*$. Then the pull back $\pi^*L_{\varepsilon\theta}$ of $L_{\varepsilon\theta}$ by $\pi\colon \overline{M} \to M$, which is used to define the Novikov cohomology of $\pm\theta$, becomes trivial as a flat bundle. Hence $HN^*(-\theta; L_{\varepsilon\theta})$ is isomorphic to $HN^*(-\theta; \mathbb{R})$ after forgetting the module structure over the Novikov ring. On the other hand, for ordinary cohomology, we have the jumping phenomenon at $\varepsilon = 0$, i.e., since θ is not an exact 1-form, $H^0(M; L_{\varepsilon\theta}) = 0$ for $\varepsilon \neq 0$ while $H^0(M; \mathbb{R}) = \mathbb{R}$ for $\varepsilon = 0$. Based on this observation, we can derive a contradiction. Hence the flux conjecture is proved.

Theorem 2.13. *The flux conjecture holds for any closed symplectic manifolds.*

Remark 2.14. The action of Hamiltonian loops on Floer cohomologies was studied by Seidel [44]. Viterbo [47] developed the theory of generating functions and explored applications to symplectic invariants. Y. G. Oh is the first to apply the Floer theoretical framework to Hofer's geometry [34], [35], partly inspired by the work of Chekanov [3] to be mentioned later. Seidel's work also stimulated progress in the study of Hofer's geometry, e.g., Entov's work [7] and Schwarz [42]. Oh generalized Schwarz's result to closed symplectic manifolds which are not necessarily symplectically aspherical, cf. Oh's contribution to this proceedings. Based on this generalization, Entov and Polterovich constructed in [8] an $\mathbb{R}$-valued quasi-homomorphism from (the universal covering group of) $\mathrm{Ham}(M, \omega)$.

There are different kinds of development from those mentioned in this section. For example, Viterbo applied the Floer cohomology to a problem in real algebraic geometry and proved that hyperbolic manifolds cannot be realized as the real part of "sufficiently positively curved" complex projective manifolds; cf. [22].

3. Floer theory for Lagrangian submanifolds

3.1. Fundamental construction. Let L_0, L_1 be closed embedded Lagrangian submanifolds in a closed symplectic manifold (P, Ω). We assume that L_0 and L_1 intersect transversely. Consider the path space $\mathcal{P}(L_0, L_1) = \{\gamma\colon [0, 1] \to P \mid \gamma(0) \in L_0,\ \gamma(1) \in L_1\}$ and define the action 1-form $\alpha = \alpha_{L_0,L_1}$ by

$$\alpha_{L_0,L_1}(\xi) = \int_0^1 \Omega(\xi(t), \dot{\gamma}(t))\, dt \quad \text{for } \xi = \{\xi(t)\} \in T_\gamma \mathcal{P}(L_0, L_1).$$

Then α_{L_0,L_1} is a "closed 1-form". In fact, a local primitive function around γ_0 is given by

$$\mathcal{A}^{\mathrm{loc}}_{L_0,L_1}(\gamma) = \int_{[0,1]\times[0,1]} w^*\Omega,$$

where $w\colon [0,1]\times[0,1] \to P$ such that $w(s,i) \in L_i$ for $i = 0, 1$, $w(0,t) = \gamma_0(t)$ and $w(1,t) = \gamma(t)$. As long as the image of w is contained in a small neighborhood of γ_0, $\mathcal{A}^{\mathrm{loc}}_{L_0,L_1}$ is well defined.

Before going further, we clarify the relation to the case of symplectomorphisms. Let ϕ be a symplectomorphism of (M,ω). Then its graph Γ_ϕ is a Lagrangian submanifold in $(M\times M, -\omega\oplus\omega)$. Denote by Δ the diagonal subset, which is the graph of the identity. Then we have the following identification:

$$G\colon L^\phi M \to \mathcal{P}(\Gamma_\phi, \Delta);\ \sigma(t) \mapsto \left(\sigma\left(1-\frac{t}{2}\right), \sigma\left(\frac{t}{2}\right)\right),$$

which satisfies $G^*\alpha_{\Gamma_\phi,\Delta} = \alpha_\phi$. In this way, the construction in this section is a generalization of the one in the previous section.

Pick a compatible almost complex structure J to equip $\mathcal{P}(L_0, L_1)$ with L^2-metric. Then the locally gradient flow line for α_{L_0,L_1} is described by $u\colon \mathbb{R}\times[0,1] \to P$ with $u(\tau, i) \in L_i$ for $i = 0, 1$, which satisfies

$$\frac{\partial u}{\partial \tau} + J(u)\frac{\partial u}{\partial t} = 0.$$

Existence of the limits $\lim_{\tau\to\pm\infty} u(\tau,t) \in L_0\cap L_1$ is equivalent to the condition that the energy $E(u)$ is finite. Note also that the zeros of α_{L_0,L_1} are exactly the constant paths at $L_0\cap L_1$.

In [9]–[13], Floer realized the idea of constructing an analogue of Morse complex for the action functional under the assumption that $\pi_2(P, L_i) = 0$ and that L_1 is a Hamiltonian deformation of L_0. In this situation the action functional admits a primitive function on $\mathcal{P}(L_0, L_1)$ and the grading of $L_0\cap L_1$, called the Maslov–Viterbo index $\mu = \mu_{L_0,L_1}$, is well defined with values in $\mathbb{Z}$. Define $CF^*(L_1, L_0)$ by the $\mathbb{Z}/2\mathbb{Z}$-module freely generated by $L_0\cap L_1$. Counting gradient flow lines connecting critical points of $\mathcal{A}_{L_0,L_1}$, we define the coboundary operator $\delta\colon CF^*(L_1, L_0) \to CF^{*+1}(L_1, L_0)$ by

$$\delta\langle p\rangle = \sum \#\mathcal{M}(p,q)\langle q\rangle,$$

where q runs over $L_0\cap L_1$ such that $\mu(q) = \mu(p) + 1$, and $\mathcal{M}(p,q)$ is the moduli space of gradient flow lines, which we call connecting orbits, of $\mathcal{A}_{L_0,L_1}$ from p to q. Under the above assumption, for a generic choice of J, the moduli space $\mathcal{M}(p,q)$ is shown to be compact if $\mu(q) - \mu(p) = 1$. If $\mu(q) - \mu(p) = 2$, $\mathcal{M}(p,q)$ may not be compact, but its end is described as the union of $\mathcal{M}(p,r)\times\mathcal{M}(r,q)$ over $r \in L_0\cap L_1$

such that $\mu(r) - \mu(p) = 1$. Hence we find that $\delta \circ \delta = 0$ and obtain the Floer complex $(CF^*(L_1, L_0), \delta)$. We denote by $HF^*(L_1, L_0)$ the resulting cohomology. It is also shown that the Floer cohomology is invariant under Hamiltonian deformation of Lagrangian submanifolds. If L_1 is a sufficiently small Hamiltonian deformation of L_0, L_1 is regarded as the graph of a C^2-small Morse function on L_0 in T^*L_0. The Morse gradient trajectories appear as Floer connecting orbits. Although, in general, there may exist non-small Floer connecting orbits, the assumption that $\pi_2(P, L_i) = 0$ excludes such a possibility. Hence $HF^*(L_1, L_0)$ is isomorphic to $H^*(L_0; \mathbb{Z}/2\mathbb{Z})$ up to a shift in the grading. It is worth mentioning that Hofer [19], [20] developed an idea similar to Floer's and established the Lagrangian intersection property under the assumption that $\pi_2(P, L) = 0$.

Without the assumption that $\pi_2(P, L_i) = 0$, there arise some problems in the above argument. As we explain below, $\delta \circ \delta$ may not vanish[1], in general. It was Y. G. Oh [30], [31], [32] who extended Floer's construction to the case that L_i are monotone and their minimal Maslov number is at least 3. (He also computed Floer cohomology for some cases, e.g., $\mathbb{R}P^n \subset \mathbb{C}P^n$.) In general, the difficulties are caused by J-holomorphic discs with boundary on L_i as well as J-holomorphic spheres which arise as "bubbles" from sequences of connecting orbits with bounded energies. As in the case of symplectomorphisms, the bubbling-off of J-holomorphic spheres is expected to occur in real codimension 2 and does not cause any essential difficulty, which can be handled by Kuranishi structures. However, the bubbling-off of J-holomorphic discs occurs in real codimension 1 and we cannot avoid it, in general. If we restrict ourselves to some portion of $\mathcal{P}(L_0, L_1)$, on which the range of the action functional is sufficiently narrow, then there do not appear effects from J-holomorphic discs and J-holomorphic spheres. In fact, Chekanov [3] gave an alternative proof for the non-degeneracy of Hofer's distance on $\mathrm{Ham}(M, \omega)$ based on such an idea.

As we noticed, the bubbling-off of J-holomorphic discs is a codimension 1 phenomenon, hence we cannot, in general, avoid such a bubbling-off phenomenon from the moduli space $\mathcal{M}(p, q)$ even though $\mu(q) - \mu(p) \leq 2$. In order to understand how $\delta \circ \delta = 0$ fails to hold, we study all J-holomorphic discs systematically. From now on we follow our joint work with K. Fukaya, Y. G. Oh and H. Ohta [15]. Firstly, we arrange elements of $\pi_2(P, L)$[2], which are represented as the union of J-holomorphic discs $w\colon (D^2, \partial D^2) \to (P, L)$ and J-holomorphic spheres $v\colon S^2 \to P$ as $\beta_0 = 0, \beta_1, \beta_2, \ldots$ such that $\int_{\beta_i} \Omega \leq \int_{\beta_{i+1}} \Omega$ and $\int_{\beta_i} \Omega \to +\infty$ as $i \to +\infty$. This can be done with the so-called Gromov weak compactness. Denote by $\mu(w)$ the Maslov index of $(w^*TP, w|_{\partial D^2})^*TL) \to (D^2, \partial D^2)$. Denote by $\mathcal{M}_{k+1}(\beta)$ the moduli space of J-holomorphic discs[3] which represent class β, with $k+1$ marked points on ∂D^2. Then the moduli space $\mathcal{M}_{k+1}(\beta)$ is of dimension $n + \mu(\beta) + k - 2$, where

[1] I heard from A. Sergeev that Floer himself had (certainly) noticed this fact. This phenomenon is not only a bad news. We used this fact in [37].

[2] More precisely, we work with the image of $\pi_2(P, L)$ in $H^2(P, L; \mathbb{Z})$.

[3] More precisely, we use the stable maps from the prestable Riemann surface with 1 boundary component of genus 0.

$n = \dim L$. In general, the transversality, i.e., the surjectivity of the linearization of the J-holomorphic curve equation, may not hold. In order to overcome this trouble, we use the framework of Kuranishi structure. Since we use the multi-valued perturbation technique, we need a compatible system of orientations on various moduli spaces. However, the moduli space of J-holomorphic discs may not be orientable[4], in general. Therefore we assume the relative spin condition for Lagrangian submanifolds as follows. Pick a triangulation of L and extend it to a triangulation of P.

Definition 3.1 (Relative spin structure). Let L be a Lagrangian submanifold. If there is a cohomology class $w \in H^2(P; \mathbb{Z}/2\mathbb{Z})$ such that $w_2(L)$ is the restriction of w to L, we call L relatively spin. Under this condition, there is an orientable vector bundle V on the 3-skeleton $P^{(3)}$ of P with $w_2(V) = w$. A relative spin structure for L is the tuple of w, V and a spin structure on the restriction of $TL \oplus V$ to $L \cap P^{(2)}$. A relative spin structure on (L_0, L_1) is the above tuple which is chosen in common for L_i, $i = 0, 1$.

Then we have the following:

Theorem 3.2. (1) *A relative spin structure on L determines a canonical orientation on the moduli spaces $\mathcal{M}_{k+1}(\beta)$, which satisfies a certain compatibility condition under the gluing operation.*

(2) *A relative spin structure on (L_0, L_1) determines a canonical orientation on the moduli spaces $\mathcal{M}(p, q)$ of connecting orbits, which satisfies a certain compatibility condition under the gluing operation.*

From now on, we assume that a Lagrangian submanifold L or a pair (L_0, L_1) of Lagrangian submanifolds are equipped with a relative spin structure. We work with $\mathbb{Q}$-coefficients rather than $\mathbb{Z}/2\mathbb{Z}$-coefficients. Clearly, a spin structure on L gives a relative spin structure with a trivial bundle V.

We define obstruction classes for L to define Floer cohomology by inductive steps as follows[5]. Start with β_1, the first non-trivial case. Since the bubbling-off does not happen in $\mathcal{M}_1(\beta_1)$, the evaluation map $ev_0 \colon \mathcal{M}_1(\beta_1) \to L$ is a cycle with $\mathbb{Q}$-coefficients. This cycle represents the first obstruction class[6] $o_1 = o(\beta_1)$. Suppose that $o_i = o(\beta_i)$ is defined for $i = 1, \dots, k$ and there exist $\mathbb{Q}$-chains $\mathcal{B}_i$ in L such that $o_i = (-1)^n \partial \mathcal{B}_i$ for $i = 1, \dots, k$. (We call such a system of $\mathcal{B}_i, i = 1, 2, \dots$ a bounding chain.) We define the next obstruction class $o_{k+1} = o(\beta_{k+1})$ as follows. The moduli space $\mathcal{M}_{k+1}(\beta)$ may have codimension 1 boundary, hence may not be a cycle. So we try to glue other (moduli) spaces along boundaries so that we finally obtain a cycle. Consider the moduli space $\mathcal{M}_{\ell+1}(\beta; \mathcal{B}_{i_1}, \dots, \mathcal{B}_{i_\ell})$ consisting of J-holomorphic discs w representing the class β such that $\beta_{k+1} = \beta + \sum_{j=1}^{\ell} \beta_{i_j}$ and intersecting $\mathcal{B}_{i_1}, \dots, \mathcal{B}_{i_\ell}$ along ∂D^2. The moduli space $\mathcal{M}_{\ell+1}(\beta; \mathcal{B}_{i_1}, \dots, \mathcal{B}_{i_\ell})$ is

[4] Vin de Silva independently studied this problem in [5].

[5] The idea of this construction was inspired by Kontsevich around 1997.

[6] In the next subsection we adopt cohomological convention. Thus we take the Poincaré dual of o_k.

described as the fiber product of the spaces with Kuranishi structures:

$$\mathcal{M}_{\ell+1}(\beta)\ {}_{ev_1,\dots,ev_\ell}\times \prod_{j=1}^{\ell} \mathcal{B}_{i_j}.$$

We can assign to them an orientation so that the union $\widehat{\mathcal{M}}_1(\beta_{k+1})$ of $\mathcal{M}_1(\beta_{k+1})$ and all possible $\mathcal{M}_{\ell+1}(\beta; \mathcal{B}_{i_1}, \dots, \mathcal{B}_{i_\ell})$ becomes a $\mathbb{Q}$-virtual cycle. Note that we have the evaluation map $ev_0\colon \mathcal{M}_{\ell+1}(\beta; P_{i_1}, \dots, P_{i_\ell}) \to L$ at the remaining marked point after taking the fiber product. Then $ev_0\colon \widehat{\mathcal{M}}_1(\beta_{k+1}) \to L$ is a $\mathbb{Q}$-cycle of L, which represents the obstruction class $o_{k+1} = o(\beta_{k+1})$. Then we can find the following:

Theorem 3.3. *Suppose that a pair (L_0, L_1) of Lagrangian submanifolds is equipped with a relative spin structure. If all the obstruction classes for L_i, $i = 0, 1$ are defined and vanish, then we can revise the definition of Floer's coboundary operator to obtain the Floer complex $(CF^*(L_1, L_0), \delta)$. Moreover, the Floer cohomology $HF^*(L_1, L_0)$ is invariant under Hamiltonian deformation of L_i.*

Our construction depends on the choice of bounding chains for L_i, $i = 0, 1$. The invariance under Hamiltonian deformations also requires a subtle argument. Namely, we must describe the relation of bounding chains under Hamiltonian deformation. These points are clarified in terms of the filtered A_∞-algebras associated to L_i, which we discuss in the next subsection. We may weaken the assumption that the obstruction classes vanish. One of them is the deformation using $\mathbb{Q}$-cycles in P. It may also happen that the effects of J-holomorphic discs with boundary on L_i, $i = 0, 1$ cancel each other. When all non-vanishing obstruction classes for L_i are of top dimension, i.e., dim L, then they are multiples of the fundamental class of L. We call the coefficient of the fundamental cycle as the potential function of L_i. If the potential function of L_i, $i = 0, 1$, coincide, they cancel each other in the construction of the Floer complex, hence the Floer cohomology. This is an extension of Oh's discovery that the Floer complex can be constructed for monotone Lagrangian submanifolds with minimal Maslov numbers are at least 2. Although we can define the Floer complex, hence the Floer cohomology under the assumption that all obstruction classes vanish, it is very difficult to compute it in general.

However, when L_1 is a Hamiltonian deformation of L_0, we can construct a certain spectral sequence with E_2-term being the ordinary cohomology with coefficients in the Novikov ring, which converges to the Floer cohomology, see Theorem 3.10 below.

3.2. The filtered A_∞-algebras associated to Lagrangian submanifolds. Based on [15], we describe the framework of the Floer theory for Lagrangian submanifolds. We generalize the idea of the construction of obstruction classes, which we mentioned in the previous subsection, and construct the filtered A_∞-algebras associated to Lagrangian submanifolds. We also include some applications at the end of this subsection.

We introduce the universal Novikov ring which we use from now on. Let R be a commutative ring with the unit. In this note, we mostly use the case that $R = \mathbb{Q}$. Let T and e be formal generators of degree 0 and 2, respectively. Set

$$\Lambda_{\mathrm{nov}} = \Big\{ \sum_{i=0}^{\infty} a_i T^{\lambda_i} e^{\mu_i} \mid a_i \in R,\ \lambda_i \in \mathbb{R},\ \mu_i \in \mathbb{Z},\ \lim_{i\to\infty} \lambda_i = \infty \Big\}.$$

If R is a field, the degree 0-part of Λ_{nov} is also a field. We also set

$$\Lambda_{0,\mathrm{nov}} = \Big\{ \sum_{i=0}^{\infty} a_i T^{\lambda_i} e^{\mu_i} \in \Lambda_{\mathrm{nov}} \mid \lambda_i \geq 0 \Big\}.$$

These rings Λ_{nov} and $\Lambda_{0,\mathrm{nov}}$ are complete with respect to the decreasing filtration by λ for T^{λ}. The Novikov rings, we mentioned before, are subrings of Λ_{nov}.

Now we shall present a rough idea of the construction of the A_∞-operations. Let $(f_i\colon P_i \to L),\ i = 1, \ldots, k$, be chains in L. We often abbreviate them as P_i. Take the fiber product

$$\mathcal{M}_{k+1}(\beta; P_1, \ldots, P_k) = \mathcal{M}_{k+1}(\beta)_{ev_1,\ldots,ev_k} \times_{f_1,\ldots,f_k} \prod_{j=1}^{k} P_j.$$

We can give an orientation to these spaces with Kuranishi structure in such a way that the following construction works. Define a chain $(\mathcal{M}_{k+1}(\beta; P_1, \ldots, P_k), ev_0)$ in L by taking the remaining marked point, i.e., $ev_0\colon \mathcal{M}_{k+1}(\beta; P_1, \ldots, P_k) \to L$. For $k \geq 2$, we set

$$\mathfrak{m}_{k,\beta}(P_1, \ldots, P_k) = (\mathcal{M}_{k+1}(\beta; P_1, \ldots, P_k), ev_0).$$

In the other cases, we set

$$\begin{aligned} \mathfrak{m}_{1,0}(P) &= (-1)^n \partial P, \\ \mathfrak{m}_{1,\beta}(P) &= (\mathcal{M}_2(\beta; P), ev_0), \quad \text{when } \beta \neq 0 \\ \mathfrak{m}_{0,\beta}(1) &= (\mathcal{M}_1(\beta), ev_0), \qquad \text{when } \beta \neq 0. \end{aligned}$$

In the last line, 1 is the unit of $R \subset \Lambda_{\mathrm{nov}}$, which is regarded as an element in $B_0C(L; \Lambda_{0,\mathrm{nov}})[1]$ below. We also set $\mathfrak{m}_{0,0}(1) = 0$. If we study the structure of compactifications of the moduli spaces $\mathcal{M}_{k+1}(\beta; P_1, \ldots, P_k)$ in a heuristic way, we expect to obtain certain algebraic relations among these operations, the so-called A_∞-relations. However, when we perform this construction in a rigorous way, we encounter several problems, e.g., transversality of the moduli spaces, transversality for taking the fiber product, etc. So we have to clarify which class of chains of L we deal with and how to take the (multi-valued) perturbation for achieving transversality, etc. Here, we give some flavor of the argument. For details see [15].

First of all, we forget the effect of non-trivial J-holomorphic discs and consider only the contribution from $\beta = 0$ (classical case). Naively, $\mathfrak{m}_{2,0}(P_1, P_2)$ should be $P_1 \cap P_2$ up to sign. However, when $P_1 = P_2$, the transversality does not hold. Thus we are forced to perturb $\mathcal{M}_{3,0}(0; P_1, P_2)$ to define $\mathfrak{m}_{2,0}(P_1, P_2)$. (It is also necessary to take a suitable countable family of chains which spans a subcomplex of the chain complex of L. We also assume that its cohomology is isomorphic to the ordinary cohomology of L.) It causes a discrepancy between $\mathfrak{m}_{2,0}(\mathfrak{m}_{2,0}(P_1, P_2), P_3)$ and $\mathfrak{m}_{2,0}(P_1, \mathfrak{m}_{2,0}(P_2, P_3))$. Namely, $\mathfrak{m}_{2,0}$ does not satisfy the associativity. Nevertheless, the above discrepancy is described using $\mathfrak{m}_{3,0}(P_1, P_2, P_3)$, which is defined by the perturbation of $\mathcal{M}_{4,0}(0; P_1, P_2, P_3)$, as follows.

$$\begin{aligned}
&\mathfrak{m}_{2,0}(\mathfrak{m}_{2,0}(P_1, P_2), P_3) - (-1)^{\deg P_1}\mathfrak{m}_{2,0}(P_1, \mathfrak{m}_{2,0}(P_2, P_3)) \\
&\quad = -\{\mathfrak{m}_{1,0} \circ \mathfrak{m}_{3,0}(P_1, P_2, P_3) + \mathfrak{m}_{3,0}(\mathfrak{m}_{1,0}(P_1), P_2, P_3) \\
&\qquad - (-1)^{\deg P_1}\mathfrak{m}_{3,0}(P_1, \mathfrak{m}_{1,0}(P_2), P_3) \\
&\qquad + (-1)^{\deg P_1 + \deg P_2}(\mathfrak{m}_{3,0}(P_1, P_2, \mathfrak{m}_{1,0}(P_3))\}.
\end{aligned}$$

Here we define the degree of P by $\deg P = n - \dim P$ and work with the cohomological framework rather than the homological framework from now on. A series of similar formulae successively hold in higher order. We call these relations the A_∞-relations. We can show that this algebraic gadget, the A_∞-algebra, obtained by the chain level intersection theory is "equivalent" to the de Rham homotopy theory in the realm of A_∞-algebras.

Next we include the effect from non-trivial J-holomorphic discs. Then we first take a suitable countably generated subcomplex $C^*(L)$ of the (co)chain complex[7] and (multi-valued) perturbations of the moduli spaces $\mathcal{M}_{k+1}(\beta; P_1, \ldots, P_k)$ to define $\mathfrak{m}_{k,\beta}(P_1, \ldots, P_k)$. We assign the degree to $P \otimes T^\lambda e^\mu \in C^*(L; \Lambda_{\mathrm{nov}})$ by $\deg P + 2\mu$. We shift the degree as $C(L; \Lambda_{\mathrm{nov}})[1]^* = C^{*+1}(L; \Lambda_{\mathrm{nov}})$. Then we can easily see that

$$\mathfrak{m}_{k,\beta} \otimes T^{\int_\beta \Omega} e^{\mu(\beta)/2} \colon \bigotimes^k C(L; \Lambda_{\mathrm{nov}})[1]^* \to C(L; \Lambda_{\mathrm{nov}})[1]^*$$

shifts the degree by $+1$, in other words, they are operations of degree $+1$. Write

$$\mathfrak{m}_k = \sum_\beta \mathfrak{m}_{k,\beta} \otimes T^{\int_\beta} e^{\mu(\beta)/2}.$$

Write

$$BC[1]^* = \bigoplus_{k=0}^\infty B_k C[1]^*$$

and

$$B_k C[1]^* = B_k C(L; \Lambda_{0,\mathrm{nov}})[1]^* = \bigotimes^k C(L; \Lambda_{0,\mathrm{nov}})[1]^*,$$

[7] More precisely, we consider the quotient complex by identifying chains, which give the same current.

the bar construction of $C^* = C^*(L; \Lambda_{0,\mathrm{nov}})$. It is a free tensor coalgebra generated by the graded free module $C[1]^*$. We extend $\mathfrak{m}_k$ to $\widehat{\mathfrak{m}}_k \colon BC[1]^* \to BC[1]^*$ as a coderivation and define $\hat{d} = \sum \widehat{\mathfrak{m}}_k$. Then we find the following:

Theorem 3.4. $\hat{d} \circ \hat{d} = 0$.

The filtered A_∞-relations are the formulae which express the above equality in terms of $\mathfrak{m}_k$. We call $(BC(L; \Lambda_{0,\mathrm{nov}})[1], \hat{d})$ the filtered A_∞-algebra associated to the Lagrangian submanifold L. So far, this object depends on the choice of the compatible almost complex structure, the countably generated subcomplex $C(L)$, various (multi-valued) perturbations, etc. We can define the notion of (gapped filtered) A_∞-algebra morphisms, homotopy equivalences, homotopy units, etc., and find the following:

Theorem 3.5. (1) *The homotopy type of the filtered A_∞-algebra*

$$(BC(L; \Lambda_{0,\mathrm{nov}})[1], \hat{d})$$

depends only on the embedding of the Lagrangian submanifold $L \subset (P, \Omega)$. The fundamental cycle of L is a homotopy unit.

(2) *A symplectomorphism ψ of (P, Ω) induces a homotopy equivalence $\hat{\psi}$ between the filtered A_∞-algebras associated to L and $\psi(L)$.*

In fact, by the algebraic theory of the (filtered) A_∞-algebras, we can derive the A_∞-algebra structure, resp. the filtered A_∞-algebra structure on $H^*(L)$, resp. $H^*(L; \Lambda_{0,\mathrm{nov}})$. One of the advantages to work in the framework of (filtered) A_∞-algebras is that quasi-isomorphisms have homotopy inverses[8]. This is not true in the category of differential graded algebras.

In general, $\mathfrak{m}_0(1)$ may not vanish. From the A_∞-relation we have

$$\mathfrak{m}_1 \circ \mathfrak{m}_1(P) = -(\mathfrak{m}_2(\mathfrak{m}_0(1), P) + (-1)^{\deg P + 1}\mathfrak{m}_2(P, \mathfrak{m}_0(1))),$$

which means that $\mathfrak{m}_1 \circ \mathfrak{m}_1$ does not necessarily vanish. This is the obstruction to define the Floer cohomology, which we discussed in the previous subsection.

Let $b \in C(L; \Lambda_{0,\mathrm{nov}})[1]^0$ with positive energy, i.e, b contains only terms with T^λ with $\lambda > 0$ and set

$$\mathfrak{m}_k^b(P_1, \ldots, P_k) = \sum \mathfrak{m}_{k+\ell}(b, \ldots, b, P_1, b, \ldots, b, P_i, b, \ldots, b, P_k, b, \ldots, b),$$

where ℓ is the number of b's appearing above in all possible ways and the sum is taken over all possibilities. We define $\hat{d}^b$ using $\mathfrak{m}_k^b$ instead of $\mathfrak{m}_k$. Then $\hat{d}^b$ also satisfies the A_∞-relation $\hat{d}^b \circ \hat{d}^b = 0$. Write $e^b = 1 + b + b \otimes b + b \otimes b \otimes b + \cdots$. Then we find the following:

Theorem 3.6. *If there exists $b \in C(L; \Lambda_{0,\mathrm{nov}})[1]^0$ which satisfies $\hat{d}(e^b) = 0$, then we have $\mathfrak{m}_0^b(1) = 0$, hence $\mathfrak{m}_1^b \circ \mathfrak{m}_1^b = 0$.*

[8] We do not claim any priority in the unfiltered case.

We call the equation $\hat{d}(e^b) = 0$ the Maurer–Cartan equation for the filtered A_∞-algebra. If there is a solution b for the Maurer–Cartan equation, the complex $(C(L;\Lambda_{0,\mathrm{nov}}), \mathfrak{m}_1^b)$ and its extension $(C(L;\Lambda_{\mathrm{nov}}), \mathfrak{m}_1^b)$ are the Bott–Morse Floer complex in the case that $L = L_0 = L_1$. We denote the resulting cohomology groups by $HF^*((L,b);\Lambda_{0,\mathrm{nov}})$ and $HF^*((L,b);\Lambda_{\mathrm{nov}})$, respectively. For a bounding chain $\mathcal{B}_i$ in the previous subsection we set

$$b = \sum \mathcal{B}_i \otimes T^{\int_\beta \Omega} e^{\mu(\beta)/2}.$$

Then b is a solution of the Maurer–Cartan equation. There is a notion of the gauge equivalence relation among solutions of the Maurer–Cartan equation. We can see that the Floer cohomologies are isomorphic for gauge equivalent b and b'. Note that the filtered A_∞-morphism maps a solution of the Maurer–Cartan equation for the source to a solution of the Maurer–Cartan equation for the target. Hence, for a symplectomorphism ψ of (P,Ω), $\psi_*(b)$, the B_1-component of $\widehat{\psi}(e^b)$ is a solution of the Maurer–Cartan equation for $\psi(L)$ if b is a solution for L. With respect to them we have the following:

$$\widehat{\psi}:\ HF^*((L,b);\Lambda_{0,\mathrm{nov}}) \cong HF^*((\psi(L),\psi_*(b));\Lambda_{0,\mathrm{nov}}).$$

Now we consider a pair (L_0, L_1) of Lagrangian submanifolds. By counting Floer connecting orbits intersecting k chains in L_1 and ℓ chains in L_0, we define the operation

$$\begin{aligned}\mathfrak{n}_{k,\ell}:\ B_kC(L_1;\Lambda_{0,\mathrm{nov}})[1] \otimes C(L_1,L_0;\Lambda_{0,\mathrm{nov}}) \otimes B_\ell C(L_0;\Lambda_{0,\mathrm{nov}})[1]\\ \longrightarrow C(L_1,L_0;\Lambda_{0,\mathrm{nov}}).\end{aligned}$$

Using the filtered A_∞-algebra structures on L_1 and L_0 as well as $\mathfrak{n}_{k,\ell}$, we obtain the coderivation $\hat{d}_{(L_1,L_0)}$ on

$$BC(L_1;\Lambda_{0,\mathrm{nov}})[1] \otimes C(L_1,L_0;\Lambda_{0,\mathrm{nov}}) \otimes BC(L_0;\Lambda_{0,\mathrm{nov}})[1].$$

We have $\hat{d}_{(L_1,L_0)} \circ \hat{d}_{(L_1,L_0)} = 0$. We call $(BC(L_1;\Lambda_{0,\mathrm{nov}})[1] \otimes C(L_1,L_0;\Lambda_{0,\mathrm{nov}}) \otimes BC(L_0;\Lambda_{0,\mathrm{nov}})[1], \hat{d}_{(L_1,L_0)})$ the filtered A_∞-bimodule associated to the pair (L_0, L_1). More precisely, we say that it is a left $C(L_1;\Lambda_{0,\mathrm{nov}})$, right $C(L_0;\Lambda_{0,\mathrm{nov}})$ filtered A_∞-bimodule. Similar to the case of the filtered A_∞-algebras, we obtain the following:

Theorem 3.7. (1) *For a pair (L_0, L_1) of Lagrangian submanifold equipped with a relative spin structure as a pair, the filtered A_∞-bimodule is uniquely defined up to homotopy equivalences.*

(2) *A pair of Hamiltonian diffeomorphisms ϕ_i, $i = 0, 1$, induces a homotopy equivalence between the filtered A_∞-bimodules with coefficients in Λ_{nov} of (L_0, L_1) and $(\phi_0(L_0), \phi_1(L_1))$.*

If there exists solutions b_i of the Maurer–Cartan equations for L_i, we can revise the Floer coboundary operator as follows:

$$\delta^{b_1,b_0}(p) = \sum \mathfrak{n}_{k,\ell}(b_1, \dots b_1, p, b_0, \dots, b_0).$$

Then we have the following:

Theorem 3.8. *Let b_i be solutions of the Maurer–Cartan equations for L_i, $i = 0, 1$. Then $\delta^{b_1,b_0} \circ \delta^{b_1,b_0} = 0$ holds.*

We denote the resulting cohomology by $HF^*((L_1, b_1), (L_0, b_0); \Lambda_{0,\mathrm{nov}})$ and its coefficient extension to Λ_{nov} by $HF^*((L_1, b_1), (L_0, b_0); \Lambda_{\mathrm{nov}})$ Then we have the following:

Corollary 3.9. *Let b_i be solutions of the Maurer–Cartan equation for L_i and ϕ_i Hamiltonian diffeomorphisms of $(P.\Omega)$. Then (ϕ_1, ϕ_0) induces an isomorphism*

$$HF^*((L_1.b_1), (L_0, b_0); \Lambda_{\mathrm{nov}}) \cong HF^*((\phi_1(L_1), \phi_{1*}(b_1)), (\phi_0(L_0), \phi_{0*}(b_0)); \Lambda_{\mathrm{nov}}).$$

In a similar way to the case of filtered A_∞-algebras, if b_i is gauge equivalent to b_i', $i = 0, 1$, the corresponding Floer cohomologies are isomorphic. Suppose that $\mathfrak{m}_0(1) = c[L]$ for some $c \in \Lambda_{0,\mathrm{nov}}$. We set $c = \mathfrak{PO}(L)$, the potential function. If $\mathfrak{PO}(L_0) = \mathfrak{PO}(L_1)$ we can modify the above construction to obtain the Floer complex. For example, if L_0 is a Lagrangian submanifold such that $\mathfrak{m}_0(1) = c[L_0]$ and L_1 is a Hamiltonian deformation of L_0, then we can obtain the Floer cohomology for (L_0, L_1).

It is not easy to compute the Floer cohomology $HF^*((L_1, b_1), (L_0, b_0))$, even when $L_1 = \phi(L_0)$ and $b_1 = \phi_*(b_0)$ for some Hamiltonian diffeomorphism ϕ. In such a case we find that it is isomorphic to the Bott–Morse Floer cohomology $HF^*((L_0, b_0); \Lambda_{\mathrm{nov}})$. Using the energy filtration, we have a spectral sequence as follows.

Theorem 3.10. *There is a spectral sequence with E_2-term being $H^*(L; \Lambda_{0,\mathrm{nov}})$ and converging to $HF^*((L_0, b_0); \Lambda_{0,\mathrm{nov}})$.*

We can also use a cycle in the ambient space P to deform the filtered A_∞-algebra associated to L. Pick a cycle $\boldsymbol{b}$ in P. Consider the moduli space of stable maps with one boundary component. In addition to the $k + 1$ boundary marked points put ℓ interior marked points. Take the fiber product

$$\mathcal{M}_{k+1,\ell}(\beta; P_1, \dots, P_k) = \mathcal{M}_{k+1,\ell}(\beta) \times_{\prod^k L \times \prod^\ell P} \Big(\prod_{i=1}^k P_i\Big) \times \Big(\prod^\ell \boldsymbol{b}\Big).$$

Summing up these moduli spaces for all ℓ, we obtain the deformed operation $\mathfrak{m}_k^{\boldsymbol{b}}$. The corresponding $\hat{d}^{\boldsymbol{b}}$ gives a deformation of the filtered A_∞-algebra structure. We can also discuss the Maurer–Cartan equation for the deformed structure, gauge equivalences, etc. Thanks to this larger class of deformations, we have the following:

Theorem 3.11. *Let L be a relatively spin Lagrangian submanifold. If the embedding $L \subset P$ induces an injection $H^*(L;\mathbb{Q}) \to H^*(P;\mathbb{Q})$, there is a $\Lambda_{0,\mathrm{nov}}^+$-cycle*[9] *$\boldsymbol{b}$ of P such that the deformed Maurer–Cartan solution $\hat{d}^{\boldsymbol{b}}(e^b) = 0$ has a solution.*

The following theorem is a direct consequence.

Theorem 3.12. *Let L be a relatively spin Lagrangian submanifold. Suppose that the embedding $L \subset P$ induces an injection on homology with rational coefficients. Then, for any Hamiltonian diffeomorphism ϕ of (P, Ω), we have*

$$\#L \cap \phi(L) \geq \sum_p \operatorname{rank} H^p(L;\mathbb{Q}).$$

Note that the graph of a Hamiltonian diffeomorphism satisfies the above assumption, hence Theorem 3.12 is a generalization of Theorem 2.2. Although the complete computation is difficult, there are cases where we have the non-vanishing result.

Theorem 3.13. *Let L be a relatively spin Lagrangian submanifold. Suppose that there is a $\Lambda_{0,\mathrm{nov}}^+$-cycle $\boldsymbol{b}$ in P and $b \in C(L;\Lambda_{0,\mathrm{nov}})[1]^0$ such that $\hat{d}^{\boldsymbol{b}}(e^b) = 0$. Suppose also that the Maslov index of any J-holomorphic disc with boundary on L is non-positive. Then, after adding correction terms which are of positive energy, the cycle $[pt]$ and the cyle $[L]$ become linearly independent, non-trivial cohomology classes in $HF^*((L,\mathfrak{b});\Lambda_{\mathrm{nov}})$.*

Here we denote by $\mathfrak{b}$ the pair $(\boldsymbol{b}, b)$. When the Maslov class μ vanishes for L, all obstruction classes belong to $H^2(L;\mathbb{Q})$. Hence we obtain the following:

Theorem 3.14. *Let L be a relatively spin Lagrangian submanifold with vanishing Maslov class such that $H^2(L;\mathbb{Q}) = 0$. Then, for any Hamiltonian diffeomorphism ϕ, $L \cap \phi(L) \neq \emptyset$. Moreover, there is $p \in L \cap \phi(L)$ with Viterbo–Maslov index* 0.

Thomas and Yau [46] used this theorem to establish the uniqueness of special Lagrangian homology spheres. From an opposite viewpoint, if L is a relatively spin Lagrangian submanifold with vanishing second rational cohomology and admits a Hamiltonian diffeomorphism ϕ such that $L \cap \phi(L) = 0$, then the Maslov class μ_L does not vanish. For instance, we have the following:

Theorem 3.15. *Let L be a Lagrangian submanifold in the symplectic vector space $(\mathbb{R}^{2n}, \omega_{can})$. If $H^2(L;\mathbb{Q}) = 0$ then $\mu_L \neq 0$. Moreover, its minimal Maslov number is at most $n+1$.*

Some results in a similar spirit were also obtained by Biran and Cieliebak [2]. Y. G. Oh obtained a more precise upper bound for the minimal Maslov number for Lagrangian tori up to a certain dimension [33]. Once we know that there exists a Hamiltonian diffeomorphism ϕ of (P, Ω) such that $L \cap \phi(L) = \emptyset$, either some

[9] $\Lambda_{0,\mathrm{nov}}^+ = \{\sum a_i T^{\lambda_i} e^{\mu_i} \in \Lambda_{\mathrm{nov}} | \lambda_i > 0\}$.

obstruction class does not vanish, or some differential in the spectral sequence in Theorem 3.10 is non-trivial. In each case we obtain the existence of non-trivial J-holomorphic discs with boundary on L. Thus, for example, we can find that any Lagrangian submanifolds in symplectic vector spaces are not exact. Namely, the restriction of the Liouville form $\lambda = \sum p_i dq^i$ to L is not an exact 1-form on L (Gromov).

Finally we discuss an analogue of the flux conjecture for Lagrangian submanifolds. Denote by $\mathrm{Lag}(L)$ the space of all Lagrangian submanifolds which are Lagrangian isotopic to L with C^1-topology. Consider the quotient $\mathrm{Lag}(L)/\mathrm{Ham}(P, \Omega)$ by the obvious action of $\mathrm{Ham}(P, \Omega)$. The question is whether $\mathrm{Lag}(L)/\mathrm{Ham}(P, \Omega)$ is Hausdorff or not. This is false in general. In fact, Chekanov's example in [4] provides a counterexample. In his example the Maslov class is non-zero. As an application of our theory [15] we find the following result which is an analogue to Theorem 2.4 (the case that the Chern number is 0).

Theorem 3.16. *Let L be a relatively spin Lagrangian submanifold L with vanishing Maslov class. Suppose that the (deformed) Maurer–Cartan equation for L has a solution. If $L' = \phi(L)$, for some $\phi \in \mathrm{Ham}(P, \Omega)$, is sufficiently C^1-close to L, then L' is regarded as the graph of an exact 1-form on L via Weinstein's tubular neighborhood theorem.*

We expect that $\mathrm{Lag}(L)/\mathrm{Ham}(P, \Omega)$ is Hausdorff under the above assumption.

Finally, we make a remark that if L is a so-called semi-positive Lagrangian submanifold, we can work with $\mathbb{Z}/2\mathbb{Z}$-coefficients rather than $\mathbb{Q}$-coefficients. We do not need the relative spin condition in this case. There is also an approach to the Floer cohomology with $\mathbb{Z}$-coefficients [17]. There are also applications in relation to "mirror symmetry" which we do not discuss here.

Heegaard diagrams and Floer homology

Peter Ozsváth* and Zoltán Szabó†

Abstract. We review the construction of Heegaard–Floer homology for closed three-manifolds and also for knots and links in the three-sphere. We also discuss three applications of this invariant to knot theory: studying the Thurston norm of a link complement, the slice genus of a knot, and the unknotting number of a knot. We emphasize the application to the Thurston norm, and illustrate the theory in the case of the Conway link.

Mathematics Subject Classification (2000). 53D, 57R.

Keywords. Heegaard diagrams, Floer homology, Thurston norm.

1. Heegaard–Floer homology of three-manifolds

Floer homology was initially introduced by Floer to study questions in Hamiltonian dynamics [8]. The basic set-up for his theory involves a symplectic manifold (M, ω), and a pair of Lagrangian submanifolds L_0 and L_1. His invariant, *Lagrangian Floer homology*, is the homology group of a chain complex generated freely by intersection points between L_0 and L_1, endowed with a differential which counts pseudo-holomorphic disks. This chain complex arises from a suitable interpretation of the Morse complex in a certain infinite-dimensional setting.

Soon after formulating Lagrangian Floer homology, Floer realized that his basic principles could also be used to construct a three-manifold invariant, *instanton Floer homology*, closely related to Donaldson's invariants for four-manifolds. In this version, the basic set-up involves a closed, oriented three-manifold Y (satisfying suitable other topological restrictions on Y; for example, the theory is defined when Y has trivial integral first homology). Again, one forms a chain complex, but this time the generators are $\mathrm{SU}(2)$ representations of the fundamental group of Y (or some suitable perturbation thereof), and the differentials count anti-self-dual Yang–Mills connections on the product of Y with the real line. This invariant plays a crucial role in Donaldson's invariants for smooth four-manifolds: for a four-manifold-with-boundary, the relative Donaldson invariant is a homology class in the instanton Floer homology groups of its boundary [4].

In the present note, we will outline an adaptation of Lagrangian Floer homology, *Heegaard–Floer homology*, which gives rise to a closed three-manifold invariant [33], [32]. This invariant also fits into a four-dimensional framework [27]. There is a

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

related invariant of smooth four-manifolds, and indeed relative invariants for this four-manifold invariant take values in the Heegaard–Floer homology groups of its boundary.

A Heegaard diagram is a triple consisting of a closed, oriented two-manifold Σ of genus g, and a pair of g-tuples of embedded, disjoint, homologically linearly independent curves $\boldsymbol{\alpha} = \{\alpha_1, \dots, \alpha_g\}$ and $\boldsymbol{\beta} = \{\beta_1, \dots, \beta_g\}$. A Heegaard diagram uniquely specifies a three-manifold, obtained as a union of two genus g handlebodies U_α and U_β. In U_α, the curves α_i bound disks, while in U_β, the curves β_i bound disks. We associate to this data a suitable version of Lagrangian Floer homology.

Our ambient manifold in this case is the g-fold symmetric product of Σ, the set of unordered g-tuples of points in Σ. This space inherits a natural complex structure from a complex structure over Σ. Inside this manifold, there is a pair of g-dimensional real tori, $\mathbb{T}_\alpha = \alpha_1 \times \cdots \times \alpha_g$ and $\mathbb{T}_\beta = \beta_1 \times \cdots \times \beta_g$. We fix also a reference point

$$w \in \Sigma - \alpha_1 - \cdots - \alpha_g - \beta_1 - \cdots - \beta_g.$$

This gives rise to a subvariety $V_w = \{w\} \times \mathrm{Sym}^{g-1}(\Sigma) \subset \mathrm{Sym}^g(\Sigma)$. We consider the chain complex generated by intersection points $\mathbb{T}_\alpha \cap \mathbb{T}_\beta$. Concretely, an intersection point of $\mathbb{T}_\alpha$ and $\mathbb{T}_\beta$ corresponds to a permutation σ in the symmetric group on g letters, together with a g-tuple of points $\boldsymbol{x} = (x_1, \dots, x_g)$ with $x_i \in \alpha_i \cap \beta_{\sigma(i)}$.

The differential again counts holomorphic disks; but some aspect of the homotopy class of the disk is recorded. We make this precise presently. For fixed $\boldsymbol{x}, \boldsymbol{y} \in \mathbb{T}_\alpha \cap \mathbb{T}_\beta$, let $\pi_2(\boldsymbol{x}, \boldsymbol{y})$ denote the space of homotopy classes of Whitney disks connecting $\boldsymbol{x}$ to $\boldsymbol{y}$, i.e. continuous maps of the unit disk $\mathbb{D} \subset \mathbb{C}$ into $\mathrm{Sym}^g(\Sigma)$, mapping the part of the boundary of $\mathbb{D}$ with negative resp. positive real part to $\mathbb{T}_\alpha$ resp. $\mathbb{T}_\beta$, and mapping i resp. $-i$ to $\boldsymbol{x}$ resp. $\boldsymbol{y}$. The algebraic intersection number of $\phi \in \pi_2(\boldsymbol{x}, \boldsymbol{y})$ with the subvariety V_w determines a well-defined map

$$n_w \colon \pi_2(\boldsymbol{x}, \boldsymbol{y}) \longrightarrow \mathbb{Z}.$$

It is also useful to think of the two-chain $\mathcal{D}(\phi)$, which is gotten as a formal sum of regions in $\Sigma - \alpha_1 - \cdots - \alpha_g - \beta_1 - \cdots - \beta_g$, where a region is counted with multiplicity $n_p(\phi)$, where here $p \in \Sigma$ is any point in this region. Given a Whitney disk, we can consider its space of holomorphic representatives $\mathcal{M}(\phi)$, using the induced complex structure on $\mathrm{Sym}^g(\Sigma)$. If this space is non-empty for all choices of almost-complex structure, then the associated two-chain $\mathcal{D}(\phi)$ has only non-negative local multiplicities. The group $\mathbb{R}$ acts on $\mathcal{M}(\phi)$ by translation. The moduli space $\mathcal{M}(\phi)$ has an expected dimension $\mu(\phi)$, which is obtained as the Fredholm index of the linearized $\bar{\partial}$-operator. This quantity, the *Maslov index*, is denoted $\mu(\phi)$.

It is sometimes necessary to perturb the holomorphic condition to guarantee that moduli spaces are manifolds of the expected dimension. It is useful (though slightly imprecise) to think of a holomorphic disk in $\mathcal{M}(\phi)$ as a pair consisting of a holomorphic surface F with marked boundary, together with a degree g holomorphic projection map π from F to the standard disk, and also a map f from F into Σ.

Here, f maps π^{-1} of the subarc of the boundary of $\mathbb{D}$ with negative resp. positive real part into the subset $\alpha_1 \cup \cdots \cup \alpha_g$ resp $\beta_1 \cup \cdots \cup \beta_g$.

We now consider the complex $CF^-(Y)$ which is the free $\mathbb{Z}[U]$-module generated by $\mathbb{T}_\alpha \cap \mathbb{T}_\beta$, with differential given by

$$\partial \boldsymbol{x} = \sum_{\boldsymbol{y} \in \mathbb{T}_\alpha \cap \mathbb{T}_\beta} \sum_{\{\phi \in \pi_2(\boldsymbol{x}, \boldsymbol{y}) \mid \mu(\phi)=1\}} \#\left(\frac{\mathcal{M}(\phi)}{\mathbb{R}}\right) U^{n_w(\phi)} \boldsymbol{y}. \tag{1}$$

In the case where Y is an integral homology sphere, the above sum is readily seen to be finite. (In the case where the first Betti number is positive, some further constraints must be placed on the Heegaard diagram.) With the help of Gromov's compactification of the space pseudo-holomorphic curves [14], one can see that $\partial^2 = 0$.

According to [33], the homology groups $HF^-(Y)$ of $CF^-(Y)$ are a topological invariant of Y. Indeed, the chain homotopy type of $CF^-(Y)$ is a topological invariant, and, since $CF^-(Y)$ is a module over $\mathbb{Z}[U]$, there are a number of other associated constructions. For example, we can form the chain complex $CF^\infty(Y)$ obtained by inverting U, i.e. a chain complex over $\mathbb{Z}[U, U^{-1}]$, with differential as in Equation (1). The quotient of $CF^\infty(Y)$ by $CF^-(Y)$ is a complex $CF^+(Y)$ which is often more convenient to work with. The corresponding homology groups are denoted $HF^\infty(Y)$ and $HF^+(Y)$ respectively. Also, there is a chain complex $\widehat{CF}$ obtained by setting $U = 0$; explicitly, it is generated freely over $\mathbb{Z}$ by $\mathbb{T}_\alpha \cap \mathbb{T}_\beta$, and endowed with the differential

$$\hat{\partial} \boldsymbol{x} = \sum_{\boldsymbol{y} \in \mathbb{T}_\alpha \cap \mathbb{T}_\beta} \sum_{\{\phi \in \pi_2(\boldsymbol{x}, \boldsymbol{y}) \mid \mu(\phi)=1, n_w(\phi)=0\}} \#\left(\frac{\mathcal{M}(\phi)}{\mathbb{R}}\right) \boldsymbol{y},$$

and its homology (also a topological invariant of Y) is denoted $\widehat{HF}(Y)$.

The invariants $HF^-(Y)$, $HF^\infty(Y)$, and $HF^+(Y)$, together with the exact sequence connecting them, are crucial ingredients in the construction of a Heegaard–Floer invariant Φ for closed, smooth four-manifolds. We will say only little more about this invariant here, referring the reader to [27] for its construction.

2. Heegaard–Floer homology of knots

Heegaard–Floer homology for three-manifolds has a refinement to an invariant for null-homologous knots in a three-manifold, as defined in [31], and also independently by Rasmussen in [38].

A knot K in a three-manifold Y is specified by a Heegaard diagram $(\Sigma, \boldsymbol{\alpha}, \boldsymbol{\beta})$ for Y, together with a pair w and z of basepoints in Σ. The knot K is given as follows. Connect w and z by an arc ξ in $\Sigma - \alpha_1 - \cdots - \alpha_g$ and an arc η in $\Sigma - \beta_1 - \cdots - \beta_g$. The arcs ξ and η are then pushed into U_α and U_β respectively, so that they both meet Σ only at w and z, giving new arcs ξ' and η'. Our knot K, then, is given by

$\xi' - \eta'$. For simplicity, we consider here the case where the ambient manifold Y is the three-sphere S^3.

The new basepoint z gives the Heegaard–Floer complex a filtration. Specifically, we can construct a map

$$F\colon \mathbb{T}_\alpha \cap \mathbb{T}_\beta \longrightarrow \mathbb{Z}$$

by

$$F(\boldsymbol{x}) - F(\boldsymbol{y}) = n_z(\phi) - n_w(\phi), \tag{2}$$

where $\phi \in \pi_2(\boldsymbol{x}, \boldsymbol{y})$. It is easy to see that this quantity is independent of the choice of ϕ, depending only on $\boldsymbol{x}$ and $\boldsymbol{y}$. Moreover, if $\boldsymbol{y}$ appears with non-zero multiplicity in $\hat{\partial}(\boldsymbol{x})$, then $F(\boldsymbol{x}) \geq F(\boldsymbol{y})$. This follows from the fact that there is a pseudo-holomorphic disks $\phi \in \pi_2(\boldsymbol{x}, \boldsymbol{y})$ with $n_w(\phi) = 0$, and also $n_z(\phi) \geq 0$, since a pseudo-holomorphic disks meets the subvariety V_z with non-negative intersection number.

Equation (2) defines F uniquely up to an overall translation. This indeterminacy will be removed presently.

The filtered chain homotopy type of this filtered chain complex is an invariant of the knot K. For example, the homology of the associated graded object, the *knot Floer homology* is an invariant of $K \subset S^3$, defined by

$$\widehat{HFK}(S^3, K) = \bigoplus_{s\in\mathbb{Z}} \widehat{HFK}(S^3, K, s),$$

where $\widehat{HFK}(S^3, K, s)$ is the homology group of the chain complex generated by intersection points $\boldsymbol{x} \in \mathbb{T}_\alpha \cap \mathbb{T}_\beta$ with $F(\boldsymbol{x}) = s$, endowed with differential

$$\partial \boldsymbol{x} = \sum_{\boldsymbol{y}\in\mathbb{T}_\alpha\cap\mathbb{T}_\beta} \sum_{\left\{\phi\in\pi_2(\boldsymbol{x},\boldsymbol{y}) \;\middle|\; \substack{\mu(\phi)=1,\\ n_w(\phi)=n_z(\phi)=0}\right\}} \#\left(\frac{\mathcal{M}(\phi)}{\mathbb{R}}\right)\boldsymbol{y}.$$

The graded Euler characteristic of this theory is the Alexander polynomial of K, in the sense that

$$\Delta_K(T) = \sum_{s\in\mathbb{Z}} \chi(\widehat{HFK}_*(K, s)) \cdot T^s. \tag{3}$$

This formula can be used to pin down the additive indeterminacy of F: we require that F be chosen so that the graded Euler characteristic is the symmetrized Alexander polynomial. In fact, this symmetry has a stronger formulation, as a relatively graded isomorphism

$$\widehat{HFK}_*(K, s) \cong \widehat{HFK}_*(K, -s). \tag{4}$$

3. Heegaard–Floer homology for links

Heegaard–Floer homology groups of knots can be generalized to the case of links in S^3. For an ℓ-component link, we consider a Heegaard diagram with genus g Heegaard surface, and two $(g + \ell - 1)$-tuples attaching circles $\boldsymbol{\alpha} = \{\alpha_1, \ldots, \alpha_{g+\ell-1}\}$

and $\boldsymbol{\beta} = \{\beta_1, \ldots, \beta_{g+\ell-1}\}$. We require $\{\alpha_1, \ldots, \alpha_{g+\ell-1}\}$ to be disjoint and embedded, and to span a g-dimensional lattice in $H_1(\Sigma; \mathbb{Z})$. The same is required of the $\{\beta_1, \ldots, \beta_{g+\ell-1}\}$. Clearly, $\Sigma - \alpha_1 - \cdots - \alpha_{g+\ell-1}$ consists of ℓ components $A_1, \ldots, A_\ell$. Similarly, $\Sigma - \beta_1 - \cdots - \beta_{g+\ell-1}$ consists of ℓ components $B_1, \ldots, B_\ell$. We assume that this Heegaard diagram has the special property that $A_i \cap B_i$ is non-empty. Indeed, for each $i = 1, \ldots, \ell$, we choose basepoints w_i and z_i to lie inside $A_i \cap B_i$. We call the collection of data $(\Sigma, \boldsymbol{\alpha}, \boldsymbol{\beta}, \{w_1, \ldots, w_\ell\}, \{z_1, \ldots, z_\ell\})$ a *2ℓ-pointed Heegaard diagram*.

A link can now be constructed in the following manner. Connect w_i and z_i by an arc ξ_i in A_i and an arc η_i in B_i. Again, the arc ξ_i resp. η_i is pushed into U_α resp. U_β to give rise to a pair of arcs ξ_i' and η_i'. The link L is given by $\cup_{i=1}^{\ell} \xi_i' - \eta_i'$. For a 2ℓ-pointed Heegaard diagram for S^3 $(\Sigma, \boldsymbol{\alpha}, \boldsymbol{\beta}, \{w_1, \ldots, w_\ell\}, \{z_1, \ldots z_\ell\})$, if L is the link obtained in this manner, we say that the Heegaard diagram is *compatible* with the link L.

We will need to make an additional assumption on the Heegaard diagram. A *periodic domain* is a two-chain in Σ of the form

$$\sum c_i(A_i - B_i),$$

where $c_i \in \mathbb{Z}$. Our assumption is that all non-zero periodic domains have some positive and some negative local multiplicities c_i. This assumption on the pointed Heegaard diagram is called *admissibility*.

Let $L \subset S^3$ be an ℓ-component link, suppose that L is embedded so that the restriction of the height function to L has b local maxima, then we can construct a compatible 2ℓ-pointed Heegaard diagram with Heegaard genus $g = b - \ell$.

For example, consider the two-component "Conway link" pictured in Figure 1. This is the $(2, -3, -2, 3)$ pretzel link, also known as L10n59 in Thistlethwaite's link table [1]. For this link, $b = 4$, and hence we can draw it on a surface of genus

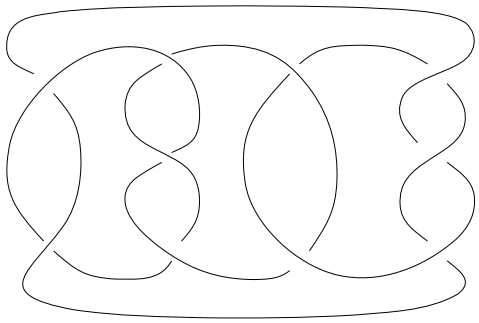

Figure 1. The Conway link.

$g = 2$, as illustrated in Figure 2. It is straightforward to verify that the space of periodic domains is one-dimensional; drawing a picture of this generator, it is also straightforward to see that the diagram is admissible.

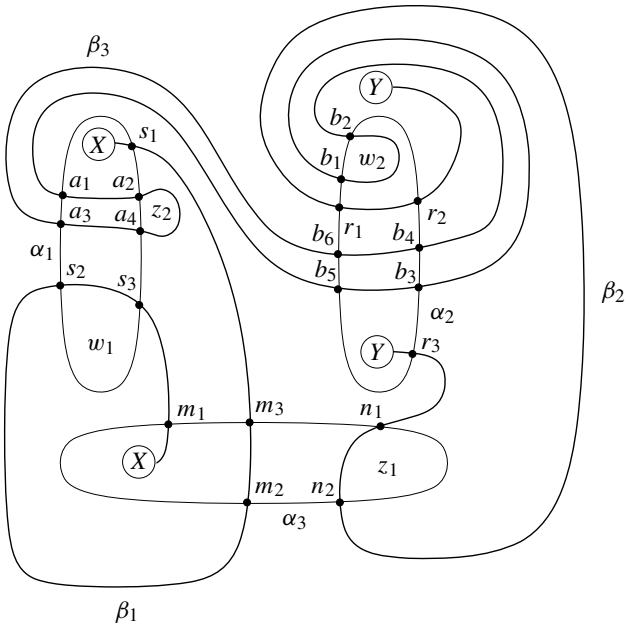

Figure 2. Pointed Heegaard diagram for the Conway link. This picture takes place on the genus two surface obtained by identifying the two disks labeled by X and the two disks labeled by Y.

Now, we work inside $\mathrm{Sym}^{g+\ell-1}(\Sigma)$, relative to the tori $\mathbb{T}_\alpha = \alpha_1 \times \cdots \times \alpha_{g+\ell-1}$ and $\mathbb{T}_\beta = \beta_1 \times \cdots \times \beta_{g+\ell-1}$, and consider intersection points of $\mathbb{T}_\alpha$ and $\mathbb{T}_\beta$; i.e. $g+\ell-1$-tuples of points $(x_1, \ldots, x_{g+\ell-1})$ with $x_i \in \alpha_i \cap \beta_{\sigma(i)}$ for some permutation σ in the symmetric group on $g+\ell-1$ letters. We then form the chain complex $\widehat{CFL}(S^3, L)$ generated freely by these intersection points.

For example, for the figure illustrated in Figure 2, the curves α_i and β_j intersect according to the pattern

$\cap$	α_1	α_2	α_3
β_1	$\{s_1, s_2, s_3\}$	$\emptyset$	$\{m_1, m_2, m_3\}$
β_2	$\emptyset$	$\{r_1, r_2, r_3\}$	$\{n_1, n_2\}$
β_3	$\{a_1, \ldots, a_4\}$	$\{b_1, \ldots, b_6\}$	$\emptyset$

Now, there are exactly two permutations of $\{1, 2, 3\}$ for which $\alpha_i \cap \beta_{\sigma(i)}$ is non-trivial for all i. This gives two types of intersection points of $\mathbb{T}_\alpha \cap \mathbb{T}_\beta$, namely, $a_i \times m_j \times r_k$ (with $i = 1, \ldots, 4$, $j = 1, \ldots, 3$, $k = 1, \ldots, 3$) and also $b_i \times n_j \times s_k$ (with $i = 1, \ldots, 6$, $j = 1, 2$, $k = 1, 2, 3$). This gives a chain complex with a total of 72 generators.

The complex $\widehat{CFL}$ has a grading, the *Maslov grading*, which is specified up to overall translation by the convention

$$\mathrm{gr}(\boldsymbol{x}) - \mathrm{gr}(\boldsymbol{y}) = \mu(\phi) - 2\sum_{i=1}^{\ell} n_{w_i}(\phi),$$

where $\phi \in \pi_2(\boldsymbol{x}, \boldsymbol{y})$ is any Whitney disk connecting $\boldsymbol{x}$ and $\boldsymbol{y}$. The parity of the Maslov grading depends on the local sign of the intersection number of $\mathbb{T}_\alpha$ and $\mathbb{T}_\beta$ at $\boldsymbol{x}$.

But $\widehat{CFL}$ has an additional grading, the $\mathbb{H}$-grading. To define this, we associate to each $\phi \in \pi_2(\boldsymbol{x}, \boldsymbol{y})$ the pair of vectors

$$n_{\boldsymbol{w}}(\phi) = (n_{w_1}(\phi), \ldots, n_{w_\ell}(\phi)) \quad \text{and} \quad n_{\boldsymbol{z}}(\phi) = (n_{z_1}(\phi), \ldots, n_{z_\ell}(\phi)).$$

We have a function $F\colon \mathbb{T}_\alpha \cap \mathbb{T}_\beta \longrightarrow \mathbb{Z}^\ell \cong H_1(S^3 - L; \mathbb{Z})$ (where the latter identification is given by the meridians of the link L) specified uniquely up to translation by the formula

$$F(\boldsymbol{x}) - F(\boldsymbol{y}) = n_{\boldsymbol{z}}(\phi) - n_{\boldsymbol{w}}(\phi),$$

where ϕ is any choice of homotopy class in $\pi_2(\boldsymbol{x}, \boldsymbol{y})$.

Endow $\widehat{CFL}(S^3, L)$ with the differential

$$\partial \boldsymbol{x} = \sum_{\boldsymbol{y} \in \mathbb{T}_\alpha \cap \mathbb{T}_\beta} \sum_{\left\{\phi \in \pi_2(\boldsymbol{x}, \boldsymbol{y}) \;\middle|\; \substack{\mu(\phi) = 1, \\ n_{\boldsymbol{w}}(\phi) = n_{\boldsymbol{z}}(\phi) = 0}\right\}} \#\left(\frac{\mathcal{M}(\phi)}{\mathbb{R}}\right) \boldsymbol{y}.$$

It is easy to see that this differential drops Maslov grading by one. Moreover, the complex naturally splits into summands indexed by elements of $\mathbb{Z}^\ell \cong H_1(S^3 - L; \mathbb{Z})$ specified by the function F. We find it natural to think of these summands, in fact, as indexed by the affine lattice $\mathbb{H} \subset H_1(S^3 - L; \mathbb{R})$ over $H_1(S^3 - L; \mathbb{Z})$, given by elements

$$\sum_{i=1}^{\ell} a_i \cdot [\mu_i],$$

where $a_i \in \mathbb{Q}$ satisfies the property that

$$2a_i + \mathrm{lk}(L_i, L - L_i)$$

is an even integer. The translational ambiguity of the map is then pinned down by the following generalization of Equation (4):

$$\widehat{HFL}_*(\vec{L}, h) \cong \widehat{HFL}_*(\vec{L}, -h). \tag{5}$$

In practice, it is easy to calculate the difference in F for any two intersection of $\mathbb{T}_\alpha$ and $\mathbb{T}_\beta$ which have the same type (i.e. same pattern of intersection $\alpha_i \cap \beta_{\sigma(i)}$). To this end, it suffices to find for each pair of intersection points $x, x' \in \alpha_i \cap \beta_j$, a disk (or more generally a compact surface with a single boundary component) in Σ which

meets α_i along one arc in its boundary and β_j along the complementary arc, carrying the intersection points of the closures of the arcs to x and x'. We then define the "relative difference" of x and x', $F^{i,j}(x) - F^{i,j}(x')$, to be $n_{\boldsymbol{z}} - n_{\boldsymbol{w}}$ for this disk (or surface). It is easy to see then that if $\boldsymbol{x}$ and $\boldsymbol{y} \in \mathbb{T}_\alpha \cap \mathbb{T}_\beta$ are two intersection points with the same type (as specified by σ), then

$$F(\boldsymbol{x}) - F(\boldsymbol{y}) = \sum_{i=1}^{g+\ell-1} F^{i,\sigma(i)}(x_i) - F^{i,\sigma(i)}(y_i),$$

where $\boldsymbol{x} = (x_1, \dots, x_{g+\ell-1})$ and $y = (y_1, \dots, y_{g+\ell-1})$. This determines $F(\boldsymbol{x}) - F(\boldsymbol{y})$ for $\boldsymbol{x}$ and $\boldsymbol{y}$ of the same type. Different types can then be compared by choosing homotopy classes connecting them (and in suitable circumstances, the translational ambiguity can be removed using Equation (5)).

We display the relative differences for the various intersection points for the diagram from Figure 2.

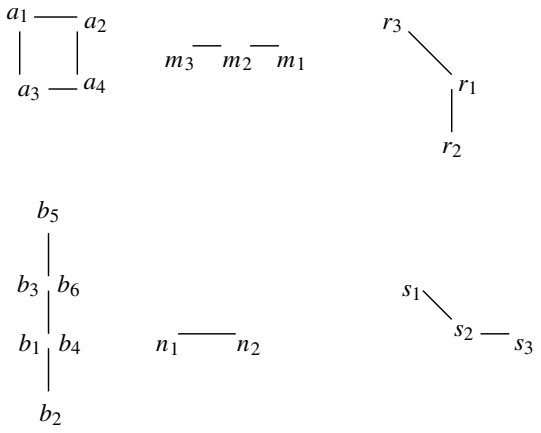

Figure 3. Generators for $\widehat{HFL}$ of the Conway link. We illustrate the relative differences of the various intersection points of α_i and β_j. A horizontal resp. vertical segment denotes two intersection points whose relative difference is one in the first resp. second component; e.g. there is a disk in Figure 2 ϕ from a_2 to a_1 with $n_z - n_w$ given by $(1, 0)$, while there is one from b_5 to b_3 with relative difference given by $(0, 1)$. Finally, for the diagonal edges, we have a disk from r_3 to r_1 with relative difference $(-1, 1)$.

It is now straightforward to verify that the ranks of the chain groups in each value of F is given as in Figure 4. It is more challenging to calculate the homology groups of $\widehat{CFL}$.

Some aspects are immediate. For example, it follows by glancing at Figure 4, and comparing Equation (5) that the homology in $\mathbb{H}$-grading $(-2, 2)$ is trivial (as there are no generators in the $\mathbb{H}$-grading $(2, -2)$), and that in $\mathbb{H}$-gradings $(-1, 2)$ and $(-2, 1)$ the groups $\widehat{HFL}$ have rank one. This already suffices to determine the convex hull

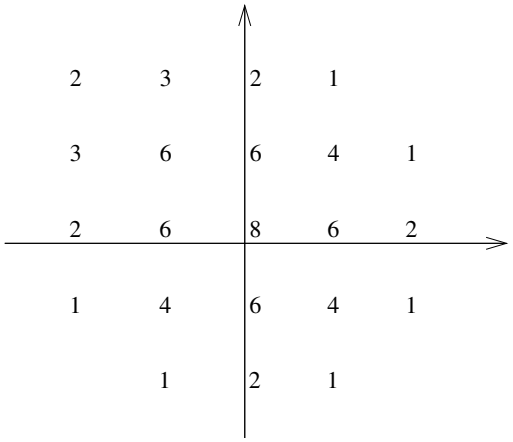

Figure 4. Generators for $\widehat{CFL}$ of the Conway link. The 72 generators of $\widehat{CFL}$ coming from the diagram in Figure 2 are partitioned into various filtration levels. In this figure, each integer represents the number of generators in the filtration level specified by its coordinates in the plane.

of $h \in \mathbb{H}$ for which $\widehat{HFL}(L, h)$ is non-trivial, as required for the application to the Thurston norm below (see esp. Equation (7)).

Also, the calculation of $\widehat{HFL}(L, (x, y))$ with $(x, y) \in \{(0, \pm 2), (\pm 2, 0)\}$ follows from the fact that for each of these $\mathbb{H}$-gradings, every generator has the same Maslov grading.

Next, consider the part in $\mathbb{H}$-grading $(1, 1)$. There are four generators

$$a_1 \times m_1 \times r_1, \quad a_2 \times m_2 \times r_1, \quad a_4 \times r_3 \times m_1, \quad b_5 \times n_1 \times s_3.$$

For the case where $\boldsymbol{x} = b_5 \times n_1 \times s_3$ and $\boldsymbol{y} \in \{a_1 \times m_1 \times r_1, a_2 \times m_2 \times r_1\}$, there is a homotopy class $\phi \in \pi_2(\boldsymbol{x}, \boldsymbol{y})$ whose associated two-chain $\mathcal{D}(\phi)$ is a hexagon. For the case where $\boldsymbol{y} = a_2 \times m_2 \times r_1$, we illustrate this in Figure 5.

A hexagon gives rise to a flow-line connecting $\boldsymbol{x}$ to $\boldsymbol{y}$. To this end, we think of a holomorphic disk in $\mathrm{Sym}^3(\Sigma)$ as a branched triple-cover F of the standard disk, together with a map of F into Σ. The given hexagonal domain in Σ can be realized as a branched triple-cover of the disk $\mathbb{D}$. Moreover, any other domain connecting $\boldsymbol{x}$ to $\boldsymbol{y}$ has negative local multiplicity somewhere. Hence, we have that

$$\partial b_5 \times n_1 \times s_3 = a_1 \times m_1 \times r_1 + a_2 \times m_2 \times r_1.$$

It can also be seen that

$$\mathrm{gr}(b_5 \times n_1 \times s_3) = \mathrm{gr}(a_4 \times m_1 \times r_3),$$

but there are no non-negative domains from $a_4 \times m_1 \times r_3$ to either of $\{a_1 \times m_1 \times r_1, a_2 \times m_2 \times r_1\}$. It follows at once that $\widehat{HFL}(L, (1, 1))$ has rank two.

With some additional work, one can verify that all the link Floer homology groups of the Conway link are as displayed below in Figure 6.

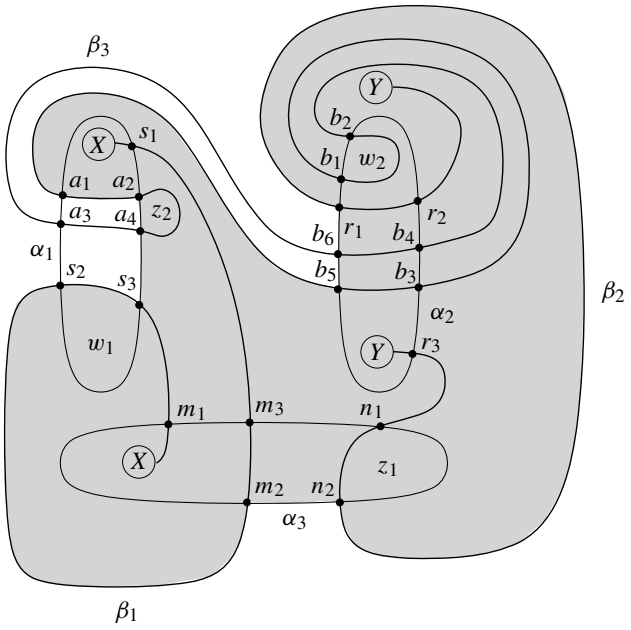

Figure 5. A flowline. The complement of the shaded region gives a hexagon connecting $b_5 \times n_1 \times s_3$ to $a_2 \times m_2 \times r_1$.

4. Basic properties

Perhaps the single most fundamental property of Heegaard–Floer homology is that it satisfies an exact triangle for surgeries. More precisely, a *triad* of three-manifolds Y_1, Y_2, Y_3 is a cyclically ordered triple of three-manifolds obtained as follows. Let M be a three-manifold with torus boundary, and fix three simple, closed curves in its boundary γ_1, γ_2, γ_3 any two of which intersect transversally in one point, and ordered so that there are orientations on the three curves so that

$$\#(\gamma_1 \cap \gamma_2) = \#(\gamma_2 \cap \gamma_3) = \#(\gamma_3 \cap \gamma_1) = -1.$$

We let Y_i be the three-manifold obtained by Dehn filling M along the curve γ_i.

Theorem 4.1. *Let Y_1, Y_2, and Y_3 be a triad of three-manifolds. Then, there is an long exact sequence of the form*

$$\cdots \longrightarrow \widehat{HF}(Y_1) \longrightarrow \widehat{HF}(Y_2) \longrightarrow \widehat{HF}(Y_3) \longrightarrow \cdots.$$

The maps in the exact triangle are induced by the three natural two-handle cobordisms connecting Y_i and Y_{i+1} (where we i as an integer modulo 3), in a manner made precise in [27].

The above surgery exact sequence is similar to an exact sequence established by Floer for instanton Floer homology (only using a restricted class of triads) [9], [2]. An

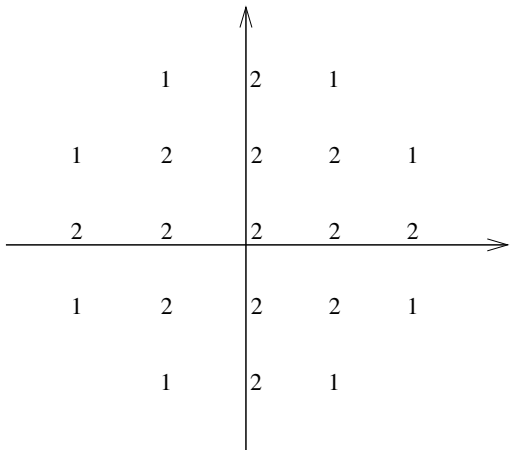

Figure 6. Ranks of $\widehat{HFL}$ for the Conway link. The ranks are displayed, along with their $\mathbb{H}$ grading, thought of as coordinates in the plane.

analogous exact sequence has been established for Floer homology of Seiberg–Witten monopoles, see [20]. There are also related exact sequences in symplectic geometry, cf. [40].

Note that there are other variants of the exact triangle, and indeed, there are certain other related calculational techniques for Heegaard–Floer homology. For example, for a knot K in an integral homology sphere Y, the filtered chain homotopy type of the induced knot invariant can be used to calculate the Floer homology groups of arbitrary surgeries on K, [28].

5. Three applications

Heegaard–Floer homology is particularly well suited to problems in knot-theory and three-manifold topology which can be formulated in terms of the existence of four-dimensional cobordisms. We focus here on a few concrete problems which can be formulated for knots and links in the three-sphere. For some other applications, see [36], [34], [22], [37].

5.1. Thurston norm. Let $K \subset S^3$ be a knot. The *Seifert genus* of K, denoted $g(K)$, is the minimal genus of any embedded surface $F \subset S^3$ with boundary K. Clearly, if $g(K) = 0$, then K is the unknot.

According to [30], knot Floer homology detects the Seifert genus of a knot, by the property that

$$g(K) = \max\{s \mid \widehat{HFK}(K, s) \neq 0\}. \tag{6}$$

There is a natural generalization of the knot genus and indeed of Equation (6). This is best formulated in terms of Thurston's norm on second homology.

Recall that if F is a compact, oriented, but possibly disconnected surface-with-boundary $F = \bigcup_{i=1}^{n} F_i$, its *complexity* is given by

$$\chi_-(F) = \sum_{\{F_i \mid \chi(F_i)\leq 0\}} -\chi(F_i).$$

Given any homology class $h \in H_2(S^3, L)$, it is easy to see that there is a compact, oriented surface-with-boundary embedded in $S^3 - \mathrm{nd}(K)$ representing h. Consider the function from $H^1(S^3 - L; \mathbb{Z})$ to the integers defined by

$$x(h) = \min_{\{F\hookrightarrow S^3-\mathrm{nd}(K) \mid [F]=\mathrm{PD}[h]\}} \chi_-(F).$$

Indeed, according to Thurston [41], this function x satisfies an inequality $x(h_1+h_2) \leq x(h_1) + x(h_2)$, and it is linear on rays, i.e. given $h \in H_2(S^3, L)$ and a non-negative integer n, we have that $x(n \cdot h) = nx(h)$. Thus, x can be naturally extended to a semi-norm on $H^1(S^3 - L; \mathbb{R})$, the *Thurston semi-norm*. In fact, this semi-norm is uniquely specified by its unit ball

$$B_x = \{h \in H^1(S^3 - L; \mathbb{R}) \mid x(h) \leq 1\},$$

which is a polytope $H^1(S^3-L; \mathbb{R})$ whose vertices lie at lattice points in $H^1(S^3-L; \mathbb{Z})$.

Equation (6) can now be generalized as follows. A *trivial component* of a link L is a component $K \subset L$ which is unknotted an geometrically unlinked from the complement $L - K$. Suppose that L is a link with no trivial components. Then, given $s \in H^1(S^3 - L)$,

$$x(h) + \sum_{i=1}^{\ell} |\langle \mu_i, h\rangle| = 2 \cdot \max_{\{s\in\mathbb{H} \mid \widehat{HFL}(L,s)\neq 0\}} \langle h, s\rangle, \tag{7}$$

where here $\langle , \rangle$ denotes the Kronecker pairing of $H_1(S^3 - L; \mathbb{R})$ with $H^1(S^3 - L; \mathbb{R})$.

This formula can be thought of more geometrically from the following point of view. Consider the dual norm $x^*\colon H_1(S^3 - L; \mathbb{R}) \longrightarrow \mathbb{R}$ given by

$$x^*(s) = \max_{\{h\in B_x\}} \langle s, h\rangle.$$

The unit ball B_{x*} is a (possibly degenerate) polytope in $H_1(S^3 - L; \mathbb{R})$ called the *dual Thurston polytope*. Equation (7) states that for a link L with no trivial components, if we take the convex hull of the set of $s \in \mathbb{H}$ with $\widehat{HFL}(L, s)$, and rescale that polytope by a factor of two, then we obtain the sum of the dual Thurston polytope with the symmetric hypercube in $H_1(S^3 - L; \mathbb{R})$ with edge-length two.

Of course, the Thurston norm can be defined for closed three-manifolds, as well. In fact, a result analogous to Equation (7) can be proved for closed three-manifolds Y,

instead of link complements. An analogous result has been shown to hold for Seiberg–Witten monopole Floer homology [19] (but at present there is no analogue of knot and link Floer homology in gauge-theoretic terms).

Although the statement of Equation (6) does not explicitly involve any four-dimensional theory, the proof of this result does use the full force of Heegaard–Floer homology, combined with Gabai's theory of sutured manifolds, and recent results in symplectic geometry. Specifically, according to a combination of theorems of Gabai [11], [12], Eliashberg–Thurston [6], and a result of Eliashberg [5] and independently Etnyre [7], if $K \subset S^3$ is a knot of genus g, then its zero-surgery $S^3_0(K)$ separates a symplectic manifold. Non-vanishing theorems for the Heegaard–Floer invariant Φ for symplectic four-manifolds, which in turn are built on the symplectic Lefshetz pencils of Donaldson [3], then give a non-vanishing result for the Heegaard–Floer $S^3_0(K)$ from which Equation (6) follows.

These results can be further generalized to give Equation (7). Specifically, an n-component link in S^3 naturally gives rise to a connected knot in the $(n-1)$-fold connected sum of $S^2 \times S^1$. A genus bound analogous to Equation (6) has been shown by Ni in [25], which in effect establishes Equation (7), in the case where h is one of the 2^ℓ cohomology classes whose evaluation on each meridian for L has absolute value equal to one. Equation (7) then follows from the manner in which the Thurston norm and link Floer homology transform under cabling, see also [16].

As an illustration of Equation (6), consider the Conway link from Figure 1. According to the calculations displayed in Figure 6, together with this equation, we conclude that the dual Thurston polytope of the Conway link is as illustrated in Figure 7.

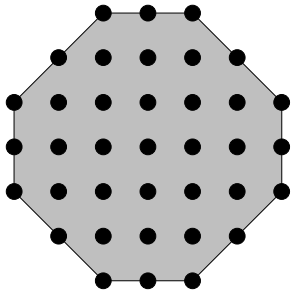

Figure 7. Dual Thurston polytope for the Conway link. Lattice points in $H_1(S^3 - L; \mathbb{Z})$ are indicated by solid circles.

Figure 7 suggests that there are surfaces F_1 the complement of the Conway link L, with ∂F_1 consisting of a longitude belonging to a first component of L, and some number of copies of the meridian of the second component, and also with $\chi_-(F_1) = 5$. In fact, such a surface can be easily obtained by puncturing a genus one Seifert surface for one of the trefoil components in two additional points. A similar surface can be found for the other component of L.

Note that a verification of the dual Thurston polytope for the Conway link can be easily obtained by more classical methods (cf. [23]); however, the computation given here is fairly easy (and hopefully illustrates the theory).

5.2. Slice genus. A *slice surface* for a knot K is a smoothly embedded surface-with-boundary $F \subset B^4$ which meets S^3 along its boundary, which is K. The *slice genus* of a knot $g_*(K)$ is the minimal genus of any slice surface for K. Heegaard–Floer homology can be used to give information about this quantity, as follows.

Recall that knot Floer homology is the homology of an associated graded object which is induced by the filtration of a chain complex which calculates $\widehat{HF}(S^3) \cong \mathbb{Z}$. But the entire filtered chain homotopy type of the complex is a knot invariant. Denote the sequence of subcomplexes $F_i \subset F_{i+1}$, so that for all sufficiently small integers i, $F_i = 0$, while for all sufficiently large integers, $F_i = \widehat{CF}(S^3)$. There is another natural invariant which can be associated to a knot, which is the minimal i for which the map $H_*(F_i) \longrightarrow \widehat{HF}(S^3)$ is non-trivial. According to [29] and independently [38],

$$|\tau(K)| \leq g^*(K).$$

Intriguingly, Rasmussen [39] has shown that a very similar algebraic construction on Khovanov's homology [17], [21], can be used to define a similar (but entirely combinatorial) numerical invariant $s(K)$. Although both $\tau(K)$ and $s(K)$ share many formal properties (and hence agree on many knots), Hedden and Ording have recently shown [15] that these two invariants are in fact distinct. Their examples are certain twisted Whitehead doubles of the trefoil.

5.3. Unknotting numbers. The *unknotting number* $u(K)$ is the minimal number of crossing changes required to transform K into an unknot. An n-step unknotting of a knot K in effect gives an immersed disk in B^4 with n double-points. Resolving these double-points, we obtain a slice surface for K with genus n. This observation immediately verifies the inequality

$$g^*(K) \leq u(K).$$

For some classes of knots, these two quantities are equal. For example, for the (p, q) torus knot, $g^*(K) = u(K) = (p-1)(q-1)/2$. This was first shown by Kronheimer and Mrowka in [18] (though it has alternative proofs now using either τ [29] or the Khovanov–Rasmussen invariant s [39]).

But there are Floer-theoretic bounds on $u(K)$ which go beyond the slice genus, cf. [35], [26].

Suppose that K has $u(K) = 1$. Then, Montesinos observed [24] that the branched double-cover of S^3 with branching locus K, denoted $\Sigma(K)$, can be realized as $\pm d/2$-surgery on a different knot $C \subset S^3$, where here $d = |\Delta_K(-1)|$. Obstructions to this can sometimes be given using Heegaard–Floer homology.

To do this in a useful manner, we must understand first $\widehat{HF}(\Sigma(K))$. For some knots, this is a straightforward matter. For example, when K is a knot which admits an alternating projection, an easy induction using Theorem 4.1 shows that $\widehat{HF}(\Sigma(K))$ is a free $\mathbb{Z}$-module of rank $|\Delta_K(-1)|$. This means that the Heegaard–Floer homology groups of these three-manifolds is as simple as possible. For any rational homology three-sphere Y (i.e. closed three-manifold with $H_1(Y;\mathbb{Q}) = 0$), the Euler characteristic of $\widehat{HF}(Y)$ is $|H_1(Y;\mathbb{Z})|$, the number of elements in $H_1(Y;\mathbb{Z})$. A rational homology three-sphere whose homology group $\widehat{HF}(Y)$ is a free module of rank $|H_1(Y;\mathbb{Z})|$ is called an *L-space*. Thus, if K is a knot with alternating projection, then $\Sigma(K)$ is an L-space.

There are obstructions to realizing an L-space as surgery on a knot in S^3, These obstructions are phrased in terms of an additional $\mathbb{Q}$-grading on the Heegaard–Floer homology [35], analogous to an invariant defined by Frøyshov [10] in the context of Seiberg–Witten theory. Moreover, this $\mathbb{Q}$-grading can be explicitly calculated for $\Sigma(K)$ for an alternating knot K from its Goeritz matrix. Rather than stating these results precisely, we content ourself here with including a picture of an eight-crossing alternating knot (8_{10}, see Figure 8) whose unknotting number can be shown to equal two via these (and presently, no other known) techniques.

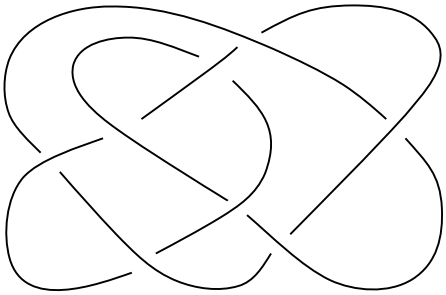

Figure 8. A knot with $u = 2$.

Combining these obstructions with recent work of Gordon and Luecke [13], one can classify all knots with 10 and fewer crossings which have unknotting number equal to one. Indeed, a different application of Heegaard–Floer homology along similar lines discovered by Owens [26] can be used to complete the unknotting number table for prime knots with nine or fewer crossings.

The cohomology of automorphism groups of free groups

Karen Vogtmann*

Abstract. There are intriguing analogies between automorphism groups of finitely generated free groups and mapping class groups of surfaces on the one hand, and arithmetic groups such as $\mathrm{GL}(n, \mathbb{Z})$ on the other. We explore aspects of these analogies, focusing on cohomological properties. Each cohomological feature is studied with the aid of topological and geometric constructions closely related to the groups. These constructions often reveal unexpected connections with other areas of mathematics.

Mathematics Subject Classification (2000). Primary 20F65; Secondary, 20F28.

Keywords. Automorphism groups of free groups, Outer space, group cohomology.

1. Introduction

In the 1920s and 30s Jakob Nielsen, J. H. C. Whitehead and Wilhelm Magnus invented many beautiful combinatorial and topological techniques in their efforts to understand groups of automorphisms of finitely-generated free groups, a tradition which was supplemented by new ideas of J. Stallings in the 1970s and early 1980s. Over the last 20 years mathematicians have been combining these ideas with others motivated by both the theory of arithmetic groups and that of surface mapping class groups. The result has been a surge of activity which has greatly expanded our understanding of these groups and of their relation to many areas of mathematics, from number theory to homotopy theory, Lie algebras to bio-mathematics, mathematical physics to low-dimensional topology and geometric group theory.

In this article I will focus on progress which has been made in determining cohomological properties of automorphism groups of free groups, and try to indicate how this work is connected to some of the areas mentioned above. The concept of assigning cohomology groups to an abstract group was originally motivated by work of Hurewicz in topology. Hurewicz proved that the homotopy type of a space with no higher homotopy groups (an *aspherical space*) is determined by the fundamental group of the space, so the homology groups of the space are in fact invariants of the group. Low-dimensional homology groups were then found to have interpretations in terms of algebraic invariants such as group extensions and derivations which had long been studied by algebraists, and a purely algebraic definition of group cohomology

*The author was partially supported by grants from the National Science Foundation

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

was also introduced. These were the beginning steps of a rich and fruitful interaction between topology and algebra via cohomological methods.

Borel and Serre studied the cohomology of arithmetic and S-arithmetic groups by considering their actions on homogeneous spaces and buildings. Thurston studied surface mapping class groups by considering their action on the Teichmüller space of a surface, and this same action was used later by Harer to determine cohomological properties of mapping class groups. Outer automorphism groups of free groups are neither arithmetic groups nor surface mapping class groups, but they have proved to share many algebraic features with both classes of groups, including many cohomological properties. The analogy is continually strengthened as more and more techniques from the arithmetic groups and mapping class groups settings are adapted to the study of automorphism groups of free groups. The adaptation is rarely straightforward, and often serves more as a philosophy than a blueprint. The connection is more than strictly empirical and philosophical, however, due to the natural maps

$$\mathrm{Out}(F_n) \to \mathrm{GL}(n, \mathbb{Z})$$

and

$$\Gamma_{g,s} \to \mathrm{Out}(F_{2g+s-1}).$$

The first map is induced by the abelianization map $F_n \to \mathbb{Z}^n$; it is always surjective and is an isomorphism for $n = 2$. In the second map, the group $\Gamma_{g,s}$ is the mapping class group of a surface of genus g with $s > 0$ punctures, which may be permuted. The map is defined using the observation that a homeomorphism of a surface induces a map on the (free) fundamental group of the surface; it is always injective and is an isomorphism for $g = s = 1$.

2. Outer space and homological finiteness results

In order to adapt techniques Borel and Serre used for arithmetic groups, and those Thurston and Harer used for mapping class groups to the context of automorphism groups of free groups, the first thing one needs is a replacement for the homogeneous or Teichmüller space. A suitable space $\mathcal{O}_n$, now called *Outer space*, was introduced by Culler and Vogtmann in 1986 [12]. The most succinct definition of Outer space is that it is the space of homothety classes of minimal free simplicial actions of $\mathrm{Out}(F_n)$ on $\mathbb{R}$-trees. (Here an $\mathbb{R}$-*tree* is a metric space with a unique arc, isometric to an interval of $\mathbb{R}$, joining any two points and actions are by isometries; an action is *simplicial* if every orbit is discreet and *minimal* if there is no proper invariant subtree.) The topology on the space can be taken to be the equivariant Gromov–Hausdorff topology, or it can be topologized as a space of projective length functions on F_n. Pre-composing an action with an element of $\mathrm{Out}(F_n)$ gives a new action, and this defines the action of $\mathrm{Out}(F_n)$ on the space. This description is efficient, but it is often easier to visualize and to work with Outer space when it is presented instead in terms of *marked graphs*.

2.1. Marked graphs. The quotient of a free action of F_n on a simplicial $\mathbb{R}$-tree is a finite graph with fundamental group F_n and a metric determined by the lengths of the edges. The action is minimal if and only if the quotient graph has no univalent or bivalent vertices. If we have a specific identification of F_n with the fundamental group of the graph then the tree, with its F_n-action, can be recovered as the universal cover of the graph. Thus another way to describe a point in Outer space is to fix a graph R_n and identification $F_n = \pi_1(R_n)$; a point is then an equivalence class of pairs (g, G), where

- G is a finite connected metric graph with no univalent or bivalent vertices,
- $g\colon R_n \to G$ is a homotopy equivalence.

We normalize the metric so that the sum of the lengths of the edges in G is equal to one; then two pairs (g, G) and (g', G') are *equivalent* if there is an isometry $h\colon G \to G'$ with $h \circ g \simeq g'$. An equivalence class of pairs is called a *marked graph*.

Varying the lengths of edges in a marked graph with k edges and total length one allows one to sweep out an open $(k-1)$-simplex of points in Outer space. Collapsing an edge which is not a loop determines a new open simplex which is a face of the original simplex. We topologize Outer space as the union of these open simplices, modulo these face identifications. A picture of Outer space for $n = 2$ is given in Figure 1.

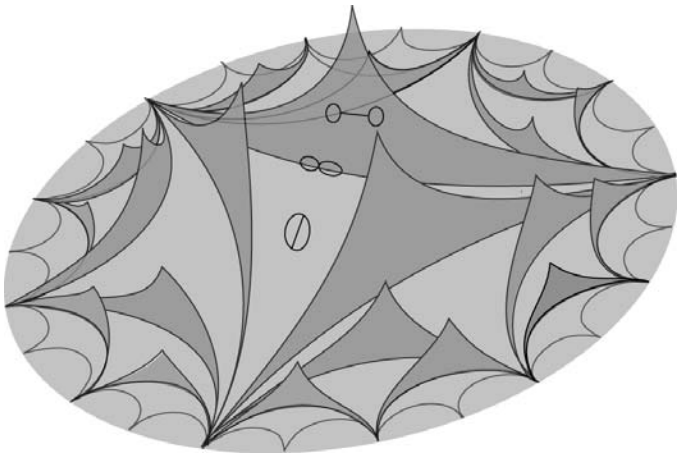

Figure 1. Outer space in rank 2.

2.2. Virtual cohomological dimension. The first cohomological results about automorphism groups of free groups were finiteness results, which followed directly by considering the topology and combinatorial structure of Outer space. Unlike homogeneous spaces and Teichmüller spaces, Outer space and its quotient are not manifolds,

as can be seen already for $n = 2$. However, observed through the prism of cohomology they resemble manifolds in several important ways, including satisfying various finiteness properties and a type of duality between homology and cohomology. As a start, we have

Theorem 2.1 ([12]). *Outer space is contractible of dimension* $3n - 4$*, and* $\mathrm{Out}(F_n)$ *acts with finite stabilizers.*

$\mathrm{Out}(F_n)$ has torsion-free subgroups of finite index, which by the above theorem must act freely on $\mathcal{O}_n$. The quotient of $\mathcal{O}_n$ by such a subgroup Γ is thus an aspherical space with fundamental group Γ, and the following corollary follows immediately:

Corollary 2.2. *The cohomological dimension of any torsion-free subgroup of finite index in* $\mathrm{Out}(F_n)$ *is at most* $3n - 4$.

Serre proved that in fact the cohomological dimension of a torsion-free subgroup of finite index in any group is independent of the choice of subgroup; this is called the *virtual cohomological dimension*, or VCD, of the group. As in the case of $\mathrm{GL}(n, \mathbb{Z})$ and mapping class groups, the quotient of $\mathcal{O}_n$ by $\mathrm{Out}(F_n)$ is not compact, and the dimension of the homogeneous space does not give the best upper bound on the virtual cohomological dimension. A solution to this problem for $\mathrm{Out}(F_n)$ is given by considering an equivariant deformation retract of $\mathcal{O}_n$, called the *spine of Outer space*. This spine can be described as the geometric realization of the partially ordered set of open simplices of $\mathcal{O}_n$, so has one vertex for every homeomorphism type of marked graph with fundamental group F_n and one k-simplex for every sequence of k forest collapses.

Theorem 2.3 ([12]). *The spine of Outer space is an equivariant deformation retract of Outer space. It has dimension* $2n - 3$ *and the quotient is compact.*

This theorem allows one to compute the virtual cohomological dimension of $\mathrm{Out}(F_n)$ precisely:

Corollary 2.4. *The virtual cohomological dimension of* $\mathrm{Out}(F_n)$ *is equal to* $2n - 3$.

Proof. For $i > 1$, let λ_i be the automorphism of $F_n = F\langle x_1, \ldots, x_n\rangle$ which multiplies x_i by x_1 on the left and fixes all other x_j. Similarly, define ρ_i to be the automorphism which multiplies x_i by x_1 on the right. The subgroup of $\mathrm{Out}(F_n)$ generated by the λ_i and ρ_i is a free abelian subgroup of $\mathrm{Out}(F_n)$ of dimension $2n - 3$, giving a lower bound on the virtual cohomological dimension. The upper bound is given by the dimension of the spine. □

2.3. Finite generation of homology. The fact that the quotient of the spine by $\mathrm{Out}(F_n)$ is compact implies immediately that any torsion-free finite-index subgroup is the fundamental group of an acyclic space with only finitely many cells in each dimension, and in particular its homology is finitely generated in all dimensions. This implies the same result for the entire group $\mathrm{Out}(F_n)$:

Corollary 2.5. *The homology of* $\mathrm{Out}(F_n)$ *is finitely-generated in all dimensions.*

The focus of this article is cohomology, but we would like to point out that Outer space and its spine can also be used to prove properties of $\mathrm{Out}(F_n)$ which are not strictly cohomological. As an example, we note that any finite subgroup of $\mathrm{Out}(F_n)$ can be realized as automorphisms of a finite graph with fundamental group F_n (see, e.g. [11]). This is equivalent to saying that any finite subgroup of $\mathrm{Out}(F_n)$ fixes some vertex of the spine of Outer space, so compactness of the quotient immediately gives the following information about the subgroup structure of $\mathrm{Out}(F_n)$.

Corollary 2.6. $\mathrm{Out}(F_n)$ *has only finitely many conjugacy classes of finite subgroups.*

Going even farther afield, we remark that the very concrete description of the spine in terms of graphs and forest collapses allows one to determine the local structure quite precisely. In particular, a neighborhood of a *rose*, i.e. a graph with one vertex and n edges, is easily identified with the space of trees with $2n$ labeled leaves, and can be used as a model for the space of phylogenetic trees in biology. This neighborhood can be given a metric of non-positive curvature, which has a computational advantage for applications to biology (see [3]).

3. The bordification and duality

There is another approach to resolving difficulties arising from the fact that the action of $\mathrm{Out}(F_n)$ on Outer space is not cocompact. Instead of finding a spine inside Outer space, one can extend Outer space and the action of $\mathrm{Out}(F_n)$ by adding cells "at infinity" to produce a larger space whose quotient is compact. This was the approach taken by Borel and Serre in their work on arithmetic groups. They defined a *bordification* of the homogeneous space and used Poincaré–Lefschetz duality for this "manifold with corners" to prove that arithmetic groups satisfy a form of duality between homology and cohomology. Specifically, a group Γ is said to be a *duality group* if there is a module D, integer d and isomorphisms $H^i(\Gamma; M) \to H_{d-i}(\Gamma; M \otimes D)$ for any integer i and Γ-module M. If Γ is a duality group, then the integer d is equal to the virtual cohomological dimension, and this is how Borel and Serre determined the (virtual) cohomological dimension of arithmetic groups.

Although Outer space is not a manifold, Bestvina and Feighn showed that torsion-free finite index subgroups of $\mathrm{Out}(F_n)$ are duality groups, i.e. $\mathrm{Out}(F_n)$ is a *virtual* duality group. They accomplished this by defining a bordification $\widehat{\mathcal{O}}_n$ of Outer space and studying its topology at infinity. This bordification has the structure of a locally finite cell complex on which $\mathrm{Out}(F_n)$ acts with finite stabilizers.

3.1. Cells in the bordification. There are only a finite number of orbit classes of open simplices in $\mathcal{O}_n$, leading one to expect that the quotient should be compact. The reason it is not is that we are leaving out some of the faces of simplices; we go to a

face by collapsing edges in the graph, but we are not allowed to reduce the rank of the graph. One might think of simply adding the missing faces to achieve cocompactness, but this destroys essential features of the action: in particular, the result is not locally finite, and simplex stabilizers are infinite. Bestvina and Feighn found a way around this by keeping track of exactly how subgraphs degenerate as you approach a missing face. Thus there is a cell "at infinity" for each marked metric graph G and sequence of nested subgraphs $G = G_0 \supset G_1 \supset \cdots \supset G_k$. Each subgraph G_i comes with its own metric of volume 1, and G_{i+1} is spanned by the edges of length zero in G_i. The idea is that the sequence consists of subgraphs which are collapsing to zero faster and faster, and the metrics keep track of the direction one is going as one approaches infinity.

3.2. Virtual duality. Bieri and Eckman showed that a group is a virtual duality group if and only if the cohomology of the group with coefficients in its integral group ring vanishes in all but one dimension, where it is free. The cohomology of $\mathrm{Out}(F_n)$ with coefficients in its integral group ring is isomorphic to the cohomology with compact supports of the bordification $\widehat{\mathcal{O}}_n$, and this in turn can be shown to satisfy Bieri and Eckmann's criteria by showing that $\widehat{\mathcal{O}}_n$ is sufficiently connected at infinity. This is what Bestvina and Feighn prove, using Morse theory techniques:

Theorem 3.1 ([2]). *The bordification $\widehat{\mathcal{O}}_n$ of Outer space is $(2n-3)$-connected at infinity.*

Corollary 3.2 ([2]). $\mathrm{Out}(F_n)$ *is a virtual duality group.*

4. The Degree Theorem and rational homology stability

We now turn attention to the group $\mathrm{Aut}(F_n)$. An advantage that $\mathrm{Aut}(F_n)$ has over $\mathrm{Out}(F_n)$ is that it comes equipped with natural inclusions $\mathrm{Aut}(F_n) \to \mathrm{Aut}(F_{n+1})$. The analogous inclusions in the general linear case induce maps $H_k(\mathrm{GL}(n,\mathbb{Z})) \to H_k(\mathrm{GL}(n+1,\mathbb{Z}))$ which were shown by Charney to be isomorphisms for n sufficiently large with respect to k [6]. The fact that the homology of $\mathrm{GL}(n,\mathbb{Z})$ stabilizes in this way serves to considerably simplify the problem of computing the homology. For example, one may determine $H_k(\mathrm{GL}(n,\mathbb{Z}))$ for any large n by performing the computations with relatively small values of n, where the size of the computation is more manageable. A more subtle and more powerful advantage is that one may work instead with the stable groups $\mathrm{GL}_\infty(\mathbb{Z}) = \lim_{n\to\infty} \mathrm{GL}(n,\mathbb{Z})$ which carry additional multiplicative structure and are amenable to homotopy theoretic methods such as the plus construction.

There is a construction completely analogous to the construction of Outer space using basepointed graphs, where the basepoint may be at a vertex or in the interior of an edge. This space $\mathcal{A}_n$ is also contractible [16], has a cocompact spine, and acts as a homogeneous space for $\mathrm{Aut}(F_n)$, which acts with finite stabilizers. (A French

colleague suggested that the space $\mathcal{A}_n$ should be called "Autre espace," but the name "Auter space" seems to have taken hold instead.) An advantage to this space is that the basepoint determines a natural Morse function on a marked metric graph, and we can use parameterized Morse theory methods to study the space. The basepoint also allows us to define a filtration of $\mathcal{A}_n$ by highly connected subspaces which, as we will see, are very useful in homology calculations and in particular for proving homology stability theorems.

4.1. The Degree Theorem. We will filter $\mathcal{A}_n$ by the *degree* of a marked graph, where the degree is defined as the number of vertices away from the basepoint counted with multiplicity (multiplicity is the valence of the vertex minus 2). The degree of a graph with fundamental group F_n is then equal to $2n$ minus the valence of the basepoint. Thus a rose has degree zero, a graph with one trivalent vertex away from the basepoint has degree one, and any graph with basepoint in the interior of an edge has degree $2n-2$. The fact that $\mathrm{Aut}(F_n)$ is generated by Nielsen automorphisms, which can be modeled by a homotopy equivalence which wraps one leaf of a rose around another, implies that the degree 1 subspace of $\mathcal{A}_n$ is connected. An analogous statement is true for higher degrees:

Theorem 4.1 (Degree Theorem, [18]). *The subspace $\mathcal{A}_{n,k}$ of Auter space consisting of marked graphs of degree at most k is $(k-1)$-connected.*

Thus $A_{n,k}$ acts as a kind of k-skeleton for Auter space. The action of $\mathrm{Aut}(F_n)$ on $\mathcal{A}_n$ changes the marking on a graph but not the homeomorphism type, so that it preserves the degree, i.e. restricts to an action on $\mathcal{A}_{n,k}$. Since $\mathcal{A}_{n,k}$ is $(k-1)$-connected and $\mathrm{Aut}(F_n)$ acts with finite stabilizers, the homology of $\mathrm{Aut}(F_n)$ with trivial rational coefficients can be identified with the rational homology of the quotient in dimensions less than k.

Because a degree k graph has only k vertices away from the basepoint (counted with multiplicity), if we ignore loops at the basepoint there are only a finite number of possibilities for such a graph. Thus the map from $\mathcal{A}_{n,k}$ to $\mathcal{A}_{n+1,k}$ given by attaching an extra loop at the basepoint is a homeomorphism for n large. As an immediate consequence, we see that the map $H_{k-1}(\mathrm{Aut}(F_n);\mathbb{Q}) \to H_{k-1}(\mathrm{Aut}(F_{n+1});\mathbb{Q})$ induced by inclusion is an isomorphism on homology n for n large.

For computational purposes, it is obviously advantageous to know exactly how large n has to be, i.e. to have the best possible bound on the stability range. An easy Euler characteristic argument shows that the map from $\mathcal{A}_{n,k}$ to $\mathcal{A}_{n+1,k}$ is a homeomorphism for $n \geq 2k$; for example for any $n \geq 4$, the degree 2 subcomplex of the spine has a contractible quotient consisting of 7 triangles glued together as in Figure 2. As a consequence we can say that $\mathrm{Aut}(F_n)$ satisfies *homology stability with slope* 2. The slope can in fact be improved to $3/2$ fairly easily by showing that the quotients in this range, though not actually homeomorphic, are nevertheless homotopy equivalent [18]; further improvement is possible using some calculations in rank 3. The best known result at this time is the following.

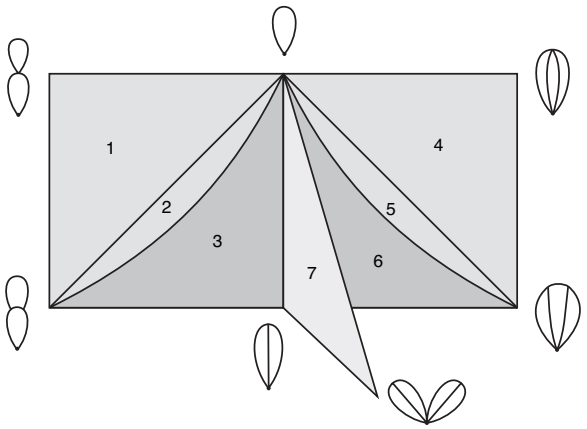

Figure 2. The degree 2 quotient.

Theorem 4.2 ([19]). *The map* $H_{k-1}(\mathrm{Aut}(F_n);\mathbb{Q}) \to H_{k-1}(\mathrm{Aut}(F_{n+1});\mathbb{Q})$ *induced by inclusion is an isomorphism on homology n for* $n \geq 5(k+1)/4$.

Homology stability is a property also shared by surface mapping class [15], with appropriate inclusions. The exact slope, for trivial rational coefficients, is known for both $\mathrm{GL}(n,\mathbb{Z})$ and for mapping class groups of bounded surfaces, but the question remains open for automorphism groups of free groups.

5. Sphere complexes and integral homology stability

5.1. Presentations of $\mathrm{Aut}(F_n)$ and stability for H_1. The first integral homology of $\mathrm{Aut}(F_n)$ is isomorphic to $\mathbb{Z}/2$ for all $n \geq 3$, as can be seen by abelianizing a presentation. There are several different presentations of $\mathrm{Aut}(F_n)$ available, including presentations due to J. Nielsen, B. Neumann, and J. McCool. A new way of obtaining a presentation is supplied by the Degree Theorem, which tells us that the degree 2 subcomplex of Auter space is simply-connected. The method of K. Brown [5] for calculating a presentation from the action of a group on a simply-connected CW-complex can then be used to find a presentation. This was carried out in [1]. The generators, for any $n \geq 4$, are the stabilizers of the seven graphs pictured in Figure 2, with appropriate numbers of loops added at the basepoint. The relations are the relations in these stabilizers, together with relations given by inclusions of edge stabilizers into vertex stabilizers and by inclusions composed with conjugations.

5.2. Quillen's method. More delicate techniques are needed to show that the k-th homology of $\mathrm{Aut}(F_n)$ with trivial integral coefficients stabilizes for n large. The general idea is borrowed from Quillen's work on homology stability for general linear

groups of fields. The simplest possible setup for using this method to prove homology stability for a sequence of groups $\{G_n\}$ is provided by having contractible simplicial complexes X_n and actions of G_n on X_n which are transitive on p-simplices for all p. The stabilizer of a p-simplex should be isomorphic to G_{n-p-1} and the quotient of X_n by the action should be highly connected. Given these conditions, one looks at the equivariant homology spectral sequence for this action, which has

$$E^1_{p,q} = \begin{cases} \bigoplus_{\sigma_p} H_q(\mathrm{stab}(\sigma_p)) & p \geq 0, \\ H_q(G_n) & p = -1, \end{cases}$$

where the direct sum is over all orbits of p-simplices. This spectral sequence converges to 0, and the map $H_k(G_{n-1}) \to H_k(G_n)$ induced by inclusion appears as the map $d^1 \colon E^1_{0,k} \to E^1_{-1,k}$. By induction, we may assume that we understand what happens below the k-th row of the spectral sequence, specifically that the E^2 page vanishes below that row. Since the entire spectral sequence converges to zero, this implies that the d^1 map in question must be onto. Further argument is needed to show that d^1 is injective; this can either be done by increasing the dimension n and applying induction again or by carefully analyzing the next d^1 map, $d^1 \colon E^1_{k,1} \to E^1_{k,0}$ and showing that this is the zero map.

In practice, conditions are usually not quite this nice: the space X_n may not be contractible, the stabilizers may not be precisely G_{n-p-1}, the action may not be transitive on simplices, etc. These difficulties can sometimes be overcome at the cost of introducing further spectral sequence arguments and/or settling for a weaker stability range.

For $G_n = \mathrm{Aut}(F_n)$, homology stability was first proved by Hatcher and Vogtmann in [18] using a complex of free factorizations of the free group F_n. They reproved this theorem in [20] using a different complex, which we describe below. The second paper (together with the erratum [21]) also contains a proof that the map from $\mathrm{Aut}(F_n)$ to $\mathrm{Out}(F_n)$ induces isomorphisms on k-th homology for n large.

The complexes used in [20] involve isotopy classes of 2-spheres embedded in a connected sum of n copies of $S^2 \times S^1$, with a small ball removed. This 3-manifold M_n has fundamental group F_n, and Laudenbach proved that the natural map from the mapping class group of M_n to $\mathrm{Aut}(F_n)$ is surjective, with kernel a 2-torsion subgroup generated by Dehn twists along 2-spheres. This kernel acts trivially on the set of isotopy classes of 2-spheres in M_n, so we obtain an action of $\mathrm{Aut}(F_n)$ on the complex formed by taking a k-simplex for every set of $k+1$ isotopy classes which can be represented by disjoint spheres. The idea of using the complex of isotopy classes of 2-spheres in M_n originated in [16], where Hatcher established many of the basic tools needed for working with such complexes.

A vertex in the complex used in [20] is a non-separating sphere together with an extra, "enveloping" sphere which cuts the sphere and the boundary of M_n off from the rest of the manifold. An alternate description of such a vertex is obtained by using embedded arcs to *tether* each side of the sphere to the boundary of M_n. A set of

$k+1$ isotopy classes of tethered 2-spheres forms a k-simplex if representatives can be found so that all spheres and tethers are disjoint. The stabilizer of a vertex is then isomorphic to $\mathrm{Aut}(F_{n-1})$, and the following theorem allows us to apply Quillen's method:

Theorem 5.1 ([20]). *The complex of isotopy classes of tethered 2-spheres in M_n is $(n-3)/2$-connected.*

As a result, we obtain the following homology stability theorem:

Theorem 5.2 ([20]). *The map $i_*\colon H_k(\mathrm{Aut}(F_n)) \to H_k(\mathrm{Aut}(F_{n+1}))$ induced by the natural inclusion is an isomorphism for $n \geq 2k+2$.*

We are also interested in showing that the map $p_*\colon H_k(\mathrm{Aut}(F_n)) \to H_k(\mathrm{Out}(F_n))$ induced by the natural projection is an isomorphism for n large. In the course of proving this, we are forced to consider the mapping class group of a connected sum of n copies of $S^1 \times S^2$ with $s \geq 0$ balls removed, modulo Dehn twists on 2-spheres. For $s = 0$ this is $\mathrm{Out}(F_n)$. We prove the homology in dimension k is independent of n and s for n and s sufficiently large. In particular, we obtain

Theorem 5.3 ([20], [21]). *The map $p_*\colon H_k(\mathrm{Aut}(F_n)) \to H_k(\mathrm{Out}(F_n))$ is an isomorphism for $n \geq 2k+4$.*

The idea of using "tethers" to tie geometric objects to a basepoint turns out to be useful in other contexts. The extra structure obtained from the tethers has the effect that the conditions for applying Quillen's method are close to ideal, so that the spectral sequence arguments needed to prove homology stability are relatively simple. In particular, tethers have led to simplified proofs of homology stability for mapping class groups of surfaces and braid groups, as well as to new proofs that several related series of groups have homology stability [17].

5.3. Galatius' theorem. Since we know that the homology of $\mathrm{Aut}(F_n)$ stabilizes, the next problem is then to compute the stable homology. Computations in dimensions less than 7 were done in [19], and produced no stable rational homology classes. Igusa showed that the map from the stable rational homology of $\mathrm{Aut}(F_n)$ to that of $\mathrm{GL}(n,\mathbb{Z})$ is the zero map [22]. This evidence led to the conjecture that the stable rational homology is trivial. On the other hand, Hatcher showed that the stable homology contains the stable homology of the symmetric group Σ_n as a direct factor, so there are lots of torsion classes [16]. The entire situation has recently been resolved by S. Galatius [13] using methods adapted from Madsen and Weiss' work on the stable homology of mapping class groups.

The commutator subgroup of $\mathrm{Aut}(F_\infty)$ is a perfect normal subgroup, so that Quillen's plus construction can be applied to the classifying space $B\,\mathrm{Aut}(F_\infty)$. The resulting space $B\,\mathrm{Aut}(F_\infty)^+$ is an infinite loop space whose homology is equal to the stable homology of $\mathrm{Aut}(F_n)$. The natural inclusions of the symmetric groups Σ_n

into $\mathrm{Aut}(F_n)$ induce an infinite loop space map $B\Sigma_\infty^+ \to B\,\mathrm{Aut}_\infty^+$, and a theorem of Barratt–Priddy and Quillen says that $B\Sigma_\infty^+$ is homotopy equivalent to $\Omega^\infty S^\infty$. The space $\Omega^\infty S^\infty$ is the most fundamental example of an infinite loop space; its homotopy groups are the stable homotopy groups of spheres. In [13] Galatius proves that $B\,\mathrm{Aut}(F_\infty)^+$ is also homotopy equivalent to $\Omega^\infty S^\infty$, showing in particular that the symmetric group and the automorphism group of a free group have the same stable homology. The proof relies on the contractibility of Outer space and the homology stability results of [20] and [21]. Galatius proceeds by defining maps of $B\,\mathrm{Out}(F_n)$ to a certain "graph spectrum" E, whose n-th space is the space of all graphs in $\mathbb{R}^n$. He proves that after passing to infinite loop spaces this map becomes a homotopy equivalence, and then that $\Omega^\infty E$ is in fact homotopy equivalent to $\Omega^\infty S^\infty$. The homology of $\Omega^\infty S^\infty$ is torsion, so that the stable rational homology of $\mathrm{Aut}(F_n)$ is trivial as conjectured.

6. Graph complexes and unstable homology

Though the stable homology of $\mathrm{Aut}(F_n)$ and $\mathrm{Out}(F_n)$ has been completely determined, at this writing the unstable homology is still largely mysterious. In this section we consider the unstable *rational* homology.

6.1. Low-dimensional calculations. The simplices in the spines of Outer space and Auter space naturally group themselves into cubes, giving these spines the structure of cube complexes. Specifically, an m-dimensional cube corresponds to a marked graph (g, G) together with a subforest Φ of G with m edges, since the set of simplices which can be obtained by collapsing the edges in the subforest in any one of the 2^{m-1} possible orders fit together to form a cube.

The quotient of a cube by a linear map is a rational homology cell, so that the cube complex structure on the spine descends to a "cell structure" on the quotient, which can be used to compute the rational homology of $\mathrm{Out}(F_n)$ and $\mathrm{Aut}(F_n)$. For $\mathrm{Aut}(F_n)$, the Degree Theorem can be used to reduce the number of cubes one must consider when computing the kth homology, and further reductions are possible by examining the structure of the quotient. In the end it is possible for $k = 2, 3$ and even 4 to do the computations by hand. For $k > 4$, however, the aid of a computer becomes essential. Computations for both $\mathrm{Aut}(F_n)$ and $\mathrm{Out}(F_n)$ for $k \leq 7$ were carried out by Hatcher and Vogtmann, Jensen and Gerlits. They showed that that $H_k(\mathrm{Aut}(F_n); \mathbb{Q}) = H_k(\mathrm{Out}(F_n); \mathbb{Q}) = 0$ for $k \leq 7$ except that $H_4(\mathrm{Aut}(F_4); \mathbb{Q}) = H_4(\mathrm{Out}(F_4); \mathbb{Q}) \cong \mathbb{Q}$ [19]. This agrees with Galatius' theorem in the stable range, and gives a tantalizing glimpse into the unstable homology. We now understand this very interesting non-trivial unstable homology class in a much more general context, as we will see below.

6.2. Graph homology of a cyclic operad. In [23], [24] Kontsevich found a remarkable correspondence between the cohomology of certain infinite-dimensional

symplectic Lie algebras and the homology of outer automorphism groups of free groups. This Lie algebra cohomology can be computed using the subcomplex of the Chevalley–Eilenberg complex spanned by symplectic invariants. The connection with $\mathrm{Out}(F_n)$ is made via Weyl's invariant theory, which allows one to interpret the complex of symplectic invariants as a chain complex indexed by finite graphs, where the vertices of these graphs are decorated by elements of the Lie operad. The homology of this graph complex can then be interpreted in terms of Outer space; this is carried out explicitly in [8].

The same formalism using the associative operad in place of the Lie operad gives a chain complex of "ribbon graphs", which computes the homology of surface mapping class groups. The commutative operad gives rise to a type of graph homology which includes information about diffeomorphism groups of odd-dimensional homology spheres. Kontsevich's construction in fact makes sense using any cyclic operad to decorate the vertices of graphs (see [8]), and it would be interesting to study the functorial properties of the resulting homology theories.

The connection with Lie algebra homology reveals new structure on the level of chain complexes. Specifically, the graph homology chain complex for any cyclic operad supports a Lie bracket and cobracket, which were studied in [10]; the Lie bracket can be shown to correspond to the classical Schouten bracket on the Lie algebra. The bracket and cobracket do not in general form a compatible Lie bialgebra structure, but do on the subcomplex spanned by connected graphs with no separating edges. For the associative and Lie operads, this subcomplex is quasi-isomorphic to the whole complex, so in particular has the same homology. For the commutative operad, this is not true, but the Lie bracket and cobracket do induce a bracket and cobracket on an appropriate quotient complex which is quasi-isomorphic to the whole complex [8]. These brackets come from a second boundary operator on the graph complex, and measure the deviation of this boundary operator from being a derivation (resp. coderivation). This second boundary operator anti-commutes with the standard boundary operator, so induces a map on graph homology. The Lie bracket and cobracket vanish on the level of homology, making graph homology together with this induced map into a differential graded algebra.

6.3. Morita cycles. Kontsevich's work also led to new discoveries by S. Morita, who had been studying some of the same Lie algebras in his work on surface mapping class groups. In particular, Morita found an infinite sequence of cocycles for these Lie algebras based on his "trace" map and showed that the first of these cocycles is non-trivial on cohomology [28]. Via Kontsevich's theorem, this cocycle produces a nontrivial homology class in $H_4(\mathrm{Out}(F_4); \mathbb{Q})$. Since we know the rational homology $H_4(\mathrm{Out}(F_4); \mathbb{Q})$ is one-dimensional, this class in fact completely computes the homology in this dimension.

Conant and Vogtmann translated Morita's cocycles into cocycles on the complex of Lie graphs. They then showed that the combinatorial information contained in an oriented graph with vertices decorated by basic elements of the Lie operad is captured

more simply by a trivalent graph together with a subforest whose edges are ordered. This allows one to reinterpret the Morita cocycles directly in terms of such forested graphs, and to give a quick proof that the first of Morita's cocycles is non-trivial. With a little more work it can be used to show that second one is also non-trivial, giving a rational homology class in $H_8(\mathrm{Out}(F_6);\mathbb{Q})$ [9]. Morita reports that R. Ohashi has recently shown that in fact $H_8(\mathrm{Out}(F_6);\mathbb{Q}) \cong \mathbb{Q}$, so that this class gives all of the homology [27].

There is a Morita cocycle corresponding to every graph consisting of two vertices joined by an odd number of edges. Both Morita and Conant-Vogtmann found generalizations which give a class in $H_{2k+r-2}(\mathrm{Out}(F_{k+r}))$ for every odd-valent graph of rank r with k vertices. One expects that all of these should be non-trivial classes, and it is possible that they determine all of the unstable rational homology of $\mathrm{Out}(F_n)$. We would therefore like to understand these cocycles as well as possible. Since they determine rational homology classes in the homology of $\mathrm{Out}(F_n)$, we should be able to find representatives in the quotient of the spine of Outer space and in the quotient of the bordification of Outer space, both of which are rationally acyclic spaces for $\mathrm{Out}(F_n)$. This is indeed possible, as is shown in [7]. In the case of the bordification, the cycles are found "at infinity." Recall that a cell at infinity is given by a marked filtered graph (see section 3). The action of $\mathrm{Out}(F_n)$ is transitive on markings, so that they disappear in the quotient. The first Morita cycle is the quotient of the single cell shown in Figure 3.

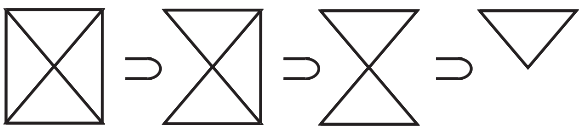

Figure 3. Generator of $H_4(\mathrm{Out}(F_4);\mathbb{Q})$ in the bordification.

For the description of this class in terms of the spine, recall that the spine of Outer space has the structure of a cube complex, where a cube is given by a marked graph together with a subforest. Again, the action of $\mathrm{Out}(F_n)$ is transitive on the markings, and the first Morita cycle is the union of the quotient of the three cubes shown in Figure 4.

Conant and Vogtmann use these descriptions in [7] to show that all of the Morita classes are unstable in the strongest possible sense: they vanish when the rank of the free group increases by one.

6.4. Rational Euler characteristic. A homological invariant of infinite groups G which is often easier to compute than the complete cohomology is the rational Euler characteristic $\chi(G)$. This is defined as the usual alternating sum of the Betti numbers for any torsion-free subgroup of finite index, divided by the index of the subgroup, and was shown by Serre to be independent of the choice of the subgroup.

Figure 4. Generator of $H_4(\mathrm{Out}(F_4);\mathbb{Q})$ in the spine.

For $\mathrm{GL}(n,\mathbb{Z})$ Harder showed that the rational Euler characteristic vanishes for all $n \geq 3$, and in general the rational Euler characteristics of arithmetic groups are closely related to values of zeta functions. For mapping class groups of closed surfaces the rational Euler characteristic vanishes for surfaces of odd genus, but for even genus it alternates in sign and is basically given by the classical Bernoulli numbers, as was shown by Harer and Zagier in [14].

The rational Euler characteristic of a group can be computed by finding a contractible complex on which the group acts cocompactly with finite stabilizers, and calculating the alternating sum, over all orbits of cells σ, of the terms

$$\frac{(-1)^{\dim(\sigma)}}{|\,\mathrm{stab}(\sigma)|}.$$

This was done for $\mathrm{Out}(F_n)$ in [29] using the spine of outer space. The result was a generating function for $\chi(\mathrm{Out}(F_n))$ built from standard generating functions for counting graphs and forests in graphs. Using this generating function, $\chi(\mathrm{Out}(F_n))$ was computed explicitly for values of n up to 100. It is strictly negative in all cases computed and seems to grow in absolute value faster than exponentially. Smillie and Vogtmann proved that $\chi(\mathrm{Out}(F_n))$ is non-zero for all even n, and computed the p-power of the denominator for many primes p.

A different approach to the problem of counting graphs and forests was given by Kontsevich, who produced an integral formula for the rational Euler characteristic of $\mathrm{Out}(F_n)$ using techniques of perturbative series and Feynman diagrams. He also produced integral formulas for the rational Euler characteristic of mapping class groups which recapture the relation with Bernoulli numbers found by Harer and Zagier. In the case of $\mathrm{Out}(F_n)$, neither the generating function nor the integral formula make it clear what the asymptotic growth rate of $\chi(\mathrm{Out}(F_n))$ might be, or even whether it is non-zero for all n. A non-zero, quickly growing Euler characteristic would indicate the presence of a large amount of unstable homology.

7. IA automorphisms and the IA quotient of Outer space

At the beginning of this article we noted the existence of a natural map from $\mathrm{Out}(F_n)$ onto $\mathrm{GL}(n,\mathbb{Z})$. The kernel of this map is called the subgroup of *IA automorphisms*

because it consists of automorphisms which induce the *identity* on the *abelianization* of F_n. It is clearly a natural object to study if one is trying to understand the relation between $\mathrm{Out}(F_n)$ and $\mathrm{GL}(n,\mathbb{Z})$. Magnus found a finite generating set for IA_n in 1934, and asked at the same time whether IA_n was finitely presentable [26].

There is an interesting application of the non-vanishing of the rational Euler characteristic of $\mathrm{Out}(F_n)$ to the study of IA_n. If the homology of IA_n were finitely generated then the rational Euler characteristic of IA_n would be defined, and the short exact sequence

$$1 \to IA_n \to \mathrm{Out}(F_n) \to \mathrm{GL}(n,\mathbb{Z}) \to 1$$

would result in the equation $\chi(IA_n)\chi(\mathrm{Out}(F_n)) = \chi(\mathrm{GL}(n,\mathbb{Z}))$. However, we know that $\chi(\mathrm{GL}(n,\mathbb{Z})) = 0$ for $n \geq 3$, while $\chi(\mathrm{Out}(F_n))$ is non-zero, at least for n even. Thus we can conclude that the homology of IA_n is not finitely generated in some dimension.

If IA_n was finitely presentable, that would imply that the second homology is finitely generated. The argument in the previous paragraph shows that the homology is not finitely generated in *some* dimension, but gives no definite conclusion about dimension 2. McCool and Krstic finally answered Magnus' question for $n = 3$ in 1997, by showing that IA_3 is *not* finitely presentable [25]. Recently Bestvina, Bux and Margalit have shown that the top-dimensional homology of IA_n vanishes, while the codimension one homology is infinitely generated. They prove this by using Morse theory to study the topology of the quotient of Outer space by IA_n, which is an aspherical space with fundamental group IA_n. This work implies the McCool–Krstic result, since it says that $H_3(IA_3) = 0$ and $H_2(IA_3)$ is infinitely generated, but still leaves open the question of finite presentability for $n \geq 4$.

8. Further reading

In this article I have focused on cohomological properties of automorphism groups of free groups, but there are many other areas in which our knowledge of these groups is rapidly expanding. These include, for example, the subgroup structure, metric theory and rigidity properties. I wrote two other survey articles which address some of these advances. The first paper [30] gives a more detailed introduction to Outer space and related spaces and mentions other powerful techniques such as Bestvina–Handel's train tracks, as well as many applications to the study of $\mathrm{Out}(F_n)$ and $\mathrm{Aut}(F_n)$. It also contains a fairly extensive bibliography and more thorough references for work on automorphisms of free groups. The focus of the more recent paper [4], which is joint with Martin Bridson, is a discussion of open problems in the field.

Noncommutative counterparts of the Springer resolution

Roman Bezrukavnikov*

Abstract. Springer resolution of the set of nilpotent elements in a semisimple Lie algebra plays a central role in geometric representation theory. A new structure on this variety has arisen in several representation theoretic constructions, such as the (local) geometric Langlands duality and modular representation theory. It is also related to some algebro-geometric problems, such as the derived equivalence conjecture and description of T. Bridgeland's space of stability conditions. The structure can be described as a noncommutative counterpart of the resolution, or as a t-structure on the derived category of the resolution. The intriguing fact that the same t-structure appears in these seemingly disparate subjects has strong technical consequences for modular representation theory.

Mathematics Subject Classification (2000). Primary 17B50, 18F99, 20G05; Secondary 20G42, 22E67.

Keywords. Derived categories of sheaves and modules, modular Lie algebras, local geometric Langlands duality.

1. Introduction

Springer resolution of the variety of nilpotent elements in a semi-simple Lie algebra is ubiquitous in geometric representation theory. In this article we show that, besides this well-known resolution of singularities, the variety of nilpotents, as well as some other closely related varieties, admits a particular *noncommutative resolution of singularities*, which arises in different representation theoretic and algebro-geometric constructions. Here by a noncommutative resolution of a singular variety Y we mean, following, e.g., [11], a coherent sheaf of associative $\mathcal{O}_Y$ algebras satisfying certain natural conditions, and defined up to a Morita equivalence.

The constructions are related to such subjects as: the (local) geometric Langlands duality program and categorification of representation theory of affine Hecke algebras, representation theory of modular Lie algebras and quantum enveloping algebras at roots of unity, Bridgeland's theory of stability conditions on triangulated categories, and categorical McKay correspondence and generalizations.

Let G be a semi-simple adjoint algebraic group, $\mathfrak{g}$ be its Lie algebra and $\mathcal{N} \subset \mathfrak{g}$ be the variety of nilpotent elements. Let $\mathcal{B}$ be the variety of Borel subalgebras in $\mathfrak{g}$, also known as the flag variety of G, and $\widetilde{\mathcal{N}} = T^*(\mathcal{B})$ be the cotangent bundle to $\mathcal{B}$. The Springer resolution is the moment map $\pi : \widetilde{\mathcal{N}} \to \mathcal{N}$.

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

Our noncommutative resolution A of $\mathcal{N}$ comes with an equivalence between the derived category $D(A)$ of modules over A and the derived category $D(\widetilde{\mathcal{N}})$ of coherent sheaves on $\widetilde{\mathcal{N}}$. Thus A is determined uniquely up to Morita equivalence by the t-structure on $D(\widetilde{\mathcal{N}})$ induced by the equivalence, i.e., by the image of the subcategory of A modules in $D(A)$ under the equivalence. We will call this t-structure the *exotic t-structure* and objects of its heart *exotic sheaves*. Thus an exotic sheaf is a complex of coherent sheaves on $\widetilde{\mathcal{N}}$ which corresponds to an A-module under the equivalence $D(A) \cong D(\widetilde{\mathcal{N}})$.

Closely related data first appeared in [2], which can be considered as a contribution to a local version of the geometric Langlands duality program [8], [37], [34]. A typical result of geometric Langlands duality is an equivalence between some derived category of constructible sheaves on a variety related to ${}^LG$ bundles on a curve C and derived category of coherent sheaves on a variety related to G local systems on C; here G and ${}^LG$ are reductive groups, which are dual in the sense of Langlands. In the local version of the theory the curve C is a punctured formal disc $\mathbb{D}$. The role of the moduli stack of ${}^LG$ bundles is played by a homogeneous space for the group ${}^LG$, where ${}^LG((t))$ stands for the group of maps from $\mathbb{D}$ to ${}^LG$ (also known as the formal loop group). An example of such a homogeneous space is the *affine flag variety* $\mathcal{F}\ell$ of ${}^LG$. For an appropriate choice of the category of constructible sheaves, the variety related to G local systems turns out to be $\widetilde{\mathcal{N}}$, or rather the quotient stack $\widetilde{\mathcal{N}}/G$ of $\widetilde{\mathcal{N}}$ by the natural action of G. An equivalence between the derived category of G-equivariant coherent sheaves on $\widetilde{\mathcal{N}}$ and a certain triangulated category of constructible sheaves on $\mathcal{F}\ell$ is proved in [2]. The image of the subcategory of perverse sheaves on $\mathcal{F}\ell$ under this equivalence turns out to consist of *equivariant exotic sheaves*, which are closely related to exotic sheaves (see Section 2.2 below).

Another construction leading to exotic sheaves is related to modular representation theory.

In the second half of the 20th century various geometric methods for representation theory of semi-simple Lie algebras over characteristic zero fields have been developed. One of the culminating points is the Localization Theorem [5], [30], motivated by a conjecture by Kazhdan and Lusztig, which provides an equivalence between the category of modules over a semi-simple Lie algebra $\mathfrak{g}$ with a fixed (integral regular) central character and the category of D-modules on the flag variety $\mathcal{B}$. In the paper [19], motivated by Lusztig's extension [45] of Kazhdan–Lusztig conjectures to the modular setting, we provide a similar result for semi-simple Lie algebras over algebraically closed fields of positive characteristic. More precisely, we establish a derived localization theorem, which is an equivalence between the derived category of appropriately defined D-modules (called crystalline, or PD D-modules) on a flag variety and the derived category of Lie algebra modules, where a part of the center, the so-called Harish-Chandra center, acts by a fixed character.

Furthermore, in the case of positive characteristic there is a close relationship between crystalline D-modules on a smooth variety X and coherent sheaves on the cotangent space T^*X [19], [48]. The algebra of crystalline differential operators has a

huge center provided by invariant polynomials of the p-curvature of a D-module. This allows one to view the differential operators as a sheaf of algebras on the cotangent bundle. This algebra turns out to be an Azumaya algebra. In the case of the flag variety this Azumaya algebra splits on the formal neighborhood of each Springer fiber. Thus the derived localization theorem yields a full embedding from the category of finite dimensional $\mathfrak{g}$-modules with a fixed (integral regular) action of the Harish-Chandra center into the derived category of coherent sheaves on $\widetilde{\mathcal{N}}$. It turns out that the image of this embedding consists precisely of exotic sheaves with proper support. A similar relation is expected between exotic sheaves over a field of characteristic zero and representations of the quantum Kac–De Concini enveloping algebra at a root of unity [32], and also with some class of $\widehat{{}^L\mathfrak{g}}$ modules at the critical level (cf. [4] and [35] respectively); here $\widehat{{}^L\mathfrak{g}}$ stands for the affine Kac-Moody algebra corresponding to the Langlands dual algebra ${}^L\mathfrak{g}$.

Thus exotic sheaves are related, on the one hand, to perverse sheaves on the affine flag variety for the dual group, and on the other hand, to modular Lie algebra representations. Comparison of these two connections allows one to apply the known deep results about weights of Frobenius acting on Ext's between irreducible perverse sheaves to numerical questions about modular representations, thereby providing a strategy for a proof of Lusztig's conjectures from [45]. The conjectures relate the classes of irreducible $\mathfrak{g}$-modules to elements of the *canonical basis* in the Borel–Moore homology of a Springer fiber; thus our work provides a categorification of the canonical bases in (co)homology of Springer fibers. See also Remark 2.21 for an application to representations of quantum groups.

I also would like to point out some parallels between exotic sheaves and objects arising in the work of algebraic geometers studying derived categories of coherent sheaves on algebraic varieties. Exotic sheaves can be described in terms of a certain action of the affine braid group B_{aff} of ${}^LG$ on $D(\widetilde{\mathcal{N}})$. This description can be reformulated in terms of a map from the set of alcoves (connected components of the complement to affine coroot hyperplanes in the dual space to the Cartan algebra of $\mathfrak{g}$ over $\mathbb{R}$) to the set of t-structures on $D(\widetilde{\mathcal{N}})$. Similar data have been used by Bridgeland in [25]–[27] to construct a component in the space of stability conditions [24], on the derived categories of coherent sheaves on certain varieties. See also Examples 2.8, 2.9 below.

The appearance of the affine braid group, which can be interpreted as the fundamental group of the set of regular semisimple conjugacy classes in the dual group ${}^LG(\mathbb{C})$, suggests a possibility that the structures described above admit a natural interpretation via homological mirror duality, which would identify our derived category of coherent sheaves with a certain Fukaya type category, where the action of the affine braid group arises from monodromy of some family over the space of regular semisimple conjugacy classes in ${}^LG(\mathbb{C})$.

Another connection to algebraic geometry is provided by [17] and [41]. As has been noted above, the derived localization theorem can be interpreted as a construction of a noncommutative resolution of the nilpotent cone $\mathcal{N}$ using crystalline differential

operators in positive characteristic. It turns out that for more general resolutions of singularities, which carry an algebraic symplectic form, a non-commutative resolution can be constructed by a similar procedure. The construction involves quantizing the algebraic symplectic variety in characteristic p, and relating modules over the quantization to coherent sheaves. It has been carried out in [17] for crepant resolutions of quotients V/Γ, where V is a vector space equipped with a symplectic form, and Γ is a finite subgroup in $\mathrm{Sp}(V)$; this yields a particular case of the so-called *categorical McKay correspondence*. The particular case when Γ is the symmetric group on n letters acting on $V = (\mathbb{A}^2)^n$ is related to representations of the rational Cherednik algebra [16]. In Kaledin's work [41] the construction is generalized to more general symplectic resolutions of singularities.

In the remainder of the text we explain some of these contexts (in the order which is roughly inverse to the above) in some detail.

This text is a mixture of an exposition of published results and announcement of yet unpublished ones; statements for which no reference is provided, and which are not well-known, are to appear in a future publication.

Notations and conventions. Throughout the text we work over an algebraically closed field $\boldsymbol{k}$; when a semi-simple group G is involved, we assume that the characteristic of $\boldsymbol{k}$ is zero or exceeds the Coxeter number of G.

For an algebraic variety X we let $\mathcal{O}_X$ denote the structure sheaf, and $D(X) = D^b(\mathrm{Coh}_X)$ be the bounded derived category of coherent sheaves on X. Given an action of an algebraic group H on X we write $\mathrm{Coh}^H(X)$ for the category of H-equivariant coherent sheaves; given a coherent sheaf of associative $\mathcal{O}_X$ algebras we let $\mathrm{Coh}(X, \mathcal{A})$ be the category of sheaves of coherent $\mathcal{A}$ modules; if $\mathcal{A}$ is H-equivariant for an algebraic group H acting on X, we let $\mathrm{Coh}^H(X, \mathcal{A})$ be the category of H-equivariant sheaves of coherent $\mathcal{A}$-modules. We write $D(X)$, $D^H(X)$, $D(\mathcal{A})$, $D^H(\mathcal{A})$ for the bounded derived category of $\mathrm{Coh}(X)$, $\mathrm{Coh}^H(X)$, $\mathrm{Coh}(X, \mathcal{A})$, $\mathrm{Coh}^H(X, \mathcal{A})$ respectively, and $K(X)$, $K^H(X)$, $K(\mathcal{A})$, $K^H(\mathcal{A})$ for the corresponding Grothendieck groups. In particular, there notations apply for an algebra A finite over the center of finite type.

The functors of pull-back, push-forward etc. between categories of sheaves are understood to be the derived functors.

Acknowledgements. I thank my coauthors S. Arkhipov, V. Ginzburg, D. Kaledin, I. Mirković, V. Ostrik and D. Rumynin for their contribution to the joint results, without which they would have never been accomplished. The project described here was conceived during IAS Special Year in Representation Theory (98/99) led by G. Lusztig. Most of the results have been obtained by unraveling the formulas in Lusztig's papers, thus they owe their existence to him. I have learned Lusztig's results and many other things from M. Finkelberg. I have also benefitted a lot from ideas of I. Mirković and his generosity in sharing them. Conversation with many people were very helpful, the incomplete list includes A. Beilinson, V. Drinfeld, D. Gaitsgory, V. Ginzburg, V. Ostrik. I am very grateful to all these people. Finally, I thank

M. Finkelberg, J. Humphreys, D. Kazhdan and I. Mirković for reading a preliminary version of this text and making helpful comments and suggestions.

2. Noncommutative resolutions and braid group actions

2.1. Braid group actions and noncommutative Springer resolution. Though the motivation for the study of our main object comes from applications to representation theory, we first describe it in the language of algebraic geometry. We briefly recall some ideas from [22], [23], [11].

Let Z be a singular algebraic variety. We refer, e.g., to [11] for the notion of a *crepant* resolution; it is easy to see that resolutions $\pi, \widetilde{\pi}$ described above are crepant.

By a *noncommutative resolution* [11][1] one means a coherent torsion free sheaf A of associative $\mathcal{O}_Z$ algebras, which is generically a sheaf of matrix algebras and has finite homological dimension. There exists also a notion of a noncommutative crepant resolution, see [11]. It has been conjectured in *loc. cit.* that any two crepant resolutions, commutative or not, are derived equivalent, in particular, for any crepant resolution $X \to Z$ and any noncommutative resolution A of Y we have an equivalence $D(X) \cong D(A)$.

2.1.1. The set-up. The notations G, $\mathfrak{g}$, $\mathcal{B}$, $\pi\colon \widetilde{\mathcal{N}} \to \mathcal{N}$ have been defined in the Introduction. Recall that $\widetilde{\mathcal{N}} = T^*(\mathcal{B})$ parametrizes pairs $(\mathfrak{b}, x)$, where $\mathfrak{b} \in \mathcal{B}$ is a Borel subalgebra, and x is the element in the nilpotent radical of $\mathfrak{b}$. The Springer map $\pi\colon \widetilde{\mathcal{N}} \to \mathcal{N}$ is given by $\pi\colon (\mathfrak{b}, x) \mapsto x$. It is embedded in the *Grothendieck simultaneous resolution* $\widetilde{\pi}\colon \widetilde{\mathfrak{g}} \to \mathfrak{g}$, where $\widetilde{\mathfrak{g}}$ is the variety of pairs $(\mathfrak{b}, x)$, $\mathfrak{b} \in \mathcal{B}$, $x \in \mathfrak{b}$, and $\widetilde{\pi}\colon (\mathfrak{b}, x) \mapsto x$. The variety $\widetilde{\mathfrak{g}}$ is smooth, and the map $\widetilde{\pi}$ is proper and generically finite of degree $|W|$, where W is the Weyl group. It factors as the composition of a resolution of singularities $\widetilde{\pi}'\colon \widetilde{\mathfrak{g}} \to \mathfrak{g} \times_{\mathfrak{h}/W} \mathfrak{h}$ and the finite projection $\mathfrak{g} \times_{\mathfrak{h}/W} \mathfrak{h} \to \mathfrak{g}$; here $\mathfrak{h}$ is the Cartan algebra of $\mathfrak{g}$. Let $\mathfrak{g}^{\mathrm{reg}} \subset \mathfrak{g}$ denote the subspace of regular (not necessarily semi-simple) elements, and $\widetilde{\mathfrak{g}}^{\mathrm{reg}}$ be the preimage of $\mathfrak{g}^{\mathrm{reg}}$ in $\widetilde{\mathfrak{g}}$; then $\widetilde{\pi}'$ induces an isomorphism $\widetilde{\mathfrak{g}}^{\mathrm{reg}} \cong \mathfrak{g}^{\mathrm{reg}} \times_{\mathfrak{h}/W} \mathfrak{h}$.

Much of the representation theory of G or $\mathfrak{g}$ is in one way or another related to the geometry of these spaces and maps.

2.1.2. Affine braid group action. For a characterization of our noncommutative resolution we need to introduce some more notation.

Let Λ be the root lattice of G. For $\lambda \in \Lambda$ we will write $\mathcal{O}(\lambda)$ for the corresponding G-equivariant line bundle on $\mathcal{B}$, and we set $\mathcal{F}(\lambda) = \mathcal{F} \otimes_{\mathcal{O}_{\mathcal{B}}} \mathcal{O}(\lambda)$ if $\mathcal{F} \in D(X)$ for some X mapping to $\mathcal{B}$.

Let W be the Weyl group, and set $W_{\mathrm{aff}} = W \ltimes \Lambda$. Then W, W_{aff} are Coxeter groups. Notice that W_{aff} is the affine Weyl group of the *Langlands dual* group ${}^L G$.

[1] The definition in *loc. cit.* is wider, we use a version convenient for our exposition.

It was mentioned above that $\widetilde{\mathfrak{g}}^{\mathrm{reg}} \cong \mathfrak{g} \times_{\mathfrak{h}/W} \mathfrak{h}$; thus W acts on this space via its action on the second factor. The formulas $\Lambda \ni \lambda\colon \mathcal{F} \mapsto \mathcal{F}(\lambda)$, $W \ni w\colon \mathcal{F} \mapsto w^*(\mathcal{F})$ are easily shown to define an action[2] of W_{aff} on the category of coherent sheaves on $\widetilde{\mathfrak{g}}^{\mathrm{reg}}$.

The characterization of our "noncommutative Springer resolution" relies on the possibility to extend this action to a weaker structure on the whole of $\widetilde{\mathfrak{g}}$. To describe this weaker structure recall that to each Coxeter group one can associate an Artin braid group; let B_{aff} denote the group corresponding to W_{aff}. It admits a topological interpretation, as the fundamental group of the space of regular semi-simple conjugacy classes in the universal cover of the dual group ${}^LG(\mathbb{C})$. For $w \in W_{\mathrm{aff}}$ consider the minimal decomposition of w as a product of simple reflection, and take the product of corresponding generators of B_{aff}. This product is well known to be independent of the choice of the decomposition of w, thus we get a map $W_{\mathrm{aff}} \to B_{\mathrm{aff}}$ which is a one-sided inverse to the canonical surjection $B_{\mathrm{aff}} \to W_{\mathrm{aff}}$. We denote this map by $w \mapsto \widetilde{w}$. The map is not a homomorphism, however, we have $\widetilde{uv} = \widetilde{u} \cdot \widetilde{v}$ for any $u, v \in W_{\mathrm{aff}}$ such that $\ell(uv) = \ell(u) + \ell(v)$, where $\ell(w)$ denotes the length of the minimal decomposition of w. Let $B_{\mathrm{aff}}^+ \subset B_{\mathrm{aff}}$ be the sub-monoid generated by $\widetilde{w}$, $w \in W_{\mathrm{aff}}$.

For a simple reflection $s_\alpha \in W$ let $\boldsymbol{S}_\alpha \subset \widetilde{\mathfrak{g}}^2$ be the closure of the graph of s_α acting on $\widetilde{\mathfrak{g}}^{\mathrm{reg}}$. We let S_α denote the intersection of $\boldsymbol{S}_\alpha$ with $\widetilde{\mathcal{N}}^2$. Let $\mathbf{pr}_i^\alpha\colon \boldsymbol{S} \to \widetilde{\mathfrak{g}}$, $\mathrm{pr}_i^\alpha\colon S \to \widetilde{\mathcal{N}}$, where $i = 1, 2$, be the projections.

Let $\Lambda^+ \subset \Lambda$ be the set of dominant weights in Λ.

For a scheme Y over $\mathfrak{g}$ we set $\widetilde{Y} = \widetilde{\mathcal{N}} \times_{\mathfrak{g}} Y$, $\widetilde{\boldsymbol{Y}} = \widetilde{\mathfrak{g}} \times_{\mathfrak{g}} Y$.

Theorem 2.1. (a) *There exists an* (*obviously unique*) *action of* B'_{aff} *on* $D(\widetilde{\mathfrak{g}})$, $D(\widetilde{\mathcal{N}})$ *such that for* $\lambda \in \Lambda^+ \subset \Lambda \subset W'_{\mathrm{aff}}$ *we have* $\tilde{\lambda}\colon \mathcal{F} \mapsto \mathcal{F}(\lambda)$ *and for a simple reflection* $s_\alpha \in W$ *we have* $\tilde{s}_\alpha\colon \mathcal{F} \mapsto (\mathbf{pr}_1^\alpha)^*(\mathbf{pr}_2^\alpha)_*\mathcal{F}$ (*respectively,* $\tilde{s}_\alpha\colon \mathcal{F} \mapsto (\mathrm{pr}_1^\alpha)^*(\mathrm{pr}_2^\alpha)_*\mathcal{F}$).

(b) *This action induces an action on* $D(\widetilde{\boldsymbol{Y}})$, $D(\widetilde{Y})$ *for any scheme* Y *over* $\mathfrak{g}$ *such that* $\mathrm{Tor}_i^{\mathcal{O}_{\mathfrak{g}}}(\mathcal{O}_{\widetilde{\mathfrak{g}}}, \mathcal{O}_Y) = 0$, *respectively* $\mathrm{Tor}_i^{\mathcal{O}_{\mathfrak{g}}}(\mathcal{O}_{\widetilde{\mathcal{N}}}, \mathcal{O}_Y) = 0$, *for* $i > 0$.

Comment on the proof. The theorem can be deduced from material of either Section 3 or 4 below.

Remark 2.2. An example of Y satisfying the assumptions of the theorem is given by a transversal slice to a nilpotent orbit. In particular, if Y is a transversal slice to a subregular orbit, then $\widetilde{\mathcal{N}} \times_{\mathfrak{g}} Y$ is well known to be the minimal resolution of a simple surface singularity. The affine braid group action in this case coincides with the one constructed by Bridgeland in [27].

Remark 2.3. The induced action of B_{aff} on the Grothendieck group $K(\widetilde{\mathcal{N}})$ factors through W_{aff}. If one passes to the category of sheaves equivariant with respect to

[2]Throughout the paper by an action of a group on a category I mean *a weak action*, i.e., a homomorphism to the group of isomorphism classes of autoequivalences. I believe that in all the examples in this text a finer structure can be established, though I have not studied this question.

the multiplicative group, acting by dilations in the fibers of the projection $\widetilde{\mathcal{N}} \to \mathcal{B}$, then the induced action factors through the *affine Hecke algebra* $\mathcal{H}$, cf. discussion after Theorem 4.2. Furthermore, this construction yields an action of $\mathcal{H}$ on the Grothendieck group $K(\pi^{-1}(e))$ for each $e \in \mathcal{N}$; these $\mathcal{H}$ modules are called the standard $\mathcal{H}$-modules. Thus the theorem provides a *categorification* of the standard modules for the affine Hecke algebra.

The next result, which plays an important technical role in the proofs, is a categorical counterpart of the quadratic relation in the affine Hecke algebra, see discussion after Theorem 4.2.

Proposition 2.4. *For every simple reflection $s_\alpha \in W_{\mathrm{aff}}$ and every $\mathcal{F} \in \mathfrak{D}$ we have a (canonical) isomorphism in the quotient category $\mathfrak{D}/\langle \mathcal{F} \rangle$*

$$\tilde{s}_\alpha(\mathcal{F}) \cong \tilde{s}_\alpha^{-1}(\mathcal{F}) \mod \langle \mathcal{F} \rangle.$$

Here $\langle \mathcal{F} \rangle$ denotes the full triangulated subcategory generated by $\mathcal{F}$.

2.1.3. The t-structure and the noncommutative resolution. We will describe certain noncommutative resolutions A, $\boldsymbol{A}$ of $\mathcal{N}$, $\mathfrak{g} \times_{\mathfrak{h}/W} \mathfrak{h}$ respectively, together with equivalences $D(A) \cong D(\widetilde{\mathcal{N}})$, $D(\boldsymbol{A}) \cong D(\widetilde{\mathfrak{g}})$, and show how they appear in representation theory. Such data is uniquely determined by the t-structures on $D(\widetilde{\mathcal{N}})$, $D(\widetilde{\mathfrak{g}})$, which are the images of the tautological t-structures on $D(A)$, $D(\boldsymbol{A})$.

Definition 2.5. Let D be a triangulated category equipped with an action of B_{aff}. A t-structure $(D^{<0},\ D^{\geq 0})$ on D will be called *braid right exact* if any $b \in B_{\mathrm{aff}}^+$ sends $D^{<0}$ to $D^{<0}$.

Theorem 2.6. (a) *Let X be either $\widetilde{Y}$ or $\widetilde{\boldsymbol{Y}}$, where $Y \to \mathfrak{g}$ is as in Theorem* 2.1.

The category $D(X)$ admits a unique t-structure which is

(i) *braid right exact, and*

(ii) *compatible with the standard t-structure on the derived category of vector spaces under the functor of derived global sections $R\Gamma$.*

(b) *There exists a vector bundle $\mathcal{E}_X$ on X, such that the functor $\mathcal{F} \mapsto R\operatorname{Hom}(\mathcal{E}, \mathcal{F})$ is an equivalence between $D(X)$ and $D(A_X)$, sending the t-structure described in* (a) *to the tautological t-structure on $D(A_X)$; here $A_X = \operatorname{End}(\mathcal{E}_X)^{\mathrm{op}}$, where the upper index denotes the opposite ring.*

Moreover, there exists a vector bundle $\mathcal{E} = \mathcal{E}_{\widetilde{\mathfrak{g}}}$ on $\widetilde{\mathfrak{g}}$, such that for any X we can take $\mathcal{E}_X$ to be the pull-back of $\mathcal{E}$ to X.

Remark 2.7. It is clear from the definitions that if X is smooth, then A_X is a noncommutative resolution of $Y \times_{\mathfrak{g}} \mathcal{N}$ or $Y \times_{\mathfrak{h}/W} \mathfrak{h}$. In particular, for $Y = \mathfrak{g}$ we get $A = A_{\widetilde{\mathcal{N}}}$, $\boldsymbol{A} = A_{\widetilde{\mathfrak{g}}}$, which are the promised noncommutative resolutions of $\mathcal{N}$, $\mathfrak{g} \times_{\mathfrak{h}/W} \mathfrak{h}$.

We will call the t-structures described in Theorem 2.6 the *exotic* t-structures, the objects of their heart will be called exotic sheaves.

Example 2.8. Let $G = \mathrm{SL}(2)$, thus $\widetilde{\mathcal{N}}$ is the total space of the line bundle $\mathcal{O}(-2)$ on $\mathbb{P}^1$, and $\widetilde{\mathfrak{g}}$ is the total space of the vector bundle $\mathcal{O}_{\mathbb{P}^1}(-1) \oplus \mathcal{O}_{\mathbb{P}^1}(-1)$. In this case we can set $\mathcal{E} \cong \mathcal{O}_{\widetilde{\mathfrak{g}}} \oplus \mathcal{O}_{\widetilde{\mathfrak{g}}}(1)$.

This t-structure on $D(\widetilde{\mathfrak{g}})$ appeared in Bridgeland's proof of the derived equivalence conjecture for varieties of dimension three [28]. More precisely, for a flop of three-folds X, $X' \mapsto Y$ Bridgeland constructs some noncommutative resolution of Y which is derived equivalent to both X and X'. The simplest example of a three-fold flop is as follows: $X = X' = \widetilde{\mathfrak{g}}$, $Y = \mathfrak{g} \times_{\mathfrak{h}/W} \mathfrak{h}$ and the two maps X, $X' \to Y$ are $\widetilde{\pi}'$ and $\widetilde{\pi}'' = \iota \circ \widetilde{\pi}'$, where ι is an involution of $\mathfrak{g} \times_{\mathfrak{h}/W} \mathfrak{h}$ given by $(x, h) \mapsto (x, -h)$. The t-structure on $D(\widetilde{\mathfrak{g}})$ given by Bridgeland's construction applied to this flop turns out to coincide with the t-structure provided by Theorem 2.6.

Example 2.9. Let Y be a transversal slice to the subregular orbit. Thus Y is isomorphic to the quotient $\mathbb{A}^2/\Gamma$ for some finite subgroup $\Gamma \subset \mathrm{SL}(2)$. The fiber product $X = \widetilde{\mathcal{N}} \times_{\mathfrak{g}} Y$ is the minimal resolution of Y. It is well known that there exists a natural equivalence $D(X) \cong D^{\Gamma}(\mathbb{A}^2)$. The exotic t-structure coincides with the one induced from the tautological t-structure on $D^{\Gamma}(\mathbb{A}^2)$. Thus A_X is Morita equivalent to the smash product algebra $\Gamma \# \mathcal{O}(\mathbb{A}^2)$. This t-structure appears also in [26].

2.1.4. Parabolic version. One can also consider the partial flag varieties $\mathcal{P} = G/P$, where $P \subset G$ is a parabolic subgroup; thus $\mathcal{P}$ parametrizes parabolic subalgebras $\mathfrak{p} \subset \mathfrak{g}$ of a given type. There exist parabolic versions of the Grothendieck–Springer spaces: $\widetilde{\mathfrak{g}}_{\mathcal{P}} = \{\mathfrak{p} \in \mathcal{P},\ x \in \mathfrak{p}\}$ and $\widetilde{\mathcal{N}}_{\mathcal{P}} = T^*(\mathcal{P})$. We have a proper map $\pi_{\mathcal{P}} \colon \widetilde{\mathfrak{g}} \to \widetilde{\mathfrak{g}}_{\mathcal{P}}$, $(gB, x) \mapsto (gP, x)$. Also, the projection $G/B \to G/P$ induces a closed embedding $\iota_{\mathcal{P}} \colon \mathcal{B} \times_{\mathcal{P}} \widetilde{\mathcal{N}}_{\mathcal{P}} \hookrightarrow \widetilde{\mathcal{N}}$; we let $\mathrm{pr}_{\mathcal{B}}^{\mathcal{P}}$ denote the projection $\mathcal{B} \times_{\mathcal{P}} \widetilde{\mathcal{N}}_{\mathcal{P}} \to \widetilde{\mathcal{N}}_{\mathcal{P}}$.

The following result easily follows from the results of [20].

Theorem 2.10. (a) *There exists a unique t-structure on $D(\widetilde{\mathfrak{g}}_{\mathcal{P}})$, whose heart contains the image of exotic sheaves under the functor $R\pi_{\mathcal{P}*} \colon D(\widetilde{\mathfrak{g}}) \to D(\widetilde{\mathfrak{g}}_{\mathcal{P}})$.*

(b) *There exists a unique t-structure on $D(\widetilde{\mathcal{N}}_{\mathcal{P}})$, such that for any object $\mathcal{F}$ in its heart the object $(\iota_{\mathcal{P}*}(\mathrm{pr}_{\mathcal{P}}^{\mathcal{B}})^*\mathcal{F})(\rho)$ is an exotic sheaf.*

One also has induced nice t-structures on $D(Y \times_{\mathfrak{g}} \widetilde{\mathfrak{g}}_{\mathcal{P}})$, $D(Y \times_{\mathfrak{g}} \widetilde{\mathcal{N}}_{\mathcal{P}})$ for Y satisfying a Tor vanishing condition; we omit the details to save space.

Example 2.11. Let $G = \mathrm{SL}(n+1)$ and $\mathcal{P} = \mathbb{P}^n$. The heart of the t-structure on $\widetilde{\mathcal{N}}_{\mathcal{P}} = T^*\mathbb{P}^n$ has a projective generator $\bigoplus_{i=0}^{n} \mathcal{O}_{T^*\mathbb{P}^n}(-i)$. The heart of the t-structure on $\widetilde{\mathfrak{g}}_{\mathbb{P}^n}$ has a projective generator $\bigoplus_{i=0}^{n} \mathcal{O}_{\widetilde{\mathfrak{g}}_{\mathcal{P}}}(i)$.

2.1.5. Reformulation in terms of t-structure assigned to alcoves. A connected component of the complement to the coroot hyperplanes H_α in the dual space to the *real* Cartan algebra $\mathfrak{h}^*_{\mathbb{R}}$ is called an alcove; in particular, the *fundamental alcove* A_0 is the locus of points where all positive coroots take value between zero and one. Let Alc be the set of alcoves. For $A_1,\ A_2 \in \mathrm{Alc}$ we will say that A_1 lies above A_2 if for any

positive coroot $\check{\alpha}$ and $n \in \mathbb{Z}$, such that the affine hyperplane $H_{\check{\alpha},n} = \{\lambda \mid \langle \check{\alpha}, \lambda \rangle = n\}$ separates A_1 and A_2, A_1 lies above $H_{\alpha,n}$, while A_2 lies below $H_{\alpha,n}$, i.e. for $\mu \in A_2$, $\lambda \in A_1$ we have $\langle \alpha, \mu \rangle < n < \langle \alpha, \lambda \rangle$.

Lemma 2.12. *There exists a unique map* $\mathrm{Alc} \times \mathrm{Alc} \to B_{\mathrm{aff}}$, $(A_1, A_2) \mapsto b_{A_1,A_2}$, *such that*

(i) $b_{A_2,A_3} b_{A_1,A_2} = b_{A_1 A_3}$ *for any* $A_1, A_2, A_3 \in \mathrm{Alc}$;

(ii) $b_{A_1,A_2} = \widetilde{w}$, *provided that* A_2 *lies above* A_1. *Here* $w \in W_{\mathrm{aff}}$ *is such that* $w(A_1) = A_2$.

The following result is equivalent to Theorem 2.6.

Theorem 2.13. *Let* $X = \widetilde{Y}$ *or* $\widetilde{\boldsymbol{Y}}$, *where* Y *is as in Theorem* 2.1. *There exists a unique collection of* t*-structures indexed by alcoves,* $(D_A^{\leq 0}(X),\ D_A^{>0}(X))$ *such that:*

(1) (Normalization) *The derived global sections functor* $R\Gamma$ *is* t*-exact with respect to the* t*-structure corresponding to* A_0.

(2) (Compatibility with the braid action) *The action of the element* b_{A_1,A_2} *sends the* t*-structure corresponding to* A_1 *to the* t*-structure corresponding to* A_2.

(3) (Monotonicity) *If* A_1 *lies above* A_2, *then* $D_{A_1}^{>0}(X) \supset D_{A_2}^{>0}(X)$.

Remark 2.14. The exotic t-structure described in Theorem 2.6 is the one attached to the fundamental alcove A_0 by the construction of Theorem 2.13.

Remark 2.15. The data described in Theorem 2.13 resemble the ones obtained by Bridgeland in the course of description of the manifold of stability conditions on some derived categories of coherent sheaves. To enhance this point we mention a positivity property of the t-structure $(D_A^{\leq 0}(X),\ D_A^{>0}(X))$; such properties play a role in the definition of stability conditions [24].

It is easy to show that each of the above t-structures induces a t-structure on the full subcategory $D^f(X) \subset D(X)$ consisting of complexes whose cohomology sheaves have proper support. Let $\mathcal{A}_A = D_A^{\leq 0}(X) \cap D_A^{\geq 0}(X)$ be the heart of the t-structure, and set $\mathcal{A}_A^f = \mathcal{A}_A \cap D^f(X)$. It is easy to show that $\mathcal{A}_A^f$ consists of objects *of finite length* in $\mathcal{A}_A$.

Assume that $\boldsymbol{k} = \mathbb{C}$ and X is smooth. Recall that for a smooth complex variety X we have the Chern character map $K(D^f(X)) \to H_*^{\mathrm{BM}}(X)$, where H_*^{BM} stands for the Borel–Moore homology of the corresponding complex variety endowed with the classical topology. We have a perfect pairing between cohomology and Borel–Moore homology.

We have a well-known identification $\mathfrak{h}^* = H^2(\mathcal{B})$.

Proposition 2.16. *For* $A \in \mathrm{Alc}$, $\mathcal{F} \in \mathcal{A}_A^f$, $\mathcal{F} \neq 0$ *and* $x \in A \subset \mathfrak{h}_{\mathbb{R}}^* \subset H^2(\mathcal{B})$ *we have*

$$\langle \mathrm{ch}(\mathcal{F}), \mathrm{pr}^*(\exp(x)) \rangle > 0,$$

where $\exp(x) = 1 + x + \frac{x^2}{2} + \cdots + \frac{x^{\dim \mathcal{B}}}{(\dim \mathcal{B})!}$, *and* pr *stands for the projection* $X \to \mathcal{B}$.

Finally, we describe compatibility of our t-structures with duality.

Let $\mathcal{S}$ denote the Grothendieck–Serre duality functor.

Proposition 2.17. *$\mathcal{S}$ sends $\mathcal{A}_A^f$ to $\mathcal{A}_{-A}^f$, where $-A$ denotes the alcove opposite to A.*

2.2. Equivariant category and mutations of exceptional sets. The categories $D(\widetilde{\mathcal{N}})$, $D(\widetilde{\mathfrak{g}})$ have equivariant versions $D^G(\widetilde{\mathcal{N}})$, $D^G(\widetilde{\mathfrak{g}})$. It turns out that these equivariant categories carry t-structures which are, on the one hand, closely related to the above t-structures on non-equivariant categories, and, on the other hand, admit a direct description in terms of generating exceptional sets in a triangulated category.

Until the end of 2.3.2 *we assume that* $\mathrm{char}(\boldsymbol{k}) = 0$.

2.2.1. Exceptional sets and mutations. Recall that an ordered set of objects $\nabla = \{\nabla^i,\ i \in I\}$ in a triangulated category is called *exceptional* if we have $\mathrm{Hom}^\bullet(\nabla^i, \nabla^j) = 0$ for $i < j$; $\mathrm{Hom}^n(\nabla^i, \nabla^i) = 0$ for $n \neq 0$, and $\mathrm{End}(\nabla^i) = \boldsymbol{k}$. A set $\Delta = \{\Delta_i,\ i \in I\}$ of objects is called *dual* to ∇ if $\mathrm{Hom}^\bullet(\Delta_i, \nabla^i) = \boldsymbol{k}$, and $\mathrm{Hom}^\bullet(\Delta_i, \nabla^j) = 0$ for $i \neq j$; it is exceptional provided ∇ is, where the order on Δ is defined to be opposite to that on ∇. Let ∇, Δ be two dual exceptional sets which generate a triangulated category $\mathfrak{D}$; assume that $\{j \mid j \leq i\}$ is finite for every $i \in I$. Then there exists a unique t-structure $(\mathfrak{D}^{\geq 0}, \mathfrak{D}^{<0})$ on $\mathfrak{D}$, such that $\nabla \subset \mathfrak{D}^{\geq 0}$; $\Delta \subset \mathfrak{D}^{\leq 0}$. This construction is closely related to the definition of a perverse sheaf, see [14] for details.

Let $(I, \preceq)$ be an ordered set, and $\nabla^i \in \mathfrak{D}$, $i \in I$ be an exceptional set. Let $\leq$ be another order on I; we assume that $\{j \mid j \leq i\}$ is finite for every $i \in I$. We let $\mathfrak{D}_{\leq i}$ be the full triangulated subcategory generated by ∇^j, $j \leq i$, and similarly for $\mathfrak{D}_{<i}$. Then for $i \in I$ there exists a unique (up to a unique isomorphism) object ∇^i_{mut} such that $\nabla^i_{\mathrm{mut}} \in \mathfrak{D}_{\leq i} \cap \mathfrak{D}^{\perp}_{<i}$, and $\nabla^i_{\mathrm{mut}} \cong \nabla^i \mod \mathfrak{D}_{<i}$ (see e.g. [14]). The objects ∇^i_{mut} form an exceptional set indexed by $(I, \leq)$.

We will say that the exceptional set $(\nabla^i_{\mathrm{mut}})$ is the $\leq$ mutation of (∇^i). This construction is related, cf. [14], to the action of the braid group on the set of exceptional sets in a given triangulated category constructed in [21], this action is also called the action by mutations.

2.2.2. Exceptional sets in $D^G(\widetilde{\mathcal{N}})$. Recall the standard partial order $\preceq$ on the set Λ of weights of G, which is given by: $\lambda \preceq \mu$ if $\mu - \lambda$ is a sum of positive roots. Then line bundles $\mathcal{O}_{\widetilde{\mathcal{N}}}(\lambda)$ generate $D^G(\widetilde{\mathcal{N}})$, and we have $\mathrm{Hom}^\bullet(\mathcal{O}(\lambda), \mathcal{O}(\mu)) = 0$ unless $\mu \preceq \lambda$ and $\mathrm{Hom}^\bullet(\mathcal{O}(\lambda), \mathcal{O}(\lambda)) = \boldsymbol{k}$ [14]. Thus for any complete order on Λ compatible with the partial order $\preceq$, the set of objects $\mathcal{O}(\lambda)$ indexed by Λ with this order is an exceptional set generating $D^G(\widetilde{\mathcal{N}})$.

We now introduce another partial ordering $\leq$ on Λ. To this end, recall the 2-sided Bruhat partial order on the affine Weyl group W_{aff}. For $\lambda \in \Lambda$ let w_λ be the minimal length representative of the coset $W\lambda \subset W_{\mathrm{aff}}$. We set $\mu \leq \lambda$ if w_μ precedes w_λ in the Bruhat order.

We fix a complete order $\leq_{\mathrm{compl}}$ on Λ compatible with $\leq$; we assume that $\{\mu \mid \mu \leq_{\mathrm{compl}} \lambda\}$ is finite for any λ. We define the exceptional set ∇_λ to be the $\leq_{\mathrm{compl}}$ mutation of the set $\mathcal{O}(\lambda)$. It follows from the above that ∇^λ is an exceptional set generating $D^G(\widetilde{\mathcal{N}})$. We define the *equivariant exotic t-structure* to be the t-structure of the exceptional set ∇^λ, the objects in the heart will be called equivariant exotic sheaves.

We now state compatibility between exotic and equivariant exotic t-structures. Roughly speaking, over an orbit in $\mathcal{N}$ of codimension $2d$ they differ by a shift by d. To state this property more precisely, we need to recall the *perverse coherent t-structure* [13]. Let H be an algebraic group (assumed for simplicity of statements connected) acting on an algebraic variety X. Let $\boldsymbol{p}$ be a function, called the perversity function, from the set of H-invariant points of the scheme X to $\mathbb{Z}$. We assume that $\boldsymbol{p}$ is *strictly monotone and comonotone*, i.e. for points $x,\ y$, such that x lies in the closure of y we have $\boldsymbol{p}(y) < \boldsymbol{p}(x) < \boldsymbol{p}(y) + \dim(y) - \dim(x)$. Then one can define the perverse t-structure on $D^H(X)$, which shares some properties with perverse t-structure on the derived category of constructible sheaves [7]. For example, each perverse coherent sheaf (i.e., object in the heart of the t-structure) has finite length, and irreducible objects are in bijection with pairs $(O, \mathcal{L})$, where $O \subset X$ is an H-orbit, and $\mathcal{L}$ is an irreducible H-equivariant vector bundle on O. In particular, if the action is such that all orbits have even dimension, then the perversity function $\boldsymbol{p}(x) = \frac{\operatorname{co}\dim x}{2}$, called the middle perversity, is strictly monotone and comonotone. It is well-known that the adjoint action of a semi-simple group G on the nil-cone $\mathcal{N}$ has even dimensional orbits.

This construction works also for the category $D^H(A)$, where A is a coherent sheaf of associative $\mathcal{O}_X$ algebras equivariant under H.

Proposition 2.18. *There exists a G-equivariant vector bundle $\mathcal{E}$ on $\widetilde{\mathcal{N}}$, such that $\mathcal{E}$, with the G-equivariant structure forgotten, is a projective generator for the heart of the exotic t-structure.*

We have an equivalence $\mathcal{F} \mapsto R\operatorname{Hom}(\mathcal{E}, \mathcal{F})$ between $D^G(\widetilde{\mathcal{N}})$ and $D^G(A)$, where $A = \operatorname{End}(\mathcal{E})^{\mathrm{op}}$. Under this equivalence the equivariant exotic t-structure corresponds to the perverse coherent t-structure of the middle perversity.

2.3. Grading on exotic sheaves and canonical bases

2.3.1. Graded equivariant category and positivity by Frobenius weights. We proceed to state a deep property of exotic sheaves related to an additional grading on the Ext spaces between them. Recall the current assumption that $\operatorname{char}(\boldsymbol{k}) = 0$.

Consider the category $D^{G\times\mathbb{G}_m}(\widetilde{\mathcal{N}})$, where $\mathbb{G}_m$ acts on $\widetilde{\mathcal{N}}$ by $t\colon x \mapsto t^2 x$. For $d \in \mathbb{Z}$ let $\mathcal{F} \mapsto \mathcal{F}(d)$ denote twisting by the d-th power of the tautological character of $\mathbb{G}_m$. We refer to [14] for an elementary description of a canonical lifting $\widetilde{\Delta}_\lambda$, $\widetilde{\nabla}^\lambda$ of Δ_λ, ∇^λ to $D^{G\times\mathbb{G}_m}$. This also fixes a lifting $\tilde{L}$ of each irreducible equivariant exotic sheaf L to $D^{G\times\mathbb{G}_m}$.

Theorem 2.19. *For irreducible exotic equivariant sheaves L_1, L_2 we have*

$$\mathrm{Ext}^i(\tilde{L}_1, \tilde{L}_2(d)) = 0$$

for $d \leq 0$ and all i.

Remark 2.20. The theorem follows from results of [12] on relation between exotic sheaves and perverse sheaves on the affine flag manifold of the dual group, see also Proposition 4.5 below. They allow to deduce the theorem from Gabber's Theorem [7] on positivity of weights of Frobenius action on Ext's between pure perverse sheaves of the same weight. Thus it is the least elementary of the results mentioned so far in this text.

The motivation for the theorem is its consequence below, which shows (in most cases) that classes of exotic sheaves form a *canonical basis* in the Grothendieck group. This is parallel to the proof of the Kazhdan–Lusztig conjecture: according to Soergel, cf. [50], the latter is equivalent to the statement that for a certain explicitly defined graded version of Bernstein–Gel'fand–Gel'fand category O the grading on Ext^1 between irreducible objects has vanishing components of non-positive degrees. The only known way to prove this vanishing is to identify category O with a category of perverse sheaves or Hodge D-modules, and use deep information about purity of Frobenius or Hodge weights.

Remark 2.21. Another application of Theorem 2.19 is explained in [14]. Together with the *Koszul duality* formalism of [9] it allows one to show that equivariant exotic sheaves control cohomology of quantum groups at a root of unity with coefficients in a tilting module.

2.3.2. Non-equivariant graded category and canonical bases. We fix $X = \widetilde{\mathcal{N}}$. Recall the category $\mathcal{A}^f = \mathcal{A}^f_{A_0} \subset \mathcal{A}$ of exotic sheaves of finite length. It is easy to see that $\mathcal{A}^f = \bigoplus_{e \in \mathcal{N}} \mathcal{A}_e$, where $\mathcal{A}_e = \mathcal{A} \cap \mathfrak{D}_e$, and $\mathfrak{D}_e \subset D(\widetilde{\mathcal{N}})$ is the full subcategory of complexes whose cohomology sheaves are set-theoretically supported on $\mathcal{B}_e = \pi^{-1}(e)$. We have $K(\mathcal{A}_e) \cong K(\mathcal{B}_e)$. Furthermore, the Chern character map provides an isomorphism $K(\mathcal{B}_e)_F \cong H^{\mathrm{BM}}_*(\mathcal{B}_e)_F$, where F denotes a coefficient field of characteristic zero ($\mathbb{C}$ or $\overline{\mathbb{Q}_l}$), see, e.g, [19].

The classes of irreducible objects form a basis in $K(\mathcal{A}_e)$. We proceed to explain the properties of the category, which are needed to relate this basis to *the canonical bases* in $H^{\mathrm{BM}}_*(\mathcal{B}_e)$. The definition of the latter is due to Lusztig [45], and follows the example of Kashiwara's characterization of crystal bases [42]. More precisely, Lusztig suggested a way to characterize a basis in $H^{\mathrm{BM}}_*(\mathcal{B}_e)$, and conjectured that a basis satisfying his axioms exists; he showed that it is then unique (up to a sign). We will not recall Lusztig's characterization in detail; instead we describe its structure and explain the properties of exotic sheaves, which imply (modulo a technicality, which is easy to check in many cases) that Lusztig's axioms are satisfied by the basis of irreducible exotic sheaves.

One can find a homomorphism $\varphi\colon \mathrm{SL}(2) \to G$, such that $d\varphi$ sends the standard upper triangular generator of $sl(2)$ to e. Then we get an action a_φ of the multiplicative group $\mathbb{G}_m$ on $\mathfrak{g}$ given $a_\varphi(t)\colon x \mapsto t^2 \cdot \mathrm{ad}(\varphi(\mathrm{diag}(t^{-1}, t)))x$. This action fixes e.

We let $\mathfrak{D}_e^{\mathbb{G}_m} \subset D^{\mathbb{G}_m}(\widetilde{\mathcal{N}})$ be the full subcategory of complexes, which are set theoretically supported on $\pi^{-1}(e)$. Twisting by the tautological character of $\mathbb{G}_m$ defines an auto-equivalence of this category, which we denote by $\mathcal{F} \mapsto \mathcal{F}(1)$. The exotic t-structure is inherited by the $\mathbb{G}_m$-equivariant category; we let $\mathcal{A}_e^{\mathrm{gr}}$ denote the heart of the latter. It is easy to see that the forgetful functor $\mathfrak{D}_e^{\mathbb{G}_m} \to \mathfrak{D}_e$ sends $\mathrm{Irr}(\mathcal{A}_e^{\mathrm{gr}})$ to $\mathrm{Irr}(\mathcal{A}_e)$, where Irr stands for the set of isomorphism classes of irreducible objects. This gives a bijection $\mathrm{Irr}(\mathcal{A}_e^{\mathrm{gr}})/\mathbb{Z} \cong \mathrm{Irr}(\mathcal{A}_e)$, where $\mathbb{Z}$ acts on $\mathrm{Irr}(\mathcal{A}_e^{\mathrm{gr}})$ by $\mathcal{F} \mapsto \mathcal{F}(n)$. We also have $K(\mathcal{A}_e^{\mathrm{gr}}) \cong K^{\mathbb{G}_m}(\mathcal{B}_e) \cong K(\mathcal{B}_e)[v, v^{-1}]$, where multiplication by v corresponds to twisting by the tautological character of $\mathbb{G}_m$.

The canonical basis in $K(\mathcal{B}_e)[v, v^{-1}]$ is characterized (up to a sign) by two properties: *invariance under an involution* and *asymptotic orthogonality* [45]. These are reflected, respectively, in categorical properties (i) and (ii) in the next theorem.

Notice that the action of B_{aff} on $\mathfrak{D}_e$ is inherited by $\mathfrak{D}_e^{\mathbb{G}_m}$. Recall that $\mathcal{S}$ is the Grothendieck–Serre duality.

In view of Theorem 2.13 and Proposition 2.17, the contravariant auto-equivalence $\widetilde{w}_0 \circ \mathcal{S}$ is t-exact with respect to the t-structure corresponding to the fundamental alcove A_0, hence it permutes irreducible objects of $\mathcal{A}_{A_0}$; here $w_0 \in W$ is the long element.

Theorem 2.22. *There exists a canonical section of the map* $\mathrm{Irr}(\mathcal{A}_e^{\mathrm{gr}}) \to \mathrm{Irr}(\mathcal{A}_e)$, $L \mapsto \tilde{L}$, *such that*

(i) *The image of the section is invariant under every automorphism of G which is identity on the image of φ_e, and also under $\widetilde{w}_0 \circ \mathcal{S}$.*

(ii) $\mathrm{Ext}^1_{\mathcal{A}_e^{\mathrm{gr}}}(\tilde{L}_1, \tilde{L}_2(i)) = 0$ *for* $i \le 0$ *and any* $L_1,\ L_2 \in \mathrm{Irr}(\mathcal{A}_e)$*; here* $\bar{\mathcal{A}}_e^{\mathrm{gr}} \subset \mathcal{A}_e$ *is the full subcategory of objects where the ideal of the point e in $\mathcal{O}(\mathfrak{g})$ acts by zero.*

Comments on the proof. The theorem can be deduced formally from Theorem 2.19 and Proposition 2.18. Thus its proof relies on ideas of geometric Langlands duality used in [2], and on Gabber's Theorem (see comments after Theorem 2.19).

Corollary 2.23. *Suppose that the involution $\tilde{\beta}$ defined in* [45], §5.11 *induces identity on the specialization at $q = 1$. Then Conjecture* 5.12 *of loc. cit., except, possibly,* 5.12 (g)*, holds; moreover, the signed basis $\boldsymbol{B}^{\pm}_{\mathcal{B}_e}$, whose existence is conjectured in loc. cit., is formed by the classes of the objects $\tilde{L}$, where L runs over irreducible objects in $\mathcal{A}_e$.*

Remark 2.24. The assumptions of the corollary are easy to check in many cases, e.g., if the nilpotent element e is regular in a Levi subalgebra.

Remark 2.25. In fact, in [45] Lusztig works with sheaves which are also equivariant under a maximal torus in the centralizer of e. We omit this version here to simplify notations, treating this set-up does not involve new ideas.

Remark 2.26. Validity of Conjecture 5.12 (g) of [45] is related to the following question. Let $Y \subset \mathfrak{g}$ be a (Slodowy) transversal slice to a G orbit in $\mathcal{N}$, and $X = \widetilde{\mathcal{N}} \times_{\mathfrak{g}} Y$. Let A_X be as in Theorem 2.6. One can show that A can be endowed with a natural grading; moreover, Theorem 2.22 is equivalent to the fact that this grading can be chosen so that the graded components of negative degree vanish, while the component of degree zero is semi-simple. The question is whether the resulting graded algebra is Koszul. If e is subregular, then the positive answer is easy to prove.

2.3.3. Independence of the (large) prime. It is not hard to show that (co)homology of the Springer fiber is independent of the ground field $\boldsymbol{k}$, i.e. we have canonical isomorphisms $H^{\mathrm{BM}}_\bullet(\mathcal{B}^{\boldsymbol{k}}_e) \cong H^{\mathrm{BM}}_\bullet(\mathcal{B}^{\mathbb{C}}_e)$, where the upper index denotes the ground field, and $H^{\mathrm{BM}}_\bullet$ stands for l-adic Borel–Moore homology, $l \neq \mathrm{char}(\boldsymbol{k})$.

The definition of the exotic t-structure is not specific to a particular ground field. This allows one to prove the following.

Proposition 2.27. *For all but finitely many prime numbers p the following is true. The classes in $H^{\mathrm{BM}}_\bullet(\mathcal{B}^{\boldsymbol{k}}_e) = H^{\mathrm{BM}}_\bullet(\mathcal{B}^{\mathbb{C}}_e)$ of irreducible exotic sheaves over $\boldsymbol{k}$ of characteristic p coincide with the classes of irreducible exotic sheaves over $\mathbb{C}$.*

3. D-modules in positive characteristic and localization theorem

3.1. Generalities on crystalline D-modules in positive characteristic

3.1.1. Definition and description of the center. Let X be a smooth variety over the field $\boldsymbol{k}$.

The sheaf $\mathcal{D} = \mathcal{D}_X$ of *crystalline differential operators* (or differential operators without divided powers, or PD differential operators) on X is defined as the enveloping of the tangent Lie algebroid, i.e., for an affine open $U \subset X$ the algebra $\mathcal{D}(U)$ contains the subalgebra $\mathcal{O}$ of functions, has an $\mathcal{O}$-submodule identified with the Lie algebra of vector fields $\mathrm{Vect}(U)$ on U, and these subspaces generate $D(U)$ subject to relations $\xi_1\xi_2 - \xi_2\xi_1 = [\xi_1, \xi_2] \in \mathrm{Vect}(U)$ for $\xi_1, \xi_2 \in \mathrm{Vect}(U)$, and $\xi \cdot f - f \cdot \xi = \xi(f)$ for $\xi \in \mathrm{Vect}(U)$ and $f \in \mathcal{O}(U)$.

If $\mathrm{char}(\boldsymbol{k}) = 0$, then $\mathcal{D}_X$ is the familiar sheaf of differential operators. From now on assume that $\boldsymbol{k}$ is of characteristic $p > 0$. Then $\mathcal{D}_X$ shares some features with the characteristic zero case; for example, $\mathcal{D}_X$ carries an increasing filtration "by order of a differential operator", and the associated graded $\mathrm{gr}(\mathcal{D}_X) \cong \mathcal{O}_{T^*X}$ canonically. On the other hand, some phenomena are special to the characteristic p setting. We have an action map $\mathcal{D}_X \to \mathrm{End}(\mathcal{O}_X)$, which is not injective, unlike in the case of characteristic zero. For example, if $X = \mathbb{A}^1 = \mathrm{Spec}(k[x])$, the section $\partial_x^p \neq 0$ of $\mathcal{D}_X$ acts by zero on $\mathcal{O}$. Also, $\mathcal{D}_X$ has a huge center; for example, if $X = \mathbb{A}^n = \mathrm{Spec}(k[x_1, \ldots, x_n])$, then x_i^p and $\partial_{x_i}^p$ are readily seen to generate the center $Z(\mathcal{D}_{\mathbb{A}^n})$ freely. More generally, for any X the center $Z(\mathcal{D}_X)$ is freely generated by elements of the form f^p, $f \in \mathcal{O}_X$

and $\xi^p - \xi^{[p]}$, $\xi \in \mathrm{Vect}_X$, where $\xi^{[p]}$ is the *restricted power* of the vector field ξ; it is characterized by $\mathrm{Lie}_{\xi^{[p]}}(f) = \mathrm{Lie}^p_\xi(f)$ for $f \in \mathcal{O}_X$, where Lie stands for the Lie derivative. The center $Z(\mathcal{D}_X)$ is canonically isomorphic to the sheaf of rings $\mathcal{O}_{T^*X^{(1)}}$ where the super-index (1) stands for Frobenius twist.[3] Thus $\mathcal{D}_X$ can be considered as a quasi-coherent sheaf of algebras on $T^*X^{(1)}$.

3.1.2. Azumaya property. Recall that an *Azumaya algebra* on a scheme X is a locally free sheaf $\mathcal{A}$ of associative $\mathcal{O}_X$ algebras, such that the fiber of $\mathcal{A}$ at every geometric point is isomorphic to a matrix algebra. The following fundamental observation is due to Mirković and Rumynin, though a weak form of it can be traced to an earlier work [40].

Theorem 3.1 ([19]). *$\mathcal{D}_X$ is an Azumaya algebra of rank $p^{2\dim(X)}$ on $T^*X^{(1)}$.*

See [48], [10] for generalizations and applications.

Recall that two Azumaya algebras $\mathcal{A}$, $\mathcal{A}'$ are called equivalent (we then write $\mathcal{A} \sim \mathcal{A}'$) if they are Morita equivalent, i.e. if there exists a coherent locally projective sheaf $\mathcal{M}$ of $\mathcal{A} - \mathcal{A}'$ bimodules, such that $\mathcal{A}' \xrightarrow{\sim} \mathrm{End}(\mathcal{M})^{\mathrm{op}}$; we will then say that $\mathcal{M}$ provides an equivalence between $\mathcal{A}$ and $\mathcal{A}'$. In particular, an Azumaya algebra $\mathcal{A}$ is *split* if $\mathcal{A} \sim \mathcal{O}_X$; this happens iff $\mathcal{A} \cong \mathrm{End}(\mathcal{E})$ for a vector bundle $\mathcal{E}$. For two equivalent Azumaya algebras $\mathcal{A}$, $\mathcal{A}'$ we have an equivalence of categories of modules $\mathrm{Coh}(X, \mathcal{A}) \cong \mathrm{Coh}(X, \mathcal{A}')$, depending on the choice of a bimodule providing the equivalence between $\mathcal{A}$ and $\mathcal{A}'$; in particular, for a split Azumaya algebra we have $\mathrm{Coh}(X, \mathcal{A}) \cong \mathrm{Coh}(X)$.

For a smooth variety X over a positive characteristic field, the Azumaya algebra $\mathcal{D}_X$ is not split unless $\dim(X) = 0$. However, it is split on the zero section, see [48] for more information.

We will also need a twisted version of differential operators. If $\mathcal{L}$ is a line bundle on X, then one can consider the sheaf $\mathcal{D}^{\mathcal{L}} = \mathcal{D}^{\mathcal{L}}_X$ of differential operators in $\mathcal{L}$. A similar argument shows that this is also an Azumaya algebra over $T^*X^{(1)}$; moreover, we have a canonical equivalence

$$\mathcal{D}_X \sim D^{\mathcal{L}}_X, \tag{1}$$

given by the bimodule $D_X \otimes_{\mathcal{O}(X)} \mathcal{L}^{-1}$.

Remark 3.2. Notice that if $\mathcal{L} = \mathcal{L}_0^p = \mathrm{Fr}^*(\mathcal{L}_0)$ for some line bundle $\mathcal{L}_0$, then we have a canonical isomorphism $\mathcal{D}^{\mathcal{L}}_X \cong \mathcal{D}_X$; however, the above equivalence $\mathcal{D}^{\mathcal{L}}_X \cong \mathcal{D}_X$ is not identity, but rather tensor product *over the ring* $\mathcal{O}^p_X = \mathcal{O}_{X^{(1)}}$ with the line bundle ${\mathcal{L}_0}^{(1)}$.

[3] Recall that Frobenius twist of a variety X over a perfect field $\boldsymbol{k}$ is defined to be isomorphic to X as an abstract scheme, with the $\boldsymbol{k}$-linear structure twisted by Frobenius. Not only $X \cong X^{(1)}$ as abstract schemes, but also $X \cong X^{(1)}$ as $\boldsymbol{k}$-schemes, provided that X is defined over $\mathbb{F}_p$. For this reason we will sometimes identify X with $X^{(1)}$ and omit Frobenius twist from notation.

3.2. Crystalline operators on $\mathcal{B}$. We now consider $X = \mathcal{B}$. We abbreviate $\mathcal{D}_{\mathcal{B}}^{\mathcal{O}(\lambda)} = \mathcal{D}^{\lambda}$.

3.2.1. Splitting the Azumaya algebra. It was mentioned above that $\mathcal{D}_{\mathcal{B}}$ splits on the zero section. In fact, we have the following stronger statement.

Theorem 3.3. (a) *There exists an Azumaya algebra $\mathcal{A}$ on $\mathcal{N}^{(1)}$, such that $\mathcal{D}^{-\rho} \cong \pi^*(\mathcal{A})$.*

(b) *For any λ we have an equivalence of Azumaya algebras on $\mathcal{N}^{(1)}$: $\mathcal{D}^{\lambda} \sim \pi^*(\mathcal{A})$.*

(c) *$\mathcal{D}^{\lambda}(\mathcal{B})$ is split on the formal neighborhood of every fiber of π.*

Sketch of proof. (a) reduces to irreducibility of baby Verma modules with highest weight $-\rho$, which follows from [29]. It implies, moreover, that the statement holds for $\mathcal{A}$ being the quotient of the enveloping algebra $U(\mathfrak{g})$ by the central ideal corresponding to $-\rho$. (b) follows from (a) in view of the equivalence (1). Finally, (c) follows from (b), since every Azumaya algebra over a complete local ring with an algebraically closed residue field splits. □

Let $\mathcal{D}^{\lambda}$-mod$^f \subset \mathrm{Coh}(\widetilde{\mathcal{N}}^{(1)}, \mathcal{D}^{\lambda})$ the full subcategory of sheaves, whose support (which is a subvariety in $\widetilde{\mathcal{N}}^{(1)}$) is proper. Let $\mathrm{Coh}^f(\widetilde{\mathcal{N}}) \subset \mathrm{Coh}(\widetilde{\mathcal{N}})$ be the full subcategory of sheaves with proper support.

Corollary 3.4. *For every $\lambda \in \Lambda$ we have an equivalence $\mathcal{D}^{\lambda}$-mod$^f \cong \mathrm{Coh}^f(\widetilde{\mathcal{N}})$.*

Proof. Since the target of π is affine, a subscheme Z in $\widetilde{\mathcal{N}}^{(1)}$ is proper iff it lies in a finite union of nilpotent neighborhoods of Springer fibers. Thus the claim follows from Theorem 3.3(b). □

For each $\lambda \in \Lambda$ and $e \in \mathcal{N}$ we fix the splitting bundle $\mathcal{E}_e^{\lambda}$ for $\mathcal{D}^{\lambda}$ on the formal neighborhood of $\pi^{-1}(e)$ as follows. For $\lambda = -\rho$ we let $\mathcal{E}_e^{\lambda}$ be the pull-back under π of a splitting bundle for the Azumaya algebra $\mathcal{A}$ on the formal neighborhood of e in $\mathcal{N}^{(1)}$. For a general λ we get $\mathcal{E}^{\lambda}$ from $\mathcal{E}^{-\rho}$ by applying the canonical equivalence (1) between $\mathcal{D}^{-\rho}$ and $\mathcal{D}^{\lambda}$; thus $\mathcal{E}^{\lambda} = \mathcal{E}^{-\rho} \otimes_{\mathcal{O}_{\mathcal{B}}} \mathcal{O}(\lambda + \rho)$.

We let F_{λ} denote the resulting equivalence between $\mathcal{D}^{\lambda}$-mod^f and $\mathrm{Coh}^f(\widetilde{\mathcal{N}})$. Notice that for $\lambda' = \lambda + p\mu$ the sheaves of algebras $\mathcal{D}^{\lambda}$ and $\mathcal{D}^{\lambda'}$ are canonically identified; however, the equivalences F_{λ} and $F_{\lambda'}$ are different, cf. Remark 3.2.

3.2.2. Derived localization in positive characteristic. Let $U = U(\mathfrak{g})$ be the enveloping algebra.

Assume first that $\mathrm{char}(\boldsymbol{k}) = 0$. Recall the famous Localization Theorem [5], [30], which provides an equivalence U^{λ}-mod $\cong \mathcal{D}^{\lambda}$-mod$(\mathcal{B})$, where λ is a dominant integral weight, $\mathcal{D}^{\lambda}$-mod denotes the corresponding twisted D-modules category, and U^{λ}-mod is the category of $\mathfrak{g}$-modules with central character corresponding to λ. For two integral weights λ, μ the categories $\mathcal{D}^{\mu}$-mod and $\mathcal{D}^{\lambda}$-mod can be identified by means of the equivalence $T_{\mu}^{\lambda}\colon \mathcal{F} \mapsto \mathcal{F} \otimes \mathcal{O}(\lambda - \mu)$. If λ, μ are dominant, then

the global sections functors intertwine this equivalence with the translation functor, which provides an equivalence U^λ-mod $\cong U^\mu$-mod.

Assume now that μ is integral regular, thus $\mu = w(\lambda+\rho)-\rho$ for some dominant integral λ, $w \in W$. Then the functor of global sections on D_μ-mod is no longer exact; however, it follows from [6] that the derived functor $R\Gamma = R\Gamma_\mu : D^b(\mathcal{D}^\mu\text{-mod}) \to D^b(U^\lambda\text{-mod})$ is still an equivalence. The triangle formed by the three equivalences $R\Gamma_\mu$, T^λ_μ, $R\Gamma_\lambda$ does not commute. Thus we get an auto-equivalence R_w of $D^b(\mathcal{D}^\lambda\text{-mod})$, $R_w = R\Gamma_\lambda^{-1} \circ R\Gamma_\mu \circ T^\mu_\lambda$. In [6] it is shown that R_w can be described by an explicit correspondence, which makes it natural to call R_w the *Radon transform*, or *the intertwining functor*. Moreover, the assignment $\widetilde{w} \mapsto R_w$ extends to an action of the Artin braid group B attached to G on $D^b(U^\lambda\text{-mod})$.

A part of this picture can be generalized to characteristic p.

The obvious characteristic p analogue of the above equivalence of abelian categories does not hold for any integral λ. Indeed, it is well known that for any coherent sheaf $\mathcal{F}$ on the (Frobenius twist of) a smooth variety the sheaf $\mathrm{Fr}^*(\mathcal{F})$ carries a flat connection; in particular, so does the sheaf $\mathrm{Fr}^*(L) = L^{\otimes p}$, where L is a line bundle. Thus for $\mathcal{F} \in \mathcal{D}^\lambda$-mod we have $\mathcal{F} \otimes L^p \in \mathcal{D}^\lambda$-mod. If L is anti-ample and the support of $\mathcal{F}$ is projective of positive dimension, then some of the higher derived functors $R^i\Gamma(\mathcal{F} \otimes L^{dp}) \neq 0$ for large d.

However, we do have an analogue of the "derived" localization theorem. From now on assume that $\mathrm{char}(\boldsymbol{k}) = p > 0$.

The center Z of U contains the subalgebra $Z_{\mathrm{HC}} = U^G \cong \mathrm{Sym}(\mathfrak{h})^W$, which we call the Harish-Chandra center. We have a natural map $\Lambda/p\Lambda \to \mathfrak{h}^*/W$, $\lambda \mapsto d\lambda$ mod W. Thus every $\lambda \in \Lambda$ defines a maximal ideal of Z_{HC}. We let $U^\lambda = U \otimes_{Z_{\mathrm{HC}}} \boldsymbol{k}$ denote the corresponding central reduction. Notice that the set of weights $\mu \in \Lambda$, such that the quotients U^λ and U^μ of U coincide, is precisely the W_{aff}-orbit of λ with respect to the action $w \bullet \lambda = p\, w\big(\frac{\lambda+\rho}{p}\big) - \rho$. We will say that $\lambda \in \Lambda$ is p-regular if the stabilizer in W of $\lambda + p\Lambda \in \Lambda/p\Lambda$ is trivial.

We also have another central subalgebra $Z_{\mathrm{Fr}} \subset U$, called the Frobenius center. It is generated by expressions of the form $x^p - x^{[p]}$, $x \in \mathfrak{g}$, where the *restricted power* map $x \mapsto x^{[p]}$ is characterized by $\mathrm{ad}(x^{[p]}) = \mathrm{ad}(x)^p$. Thus maximal ideals of Z_{Fr} are in bijection with points of $\mathfrak{g}^* \cong \mathfrak{g}$.

Let U^λ-mod denote the category of finitely generated U^λ-modules, and let $U^\lambda\text{-mod}^f \subset U^\lambda$-mod be the full subcategory of finite length modules.

For a pair $\lambda \in \Lambda$, $e \in \mathfrak{g}^*$ let $U^\lambda_{\hat{e}}$-mod be the category of finitely generated U^λ-modules, which are killed by some power of the maximal ideal of e in Z_{Fr}. This category is zero unless $e \in \mathcal{N}$. We also have $U^\lambda\text{-mod}^f = \bigoplus_{e\in\mathcal{N}} U^\lambda_{\hat{e}}\text{-mod}$.

Let $\mathcal{D}^\lambda_{\hat{e}}$-mod $\subset \mathcal{D}^\lambda$-mod be the full subcategory of objects which are supported on a nilpotent neighborhood of $\pi^{-1}(e)$; here we think of $\mathcal{D}^\lambda$ modules as sheaves on $\widetilde{\mathcal{N}}^{(1)}$ with an additional structure.

Theorem 3.5 ([19]). (a) *We have a natural isomorphism* $\Gamma(\mathcal{D}^\lambda) \cong U^\lambda$ *for every* $\lambda \in \Lambda$.

(b) *If $\lambda \in \Lambda$ is p-regular, then the derived global sections functor provides an equivalence $R\Gamma_\lambda \colon D(\mathcal{D}^\lambda) \xrightarrow{\sim} D(U^\lambda)$. It restricts to equivalences $D^b(\mathcal{D}^\lambda\text{-mod}^f) \cong D^b(U^\lambda\text{-mod}^f)$, $D^b(\mathcal{D}^\lambda_{\hat{e}}\text{-mod}) \cong D^b(U^\lambda_{\hat{e}}\text{-mod})$.*

Remark 3.6. This theorem has several versions and generalization. One can work with the more general categories of twisted D-modules, thereby obtaining a category of modules over an Azumaya algebra on the formal neighborhood of $\widetilde{\mathcal{N}}$ in $\widetilde{\mathfrak{g}}$, or more general subschemes or formal completions of $\widetilde{\mathfrak{g}}$. For singular weights λ there is a version of the theorem that relates derived categories of modules to sheaves on (the neighborhoods of) *parabolic Springer fibers* [20]. Another construction works with differential operators on a partial flag variety G/P for a parabolic subgroup $P \subset G$, *loc. cit.,* cf. also subSection 2.1.4 above.

For a scheme Y mapping to $\mathfrak{g}$ and satisfying the Tor vanishing conditions of Theorem 2.1 we have an equivalence between the derived category of modules over Azumaya algebras on $\widetilde{\boldsymbol{Y}}, \widetilde{Y}$ obtained as pull-back of the algebra of (twisted) differential operators and derived category of modules over the algebra of global sections.

If Y is a transversal slice to a nilpotent orbit, then the algebra of global sections of the Azumaya algebra on $\widetilde{Y}$ is probably related to Premet's quantization of Slodowy slices and generalized Whittaker D-modules, see [49], [38].

There exists a generalization of this result for Y not satisfying the Tor vanishing condition. It involves coherent sheaves on the *differential graded* scheme, which is the derived fiber product of Y and $\widetilde{\mathfrak{g}}$ over $\mathfrak{g}$. The particular case $Y = \{0\}$ is closely related to the description of the derived category of the principal block in representations of a quantum group at a root of unity provided by [3].

Proposition 3.7. (a) *A weight $\lambda \in \Lambda$ is p-regular iff $\frac{\lambda+\rho}{p}$ lies in some alcove.*

(b) *The t-structure on $\mathcal{D}^0$-mod induced by the equivalence $R\Gamma^\lambda \circ T_0^\lambda$ for a p-regular λ depends only on the alcove of $\frac{\lambda+\rho}{p}$ (see the beginning of Section 3.2.2 for notation).*

Thus we get a collection of t-structure on $\mathcal{D}^0$-mod indexed by alcoves; we denote the t-structure attached to $A \in \mathrm{Alc}$ by $D_A^{<0}(\mathcal{D})$, $D_A^{\geq 0}(\mathcal{D})$. The following properties of the collection follow from [19], [20].

Theorem 3.8. (a) *Let A_1, A_2 be two alcoves. If A_1 lies above A_2, then $D_{A_1}^{>0}(\mathcal{D}) \supset D_{A_2}^{>0}(\mathcal{D})$.*

(b) *There exists an action of B_{aff} on $D(\mathcal{D})$, such that the following holds. Let $\lambda \in \Lambda$, $\frac{\lambda+\rho}{p} = w\left(\frac{\rho}{p}\right)$ for $w \in W_{\mathrm{aff}}$, and let A be the alcove of $\frac{\lambda+\rho}{p}$. Then $R\Gamma_\lambda \cong R\Gamma_0 \circ b_{A_0,A_1}$. Thus b_{A_0,A_1} sends the t-structure $D_{A_0}^{<0}(\mathcal{D})$, $D_{A_0}^{\geq 0}(\mathcal{D})$ to the t-structure $D_A^{<0}(\mathcal{D})$, $D_A^{\geq 0}(\mathcal{D})$.*

(c) *The restriction of the B_{aff} action to $D^b(\mathcal{D}^\lambda - mod^f) \cong D^b(\mathrm{Coh}^f(\widetilde{\mathcal{N}}))$ coincides with the restriction of the action from Theorem 2.1.*

(d) *The derived global sections functor* $R\Gamma$ *on* $D^b(\mathrm{Coh}^f(\widetilde{\mathcal{N}}))$ *is* t*-exact with respect to the* t*-structure induced from* $(D^{<0}_{A_0}(\mathcal{D}),\ D^{\geq 0}_{A_0}(\mathcal{D}))$ *via the equivalence* F_0 (*see the end of Section* 3.2.1 *for notation*).

Corollary 3.9. *The* t*-structure on* $\mathrm{Coh}^f(\widetilde{\mathcal{N}})$ *induced by the exotic* t*-structure coincides with the one induced from* $(D^{<0}_{A_0}(\mathcal{D}),\ D^{\geq 0}_{A_0}(\mathcal{D}))$ *via the equivalence* F_0 (*see the end of* 3.2.1).

In particular, we have a Morita equivalence $\mathcal{A}_e \sim U\text{-mod}^{\lambda}_{\hat{e}}$ *for every* p*-regular* $\lambda \in \Lambda$.

The corollary follows by comparing Theorem 3.8 with Theorem 2.13.

Corollary 3.10. (a) *Let* U^{λ}_e *denote the specialization of the enveloping algebra* $U(\mathfrak{g})$ *at the central character corresponding to* $e \in \mathcal{N}$ *and a regular integral weight* λ. *Then we have a canonical isomorphism* $K(U^{\lambda}_e)_F \cong H^{\mathrm{BM}}_{\bullet}(\mathcal{B}_e)_F$, *where* F *is a field of characteristic zero.*

(b) *The image of the set of classes of irreducible modules under this isomorphism is independent of the base field* $\boldsymbol{k}$, *except for a finite number of values of the characteristic.*

Part (a) of the corollary follows directly from Theorem 3.5 (cf. the discussion preceding Proposition 2.16), while part (b) follows from Corollary 3.9 and Proposition 2.27.

Remark 3.11. For $e = 0$ part (a) of the proposition is standard, and part (b) can be deduced from [1]. Our method uses the principal tool of [1], namely, the reflection functors, in the disguise of the braid group action; geometry of the Springer map is the new ingredient.

In fact, we have the following stronger, though more difficult statement. We will say that a basis in $H^{\mathrm{BM}}_{\bullet}(\mathcal{B}_e)$ is canonical if it is the image of a basis in the equivariant Grothendieck group $K^{\mathbb{G}_m}(\mathcal{B}_e)$, satisfying Lusztig's axioms [45], under forgetting the equivariance composed with the Chern character map. According to a result of [45] such a basis is unique up to multiplication of some of its elements by -1, if it exists.

Corollary 3.12. *Enforce the assumption of Corollary* 2.23. *Then for almost all* $p = \mathrm{char}(\boldsymbol{k})$ *the isomorphism* $K^0(U\text{-mod}^0_e)_F \cong H^{\mathrm{BM}}_*(\mathcal{B}_e)_F$ *of Corollary* 3.10 (a) *sends classes of irreducible objects to elements of a canonical basis. Thus Conjecture* 17.2 *of* [45] *holds in this case.*

This corollary is immediate from Corollary 2.23 together with Theorem 3.8(d). Thus its proof, unlike the proof of Corollary 3.10, relies on Gabber's Theorem [7] and ideas of local geometric Langlands duality, on which the results of [2] are based.

Remark 3.13. For large p the particular case $e = 0$ of the Conjecture 17.2 of [45] is well known to imply the previous Lusztig conjectures [46], which describe characters of algebraic groups in finite characteristics. Lusztig's program for a proof of these

conjectures for indefinitely large p has been carried out by several authors. An alternative proof is given in [3].

None of the available methods gives a proof of the conjectures for some particular fixed value of p.

Notice that the strategy of proof of this conjecture (for indefinitely large p) outlined above does not use quantum groups.

4. Perverse sheaves on affine flags of the dual group (local geometric Langlands)

4.1. Generalities on geometric Langlands duality. Recall that ${}^LG$ is the group dual to G in the sense of Langlands. Several good surveys of geometric Langlands duality program has appeared recently [33], [34], [37], so I will only briefly recall the set-up.

The geometric Langlands duality is a categorification of the classical Langlands duality for function fields. The latter seeks to attach an automorphic form to a homomorphism from a version of the Galois group to ${}^LG$. In other words, the problem is to provide a spectral decomposition for Hecke operators acting in the space of automorphic functions, and relate the space of spectral parameters to homomorphisms of the Galois group to the dual group. As was probably first observed by A. Weil, in the case of a function field the automorphic space in question is the set of isomorphism classes of G-bundles, possibly with an additional level structure, on an algebraic curve over $\mathbb{F}_q$. Thus it is the set of $\mathbb{F}_q$ points of the corresponding moduli space (stack).

Passage to the geometric duality theory is based on the following variation of Grothendieck's sheaf-function correspondence principle. The variation says that for an algebraic variety (or stack) over $\mathbb{F}_q$ a natural categorification of the space of functions on the set $X(\mathbb{F}_q)$ is the derived category of l-adic sheaves on X. Thus the objective of the geometric duality theory is a spectral decomposition of the derived category of l-adic sheaves on a moduli space of G-bundles, where the space of spectral parameters is identified with the space of ${}^LG$ local systems. It is a non-trivial, and not completely solved, problem to assign a formal meaning to the previous sentence; however, in some cases it amounts to an equivalence between the l-adic derived category of the moduli stack and the derived category of coherent sheaves on a stack mapping to the stack of local systems.

The above formulations referred to a more developed *global* version of the theory. However, the classical Langlands conjectures have both a global and a local version. The global one provides a conjectural classification of automorphic representations of the group of adele points of a reductive group over a global field, i.e. either a number field, or the field of rational functions on a curve over a finite field. The local one describes all irreducible representations of a reductive group over a local field; recall that a local function field is a field of formal Laurent series $\mathbb{F}_q((t))$. The geometric theory studies the derived category of l-adic sheaves on homogeneous spaces of the

formal loop group $\boldsymbol{^L G}((t))$ of the dual group ${}^L G$. It is a group ind-scheme over $\mathbb{F}_q$, whose group of $\mathbb{F}_q$ points is identified with ${}^L G(\mathbb{F}_q((t)))$. The results are expected to link such l-adic derived categories to coherent sheaves on spaces related to G-local systems on the punctured formal disc, cf. [35].

4.2. Results of [2], [12], [15]. Some particular results of this type have been achieved in *loc. cit.*

4.2.1. Statement of a result. Recall that the Iwahori subgroup $I \subset {}^L G((\mathbb{F}_q(t)))$ consists of those maps from the punctured formal disc to ${}^L G$, which can be extended to a map from the whole disc, so that the image of the closed point is contained in a fixed Borel subgroup ${}^L B \subset {}^L G$.

We have a group subscheme (pro-algebraic group) $\boldsymbol{I} \subset \boldsymbol{^L G}((t))$, such that $\boldsymbol{I}(\mathbb{F}_q) = I$. The affine flag space $\mathcal{F}\ell$ of ${}^L G$ is the homogeneous space $\boldsymbol{^L G}((t))/\boldsymbol{I}$. It is an ind-algebraic variety such that $\mathcal{F}\ell(\mathbb{F}_q) = {}^L G(\mathbb{F}_q((t)))/I$. The group $\boldsymbol{I}$ acts on $\mathcal{F}\ell$. The orbits of this action, called affine Schubert cells, are in bijection with the affine Weyl group W_{aff}.

Let $\mathcal{P}$ denote the category of perverse sheaves on $\mathcal{F}\ell$, which are equivariant with respect to the prounipotent radical of $\boldsymbol{I}$. Let $\mathcal{P}^I \subset \mathcal{P}$ be the full subcategory of $\boldsymbol{I}$ equivariant sheaves.

Let ${}^{nf}\mathcal{P}^I \subset \mathcal{P}^I$ be the Serre subcategory generated by irreducible objects, corresponding to those $w \in W_{\mathrm{aff}}$, which are not the minimal length representatives of a left W coset. Let ${}^f\mathcal{P} = \mathcal{P}/{}^{nf}\mathcal{P}$ be the Serre quotient category.

Remark 4.1. To clarify the definition of ${}^f\mathcal{P}$ we remark that this category can be also described as the category of Iwahori–Whittaker sheaves [2]. Thus it is related to the Whittaker model, which is one of the main tools in representation theory of reductive groups over local and global fields.

Theorem 4.2. (a) ([15]) *We have a canonical equivalence* $D^b(\mathcal{P}) \cong D^G(\widetilde{\mathfrak{g}} \times_{\mathfrak{g}} \widetilde{\mathcal{N}})$.

(b) ([2]) *We have a canonical equivalence* $D^b({}^f\mathcal{P}) \cong D^G(\widetilde{\mathcal{N}})$. *The image of* ${}^f\mathcal{P}$ *under this equivalence consists of equivariant exotic sheaves.*

The theorem is motivated by the known isomorphisms of Grothendieck groups; the question of possibility of such (or similar) equivalence has been raised, e.g., by V. Ginzburg, see Introduction to [31]. More precisely, the Grothendieck groups of the two categories appearing in Theorem 4.2 (a) are isomorphic to the group algebra of the affine Weyl group of ${}^L G$. A more interesting version of the isomorphism is obtained by replacing the categories by their graded version: $D^G(\widetilde{\mathfrak{g}} \times_{\mathfrak{g}} \widetilde{\mathcal{N}})$ is replaced by $D^{G \times \mathbb{G}_m}(\widetilde{\mathfrak{g}} \times \widetilde{\mathcal{N}})$, while the definition of the graded version of $\mathcal{P}$ is more subtle (cf. Proposition 4.5 below and also [9]). The corresponding Grothendieck groups turn out to be isomorphic to *the affine Hecke algebra*, see [31], [44].

Similarly, the Grothendieck groups of both categories appearing in Theorem 4.2 (b) are identified with the *anti-spherical* module over the extended affine Weyl group,

while in the graded version of the theory we get the anti-spherical module over the affine Hecke algebra. Here by the anti-spherical module we mean the induction of the sign representation from the finite Weyl group (respectively, Hecke algebra) to the affine one.

I would like to emphasize that this isomorphism of the two realizations of the affine Hecke algebra is the key step in the proof of classification of its representations due to Kazhdan and Lusztig [43] (see also [31]), which establishes a particular case of the local Langlands conjecture. This is another illustration of the relation of Theorem 4.2 to local Langlands duality.

The proof of Theorem 4.2 builds on previously known constructions of categories related to G in terms of perverse sheaves on homogeneous spaces for ${}^{\boldsymbol{L}}\boldsymbol{G}((t))$. The first important result is *the geometric Satake isomorphism* [39], [47], [8], which identifies the tensor category $\mathrm{Rep}(G)$ of algebraic representations with the category of perverse sheaves on the affine Grassmannian $\mathcal{G}r = {}^{\boldsymbol{L}}\boldsymbol{G}((t))/{}^{L}\boldsymbol{G}_O$ equivariant with respect to ${}^{L}\boldsymbol{G}_O$. Here ${}^{L}\boldsymbol{G}_O \subset {}^{\boldsymbol{L}}\boldsymbol{G}((t))$ is the group subscheme, such that ${}^{L}\boldsymbol{G}_O(\mathbb{F}_q)$ consists of maps which extend to the non-punctured disc. Furthermore, Gaitsgory [36] used this result to provide a categorification of the description of the *center* of the affine Hecke algebra. Using some ideas of I. Mirković we observe that the so-called Wakimoto sheaves provide a categorification of the maximal abelian subalgebra in the affine Hecke algebra due to Bernstein, see, e.g., [31], [44]. The maximal projective object in the category of sheaves on the finite dimensional flag variety of ${}^{L}G$ smooth along the Schubert stratification, which plays a central role in Soergel's description of category O, cf. [50], is a categorification of the q anti-symmetrizer (an element of the finite Hecke algebra, which acts by zero in all irreducible representation except for the sign representation). Under the equivalence of Theorem 4.2 (a) it corresponds to the structure sheaf of $\widetilde{\mathfrak{g}} \times_{\mathfrak{g}} \widetilde{\mathcal{N}}$. A combination of these ingredients yields a proof of the theorem.

4.2.2. Possible generalizations. It is natural to ask if the multiplication in the affine Hecke algebra corresponds to a monoidal structure on the derived categories of coherent sheaves and constructible sheaves appearing in Theorem 4.2 (a). In order to get such a monoidal structure, we need to replace the categories defined above by closely related ones with the same Grothendieck group. One way to do it is as follows. Let $\boldsymbol{I}'$ be the pro-unipotent radical of $\boldsymbol{I}$. Let $\mathcal{P}'$ be the category of perverse sheaves on "the basic affine space" ${}^{\boldsymbol{L}}\boldsymbol{G}((t))/\boldsymbol{I}'$, which are $\boldsymbol{I}$-monodromic with unipotent monodromy. Then convolution provides the derived category $D^b(\mathcal{P}')$ with a monoidal structure. Notice that this monoidal category does not have a unit object, though this can be repaired by adding some pro-objects to the category, the unit object is then the free pro-unipotent local system on $\boldsymbol{I}/\boldsymbol{I}' \subset {}^{\boldsymbol{L}}\boldsymbol{G}((t))/\boldsymbol{I}'$.

On the dual side we consider the category $D^G(\widetilde{\mathfrak{g}} \times_{\mathfrak{g}} \widetilde{\mathfrak{g}})$. One can show that convolution provides this category with a monoidal structure. Let $\mathrm{Coh}^G(\widetilde{\mathfrak{g}} \times_{\mathfrak{g}} \widetilde{\mathfrak{g}})' \subset \mathrm{Coh}^G(\widetilde{\mathfrak{g}} \times_{\mathfrak{g}} \widetilde{\mathfrak{g}})$ denote the full subcategory of complexes, whose cohomology sheaves are set-theoretically supported on the preimage of $\mathcal{N} \subset \mathfrak{g}$. A standard

argument shows that it yields a full embedding of derived categories $D^G(\widetilde{\mathfrak{g}} \times_{\mathfrak{g}} \widetilde{\mathfrak{g}})' := D^b(\mathrm{Coh}^G(\widetilde{\mathfrak{g}} \times_{\mathfrak{g}} \widetilde{\mathfrak{g}})')$ into $D^G(\widetilde{\mathfrak{g}} \times_{\mathfrak{g}} \widetilde{\mathfrak{g}})$. The full subcategory $D^G(\widetilde{\mathfrak{g}} \times_{\mathfrak{g}} \widetilde{\mathfrak{g}})' \subset D^G(\widetilde{\mathfrak{g}} \times_{\mathfrak{g}} \widetilde{\mathfrak{g}})$ is closed under the convolution product, though it does not contain the unit object $\delta_*(\mathcal{O})$, where $\delta\colon \widetilde{\mathfrak{g}} \to \widetilde{\mathfrak{g}} \times_{\mathfrak{g}} \widetilde{\mathfrak{g}}$ is the diagonal embedding.

It is easy to see that the push-forward (respectively, pull-back) functors $\mathrm{Coh}^G(\widetilde{\mathfrak{g}} \times_{\mathfrak{g}} \widetilde{\mathcal{N}}) \to \mathrm{Coh}^G(\widetilde{\mathfrak{g}} \times_{\mathfrak{g}} \widetilde{\mathfrak{g}})'$, $\mathcal{P} \to \mathcal{P}'$ induce isomorphisms of Grothendieck groups.

Theorem 4.3 ([15]). *We have a natural monoidal equivalence* $D(\mathcal{P}') \cong D^G(\widetilde{\mathfrak{g}} \times_{\mathfrak{g}} \widetilde{\mathfrak{g}})'$.

Remark 4.4. Another version of Theorem 4.2 links the monoidal $\boldsymbol{I}$ equivariant derived category to the monoidal derived category of G-equivariant coherent sheaves on the fiber square of $\widetilde{\mathcal{N}}$ over $\mathfrak{g}$. An additional subtlety in this case is related to nonvanishing of $\mathrm{Tor}^{\mathcal{O}_{\mathfrak{g}}}_{>0}(\mathcal{O}_{\widetilde{\mathcal{N}}}, \mathcal{O}_{\widetilde{\mathcal{N}}})$. One actually has to take these Tor groups into account by working with the *derived fiber product*, which is a differential-graded scheme, rather than an ordinary scheme. This issue does not arise in the other settings mentioned above, because $\mathrm{Tor}^{\mathcal{O}_{\mathfrak{g}}}_{>0}(\mathcal{O}_{\widetilde{\mathfrak{g}}}, \mathcal{O}_{\widetilde{\mathfrak{g}}}) = 0 = \mathrm{Tor}^{\mathcal{O}_{\mathfrak{g}}}_{>0}(\mathcal{O}_{\widetilde{\mathfrak{g}}}, \mathcal{O}_{\widetilde{\mathcal{N}}})$. However, one has to work with differential graded schemes in order to define the convolution product on $D^G(\widetilde{\mathfrak{g}} \times_{\mathfrak{g}} \widetilde{\mathfrak{g}})$.

4.2.3. Relation to the material of Section 2. Many of the constructions from Section 2 are motivated by the equivalences of Theorem 4.2.

For example, the categories $D(\mathcal{P})$, $D(\mathcal{P}')$ carry a natural B_{aff} action by *Radon transforms*, cf. beginning of Section 3.2.2, where a similar structure for a finite dimensional flag variety is mentioned. To define the action we recall that the $\boldsymbol{L}\boldsymbol{G}((t))$ orbits on $\mathcal{F}\ell^2$ are indexed by the affine Weyl group. If $\mathcal{F}\ell^2_w$ is the orbit corresponding to $w \in W_{\mathrm{aff}}$, and $\mathrm{pr}^w_i\colon \mathcal{F}\ell^2_w \to \mathcal{F}\ell$ are the projections, where $i = 1, 2$ then we define a functor $R_w\colon D(\mathcal{P}) \to D(\mathcal{P})$ by $R_w(\mathcal{F}) = \mathrm{pr}^w_{2*}\mathrm{pr}^{w*}_1(\mathcal{F})$. Then we have an action of B_{aff} on $D(\mathcal{P})$, $D({}^f\mathcal{P})$, such that $\widetilde{w} \mapsto R_w$. Under the equivalences of Theorem 4.2 (b) this action corresponds to the action described in Section 2.

Finally, I would like to quote the statement that allows to link the grading on Ext spaces appearing in Theorem 2.19 to Frobenius weights, thus providing a way to prove Theorem 2.19. To state it we introduce the following notation. Let Φ be either of the two equivalences appearing in Theorem 4.2. Let Fr be the autoequivalence of the corresponding category of constructible sheaf, sending a sheaf to its pull-back under the Frobenius morphism. Let $\boldsymbol{q}$ be an automorphism of either $\widetilde{\mathcal{N}}$ or $\widetilde{\mathfrak{g}} \times_{\mathfrak{g}} \widetilde{\mathcal{N}}$ given by $(\mathfrak{b}, x) \mapsto (\mathfrak{b}, qx)$ or $(\mathfrak{b}_1, \mathfrak{b}_2, x) \mapsto (\mathfrak{b}_1, \mathfrak{b}_2, qx)$ respectively; here q stands for the cardinality of the base finite field $\mathbb{F}_q$.

Proposition 4.5 (cf. [2]). *We have a canonical isomorphism* $\Phi \circ \boldsymbol{q}^* \cong \mathrm{Fr} \circ \Phi$.

Spaces of quasi-maps into the flag varieties and their applications

Alexander Braverman

Abstract. Given a projective variety X and a smooth projective curve C one may consider the moduli space of maps $C \to X$. This space admits certain compactification whose points are called quasi-maps. In the last decade it has been discovered that in the case when X is a (partial) flag variety of a semi-simple algebraic group G (or, more generally, of any symmetrizable Kac–Moody Lie algebra) these compactifications play an important role in such fields as geometric representation theory, geometric Langlands correspondence, geometry and topology of moduli spaces of G-bundles on algebraic surfaces, 4-dimensional super-symmetric gauge theory (and probably many others). This paper is a survey of the recent results about quasi-maps as well as their applications in different branches of representation theory and algebraic geometry.

Mathematics Subject Classification (2000). Primary 22E46; Secondary 14J60, 14J81.

Keywords. Quasi-maps, Schubert varieties, geometric Langlands duality, supersymmetric gauge theory.

1. Introduction

The spaces of quasi-maps into the flag varieties were introduced by V. Drinfeld about 10 years ago and since then proved to play an important role in various parts of geometric representation theory; more recently it was discovered that some related constructions are useful also in more classical algebraic geometry as well as in some questions coming from mathematical physics.

This paper constitutes at attempt to give a more or less self-contained presentation of the results related to such spaces. The origin of quasi-maps is as follows: let C be a smooth projective algebraic curve (over an algebraically closed field k) and let $X \subset \mathbb{P}^N$ be a projective variety over k. One can look at the space $\mathrm{Maps}^d(C, X)$ of maps $C \to X$ such that the composite map $C \to X \to \mathbb{P}^N$ has degree $d \in \mathbb{Z}_+$. These are quasi-projective schemes of finite type; in many problems of both representation theory and algebraic geometry it is important to have a natural compactification of this scheme; one compactification of this sort is provided by the space $\mathrm{QMaps}^d(C, X)$ of *quasi-maps* from C to X (cf. Section 2 for the precise definition). The main property

Proceedings of the International Congress of Mathematicians, Madrid, Spain, 2006

of the scheme $\mathrm{QMaps}^d(C, X)$ is that it possesses a stratification of the form

$$\mathrm{QMaps}^d(C, X) = \bigcup_{d'=0}^{d} \mathrm{Maps}^{d'}(C, X) \times \mathrm{Sym}^{d-d'}(C)$$

where $\mathrm{Sym}^a(C)$ denote the a-th symmetric power of the curve C. In other words, in order to specify a point of $\mathrm{QMaps}^d(C, X)$ one must specify an honest map $C \to X$ of degree $d' \leq d$ together with $d - d'$ unordered points of C.

We must warn the reader from the very beginning that the scheme $\mathrm{QMaps}^d(C, X)$ depends on the embedding $X \subset \mathbb{P}^N$. However, in many cases such an embedding is given to us in the original problem. More generally, when X is a closed subscheme of a product $\mathbb{P}^{N_1} \times \cdots \times \mathbb{P}^{N_l}$ we may speak about $\mathrm{QMaps}^{d_1,\ldots,d_l}(C, X)$. For example, if X is the complete flag variety of a semi-simple algebraic group G then X has a canonical embedding as above (in this case l is the rank of G). We discuss the details in Section 2.

We then turn to applications of quasi-maps. In Section 3 we explain the relation between quasi-maps spaces and the so-called *semi-infinite Schubert varieties*. In particular, we explain the calculation of the Intersection Cohomology sheaf of the quasi-maps spaces and relate it to Lusztig's periodic polynomials. We also mention that quasi-maps could be used to construct some version of the category of perverse sheaves on the (still not rigorously defined) *semi-infinite flag variety* and relate this category with the category of representations of the so-called *small quantum group*.

In Section 4 we discuss the results of [10] where the stacks $\overline{\mathrm{Bun}}_B$ are used in order to construct the so-called *geometric Eisenstein series* (thus the contents of [10] have to do with application of the stacks $\overline{\mathrm{Bun}}_B$ (which are close relatives of the scheme $\mathrm{QMaps}(C, X)$) to geometric Langands correspondence; the rest of the paper is independent of this section and therefore and can be easily skipped by a non-interested reader).

In Section 5 we discuss quasi-maps into affine (partial) flag varieties and their relation to the Uhlenbeck compactifications of moduli spaces of G-bundles on algebraic surfaces. In Section 6 we explain how to apply these constructions to certain enumerative questions related to quantum cohomology of the flag manifolds as well as to $N = 2$ super-symmetric 4-dimensional gauge theory. Section 7 is devoted to the discussion of some open questions related to the above subjects.

Acknowledgements. This paper is mostly based on the author's joint papers with various people including S. Arkhipov, R. Bezrukavnikov, P. Etingof, M. Finkelberg, D. Gaitsgory and I. Mirkovic; I am grateful to all of them for being very fruitful and patient collaborators. I am also grateful to J. Bernstein, V. Drinfeld and D. Kazhdan for their constant guidance and to H. Nakajima, N. Nekrasov and A. Okounkov for interesting and illuminating discussions related to Section 6 of this paper.

2. Definition of quasi-maps

In this section we introduce quasi-maps' spaces and some of their relatives. The reader may skip the details for most applications.

2.1. Maps and quasi-maps into a projective variety. Let X be a closed subvariety of the projective space $\mathbb{P}^N$ and let C be a smooth projective curve. For any integer $d \geq 0$ we may consider the space $\mathrm{Maps}^d(C, X)$ consisting of maps $C \to X$ such that the composition $C \to X \to \mathbb{P}^N$ has degree d. This space has a natural scheme structure and it is in fact quasi-projective. However, it is well known that in general it does not have to projective (in fact it is almost never projective).

Example. Let $X = \mathbb{P}^N$. In this case $\mathrm{Maps}^d(C, X)$ classifies the following data:

- A line bundle $\mathcal{L}$ on C of degree $-d$.
- An embedding of vector bundles $\mathcal{L} \hookrightarrow \mathcal{O}_C^{N+1}$.

The reason is that every such embedding defines a one-dimensional subspace in $\mathbb{C}^{N+1}$ for every point $c \in C$ and thus we get a map $C \to \mathbb{P}^N$.

Consider, for example, the case when $C = \mathbb{P}^1$. In that case $\mathcal{L}$ must be isomorphic to the line bundle $\mathcal{O}_{\mathbb{P}^1}(-d)$ (note that such an isomorphism is defined uniquely up to a scalar) and thus $\mathrm{Maps}^d(\mathbb{P}^1, \mathbb{P}^N)$ becomes an open subset in the projectivization of the vector space $\mathrm{Hom}(\mathcal{O}_{\mathbb{P}^1}(-d), \mathcal{O}_{\mathbb{P}^1}^{N+1}) \simeq \mathbb{C}^{(N+1)(d+1)}$, i.e. $\mathrm{Maps}^d(\mathbb{P}^1, \mathbb{P}^N)$ is an open subset of $\mathbb{P}^{(N+1)(d+1)-1}$. The reason that it does not coincide with it is that not every non-zero map $\mathcal{O}_{\mathbb{P}^1}(-d) \to \mathcal{O}_{\mathbb{P}^1}^{N+1}$ gives rise a map $\mathbb{P}^1 \to \mathbb{P}^N$ – we need to consider only those maps which do not vanish in every fiber.

The above example suggests the following compactification of $\mathrm{Maps}^d(C, X)$. Namely, we define the space of *quasi-maps from C to X of degree d* (denoted by $\mathrm{QMaps}^d(C, X)$) to be the scheme classifying the following data:

1) A line bundle $\mathcal{L}$ on C of degree $-d$.

2) A non-zero map $\kappa\colon \mathcal{L} \to \mathcal{O}_C^{N+1}$.

3) Note that κ defines an honest map $U \to \mathbb{P}^N$ where U is an open subset of C. We require that the image of this map lies in X.

For example it is easy to see that if $X = \mathbb{P}^N$ and $C = \mathbb{P}^1$ then $\mathrm{QMaps}^d(C, X) \simeq \mathbb{P}^{(N+1)(d+1)-1}$.

In general $\mathrm{QMaps}^d(C, X)$ is projective. Also, set-theoretically it can be explicitly described in the following way. Assume that we are given a quasi-map $(\mathcal{L}, \kappa)$ as above. Then κ might have zeros at points $c_1, \ldots, c_k$ of C of order $a_1, \ldots, a_k$ respectively. On the other hand, it follows from 3) above that κ defines an honest map from the complement to the points $c_1, \ldots, c_k$ to X. Since X is projective this map can be extended to the whole of C. Let us call this map κ'. It is easy to see that κ' has degree $d - \sum a_i$. Also one can recover κ from κ' and the collection $(c_1, a_1), \ldots, (c_k, a_k)$. Thus it follows that $\mathrm{QMaps}^d(C, X)$ is equal to the disjoint union of locally closed

subvarieties of the following form:

$$\mathrm{QMaps}^d(C, X) = \bigcup_{0 \leq d' \leq d} \mathrm{Maps}^{d'}(C, X) \times \mathrm{Sym}^{d-d'}(C). \tag{2.1}$$

Here $\mathrm{Sym}^{d-d'}(C)$ denotes the corresponding symmetric power of C.

Here is a generalization of the above construction. Assume that X is embedded into a product $\mathbb{P}^{N_1} \times \cdots \times \mathbb{P}^{N_k}$ of projective spaces. Then, in a similar fashion one can talk about $\mathrm{Maps}^{d_1,\ldots,d_l}(C, X)$ (here all $d_i \geq 0$) and $\mathrm{QMaps}^{d_1,\ldots,d_l}(C, X)$.

2.2. The case of complete flag varieties. Let now G be a semi-simple simply connected algebraic group over k and let $\mathfrak{g}$ denote its Lie algebra. We want to take X to be the complete flag variety of G. If we choose a Borel subgroup B of G then $X = G/B$. We shall sometimes denote this variety by $X_{G,B}$ (later we shall also consider the *partial flag varieties* G/P associated with a parabolic subgroup $P \subset G$; this variety will be denoted by $X_{G,P}$).

Let $V_1, \ldots, V_l$ denote the fundamental representations of G. It is well known that $X_{G,B}$ has a canonical (Plücker) embedding into $\prod_{i=1}^{l} \mathbb{P}(V_i^*)$. This enables us to talk about quasi-maps into X.

We can describe the set of parameters $(d_1, \ldots, d_l)$ in a little bit more invariant terms. First, let us denote by T the Cartan group of G and let Λ_G denote the coweight lattice of G; by definition $\Lambda_G = \mathrm{Hom}(\mathbb{C}^*, T)$ (in the case $k = \mathbb{C}$). We have the natural well-known identification $\Lambda_G = H_2(X, \mathbb{Z})$. This allows us to talk about maps $C \to X$ of degree $\theta \in \Lambda_G$. Also if we let $(\omega_1, \ldots, \omega_l)$ denote the fundamental weights of G then we can also identify Λ_G with $\mathbb{Z}^l$ by sending a coweight θ to $d_1 = (\theta, \omega_1), \ldots d_l = (\lambda, \theta_l)$. Under these identification $\mathrm{Maps}^{\theta}(C, X)$ is the same as $\mathrm{Maps}^{d_1,\ldots,d_l}(C, X)$ in the sense of the previous subsection. It is also clear that this space may be non-empty only if all $d_i \geq 0$. We say that θ is positive if all $d_i \geq 0$ and denote the semigroup of all positive θ's by Λ_G^+.

In the case $C = \mathbb{P}^1$ we shall denote the space $\mathrm{Maps}^{\theta}(C, X_{G,B})$ by $\mathcal{M}^{\theta}_{G,B}$ and the space $\mathrm{QMaps}^{\theta}(C, X_{G,B})$ by $\mathcal{QM}^{\theta}_{G,B}$.

2.3. Laumon's resolution. Consider the case $G = \mathrm{SL}(n)$ (thus $l = n - 1$). In this case $X_{G,B}$ is just the variety of complete flags $0 \subset V_1 \subset V_2 \subset \cdots \subset V_n = \mathbb{C}^n$, $\dim V_i = i$. Thus, a map $C \to X_{G,B}$ is the same as a complete flag of subbundles

$$0 \subset \mathcal{V}_1 \subset \mathcal{V}_2 \subset \cdots \subset \mathcal{V}_n = \mathcal{O}_C^n.$$

where the rank of $\mathcal{V}_i$ is equal to i. Also we have $d_i = -\deg \mathcal{V}_i$.

Define now the space $\mathrm{QMaps}^{L,\theta}(C, X_{G,B})$ to consist of all flags as above where $\mathcal{V}_i$ is an arbitrary *subsheaf* of $\mathcal{O}_C^n$ of degree $-d_i$. The space was considered by G. Laumon in [32]. It is known (cf. [30]) that the natural open embedding of $\mathrm{Maps}^{\theta}(C, X_{G,B})$ into both $\mathrm{QMaps}^{\theta}(C, X_{G,B})$ and $\mathrm{QMaps}^{L,\theta}(C, X_{G,B})$ extends to a projective morphism $\mathrm{QMaps}^{L,\theta}(C, X_{G,B}) \to \mathrm{QMaps}^{\theta}(C, X_{G,B})$. In the case $C = \mathbb{P}^1$ the space

$\mathrm{QMaps}^{L,\theta}(\mathbb{P}^1, X_{G,B})$ is smooth and provides in fact a small resolution of singularities of $\mathrm{QMaps}^{\theta}(\mathbb{P}^1, X_{G,B})$.

2.4. The stacks $\overline{\mathbf{Bun}}_{\boldsymbol{B}}$. Let us fix a curve C as above and let G again be a semi-simple simply connected algebraic group with a Borel subgroup B (more generally, one can assume that G is any reductive group whose derived group is simply connected; e.g. one may also consider the case $G = \mathrm{GL}(n)$). We may consider the algebraic stack $\mathrm{Bun}_G = \mathrm{Bun}_G(C)$ classifying principal algebraic G-bundles on C. Similarly we may consider the stack Bun_B which classifies B-bundles. The embedding $B \to G$ gives rise to a the natural morphism $p\colon \mathrm{Bun}_B \to \mathrm{Bun}_G$. In the case $G = \mathrm{GL}(n)$ the stack Bun_G classifies vector bundles of rank n on C and the stack Bun_B classifies flags of the forms

$$0 \subset \mathcal{V}_1 \subset \mathcal{V}_2 \subset \cdots \subset \mathcal{V}_n$$

where each $\mathcal{V}_i$ is a vector bundle of rank i on C and the embedding $\mathcal{V}_i \to \mathcal{V}_{i+1}$ are embeddings of vector bundles.

We have the natural projection $B \to T$ (where T as before denotes the Cartan group of G). Hence we also have the natural map $q\colon \mathrm{Bun}_B \to \mathrm{Bun}_T$. In the case $G = \mathrm{GL}(n)$ considered above the group T can be thought of as the group of diagonal matrices; hence T is naturally isomorphic to $\mathbb{G}_m^n$. [1] Thus Bun_T classifies n-tuples $(\mathcal{L}_1, \ldots, \mathcal{L}_n)$ of line bundles on C. In terms of the above description of Bun_B the map q sends any flag $0 \subset \mathcal{V}_1 \subset \mathcal{V}_2 \subset \cdots \subset \mathcal{V}_n$ to $(\mathcal{V}_1, \mathcal{V}_2/\mathcal{V}_1, \ldots, \mathcal{V}_n/\mathcal{V}_{n-1})$.

It is easy to see that in general the connected components of Bun_T are classified by elements of the lattice $\Lambda_G = \Lambda_T$. For each $\theta \in \Lambda_G$ we set $\mathrm{Bun}_B^{\theta} = q^{-1}(\mathrm{Bun}_T^{\theta})$. It is easy to see that the assignment $\theta \mapsto \mathrm{Bun}_B^{\theta}$ also defines a bijection between Λ_G and the set of connected components of Bun_B.

For each $\theta \in \Lambda_G$ the map $p\colon \mathrm{Bun}_B^{\theta} \to \mathrm{Bun}_G$ is representable. Moreover, it is clear that the fiber of this map over the trivial bundle in Bun_G is exactly our space $\mathrm{Maps}^{\theta}(C, X_{G,B})$ (note that the stack Bun_B^{θ} exists for any $\theta \in \Lambda_G$ but its fiber over the trivial bundle is non-empty only if $\theta \in \Lambda_G^+$). In general, the fibers of p (for fixed θ) are quasi-projective (but not projective) varieties; for various purposes (discussed, in particular, in other parts of this paper) it is useful to have a relative compactification $\overline{\mathrm{Bun}}_B^{\theta} \to \mathrm{Bun}_G$ such that its fiber over the trivial bundle in Bun_G will be exactly $\mathrm{QMaps}^{\theta}(C, X_{G,B})$. Such a compactification indeed can be constructed; let us give its explicit description (in particular, this will give a slightly different (but equivalent) definition of $\mathrm{QMaps}^{\theta}(C, X_{G,B})$.

We want to define $\overline{\mathrm{Bun}}_B$ as a solution to some moduli problem. Since $\overline{\mathrm{Bun}}_B$ is going to be an algebraic stack we must define the *groupoid* of S-points of $\overline{\mathrm{Bun}}_B$ for any scheme S over $\mathbb{C}$.

Let $\check{\Lambda}_G$ be the dual lattice of Λ_G. This is the weight lattice of the group G [2] We

[1] Here $\mathbb{G}_m$ denotes the multiplicative group

[2] The reader may find this notation a bit bizarre, since usually one uses the $\check{}$-notation for coweights and not for weights. However, it turns out that here it is much more convenient to use our notation; the main reason for this

define an S-point of $\overline{\mathrm{Bun}}_B$ to be a triple $(\mathcal{F}_G, \mathcal{F}_T, \kappa^{\check{\lambda}},\ \forall \check{\lambda} \in \check{\Lambda}_G^+)$, where $\mathcal{F}_G$ and $\mathcal{F}_T$ are as above, and $\kappa^{\check{\lambda}}$ is a map of coherent sheaves

$$\mathcal{L}^{\check{\lambda}}_{\mathcal{F}_T} \hookrightarrow \mathcal{V}^{\check{\lambda}}_{\mathcal{F}_G},$$

such that for every geometric point $s \in S$ the restriction $\kappa^{\check{\lambda}}|_{X\times s}$ is an injection. The last condition is equivalent to saying that $\kappa^{\check{\lambda}}$ is an injection such that the quotient $\mathcal{V}^{\check{\lambda}}_{\mathcal{F}_G}/\operatorname{Im}(\kappa^{\check{\lambda}})$ is S-flat.

The system of embeddings $\kappa^{\check{\lambda}}$ must satisfy the so-called *Plücker relations* which can be formulated as follows.

First, for $\check{\lambda} = 0$, κ^0 must be the identity map $\mathcal{O} \simeq \mathcal{L}^0_{\mathcal{F}_T} \to \mathcal{V}^0_{\mathcal{F}_G} \simeq \mathcal{O}$. Secondly, for two dominant integral weights $\check{\lambda}$ and $\check{\mu}$, the map

$$\mathcal{L}^{\check{\lambda}}_{\mathcal{F}_T} \otimes \mathcal{L}^{\check{\mu}}_{\mathcal{F}_T} \xrightarrow{\kappa^{\check{\lambda}}\otimes\kappa^{\check{\mu}}} \mathcal{V}^{\check{\lambda}}_{\mathcal{F}_G} \otimes \mathcal{V}^{\check{\mu}}_{\mathcal{F}_G} \simeq (\mathcal{V}^{\check{\lambda}} \otimes \mathcal{V}^{\check{\mu}})_{\mathcal{F}_G}$$

must coincide with the composition

$$\mathcal{L}^{\check{\lambda}}_{\mathcal{F}_T} \otimes \mathcal{L}^{\check{\mu}}_{\mathcal{F}_T} \simeq \mathcal{L}^{\check{\lambda}+\check{\mu}}_{\mathcal{F}_T} \xrightarrow{\kappa^{\check{\lambda}+\check{\mu}}} \mathcal{V}^{\check{\lambda}+\check{\mu}}_{\mathcal{F}_G} \to (\mathcal{V}^{\check{\lambda}} \otimes \mathcal{V}^{\check{\mu}})_{\mathcal{F}_G}.$$

It is easy to see that if all the maps $\kappa^{\check{\lambda}}$ are *embeddings of subbundles* (i.e. $\kappa^{\check{\lambda}}$ does not vanish on any fiber over any $c \in C$ then the collection $(\mathcal{F}_G, \mathcal{F}_T)$ together with all $\kappa^{\check{\lambda}}$ defines a point of Bun_B.

Here is another (somewhat more geometric) definition of $\overline{\mathrm{Bun}}_B$ (note that restricting to the fiber over the trivial bundle we get yet another definition of $\mathrm{QMaps}^{\theta}(C, X)$.

Let us denote by $U \subset B$ the unipotent radical of B. Since we have the natural isomorphism $G/U = T$ it follows that the variety G/U is endowed with a natural right action of T (of course, it also has a natural left G-action).

It is now easy to see that the stack Bun_B classifies the following data:

$$(\mathcal{F}_G;\, \mathcal{F}_T;\, \kappa\colon \mathcal{F}_G \to G/U \overset{T}{\times} \mathcal{F}_T),$$

where $\mathcal{F}_G$ is a G-bundle, $\mathcal{F}_T$ is a T-bundle and κ is a G-equivariant map.

Recall that G/U is a quasi-affine variety and let $\overline{G/U}$ denote its affine closure. The groups G and T act on G/U and therefore also on $\overline{G/U}$. The basic example of these varieties that one should keep in mind is the case $G = \mathrm{SL}(2)$. In this case G/U can be naturally identified with $\mathbb{A}^2\backslash\{0\}$ and $\overline{G/U} = \mathbb{A}^2$ (here $\mathbb{A}^2$ denotes the affine plane).

We claim now that an S-point of $\overline{\mathrm{Bun}}_B$ is the same as a triple $(\mathcal{F}_G, \mathcal{F}_T, \kappa)$, where $\mathcal{F}_G$ (resp., $\mathcal{F}_T$) is an S-point of Bun_G (resp., of Bun_T) and κ is a G-equivariant map

$$\mathcal{F}_G \to \overline{G/U} \overset{T}{\times} \mathcal{F}_T,$$

comes from the fact that many results will be formulated in terms of the Langlands dual group $\check{G}$ whose *weight* lattice is Λ_G!

such that for every geometric point $s \in S$ there is a Zariski-open subset $C^0 \subset C \times s$ such that the map

$$\kappa|_{C^0} : \mathcal{F}_G|_{C^0} \to \overline{G/U} \overset{T}{\times} \mathcal{F}_T|_{C^0}$$

factors through $G/U \overset{T}{\times} \mathcal{F}_T|_{C^0} \subset \overline{G/U} \overset{T}{\times} \mathcal{F}_T|_{C^0}$.

2.5. Quasi-maps into partial flag varieties. Let now $P \subset G$ be an arbitrary parabolic subgroup of G. Then as before we may consider the stack Bun_P of principal P-bundles on C; this stack is again naturally mapped to Bun_G and we would like to find some natural relative compactification of it. It turns out that in this case there exist *two different* natural compactifications $\overline{\mathrm{Bun}}_P$ and $\widetilde{\mathrm{Bun}}_P$ such that the embedding of Bun_P into both of them extends to a projective morphism $\widetilde{\mathrm{Bun}}_P \to \overline{\mathrm{Bun}}_P$. We refer the reader to [10] for the corresponding definitions. Here we shall only explain the geometric source for the existence of two such compactifications.

As was explained above the stacks $\overline{\mathrm{Bun}}_B$ are closely related with the varieties G/U and their affine closures $\overline{G/U}$; it is of crucial importance that G/U has a free T-action such that $(G/U)/T = G/B$.

Given a parabolic subgroup P as above one can attach two quasi-affine G-varieties to it: the first one is $G/[P, P]$ and the second one is G/U_P (here U_P denotes the unipotent radical of P; note that if P is a Borel subgroup of G then $[P, P] = U_P$). Let M denote the Levi group of P; by definition $M = P/U_P$. Also, one has the natural isomorphism $P/[P, P] = M/[M, M]$. Thus the first variety has a natural free action of $M/[M, M]$ and the second has an action of M; moreover, one has $(G/[P, P])/(M/[M, M]) = G/P = (G/U_P)/M$. Thus one can use the quasi-affine closures of $G/[P, P]$ and of G/U_P to construct two relative compactifications $\overline{\mathrm{Bun}}_P$ and $\widetilde{\mathrm{Bun}}_P$ of the stack Bun_P in the way similar to what was explained above for $P = B$.

Taking the fibers of the above stacks over the trivial bundle in Bun_G we get two different versions of quasi-maps from C to $G/P = X_{G,P}$. In what follows we shall denote by $\mathcal{QM}^{\theta}_{G,P}$ the space of quasi-maps $\mathbb{P}^1 \to X_{G,P}$ coming from $\overline{\mathrm{Bun}}_P$ (the compactification having to do with the variety G/P). Here θ should be a positive element of the lattice $\Lambda_{G,M}$ which is the lattice of cocharacters of $M/[M, M]$.

It turns out that many of the above definitions may be given also when $\mathfrak{g}$ is replaced by an affine Kac–Moody Lie algebra; the corresponding spaces of maps and quasi-maps are closely related to moduli spaces of G-bundles on a rational algebraic surface. This will be discussed in Section 5 (for more details the reader should consult [8]).

3. Quasi-maps into flag varieties and semi-infinite Schubert varieties

3.1. Ordinary Schubert varieties and their singularities. Let G as a before be a semi-simple simply connected algebraic group and let B be a Borel subgroup of it.

Recall that we denote $X_{G,B} = G/B$. It is well known that the set of B-orbits on $X_{G,B}$ is in one-to-one correspondence with the elements of the Weyl group W of G. For each $w \in W$ we denote the corresponding orbit by $X^w_{G,B}$. It is also known that each $X^w_{G,B}$ is isomorphic to the affine space $\mathbb{A}^{\ell(w)}$ where $\ell\colon W \to \mathbb{Z}_+$ is the length function.

The closure $\overline{X}^w_{G,B} \subset X_{G,B}$ of $X^w_{G,B}$ is usually called the Schubert variety attached to W. The singularities of these varieties play a very important role in various branches of representation theory. It is known (cf. [14] and references therein) that these varieties are normal and have rational singularities. Let $\mathrm{IC}^w_{G,B}$ denote the intersection cohomology sheaf of $X^w_{G,B}$. It is also well known that the stalks of $\mathrm{IC}^w_{G,B}$ can be described in terms of the *Kazhdan–Lusztig polynomials* attached to W (cf. [29]).

More generally, given two parabolic subgroups $P, Q \subset G$ one may study the closures of Q-orbits on G/P; these are the most general *parabolic Schubert varieties*. The stalks of their IC-sheaves are computed by *parabolic Kazhdan–Lusztig polynomials*.

One can generalize the above construction to the loop (or affine) groups associated with G. Namely, given a parabolic subgroup P as above one may construct two different affine flag varieties $X^{\mathrm{aff}}_{G,P}$ and $\boldsymbol{X}^{\mathrm{aff}}_{G,P}$ associated with the pair G, P. We shall refer to the first one as the corresponding *thin flag affine partial flag variety* and to the second one as the *thick partial affine flag variety* (in principle, there exist more general partial affine flag varieties but we shall never consider them in this paper). Set-theoretically, we can describe $X^{\mathrm{aff}}_{G,P}$ and $\boldsymbol{X}^{\mathrm{aff}}_{G,P}$ as follows.

Let $\mathcal{K} = \mathbb{C}((t))$ be the field of formal Laurent power series; let $\mathcal{O} \subset \mathcal{K}$ be the ring of Taylor series. Consider the "loop" group $G(\mathcal{K})$ of $\mathcal{K}$-points of G. Let $I_P \subset G(\mathcal{K})$ denote the subgroup of $G(\mathcal{O}) \subset G(\mathcal{K})$ consisting of those Taylor series whose value at $t = 0$ lies in $P \subset G$. When $P = B$ is a Borel subgroup we shall write just I instead of I_B and call it the Iwahori subgroup of $G((t))$. We shall also denote by $I^0 \subset I$ its pro-unipotent radical (it consists of those Taylor series as above whose value at $t = 0$ lies in the unipotent radical U of B). Note also that when $P = G$ we have $I_G = G(\mathcal{O})$.

Similarly, we can define the group $\boldsymbol{I}_P \subset G[t^{-1}]$ consisting of those polynomials in t^{-1} whose value at $t = \infty$ lies in P. Thus on level of $\mathbb{C}$-points we have

$$X^{\mathrm{aff}}_{G,P} = G(\mathcal{K})/I_P; \quad \boldsymbol{X}^{\mathrm{aff}}_{G,P} = G(\mathcal{K})/\boldsymbol{I}_P.$$

We shall be mostly talking about Schubert varieties in $X^{\mathrm{aff}}_{G,P}$ (the flag varieties $\boldsymbol{X}^{\mathrm{aff}}_{G,P}$ will also appear in Section 5 of this paper). By definition, these are closures of I_Q-orbits in some $X^{\mathrm{aff}}_{G,P}$. These are known to be finite-dimensional normal projective varieties having rational singularities (cf. [14]). In the case when $P = Q = B$ (i.e. when we are dealing with I-orbits on $X^{\mathrm{aff}}_{G,B}$) the orbits are classified by elements of the affine Weyl group W_{aff} (by definition, this is the semi-direct product of the Weyl group W of G and the lattice Λ_G). At the other extreme, when $P = Q = G$ we are dealing with $G(\mathcal{O})$-orbits on $G(\mathcal{K})/G(\mathcal{O})$; these orbits are in one-to-one correspondence

with Λ_G/W. The latter set can be identified with the set of dominant weights of the Langlands dual group $\check{G}$.

One of the reasons that the complete flag variety $X_{G,B}$ plays a distinguished role in representation theory is the Beilinson–Bernstein localization theorem (cf. [4]) which allows one to realize representations of the Lie algebra $\mathfrak{g}$ (with fixed central character of the universal enveloping algebra $U(\mathfrak{g})$) in terms of algebraic D-modules on $X_{G,B}$. In this way the category of B-equivariant (or, more generally, U-equivariant) modules corresponds to the regular block of the so-called category $\mathcal{O}$. Similar (but much less understood) statements hold in the affine case too. Namely let $\mathfrak{g}_{\mathrm{aff}}$ denote the affine Lie algebra corresponding to $\mathfrak{g}$. By definition this algebra is a central extension of the loop algebra $\mathfrak{g}((t))$:

$$0 \to \mathbb{C} \to \mathfrak{g}_{\mathrm{aff}} \to \mathfrak{g}((t)) \to 0.$$

Then one gets a geometric realization (of some part of) the category for the corresponding affine Lie algebra $\mathfrak{g}_{\mathrm{aff}}$; the variety $X^{\mathrm{aff}}_{G,B}$ allows to realize $\mathfrak{g}_{\mathrm{aff}}$-modules at the negative level and the variety $\boldsymbol{X}^{\mathrm{aff}}_{G,B}$ has to do with $\mathfrak{g}_{\mathrm{aff}}$-modules on the positive level. We refer the reader to [27] and references therein for more details.

3.2. The semi-infinite flag manifold. The semi-infinite flag manifold $X^{\frac{\infty}{2}}_{G,B}$ is usually defined as the quotient $G(\mathcal{K})/T(\mathcal{O}) \cdot U(\mathcal{K})$. In terms of algebraic geometry this "space" seems to be widely infinite-dimensional. However, one still would like to think of it as some kind of geometric object; this should have many applications to representation theory.

More specifically, we would like to mention the following two problems:

1) Construct the category of D-modules (or perverse sheaves) on $X^{\frac{\infty}{2}}_{G,B}$ and relate it to some other abelian categories coming from representation theory of affine Lie algebras and quantum groups.

2) It is easy to see that the orbits of the Iwahori group I on $X^{\frac{\infty}{2}}_{G,B}$ are classified by elements of the affine Weyl group W_{aff} attached to G. We shall denote by $X^{w,\frac{\infty}{2}}_{G,B}$ the orbit corresponding to $w \in W_{\mathrm{aff}}$. Then the problem reads as follows: explain in what sense the singularities of the closures of $\overline{X}^{w,\frac{\infty}{2}}_{G,B}$ are finite-dimensional and "understand" those singularities. In particular, one should be able to compute the stalks of the IC-sheaves associated to those singularities and relate them to the periodic polynomials defined in [36]. More generally, one can study I_P-orbits on $X^{\frac{\infty}{2}}_{G,B}$ together with their closures. We shall refer to them as the (not yet constructed) *semi-infinite Schubert varieties*.

In particular, the $G(\mathcal{O})$-orbits on $X^{\frac{\infty}{2}}_{G,B}$ are classified by elements of Λ_G; for each $\mu \in \Lambda_G$ we shall denote the corresponding orbit simply by S^μ. It is easy to see that if the closure $\overline{S}^\mu$ of S^μ makes any reasonable sense then it must be equal to the union of all S^ν's with $\nu - \mu \in \Lambda^+_G$. Also, the lattice $\Lambda_G = T(\mathcal{K})/T(\mathcal{O})$ acts on $X^{\frac{\infty}{2}}_{G,B}$ on the right and every $\gamma \in \Lambda_G$ maps the orbit S^μ to $S^{\mu+\gamma}$. Hence the singularity of $\overline{S}^\mu$

in the neighborhood of a point of S^ν depends only on $\nu - \mu \in \Lambda_G^+$. In particular, if the intersection cohomology sheaf $\mathrm{IC}(\overline{S}^\mu)$ makes sense, then its stalk at a point of S^ν should only depend on $\nu - \mu = \theta$. In fact, from the results of [35], [36] and references therein it is natural to expect that this stalk comes from the graded vector space U_θ computed as follows: let $\check{\mathfrak{g}}$ denote the Langlands dual Lie algebra whose root system is dual to that of $\mathfrak{g}$. We have its triangular decomposition $\check{\mathfrak{g}} = \check{\mathfrak{n}}_- \oplus \check{\mathfrak{t}} \oplus \check{\mathfrak{n}}_+$. Also $\check{\mathfrak{t}} = \mathfrak{t}^*$ and we may identify Λ_G with the root lattice $\check{\mathfrak{g}}$. Consider the symmetric algebra $\mathrm{Sym}(\mathfrak{n}_+)$ with the natural even grading on it (defined by the requiring that the subspace $\check{\mathfrak{n}}_+ \subset \mathrm{Sym}(\mathfrak{n}_+)$ has degree 2). The dual Cartan torus $\check{T}$ acts on this algebra (since it acts on $\mathfrak{n}_+$); for each $\theta \in \Lambda_G^+$ we may consider the subspace $\mathrm{Sym}(\mathfrak{n}_+)_\theta \subset \mathrm{Sym}(\mathfrak{n}_+)$ on which $\check{T}$ acts by the character θ. This space inherits the grading from $\mathrm{Sym}(\mathfrak{n}_+)$. Let also $\check{\rho} \in \check{\Lambda}_G$ denote the half-sum of the positive roots of G. Then, guided by the results of *loc. cit.* one expects to have

$$U_\theta \simeq \mathrm{Sym}(\mathfrak{n}_+)_\theta[2\langle\theta, \check{\rho}\rangle]. \tag{3.1}$$

The general principle (due to Drinfeld) says that one should be able to use the quasi-maps spaces $\mathcal{QM}^\theta_{G,B}$ (or, the stacks $\overline{\mathrm{Bun}}_B$ for any smooth projective curve C) as "finite-dimensional models" for the semi-infinite flag manifolds and the semi-infinite Schubert varieties. In particular, one expects to be able construct the correct category of D-modules using quasi-maps as well as to turn (3.1) into a mathematical theorem. This has indeed been performed in the works [1], [15] and [9]. Let us give a brief sketch of the results of *loc. cit.*

3.3. Localization theorem for the small quantum group. Let us turn to some illustrations of the above principle. First of all, in [1] we propose a definition of the category $\mathrm{Perv}(X^{\frac{\infty}{2}}_{G,B})$ in terms of the stacks $\overline{\mathrm{Bun}}_B$. We give a representation-theoretic interpretation of the corresponding subcategory $\mathrm{Perv}_{I^0}(X^{\frac{\infty}{2}}_{G,B})$ consisting of I^0-equivariant perverse sheaves; it turns out to be equivalent to the *regular block* of category of graded representations of the so-called *small quantum group* $\mathfrak{u}_\ell$ attached to the Lie algebra $\mathfrak{g}$; here ℓ denotes a root of unity satisfying some mild assumptions (cf. [1] for more details). This result was conjectured by B. Feigin in the early 90s. Another representation-theoretic interpretation of the same category (in terms of representations of the affine Lie algebra $\mathfrak{g}_{\mathrm{aff}}$) should appear soon in the works of Frenkel and Gaitsgory.

3.4. Computation of the IC-sheaf. Another check of the above principle will be to compute the stalks of the IC-sheaves of the spaces $\mathcal{QM}^\theta_{G,B}$ (or the stacks $\overline{\mathrm{Bun}}_B$) and compare it with (3.1). This was done in [15]; also in [9] this was generalized to arbitrary parabolic $P \subset G$. More specifically, the space $\mathcal{QM}^\theta_{G,B}$ possesses the

following stratification (similar to (2.1)):

$$\mathcal{QM}^{\theta}_{G,B} = \bigcup_{\mu\in\Lambda^+_G} \mathcal{M}^{\theta-\mu}_{G,B} \times \mathrm{Sym}^{\mu}(\mathbb{P}^1). \tag{3.2}$$

Here by $\mathrm{Sym}^{\mu}(\mathbb{P}^1)$ we mean the space of all colored divisors $\sum \mu_i x_i$ where $\mu_i \in \Lambda^+_G$, $x_i \in \mathbb{P}^1$ and $\sum \mu_i = \mu$. Then we have

Theorem 3.1. *The stalk of* $\mathrm{IC}_{\mathcal{QM}^{\theta}_{G,B}}$ *at a point of* $\mathcal{QM}^{\theta}_{G,B}$ *corresponding to a colored divisor* $\sum \mu_i x_i$ *as above is equal to* $\otimes_i \mathrm{Sym}(\check{\mathfrak{n}}_+)_{\mu_i}[2\langle\mu_i, \check{\rho}\rangle]$. *In particular, the stalk of* $\mathrm{IC}_{\mathcal{QM}^{\theta}_{G,B}}$ *at the "most singular" points of* $\mathcal{QM}^{\theta}_{G,B}$ *corresponding to the divisor of the form* $\theta \cdot x$ *(for some* $x \in \mathbb{P}^1$*) is equal to* $U_\theta = \mathrm{Sym}(\mathfrak{n}_+)_\theta[2\langle\theta, \check{\rho}\rangle]$.

The proof of Theorem 3.1 relies on many things, in particular the results of [37] about semi-infinite orbits in the affine Grassmannian of G.

3.5. Geometric construction of the universal Verma module. We have seen that one can read off some information related to the Langlands dual Lie algebra from the singularities of the quasi-maps' spaces. It is natural to ask if one could push this a little further and get a geometric construction of $\check{\mathfrak{g}}$-modules (in Section 5 we are going to generalize it to affine Lie algebras).

Of course, the most interesting modules that one would like to get in this way are the finite-dimensional modules. This, however, has not been done yet. In this section we explain how to use the spaces of quasi-maps in order to construct the "universal Verma module" for the Lie algebra $\check{\mathfrak{g}}$. We also give geometric interpretation of the Shapovalov form and the Whittaker vectors (cf. the definitions below). We shall generalize this in Subsection 5.3 to the case of affine Lie algebras. These constructions will play the crucial role in Section 6 where we discuss applications of our techniques to some questions of enumerative algebraic geometry.

First, let Y be a scheme endowed with an action of a reductive algebraic group L (in most applications L will actually be a torus). We denote by $\mathrm{IH}_L(Y)$ the intersection cohomology of Y with complex coefficients. This is a module over the algebra $\mathcal{A}_L = H^*_L(pt)$ which is known to be isomorphic to the algebra of polynomial functions on the Lie algebra $\mathfrak{l}$ of L which are invariant under the adjoint action of L. We let $\mathcal{K}_L$ denote the field of fractions of $\mathcal{A}_L$.

We now take Y to be the space ${}^{\mathrm{b}}\mathcal{QM}^{\theta}_{G,B}$ of *based* quasi-maps $\mathbb{P}^1 \to X_{G,B}$. By definition, this is the locally closed subscheme of $\mathcal{QM}^{\theta}_{G,B}$ corresponding to those quasi-maps which are first of all well-defined as *maps* around $\infty \in \mathbb{P}^1$ and such that their value at ∞ is equal to the point $e_{G,B} \in X_{G,B}$ corresponding to the unit element of G under the identification $X_{G,B} = G/B$. This scheme is endowed with a natural action of the torus $T \times \mathbb{C}^*$ (here T acts on $X_{G,B}$ preserving $e_{G,B}$ and $\mathbb{C}^*$ acts on $\mathbb{P}^1$

preserving ∞). Define

$$\mathrm{IH}^{\theta}_{G,B} = \mathrm{IH}^{*}_{T\times\mathbb{C}^*}({}^{\mathrm{b}}\mathcal{QM}^{\theta}_{G,B}) \underset{\mathcal{A}_{T\times\mathbb{C}^*}}{\otimes} \mathcal{K}_{T\times\mathbb{C}^*}, \quad \mathrm{IH}_{G,B} = \bigoplus_{\theta\in\Lambda^{+}_{G,B}} \mathrm{IH}^{\theta}_{G,B}.$$

Each $\mathrm{IH}^{\theta}_{G,B}$ is a finite-dimensional vector space over the field $\mathcal{K}_{T\times\mathbb{C}^*}$ which can be thought of as the field of rational functions of the variables $a \in \mathfrak{t}$ and $\hbar \in \mathbb{C}$. Moreover, $\mathrm{IH}^{\theta}_{G,B}$ is endowed with a (non-degenerate) Poincaré pairing $\langle\cdot,\cdot\rangle^{\theta}_{G,P}$ taking values in $\mathcal{K}_{T\times\mathbb{C}^*}$ (one has to explain why the Poincaré pairing is well defined since ${}^{\mathrm{b}}\mathcal{QM}^{\theta}_{G,B}$ is not projective; this is a corollary of (some version of) the localization theorem in equivariant cohomology – cf. [5] for more details).

In [5] we construct a natural action of the Lie algebra $\check{\mathfrak{g}}$ on the space $\mathrm{IH}_{G,B}$. Moreover, this action has the following properties. First of all, let us denote by $\langle\cdot,\cdot\rangle_{G,B}$ the direct sum of the pairings $(-1)^{\langle\theta,\check{\rho}\rangle}\langle\cdot,\cdot\rangle^{\theta}_{G,B}$.

Recall that the Lie algebra $\check{\mathfrak{g}}$ has its triangular decomposition $\check{\mathfrak{g}} = \check{\mathfrak{n}}_+ \oplus \check{\mathfrak{t}} \oplus \check{\mathfrak{n}}_-$. Let $\kappa\colon \check{\mathfrak{g}} \to \check{\mathfrak{g}}$ denote the Cartan anti-involution which interchanges $\check{\mathfrak{n}}_+$ and $\check{\mathfrak{n}}_-$ and acts as identity on $\check{\mathfrak{t}}$. For each $\lambda \in \mathfrak{t} = (\check{\mathfrak{t}})^*$ we denote by $M(\lambda)$ the corresponding Verma module with lowest weight λ; this is a module generated by a vector v_λ with (the only) relations

$$t(v_\lambda) = \lambda(t)v_\lambda \ \text{ for } t \in \check{\mathfrak{t}} \quad \text{and} \quad n(v_\lambda) = 0 \ \text{ for } n \in \check{\mathfrak{n}}_-.$$

Then:

1) $\mathrm{IH}_{G,B}$ (with the above action) becomes isomorphic to $M(\lambda)$ where $\lambda = \frac{a}{\hbar} + \rho$.

2) $\mathrm{IH}^{\theta}_{G,B} \subset \mathrm{IH}_{G,B}$ is the $\frac{a}{\hbar} + \rho + \theta$-weight space of $\mathrm{IH}_{G,B}$.

3) For each $g \in \check{\mathfrak{g}}$ and $v, w \in \mathrm{IH}_{G,B}$ we have

$$\langle g(v), w\rangle_{G,B} = \langle v, \kappa(g)w\rangle_{G,B}.$$

4) The vector $\sum_\theta 1^{\theta}_{G,B}$ (lying in the corresponding completion of $\mathrm{IH}_{G,B}$) is a Whittaker vector (i.e. an $\mathfrak{n}_-$-eigen-vector) for the above action.

We are not going to explain the construction of the action in this survey paper. Let us only make a few remarks about it. In the case $G = \mathrm{SL}(n)$ the smallness result of [30] allows to replace the intersection cohomology of ${}^{\mathrm{b}}\mathcal{QM}^{\theta}_{G,B}$ by the ordinary cohomology of the corresponding based version of the Laumon resolution ${}^{\mathrm{b}}\mathcal{QM}^{L,\theta}_{G,B}$; on the latter (equivariant localized) cohomology the action of the Chevalley generators of $\check{\mathfrak{g}} = \mathfrak{sl}(n)$ can be defined by means of some explicit correspondences (this is similar to the main construction of [17]; also in [7] we generalize this to the case when equivariant cohomology is replaced by equivariant K-theory. In this case the action of the Lie algebra $\mathfrak{sl}(n)$ is replaced by the action of the corresponding quantum group $U_q(\mathfrak{sl}(n))$). Also for any G the fact, that the dimension of $\mathrm{IH}^{\theta}_{G,B}$ can be easily deduced from Theorem 3.1. Our construction of the $\check{\mathfrak{g}}$-action on $\mathrm{IH}_{G,B}$ is very close to the construction in Section 4 of [15].

4. The stack $\overline{\mathrm{Bun}}_B$ and geometric Eisenstein series

This section is devoted to an application of the stacks $\overline{\mathrm{Bun}}_B$ to some questions of *geometric Langlands correspondence*. A reader who is not interested in the subject may skip this section since it will never be used in the future. In fact we are going to discuss only one such application (which was the first one historically) – the construction of *geometric Eisenstein series*. Let us note, though, that the stacks $\overline{\mathrm{Bun}}_B$ have appeared in many other works on the subject. For example they play the crucial role in the geometric proof of Casselman–Shalika formula by E. Frenkel, D. Gaitsgory and K. Vilonen (cf. [18]) as well as in D. Gaitsgory's work (cf. [20]) on the so-called "vanishing conjecture" which implies (the main portion of) the geometric Langlands conjecture for $\mathrm{GL}(n)$, as well as de Jong's conjecture about representations of Galois groups of functional fields (cf. [22]). A good review of these results may be found in [21].

All the results discussed below are taken from [10].

4.1. The usual Eisenstein series. Let X be a curve over $\mathbb{F}_q$ and let G be a reductive group. The classical theory of automorphic forms is concerned with the space of functions on the quotient $G_{\mathbb{A}}/G_{\mathcal{K}}$, where $\mathcal{K}$ (resp., $\mathbb{A}$) is the field or rational functions on X (resp., the ring of adèles of $\mathcal{K}$). In this paper, we will consider only the unramified situation, i.e. we will study functions (and afterwards perverse sheaves) on the double quotient $G_{\mathbb{O}}\backslash G_{\mathbb{A}}/G_{\mathcal{K}}$.

Let T be a Cartan subgroup of G. There is a well-known construction, called the *Eisenstein series operator* that attaches to a compactly supported function on $T_{\mathbb{O}}\backslash T_{\mathbb{A}}/T_{\mathcal{K}}$ a function on $G_{\mathbb{O}}\backslash G_{\mathbb{A}}/G_{\mathcal{K}}$:

Consider the diagram

$$\begin{array}{ccc} B_{\mathbb{O}}\backslash B_{\mathbb{A}}/B_{\mathcal{K}} & \xrightarrow{q} & T_{\mathbb{O}}\backslash T_{\mathbb{A}}/T_{\mathcal{K}} \\ \downarrow{\scriptstyle p} & & \\ G_{\mathbb{O}}\backslash G_{\mathbb{A}}/G_{\mathcal{K}}, & & \end{array}$$

where B is a Borel subgroup of G. Up to a normalization factor, the Eisenstein series of a function S on $T_{\mathbb{O}}\backslash T_{\mathbb{A}}/T_{\mathcal{K}}$ is $p_!(q^*(S))$, where q^* denotes pull-back and $p_!$ is integration along the fiber.

Our goal is to study a geometric analog of this construction.

Let Bun_G denote the stack of G–bundles on X. One may regard the derived category of constructible sheaves on Bun_G (denoted $\mathrm{Sh}(\mathrm{Bun}_G)$) as a geometric analog of the space of functions on $G_{\mathbb{O}}\backslash G_{\mathbb{A}}/G_{\mathcal{K}}$. Then, by geometrizing the Eisenstein series operator, we obtain an Eisenstein series functor Eis' similar to the above one, where the intermediate stack is Bun_B – the stack of B – bundles on X.

However, this construction has an immediate drawback – it is not sufficiently functorial (for example it does not commute with Verdier duality), the reason being

that the projection $p\colon \mathrm{Bun}_B \to \mathrm{Bun}_G$ has non-compact fibers. Therefore, it is natural to look for a relative compactification of Bun_B along the fibers of the projection p.

It turns out that the compactification $\overline{\mathrm{Bun}}_B$ discussed indeed does the job, i.e. we can use it to define the corrected functor $\mathrm{Eis}\colon \mathrm{Sh}(\mathrm{Bun}_T) \to \mathrm{Sh}(\mathrm{Bun}_G)$. The paper [10] is devoted to the investigation of various properties of this functor.

In fact, all the technical results about the functor Eis essentially reduce to questions about the geometry of $\overline{\mathrm{Bun}}_B$ and the behaviour of the intersection cohomology sheaf on it.

We should say right away that the pioneering work in this direction was done by G. Laumon in [32], who considered the case of $G = \mathrm{GL}(n)$ using his own compactification $\overline{\mathrm{Bun}}_B^L$ of the stack Bun_B. In the sequel we will explain how the two approaches are related.

4.2. Survey of the main results of [10]. Once the stack $\overline{\mathrm{Bun}}_B$ is constructed, one can try to use it to define the "compactified" Eisenstein series functor $\mathrm{Eis}\colon \mathrm{Sh}(\mathrm{Bun}_T) \to \mathrm{Sh}(\mathrm{Bun}_G)$. Let p and q denote the natural projections from $\overline{\mathrm{Bun}}_B$ to Bun_G and Bun_T, respectively. The first idea would be to consider the functor $\mathcal{S} \in \mathrm{Sh}(\mathrm{Bun}_T) \mapsto p_!(q^*(\mathcal{S})) \in \mathrm{Bun}_G$. However, this is too naive, since if we want our functor to commute with Verdier duality, we need to take into account the singularities of $\overline{\mathrm{Bun}}_B$. Therefore, one introduces a *kernel* on $\overline{\mathrm{Bun}}_B$ given by its intersection cohomology sheaf. I.e., we define the functor Eis by

$$\mathcal{S} \mapsto p_!(q^*(\mathcal{S}) \otimes \mathrm{IC}_{\overline{\mathrm{Bun}}_B}),$$

up to a cohomological shift and Tate's twist. Similarly, one defines the functor $\mathrm{Eis}_M^G\colon \mathrm{Sh}(\mathrm{Bun}_M) \to \mathrm{Sh}(\mathrm{Bun}_G)$, where M is the Levi quotient of a parabolic P.

The first test whether our definition of the functor Eis is "the right one" would be the assertion that Eis (or more generally Eis_M^G) indeed commutes with Verdier duality. It can be shown that our Eis indeed passes this test.

Let us again add a comment of how the functor Eis is connected to Laumon's work. One can define functors $\mathrm{Eis}^L\colon \mathrm{Sh}(\mathrm{Bun}_T) \to \mathrm{Sh}(\mathrm{Bun}_G)$ using Laumon's compactification. (In the original work [32], Laumon did not consider Eis^L as a functor, but rather applied it to specific sheaves on Bun_T.) However, from the smallness result of [30] it follows that the functors Eis^L and Eis are canonically isomorphic.

Once we defined the functors $\mathrm{Eis} = \mathrm{Eis}_T^G\colon \mathrm{Sh}(\mathrm{Bun}_T) \to \mathrm{Sh}(\mathrm{Bun}_G)$, $\mathrm{Eis}_M^G\colon \mathrm{Sh}(\mathrm{Bun}_M) \to \mathrm{Sh}(\mathrm{Bun}_G)$ and a similar functor for M, $\mathrm{Eis}_T^M\colon \mathrm{Sh}(\mathrm{Bun}_T) \to \mathrm{Sh}(\mathrm{Bun}_M)$, it is by all means natural to expect that these functors compose nicely, i.e. that $\mathrm{Eis}_T^G \simeq \mathrm{Eis}_M^G \circ \mathrm{Eis}_T^M$.

For example, if instead of Eis we used the naive (uncompactified) functor Eis$'$, the analogous assertion would be a triviality, since $\mathrm{Bun}_B \simeq \mathrm{Bun}_P \underset{\mathrm{Bun}_M}{\times} \mathrm{Bun}_{B(M)}$, where $B(M)$ is the Borel subgroup of M.

The problem with our definition of Eis_M^G is that there is no map between the relevant compactifications, i.e. from $\overline{\mathrm{Bun}}_B$ to $\widetilde{\mathrm{Bun}}_P$. Nevertheless, the assertion that $\mathrm{Eis}_T^G \simeq \mathrm{Eis}_M^G \circ \mathrm{Eis}_T^M$ does hold. This in fact is a non-trivial theorem proved in [10].

Here are the main properties of the Eisenstein series functor.

4.3. Behaviour with respect to the Hecke functors. Classically, on the space of functions on the double quotient $G_{\mathbb{O}}\backslash G_{\mathbb{A}}/G_{\mathcal{K}}$ we have the action of $\otimes_{x\in X}\mathcal{H}_x(G)$, where x runs over the set of places of $\mathcal{K}$, and for each $x \in X$, $\mathcal{H}_x(G)$ denotes the corresponding spherical Hecke algebra of the group G.

Similarly, $\otimes_{x\in X}\mathcal{H}_x(T)$ acts on the space of functions on $T_{\mathbb{O}}\backslash T_{\mathbb{A}}/T_{\mathcal{K}}$. In addition, for every x as above, there is a canonical homomorphism $\mathcal{H}_x(G) \to \mathcal{H}_x(T)$ described as follows:

Recall that there is a canonical isomorphism (due to Satake) between $\mathcal{H}_x(G)$ and the Grothendieck ring of the category of finite-dimensional representations of the Langlands dual group $\check{G}$. We have the natural restriction functor $\mathrm{Rep}(\check{G}) \to \mathrm{Rep}(\check{T})$, and our homomorphism $\mathcal{H}_x(G) \to \mathcal{H}_x(T)$ corresponds to the induced homomorphism $K(\mathrm{Rep}(\check{G})) \to K(\mathrm{Rep}(\check{T}))$ between Grothendieck rings.

The basic property of the Eisenstein series operators is that it intertwines the $\mathcal{H}_x(G)$-action on $G_{\mathbb{O}}\backslash G_{\mathbb{A}}/G_{\mathcal{K}}$ and the $\mathcal{H}_x(T)$-action on $T_{\mathbb{O}}\backslash T_{\mathbb{A}}/T_{\mathcal{K}}$ via the above homomorphism.

Our result below is a reflection of this phenomenon in the geometric setting. Now, instead of the Hecke algebras, we have the action of the Hecke functors on $\mathrm{Sh}(\mathrm{Bun}_G)$. Namely, for $x \in X$ and an object $V \in \mathrm{Rep}(\check{G})$, one defines the *Hecke functor*

$$\mathcal{S} \mapsto {}_xH_G(V, \mathcal{S})$$

from $\mathrm{Sh}(\mathrm{Bun}_G)$ to itself. The existence of such functors comes from the so-called *geometric Satake isomorphism* – cf. [37] and references therein.

We claim that for any $\mathcal{S} \in \mathrm{Sh}(\mathrm{Bun}_T)$ we have

$${}_xH_G(V, \mathrm{Eis}(\mathcal{S})) \simeq \mathrm{Eis}({}_xH_T(\mathrm{Res}^G_T(V), \mathcal{S})).$$

This result is more or less equivalent to one of the main results of [37]. A similar statement holds for the non-principal Eisenstein series functor Eis^G_M.

As a corollary, we obtain that if $E_{\check{M}}$ is an $\check{M}$-local system on X and $\mathrm{Aut}_{E_{\check{M}}}$ is a perverse sheaf (or a complex of sheaves) on Bun_M, corresponding to it in the sense of the geometric Langlands correspondence, then the complex $\mathrm{Eis}^G_M(\mathrm{Aut}_{E_{\check{M}}})$ on Bun_G is a Hecke eigen-sheaf with respect to the induced $\check{G}$-local system.

In particular, we construct Hecke eigen-sheaves for those homomorphisms $\pi_1(X) \to \check{G}$, whose image is contained in a maximal torus of $\check{G}$.

4.4. The functional equation. It is well known that the classical Eisenstein series satisfy the functional equation. Namely, let χ be a character of the group $T_{\mathbb{O}}\backslash T_{\mathbb{A}}/T_{\mathcal{K}}$ and let $\mathrm{w} \in W$ be an element of the Weyl group. We can translate χ by means of w and obtain a new (Grössen)-character χ^{w}.

The functional equation is the assertion that the Eisenstein series corresponding to χ and χ^{w} are equal, up to a ratio of the corresponding L-functions.

Now let $\mathcal{S}$ be an arbitrary complex of sheaves on Bun_T and let $\mathrm{w}\cdot\mathcal{S}$ be its w-translate. One may wonder whether there is any relation between $\mathrm{Eis}(\mathcal{S})$ and $\mathrm{Eis}(\mathrm{w}\cdot\mathcal{S})$.

We single out a subcategory in $\mathrm{Sh}(\mathrm{Bun}_T)$, corresponding to sheaves which we call "regular", for which we answer the above question. We show that for a regular sheaf $\mathcal{S}$ we have

$$\mathrm{Eis}(\mathcal{S}) \simeq \mathrm{Eis}(\mathrm{w}\cdot\mathcal{S}).$$

(It is easy to see that one should not expect the functional equation to hold for non-regular sheaves.)

A remarkable feature of this assertion is that the L-factors that enter the classical functional equation have disappeared. An explanation of this fact is provided by the corresponding result from [10] which says that the definition of Eis via the intersection cohomology sheaf on $\overline{\mathrm{Bun}}_B$ already incorporates the L-function.

We remark that an assertion similar to the above functional equation should hold also for non-principal Eisenstein series. Unfortunately, this seems to be beyond the access of our methods.

Using the above results we obtain a proof of the following very special case of the Langlands conjecture. Namely, we prove that if we start with an unramified irreducible representation of $\pi_1(X)$ into $\check{G}$, such that $\pi_1(X)^{\mathrm{geom}}$ [3] maps to $\check{T} \subset \check{G}$, then there exists an unramified automorphic form on $G_{\mathbb{A}}$ which corresponds to this representation in the sense of Langlands.

This may be considered as an application of the machinery developed in [10] to the classical theory of automorphic forms.

5. Quasi-maps into affine flag varieties and Uhlenbeck compactifications

In this section we take the base field to be $\mathbb{C}$.

5.1. The problem. Let G be an almost simple simply connected group over $\mathbb{C}$, with Lie algebra $\mathfrak{g}$, and let $\boldsymbol{S}$ be a smooth projective surface.

Let us denote by $\mathrm{Bun}_G^d(\boldsymbol{S})$ the moduli space (stack) of principal G-bundles on $\boldsymbol{S}$ of second Chern class $d \in \mathbb{Z}$. It is easy to see that $\mathrm{Bun}_G^d(\boldsymbol{S})$ cannot be compact and for many reasons it is natural to expect that there exists a compactification of $\mathrm{Bun}_G^d(\boldsymbol{S})$ which looks like a union

$$\bigcup_{b\in\mathbb{N}} \mathrm{Bun}_G^{d-b}(\boldsymbol{S}) \times \mathrm{Sym}^b(\boldsymbol{S}). \tag{5.1}$$

Note the striking similarity between (5.1) and (2.1).

[3] Here $\pi_1(X)^{\mathrm{geom}}$ denotes the geometric fundamental group of X – i.e. the fundamental group of X over the algebraic closure of $\mathbb{F}_q$

In the differential-geometric framework of moduli spaces of K-instantons on Riemannian 4-manifolds (where K is the maximal compact subgroup of G) such a compactification was introduced in the pioneering work [45]. Therefore, we shall call its algebro-geometric version the Uhlenbeck space, and denote it by $\mathcal{U}_G^d(\boldsymbol{S})$.

Unfortunately, one still does not know how to construct the spaces $\mathcal{U}_G^d(\boldsymbol{S})$ for a general group G and an arbitrary surface $\boldsymbol{S}$. More precisely, one would like to formulate a moduli problem, to which $\mathcal{U}_G^d(\boldsymbol{S})$ would be the answer, and so far this is not known. In this formulation the question of constructing the Uhlenbeck spaces has been posed (to the best of our knowledge) by V. Ginzburg. He and V. Baranovsky (cf. [3]) have made the first attempts to solve it, as well as indicated the approach adopted in this paper. The reader may also consult [2] for a different algebro-geometric approach to Uhlenbeck spaces.

A significant simplification occurs for $G = \mathrm{SL}_n$. Let us note that when $G = \mathrm{SL}_n$, there exists another natural compactification of the stack $\mathrm{Bun}_n^d(\boldsymbol{S}) := \mathrm{Bun}_{\mathrm{SL}_n}^d(\boldsymbol{S})$ (called the Gieseker compactification), by torsion-free sheaves of generic rank n and of second Chern class a, called the Gieseker compactification, which in this paper we will denote by $\widetilde{\mathfrak{N}}_n^d(\boldsymbol{S})$. One expects that there exists a proper map $\mathsf{f}\colon \widetilde{\mathfrak{N}}_n^d(\boldsymbol{S}) \to \mathcal{U}_{\mathrm{SL}_n}^d(\boldsymbol{S})$, described as follows:

A torsion-free sheaf $\mathcal{M}$ embeds into a short exact sequence

$$0 \to \mathcal{M} \to \mathcal{M}' \to \mathcal{M}_0 \to 0,$$

where $\mathcal{M}'$ is a vector bundle (called the saturation of $\mathcal{M}$), and $\mathcal{M}_0$ is a finite-length sheaf. The map should send a point of $\widetilde{\mathfrak{N}}_n^d(\boldsymbol{S})$ corresponding to $\mathcal{M}$ to the pair $(\mathcal{M}', \mathrm{cycle}(\mathcal{M}_0)) \in \mathrm{Bun}_n^{d-b}(\boldsymbol{S}) \times \mathrm{Sym}^b(\boldsymbol{S})$, where b is the length of $\mathcal{M}_0$, and $\mathrm{cycle}(\mathcal{M}_0)$ is the cycle of $\mathcal{M}_0$. In other words, the map must "collapse" the information of the quotient $\mathcal{M}' \to \mathcal{M}_0$ to just the information of the length of $\mathcal{M}_0$ at various points of $\boldsymbol{S}$.

Since the spaces $\widetilde{\mathfrak{N}}_n^d(\boldsymbol{S})$, being a solution of a moduli problem, are easy to construct, one may attempt to construct the Uhlenbeck spaces $\mathcal{U}_{\mathrm{SL}_n}^d(\boldsymbol{S})$ by constructing an explicit blow down of the Gieseker spaces $\widetilde{\mathfrak{N}}_n^d(\boldsymbol{S})$. This has indeed been performed in the works of J. Li (cf. [33]) and J. W. Morgan (cf. [38]).

The problem simplifies even further, when we put $\boldsymbol{S} = \mathbb{P}^2$, the projective plane, and consider bundles trivialized along a fixed line $\mathbb{P}^1 \subset \mathbb{P}^2$. In this case, the sought-for space $\mathcal{U}_n^d(\boldsymbol{S})$ has been constructed by S. Donaldson and thoroughly studied by H. Nakajima (cf. e.g. [39]) in his works on quiver varieties.

In [8] we consider the case of an arbitrary group G, but the surface equal to $\mathbb{P}^2$ (and we will be interested in bundles trivialized along $\mathbb{P}^1 \subset \mathbb{P}^2$, i.e., we will work in the Donaldson–Nakajima set-up.)

In fact we are able to construct the Uhlenbeck spaces $\mathcal{U}_G^d$, but only up to nilpotents. I.e., we will have several definitions, two of which admit modular descriptions, and which produce the same answer on the level of reduced schemes. We do not know, whether the resulting schemes actually coincide when we take the nilpotents into

account. And neither do we know whether the resulting reduced scheme is normal.

We should say that the problem of constructing the Uhlenbeck spaces can be posed over a base field of any characteristic. However, the proof of one the main results of [10], which insures that our spaces $\mathcal{U}_G^d$ are invariantly defined, uses the char $= 0$ assumption. It is quite possible that in order to treat the char $= p$ case, one needs a finer analysis.

5.2. A sketch of the construction. The construction of $\mathcal{U}_G^d$ used in [8] is a simplification of a suggestion of Drinfeld's (the latter potentially works for an arbitrary surface $\boldsymbol{S}$). We are trying to express points of $\mathcal{U}_G^d$ (one may call them quasi-bundles) by replacing the original problem for the surface $\mathbb{P}^2$ by another problem for the curve $\mathbb{P}^1$. Let us first generalize the problem to the case of G-bundles with a parabolic structure along a fixed straight line.

Namely, let $\boldsymbol{S} = \mathbb{P}^2$ and let $\mathbb{P}^1_\infty \subset \boldsymbol{S}$ be the "infinite line" (so that $\boldsymbol{S} \backslash \mathbb{P}^1_\infty = \mathbb{C}^2$). Let also Let $C \simeq \mathbb{P}^1 \subset \boldsymbol{S}$ denote the horizontal line in $\boldsymbol{S}$. Choose a parabolic subgroup $P \subset G$. Let $\mathrm{Bun}_{G,P}$ denote the moduli space of the following objects:

1) A principal G-bundle $\mathcal{H}_G$ on $\boldsymbol{S}$;

2) A trivialization of $\mathcal{H}_G$ on $\mathbb{P}^1_\infty \subset \boldsymbol{S}$;

3) A reduction of $\mathcal{H}_G$ to P on C compatible with the trivialization of $\mathcal{H}_G$ on C.

Let us describe the connected components of $\mathrm{Bun}_{G,P}$. Let M be the Levi group of P. Denote by $\check{M}$ the *Langlands dual* group of M and let $Z(\check{M})$ be its center. We denote by $\Lambda_{G,P}$ the lattice of characters of $Z(\check{M})$. Let also $\Lambda^{\mathrm{aff}}_{G,P} = \Lambda_{G,P} \times \mathbb{Z}$ be the lattice of characters of $Z(\check{M}) \times \mathbb{C}^*$. Note that $\Lambda^{\mathrm{aff}}_{G,G} = \mathbb{Z}$.

The lattice $\Lambda^{\mathrm{aff}}_{G,P}$ contains canonical semi-group $\Lambda^{\mathrm{aff},+}_{G,P}$ of positive elements. It is not difficult to see that the connected components of $\mathrm{Bun}_{G,P}$ are parameterized by the elements of $\Lambda^{\mathrm{aff},+}_{G,P}$:

$$\mathrm{Bun}_{G,P} = \bigcup_{\theta_{\mathrm{aff}} \in \Lambda^{\mathrm{aff},+}_{G,P}} \mathrm{Bun}^{\theta_{\mathrm{aff}}}_{G,P}.$$

Typically, for $\theta_{\mathrm{aff}} \in \Lambda^{\mathrm{aff}}_{G,P}$ we shall write $\theta_{\mathrm{aff}} = (\theta, d)$ where $\theta \in \Lambda_{G,P}$ and $d \in \mathbb{Z}$.

One would also like to construct the corresponding "Uhlenbeck scheme" $\mathcal{U}^{\theta_{\mathrm{aff}}}_{G,P}$ stratified in the following way (the reader should compare it with (3.2)):

$$\mathcal{U}^{\theta}_{G,P} = \bigcup_{\mu_{\mathrm{aff}} \in \Lambda^{\mathrm{aff},+}_{G,P}} \mathrm{Bun}^{\theta_{\mathrm{aff}} - \mu_{\mathrm{aff}}}_{G,P} \times \mathrm{Sym}^{\mu_{\mathrm{aff}}}(\mathbb{C}^2). \tag{5.2}$$

The idea of the construction is as follows. Let us consider the scheme classifying triples $(\mathcal{F}_G, \beta, \gamma)$, where

1) $\mathcal{F}_G$ is a principal G-bundle on $\mathbb{P}^1$;

2) β is a trivialization of $\mathcal{F}_G$ on the formal neighborhood of $\infty \in \mathbb{P}^1$;

3) γ is a reduction to P of the fiber of $\mathcal{F}_G$ at $0 \in \mathbb{P}^1$.

It is easy to see that this scheme is canonically isomorphic to the thick partial flag variety $\boldsymbol{X}^{\mathrm{aff}}_{G,P} = G(\mathcal{K})/\boldsymbol{I}_P$. Under this identification the point $e^{\mathrm{aff}}_{G,P} \in \boldsymbol{X}^{\mathrm{aff}}_{G,P}$ corresponding to the unit element of G corresponds to the trivial $\mathcal{F}_G$ with the trivial trivialization.

It is explained in [8] that the variety $\mathrm{Bun}_{G,P}$ is canonically isomorphic to the scheme classifying *based maps* from (C, ∞_C) to $(\boldsymbol{X}^{\mathrm{aff}}_{G,P}, e^{\mathrm{aff}}_{G,P})$ (i.e. maps from C to $\boldsymbol{X}^{\mathrm{aff}}_{G,P}$ sending ∞_C to $e^{\mathrm{aff}}_{G,P}$).

One of the main results of [8] gives an explicit description of the Intersection Cohomology sheaf of all $\mathcal{U}^{\theta_{\mathrm{aff}}}_{G,P}$. We shall not reproduce the full answer here; we shall only say that this answer is formulated in terms of the Lie algebra $\check{\mathfrak{g}}_{\mathrm{aff}}$ – the affine Lie algebra whose Dynkin diagram is dual to that of $\mathfrak{g}_{\mathrm{aff}}$. Note that in general $\check{\mathfrak{g}}_{\mathrm{aff}} \neq (\check{\mathfrak{g}})_{\mathrm{aff}}$; in fact $\check{\mathfrak{g}}_{\mathrm{aff}}$ may result to be a twisted affine Lie algebra (thus it is not isomorphic to the affinization of any finite-dimensional $\mathfrak{g}$). We regard it as one of the first glimpses to (not yet formulated) Langlands duality for affine Lie algebras.

The proof of our computation of the IC-sheaves is also of independent interest. Namely, since in the affine case the results of [37] are not available we must have a different way to see the algebra $\check{\mathfrak{g}}_{\mathrm{aff}}$ from the above geometry. In [8] we first do on the combinatorial level; namely we realize the canonical *Kashiwara crystal* discussed in [28] in terms of the varieties $\mathrm{Bun}^{\theta_{\mathrm{aff}}}_{G,B}$ (the idea of this realization is based on the earlier work [11]). We then use this geometric construction of crystals to compute the IC-sheaves of $\mathcal{U}^{\theta_{\mathrm{aff}}}_{G,B}$ (the answer is very similar to Theorem 3.1) which subsequently allows us to do it also for all $\mathcal{U}^{\theta_{\mathrm{aff}}}_{G,P}$ using techniques similar to those developed in [9] (in particular, we compute the IC-sheaf for $P = G$ which is probably the most interesting case).

5.3. The universal Verma module for $\check{\mathfrak{g}}_{\mathrm{aff}}$. The scheme $\mathcal{U}^{\theta_{\mathrm{aff}}}_{G,B}$ is endowed with a natural action of $T \times (\mathbb{C}^*)^2$ (here $T \subset G$ acts by changing the trivialization of $\mathcal{H}_G$ (cf. the previous subsection) at $\mathbb{P}^1_\infty$ and $(\mathbb{C}^*)^2$ acts on $\boldsymbol{S} = \mathbb{P}^2$ preserving $\mathbb{P}^1_\infty$ and C). Note that the field $\mathcal{K}_{T\times(\mathbb{C}^*)^2}$ can be thought of as a field of rational functions of the variables $a \in \mathfrak{t}$, $\varepsilon_1, \varepsilon_2 \in \mathbb{C}$. Define

$$\mathrm{IH}^{\theta_{\mathrm{aff}}}_{G,B} = \mathrm{IH}^*_{T\times(\mathbb{C}^*)^2}(\mathcal{U}^{\theta_{\mathrm{aff}}}_{G,B}) \underset{\mathcal{A}_{T\times(\mathbb{C}^*)^2}}{\otimes} \mathcal{K}_{T\times(\mathbb{C}^*)^2}, \quad \mathrm{IH}^{\mathrm{aff}}_{G,B} = \bigoplus_{\theta\in\Lambda^{\mathrm{aff},+}_{G,B}} \mathrm{IH}^{\theta_{\mathrm{aff}}}_{G,B}.$$

Thus $\mathrm{IH}^{\theta_{\mathrm{aff}}}_{G,B}$ is a vector space over $\mathcal{K}_{T\times(\mathbb{C}^*)^2}$ which is endowed with an intersection pairing $\langle\cdot,\cdot\rangle_{\theta_{\mathrm{aff}}}$ taking values in $\mathcal{K}_{T\times(\mathbb{C}^*)^2}$. Also, for each θ_{aff} as above we have the canonical element $1^{\theta_{\mathrm{aff}}}_{G,B} \in \mathrm{IH}^{\theta_{\mathrm{aff}}}_{G,B}$ corresponding to the unit cohomology class.

In [5] we show that the Lie algebra $\check{\mathfrak{g}}_{\mathrm{aff}}$ acts naturally on $\mathrm{IH}^{\theta_{\mathrm{aff}}}_{G,B}$; the corresponding $\check{\mathfrak{g}}_{\mathrm{aff}}$-module is naturally isomorphic to the Verma module $M(\lambda_{\mathrm{aff}})$ where $\lambda_{\mathrm{aff}} = \frac{(a,\varepsilon_2)}{\varepsilon_1} + \rho_{\mathrm{aff}}$ (cf. [5] for more details). Note that this is very similar to statement 1) from Subsection 3.5; we also have analogs of the statements 2), 3), 4).

6. Applications to gauge theory and quantum cohomology of (affine) flag manifolds

6.1. The partition function. Recall that in the previous section we considered the moduli space Bun_G^d of G-bundles on $\boldsymbol{S} = \mathbb{P}^2$ trivialized at $\mathbb{P}^1_\infty \subset \boldsymbol{S}$ and having 2nd Chern class equal to d. We also have the scheme $\mathcal{U}_G^d$ containing Bun_G^d as an open subset. The group $G \times \mathrm{GL}(2)$ acts naturally on $\mathcal{U}_G^d$ where G acts by changing the trivialization at $\mathbb{P}^1_\infty$ and $\mathrm{GL}(2)$ acts on $\boldsymbol{S}$ preserving $\mathbb{P}^1_\infty$.

Thus we may consider (cf. [5] [41], [40] for precise definitions) the *equivariant integral*

$$\int_{\mathcal{U}_G^d} 1^d$$

of the unit $G \times \mathrm{GL}(2)$-equivariant cohomology class (which we denote by 1^d) over $\mathcal{U}_G^d$; the integral takes values in the field $\mathcal{K}$ which is the field of fractions of the algebra $\mathcal{A} = H^*_{G\times \mathrm{GL}(2)}(pt)$. Note that $\mathcal{A}$ is canonically isomorphic to the algebra of polynomial functions on the Lie algebra $\mathfrak{g} \times \mathfrak{gl}(2)$ which are invariant with respect to the adjoint action. Thus each $\int_{\mathcal{U}_G^d} 1^d$ may naturally be regarded as a rational function of $a \in \mathfrak{t}$ and $(\varepsilon_1, \varepsilon_2) \in \mathbb{C}^2$; this function must be invariant with respect to the natural action of W on $\mathfrak{t}$ and with respect to interchanging ε_1 and ε_2.

Consider now the generating function

$$\mathcal{Z} = \sum_{d=0}^{\infty} Q^d \int_{\mathcal{U}_G^d} 1^d.$$

It can (and should) be thought of as a function of the variables $\mathfrak{q}$ and $a, \varepsilon_1, \varepsilon_2$ as before. In [41] it was conjectured that the first term of the asymptotic in the limit $\lim_{\varepsilon_1,\varepsilon_2\to 0} \ln \mathcal{Z}$ is closely related to *Seiberg–Witten prepotential* of G.[4] This can be thought of as a rigorous mathematical formulation of the results of Seiberg and Witten from 1994. For $G = \mathrm{SL}(n)$ this conjecture has been proved in [42] and [40]. Also in [41] an explicit combinatorial expression for $\mathcal{Z}$ has been found. We are going to give a sketch of the proof of this conjecture for arbitrary G.

6.2. Parabolic generalization of the partition function. Recall from the previous section that for any parabolic $P \subset G$ we have the varieties $\mathrm{Bun}^{\theta_{\mathrm{aff}}}_{G,P}$ and $\mathcal{U}^{\theta}_{G,P}$. The latter contains the former as a dense open subset. Is is easy to see that $\mathcal{U}^{\theta}_{G,P}$ has a natural action of the group $M \times (\mathbb{C}^*)^2$ where M denotes the Levi subgroup of P. Also

[4] In fact, in [41] this conjecture is only formulated for $G = \mathrm{SL}(n)$ but the generalization to other groups is pretty straightforward. Also, one can reformulate everything in the language of moduli spaces of anti-selfdual connections of the 4-sphere S^4 rather than in terms of holomorphic (= algebraic) G-bundles on $\mathbb{P}^2$; this, perhaps, is closer to the physical origins of the problem.

we have the field $\mathcal{K}_{M\times(\mathbb{C}^*)^2}$ which is isomorphic to the field of rational functions on $\mathfrak{m}\times\mathbb{C}^2$ which are invariant with respect to the adjoint action.

Let $T\subset M$ be a maximal torus. Then one can show that $(\mathcal{U}^{\theta_{\mathrm{aff}}}_{G,P})^{T\times(\mathbb{C}^*)^2}$ consists of one point. This guarantees that we may consider the integral $\int_{\mathcal{U}^{\theta_{\mathrm{aff}}}_{G,P}} 1^{\theta_{\mathrm{aff}}}_{G,P}$ where $1^{\theta_{\mathrm{aff}}}_{G,P}$ denotes the unit class in $H^*_{M\times(\mathbb{C}^*)^2}(\mathcal{U}^{\theta_{\mathrm{aff}}}_{G,P},\mathbb{C})$. The result can be thought of as a rational function on $\mathfrak{m}\times\mathbb{C}^2$ which is invariant with respect to the adjoint action of M. Define

$$\mathcal{Z}^{\mathrm{aff}}_{G,P}=\sum_{\theta\in\Lambda^{\mathrm{aff}}_{G,P}}\mathfrak{q}^{\theta_{\mathrm{aff}}}_{\mathrm{aff}}\int\limits_{\mathcal{U}^{\theta_{\mathrm{aff}}}_{G,P}}1^{\theta_{\mathrm{aff}}}_{G,P}. \tag{6.1}$$

One should think of $\mathcal{Z}^{\mathrm{aff}}_{G,P}$ as a formal power series in $\mathfrak{q}_{\mathrm{aff}}\in Z(\check{M})\times\mathbb{C}^*$ with values in the space of ad-invariant rational functions on $\mathfrak{m}\times\mathbb{C}^2$. Typically, we shall write $\mathfrak{q}_{\mathrm{aff}}=(\mathfrak{q},Q)$ where $\mathfrak{q}\in Z(\check{M})$ and $Q\in\mathbb{C}^*$. Also we shall denote an element of $\mathfrak{m}\times\mathbb{C}^2$ by $(a,\varepsilon_1,\varepsilon_2)$ or (sometimes it will be more convenient) by $(a,\hbar,\varepsilon)$ (note that for general P (unlike in the case $P=G$) the function $\mathcal{Z}^{\mathrm{aff}}_{G,P}$ is not symmetric with respect to switching ε_1 and ε_2).

6.3. The "finite-dimensional" analog. Recall that the space $\mathcal{U}^{\theta_{\mathrm{aff}}}_{G,P}$ is closely related to the space of based quasi-maps $C=\mathbb{P}^1\to\boldsymbol{X}^{\mathrm{aff}}_{G,P}$ of degree θ_{aff}. Since the scheme $\boldsymbol{X}^{\mathrm{aff}}_{G,P}$ may (and should) be thought of as a partial flag variety for $\mathfrak{g}_{\mathrm{aff}}$ it is natural to consider the following "finite-dimensional" analog of the above problem. Recall that we denote by ${}^{\mathrm{b}}\mathcal{M}^{\theta}_{G,P}$ the moduli space of based maps from (C,∞_C) to $(X_{G,P},e_{G,P})$ of degree θ, i.e. the moduli space of maps $C\to X_{G,P}$ which send ∞_C to $e_{G,P}$. This space is acted on by the group $M\times\mathbb{C}^*$.

We now introduce the "finite-dimensional" analog of the partition function (6.1). As before let

$$\mathcal{A}_{M\times\mathbb{C}^*}=H^*_{M\times\mathbb{C}^*}(pt,\mathbb{C})$$

and denote by $\mathcal{K}_{M\times\mathbb{C}^*}$ its field of fractions. Let also $1^{\theta}_{G,P}$ denote the unit class in the $M\times\mathbb{C}^*$-equivariant cohomology of ${}^{\mathrm{b}}\mathcal{QM}^{\theta}_{G,P}$. Then we define

$$\mathcal{Z}_{G,P}=\sum_{\theta\in\Lambda^{\theta}_{G,P}}\mathfrak{q}^{\theta}\int\limits_{{}^{\mathrm{b}}\mathcal{QM}^{\theta}_{G,P}}1^{\theta}_{G,P}. \tag{6.2}$$

This is a formal series in $q\in Z(\check{M})$ with values in the field $\mathcal{K}_{M\times\mathbb{C}^*}$ of M-invariant rational functions on $\mathfrak{m}\times\mathbb{C}$.

In fact the function $\mathcal{Z}_{G,P}$ is a familiar object in Gromov–Witten theory: in [5] we show that up to a simple factor $\mathcal{Z}_{G,P}$ is the so-called *equivariant J-function* of $X_{G,P}$; this function is in some sense responsible for the (small) quantum cohomology of $X_{G,P}$. Thus the problem of computation of the function $\mathcal{Z}^{\mathrm{aff}}_{G,P}$ may be

thought of as the problem of computation of the (not yet rigorously defined) quantum cohomology of the affine flag manifolds $\boldsymbol{X}^{\mathrm{aff}}_{G,P}$. Note that in the case $G = \mathrm{SL}(n)$ and $P = B$ a heuristic computation of the latter ring in terms of the so-called *periodic Toda lattice* was done in [25]; our results discussed presented in the next subsection are compatible with this computation.

6.4. Computation of the partition functions in the Borel case. We believe that it should be possible to express the function $\mathcal{Z}_{G,P}$ (resp. the function $\mathcal{Z}^{\mathrm{aff}}_{G,P}$) in terms of representation theory of the Lie algebra $\check{\mathfrak{g}}$ (resp. $\check{\mathfrak{g}}_{\mathrm{aff}}$) – by the definition this is a Lie algebra whose root system is dual to that of $\mathfrak{g}$ (resp. to that of $\mathfrak{g}_{\mathrm{aff}}$). One of the main results of [5] gives such a calculation of the functions $\mathcal{Z}_{G,B}$ and $\mathcal{Z}^{\mathrm{aff}}_{G,B}$ where $B \subset G$ is a Borel subgroup of G. Roughly speaking we show that $\mathcal{Z}_{G,B}$ (resp. $\mathcal{Z}^{\mathrm{aff}}_{G,B}$) is equal to *Whittaker matrix coefficient* of the Verma module over $\check{\mathfrak{g}}$ (resp. over $\check{\mathfrak{g}}_{\mathrm{aff}}$) whose lowest weight given by $\frac{a}{\hbar}+\rho$ (resp. $\frac{(a,\varepsilon_1)}{\varepsilon_2}+\rho_{\mathrm{aff}}$ where a, $\hbar$, ε_1 and ε_2 are as in Subsection 5.3 (here we regard (a,ε_1) as a weight for the dual affine algebra $\check{\mathfrak{g}}_{\mathrm{aff}}$; this is explained carefully in Section 3 of [5]). These statements in fact follow immediately from the results of Subsections 3.5 and 5.3 after one formulates the definition of equivariant integration using intersection cohomology (this is done is [5]).

The above description of the partition function allows one to produce certain differential equations which are satisfied by the functions $\mathcal{Z}_{G,B}$ and $\mathcal{Z}^{\mathrm{aff}}_{G,B}$. More precisely, we show that the function $\mathfrak{q}^{\frac{a}{\hbar}}\mathcal{Z}_{G,B}$ is an eigen-function of the *quantum Toda hamiltonians* associated with $\check{\mathfrak{g}}$ with eigen-values determined (in the natural way) by a (we refer the reader to [13] for the definition of (affine) Toda integrable system and its relation with Whittaker functions). In this way we reprove the results of [24] and [31] about (equivariant) quantum cohomology of the flag varieties $X_{G,P}$. In the affine case one can also show that $\mathfrak{q}^{\frac{a}{\hbar}}\mathcal{Z}^{\mathrm{aff}}_{G,B}$ is an eigen-function of a certain differential operator which has order 2 ("non-stationary analog" of the affine quadratic Toda hamiltonian). In [6] we explain how this allows to compute the asymptotics of *all* the functions $\mathcal{Z}^{\mathrm{aff}}_{G,P}$ when $\varepsilon_1, \varepsilon_2 \to 0$ in another publication. We also show in [6] that this implies the Nekrasov conjecture mentioned above for arbitrary G.

7. Some open problems

In this section we present a list of open problems that related to the subjects in the preceding sections of the paper.

7.1. Normality and rational singularities. We conjecture that the schemes $\mathcal{QM}^{\theta}_{G,P}$ and $\mathcal{U}^{\theta_{\mathrm{aff}}}_{G,P}$ are normal and have rational singularities. From purely technical point of view one needs to know this in order to attack problem 2. On the other hand, this statement seems to be important for the following reason. It is explained in [9] and [14] that one should think about the singularities of the schemes $\mathcal{QM}^{\theta}_{G,P}$ as a

finite-dimensional model for the singularities of the so-called *semi-infinite Schubert varieties* (cf. [14] for a more detailed discussion of this). On the other hand, one knows (cf. [13] and references therein) that usual (both finite and affine) Schubert varieties *are* normal and have rational singularities. Hence in the case of $\mathcal{QM}^{\theta}_{G,P}$ our conjectures can be thought of as a generalization of this result to the semi-infinite Schubert varieties. In some special case these conjectures were proved in [43].

7.2. Computation of parabolic partition functions. It would be very interesting to express the functions $\mathcal{Z}_{G,P}$ (resp. $\mathcal{Z}^{\mathrm{aff}}_{G,P}$) in terms of representation theory of the algebra $\check{\mathfrak{g}}$ (resp. $\check{\mathfrak{g}}_{\mathrm{aff}}$). Let us note that a combinatorial expression for all these functions in the case $G = \mathrm{SL}(n)$ was found in [34], but we do not know how to interpret this answer in terms of representation theory.

7.3. Other cohomology theories. The functions $\mathcal{Z}_{G,P}$ and $\mathcal{Z}^{\mathrm{aff}}_{G,P}$ have their K-theoretic counterparts $\mathcal{Z}^{K}_{G,P}$ and $\mathcal{Z}^{K,\mathrm{aff}}_{G,P}$ (to define those one needs to replace the equivariant integrals considered in (6.1) and (6.2) by the corresponding integrals in equivariant K-theory). The function $\mathcal{Z}^{K}_{G,P}$ is exactly the K-theoretic J-function of $\mathcal{G}_{G,P}$ as defined in [22]. We would like to express these functions using the representation theory of the quantum group $U_q(\check{\mathfrak{g}})$ (resp. $U_q(\check{\mathfrak{g}}_{\mathrm{aff}})$). Presumably, in order to do this one should be able to construct geometrically some representations of these quantum groups. For $P = B$ and $G = \mathrm{SL}(n)$ this is done in [7]. For $P = G = \mathrm{SL}(n)$ the K-theoretic partition function $\mathcal{Z}^{K,\mathrm{aff}}_{G}$ was also studied in [28].

Let us also recall that in [6] the authors use the results described in Section 6.4 in order to connect certain asymptotic of the function $\mathcal{Z}^{\mathrm{aff}}_{G,P}$ with the *Seiberg–Witten prepotential* corresponding to the classical Toda integrable system associated with the Lie algebra $\check{\mathfrak{g}}_{\mathrm{aff}}$. We would like to generalize this to the K-theoretic partition functions. This should involve some interesting interplay between quantum affine algebras and certain difference equations (which should be thought of non-stationary deformations of known integrable difference equations of Toda type). The corresponding classical integrable system describing the asymptotic should be the so-called *relativistic Toda system* associated with the Lie algebra $\check{\mathfrak{g}}_{\mathrm{aff}}$.

It would also be interesting to generalize this to the case when K-theory is replaced by any elliptic cohomology theory. Again, for $P = G = \mathrm{SL}(n)$ (in the affine case) this is done in [26].

7.4. Chern classes of the tangent bundle and the Calogero–Moser system. As was mentioned above the partitions functions $\mathcal{Z}^{\mathrm{aff}}_{G,P}$ are related to the pure $N = 2$ super-symmetric gauge theory in 4 dimensions. One should also have an extension of the above result for gauge theory *with matter*. This means that instead of considering equivariant integrals of the unit cohomology class we should consider integrals of the Chern classes of various natural bundles on the moduli spaces in question. For example in the case of *adjoint matter* one should integrate the Chern polynomial of the tangent bundle of $\mathcal{U}^{\theta_{\mathrm{aff}}}_{G,P}$ (this, of course, has to be properly interpreted since the

variety in question is singular). For $P = G = \mathrm{SL}(n)$ such functions are studied in [28] and the corresponding asymptotic of the partition function is shown there to be related with the prepotential of the classical *elliptic Calogero–Moser* integrable system. We expect that for $P = B$ (and for general G) the corresponding partition function should be closely related with the universal eigen-function of the corresponding non-stationary deformation of the quantum Calogero–Moser hamiltonian associated with the Lie algebra $\check{\mathfrak{g}}_{\mathrm{aff}}$. Similar statement should also hold in the finite case (i.e. when we integrate over $\mathcal{QM}^{\theta}_{G,B}$'s and not over $\mathcal{U}^{\theta_{\mathrm{aff}}}_{G,B}$'s). In particular, in the finite case we should get a geometric interpretation of the universal eigen-function of the quantum Calogero–Moser system associated with the Lie algebra $\check{\mathfrak{g}}$.

7.5. Functional equation for parabolic Eisenstein series. It will be very important to generalize the functional equation for geometric Eisenstein series discussed in Subsection 4.4 to the case of parabolic Eisenstein series. More precisely, given a parabolic subgroup $P \subset G$ with the Levi subgroup M in Section 4 we discussed the Eisenstein series functor Eis^G_M. In fact this notation is slightly misleading since this functor actually depends not just on M but also on P. Let us now use the notation $\mathrm{Eis}^G_{M,P}$ for it. With this notation the "functional equation" problem reads as follows: given two parabolic subgroups $P, Q \subset G$ containing *the same* Levi subgroup M, construct as isomorphism between the functors $\mathrm{Eis}^G_{M,P}$ and $\mathrm{Eis}^G_{M,Q}$ restricted to some large subcategory of "regular" sheaves inside $\mathrm{Sh}(M)$.

On the local Langlands and Jacquet–Langlands correspondences

Guy Henniart

Abstract. Let F be a locally compact non Archimedean field, and D a division algebra with centre F and finite dimension d^2 over F. Fix an integer $r \geqslant 1$, and let $G = \mathrm{GL}_n(F)$, $G' = \mathrm{GL}_r(D)$, where $n = rd$. Smooth irreducible representations of G' are related to those of G via the Jacquet–Langlands correspondence, whereas the Langlands correspondence relates such representations of G to degree n representations of the absolute Galois group of F. We review some recent results on those correspondences, in particular on their explicit description.

Résumé. Soient F un corps commutatif localement compact non archimédien, et D un corps gauche de centre F et de dimension finie d^2 sur F. Fixons un entier $r \geqslant 1$ et posons $n = rd$, $G' = \mathrm{GL}_r(D)$, $G = \mathrm{GL}_n(F)$. Les représentations lisses irréductibles de G' sont reliées à celles de G par la correspondance de Jacquet–Langlands, tandis que la correspondance de Langlands relie celles de G aux représentations de dimension n du groupe de Galois absolu de F. Nous passons en revue quelques résultats récents concernant ces correspondances, et en particulier leur description explicite.

Mathematics Subject Classification (2000). Primary 22E50.

Keywords. Local field, smooth representations, Jacquet–Langlands correspondence, Langlands correspondence.

1. Smooth representations

Let F be a locally compact non-Archimedean field, and p its residue characteristic. So F is a finite extension of the field $\mathbb{Q}_p$ of p-adic numbers, or of the field of Laurent power series $\mathbb{F}_p((X))$ in one variable X.

If $\mathbb{H}$ is a reductive linear algebraic over F, then the group $H = \mathbb{H}(F)$, with its natural topology coming from F, is locally profinite: there is a basis of neighbourhoods of identity consisting of open compact subgroups. We shall be interested only in the following special cases. We let D be a division algebra with centre F and finite dimension over F; that dimension is necessarily a square d^2, $d \geqslant 1$. We fix an integer $r \geqslant 1$, put $n = rd$, and write G'_r or simply G' for $\mathrm{GL}_r(D)$ and G_n or simply G for $\mathrm{GL}_n(F)$. Both are examples of groups H as above, and G is the special case of G' where $d = 1$, $n = r$.

A representation of a locally profinite group H, on a complex vector space V, is *smooth* if every vector v in V has open stabilizer in H. With obvious morphisms smooth representations of H form an abelian category.

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

Simple objects in that category are called *irreducible*: a smooth representation (π, V) of H is irreducible if V is non-zero and contains no subspace invariant under H, other than $\{0\}$ and V. We write $\mathcal{A}(H)$ for the set of isomorphism classes of irreducible smooth representations of H.

A *character* of H is a group homomorphism into $\mathbb{C}^\times$, with open kernel. Characters of H parametrize isomorphism classes of smooth 1-dimensional representations.

We consider only locally profinite groups H such that for one – and hence for all – open compact subgroups K, H/K is *countable*. In that case Schur's lemma is valid for an irreducible smooth representation (π, V) of H, and in particular the centre $Z(H)$ of H acts on V via a character ω_π called the *central character* of π. In our case the centre of G' or G is made out of scalar matrices, and will be identified with $F^\times$.

2. Coefficients

If (π, V) is a smooth representation of a locally profinite group H, the group H acts on $V^* = \mathrm{Hom}(V, \mathbb{C})$ by $g \mapsto {}^t\pi(g^{-1})$. The subspace $V^\vee$ of V^* of linear functionals which are *smooth*, i.e. stabilized by an open subgroup of H, carries a smooth representation $(\pi^\vee, V^\vee)$ of V, called the *contragredient* of (π, V). The natural embedding $V \to V^{\vee\vee}$ is an isomorphism if and only if (π, V) is *admissible*, which means that for all open compact subgroups K of H, the subspace V^K of fixed points under K is finite-dimensional; in that case $(\pi^\vee, V^\vee)$ is also admissible. When H is reductive over F, a smooth representation of H of finite length is admissible.

A *coefficient* of (π, V) is a function c on H of the form $c(g) = \lambda(\pi(g)v)$ where $v \in V$, $\lambda \in V^\vee$. If (π, V) has a central character ω_π, then $c(zg) = \omega_\pi(z)c(g)$ for $z \in Z(H)$, $g \in H$.

Let (π, V) be *irreducible*. We say that it is *cuspidal* if the support of any coefficient is compact modulo $Z(H)$; we say it is *square integrable* (L^2) if ω_π is unitary and for any coefficient c of π, its absolute value $|c|$ is square integrable on $H/Z(H)$, for any Haar measure on that quotient group. We let $\mathcal{A}^o(H)$ (resp. $\mathcal{A}^2(H)$) be the subset of $\mathcal{A}(H)$ made out of cuspidal (resp. L^2) representations.

3. The Jacquet–Langlands correspondence

That correspondence is a special case of Langlands' functoriality principle, which very roughly speaking says that two groups sharing many conjugacy classes should share a large part of their representation theory. That is precisely the case for our groups G' and G.

An element g' of G' has a reduced characteristic polynomial $P(g')$, which is a monic polynomial of degree $n = rd$ in $F[T]$. We say that g' is regular semisimple if $P(g')$ has no repeated root in an algebraic closure of F, and that g' is regular elliptic

if moreover $P(g')$ is irreducible in $F[T]$. Two regular semisimple elements of G' are conjugate in G' if and only if they have the same characteristic polynomial. The set G'^s of regular semisimple elements in G' is open and dense, and the set G'^e of regular elliptic elements is open.

All that applies to G as a special case. For $g' \in G'^s$, there is $g \in G^s$, unique up to conjugation, such that $P(g) = P(g')$. For $g \in G^s$, there is a $g' \in G'^s$ such that $P(g) = P(g')$ if and only if all irreducible factors of $P(g)$ have degree a multiple of d; that is obviously the case for $g \in G^e$.

To express how G and G' can share some of their representation theory, recall that if we fix a Haar measure dg' on G', the convolution algebra $\mathcal{H}(G')$ of locally constant compactly supported functions on G' acts in any smooth representation (π', V') of G' via $\pi'(f)v' = \int_{G'} f(g')\pi(g')\,dg'$, for v' in V' and f in $\mathcal{H}(G')$. If (π', V') is admissible (in particular when π' has finite length), $\pi(f)$ has finite dimensional range hence has a trace.

Theorem 1. *Let (π', V') be a finite length smooth representation of G'. There is a unique locally constant function $\chi_{\pi'}$ on G'^s, locally integrable on G', such that for $f \in \mathcal{H}(G')$ we have* $\operatorname{tr} \pi'(f) = \int_{G'} \chi_{\pi'}(g') f(g')\,dg'$.

Note that by uniqueness $\chi_{\pi'}$ is invariant under conjugation. Also it does not depend on the choice of Haar measure dg' on G'. If f has support in G'^s, the result is due to Harish Chandra [27], [28], as is the general case when F has characteristic 0 [27]. When F has positive characteristic, it is more difficult and is due to B. Lemaire, first for G [46] and recently for G' [47].

Corollary. *Let $\pi'_1, \dots, \pi'_s$ be inequivalent smooth irreducible representations of G'. Then the functions $\chi_{\pi'_1}, \dots, \chi_{\pi'_s}$ are linearly independent.*

The Jacquet–Langlands correspondence is expressed by the following result.

Theorem 2. *There is a unique bijection $\pi \leftrightarrow \pi'$ between $\mathcal{A}^2(G)$ and $\mathcal{A}^2(G')$ such that $\chi_\pi(g) = (-1)^{n-r}\chi_{\pi'}(g')$ whenever $g \in G^e$, $g' \in G'^e$, $P(g) = P(g')$.*

When $n = 2$, where G' is $D^\times$, D the quaternion division algebra over F, the result is due to Jacquet and Langlands [39], hence the name. For $n = 3$ it is due to Flath [22] when F has characteristic 0 and to the author [33] in general. When $n > 3$, $r = 1$, it was established by Rogawski [50] in characteristic 0 and Badulescu [2] in positive characteristic.

Finally the general case $n > 3$, $r > 1$ was obtained by Deligne, Kazhdan and Vignéras [21] in characteristic 0 and Badulescu [3] in positive characteristic. Note that the method is global, it uses automorphic forms and trace formulas. Only when $n = 2$ a purely local proof is known [24], see also [14].

Remarks. 1) If $\pi \leftrightarrow \pi'$ as above, then $\omega_\pi = \omega_{\pi'}$ and $\pi^\vee \leftrightarrow \pi'^\vee$.

2) For π' a smooth representation of G' and χ a character of $F^\times$, we let $\chi\pi'$ be the smooth representation $g' \mapsto \chi \circ \operatorname{Nrd}(g')\pi'(g')$, where Nrd is the reduced norm

(the determinant in the special case of G). For $\pi \leftrightarrow \pi'$ as above, and χ unitary, then $\chi\pi \in \mathcal{A}^2(G)$, $\chi\pi' \in \mathcal{A}^2(G')$ and $\chi\pi \leftrightarrow \chi\pi'$.

4. Extending the Jacquet–Langlands correspondence

When $r > 1$, the groups G and G' share more conjugacy classes than just elliptic ones.

Theorem 3 ([4]). *If $\pi \in \mathcal{A}^2(G)$ and $\pi' \in \mathcal{A}^2(G')$ correspond as above, then*

$$\chi_\pi(g) = (-1)^{n-r}\chi_{\pi'}(g') \text{ whenever } g \in G^s,\ g' \in G'^s,\ P(g) = P(g').$$

It is natural to expect that G and G' also share more of their representation theory than just discrete series.

From Remark 2 of § 3, we readily extend the Jacquet–Langlands correspondence a bit, as follows.

A smooth representation π' of G' is called *essentially* L^2 if it is of the form $\chi\pi'_0$, where π'_0 is L^2 and χ is a character of $F^\times$. Writing $\mathcal{A}^d(G')$ for the essentially L^2 elements in $\mathcal{A}(G')$, we get a unique bijection $\pi \leftrightarrow \pi'$ between $\mathcal{A}^d(G)$ and $\mathcal{A}^d(G')$, for which the assertion of Theorem 3 is still valid, and then $\chi\pi \leftrightarrow \chi\pi'$ for all characters χ of $F^\times$, if $\pi \leftrightarrow \pi'$.

To go further, we have to use parabolic induction. For $i = 1, 2$, let r_i be a positive integer, and (π'_i, V_i) a smooth representation of G'_{r_i}. We consider the space $\mathcal{F}$ of functions $f : G'_{r_1+r_2} \to V_1 \otimes V_2$ which satisfy

$$f(mu\ g) = \delta(m)^{1/2}(\pi'_1(g_1) \otimes \pi'_2(g_2))(f(g))$$

for any $g \in G'_{r_1+r_2}$, any diagonal block matrix m in $G'_{r_1+r_2}$ with diagonal blocks $g_1 \in G'_{r_1}$ and $g_2 \in G'_{r_2}$, and any upper unipotent block matrix u with diagonal blocks 1_{r_1} and 1_{r_2}. Here δ is a specific character of $G'_{r_1} \times G'_{r_2}$ with positive real values, called the *modulus character*. The group $G'_{r_1+r_2}$ acts on $\mathcal{F}$ by right translations and the subspace $\mathcal{F}^\infty$ of functions stabilized by an open subgroup of $G'_{r_1+r_2}$ carries a smooth representation $i(\pi'_1, \pi'_2)$ of $G'_{r_1+r_2}$.

Note. The rôle of the modulus character is that if π'_1 and π'_2 are unitary – i.e. there is a G'_{r_i}-invariant hermitian positive definite form on the space V_i – then so is $i(\pi'_1, \pi'_2)$.

If π'_1 and π'_2 have finite length, the same is true of $i(\pi'_1, \pi'_2)$. Writing $\mathcal{R}'_r$ for the Grothendieck group of the category of finite length smooth representations of G'_r – this is a free $\mathbb{Z}$-module with basis $\mathcal{A}(G'_r)$ – we get a $\mathbb{Z}$-linear multiplication $\mathcal{R}'_{r_1} \times \mathcal{R}'_{r_2} \to \mathcal{R}'_{r_1+r_2}$ such that $[\pi'_1] \times [\pi'_2] = [i(\pi'_1, \pi'_2]$ where $[\pi']$ is the class in the Grothendieck group of the smooth representation π' of finite length. Putting $\mathcal{R}' = \bigoplus_{r \geqslant 1} \mathcal{R}'_r$, we get a graded ring ([61] for $d = 1$, [58]) which is *commutative*; as a special we get a graded ring $\mathcal{R} = \bigoplus_{k \geqslant 1} \mathcal{R}_k$ for the groups G_k.

Theorem (Badulescu, [4]). a) *There is a unique $\mathbb{Z}$-linear map $JL\colon \mathcal{R} \to \mathcal{R}'$ sending $\mathcal{R}_k$ to 0 if $d \nmid k$ and to $\mathcal{R}'_{k/d}$ if $d \mid k$, such that for $\pi \in \mathcal{R}$ and $\pi' = JL(\pi)$ we have*

$$\chi_\pi(g) = (-1)^{n-r}\chi_{\pi'}(g') \text{ whenever } g \in G^s_{rd},\ g' \in G'^s_r,\ P(g) = P(g').$$

b) *The map JL is the unique ring homomorphism which is trivial on $\mathcal{R}_k$ when $d \nmid k$ and extends the Jacquet–Langlands correspondence on $\mathcal{A}^d(G_{rd})$ for any integer $r \geqslant 1$.*

In fact $\mathcal{R}$ and $\mathcal{R}'$ are even Hopf algebras with a canonical involution, the Aubert–Bernstein–Zelevinsky involution [1], [61], and JL is a Hopf-algebra homomorphism, which preserves the involutions, up to predictable signs. The kernel of JL is the ideal generated by the $\mathcal{R}_k$ for $d \nmid k$.

It is expected that when π is a *unitary* smooth irreducible representation of G_k, then $JL([\pi])$ is either 0 – in particular if $d \nmid k$ – or plus or minus the class of a unitary smooth *irreducible* representation of $G'_{k/d}$. Badulescu [5] has proved that when π is a local component of some discrete series representation of $\mathrm{GL}_k(\mathbb{A}_E)$, where E is a number field with completion F at some finite place.

Remark. The unitary elements in $\mathcal{A}(G_k)$ have been classified by Tadić [57], and a similar classification is expected for $\mathcal{A}(G'_r)$ [58]. By recent work of Tadić, Badulescu and Renard [4], [5], [6], it is enough to prove the following conjecture, a result due to Bernstein [7] for G_k.

Conjecture. Let $\pi_i \in \mathcal{A}(G'_{r_i})$, $i = 1, 2$, be unitary. Then $\pi_1 \times \pi_2$ is irreducible.

5. The Langlands correspondence

Let $\overline{F}$ be a separable algebraic closure of F. The group $\mathrm{Gal}(\overline{F}/F)$ is then profinite, and class field theory gives a canonical bijection between characters of $\mathrm{Gal}(\overline{F}/F)$ and finite order characters of $F^\times$. Replacing $\mathrm{Gal}(\overline{F}/F)$ by a variant, the Weil group W_F [60, Appendix II], even gives a bijection between characters of W_F and characters of $F^\times = \mathrm{GL}_1(F)$.

It was Langlands' fundamental intuition that irreducible smooth representations of G_n, $n \geqslant 2$, are intimately related to degree n smooth representations of W_F, cuspidal representations of G_n corresponding to irreducible representations of W_F. Write $\mathcal{G}^o(n)$ for the set of isomorphism classes of irreducible degree n smooth representations of W_F.

Theorem. *There is a unique family of bijective maps $\mathcal{G}^o(n) \to \mathcal{A}^o(G_n)$, $\sigma \mapsto \pi(\sigma)$, such that*

1) *for $n = 1$, it is given by class field theory;*

2) *for $n, m \geqslant 1$, $\sigma \in \mathcal{G}^o(n)$, $\tau \in \mathcal{G}^o(m)$ we have*

$$L(\sigma \otimes \tau, s) = L(\pi(\sigma) \times \pi(\tau), s) \quad \text{and} \quad \varepsilon(\sigma \otimes \tau, s, \psi) = \varepsilon(\pi(\sigma) \times \pi(\tau), s, \psi)$$

for all non-trivial characters ψ of F.

Here the L-factors are of the form $P(p^{-s})^{-1}$, $P \in \mathbb{C}[X]$, $P(0) = 1$, and the ε factors are monomials in p^{-s}. The L-factor on the left is Artin's, whereas the ε-factors on the left have been defined by Langlands and Deligne [20], generalizing Tate's thesis [59] which concerns characters of $F^\times$, i.e. one dimensional representations of W_F. The L-factors and ε-factors on the left are those defined by Jacquet, Piatetski–Shapiro, and Shalika [40], or equivalently Shahidi [54], [55], a very different generalization of Tate's thesis. It is wonderfully ironic that both generalizations turn out to be "the same".

Remark. The central character of $\pi(\sigma)$, for $\sigma \in \mathcal{G}^o(n)$, corresponds to the character $\det \sigma$ of W_F via class field theory. Also $\pi(\sigma^\vee) = \pi(\sigma)^\vee$.

The theorem is due to Laumon, Rapoport and Stuhler [45] when F has positive characteristic, and to M. Harris and R. Taylor [32], see also [30], [31] for p-adic fields. Both proofs are global and geometric, using automorphic forms, trace formulas and the geometry of Drinfeld or Shimura modular varieties. They also rely on counting arguments due to the author [34].

The proof in positive characteristic is easier because one can exploit then the functional equation for the L function of an ℓ-adic representation of global Galois groups. Of course the theorem is now also a consequence of L. Lafforgue's result [43] establishing the Langlands conjecture for global fields of positive characteristic. In characteristic zero, the set of Galois L-functions for which one can prove a functional equation is much more restricted, and one has to use Harris' approach [29]. The method in [32] uses heavily the geometry of Shimura varieties at places of bad reduction, which has the advantage of yielding a geometric model for the Langlands correspondence – that is also the case for [45]. The author has given a simpler proof [36], which uses the same Shimura varieties but only at places of good reduction, where it is much easier to get – but one does not get the geometric model that way.

It is highly desirable to find a proof not relying on geometry, and ideally a purely local proof. However the program of C. J. Bushnell and the author [9 and references therein] faces obstacles in establishing the necessary properties of the ε-factors for pairs above. In the simplest cases $n = 2, 3$ the following can be proved ([41] for $n = 2$, [33] for $n = 3$) without geometry.

Theorem. *Let n be 2 or 3. There is a unique bijective map $\mathcal{G}^o(n) \to \mathcal{A}^o(G_n)$, $\sigma \mapsto \pi(\sigma)$, such that $\varepsilon(\chi\sigma, s, \psi) = \varepsilon(\chi\pi(\sigma), s, \psi)$ for all non-trivial additive characters ψ of F and all characters χ of $F^\times$.*

Here $\chi\sigma$ denotes the representation $g \mapsto \tilde{\chi}(g)\sigma(g)$ of W_F, where $\tilde{\chi}$ is the character of W_F corresponding to χ via class field theory.

The proof uses automorphic forms on global fields and trace formulas, even for $n = 2$. It is only recently that Bushnell and the author found a proof for $n = 2$, essentially local, which *does not* use *automorphic forms* [14].

Remark. The Langlands correspondence preserves more than the L and ε factors considered in the theorem. For example, the author shows in [37] that if $\sigma \in \mathcal{G}^o(n)$

then

$$L(\Lambda^2\sigma, s) = L(\tau(\sigma), \Lambda^2, s) \text{ and}$$
$$L(S^2\sigma, s) = L(\tau(\sigma), S^2, s)$$

where the L-factors on the right are those defined by Shahidi [55]. The corresponding ε-factors are also preserved, at least up to a non-zero constant (depending on σ).

6. Explicit Langlands correspondence in the tame case

All elements of $\mathcal{A}^o(G_n)$ have been constructed explicitly by Bushnell and Kutzko [15], see also [8]: for each $\pi \in \mathcal{A}^o(G_n)$ they describe an open subgroup J of G_n, which contains the centre Z and is compact mod Z, and a finite dimensional smooth irreducible representation λ of J such that π is obtained from λ by smooth induction (a simpler variant of the construction in § 4). When n is prime to p, the so-called *tame case*, the construction goes back to R. Howe [38], and when $n = p$ to Carayol [19], but the general case is much harder.

It is natural to ask for an explicit description of the Langlands correspondence in terms of such a construction. When p divides n it is out of reach at present: only the case $n = p = 2$ is reasonably settled [42], [14]. In the tame case Howe parametrized both $\mathcal{G}^o(n)$ and $\mathcal{A}^o(G_n)$ in terms of *admissible pairs* $(E/F, \theta)$, where E/F is a degree n extension, θ a character of $E^\times$ not factorizing through an intermediate norm $N_{F/E'}$ $F \subset E' \subset E$, $E' \neq E$, and such that if θ restricted to principal units of E does factorize, then E/E' is unramified. There is then a canonical map $(E/F, \theta) \mapsto \pi(E/F, \theta)$ giving a bijection between admissible pairs up to isomorphism and $\mathcal{A}^o(G_n)$; see [49] for a precise construction, or [12].

On the other hand, if $(E/F, \theta)$ is an admissible pair, θ can be seen as a character of the Weil group W_E, which is an open subgroup of index n of the Weil group W_F. We can then form $\sigma(E/F, \theta)$, the degree n smooth representation of W_F induced from the character θ of W_E. The map $(E/F, \theta) \mapsto \sigma(E/F, \theta)$ gives a bijection between admissible pairs, up to isomorphism, and $\mathcal{G}^o(n)$.

However, the determinant of $\sigma(E/F, \theta)$, seen as a character of $F^\times$, differs in general from the central character of $\pi(E/F, \theta)$, so $\pi(E/F, \theta)$ cannot be $\pi(\sigma(E/F, \theta))$. Recently C.J. Bushnell and the author obtained the following result, in the more general *essentially tame* situation where n is not necessarily prime to p but E/F is still tamely ramified of degree n.

Theorem ([12]). *Let $(E/F, \theta)$ be an admissible pair with E/F tamely ramified of degree n. Then there is a unique tamely ramified character $\mu = \mu(E/F, \theta)$ of $E^\times$ such that $\pi(\sigma(E/F, \theta)) = \pi(E/F, \mu\theta)$.*

The twisting character μ has been computed, at least when E/F is totally ramified [13]. The answer is easy to state only when n is odd; moreover when n is even, the answer *does not* coincide in general with the recipe conjectured in [49].

7. Explicit Jacquet–Langlands correspondence, $r = 1$

An explicit construction of $\mathcal{A}(G'_r)$ or even its cuspidal part $\mathcal{A}^o(G'_r)$, is not known in general (see § 8). However, when $r = 1$, the group $G'_1 = D^\times$ is compact modulo its centre Z and all its irreducible smooth representations are cuspidal and finite-dimensional. They have been constructed by E.-W. Zink [62] and, in terms closer to [15], by P. Broussous [16]. In the tame case, when d is prime to p, the construction goes back to R. Howe [38], see also [48], [49]: there is a natural construction $(E/F, \theta) \mapsto \pi'(E/F, \theta)$ which parametrizes $\mathcal{A}(G'_1) = \mathcal{A}(D^\times)$ via isomorphism classes of admissible pairs of degree $[E : F]$ dividing d.

In the case where E/F is totally ramified of degree n, there is an unramified quadratic character η of $E^\times$ such that $\pi(E/F, \theta)$ corresponds to $\pi'(E/F, \eta\theta)$ via the Jacquet–Langlands correspondence [35, when n is prime]. A similar answer is expected in general but does not seem to be available yet.

More interesting, because the construction is much more involved, is the *totally wild* case, when n is power of p and we consider $\pi \in \mathcal{A}^o(G_n)$ such that there is no unramified character χ of $F^\times$ for which $\chi\pi$ is isomorphic to π. In that case [15] π is constructed from a so-called "*simple*" pair (β, θ) where β is an element of G generating a totally ramified extension E/F of degree n; to such an element β are attached two open subgroups $J = J(\beta)$ and $H^1 = H^1(\beta)$, θ is a character of H^1 of a very specific shape, and π is induced from a representation λ of J with restriction to H^1 isotypic of type θ. There certainly exists $\beta' \in G'$ with $P(\beta) = P(\beta')$ and there is a natural procedure to deduce from θ a similar character θ' of some open compact subgroup $H^1(\beta')$ of $D^\times$ and then from λ a similar representation λ' of an open compact subgroup $J(\beta')$ which induces to $\pi' \in \mathcal{A}(D^\times)$. The main result of [11] (see [10] when $n = p$) states that, at least when p is odd, π corresponds to π' under the Jacquet–Langlands correspondence.

8. Construction and explicit Jacquet–Langlands correspondence, $1 < r < n$

Generalizing the above constructions to intermediate cases $1 < r < n$ is not easy, even when restricting to tame or totally wild situations! Moreover one wants to deal with L^2 representations and not only with cuspidal ones.

This is already visible in the so-called "*level-zero*" case, where one considers the Jacquet–Langlands correspondence $\pi \leftrightarrow \pi'$ for π corresponding to a tamely ramified representation of W_F: in $G'_r = \mathrm{GL}_r(D)$, this translates into the property that in the space of π' there is a non-zero vector fixed under the compact open subgroup $1 + P_D M_r(O_D)$ where O_D is the ring of integers of D and P_D its maximal ideal. We say that such $\pi' \in \mathcal{A}^d(G'_r)$ have *level zero*. Level zero elements of $\mathcal{A}^d(G'_r)$ or $\mathcal{A}^d(G_n)$, $n = rd$, are parametrized by admissible pairs $(E/F, \theta)$, where E/F is unramified of degree dividing n, and θ is a tamely ramified character of $E^\times$. However

it is hard to label exactly the representation corresponding to $(E/F, \theta)$, and even more difficult to get the Jacquet–Langlands correspondence explicit in that level zero case. That was recently accomplished by Grabitz, Silberger and Zink [26], [56].

The higher level case is even more difficult, and has been subject to investigations of P. Broussous and M. Grabitz [17], [18], [25] and V. Sécherre [51], [52], [53]. By analogy with [61] and [15], they construct "*simple*" *pairs* (β, θ) as above in G'_r. Sécherre then follows the procedure of [15], and constructs [51], [52] from a simple pair (β, θ) a *simple type* (J, λ) in G'_r as in § 7, and controls its intertwining, so that in particular it is known when λ gives rise by induction to cuspidal smooth irreducible representations of G'_r; in the contrary case, Sécherre computes the intertwining algebra, which in particular tells how many elements in $\mathcal{A}^d(G'_r)$ one can get from λ [53]. It remains to prove that all of $\mathcal{A}^d(G'_r)$ has been obtained: this is the problem of *exhaustion*. Grabitz has obtained some partial results in that direction [25].

This is only for the explicit construction of $\mathcal{A}^d(G'_r)$ in the higher level case: describing the Jacquet–Langlands correspondence explicitly is harder.

As a final remark, let me mention that once exhaustion is proved, Sécherre's result on the intertwining algebra will imply the conjecture of Tadić mentioned in § 4.

An invitation to bounded cohomology

Nicolas Monod

Abstract. A selection of aspects of the theory of bounded cohomology is presented. The emphasis is on questions motivating the use of that theory as well as on some concrete issues suggested by its study. Specific topics include rigidity, bounds on characteristic classes, quasification, orbit equivalence, amenability.

Mathematics Subject Classification (2000). Primary 55N; Secondary 20F.

Keywords. Bounded cohomology.

1. Introduction

This lecture is an invitation to explore bounded cohomology. It is not an attempt to collect all recent advances in that topic, much less an ex cathedra exposition of the theory. I will try to illustrate how problems from diverse origins can be translated into the framework of bounded cohomology, and how in return this theory prompts a few concrete problems. A number of questions are suggested, ranging from teasers to the ill-defined.

The terminology *bounded cohomology* proposed by M. Gromov [67] refers to the following concrete definition. Recall that the ordinary (singular) cohomology $\mathrm{H}^*(M, \mathbf{R})$ of a manifold M can be defined by the complex of all *singular cochains* on M, which are just all real-valued functions on the set of singular simplices. The subspace of *bounded* functions yields a subcomplex and hence cohomology groups $\mathrm{H}^*_\mathrm{b}(M, \mathbf{R})$. Moreover, the inclusion map of this subcomplex determines a natural transformation $\mathrm{H}^*_\mathrm{b}(M, \mathbf{R}) \to \mathrm{H}^*(M, \mathbf{R})$ called the *comparison map*.

This definition can be imitated for groups. One of the definitions of Eilenberg–MacLane cohomology $\mathrm{H}^*(G, V)$ of a group G with coefficients in some module V is given by the complex of all G-equivariant V-valued functions on G^{n+1}. Considering only those functions that are bounded one obtains a complex

$$0 \longrightarrow \mathrm{C}_\mathrm{b}(G, V)^G \longrightarrow \mathrm{C}_\mathrm{b}(G^2, V)^G \longrightarrow \mathrm{C}_\mathrm{b}(G^3, V)^G \longrightarrow \cdots$$

whose cohomology is the *bounded cohomology* $\mathrm{H}^*_\mathrm{b}(G, V)$ and comes again with a *comparison map* $\mathrm{H}^*_\mathrm{b}(G, V) \to \mathrm{H}^*(G, V)$. One needs here to make sense of boundedness for V-valued maps; for instance, V could be a Banach space with isometric G-representation. We will usually assume that this *coefficient module* is dual (e.g.

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

$V = \mathbf{R}$ or a unitary representation on Hilbert space). More generally, when G is a locally compact group we (ab)use the same notations H^*, H^*_b for the *continuous* (bounded) cohomology; for present purposes, it is simply defined by requiring that all cochains be continuous[1].

I will mainly concentrate on the group case; a theorem of M. Gromov of fundamental importance states that the morphism $\mathrm{H}^*_\mathrm{b}(\pi_1(M), \mathbf{R}) \to \mathrm{H}^*_\mathrm{b}(M, \mathbf{R})$ induced by the classifying map is an isomorphism (Corollary p. 40 in [67]; see also [11]).

The above definitions, especially in the group case, might seem artificial. The next section is an attempt to challenge this perception. Nevertheless, I should point out that *there is not a single countable group G for which $\mathrm{H}^*_\mathrm{b}(G, \mathbf{R})$ is known, unless it is known to vanish in all degrees.* For instance, here is what is known for the free group $\mathbf{F}_2$ and trivial coefficients: $\mathrm{H}^1_\mathrm{b}(\mathbf{F}_2, \mathbf{R})$ vanishes, $\mathrm{H}^2_\mathrm{b}(\mathbf{F}_2, \mathbf{R})$ and $\mathrm{H}^3_\mathrm{b}(\mathbf{F}_2, \mathbf{R})$ are infinite-dimensional [11, §3], [66], [139].

However, in the case of *connected* groups, all known results seem to indicate that bounded cohomology with trivial coefficients is much better behaved than for discrete groups. The connected case can be reduced to semi-simple Lie groups, prompting the following question.

Problem A. Let G be a connected semisimple Lie group with finite centre. Is the comparison map

$$\mathrm{H}^*_\mathrm{b}(G, \mathbf{R}) \longrightarrow \mathrm{H}^*(G, \mathbf{R})$$

an isomorphism?

At this time, it seems that the question of injectivity and surjectivity of this comparison map are two quite different issues; existing proofs are of a very different nature. Perhaps this will change with a better understanding of the bounded cohomology of Lie groups. But for the time being, I would like to single out the subquestion below because it is the aspect most relevant for several questions discussed in this text.

Problem A′. Is the comparison map of Problem A surjective?

A related conjecture was proposed by J. Dupont [43]; compare also the introduction of [14] and 9.3.8, 9.3.9 in [112]. One can also ask the same questions more generally for products of semisimple algebraic groups over local fields. For more general coefficient modules, even if only irreducible unitary representations are considered, both injectivity and surjectivity fail [25].

2. Three ways to stumble upon H^*_b

I will now sketch briefly three circumstances leading naturally to study bounded cohomology: (1) group algebras; (2) bounds and refinements of classical invariants; (3) quasification.

[1] I emphasise that when G is not discrete, this is not the same as the cohomology of the classifying space BG.

2.1. Cohomology of group algebras. The usual Eilenberg–MacLane cohomology of a discrete group Γ can be seen as a particular case of the cohomology of algebras; namely, it is isomorphic to the cohomology of the group algebra $A = \mathbf{R}\Gamma$.[2] Here A is the free $\mathbf{R}$-vector space on Γ endowed with the convolution product. In other words, it is the universal object obtained by forcing upon the group Γ an $\mathbf{R}$-linear structure extending the multiplication in Γ. Recall that the cohomology of A is defined by Ext-functors, which means that one considers complexes of linear morphisms

$$A \otimes \cdots \otimes A \longrightarrow \mathbf{R}$$

to $\mathbf{R}$ or more generally to suitable coefficient modules.

Now, this free vector space A brings along its "free norm", that it, the ℓ^1-norm; the latter extends as the *projective tensor norm* on the above tensor products [72, I§1.1]. Why not, then, take this topology into account and compute the cohomology of the *topological algebra* A? This amounts to considering complexes of *continuous* linear morphisms

$$A \otimes_\pi \cdots \otimes_\pi A \longrightarrow \mathbf{R},$$

where $\otimes_\pi$ is the notation indicating the choice of the projective tensor norm. The point is that *this cohomology is nothing else than the bounded cohomology of* Γ, as follows readily from the properties of $\otimes_\pi$. Once we deal with this *continuous cohomology* of A, we may of course replace A by its completion $\ell^1(\Gamma)$ without affecting the outcome. In conclusion, *the bounded cohomology of groups is a particular case of the cohomology of Banach algebras* as exposed in B. Johnson's 1972 memoir [89] (see also A.Ya. Helemskiĭ [76]). I would like to point out that the group algebra case (that is, bounded cohomology) was indeed prominent in B. Johnson's memoir. One can find therein several aspects that became intensively studied later, such as quasimorphisms, amenability and the problem of the existence of outer derivations. Nevertheless, it is M. Gromov's paper (which also refers to ideas of W. Thurston) that gave all its impetus to the theory.

Here are two questions to conclude this outline. First, we point out that for C *-algebras and specifically von Neumann algebras, other cohomologies have been studied, such as *completely bounded cohomology*, where the notion of boundedness is quite different from our setting; see Christensen–Effros–Sinclair [33]. Consider the von Neumann algebra $L(\Gamma)$ associated to a countable group Γ, which is the completion of A for a much weaker topology than above. Then, there is not anymore a straightforward correlation between Γ-modules and $L(\Gamma)$-bimodules as there was for $\ell^1(\Gamma)$. However, there is a precise analogy instead: the theory of *correspondences* (see A. Connes [36] and S. Popa [130]). Whilst this will not provide a precise dictionary from the Eilenberg–MacLane cohomology of Γ to some cohomology of $L(\Gamma)$, it still

[2] For exact statements, one needs to give more details on how to handle the coefficients involved; for instance, A is suitable for coefficients that are real vector spaces. Moreover, Hochschild cohomology of algebras involves A-bimodules as coefficients, whilst a priori the cohomology of Γ is defined for modules. Not taking this into account would identify the Hochschild cohomology with a sum of Eilenberg–MacLane cohomology of centralisers of representatives of the conjugacy classes of Γ. We will omit all details here.

raises the interesting possibility to define for $L(\Gamma)$ an analogue of the L^2-cohomology of Γ in the sense of M. Atiyah [4], Cheeger–Gromov [31] and W. Lück [101]. Such an analogue has been proposed by A. Connes and D. Shlyakhtenko in [38].

Here is how this programme connects to the topic of our discussion. For present purposes, let us think of the L^2-cohomology of Γ as the Eilenberg–MacLane cohomology $\mathrm{H}^*(\Gamma, \ell^2(\Gamma))$, where $\ell^2(\Gamma)$ is endowed with the regular representation[3]. The *bounded* cohomology $\mathrm{H}^*_\mathrm{b}(\Gamma, \ell^2(\Gamma))$ has also proved very useful in degree two (see Sections 4.1 and 4.2), even though one cannot *measure* its size as is done by means of the von Neumann dimension in the case of $\mathrm{H}^*(\Gamma, \ell^2(\Gamma))$.

Problem B. Perform a construction analogous to Connes–Shlyakhtenko [38] but corresponding to $\mathrm{H}^*_\mathrm{b}(\Gamma, \ell^2(\Gamma))$ instead of $\mathrm{H}^*(\Gamma, \ell^2(\Gamma))$. Provide non-triviality results, at least in degree two.

The second question is more indeterminate:

Problem C. Consider the cyclic cohomology of locally convex algebras $\mathcal{A}$ as in §II.5 of A. Connes' [37]. What can be said for $\mathcal{A} = \ell^1(\Gamma)$?

The cyclic homology of the group algebra $A = \mathbf{R}\Gamma$ (devoid of any topology) has been studied notably by D. Burghelea [29]. For an example with a locally convex completion of A, smaller than $\ell^1(\Gamma)$ and closer to the spirit of [37], see R. Ji [87].

2.2. Refinements of ordinary cohomology and numerical bounds. Certain classical cohomology classes are given by explicit cocyles that happen to be bounded. This is of particular interest for characteristic classes, since explicit bounds on characteristic numbers of flat bundles carry important geometric information, such as in the Milnor–Wood inequality; we refer to J. Dupont [43] for more on such bounds.

Here is an example of this situation: The *Euler number* of a flat oriented n-vector bundle over a compact manifold M measures the obstruction to finding a non-vanishing section. It can be computed by triangulating M, choosing generic "affine" sections over the resulting simplices and then adding up obstruction signs ± 1 for each simplex – see D. Sullivan [141] and J. Smillie [138]; compare also [7, F.4]. The resulting number is clearly bounded in terms of the number of simplices, though this bound is mysterious. One obtains a nice conceptual bound by observing that the Euler class of $\mathrm{GL}^+_n(\mathbf{R})$ has an explicit cocycle representative which is bounded, e.g. as in Ivanov–Turaev [86] (GL^+_n refers to the group of matrices with positive determinant).

Problem D. Let $\pi = (B \to M)$ be a flat oriented n-vector bundle over a compact manifold M. Given additional structure on π, define a natural class $\mathcal{E}_\mathrm{b}(\pi)$ in $\mathrm{H}^n_\mathrm{b}(M, \mathbf{R})$ whose image in $\mathrm{H}^n(M, \mathbf{R})$ is the Euler class $\mathcal{E}(\pi)$ of π.

[3] This is correct under the finiteness assumption F_n, where n is the degree of the cohomology considered. For the general case, one should follow W. Lück [101].

In particular, given a compact orientable n-manifold M with additional structure, find a natural definition of $\mathcal{E}_{\mathrm{b}}(M) \stackrel{\text{def}}{=} \mathcal{E}_{\mathrm{b}}(TM \to M)$.

I should certainly be a bit more specific here, since after all one way to see the Milnor–Wood inequality is to consider an explicit cocycle for the Euler class $\mathcal{E}$ that witnesses its boundedness. However, this is quite different from having a *natural invariant* in $\mathrm{H}^n_{\mathrm{b}}(M, \mathbf{R})$, already because the map $\mathrm{H}^n_{\mathrm{b}}(M, \mathbf{R}) \to \mathrm{H}^n(M, \mathbf{R})$ can be far from injective. The fact that additional structure on M should be required to rigidify the situation is suggested by the fact that $\mathrm{H}^n_{\mathrm{b}}(M, \mathbf{R})$ is canonically isometrically isomorphic to the bounded cohomology of the fundamental group $\Gamma = \pi_1(M)$ [67, p. 40]. By contrast, the Euler class *as class of* $B\mathrm{GL}^+_n(\mathbf{R})$ is unbounded (compare also footnote 1); thus the idea would be to transit via the *group cohomology*:

Consider for instance the setting of compact orientable manifolds supporting an affine structure. In that case the Euler class $\mathcal{E}(M)$ will come from the structure group $\mathrm{GL}^+_n(\mathbf{R})$ by pull-back through the holonomy representation of $\pi_1(M)$ via $\mathrm{H}^n(\pi_1(M), \mathbf{R})$ and the classifying map. In that case one would have a completely canonical choice for $\mathcal{E}_{\mathrm{b}}(M)$ if, as suggested by Problem A, one proves

$$\mathrm{H}^*_{\mathrm{b}}(\mathrm{PSL}_n(\mathbf{R}), \mathbf{R}) \cong \mathrm{H}^*(\mathrm{PSL}_n(\mathbf{R}), \mathbf{R}).$$

Indeed, an easy argument shows that this would imply

$$\mathrm{H}^n_{\mathrm{b}}(\mathrm{GL}^+_n(\mathbf{R}), \mathbf{R}) \cong \mathrm{H}^n(\mathrm{GL}^+_n(\mathbf{R}), \mathbf{R}), \quad n \neq 1.$$

A motivation for Problem D is the following.

Problem D′. Use a natural definition of $\mathcal{E}_{\mathrm{b}}(M)$ to prove that, for any compact orientable manifold M supporting an affine structure, $\mathcal{E}_{\mathrm{b}}(M)$ vanishes.

This would settle the Chern–Sullivan problem of the vanishing of the Euler-Poincaré number of such manifolds M.

The example of the boundedness of the Euler class can be considerably generalised: M. Gromov proves in [67] that all primary[4] characteristic classes are bounded, at least when viewed as classes of the structure group made discrete. A different proof avoiding the use of H. Hironaka's resolution of singularities was provided by M. Bucher-Karlsson in her thesis [14]; it is also shown in [14, p. 60] how it follows that these primary characteristic classes are bounded already when viewed as classes of the topological group G. In other words, they lie in the image of the comparison map $\mathrm{H}^*_{\mathrm{b}}(G, \mathbf{R}) \to \mathrm{H}^*(G, \mathbf{R})$.

Problem E. Prove the same statement for secondary characteristic classes[5].

As pointed out in [14], this would then solve Problem A′. Indeed, J. Dupont and F. Kamber proved in [44] that, as an algebra, $\mathrm{H}^*(G, \mathbf{R})$ is generated by primary and

[4] More precisely, the characteristic classes of flat G-bundles, where G is an algebraic subgroup of $\mathrm{GL}_n(\mathbf{R})$.

[5] See Cheeger–Simons [32] and M. Bucher-Karlsson [14] for the definition of secondary classes.

secondary classes when G is a connected semisimple Lie group with finite centre. (The product is easily seen to preserve boundedness of cohomology classes.)

Once a natural bounded representative has been identified for a classical cohomological invariant, this opens the door to a refined invariant: Indeed, the *bounded class* of that bounded cocycle contains a priori much more information than the class one started with. This is because it is easier for cocycles to be cohomologous than to be "boundedly cohomologous", that is, equivalent modulo *bounded coboundaries*.

A beautiful illustration of this phenomenon has been given by É. Ghys in [63] and goes as follows. Recall that if a group Γ acts by orientation-preserving homeomorphisms on the circle, it inherits an Euler class in $\mathrm{H}^2(\Gamma, \mathbf{Z})$. This class has a canonical representative taking only values $\{0, 1\}$, thus determining a bounded class. Whilst the original class determines only the obstruction to lifting the Γ-action to an action on the line, É. Ghys proves that the bounded class completely characterises the action up to semi-conjugacy.

Another important benefit of identifying an ordinary cohomology class as being bounded is the *Gromov seminorm*. Since *homology* classes are given by cycles, i.e. formal *finite* linear combinations of simplices (singular or otherwise), there is a numerical invariant attached to every homological class, the Gromov seminorm, which is by definition the infimum of the total mass of all linear combinations representing that class. This is a method of assigning a *numerical invariant* to cohomological invariants. For instance, this number is computed for the Kähler class by Domic–Toledo [42] and Clerc–Ørsted [34].

In particular, M. Gromov [67] defines the *simplicial volume* of a closed (connected, orientable) manifold M to be the seminorm of its fundamental class (for the relative case, see also [99]). This invariant, besides its own interest, provides bounds for the minimal volume of M over all (suitably normalised) Riemannian structures, as explained by M. Gromov in [67]. The relevance of bounded cohomology is that any upper bound on a *cocycle* with non-trivial homological pairing on the given cycle provides a non-trivial lower bound on the Gromov seminorm of the cycle.

W. Thurston and M. Gromov (see the 1978 notes [142] and [67]) have shown how to use negative curvature to prove the boundedness of fundamental classes – equivalently, the positivity of the simplicial volume. The case of symmetric spaces has been solved only quite recently, with J.-F. Lafont and B. Schmidt proving in [100] that *the simplicial volume of any closed locally symmetric space of non-compact type is positive*. (A crucial ingredient of their proof is the work of C. Connell and B. Farb [35].) Actually, the case of the symmetric space of $\mathrm{SL}_3(\mathbf{R})$ is not covered by [100]; it was claimed in [134], but the proof therein is incomplete. However a proof is provided by M. Bucher-Karlsson in [13]. M. Gromov has conjectured more generally that closed manifolds with non-positive curvature and negative Ricci curvature have positive simplicial volume.

2.3. Quasification. The word *quasification* is meant to refer to the process whereby a geometric or algebraic notion is modified to an approximate variant; typically, a

defining equality or inequality is relaxed by imposing that it hold up to some constants only. Here are a few examples of this overly vague principle.

(i) *Quasi-isometries.* Whereas a map $f\colon X \to Y$ between metric spaces X, Y is called isometric if $d_Y(f(x), f(x'))$ equals $d_X(x, x')$ for all $x, x' \in X$, it is said to be *quasi-isometric* if there is some constant $C \neq 0$ such that

$$C^{-1}d_X(x, x') - C \;\leq\; d_Y(f(x), f(x')) \;\leq\; Cd_X(x, x') + C \quad \text{for all } x, x' \in X.$$

A *quasi-isometry* is a quasi-isometric map whose image has finite codiameter. Here are two important motivations for this notion: (1) Geometric rigidity questions such as Mostow's strong rigidity [119] lead to consider quasi-isometries of symmetric spaces arising from a homotopy equivalence between two of its compact quotients; (2) Geometric group theory has had considerable success, following M. Gromov, in viewing finitely generated groups as metric spaces and studying their geometry [68], [71]; however, this point of view is well-defined only up to quasi-isometry.

As a matter of terminology, a *rough isometry* shall be a quasi-isometry where additive constants only are allowed:

$$d_X(x, x') - C \;\leq\; d_Y(f(x), f(x')) \;\leq\; d_X(x, x') + C.$$

(ii) *Gromov-hyperbolicity.* In the context of point (2) in (i) above, one calls a geodesic metric space *Gromov-hyperbolic* if any finite configuration of points is roughly isometric to a configuration in a tree; the additive constant is allowed to depend on the space and the number of points only. (For comparison with more usual definitions, see 2 §2, Theorem 12 (ii) in [64].) This notion is a quasi-isometry invariant even though it is a priori defined by rough isometries.

The theory of those finitely generated groups that are Gromov-hyperbolic as metric spaces is one of the major contribution to modern group theory; we refer to M. Gromov [69].

(iii) *Hyers–Ulam stability.* D. Hyers observed in [80] that whenever a mapping f between Banach spaces satisfies the additive equation upon some constant δ, then f is at finite distance (at most δ) of a truly additive mapping. A subsequent joint paper with S. Ulam [81] proposed the more delicate question of the stability of the equation defining isometries; more precisely: *If f is a rough isometry, is it close to an isometry?* After many partial results spanning half a century (starting with the Hilbertian case in [81]), the general case was solved affirmatively by P. Gruber [73] and J. Gevirtz [62] and the sharp constant provided by M. Omladič and P. Šemrl [122] in 1995.

The stability question was broadened to other contexts by Hyers–Ulam [82], [83] and a great many other authors. Within the context of isometries, three examples are: quaternionic hyperbolic spaces (P. Pansu [125]), higher rank symmetric spaces and buildings (Eskin–Farb [47] and Kleiner–Leeb [97]), hyperbolic buildings (Bourdon–Pajot [10]).

The connection between quasification and bounded cohomology appears when one considers the stability of *cocycles*. Indeed, suppose that f is "almost an n-cocycle"

for a group G in the Hyers–Ulam sense, say for a Banach G-module V. Specifically, in the model of the *inhomogeneous* bar-resolution, f is a map $G^n \to V$ with the property that

$$g_1 f(g_2, \dots, g_{n+1}) + \sum_{j=1}^{n} (-1)^j f(g_1, \dots, g_j g_{j+1}, \dots g_{n+1}) + (-1)^{n+1} f(g_1, \dots, g_n)$$

is bounded independently of $g_1, \dots g_{n+1} \in G$. The map $\delta f \colon G^{n+1} \to V$ defined by the above expression is therefore a bounded $(n+1)$-cocycle; indeed it is certainly a cocycle since it is defined as a coboundary. The latter observation means that δf represents a trivial class in usual cohomology $\mathrm{H}^{n+1}(G, V)$. But is it trivial as bounded cohomology class in $\mathrm{H}_{\mathrm{b}}^{n+1}(G, V)$? The definition of bounded cohomology gives us the answer: this class is trivial if and only if f is at finite distance of an actual n-cocycle $G^n \to V$. In conclusion, the Hyers–Ulam stability problem for $\mathrm{H}^n(G, V)$ is exactly captured by the kernel of the comparison map

$$\mathrm{EH}_{\mathrm{b}}^{n+1}(G, V) \stackrel{\text{def}}{=} \mathrm{Ker}\big(\mathrm{H}_{\mathrm{b}}^{n+1}(G, V) \longrightarrow \mathrm{H}^{n+1}(G, V)\big)$$

in one degree higher: $\mathrm{EH}_{\mathrm{b}}^{n+1}$ describes "n-quasicocycles". This could be made formal by introducing suitably complexes of quasicocycles and defining the corresponding cohomology groups $\mathrm{H}^*_{\mathrm{quasi}}(G, V)$. It is then straightforward to verify that one has an infinite exact sequence

$$\begin{aligned} \cdots \to \mathrm{H}^{n-1}_{\mathrm{quasi}}(G, V) \to \mathrm{H}^n_{\mathrm{b}}(G, V) \to \mathrm{H}^n(G, V) \\ \to \mathrm{H}^n_{\mathrm{quasi}}(G, V) \to \mathrm{H}^{n+1}_{\mathrm{b}}(G, V) \to \cdots \end{aligned}$$

Consider the simplest case, namely $n = 1$ and $V = \mathbf{R}$:

Definition 2.1. A *quasimorphism* is a map $f \colon G \to \mathbf{R}$ such that

$$\sup_{g,h \in G} |f(g) - f(gh) + f(h)| < \infty.$$

A quasimorphism is *non-trivial* if it is not a bounded perturbation of a homomorphism, or equivalently if it determines a non-zero class in $\mathrm{H}^2_{\mathrm{b}}(G, \mathbf{R})$.

B. Johnson proves already in [89, 2.8] that the free group $\mathbf{F}_2$ admits a non-trivial quasimorphism. This was considerably generalised and it is now known that $\mathrm{EH}^2_{\mathrm{b}}(G, \mathbf{R})$ is infinite-dimensional for (non-elementary) free groups, surface groups, Gromov-hyperbolic groups, free products (R. Brooks [11], Brooks-Series [12], Y. Mitsumatsu [111], Barge–Ghys [5], Epstein–Fujiwara [46], K. Fujiwara [49], [50], R. Grigorchuk [66]); generalising all the previous cases, for all groups acting on a Gromov-hyperbolic metric space in a *weakly proper* way (Bestvina–Fujiwara [8]; see also U. Hamenstädt [74]). Moreover, J. Manning [102, 4.29] shows that if there is

any quasimorphism that is what he calls *bushy*, then, already $H_b^2(G, \mathbf{R})$ is infinite-dimensional. (Contrary to what has sometimes been suggested, $EH_b^2(G, \mathbf{R})$ may however be of finite non-zero dimension [115]; thus not every quasimorphism is bushy.) Very interesting quasimorphism of a completely different nature have been constructed by Entov–Polterovich [45], Biran–Entov–Polterovich [9], Gambaudo–Ghys [58] and P. Py [131]. There, quasification is the additional freedom that allows to extend the Calabi homomorphism as a quasimorphism to larger groups that do not admit any non-zero homomorphism.

One checks that amenable groups do not have non-trivial quasimorphisms. In a completely opposed direction, it was proved in [23], [24] that irreducible lattices in semisimple Lie groups of higher rank have no non-trivial quasimorphisms. Interestingly, this property is not quasi-isometry invariant [23, 1.7].

Increasing the generality, let us consider unitary representations V. Since $H^1(G, V)$ classifies affine isometric actions on the Hilbert space V, it follows that $EH_b^2(G, V)$ contains information about *rough G-actions* on V, namely maps ϱ from G to the affine isometry group of V such that

$$\sup_{g,h\in G} \sup_{v\in V} \| \varrho(g)(\varrho(h)v) - \varrho(gh)v \| < \infty$$

(this forces the linear part of ϱ to be an actual representation).The results of [23], [24] show that any such rough action of a higher rank lattice has bounded "orbits". Using Hyers–Ulam stability [81], we deduce the following corollary for higher rank lattices: *Every action by rough isometries (of a given constant) on a Hilbert space has bounded orbits.*

Another natural problem is to consider *ε-representations* (or *near representations*) of the group G on a Hilbert space V, that is, maps $\pi : G \to U(V)$ to the unitary group U such that

$$\sup_{g,h\in G} \| \pi(g)\pi(h) - \pi(gh) \|_{\mathrm{op}} < \varepsilon,$$

wherein the norm is now the operator norm. The corresponding stability question is now: How close is π to an actual unitary representation? (In operator norm.)

When G is finite or more generally compact (with appropriate continuity addenda), la Harpe–Karoubi proved that for every $\delta > 0$ there is $\varepsilon > 0$ such that every ε-representation of Γ is δ-close to a unitary representation [40]. This was then established for amenable groups by D. Kazhdan in [95] using an ingenious notion of ε-cocycles. This device is however not obviously related to bounded cohomology.

Problem F. Can one reformulate in terms of bounded cohomology the problem of the stability of unitary representations?

D. Kazhdan also gives an example showing that for surface groups the phenomenon of stability of unitary representations fails to hold (Theorem 2 in [95]).

Problem F′. Prove (or disprove): Let Γ be a lattice in a connected simple Lie group of real rank at least two, e.g. $\Gamma = \mathrm{SL}_3(\mathbf{Z})$. Then for every $\delta > 0$ there is $\varepsilon > 0$ such that every ε-representation of Γ is δ-close to a unitary representation.

Notice that this conjectural stability does not follow from Kazhdan's property (T); just as for bounded cohomology, a stronger rigidity property of higher rank groups needs to be used. Indeed, any group G with a non-trivial quasimorphism $f\colon G \to \mathbf{R}$ lacks the stability of unitary representations: Consider for $\eta \in \mathbf{R}$ the map $\pi : G \to \mathrm{U}(\mathbf{C})$ for which $\pi(g)$ is the multiplication by $e^{i\eta f(g)}$. This is an ε-representations when η is small enough, but will not be quite close to a representation. Now recall that any non-elementary hyperbolic group admits non-trivial quasimorphisms and that there are many hyperbolic groups with property (T).

3. The rôle of amenability

The relevance of amenability to bounded cohomology has been patent ever since B. Johnson's memoir [89], where it is shown that a locally compact group G is amenable if and only if $\mathrm{H}^n_{\mathrm{b}}(G, V)$ vanishes for all $n > 0$ and all dual Banach modules V (compare also G. Noskov [120]). Since $\mathrm{H}^n_{\mathrm{b}}(G, V)$ appears in [89] as the Banach algebra cohomology of the group algebra of G, B. Johnson uses this characterisation to *define* the amenability of general Banach algebras. This suggests to consider the "bounded-cohomology dimension" of a group (or Banach algebra); more precisely:

Definition 3.1. (i) Let $\dim^{\sharp}_{\mathrm{b}}(G) \in \mathbf{N} \cup \{\infty\}$ denote the smallest integer such that $\mathrm{H}^n_{\mathrm{b}}(G, V)$ vanishes for all $n > \dim^{\sharp}_{\mathrm{b}}(G)$ and all dual Banach modules V.

(ii) Let $\dim_{\mathrm{b}}(G) \in \mathbf{N} \cup \{\infty\}$ denote the smallest integer such that $\mathrm{H}^n_{\mathrm{b}}(G, V)$ vanishes for all $n > \dim_{\mathrm{b}}(G)$ and *all* Banach modules V.

Thus G is amenable if and only if $\dim^{\sharp}_{\mathrm{b}}(G) = 0$. There is a priori a hierarchy of increasingly weak generalisations of amenability given by $\dim^{\sharp}_{\mathrm{b}}(G) = n$, $n \in \mathbf{N}$ (compare [89], §10.10; standard homological techniques reduce the property $\dim^{\sharp}_{\mathrm{b}}(G) \leq n$ to showing vanishing in degree $n+1$ only). It is not clear whether this hierarchy is really non-trivial; we refer to Section 5.4, where it is shown for instance that $\dim^{\sharp}_{\mathrm{b}} \neq 1, 2$. The dimension $\dim_{\mathrm{b}}(G)$ seems more mysterious; see [88] for some results.

3.1. Amenable actions. Just as *proper* G-spaces are relevant to compute the usual cohomology of a group G, there is a notion of *amenable* G-spaces relevant for bounded cohomology. Recall that properness is reflected in the possibility to perform finite (or compact) averaging, at least when the coefficient modules are topological vector spaces. The notion of averaging is the naïve one when the proper G-space is a homogeneous space G/K with finite or compact isotropy $K < G$, and can be carried out e.g. using Bruhat functions in the more general case.

The idea now is that *bounded* cocycles should allow averaging under more general circumstances: after all, the definition of amenable groups is that they permit equivariant averaging of bounded functions. The analogue of properness should accordingly generalise homogeneous G-spaces G/K with *amenable* isotropy group $K < G$. This is precisely the notion introduced by R. Zimmer [145], [146]: A Lebesgue space (S, ν) with non-singular G-action is called *amenable* if (i) the stabiliser of ν-almost every point is an amenable subgroup of G, (ii) the equivalence relation on S induced by the action is amenable. (This, however, is not Zimmer's original formulation.)

An important feature of this approach is that one has to work within the measurable category, because the general averaging process arising from amenability does not preserve continuity.

As suggested by the analogy with properness, one has the following result: *The G-space S is amenable if and only if the G-module $L^\infty(S)$ is relatively injective* in a sense suitably adapted to bounded cohomology [24], [112]. It then follows from functorial machinery that the bounded cohomology $\mathrm{H}_\mathrm{b}^*(G, V)$ of a locally compact group G in a coefficient module V is canonically realised by the complex

$$0 \longrightarrow L^\infty(S, V)^G \longrightarrow L^\infty(S^2, V)^G \longrightarrow L^\infty(S^3, V)^G \longrightarrow \cdots .$$

Such a statement does require a functorial theory for the bounded cohomology of groups. Even though H_b^2 lacks the basic properties of cohomological functors, such a machinery has been developed; see R. Brooks [11], N. Ivanov [85], G. Noskov [120], [121] for discrete groups and [24], [112] for locally compact groups and for the connection with amenable spaces.

All this would not be very useful without interesting examples of amenable spaces; the foremost example is provided by *Poisson boundaries* of random walks. Recall that a random walk on G is given by a probability μ on G, which for simplicity we assume *full*, that is: (i) μ is absolutely continuous with respect to Haar measures, (ii) the support of μ generates G as a semi-group. To such a random walk one associates a non-singular G-space $S = \partial_\mu G$, the *Poisson boundary*; see H. Furstenberg [53], [54], [55], Kaĭmanovich–Vershik [94], V. Kaĭmanovich [90], A. Furman [52]. R. Zimmer proved that this G-space is amenable [144], [145]. (For another proof, see [92].)

One reason why the Poisson boundary $S = \partial_\mu G$ is a useful example of amenable space is that it is much "smaller" than the only obvious amenable G-space, G itself. Specifically, for μ symmetric, the diagonal action on S^2 is ergodic, as shown by L. Garnett [60, Remark p. 301] (generalising an argument which goes back to a 1939 paper of E. Hopf [79]). In fact, it satisfies even a much stronger double ergodicity property introduced in [24], [112]: *Every G-equivariant measurable map on S^2 to every continuous separable Banach G-module is constant.* (The existence of random walks with this property was established in [24], whilst the general – and nicer – proof was later provided by V. Kaĭmanovich in [91].) If we consider the above complex, we deduce that in this situation we have a canonical identification

$$\mathrm{H}_\mathrm{b}^2(G, V) \;\cong\; \big\{\text{cocycles in } L^\infty(S^3, V)^G\big\}/\{\text{constants}\}.$$

This concrete realisation is one of the most useful facts for studying bounded cohomology, as it allows to control explicitly whether or not a cocycle represents a non-vanishing class. Not only is this crucial to prove vanishing as well as non-vanishing theorems; it is also the main ingredient to prove cohomological statements such as the splitting

$$\mathrm{H}^2_{\mathrm{b}}(G_1 \times G_2, V) \;\cong\; \mathrm{H}^2_{\mathrm{b}}(G_1, V^{G_2}) \oplus \mathrm{H}^2_{\mathrm{b}}(G_2, V^{G_1})$$

for product groups $G = G_1 \times G_2$, see [24]. I emphasise that the occurrence of the space of G_i-invariants V^{G_i} is what distinguishes this statement from a mere Künneth formula and makes it consequential for rigidity applications (just as Y. Shalom's splitting formula for usual cohomology implies rigidity statements in [136]).

3.2. Amenability degree. The remarkable properties of the Poisson boundary suggest the following notion.

Definition 3.2. Let G be a countable group (or more generally a locally compact σ-compact group). Define the *amenability degree* $a(G) \in \mathbf{N} \cup \{\infty\}$ to be the supremum of all integers n for which there is some amenable G-space (X, μ) such that the diagonal G-action on X^n has finitely many ergodic components.

For an amenable group G, the amenability degree is $a(G) = \infty$ since one can take X to be a point. On the other hand, the properties of Poisson boundaries show that $a(G) \geq 2$ for *any* G. We claim: *Every non-elementary Gromov-hyperbolic group G satisfies $a(G) = 2$.* Indeed, this holds more generally[6] for all groups G with infinite-dimensional $\mathrm{H}^2_{\mathrm{b}}(G, \mathbf{R})$ in view of the discussion in Section 3.1:

Proposition 3.3. *If G has infinite-dimensional $\mathrm{H}^n_{\mathrm{b}}(G, \mathbf{R})$, then $a(G) \leq n$.*

Problem G. What are the possible values of $a(G)$? Can one have $3 < a(G) < \infty$?

Note that $G = \mathrm{PSL}_2(\mathbf{R})$ satisfies $a(G) \geq 3$ in view of its canonical action on the projective line. I have no example ready of a countable group G with $2 < a(G) < \infty$.

Problem H. Does $a(G) = \infty$ imply that G is amenable?

The latter question has a connection to an old question[7] about R. Thompson's group F, namely: *is it is or is it ain't amenable?* A positive answer to Problem H would prove that F is non-amenable.

Proof. Recall first that F can be defined as the group of all piecewise affine homeomorphisms of the interval $[0, 1]$ with finitely many breakpoints at dyadic rationals and whose slopes are all powers of two [30]. The similar definition with $X = \mathbf{R}/\mathbf{Z}$ instead of $[0, 1]$ yields a group T whose diagonal action on X^n is ergodic for all n (indeed, its

[6] But the hyperbolic case can also be treated by a more geometric argument.

[7] Reportedly already considered by R. Thompson in the sixties, and then independently asked by R. Geoghegan in 1979.

action on dyadic rationals is oligomorphic). The stabiliser of any dyadic point of X is isomorphic to F, whilst the stabiliser of a non-dyadic point is an increasing union of groups isomorphic to F. Thus, if F is amenable, every stabiliser is amenable. On the other hand, the equivalence relation of the T-action on X can be seen to be hyperfinite in the Borel sense. It follows that the T-action on X would be amenable with respect to any quasi-invariant measure, and $a(T) = \infty$ would follow. On the other hand, it is well-known and easy to verify that T contains non-Abelian free subgroups, hence is non-amenable. (The above line of reasoning would actually imply that the T-action on $\mathbf{R}/\mathbf{Z}$ is amenable in the topological sense of [3].) □

A first step towards Problems G and H could be the following question.

Problem I. Let B be the Poisson boundary of a symmetric (full) random walk on the group G. Suppose that the diagonal G-action on B^4 is ergodic. Does it follow that G is amenable?

One can perhaps investigate this question by considering the space of *pairs of bi-infinite random paths* on G, where a bi-infinite random path refers to a random sequence

$$(\dots, x_{-2}, x_{-1}, x_0, x_1, \dots, x_n, \dots), \quad x_i \in G,\ i \in \mathbf{Z},$$

where all increments $x_n^{-1}x_{n+1}$ are i.i.d. according to the random walk (and, say, x_0 follows Haar measure class). The diagonal G-action commutes with the shift of indices and one can try to construct invariants of pairs of such paths under some assumption similar to non-recurrence of the random walk. For instance, consider the length in $\mathbf{N}$, or location in G, of the shortest segment in a Cayley graph connecting two paths; even equivariant G-valued "invariants" prevent higher ergodicity. Whilst there is a natural map from pairs of bi-infinite paths to B^4, it is not clear whether Problem I can be solved in this way.

4. Rigidity

Bounded cohomology has proved to be very useful to establish rigidity results. One can distinguish roughly three settings: obstructions, invariants, superrigidity.

(i) *Obstructions.* The idea here is simply to play off vanishing against non-vanishing; that is, to prove that for certain groups Γ, H there can be no non-trivial homomorphism $\Gamma \to H$ because (a) Γ has a vanishing property for $\mathrm{H}_{\mathrm{b}}^*$ and (b) H and certain of its subgroups have non-zero classes in $\mathrm{H}_{\mathrm{b}}^*$. Of course, the sense in which homomorphisms are non-trivial need to be precised and will affect which subgroups of H are considered. Interestingly, parts (a) and (b) are in general of a completely different nature and are proved by very different means (and often by different authors).

Example 4.1. This rather coarse strategy can be quite effective. For instance, if Γ is a higher rank lattice, it can be used to re-prove the following result of Farb–Kaĭmanovich–Masur [93], [48]: *Every representation of* Γ *into any mapping class*

group has finite image. Indeed, Γ has no non-trivial quasimorphisms [23], [24]. On the other hand, by [8] any non virtually Abelian subgroup of mapping class groups has an infinite-dimensional space of quasimorphisms. It follows that any image of Γ in a mapping class group is virtually Abelian and hence finite. (Notice that this proof does not use Margulis' normal subgroup theorem.)

(ii) *Invariants.* Sometimes one particular invariant in $\mathrm{H}_{\mathrm{b}}^*$ classifies homomorphisms. A first example appeared in Section 2.2 with É. Ghys' study of actions on the circle up to semi-conjugacy. Another is A. Iozzi's proof [84] of Matsumoto's theorem [106]. Here is a further instance due to Burger–Iozzi [18] and Burger–Iozzi–Wienhard [20]:

Example 4.2. Let X be an irreducible Hermitian symmetric space not of tube type, and let $H = \mathrm{Is}^0(X)$ be (the connected component of) its isometry group. By [23], $\mathrm{H}_{\mathrm{b}}^2(H, \mathbf{R})$ is generated by a bounded representative ω of the Kähler class of X. It is proved in [20] that for any finitely generated group Γ, the Zariski-dense representations $\pi\colon \Gamma \to H$ are classified up to conjugacy by the invariant $\pi^*\omega$ in $\mathrm{H}_{\mathrm{b}}^2(\Gamma, \mathbf{R})$. (The case $H = \mathrm{SU}(p, q)$ was previously proved in [18].)

A more refined analysis is possible for representations of surface groups by considering the *Toledo number* associated to the pull-back of the Kähler class; see the study of maximal representations presented by Burger–Iozzi–Wienhard [22] and some of its consequences [19]. Of particular importance in this context are *tight homomorphisms*, namely those representations π for which π^* preserves the norm of the Kähler class [21], [143].

(iii) *Superrigidity.* The use of richer coefficient modules, specifically of the *regular representation* $V = \ell^2(\Gamma)$, allows in some cases to encode the entire geometric situation into $\mathrm{H}_{\mathrm{b}}^2(\Gamma, V)$. This is described in the next two sections.

Non-trivial coefficients of L^∞ type have been used in [113] to establish cohomological stabilization of the general linear groups. They have also been used by Burger–Iozzi to study representations that are maximal for yet another invariant, the *generalized Toledo number*, establishing deformation rigidity for representations into $\mathrm{SU}(m, 1)$ of lattices in $\mathrm{SU}(n, 1)$ ($m \geq n \geq 2$), extending the famous result of Goldman–Millson [65] to *non-uniform* lattices [15], [16], [17].

4.1. Negative curvature made cohomological. M. Gromov suggests in [71, $7.\mathrm{E}_1$] how to turn the thin triangle property of negatively curved manifolds into a cohomological invariant (and refers to Z. Sela [135]); in his construction, Kazhdan's property (T) is used to ensure non-triviality. Building on similar ideas and using the multiple ergodicity of Poisson boundaries (Section 3.1), it is shown in [117], [110] that one has $\mathrm{H}_{\mathrm{b}}^2(\Gamma, \ell^2(\Gamma)) \neq 0$ for a large class of "negatively curved" groups Γ (see also [75]).

This result can be combined with rigidity techniques (such as Furstenberg maps) and cohomological results from [24], [112] in order to obtain superrigidity theorems. Specifically, it can be fed into the splitting formula at the end of Section 3.1 to obtain

geometric information. As a first illustration, consider the result below; here $\mathrm{H}_{\mathrm{b}}^2$ is used as a tool to control completely all existing homomorphisms, rather than just provide an obstruction when no homomorphism exists.

Let $\Gamma < G = G_1 \times G_2$ be a lattice in a product of arbitrary locally compact groups that is *irreducible* in the sense that its projection to each G_i is dense. Let $H = \mathrm{Isom}(X)$ be the isometry group of a metric space X that is negatively curved in the sense that it is either a proper CAT(-1) space or a Gromov-hyperbolic graph of bounded valency.

Theorem ([116, 1.5]). *Any non-elementary homomorphism $\Gamma \to H$ extends to a continuous homomorphism $G \to H$ (which must factor through some G_i), possibly after factoring out a compact normal subgroup of H.*

A similar statement holds more generally for cocycles in the sense of R. Zimmer [146].

(Compare [117], [110].) For previous results concerning algebraic groups, see Margulis [103], [104], Burger–Mozes [26], S. Adams [1] and Y. Gao [59]; for results in the setting of CAT(0) spaces, see [114]. The theorem above applies e.g. when G is a semisimple group, or when Γ is a Burger–Mozes group [27], [28], or when Γ is a Kac–Moody group [132], [133].

Problem J. Does there exist a geometric characterisation of the non-vanishing of $\mathrm{H}_{\mathrm{b}}^2(\Gamma, \ell^2(\Gamma))$? Is it a quasi-isometry invariant amongst finitely generated groups?

If this property could be reformulated e.g. in terms of quasi-actions on suitable negatively curved spaces, then such a reformulation could be construed as an analogue of J. Stalling's famous splitting theorem [140]. Indeed, in all known cases our classes in $\mathrm{H}_{\mathrm{b}}^2(\Gamma, \ell^2(\Gamma))$ are in the kernel of the comparison map. Therefore, they appear as *quasifications* of the space $\mathrm{H}^1(\Gamma, \mathbf{R}\Gamma)$ relevant to Stalling's theorem.

Remark 4.3. In a different direction, there is indeed a characterisation of Gromov-hyperbolic groups due to I. Mineyev [109]; the main ingredient therein is the surjectivity of the comparison map in degree two, see M. Gromov [69, 8.3.T] and I. Mineyev [108]. It is unclear whether one could obtain interesting definitions of a *rank* by postulating surjectivity in a given higher degree. Using another type of exotic cohomology, namely ℓ^∞ cohomology, S. Gersten also provided a characterisation of hyperbolicity (see [61] and compare [2]).

4.2. Orbit equivalence. Consider ergodic free measure-preserving actions of a countable group Γ on a probability space (X, μ). The quotient space X/Γ is completely singular, but can nevertheless be investigated by shifting the focus to the type II_1 *measured equivalence relation* $\mathcal{R} \subseteq X \times X$ induced by the action. Accordingly, one calls two actions (by possibly different groups) *orbit equivalent* (OE) if the resulting relations are isomorphic. The Ornstein–Weiss theorem [123] implies that *all*

such action of all amenable countable groups are OE. It is therefore of interest to find obstructions to OE or better yet rigidity results.

The context of Section 4.1 comes into play as follows. Let $\Gamma = \Gamma_1 \times \Gamma_2$ be a product of torsion-free groups with $\mathrm{H}^2_{\mathrm{b}}(\Gamma_i, \ell^2(\Gamma_i)) \neq 0$, e.g. non-elementary hyperbolic groups. Consider a Γ-space (X, μ) that is *irreducible* in the sense that each Γ_i-action is ergodic.

Theorem ([118, 1.6]). *Any Γ-space that is OE to X is actually conjugated to X, possibly twisting the action by an automorphism of Γ.*

Theorem ([118, 1.9]). *If any mildly mixing action of any torsion-free group Λ is OE to X, then Λ is isomorphic to Γ and the actions are conjugated.*

Compare with Hjorth–Kechris [78]. One can also use our techniques to show [118, 1.14]: *There exists a continuum of mutually non weakly isomorphic relations of type II_1 with trivial outer automorphism group.*

5. Randomorphisms

The notion of *randomorphism* between two groups is proposed below. It is closely connected to orbit equivalence and related ideas; thus, not much originality is claimed, except perhaps for the language proposed, which I believe has its own appeal.

5.1. Random maps. The space G^H of all maps $f\colon H \to G$ between the countable groups H, G has a natural structure of Polish space, given by the product uniform structure (with G viewed discrete). Therefore, it makes sense to think of "random maps" $f\colon H \to G$ simply as probability measures on this nice Polish space. To avoid redundancy coming from the free G-action(s), we define the Polish space

$$[H, G] \stackrel{\text{def}}{=} \{f\colon H \to G \ :\ f(e) = e\}$$

(a closed subspace of G^H). There is a natural H-action on $[H, G]$ defined by

$$(h.f)(x) \stackrel{\text{def}}{=} f(xh)f(h)^{-1} \quad \text{for } f \in [H, G],\ h, x \in H.$$

The basic observation is that a homomorphism $H \to G$ is nothing but an H-fixed point for this action.

Definition 5.1. A *randomorphism* from H to G is an H-invariant probability measure on $[H, G]$.

Notice that the subset of injective maps is closed in $[H, G]$. This suggest a naïve notion of injectivity for randomorphisms:

Definition 5.2. A randomorphism is a *randembedding* if it is supported on the injective maps. We say that H is a *random subgroup* of G if it admits a randembedding into G.

Compare with the notion of *placement* proposed by M. Gromov [70, 4.5] and with Y. Shalom's related viewpoint on uniform embeddings [137]. One can verify that a point in $[H, G]$ is almost periodic (i.e. its H-orbit relatively compact) if the corresponding map is Lipschitz in the appropriate sense.

Definition 5.3. A randomorphism, randembedding or random subgroup is *geometric* if the corresponding measure is compactly supported in $[H, G]$.

Problem K. Which groups admit the non-Abelian free group $\mathbf{F}_2$ as a geometric random subgroup?

The following has been proved by D. Gaboriau and independently R. Lyons (private communication); Gaboriau's proof uses percolation techniques, relying among other things on [124] and [77].

Theorem 5.4. *Every non-amenable group admits* $\mathbf{F}_2$ *as a random subgroup.*

5.2. Back to orbit equivalence. If the two countable groups G, H have OE actions as in Section 4.2 on (X, μ) and (Y, ν) respectively, then there is a measure space isomorphism $F\colon X \to Y$ such that $F(H.x) = G.F(x)$ almost everywhere. One can also consider the more general situation where $F(H.x) \subseteq G.F(x)$; for instance, H could be a subgroup of a group having an action orbit equivalent to the G-action. By freeness, there is a measurable map

$$\alpha\colon H \times X \longrightarrow G$$

defined almost everywhere by $F(h.x) = \alpha(h, x).F(x)$. This map is a *cocycle* in that is satisfies

$$\alpha(hk, x) = \alpha(h, k.x)\alpha(k, x) \quad \text{for } h, k \in H,\ \mu - \text{a.e. } x \in X.$$

The cocycle α yields a measurable map $\hat{\alpha}\colon X \to [H, G]$ defined by $\hat{\alpha}(x)(h) = \alpha(h, x)$. This map is H-equivariant, and therefore the measure $\hat{\alpha}_*\mu$ is a randomorphism from H to G.

Observe that regardless of any measure, there is a *tautological cocycle* $E\colon H \times [H, G] \to G$ with respect to the H-action on $[H, G]$ defined by $E(h, f) = f(h)$. In the above construction, the map $\hat{\alpha}$ intertwines the cocycle α to the tautological cocycle. Therefore, $[H, G]$ together with its tautological cocycle has a way to reflecting all OE cocycles within the space of all invariant probability measures on $[H, G]$.

The Ornstein–Weiss theorem [123] shows in particular that every amenable group is a random subgroup of $\mathbf{Z}$. Therefore, one has the following striking "Random Tits Alternative":

Any countable group is either a random subgroup[8] *of* $\mathbf{Z}$ *or has* $\mathbf{F}_2$ *as a random subgroup.*

[8] actually, *measure equivalent* to $\mathbf{Z}$; compare Section 5.5.

The viewpoint of measured relations and OE allows to formulate a related question: Does *any* non-amenable type II_1 relation contains the orbits of a $\mathbf{F}_2$-action? (See Kechris–Miller [96, 28.14] and D. Gaboriau [57, 5.16]). This is only known to hold for relations of non-trivial *cost* (M. Pichot [126], Kechris–Miller [96, 28.8]; see [56] for the notion of cost).

5.3. Modules. Just as a homomorphism $H \to G$ yields a pull-back functor from G-modules to H-modules, we can define pull-backs through randomorphisms:

Definition 5.5. Let V be a coefficient G-module, μ a randomorphism from H to G and $1 \leq p \leq \infty$. The *L^p-pull-back* of V through μ is the Banach space $L^p(\mu, V)$ endowed with the H-action

$$(h.\varphi)(f) \stackrel{\text{def}}{=} f(h^{-1})^{-1}\varphi(h^{-1}.f), \quad h \in H,\ \varphi \in L^p(\mu, V),\ f \in [H, G].$$

We are mostly interested in $p = 2, \infty$. For instance, analysing the case $V = \ell^2(G)$ shows:

Lemma 5.6. *A random subgroup of an amenable group is itself amenable.*

Recall that in the case of injective homomorphisms, the pull-back has an adjoined functor called (*co-*)*induction*. There is again an analogue for randembeddings. Consider G^H with precomposition by right H-translation and postcomposition by right G-translation. This is isomorphic to the E-twisted (cf. [146, p .65]) product H-space $[H, G] \times G$ endowed with an additional G-action by right multiplication. Therefore, it inherits an invariant σ-finite regular Borel measure $\widetilde{\mu}$ defined as the product of μ with the counting measure. The following generalises induction (compare [70, 4.5.C] and [118, 4.1]).

Definition 5.7. Let V be a coefficient H-module, μ a randembedding from H to G and $1 \leq p \leq \infty$. The *L^p-induced module* of V through μ is the Banach space $L^p(\widetilde{\mu}, V)^H$ of H-equivariant maps endowed with the G-action by right translations.

5.4. Application to bounded cohomology. The induction methods used in [118] can be seen to yield the following.

Proposition 5.8. *Let H be a random subgroup of G and V a coefficient H-module. Let W be the L^∞-induced module. For every $n \geq 0$ there is an injection $\mathrm{H}^n_{\mathrm{b}}(H, V) \hookrightarrow \mathrm{H}^n_{\mathrm{b}}(G, W)$.*

(Due to the unwieldy nature of L^∞ spaces, it is essential in [118] to have a similar injectivity statement for the L^p-induced module with $p < \infty$, e.g. $p = 2$. However, the latter is only known to hold when $n \leq 2$.)

Corollary 5.9. *If H is a random subgroup of G, then $\dim^\sharp_{\mathrm{b}}(H) \leq \dim^\sharp_{\mathrm{b}}(G)$.*

Appealing to Theorem 5.4, we conclude:

Corollary 5.10. *No group can have* $\dim_b^\sharp = 1, 2$.

Problem L. Is $\dim_b^\sharp(\mathbf{F}_2)$ infinite? If so, is even $H_b^n(\mathbf{F}_2, \mathbf{R})$ non-zero for all $n \geq 2$?

If $\dim_b^\sharp(\mathbf{F}_2) = \infty$, then it follows that the hierarchy proposed by B. Johnson (cf. beginning of Section 3) collapses completely, since we then have $\dim_b^\sharp(G) = 0$ or ∞ for every group G, according to whether it is amenable or not.

5.5. Categorical approach. As we have seen, orbit equivalences yield randomorphisms. However orbit equivalence is symmetrical; the intuition is that these randomorphism should more precisely be "isomorphisms" in an appropriate category whose morphisms are represented by randomorphisms. A related problem is that the notion of randembedding of Definition 5.2 does not follow the usual categorical pattern that should define mono-randomorphisms. A third issue is that it is unclear when a randomorphism should be considered to be an epimorphism.

In order to address these points, it is necessary to define the composition of two randomorphisms. It seems that there are (at least) two natural composition products:

(i) The independent product. Let G, H, L be countable groups. The composition map

$$[L, H] \times [H, G] \longrightarrow [L, G], \quad (f, f') \longmapsto f' \circ f$$

is continuous. Given probability measures μ, ν on $[L, H]$ respectively $[H, G]$, denote by $\nu \circ \mu$ the image of the product measure $\mu \times \nu$ under this map. Thus $\nu \circ \mu$ is the product of *independently* chosen random maps. If both μ, ν are randomorphisms, then so is $\nu \circ \mu$. The main defect of the independent product is the scarcity of randomorphisms that are invertible for this product.

(ii) The fibred product. Another product has the flavour of groupoids and is defined as follows. Two randomorphisms μ from L to H and ν from H to G are *composable* if there is an isomorphism of Lebesgue spaces

$$F : \big([L, H], \mu\big) \xrightarrow{\cong} \big([H, G], \nu\big)$$

which is equivariant with respect to the tautological cocycle $L \times [L, H] \to H$; that is, $F(\ell.f) = f(\ell).F(f)$ μ-a.e. In that case we define the *fibred product* $\nu \underset{F}{\cdot} \mu$ as the image of μ under the map

$$[L, H] \longrightarrow [L, G], \quad f \longmapsto F(f) \circ f.$$

Both products are a particular case of the construction that associates a randomorphism from L to G to the data of a randomorphism from L to H together with a measurable map from $[L, H]$ to probability measures on $[H, G]$ that is equivariant with respect to the tautological cocycle. In all cases the verification follows from the formula $\ell.(f' \circ f) = (f(\ell).f') \circ (\ell.f)$.

Problem M. (i) Subsume both product in one categorical construction, for instance by defining a suitable equivalence relation on randomorphisms. (ii) Produce an interesting definition of a group of auto-randomorphisms of a given group G. (iii) Reformulate A. Furman's results [51] as a determination of this group for higher rank lattices.

5.6. Random forests. Let G be a countable group and $A \subseteq G$ a non-empty finite subset. Define the compact G-space of unoriented[9], labelled 4-regular graphs as

$$\mathcal{G}_A \stackrel{\text{def}}{=} \left\{(x_{i,g}) \in \prod_{g\in G}(gA)^{\mathbf{Z}/4\mathbf{Z}} : x_{h,i+2} = g \text{ when } h = x_{g,i}\right\}.$$

The topology is the product topology and $k \in G$ acts by $(kx)_{g,i} = k(x_{k^{-1}g,i})$.

Definition 5.11. The space $\mathcal{F}_A$ of 4-forests is the closed G-invariant subspace $\mathcal{F}_A \subseteq \mathcal{G}_A$ of those elements $(x_{i,g})$ for which every connected component is acyclic.

An immediate application of Tarski's theorem on paradoxical decompositions (or of appropriate proofs of it) yields:

Proposition 5.12. *The group G is non-amenable if and only if $\mathcal{F}_A \neq \varnothing$ for A large enough.*

Problem K′. For which groups does there exists an invariant probability measure on $\mathcal{F}_A$ for some A?

Notice that there is a canonical continuous map $\mathcal{F}_A \longrightarrow [\mathbf{F}_2, G]$ which is $\mathbf{F}_2$-equivariant when the left hand side is endowed with the natural $\mathbf{F}_2$-action defined by the labelling of the forests. Moreover, this map ranges in the space of injections. Therefore, groups with a measure as in Problem K′ will have a geometric random free subgroup as in Problem K.

6. Additional questions

Here is the motivation that prompted me to consider randomorphisms to begin with. It is an old observation of J. Dixmier [41] and M. Day [39] that every uniformly bounded representation of an amenable group is *unitarizable*, i.e. conjugated to a unitary representation. The problem of the converse to this statement proposed in J. Dixmier's 1950 article [41] is still open, despite remarkable work most notably by G. Pisier (see [128], [129] and [127]).

It is nevertheless possible to show very explicitly that any group containing $\mathbf{F}_2$ has uniformly bounded representations that are not unitarizable (see e.g. Theorem 2.1 and Lemma 2.7 in [128]). On the other hand, one can also induce such representations from *random subgroups* exactly as explained above and still obtain uniformly bounded representations.

[9] We make the usual convention that an unoriented edge consists of two opposed oriented edges.

Problem N. (i) Is the uniformly bounded representation induced as above non-unitarizable? (ii) Is this true at least for randembeddings of $\mathbf{F}_2$ arising from an invariant measure on the space of forests?

We have seen that the vanishing of H_b^* with general dual coefficients characterises amenability; however, it is not enough to consider trivial coefficients $\mathbf{R}$ even in all degrees. Indeed, refining the method of J. Mather [105], Matsumoto–Morita [107] have proved that the (non-amenable) group of compactly supported homeomorphisms of $\mathbf{R}^n$ has vanishing H_b^* with trivial coefficients. Is the situation nicer for linear groups?

Problem O. (i) Let $\Gamma < \mathrm{GL}_d(\mathbf{C})$ be a subgroup that is not virtually soluble (equivalently, Γ is non-amenable). Is $H_b^n(\Gamma, \mathbf{R})$ non-zero for some $1 < n < d^2$? (ii) If not, is there at least a *separable* dual Banach Γ-module V with $H_b^n(\Gamma, V)$ non-zero for some $n \geq 2$?

One way to approach the problem would be to prove first the conjecture proposed as Problem A′. This done, one needs to deduce geometric finiteness properties from the annihilation of the pull-back $H_b^*(G, \mathbf{R}) \to H_b^*(\Gamma, \mathbf{R})$. The latter step is not at all hopeless, especially in view of the results of B. Klingler for usual cohomology in [98].

One hint to the difficulties that could arise (in addition to Problem A′) is the fact that B. Klingler needs non-trivial coefficient modules. However, as mentioned in the introduction, the analogous statement to Problems A and A′ fails already for unitary representations. Therefore, either one needs to construct cohomology classes for such representations that are genuinely new (as in [25]) and prove results similar to those of [98] for such classes, or one needs to argue that even trivial coefficients suffice because pull-back in bounded cohomology tends to be injective in cases where the usual pull-back is not. (For example, the volume form of the hyperbolic plane restricts non-trivially in H_b^2 to free lattice subgroups of $\mathrm{PSL}_2(\mathbf{R})$, whilst it vanishes when sent to usual cohomology.)

An alternative approach for linear groups could be to consider more generally polynomially bounded cocycles.

Problem P. Let $G = \boldsymbol{G}(k)$ be a simple group of k-rank $r > 0$ over a local field k. Quasify B. Klingler's cocycles [98] in order to obtain new classes in degree $r + 1$ for cohomology with polynomial growth degree $r - 1$ (in a suitable module).

I suspect that $(r + 1)$-cohomology with polynomial growth degree $r - 1$ is indeed the right place to look for "rank r phenomena".

Ch. Bavard proves [6] that a group has non-trivial quasimorphisms if and only if its *stable commutator length* is non-zero.

Problem Q (M. Abért). Let k be a countable field of infinite transcendence degree over its prime field. Does the group $\mathrm{SL}_3(k[X])$ have non-trivial quasi-morphisms?

The interest of $\mathrm{SL}_3(k[X])$ in connection with Ch. Bavard's result is that for fields k as above this group is known to have infinite commutator width, which is a priori not enough to control the stable length.

Finally a question from [113]. For a prime p, denote by $v_p\colon \mathbf{Q}\setminus\{0\}\to\mathbf{Z}$ the p-adic valuation (normalised by $v_p(p^n)=-n$). If q is another prime, define $D_{p,q}\colon \mathbf{Q}\setminus\{0,1\}\to\mathbf{Z}$ by

$$D_{p,q}(x)=v_p(x)v_q(1-x)-v_q(x)v_p(1-x).$$

This function is obviously unbounded; on the other hand, one can form arbitrary linear combinations of such $D_{p,q}$ by varying the primes p,q.

Problem R. Is the function $\sum_{p<q}\alpha_{p,q}D_{p,q}$ unbounded on $\mathbf{Q}\setminus\{0,1\}$ for every family of real numbers $\{\alpha_{p,q}\}$ (unless they are all zero)?

It was observed in [113] that a positive answer would imply $\mathrm{H}^3_{\mathrm{b}}(\mathrm{GL}_2(\mathbf{Q}),\mathbf{R})=0$. Moreover, it follows from the stabilisation results of [113] that the latter vanishing would imply $\mathrm{H}^3_{\mathrm{b}}(\mathrm{GL}_n(\mathbf{Q}_p),\mathbf{R})=0$ for all $n\in\mathbf{N}$ and all primes p.

Fibration de Hitchin et structure endoscopique de la formule des traces

Bao-Châu Ngô

Abstract. The Hitchin fibration is a well suited tool to study the geometric side of the trace formula for Lie algebra from the point of view of moduli spaces of vector bundles over a curve. The endoscopy groups appear naturally when we decompose the cohomology of the Hitchin fibration by its natural symmetries. Following this dictionary, we can formulate a global and geometric version of Langlands–Shelstad's fundamental lemma. This conjecture has been proved in the case of unitary groups in a joint work with G. Laumon.

Résumé. La fibration de Hitchin fournit un outil adapté pour explorer le côté géométrique de la formule des traces pour l'algèbre de Lie du point de vue des espaces de module des fibrés sur une courbe. Les groupes d'endoscopie apparaissent naturellement quand on cherche à décomposer la cohomologie de la fibration de Hitchin par ses symétries naturelles. En poursuivant ce dictionnaire, on peut formuler une version globale et géométrique du lemme fondamental de Langlands et Shelstad. Cette conjecture a été démontrée dans le cas particulier des groupes unitaires dans un travail en commun avec G. Laumon.

Mathematics Subject Classification (2000). Primary 14H60, 11F72 ; Secondary 22E35.

Keywords. Trace formula, endoscopy groups, fundamental lemma, moduli spaces of vector bundles.

Mots-clés. Formule des traces, groupes endoscopiques, lemme fondamental, espace de module des fibrés.

1. Commentaires historiques

La stabilisation de la formule des traces est l'un des objectifs de la théorie des représentations automorphes. On ne saurait mieux l'introduire que Langlands l'a fait dans les premières lignes de [15] :

En principe la formule des traces exprime la trace comme une somme sur les classes de conjugaison d'un groupe $G(F)$, F étant un corps global et G un groupe réductif. Donc si l'on veut par exemple comparer la trace pour un groupe quasi-déployé G^* et une forme intérieure G comme on l'a fait dans [13] *il faut trouver une application naturelle de l'ensemble des classes de conjugaison de $G(F)$ dans celui des classes de $G^*(F)$, ce qui est en général impossible. En revanche, si on passe*

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

aux classes de conjugaison stable une telle application existe et facile à définir. Par conséquent pour imiter les méthodes de [13] *il faut d'abord trouver une formule des traces qui s'exprime comme somme sur les classes de conjugaison stable ...*

Les travaux de Langlands et Kottwitz ont fait surgir les groupes endoscopiques de la structure interne de la somme sur les classes de conjugaison elliptiques de $G(F)$. Pour stabiliser la partie elliptique de la formule des traces, il reste à démontrer la conjecture de transfert et le lemme fondamental. Ces conjectures consistent en gros en une comparaison d'intégrales orbitales sur G et sur un groupe endoscopique H. Les travaux de Langlands et Kottwitz sur la partie elliptique ont été considérablement généralisés par Arthur à toute la formule des traces [1].

Les méthodes dites élémentaires ont permis d'établir ces conjectures dans les cas suivants : SL(2) par Labesse et Langlands [14], U(3) par Rogawski [23], Sp(4) par Hales [9], Weissauer [28] et SL(n) par Waldspurger [24]. De plus, Waldspurger a démontré que dans le cas des algèbres de Lie, le lemme fondamental implique la conjecture de transfert [26].

Plus récemment, les travaux de Goresky, Kottwitz et MacPherson [7], de Laumon [17], [18], de Laumon et moi-même [20] donnent un espoir qu'on pourrait démontrer le lemme fondamental en général par des méthodes géométriques. Nous renvoyons à l'exposé Bourbaki de J.-F. Dat [4] et au rapport de Laumon dans ces volumes pour un survol de l'approche géométrique du lemme fondamental.

L'objet du présent rapport est de décrire géométriquement la structure endoscopique de la partie anisotrope la formule des traces [15], [12] suivant [21]. Cette étape se trouve historiquement en amont du lemme fondamental. Du point de vue géométrique, elle permet d'interpoler le lemme fondamental dans une déformation naturelle et d'utiliser des arguments en famille comme la notion de faisceaux pervers purs qui sont déterminants dans [20].

Notre interprétation géométrique est fondée sur la fibration de Hitchin. C'est une variante globale des fibres de Springer affines que Goresky, Kottwitz et MacPherson ont utilisées pour interpréter les intégrales orbitales locales. Les fibres de la fibration de Hitchin pour GL(n) sont des jacobiennes compactifiées de même type que celles qui sont construites par Laumon dans [17].

L'inconvénient de l'approche géométrique est qu'elle s'adapte bien mal à la caractéristique zéro. Heureusement, grâce aux travaux de Waldspurger [27] et de Cluckers–Loeser [3], le lemme fondamental en caractéristique zéro peut se déduire du lemme fondamental en caractéristique positive.

2. Fibration de Hitchin

Soit X une courbe projective lisse sur un corps k. Soit D un diviseur de X de degré $\deg(D) > 2g - 2$ où $g > 2$ est le genre de X. Soit G un groupe réductif sur k ou plus généralement un schéma en groupes réductifs sur X. Pour un triplet (X, D, G)

donné, on considère l'espace de module $\mathcal{M}$ des couples (E, ϕ) où E est un G-torseur sur X et où ϕ est une section

$$\phi \in \mathrm{H}^0(X,\ \mathrm{ad}(E)(D))$$

où $\mathrm{ad}(E)$ est le fibré vectoriel qui se déduit du G-torseur E et de la représentation adjointe de G et où on a noté $V(D) = V \otimes_{\mathcal{O}_X} \mathcal{O}_X(D)$ pour tout fibré vectoriel V sur X. Il est plus agréable de considérer le champ algébrique $\mathcal{M}$, voir [19], plutôt que l'espace de module grossier associé à l'ouvert semi-stable de ce champ. La structure symplectique sur $\mathcal{M}$, qui existe naturellement dans le cas où D est le diviseur canonique de X, ne semble pas jouer de rôle dans notre problème.

Dans le cas où $G = \mathrm{GL}(n)$, la donnée de E consiste en la donnée d'un fibré vectoriel V de rang n sur X et celle de ϕ est équivalente à la donnée d'un endomorphisme tordu $\phi\colon V \to V(D)$. On renvoie à [10] pour une description similaire dans le cas où G est un groupe classique.

Soit $\mathfrak{g}$ l'algèbre de Lie de G, $k[\mathfrak{g}]$ l'anneau des fonctions polynômiales sur $\mathfrak{g}$. Soit $\mathfrak{t}$ l'algèbre de Lie d'un tore maximal T de G et soit W le groupe de Weyl. Si k est un corps de caractéristique nulle ou grande par rapport à $\mathfrak{g}$, on sait d'après Chevalley et Kostant que l'anneau des invariants $k[\mathfrak{g}]^G = k[\mathfrak{t}]^W$ est un anneau des polynômes $k[u_1, \ldots, u_r]$ où r est le rang de G et où $u_1, \ldots, u_r$ sont des polynômes homogènes de degrés $d_1, \ldots, d_r$. Notons

$$\mathfrak{t}/W = \mathrm{Spec}(k[\mathfrak{t}]^W) = \mathrm{Spec}(k[u_1, \ldots, u_r]).$$

L'inclusion $k[\mathfrak{g}]^G \to k[\mathfrak{g}]$ définit le morphisme caractéristique de Chevalley

$$\chi\colon \mathfrak{g} \to \mathfrak{t}/W \tag{1}$$

qui généralise la construction du polynôme caractéristique dans le cas $\mathrm{GL}(n)$. En appliquant χ à la section $\phi \in \mathrm{H}^0(X, \mathrm{ad}(E)(D))$, on trouve une section

$$a \in \bigoplus_{i=1}^{r} \mathrm{H}^0(X, \mathcal{O}_X(d_i D)).$$

Il revient au même de dire que a est une section globale $(\mathfrak{t}/W) \times^{\mathbb{G}_m} L_D$ où L_D est le $\mathbb{G}_m$-torseur sur X associé au fibré en droites $\mathcal{O}_X(D)$.

On obtient ainsi une fibration

$$m\colon \mathcal{M} \to \mathcal{A}$$

où $\mathcal{A} = \bigoplus_{i=1}^{r} \mathrm{H}^0(X, \mathcal{O}_X(d_i D))$ est un espace affine sur k dont la dimension dépend du triplet (X, D, G). Dans le cas $G = \mathrm{GL}(n)$, pour tout point (V, ϕ) de $\mathcal{M}$, on a $m(V, \phi) = (a_1, \ldots, a_n)$ où $a_i \in \mathrm{H}^0(X, \mathcal{O}_X(iD))$ est la trace de $\wedge^i \phi\colon \wedge^i V \to \wedge^i V(iD)$.

Supposons que $k = \mathbb{F}_q$ est un corps fini. En suivant le comptage de Weil des fibrés vectoriels sur une courbe, on peut exprimer formellement le nombre pondéré des points de $\mathcal{M}(\mathbb{F}_q)$

$$|\mathcal{M}(\mathbb{F}_q)| = \sum_{(E,\phi)\in\mathcal{M}(\mathbb{F}_q)} \frac{1}{\mathrm{Aut}(E,\phi)}$$

en termes d'intégrales adéliques. Soient F le corps des fonctions rationnelles sur X, F_v le complété de F en un point fermé $v \in |X|$, $\mathcal{O}_v$ l'anneau des entiers de F_v et $\mathbb{A}_F$ l'anneau des adèles de F. On a alors

$$|\mathcal{M}(\mathbb{F}_q)| = \sum_{\xi\in \ker^1(F,G)} \sum_{\gamma\in\mathfrak{g}^\xi(F)/\sim} O_\gamma(1_D) \tag{2}$$

où

- $\ker^1(F, G)$ est l'ensemble des classes d'isomorphisme des G-torseurs sur F, triviaux localement sur chaque F_v ;
- $\mathfrak{g}^\xi$ est la forme de $\mathfrak{g}$ sur F définie par ξ ;
- γ parcourt l'ensemble des classes de conjugaison de $\mathfrak{g}^\xi(F)$;
- $O_\gamma(1_D)$ est l'intégrale orbitale globale

$$O_\gamma(1_D) = \int_{G_\gamma(F)\backslash G(\mathbb{A}_F)} 1_D(\mathrm{ad}(g)^{-1}\gamma)\, dg$$

de la fonction

$$1_D = \bigotimes_{v\in|X|} 1_{D_v},$$

1_{D_v} étant la fonction caractéristique du compact ouvert $\varpi^{-d_v}\mathfrak{g}(\mathcal{O}_v)$ de $\mathfrak{g}(F_v)$, les entiers d_v étant définis par la formule $D = \sum_{v\in|X|} d_v v$;

- dg est la mesure de Haar normalisée de $G(\mathbb{A})$ de telle façon que $G(\mathcal{O}_\mathbb{A})$ ait volume 1.

L'égalité ci-dessus n'a pas de sens numérique, ses deux membres n'étant pas finis, mais elle peut s'interpréter en termes d'équivalence de catégories. L'égalité heuristique peut néanmoins servir comme un bon guide. On reconnaît dans le membre de droite l'expression formelle du côté géométrique de la formule des traces pour l'algèbre de Lie. Cette égalité formelle est donc le début d'un dictionnaire que nous allons poursuivre.

Pour $a \in \mathcal{A}(\mathbb{F}_q)$, on note $\mathcal{M}_a = m^{-1}(a)$ la fibre de m en a. Le point a peut être vu comme un élément de $(\mathfrak{t}/W)(F)$ vérifiant une condition d'intégralité par rapport à D. Supposons désormais que a est une caractéristique semi-simple régulière c'est-à-dire il correspond à un F-point du l'ouvert $\mathfrak{t}/W$ où le morphisme $\mathfrak{t} \to \mathfrak{t}/W$ est étale. Cette condition semi-simple régulière définit un ouvert non vide $\mathcal{A}^\heartsuit$ de $\mathcal{A}$. Pour tout

$a \in \mathcal{A}(\mathbb{F}_q)$, on a formellement

$$|\mathcal{M}_a(\mathbb{F}_q)| = \sum_{\xi \in \ker^1(F,G)} \sum_{\substack{\gamma \in \mathfrak{g}^\xi(F)/\sim \\ \chi(\gamma)=a}} O_\gamma(1_D). \tag{3}$$

Lorsque $a \in \mathcal{A}^\heartsuit(\mathbb{F}_q)$ la seconde somme s'étend donc sur une classe de conjugaison stable globale dans $\mathfrak{g}^\xi(F)$. Ainsi la fibration de Hitchin correspond essentiellement au découpage de la formule des traces en des classes de conjugaison stable globale.

Notons aussi que d'après la formule des traces de Grothendieck–Lefschetz, on a aussi formellement

$$|\mathcal{M}_a(\mathbb{F}_q)| = \mathrm{Tr}(\mathrm{F}_q, (m_*\mathbb{Q}_\ell)_a) \tag{4}$$

où $m_*\mathbb{Q}_\ell$ est l'image directe dérivée du faisceau constant $\mathbb{Q}_\ell$ et où F_q est l'endomorphisme de Frobenius géométrique. Ainsi le complexe $m_*\mathbb{Q}_\ell$ interpole les sommes (3) dépendant du paramètre a.

Notons que lorsque a appartient à l'ouvert anisotrope $\mathcal{A}^{\mathrm{ani}}$ de $\mathcal{A}^\heartsuit$, les deux côtés de (3) sont des sommes finies et on a dans ce cas une égalité numérique au lieu d'une équivalence de catégories. Nous envoyons à [21] pour la définition précise des ouverts $\mathcal{A}^{\mathrm{ani}} \subset \mathcal{A}^\heartsuit$ de $\mathcal{A}$. Pour les lecteurs familiers avec les courbes spectrales de [10], mentionnons que dans le cas $G = \mathrm{GL}(n)$ et la caractéristique p est plus grande que n, $\mathcal{A}^\heartsuit$ consiste en les caractéristiques a telles que la courbe spectrale Y_a est réduite. L'ouvert $\mathcal{A}^{\mathrm{ani}}$ est non vide seulement pour les G semi-simples et contient alors les $a \in \mathcal{A}$ telle que la courbe spectrale Y_a est irréductible dans le cas $\mathrm{SL}(n)$. Pour les groupes classiques, $a \in \mathcal{A}^{\mathrm{ani}}$ si l'involution naturelle du groupe classique agit trivialement sur l'ensemble des composantes irréductibles de la courbe spectrale définie dans [9]. Les formules (2) et (3) ont un sens numérique quand nous nous limitons à la partie anisotrope.

Théorème 2.1. *La fibration de Hitchin $m\colon \mathcal{M} \to \mathcal{A}$ est lisse sur l'ouvert $\mathcal{A}^\heartsuit$ et est propre sur l'ouvert $\mathcal{A}^{\mathrm{ani}}$.*

Les arguments nécessaires pour démontrer ce théorème étaient déjà dans la littérature, voir notamment [2] et [6], seules les définitions des ouverts $\mathcal{A}^\heartsuit$ et $\mathcal{A}^{\mathrm{ani}}$ ont apparu plus tard dans [21]. L'énoncé de lissité a été démontré dans [21], celui de propreté dans le cas particulier du groupe unitaire dans [20].

3. Stabilisation de la partie anisotrope

La partie anisotropique de la somme (3) peut être transformée de la même façon que la stabilisation de la partie elliptique de la formule des traces suivant Langlands et Kottwitz [15] et [12]. À la différence de la formule des traces, le comptage de points de $\mathcal{M}$, tout comme celui des points des variétés de Shimura et de Drinfeld, comporte en plus une première sommation sur $\ker^1(F, G)$ qui, en fait, simplifie la stabilisation.

Supposons que a est semi-simple régulier. Donnons-nous un élément $\gamma_0 \in \mathfrak{g}(F)$ d'image $\chi(\gamma_0) = a$. Le centralisateur I_{γ_0} est un tore qui ne dépend pas du choix de γ_0. On le notera I_a et on le supposera *anisotrope*. Le tore dual $\hat{I}_a$ est muni d'une action finie de $\Gamma = \mathrm{Gal}(\overline{F}/F)$ telle que $\hat{I}_a^{\Gamma}$ est fini.

Pour tout $\xi \in \ker^1(F, G)$, les classes de conjugaison $\gamma \in \mathfrak{g}^{\xi}(F)$ telles que $\chi(\gamma) = a$ sont en bijection avec les classes de cohomologie

$$\alpha = \mathrm{inv}(\gamma_0, \gamma) \in \mathrm{H}^1(F, I_a)$$

dont l'image dans $\mathrm{H}^1(F, G)$ est l'élément ξ. Ainsi l'ensemble des paires (ξ, γ) de la somme (3) où $\xi \in \ker^1(F, G)$ et γ est une classe de conjugaison de $\mathfrak{g}^{\xi}(F)$ d'image $a \in \mathscr{A}^{\mathrm{ani}}(\mathbb{F}_q)$ est en bijection avec

$$\ker[\mathrm{H}^1(F, I_a) \to \bigoplus_{v \in |X|} \mathrm{H}^1(F_v, G)].$$

Pour toute place $v \in |X|$, donner une classe de conjugaison $\gamma_v \in \mathfrak{g}(F_v)$ telle que $\chi(\gamma_v) = a$ revient à donner son invariant

$$\alpha_v = \mathrm{inv}_v(\gamma_0, \gamma_v) \in \ker[\mathrm{H}^1(F_v, I_a) \to \mathrm{H}^1(F_v, G)].$$

D'après Kottwitz, ce groupe peut être décrit en termes des groupes duaux de la façon suivante. Soit Γ_v le groupe de Galois local $\mathrm{Gal}(\overline{F}_v/F_v)$. D'après la dualité de Nakayama, donner un élément $\alpha_v \in \mathrm{H}^1(F_v, I_a)$ revient à donner un caractère d'ordre fini $\alpha_v : \hat{I}_a^{\Gamma_v} \to \mathbb{C}^{\times}$. Pour que l'élément α_v ait l'image triviale dans $\mathrm{H}^1(F_v, G)$, il faut et il suffit que la restriction du caractère α_v à $Z_{\hat{G}}^{\Gamma_v}$ est triviale où $Z_{\hat{G}}$ est le centre du groupe dual $\hat{G}$.

Pour qu'une collection de classes de conjugaison $(\gamma_v)_{v \in |X|}$ de $\mathfrak{g}(F_v)$ avec $\chi(\gamma_v) = a$ provienne d'une paire (ξ, γ) de la somme (3), il faut et il suffit que $\gamma_v = \gamma_0$ pour presque tout v et que

$$\sum_{v \in |X|} \alpha_v|_{\hat{I}_a^{\Gamma}} = 0 \tag{5}$$

où $\alpha_v = \mathrm{inv}_v(\gamma_0, \gamma_v)$. Si c'est le cas, le nombre des paires (ξ, γ) qui s'envoie sur cette collection $(\gamma_v)_{v \in |X|}$ est égal au cardinal du groupe

$$\ker^1(F, I_a) = \ker[\mathrm{H}^1(F, I_a) \to \bigoplus_{v \in |X|} \mathrm{H}^1(F_v, I_a)].$$

La somme (3) se récrit comme suit

$$|\ker^1(F, I_a)|\, \tau(I_a) \sum_{(\gamma_v)_{v \in |X|}} \prod_v O_{\gamma_v}(1_{D_v}) \tag{6}$$

où les γ_v sont des classes de conjugaison de $\mathfrak{g}(F_v)$ vérifiant l'équation (5). En mettant en facteur le nombre de Tamagawa $\tau(I_a)$, on trouve une somme de produits d'intégrales orbitales locales $\prod_v O_{\gamma_v}(1_{D_v})$ au lieu des intégrale globales $O_\gamma(1_D)$.

En appliquant la formule d'Ono [22]

$$|\ker^1(F, I_a)|\,\tau(I_a) = |\pi_0(\hat{I}_a^\Gamma)|,$$

la somme (3) devient

$$|\pi_0(\hat{I}_a^\Gamma)| \sum_{(\gamma_v)_{v\in|X|}} \prod_v O_{\gamma_v}(1_{D_v}) \tag{7}$$

où les (γ_v) vérifie la condition (5). Notons qu'avec l'hypothèse I_a anisotrope, le groupe $\hat{I}_a$ est un groupe fini de sorte que $\pi_0(\hat{I}_a^\Gamma) = \hat{I}_a^\Gamma$.

En utilisant la transformation de Fourier sur le groupe fini $\hat{I}_a^\Gamma$, la somme (3) devient

$$|\mathcal{M}_a(\mathbb{F}_q)| = \sum_{\kappa\in\hat{I}_a^\Gamma} O_a^\kappa(1_D) \tag{8}$$

avec

$$O_a^\kappa(1_D) = \prod_{v\in|X|} \sum_{\substack{\gamma_v\in\mathfrak{g}(F_v)/\sim\\ \chi(\gamma_v)=a}} \langle \mathrm{inv}_v(\gamma_0, \gamma_v), \kappa\rangle\, O_{\gamma_v}(1_{D_v}) \tag{9}$$

qui ne dépend pas du choix de $\gamma_0 \in \mathfrak{g}(F)$. Nous appelons cette expression la κ-décomposition de (3). Elle ne dépend en fait pas du choix de l'élément γ_0. Ceci suggère l'existence d'une décomposition naturelle de la cohomologie de la fibre $\mathcal{M}_a$.

D'après [15] et [12, 9.6], cette κ-décomposition s'organise quand a varie en une somme en les classes $[\kappa]$ de $\hat{G}$-conjugaison des éléments d'ordre fini de $\hat{G}$. À la suite de (8), la partie anisotropique de (2) se récrit comme suit

$$|\mathcal{M}^{\mathrm{ani}}(\mathbb{F}_q)| = \sum_{[\kappa]\in\hat{G}/\sim} \sum_{a\in\mathcal{A}^{\mathrm{ani}}(\mathbb{F}_q)} \sum_{\kappa\in\hat{I}_a^\Gamma\cap[\kappa]} O_a^\kappa(1_D). \tag{10}$$

Précisons ce que nous entendons par $\kappa \in \hat{I}_a^\Gamma \cap [\kappa]$. Il existe un plongement du tore dual $\hat{I}_a$ du centralisateur I_a dans $\hat{G}$ bien défini à $\hat{G}$-conjugaison près. Le sous-ensemble de $\hat{I}_a^\Gamma$ des éléments dont l'image dans $\hat{G}$ appartient à la classe de conjugaison $[\kappa]$ est donc bien défini. Cette formule ci-dessus suggère l'existence d'une $[\kappa]$-décomposition de la restriction de $m_*\mathbb{Q}_\ell$ à l'ouvert $\mathcal{A}^{\mathrm{ani}}$.

Nous allons maintenant analyser la condition nécessaire pour que l'intersection $\hat{I}_a \cap [\kappa]$ soit non vide. Pour simplifier, supposons que G est un groupe semi-simple adjoint déployé. La monodromie du tore I_a est donnée par un homomorphisme $\Gamma \to W$ d'image un sous-groupe Σ_a de W bien défini à W-conjugaison près. Soit κ un représentant de $[\kappa]$ appartenant au tore maximal $\hat{T}$ de $\hat{G}$. Soit W_κ le sous-groupe de W des éléments qui fixent κ. Pour que $\hat{I}_a \cap [\kappa]$ soit non vide, il est nécessaire que Σ_a soit conjugué à un sous-groupe de W_κ. Si on suppose en plus que Σ_a est conjugué à $[W_\kappa]$, alors le cardinal de l'intersection $\hat{I}_a \cap [\kappa]$ est égal à $|\mathrm{Nor}(W_\kappa)|/|W_\kappa|$.

4. Symétries de la fibration de Hitchin

Dans le cas $G = \mathrm{GL}(n)$, pour tout $a = (a_i) \in \mathcal{A}(\bar{k})$, on a une courbe spectrale Y_a définie comme la courbe d'équation

$$t^n - a_1 t^{n-1} + \cdots + (-1)^n a_n = 0$$

tracée sur l'espace total du fibré en droites $\mathcal{O}_X(D)$. Si $a \in \mathcal{A}^\heartsuit(\bar{k})$, la courbe spectrale Y_a est réduite et la fibre $\mathcal{M}_a$ est la jacobienne compactifiée de Y_a classifiant les $\mathcal{O}_{Y_a}$-modules sans torsion de rang générique 1. Le groupe de symétries naturelles de Y_a est dans ce cas la jacobienne de Y_a classifiant les $\mathcal{O}_{Y_a}$-modules inversibles.

La construction de ces symétries dans le cas général repose sur une propriété simple des centralisateurs. Soit I le $\mathfrak{g}$-schéma en groupes des centralisateurs

$$I_x = \{g \in G \mid gxg^{-1} = x\}.$$

Soit $\mathfrak{g}^{\mathrm{reg}}$ l'ouvert de $\mathfrak{g}$ des éléments réguliers de $\mathfrak{g}$. Soit $\chi : \mathfrak{g} \to \mathfrak{t}/W$ le morphisme caractéristique de Chevalley *cf.* (1). Rappelons qu'on a une action naturelle de $\mathbb{G}_m$ sur $\mathfrak{t}/W$ qui fait de χ un morphisme $\mathbb{G}_m$-équivariant. On renvoie à [21, 3.2] pour la démonstration du lemme suivant.

Lemme 4.1. *Il existe un unique schéma en groupes affine lisse $\mathbb{G}_m$-équivariant J sur $\mathfrak{t}/W$ muni d'un homomorphisme G-équivariant $\chi^* J \to I$ dont la restriction à $\mathfrak{g}^{\mathrm{reg}}$ est un isomorphisme.*

Un point $a \in \mathcal{A}^\heartsuit(\bar{k})$ définit un morphisme $a : X \to [(\mathfrak{t}/W)/\mathbb{G}_m]$. L'image inverse $J_a = a^*[J/\mathbb{G}_m]$ est un schéma en groupes lisse sur X qui sur un ouvert dense U_a est un tore. Considérons le champ P_a des J_a-torseurs. On a une action de P_a sur $\mathcal{M}_a$ qui résulte de l'homomorphisme $\chi^* J \to I$. De plus, lorsque a varie dans $\mathcal{A}^\heartsuit$, les P_a s'organisent en un champ de Picard relatif lisse [21]. Cette construction a été inspirée par la lecture de [6]. Le champ de Picard P_a a été considéré aussi dans [5].

D'après un théorème de Grothendieck [8, 15.6.4], il existe un ouvert de Zariski P^0 de P telle que la fibre P_a^0 est la composante neutre de P_a, car P est lisse sur $\mathcal{A}^\heartsuit$. En prenant le faisceau quotient P/P^0, on obtient un faisceau en groupes abéliens $\pi_0(P)$ pour la topologie étale de $\mathcal{A}^\heartsuit$ tel que pour tout $a \in \mathcal{A}^\heartsuit(\bar{k})$, la fibre $\pi_0(P)_a$ est le groupe des composantes connexes $\pi_0(P_a)$. On a une description très précise de ce faisceau dans le cas où G est un groupe semi-simple adjoint.

Soit $X \times \mathcal{A}^\heartsuit \to [(\mathfrak{t}/W)/\mathbb{G}_m]$ le morphisme tautologique. Soit U l'image inverse de l'ouvert régulier semi-simple de $\mathfrak{t}/W$. Soit $\widetilde{U}$ le revêtement fini étale galoisien de groupe de Galois W défini comme l'image inverse du revêtement $\mathfrak{t} \to \mathfrak{t}/W$. Puisqu'on n'est dans $\mathcal{A}^\heartsuit$, le morphisme $\widetilde{U} \to \mathcal{A}^\heartsuit$ est un morphisme lisse à fibres non vides. D'après [8, 15.6.4] et [21, 6.2], il existe un faisceau $\pi_0(\widetilde{U})$ pour la topologie étale de $\mathcal{A}^\heartsuit$ tel que pour tout $a \in \mathcal{A}^\heartsuit(\bar{k})$, la fibre de $\pi_0(\widetilde{U})$ est l'ensemble des composantes connexes de $\widetilde{U}_a$. Notons que W agit sur $\pi_0(\widetilde{U})$ et que cette action est transitive fibre par fibre.

Proposition 4.2. *Il existe un homomorphisme surjectif canonique*

$$\mathbb{X}^\vee \times^W \pi_0(\widetilde{U}) \to \pi_0(P) \tag{11}$$

qui est un isomorphisme si G est un groupe semi-simple adjoint. Ici $\mathbb{X}^\vee$ est le groupe des cocaractères du tore T muni de l'action de W et le signe $\times^W$ désigne un produit contracté par l'action diagonale de W.

Pour tout $a \in \mathcal{A}^\heartsuit(\bar{k})$, en vertu du lemme d'homotopie, le groupe P_a agit sur $\mathrm{H}^i(\mathcal{M}_a, \mathbb{Q}_\ell)$ à travers le groupe des composantes connexes $\pi_0(P_a)$. Sur l'ouvert anisotropique $\mathcal{A}^{\mathrm{ani}}$, les groupes $\pi_0(P_a)$ sont finis. On peut donc décomposer

$$\mathrm{H}^i(\mathcal{M}_a, \mathbb{Q}_\ell) = \bigoplus_\kappa \mathrm{H}^i(\mathcal{M}_a, \mathbb{Q}_\ell)_\kappa \tag{12}$$

où κ parcourt l'ensemble des caractères du groupe $\pi_0(P_a)$. Ce groupe est un quotient de $\mathbb{X}^\vee_\Gamma$ si bien que ses caractères sont des éléments de $\hat{T}^\Gamma$. Cette décomposition correspond via le dictionnaire faisceaux-fonctions à la formule (8). En effet, d'après [21, 4.6] le champ quotient $[\mathcal{M}_a/P_a]$, est un produit des champs définis localement de la même façon qu'une intégrale orbitale globale divisée par un nombre de Tamagawa du centralisateur est égal au produit des intégrales orbitales locales.

Globalement sur $\mathcal{A}^{\mathrm{ani}}$, le groupe P agit sur les faisceaux de cohomologie perverse ${}^p\mathrm{H}^i(m^{\mathrm{ani}}_* \mathbb{Q}_\ell)$ et cette action se factorise à travers le faisceau $\pi_0(P)$ en vertu d'une variante du lemme d'homotopie [20, 3.2.3]. Pour chaque ouvert étale U de $\mathcal{A}^{\mathrm{ani}}$, soit $\pi_0(P)(U)^*$ le groupe des caractères de $\pi_0(P)(U)$ et soit $\pi_0(P)^{\mathrm{co}}$ le cofaisceau associé à ce précofaisceau $U \mapsto \pi_0(P)^{\mathrm{co}}$. On envoie à [21, §8] pour un petit résumé de la notion de cofaisceau. On en déduit une décomposition de ${}^p\mathrm{H}^i(m^{\mathrm{ani}}_* \mathbb{Q}_\ell)$ selon l'ensemble des sections globales du cofaisceau $\pi_0(P)^{\mathrm{co}}$. La description (11) du faisceau $\pi_0(P)$ permet de définir une application canonique de l'ensemble des sections globales $\Gamma(\mathcal{A}^{\mathrm{ani}}, \pi_0(P)^{\mathrm{co}})$ dans l'ensembles des classes de $\hat{G}$-conjugaison $[\kappa]$ des éléments κ d'ordre fini de $\hat{G}$, voir [21, 8.4]. On en déduit une décomposition

$${}^p\mathrm{H}^i(m^{\mathrm{ani}}_* \mathbb{Q}_\ell) = \bigoplus_{[\kappa]} {}^p\mathrm{H}^i(m^{\mathrm{ani}}_* \mathbb{Q}_\ell)_{[\kappa]} \tag{13}$$

qui correspond à (10) au niveau des fonctions.

Pour simplifier les notations, considérons le faisceau pervers gradué

$$(m^{\mathrm{ani}}_{*,\mathrm{gr}} \mathbb{Q}_\ell)_{[\kappa]} = \bigoplus_{i \in \mathbb{Z}} {}^p\mathrm{H}^i(m^{\mathrm{ani}}_* \mathbb{Q}_\ell)_{[\kappa]}.$$

On peut estimer le support de $(m^{\mathrm{ani}}_{*,\mathrm{gr}} \mathbb{Q}_\ell)_{[\kappa]}$. Pour simplifier, supposons de nouveau G semi-simple adjoint et déployé. On peut stratifier $\mathcal{A}$ de la façon suivante

$$\mathcal{A} = \bigsqcup_{[\Sigma]} \mathcal{A}_{[\Sigma]}$$

où $[\Sigma]$ parcourt l'ensemble des classes de conjugaison de sous-groupes Σ de W. Un point géométrique $a \in \mathcal{A}(\bar{k})$ appartient à la strate $[\Sigma]$ si le groupe de monodromie du tore I_a est $[\Sigma]$. Une autre strate $\mathcal{A}_{[\Sigma']}$ est incluse dans l'adhérence de $\mathcal{A}_{[\Sigma]}$ si Σ' est conjuguée à un sous-groupe de Σ.

Proposition 4.3. *Le morceau ${}^p\mathrm{H}^i(m_*^{\mathrm{ani}}\mathbb{Q}_\ell)_{[\kappa]}$ est supporté par $\mathcal{A}_{[W_\kappa]}$ où W_κ est le fixateur dans W d'un représentant $\kappa \in \hat{T}$ de $[\kappa]$.*

La cohomologie perverse de la fibration de Hitchin se décompose donc en morceaux de différents supports. On appelle stables les morceaux correspondant aux $\kappa \in Z_{\hat{G}}$. Son support est a priori tout l'espace $\mathcal{A}^{\mathrm{ani}}$. Il y a lieu de penser que ces morceaux stables ne contiennent pas de facteurs directs de support strictement plus petit. Ceci est probablement une conjecture difficile.

5. Groupes endoscopiques

Pour simplifier l'exposition, supposons que G est un groupe semi-simple adjoint déployé. Le groupe dual $\hat{G}$ est alors un groupe semi-simple simplement connexe muni de l'action triviale de Γ. Soit $\kappa \in \hat{G}$ un élément d'ordre fini. Le centralisateur $\hat{G}_\kappa$ est alors un groupe réductif connexe qu'on notera $\hat{H}$. Soit H le groupe déployé sur k dont le dual est $\hat{H}$. Il n'y a qu'une faible relation entre H et G : ils partagent un tore maximal T et le groupe de Weyl W_H de H est un sous-groupe de réflexions du groupe de Weyl W de G. Avec l'hypothèse G adjoint, W_H est le fixateur W_κ de κ dans W.

Considérons l'espace de module des Hitchin pour le triplet (X, D, H) qui paramètre les couples (E_H, ϕ) où E_H est un H-torseurs sur X et où ϕ est une section globale de $\mathrm{ad}(E_H)(D)$. On a aussi une fibration de Hitchin

$$n : \mathcal{N} \to \mathcal{B}$$

où $\mathcal{B}$ est l'espace des sections globales du fibré $(\mathfrak{t}/W_H) \times^{\mathbb{G}_m} L_D$. Le morphisme évident $\mathfrak{t}/W_H \to \mathfrak{t}/W$ induit un morphisme $\pi : \mathcal{B} \to \mathcal{A}$. Par restriction à $\mathcal{B}^\heartsuit$, on obtient un morphisme non ramifié $\pi^\heartsuit : \mathcal{B}^\heartsuit \to \mathcal{A}^\heartsuit$ d'image $\bar{\mathcal{A}}_{W_H}$. Au-dessus de l'ouvert $\mathcal{A}_{W_H}$ de $\bar{\mathcal{A}}_{W_H}$, le morphisme

$$\pi_{W_H} : \mathcal{B}_{W_H} \to \mathcal{A}_{W_H}$$

est un morphisme fini et étale de degré $|\mathrm{Nor}(W_H)|/|W_H|$ égal au cardinal de l'ensemble $\hat{I}_a^\Gamma \cap [\kappa]$ pour tout point géométrique $a \in \mathcal{A}_{W_H}(\bar{k})$.

Sur $\mathcal{B}^\heartsuit$, on a un champ de Picard Q des symétries de la fibration de Hitchin $n : \mathcal{N} \to \mathcal{B}$. L'action qui s'en déduit sur $n_*^\heartsuit\mathbb{Q}_\ell$ se factorise à travers le faisceau $\pi_0(Q)$. Sur la strate ouverte $\mathcal{N}_{\Sigma_H}$ de $\mathcal{N}$, le faisceau $\pi_0(Q)$ est le faisceau constant de valeur $Z_{\hat{H}}$.

Dans la décomposition $n_*^{\mathrm{ani}}\mathbb{Q}_\ell$, on a donc un morceau stable $(n_*^{\mathrm{ani}}\mathbb{Q}_\ell)_\kappa$ correspondant à l'élément $\kappa \in [\kappa]$ qui a servi à définir $\hat{H}$. De même, on a un κ-morceau

$(\pi_{W_H}^* m_*^{\mathrm{ani}}\mathbb{Q}_\ell)_\kappa$. D'après la proposition 4.3, on sait que ces deux morceaux sont sommes directes de faisceaux pervers purs. Suivant Langlands et Shelstad [16], il serait tentant de formuler la conjecture suivante.

Conjecture 5.1. Il existe
- un nombre entier naturel d
- un système local $\mathcal{L}$ de rang 1 et d'ordre 2 sur $\mathcal{B}_{\Sigma_H}$
- un $Z_{\hat{H}}$-torseur Υ sur $\mathcal{B}_{\Sigma_H}$

tels qu'il existe un isomorphisme de faisceaux pervers gradués au-dessus de $\mathcal{B}_{W_H}$

$$((n_*^{\mathrm{ani}}\mathbb{Q}_\ell)_\kappa^\Upsilon \otimes \mathcal{L}[-2d](-d)) \to (\pi_{W_H}^* m_*^{\mathrm{ani}}\mathbb{Q}_\ell)_\kappa$$

où l'exposant Υ consiste à tordre l'objet muni d'une action de $Z_{\hat{H}}$ par le $Z_{\hat{H}}$-torseur Υ, où $[-2d]$ est le décalage dans la graduation et où $(-d)$ est le twist à la Tate.

Par adjonction, on déduit de cette conjecture un isomorphisme de faisceaux pervers gradués sur $\mathcal{A}_{W_H}$

$$(\pi_{W_H})_*((n_*^{\mathrm{ani}}\mathbb{Q}_\ell)_\kappa^\Upsilon \otimes \mathcal{L}[-2d](-d)) \to (m_*^{\mathrm{ani}}\mathbb{Q}_\ell)_{[\kappa]}.$$

Il est très tentant de penser que cet isomorphisme s'étend à $\bar{\mathcal{A}}_{W_H}$ car en mettant ensemble ces isomorphismes pour les différents groupes endoscopiques, on obtiendrait géométriquement la stabilisation complète de la partie anisotrope de la formule des traces. Pour le moment, il manque un peu d'exemples pour que cette conjecture plus générale soit complètement convaincante.

Soit $b \in \mathcal{B}_{W_H}(\mathbb{F}_q)$ un $\mathbb{F}_q$-point de $\mathcal{B}_{W_H}$ d'image $a \in \mathcal{A}_{W_H}(\mathbb{F}_q)$. La conjecture 5.1 implique l'égalité suivante qui est une forme globale du lemme fondamental

$$O_a^\kappa(1_D) = q^d \epsilon_b(\mathcal{L})\epsilon_b(\kappa, \Upsilon) O_{H,b}^\kappa(1_D).$$

Ici $\epsilon_b(\mathcal{L}) \in \{\pm 1\}$ est le signe défini par la fibre en b du système local $\mathcal{L}$ de rang 1 d'ordre 2 et $\epsilon_b(\kappa, \Upsilon)$ est la racine d'unité définie par la fibre en b du système local de rang 1 obtenu en poussant le $Z_{\hat{H}}$-torseur Υ par le caractère κ. Les intégrales $O_a^\kappa(1_D)$ et $O_{H,b}^\kappa(1_D)$ sont des produits de κ-intégrales orbitales locales. La κ-intégrale orbitale pour H est une intégrale orbitale stable car $\kappa \in Z_{\hat{H}}$. Il est très probable qu'on peut déduire la forme usuelle locale du lemme fondamental, conjecturée par Langlands et Shelstad [16], à partir de cette forme globale. En particulier, le nombre $q^d \epsilon_b(\mathcal{L})\epsilon_b(\kappa, \Upsilon)$ doit être le produit en toutes les places de facteurs de transfert de Langlands–Shelstad.

Pour formuler la conjecture 5.1 de façon plus précise, il est nécessaire de construire les différents ingrédients d, $\mathcal{L}$ et Υ. Dans le cas du groupe unitaire, d et $\mathcal{L}$ ont été construits dans [20], et Υ est trivial. Les constructions de d et $\mathcal{L}$ se généralisent sans trop de difficultés au cas général. Il existe aussi en général un candidat naturel pour Υ dont la construction reste toutefois conditionnelle.

Dans le cas des groupes unitaires, la conjecture a été démontrée dans [20]. Le cas général reste ouvert.

Remerciements. J'exprime ma reconnaissance à J.-F. Dat, V. Drinfeld, A. Genestier, R. Kottwitz, J.-P. Labesse, L. Lafforgue, R. Langlands, C. Moeglin, M. Rapoport et tout particulièrement à G. Laumon pour l'encouragement et l'aide qu'ils m'ont apportés lors de différents stades de ce projet. Je remercie G. Laumon et Ngô Dac Tuân pour leur relecture attentive de ce rapport.

Hecke algebras and harmonic analysis

Eric M. Opdam*

Abstract. Iwahori–Hecke algebras are ubiquitous. One encounters these algebras in subjects as diverse as harmonic analysis, equivariant K-theory, orthogonal polynomials, quantum groups, knot theory, algebraic combinatorics, and integrable models in statistical physics. In this exposition we will mostly concentrate on the analytic aspects of affine Hecke algebras and study them from the perspective of operator algebras. We will discuss the Plancherel theorem for these type of algebras, and based on a conjectural invariance property of their (operator algebraic) K-theory, study the structure of the tempered dual.

Mathematics Subject Classification (2000). Primary 20C08; Secondary 22D25, 43A90.

Keywords. Hecke algebra, Plancherel measure, tempered dual, K-theory.

1. Introduction

Let G be a group and let $K \subset G$ be an almost normal subgroup of G, i.e. a subgroup whose double cosets are finite unions of one-sided cosets. The Hecke algebra of the pair (G, K) is the convolution algebra of $\mathbb{Z}$-valued functions with finite support on the double coset space $K\backslash G/K$. More generally, given a K-module (M, σ) (over some commutative, unital ring R) one considers the convolution algebra $H_R(G, K, \sigma)$ of $\mathrm{End}_R(M^\vee)$-valued $(K, \sigma^\vee)$-spherical functions which are supported on finitely many double cosets of K. Hecke algebras were introduced in this abstract setting by Shimura in the 1950s, following the original work of Hecke on certain linear operators acting in a space of modular forms. The study of representations of Hecke algebras in spaces of modular forms is of basic importance for the study of modular forms.

Later it became apparent that this concept is also fundamental for understanding the representation theory of finite reductive groups, and this seems also true for p-adic reductive groups. Let k be a non-archimedean local field and let G be the group of k-points of a connected reductive group defined over k, equipped with the locally compact, totally disconnected Hausdorff topology it inherits from k. Any compact open subgroup $K \subset G$ is almost normal, hence in this situation we have a large supply of Hecke algebras of the form $H_{\mathbb{C}}(G, K, \sigma)$ where (V_σ, σ) is a complex finite dimensional smooth representation of K.

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

The fundamental and beautiful result which is the underpinning of the application of these Hecke algebras to the representation theory of G is Bernstein's Decomposition Theorem [11]. It states that the category of smooth representations of G has a canonical decomposition as a product of blocks $\mathfrak{R}_{\mathfrak{s}}$ which are parametrized by the components $\mathfrak{s}$ of the Bernstein variety Σ of "supercuspidal pairs" (L, ρ) modulo G-conjugacy, where $L \subset G$ is a Levi-subgroup, and where ρ is an irreducible supercuspidal representation of L, i.e. a representation whose matrix coefficients are compactly supported modulo the center of L. Each block is by construction equivalent to the category of modules over a two sided ideal $C_c^\infty(G)_{\mathfrak{s}}$ of the convolution algebra $C_c^\infty(G)$ of compactly supported, locally constant complex valued functions on G (for the sake of this exposition I will refrain from calling $C_c^\infty(G)$ the Hecke algebra of G, although it is customary to so).

It is a major question how to describe the blocks $\mathfrak{R}_{\mathfrak{s}}$. Bushnell and Kutzko [16], [17] introduced the notion of $\mathfrak{s}$-types. A pair (K, σ) is called an $\mathfrak{s}$-type if the block $\mathfrak{R}_{\mathfrak{s}}$ consists precisely of those smooth representations of G which are generated by their (K, σ) isotypic component. In that case the functor $V \to \mathrm{Hom}_K(V_\sigma, V|_K)$ is an equivalence from $\mathfrak{R}_{\mathfrak{s}}$ to the category of $\mathcal{H}_{\mathbb{C}}(G, K, \sigma)$-modules. This notion of types originates from the work of Borel [14], who showed that an irreducible smooth G-module V is a subquotient of the unramified principal series iff V contains fixed vectors with respect to an Iwahori subgroup $B \subset G$ (the corresponding component of Σ is called the "Borel component"). Through the work of Bushnell and Kutzko (loc. cit.), Morris [51], [52], and Moy and Prasad [53] $\mathfrak{s}$-types are known to exist in many cases. For instance $\mathfrak{s}$-types always exist for "level 0" components $\mathfrak{s}$.

The algebra $H_{\mathbb{C}}(G, K, \sigma)$ comes equipped with a trace $\mathrm{tr}\colon f \to \mathrm{trace}(f(e))$ and a $*$ structure $f^*(g) = f(g^{-1})^*$. This defines a canonical C^*-algebra closure $C_r^*(H, K, \sigma)$ of $H_{\mathbb{C}}(G, K, \sigma)$ (the reduced C^*-algebra) which is of type I and comes with the distinguished faithful trace tr. The equivalence between a block $\mathfrak{R}_{\mathfrak{s}}$ and the module category of the Hecke algebra $H_{\mathbb{C}}(G, K, \sigma)$ of an $\mathfrak{s}$ respects this structure, and the Plancherel measure of G restricted to the irreducible representations in the block $\mathfrak{R}_{\mathfrak{s}}$ coincides with the spectral measure of the trace tr. We normalize tr to obtain a tracial state τ on $C_r^*(H, K, \sigma)$, and we refer to its spectral measure as the "Plancherel measure of $H_{\mathbb{C}}(G, K, \sigma)$". The theory of types seeks to decompose the harmonic analysis on G essentially in two separate parts: (1) knowledge of the supercuspidal representations of all Levi subgroups $L \subset G$ and (2) knowledge of the Plancherel measure of the Hecke algebras $H_{\mathbb{C}}(G, K, \sigma)$ [15].

As a complement to these results, the structure of the Hecke algebra $H_{\mathbb{C}}(G, K, \sigma)$ of an $\mathfrak{s}$-type can be described fairly explicitly in various cases. In the case of the Borel component this algebra is the *Iwahori–Hecke algebra* $\mathcal{H}(W, q)$ [32], where W is an extended affine Weyl group which can be attached to G by Bruhat–Tits theory, and where q is a label function on W which is defined in terms of the structure of a (generalized) affine BN-pair for G and the cardinality $\boldsymbol{q}$ of the residue field of k. By results of Morris (loc. cit.) and Lusztig [41] the Hecke algebra $H_{\mathbb{C}}(G, K, \sigma)$ of a type (K, σ) of level 0 is always a twisted crossed product of an Iwahori–Hecke algebra of

the form $\mathcal{H}(W', q')$ (for a certain affine Weyl group W' and label function q') and a group $C(K, \sigma)$ (where the 2-cocycle lives on $C(K, \sigma)$). These results draw heavily on the work of Howlett and Lehrer [31] who successfully followed a similar approach for the representation theory of finite groups of Lie type.

The above exposition makes a quite compelling case for the study of an Iwahori–Hecke algebra $\mathcal{H}(W, q)$ as an object of (harmonic) analysis and the spectral problem described above. Indeed, this point of view did not go unnoticed and in some sense was already promoted by Matsumoto in [47]. But it turns out that it is quite difficult to carry it out. The description of the support of the Plancherel measure amounts to the description of the tempered dual of $\mathcal{H}(W, q)$. Using geometric methods of a completely different nature this problem was solved explicitly by Kazhdan and Lusztig in their profound paper [34], in the special case of the "Borel component" when in addition G is split semisimple and of adjoint type. Lusztig [41], [42] has in principle solved such classification problems in greater generality, when G splits over an unramified extension of k, and σ is a cuspidal unipotent representation. These methods do not give information on the Plancherel measures.

Iwahori–Hecke algebras also play a fundamental role in a wide range of other areas for some of which the aforementioned spectral problems are of immediate interest, such as integrable models in mathematical physics (the Calogero–Moser systems [29], [54], and also the generalized quantum Bose gas with delta function potential and the nonlinear Schrödinger equation [27], [24]), and the theory of multivariable orthogonal polynomials and special functions [46], [19]. These applications have led to interesting new directions in the theory of Hecke algebras (most notably Ivan Cherednik's double affine Hecke algebra [18], [19]) and this in fact raises challenging new questions in harmonic analysis. We also mention the role of the Hecke algebra for unitarizability of Iwahori-spherical representations [5], [6].

Therefore it is a problem of considerable interest to describe the Plancherel measure of the Iwahori–Hecke algebras $\mathcal{H}(W, q)$ of affine type (simply called "affine Hecke algebras" in the sequel) explicitly, and it is this problem that we will address in this paper. The paper has three parts. In the sections 2–4 we review results of [56] on the L^2-completion of the affine Hecke algebra. The main results are: (1) An algebraic characterization of the central support of the tempered spectrum. (2) The Plancherel density depends up to constants independent of $\boldsymbol{q}$ only on the central character. (3) An explicit product formula for the formal dimensions of the discrete series, up to constants independent of $\boldsymbol{q}$. The sections 5–6 give an overview of the joint work of Patrick Delorme and myself [22], [23] on the Schwartz algebra completion of the affine Hecke algebra. Here we discuss the geometric structure of the tempered dual by means of the analogue of results of Harish-Chandra [25], [26] and Knapp–Stein [36] on analytic R-groups. Finally in Sections 7–8 we discuss various natural conjectures on the K-theory of the Schwartz algebra. In the three parameter example of type C_n^{aff} we indicate how these conjectures lead in fact to complete description of the tempered dual. In striking contrast to the geometric methods mentioned above, the affine Hecke algebras with generic unequal parameters should be considered as

the most basic cases from this point of view. Using the conjectures, all non-generic cases are understood by deformation to the generic case.

2. Affine Hecke algebras

The structure of an affine Hecke algebra $\mathcal{H} = \mathcal{H}(\mathcal{R}, q)$ is determined by an affine root datum (with basis) $\mathcal{R}$ together with a label function q defined on the extended affine Weyl group W associated to $\mathcal{R}$. We refer the reader to [39], [56], [22] for the details of the definition of the algebra $\mathcal{H}(\mathcal{R}, q)$, which we will only briefly review here.

Let $\mathcal{R} = (X, R_0, Y, R_0^\vee, F_0)$ be a root datum (with basis $F_0 \subset X$ of simple roots of $R_0 \subset X$). This means that R_0 is a (reduced, integral) root system with basis of simple roots F_0, that $R_0^\vee$ is the coroot system of R_0, and that X, Y are lattices in duality such that $R_0 \subset X$ and $R_0^\vee \subset Y$. For example take $X = P(R_0)$, the weight lattice of R_0, and $Y = Q(R_0^\vee)$, the root lattice of $R_0^\vee$. If $\mathfrak{a} := \mathbb{R} \otimes_{\mathbb{Z}} Y$ is spanned by the coroots we call $\mathcal{R}$ semisimple.

Let $W_0 = W(R_0)$ denote the Weyl group of the reduced integral root system R_0. The extended affine Weyl group W associated with $\mathcal{R}$ is by definition $W = W_0 \ltimes X$. The affine root system R is equal to $R := R_0^\vee \times \mathbb{Z} \subset Y \times \mathbb{Z}$. We view elements of $Y \times \mathbb{Z}$ as affine linear functions on X with values in $\mathbb{Z}$. Observe that R is closed for the natural action of W on the set of integral affine linear functions $Y \times \mathbb{Z}$ on X. Furthermore R is the disjoint union of the sets of positive and negative affine roots $R = R_+ \cup R_-$ as usual, and we define the length function l on W by

$$l(w) := |R_+ \cap w^{-1} R_-|. \tag{2.1}$$

A label function $q\colon W \to \mathbb{C}^\times$ is a function which is length multiplicative (i.e. $q(uv) = q(u)q(v)$ if $l(uv) = l(u) + l(v)$) and which in addition satisfies $q(\omega) = 1$ if $l(\omega) = 0$. Thus a label function is completely determined by its values on the set S^{aff} of affine simple reflections in W. It follows easily that its restriction to S^{aff} is constant on W-conjugacy classes of simple reflections. Conversely, any $\mathbb{C}^\times$-valued function on S^{aff} with this property extends uniquely to a label function.

For the purpose of this analytic approach to affine Hecke algebras we will work with positive real label functions only.

Definition 2.1. We denote the set of all positive real label functions for $\mathcal{R}$ by $\mathcal{Q} = \mathcal{Q}_{\mathcal{R}}$. For later reference, we choose a base $\boldsymbol{q} > 1$ and define $f_s \in \mathbb{R}$ such that $q(s) = \boldsymbol{q}^{f_s}$ for all $s \in S^{\mathrm{aff}}$.

Definition 2.2. Given a root datum $\mathcal{R}$ and a positive real label function $q \in \mathcal{Q}$ there exists a unique complex associative unital algebra $\mathcal{H}$ with $\mathbb{C}$-basis N_w ($w \in W$) subject to the following relations (here $q(s)^{1/2}$ denotes the positive square root of $q(s)$):

(a) $N_{uv} = N_u N_v$ for all $u, v \in W$ such that $l(uv) = l(u) + l(v)$.

(b) $(N_s + q(s)^{-1/2})(N_s - q(s)^{1/2}) = 0$ for all $s \in S^{\mathrm{aff}}$.

We call $\mathcal{H} = \mathcal{H}(\mathcal{R}, q)$ the affine Hecke algebra associated with the pair $(\mathcal{R}, q)$.

Remark 2.3. We equip $\mathcal{Q}$ in the obvious way with the structure of the vector group $\mathbb{R}_+^N$ where N denotes the number of W-conjugacy classes in S^{aff}. Given the base $\boldsymbol{q} > 1$ we identify $\mathcal{Q}$ with the finite dimensional real vector space of real functions $s \to f_s$ on S^{aff} which are constant on W-conjugacy classes (see Definition 2.1). In this sense we speak of (linear) *hyperplanes* in $\mathcal{Q}$ (this notion is independent of $\boldsymbol{q}$). By a *half line* in $\mathcal{Q}$ we mean a family of label functions $q \in \mathcal{Q}$ in which the $f_s \in \mathbb{R}$ are kept fixed and are not all equal to 0 and $\boldsymbol{q}$ is varying in $\mathbb{R}_{>1}$. As we will see later, for many problems it is interesting to consider the family of Hecke algebras when q varies in a half line in $\mathcal{Q}$ ("changing the base").

2.1. Root labels for the non-reduced root system. The label function q on W can also be defined in terms of root labels for a certain possibly non-reduced root system which is associated with $\mathcal{R}$. We define R_{nr} associated with $\mathcal{R}$ by

$$R_{\mathrm{nr}} := R_0 \cup \{2\alpha \mid \alpha^\vee \in R_0^\vee \cap 2Y\}. \tag{2.2}$$

Observe that $a + 2 \in Wa$ for all $a \in R$, but that $a + 1 \in Wa$ iff $a = \alpha^\vee + n$ with $2\alpha \notin R_{\mathrm{nr}}$. For affine simple roots $a \in F^{\mathrm{aff}}$ (and thus in particular for $a \in F_0^\vee$) we define

$$q_{a+1} := q(s_a), \tag{2.3}$$

and we extend this to a W-invariant function $a \to q_a$ on the affine root system R (this is possible in a unique fashion). Now for $\alpha = 2\beta \in R_{\mathrm{nr}} \backslash R_0$ we define

$$q_{\alpha^\vee} := \frac{q_{\beta^\vee + 1}}{q_{\beta^\vee}}. \tag{2.4}$$

In this way the set of label functions q on W corresponds bijectively to the set of positive W_0-invariant functions $R_{\mathrm{nr}} \ni \alpha \to q_{\alpha^\vee}$.

2.2. Bernstein presentation. There is another, extremely important presentation of the algebra $\mathcal{H}$, due to J. Bernstein (unpublished) and Lusztig [39]). Since the length function is additive on the dominant cone X^+, the map $X^+ \ni x \to N_x$ is a homomorphism of the commutative monoid X^+ with values in $\mathcal{H}^\times$, the group of invertible elements of $\mathcal{H}$. Thus there exists a unique extension to a homomorphism $X \ni x \to \theta_x \in \mathcal{H}^\times$ of the lattice X with values in $\mathcal{H}^\times$.

The abelian subalgebra of $\mathcal{H}$ generated by $\theta_x, x \in X$, is denoted by $\mathcal{A}$. Let $\mathcal{H}_0 = \mathcal{H}(W_0, q_0)$ be the finite type Hecke algebra associated with W_0 and the restriction q_0 of q to W_0. Then the Bernstein presentation asserts that both the collections $\theta_x N_w$ and $N_w \theta_x$ ($w \in W_0, x \in X$) are bases of $\mathcal{H}$ over $\mathbb{C}$, subject only to the cross relation

(for all $x \in X$ and $s = s_\alpha$ with $\alpha \in F_0$):

$$\theta_x N_s - N_s \theta_{s(x)} = \begin{cases} (q_{\alpha^\vee}^{1/2} - q_{\alpha^\vee}^{-1/2}) \frac{\theta_x - \theta_{s(x)}}{1-\theta_{-\alpha}} & \text{if } 2\alpha \notin R_{\mathrm{nr}}, \\ ((q_{\alpha^\vee/2}^{1/2} q_{\alpha^\vee}^{1/2} - q_{\alpha^\vee/2}^{-1/2} q_{\alpha^\vee}^{-1/2}) + (q_{\alpha^\vee}^{1/2} - q_{\alpha^\vee}^{-1/2})\theta_{-\alpha}) \frac{\theta_x - \theta_{s(x)}}{1-\theta_{-2\alpha}} & \text{if } 2\alpha \in R_{\mathrm{nr}}. \end{cases} \quad (2.5)$$

2.3. The center $\mathcal{Z}$ of $\mathcal{H}$. From the Bernstein presentation of $\mathcal{H}$ one easily derives the following fundamental result, the description of the center of $\mathcal{H}$.

Theorem 2.4 (Bernstein). *The center $\mathcal{Z}$ of $\mathcal{H}$ is equal to $\mathcal{A}^{W_0}$. In particular, $\mathcal{H}$ is finitely generated over its center.*

As an immediate consequence we see that irreducible representations of $\mathcal{H}$ are finite dimensional by application of (Dixmier's version of) Schur's lemma.

We denote by T the complex algebraic torus $T = \mathrm{Hom}(X, \mathbb{C}^\times)$ of complex characters of the lattice X. The space $\mathrm{Spec}(\mathcal{Z})$ of complex homomorphisms of $\mathcal{Z}$ is thus canonically isomorphic to the (categorical) quotient $W_0\backslash T$. By Bernstein's theorem and Schur's lemma we obtain a continuous, finite, surjective map

$$z\colon \mathrm{Irr}(\mathcal{H}) \to \mathrm{MaxSpec}(\mathcal{Z}) = W_0\backslash T, \quad [\pi] \mapsto z(\pi), \quad (2.6)$$

where $\mathrm{Irr}(\mathcal{H})$, the set of equivalence classes of irreducible representations of $\mathcal{H}$, is given the usual Jacobson topology via its identification with the primitive ideal spectrum of $\mathcal{H}$. We call this map the (algebraic) *central character*.

3. L^2-theory and abstract Plancherel theorem

We will study $\mathcal{H}$ via certain topological completions of $\mathcal{H}$. In this section we will study the L^2-completion of $\mathcal{H}$ and the associated reduced C^*-algebra of $\mathcal{H}$.

3.1. $\mathcal{H}$ as a Hilbert algebra. It is a basic fact that the anti-linear map $*$ on $\mathcal{H}$ defined by

$$\Big(\sum_{w\in W} c_w N_w\Big)^* = \sum_{w\in W} \overline{c_w} N_{w^{-1}} \quad (3.1)$$

is an anti-involution of $\mathcal{H}$, making $(\mathcal{H}, *)$ into an involutive algebra. In addition, the linear functional τ defined by

$$\tau\Big(\sum_{w\in W} c_w N_w\Big) = c_e \quad (3.2)$$

is a positive trace on $(\mathcal{H}, *)$. In particular, the sesquilinear pairing $(x, y) := \tau(x^* y)$ defines a pre-Hilbert structure on $\mathcal{H}$.

Definition 3.1. We call $L^2(\mathcal{H})$ the Hilbert space completion of $\mathcal{H}$. Observe that the elements N_w ($w \in W$) form a Hilbert basis for $L^2(\mathcal{H})$.

It is easy to see that the regular representation of $\mathcal{H}$ extends to a representation of $\mathcal{H}$ in $B(L^2(\mathcal{H}))$, the algebra of bounded linear operators on $L^2(\mathcal{H})$. This gives $\mathcal{H}$ the structure of a unital Hilbert algebra, with its Hermitian form defined by the finite positive trace τ.

3.2. The reduced C^*-algebra $\mathfrak{C}$ of $\mathcal{H}$. The following results on the reduced C^*-algebra of $\mathcal{H}$ go back to [47].

Definition 3.2. We define the reduced C^*-algebra $\mathfrak{C}$ of $\mathcal{H}$ as the norm closure of $\lambda(\mathcal{H}) \subset B(L^2(\mathcal{H}))$, where λ denotes the left regular representation of $\mathcal{H}$. We identify $\mathfrak{C}$ with a dense subspace of $L^2(\mathcal{H})$ via the continuous injection $\mathfrak{C} \ni x \to x(1) \in L^2(\mathcal{H})$.

Let λ (resp. ρ) denote the left (resp. right) regular representation of $\mathfrak{C}$ on $L^2(\mathcal{H})$. One has the following basic statements:

Corollary 3.3. *The C^*-algebra completion $\mathfrak{C}$ of $\mathcal{H}$ has type I, and τ extends to a finite tracial state of $\mathfrak{C}$ such that $\lambda = \lambda_\tau$ (resp. $\rho = \rho_\tau$), where λ_τ (resp. ρ_τ) denotes the left (resp. right) GNS-representation of $\mathfrak{C}$ associated with τ.*

Standard results in the spectral theory of C^*-algebras of type I yield the following:

Corollary 3.4. *There exists a unique positive Borel measure μ_{Pl} on $\hat{\mathfrak{C}}$, the Plancherel measure of $\mathcal{H}$, such that we have the following decomposition of τ in irreducible characters of $\mathfrak{C}$:*

$$\tau = \int_{\pi \in \hat{\mathfrak{C}}} \chi_\pi d\mu_{\mathrm{Pl}}(\pi). \tag{3.3}$$

4. The Plancherel measure

We will now address the problem to describe the spectrum $\hat{\mathfrak{C}}$ of $\mathfrak{C}$ and the Plancherel measure μ_{Pl}. The spectrum of $\mathfrak{C}$ is a rather complicated topological space. But it turns out that μ_{Pl}-almost everywhere it can be described by a simpler structure, namely a compact orbifold. This orbifold is represented by (in the sense of [50]) a groupoid of unitary standard induction data $\mathcal{W}_{\Xi_u}$ which is canonically associated with the affine Hecke algebra $\mathcal{H}$ (see [56], [22]). Its space of objects Ξ_u consists of induction data of $\mathcal{H}$ and the arrows $\mathcal{W}_{\Xi_u}$ are twisting isomorphisms between induction data. We will exhibit an explicit (up to some positive real multiplicative constants which are independent of the base $\boldsymbol{q}$)) positive measure μ on the compact orbifold $|\Xi_u| := \mathcal{W}\backslash\Xi_u$ such that a suitable open dense subset of $(|\Xi_u|, \mu)$ with a complement of measure 0 describes $(\hat{\mathfrak{C}}, \mu_{\mathrm{Pl}})$ almost everywhere.

The method in [56] to find this almost explicit Plancherel formula is a calculation of residues, starting from a basic complex analytic representation of τ as an integral over a certain rational n-form with values in the linear dual of $\mathcal{H}$, over a coset $pT_u \subset T$ of the compact real form T_u with $p \in T_{\mathrm{rs}} := \mathrm{Hom}(X, \mathbb{R}_+)$ far in the negative chamber [55]. Although such residue computations are certainly not new (see e.g. [1], [2], [38], [49]), the treatment of the uniqueness of residue data is new and is based on a simple geometric lemma in distribution theory which goes back to joint work with Gert Heckman [27]. This improved treatment of the residues is surprisingly powerful. It is sufficient to compute the Plancherel measure of the center $\mathcal{Z}$ of $\mathcal{H}$ explicitly, and in particular the central projection of the support of the Plancherel measure follows exactly [56] (see also [30]). In combination with Lusztig's results on the structure of completions of affine Hecke algebras at central characters (see [39]) we reorganize in [56] the residues according to parabolic induction and we *derive* the Maass–Selberg relations, the unitarity of the normalized intertwining operators, and finally the explicit (up to positive real factors) product formula for the Plancherel density.

4.1. The discrete series representations. Let us first recall the definition of the discrete series and of tempered representations:

Definition 4.1. An irreducible representation (V, π) of $\mathcal{H}$ is called a *discrete series representations* if it is equivalent to a subrepresentation of $(L^2(\mathcal{H}), \lambda)$. Equivalently, (V, π) is a discrete series representation if its character χ_π extends continuously to $L^2(\mathcal{H})$.

Remark 4.2. As an immediate consequence of this definition, a discrete series representation (V, π) can be equipped with an Hermitian inner product $\langle \cdot, \cdot \rangle$ with respect to which $\pi(h^*) = \pi(h)^*$ for all $h \in \mathcal{H}$. Such a Hilbert space representation of $\mathcal{H}$ is called unitary.

We will describe an *algebraic criterion* for a central character $W_0 t \in W_0 \backslash T$ to be the central character of a discrete series representation. For this we need to introduce the Macdonald c-function (see [45], [55]). This c-function is introduced as an element of the field of fractions of $\mathcal{A}$. The ring $\mathcal{A}$ can be interpreted as the ring of regular functions on T via $\theta_x \to x$, and thus the c-function can be interpreted as a rational function on T. Explicitly, we put

$$c := \prod_{\alpha \in R_{1,+}} c_\alpha, \tag{4.1}$$

where c_α is defined for $\alpha \in R_1$ by

$$c_\alpha := \frac{(1 + q_{\alpha^\vee}^{-1/2} \theta_{-\alpha/2})(1 - q_{\alpha^\vee}^{-1/2} q_{2\alpha^\vee}^{-1} \theta_{-\alpha/2})}{1 - \theta_{-\alpha}}. \tag{4.2}$$

The square roots here are positive square roots; observe that this formula makes sense: if $\alpha/2 \notin X$ then we have $q_{2\alpha^\vee} = 1$ (since $2\alpha^\vee \notin R_{\mathrm{nr}}$) and thus the numerator reduces to $(1 - q_{\alpha^\vee} \theta_{-\alpha})$.

We remark that there is no problem in defining the pole order of the rational function

$$\nu(t) := (c(t)c(t^{-1}))^{-1} \tag{4.3}$$

at a point $t_0 \in T$, since $\nu(t)$ is equal to a product of the rational functions of the form $(c_\alpha(t)c_\alpha(t^{-1}))^{-1}$ (with $\alpha \in R_1$). This function is the pull back via $\alpha/2$ (or α) of a rational function on $\mathbb{C}^\times$ and so it has a well defined pole order at t_0. The pole order of $\nu(t)$ at t_0 is defined as the sum of these pole orders.

The following theorem is of crucial importance.

Theorem 4.3 ([56, Corollary A.12]). *For any point $t_0 \in T$, the pole order of $\nu(t)$ at t_0 is at most equal to the rank* $\mathrm{rk}(R_0)$ *of R_0.*

Definition 4.4. We call $t_0 \in T$ a *residual point* if the pole order of $\nu(t)$ at t_0 is equal to the rank $\mathrm{rk}(X)$ of X.

Theorem 4.3 was proved in [56] by reducing it to a case by case inspection using the classification of residual points for graded Hecke algebras in [27], Section 4 [1]. The following result follows easily from Theorem 4.3.

Corollary 4.5. *For any root datum $\mathcal{R}$ and positive real label function q the set of residual points in T is a finite union of W_0-orbits. This set is nonempty only if* $\mathrm{rk}(R_0) = \mathrm{rk}(X)$.

Example 4.6 (The split adjoint case). *By the split adjoint case we mean that $f_s = 1$ for all $s \in S^{\mathrm{aff}}$ and $X = P$. The work of Kazhdan and Lusztig* [34] *implies* (*see* [56]*, Appendix B for the translation*) *that the residual points are the points of T of the following form. Let G be the Langlands dual group, i.e. the complex semisimple group with root datum $\mathcal{R}$* (*G is simply connected*)*. Then T is a maximal torus for G. Let $s \in T_u$ be such that $G_s \subset G$ is semisimple. Let $\mathcal{O}$ be a distinguished unipotent orbit of G_s and choose a homomorphism $\phi\colon \mathrm{SL}_2(\mathbb{C}) \to G_s$ with the property that*

$$\phi\begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix} \in \mathcal{O} \quad \text{and} \quad c := \phi\begin{pmatrix} \boldsymbol{q}^{1/2} & 0 \\ 0 & \boldsymbol{q}^{-1/2} \end{pmatrix} \in T.$$

Then $r = sc \in T$ is a residual point, and all residual points in this case are of this form.

In general there exists an effective algorithm to classify the set of residual points for any root datum $\mathcal{R}$ with indeterminate positive real label function q (see [56, Theorem A.7]). The residual points come in finitely many generic families of residual points:

[1] The notion of a residual point in [27] seems more restrictive at first sight since it involves the existence of a full flag of intermediate "residual subspaces". In [56], Lemma A.11 we show however that this technical condition is always fulfilled. The existence of such full flags is the main tool for the classification of residual points in [27].

Proposition 4.7. *Let $\mathcal{R}$ be a semisimple root datum. There exists a nonempty finite W_0-invariant set* Res *of generic residual points $r\colon \mathcal{Q} \to T$ of $\mathcal{R}$. If $r \in$ Res then $r(q) = s.c(q)$ where $s \in T_u$ (T_u denoting the compact real form of T) is independent of q, and such that* $\mathrm{rank}(R_{0,s}) = \mathrm{rank}(R_0)$, *and where $c\colon \mathcal{Q} \to T_{\mathrm{rs}}$ (T_{rs} being the connected component of the split real form of T) is a group homomorphism such that for all $\alpha \in R_0$, $\alpha(c)^2$ is a monomial in the root labels $q_{\beta^\vee}$ ($\beta \in R_{\mathrm{nr}}$). For each generic residual point $r \in$ Res there exists an open set $\mathcal{Q}_r \subset \mathcal{Q}$ (depending only on the orbit $W_0 r$) which is the complement of finitely many (rational) hyperplanes in $\mathcal{Q}$, such that $r(q_0)$ is residual iff $q_0 \in \mathcal{Q}_r$ (see* [56, *Theorem A*.14]).

Remark 4.8. For each $\mathcal{R}$ one can explicitly determine the generic residual points r and the sets $\mathcal{Q}_r$. From the classification one can check that all residual points $r \in T$ of $\mathcal{R}$ have the important property that $\overline{r^{-1}} \in W_0 r$.

The following theorem expresses the central support of the discrete series representations of $\mathcal{H}$ in terms of residual points of T.

Theorem 4.9 ([56, Theorem 3.29]). *An orbit $W_0 r \in W_0\backslash T$ is the algebraic central character of a discrete series representation of $\mathcal{H}$ if and only if $r \in T$ is a residual point. In particular, the set $\Delta_{\mathcal{R}}$ of equivalence classes of discrete series representations of $\mathcal{H}$ is finite, and is nonempty only if* $\mathrm{rk}(R_0) = \mathrm{rk}(X)$.

As a consequence of the residue calculus one obtains an almost explicit *product formula* for the formal dimension (the Plancherel mass) of the discrete series as a function of the base $\boldsymbol{q}$.

Theorem 4.10 ([56, Corollary 3.32, Theorem 5.6]). *In this theorem we fix $f_s \in \mathbb{R}$ and we denote the corresponding half line in $\mathcal{Q}$ by $\mathcal{L} \subset \mathcal{Q}$ (see Remark* 2.3).

Notice that for each $r \in$ Res we have either $\mathcal{L} \subset \mathcal{Q}_r$ or $\mathcal{L} \cap \mathcal{Q}_r = \emptyset$. Let $r \in$ Res be such that $\mathcal{L} \subset \mathcal{Q}_r$. Via scaling isomorphisms [56, *Theorem* 5.6] *there exists a finite (trivial) fibration $\Delta_{W_0 r} \to \mathcal{L}$ whose fiber at $q \in \mathcal{L}$ is $\Delta_{W_0 r(q)}$, the finite set of discrete series representations of $\mathcal{H}(\mathcal{R}, q)$ with algebraic central character $W_0 r(q)$.*

Recall that we view $\boldsymbol{q} > 1$ as coordinate on $\mathcal{L}$. The expressions $\alpha(r) = \alpha(r(q))$ and $q_{\alpha^\vee}$ ($\alpha \in R_{\mathrm{nr}}$) with $q \in \mathcal{L}$ are thus viewed as functions of $\boldsymbol{q} > 1$. For each connected component $\delta \subset \Delta_{W_0 r}$ there exists a nonzero real constant $d_\delta \in \mathbb{R}^\times$ independent of $\boldsymbol{q}$ *such that for all $q \in \mathcal{L}$,*

$$\mu_{\mathrm{Pl}}(\{\delta(q)\}) = d_\delta \frac{q(w_0) \prod'_{\alpha \in R_1} (\alpha(r) - 1)}{\prod'_{\alpha \in R_1} (q_{\alpha^\vee}^{1/2} \alpha(r)^{1/2} + 1) \prod'_{\alpha \in R_1} (q_{\alpha^\vee}^{1/2} q_{2\alpha^\vee} \alpha(r)^{1/2} - 1)} \tag{4.4}$$

where $\prod'$ denotes the product in which we omit the factors which are equal to 0.

Remark 4.11. (a) Observe that only the constant d_δ depends on δ; the other factors only depend on the central character $W_0 r$ of δ.

(b) It was shown by Mark Reeder [57] that this leads to an effective way to determine L-packets of square integrable unipotent representations for exceptional

p-adic Chevalley groups (also see [28]) by considering the almost explicit product formulae for the Plancherel densities of the unipotent representations as a function of $\boldsymbol{q}$, the cardinality of the residue field [2]. Lusztig [41], [42] has given a more general parameterization of the unipotent L packets from a different point of view. In the cases considered the partitions of the set of square integrable unipotent representations coincide [57].

(c) This formula is explicit up to the nonzero real constant d_δ. We remark that if the restrictions $\chi_\delta|_{\mathcal{A}}$ of the characters χ_δ with $\delta \in \Delta_{W_0 r}$ are linearly independent then $d_\delta \in \mathbb{Q}$ for all $\delta \in \Delta_{W_0 r}$ ([56, Remark 3.35]). However we do not know this linear independence, and in fact for the more general class of tempered representations of $\mathcal{H}(\mathcal{R}, q)$ it is easy to find counterexamples for this. In any case, we conjecture that $d_\delta \in \mathbb{Q}$ (see [56], Conjecture 2.27).

(d) The constants d_δ were computed for the exceptional root systems (in the case $q(s) = \boldsymbol{q}$ for all $s \in S^{\mathrm{aff}}$, and $X = P$) in terms of the Kazhdan–Lusztig parameters of δ by Mark Reeder [57].

(e) An irreducible representation of $\mathcal{H}$ is a discrete series if and only if its matrix coefficients have exponential decay with respect to the norm function $\mathcal{N}$ on W (see Definition 5.1); this follows from the Casselman conditions (see [56, Lemma 2.22, Theorem 6.1(ii)]). In particular these matrix coefficients belong to the Schwartz algebra $\mathcal{S} \subset \mathfrak{C}$ (see Definition 5.1), and this shows that the discrete series are isolated points in $\hat{\mathfrak{C}}$.

4.2. Standard parabolic structures. We will now concentrate on the higher dimensional spectral series. Let $\mathcal{P}$ denote the power set of F_0. Let $R_P \subset R_0$ be the root subsystem $\mathbb{R}P \cap R_0$. Notice that P is a basis of simple roots for R_P. With $P \in \mathcal{P}$ we associate the sub root datum $\mathcal{R}^P := (X, R_P, Y, R_P^\vee, P)$. The associated nonreduced root system $R_{\mathrm{nr}}(\mathcal{R}^P)$ is equal to $R_{\mathrm{nr}}(\mathcal{R}^P) = \mathbb{R}P \cap R_{\mathrm{nr}}$ hence we can restrict the root labels on R_{nr} to $R_{P,\mathrm{nr}}$. This defines a label function q^P for the affine Weyl group of the root datum $\mathcal{R}^P$. We now define the subalgebra

$$\mathcal{H}^P := \mathcal{H}(\mathcal{R}^P, q^P) \hookrightarrow \mathcal{H}. \tag{4.5}$$

This affine Hecke algebra will typically not be semisimple. Its semisimple quotient is called $\mathcal{H}_P$, the quotient of $\mathcal{H}^P$ by the two sided ideal generated by $\theta_x - 1$ where $x \in Z^P := \{x \in X \mid x(\alpha^\vee) = 0 \forall \alpha \in P\}$. Notice that the elements θ_x with $x \in Z^P$ are central in $\mathcal{H}^P$. Let us denote by X_P the quotient $X_P = X/Z^P$, and by $Y_P = Y \cap \mathbb{R}P^\vee \subset Y$ its dual lattice. This gives us a semisimple root datum $\mathcal{R}_P := (X_P, R_P, Y_P, R_P^\vee, P)$. Again we see that $R_{\mathrm{nr}}(\mathcal{R}_P) = \mathbb{R}P \cap R_{\mathrm{nr}}$, so from the restriction of the root labels on R_{nr} to $R_{\mathrm{nr}}(\mathcal{R}^P)$ we can define a label function q_P on

[2] At the time when [57] was written, (4.4) was only conjectural for general discrete series representations (see [28]). Instead Reeder used a general Euler–Poincaré type formula for the formal dimension of a discrete series representation of a semisimple p-adic group (see [59]), which requires case-by-case considerations and presents serious computational difficulties. With (4.4) at hand some of these aspects of [57] can be simplified.

the affine Weyl group of $\mathcal{R}_P$. It is now easy to check that the semisimple quotient $\mathcal{H}_P$ of $\mathcal{H}^P$ is equal to

$$\mathcal{H}^P \twoheadrightarrow \mathcal{H}_P = \mathcal{H}(\mathcal{R}_P, q_P). \tag{4.6}$$

4.3. Twisting. Let $T_P = \mathrm{Hom}(X_P, \mathbb{C}^\times) \subset T$ be the character torus of X_P. Let T^P be the connected component of e of the subgroup $\{t \in T \mid \alpha(t) = 1\} \subset T$. We see that $T = T_P T^P$, that $K_P := T_P \cap T^P$ is a finite abelian group, and that T^P is pointwise fixed by the action of W_P on T.

Using the cross relations (2.5) we check that $t \in T^P$ gives rise to an automorphism

$$\phi_t : \mathcal{H}^P \to \mathcal{H}^P, \quad \phi_t(\theta_x N_w) = t(x)\theta_x N_w \tag{4.7}$$

of $\mathcal{H}^P$ (where $w \in W_P$).

Definition 4.12. Let Δ_P denote the set of equivalence classes of discrete series representations of $\mathcal{H}_P$. For $\delta \in \Delta_P$ and $t \in T^P$ we write $\delta_t = \tilde{\delta} \circ \phi_t$ for the twist by ϕ_t of the lift $\tilde{\delta}$ of δ to $\mathcal{H}^P$. Observe that for $k \in K_P$, ϕ_k descends to an automorphism ψ_k of $\mathcal{H}_P$.

Let $\mathfrak{W}_{P,P'} = \{w \in W_0 \mid w(P) = P'\}$. If $w \in \mathfrak{W}_{P,P'}$ then w induces an isomorphism of root data $w : \mathcal{R}^P \to \mathcal{R}^{P'}$ and $w : \mathcal{R}_P \to \mathcal{R}_{P'}$ which is compatible with the label functions. This defines corresponding isomorphisms

$$\phi_w : \mathcal{H}^P \to \mathcal{H}^{P'}; \quad \psi_w : \mathcal{H}_P \to \mathcal{H}_{P'} \tag{4.8}$$

of affine Hecke algebras.

Definition 4.13. Let $\delta \in \Delta_P$. We denote by $\delta^w = \delta \circ \psi_w^{-1} \in \Delta_{P'}$ the twist of δ by the isomorphism ψ_w. We define $(\delta_t)^w$ (with $t \in T^P$, $w \in \mathfrak{W}_{P,P'}$) similarly. Observe that $(\widetilde{\delta^w})_{wt} = (\delta_t)^w$. We denote by $\delta^k = \delta \circ \psi_k^{-1} \in \Delta_P$ the twist of δ by the automorphism ψ_k of $\mathcal{H}_P$. Observe that $(\widetilde{\delta^k})_{kt} = \delta_t$ if $k \in K_P$ and $t \in T^P$.

4.4. The groupoid of standard induction data. First of all, we denote by $\mathfrak{W}$ the (standard) Weyl groupoid, the groupoid whose set of objects is $\mathcal{P}$ and whose space of arrows from P to P' is equal to $\mathfrak{W}_{P,P'}$. This groupoid acts in an obvious way on the groupoid $\mathcal{K}$ whose set of objects is also $\mathcal{P}$ and whose space of arrows is described by $\mathcal{K}_{P,P'} = \emptyset$ if $P \neq P'$, and $\mathcal{K}_{P,P} = K_P$. We denote by $\mathcal{W}$ the semidirect product $\mathcal{W} = \mathcal{K} \rtimes \mathfrak{W}$, i.e. $\mathcal{W}$ is the finite groupoid whose set of objects is $\mathcal{P}$ and whose set of arrows from P to P' equals $\mathcal{W}_{P,P'} = K_{P'} \times \mathfrak{W}_{P,P'}$. The composition of arrows is given by $(k \times u)(l \times v) = ku(l) \times uv$.

The above twisting action on induction data coming from $\mathcal{H}_P$ naturally gives rise to an action of the groupoid $\mathcal{W}$ on the set Ξ of induction data of the various subquotient algebras $\mathcal{H}_P$ with $P \in \mathcal{P}$. Let Ξ be the set of triples (P, δ, t) with $P \in \mathcal{P}$, $\delta \in \Delta_P$ and $t \in T^P$. We see that Ξ is a finite union of complex algebraic tori of the form

$\Xi_{(P,\delta)} = \{(P, \delta, t) \mid t \in T^P\}$. In particular Ξ is fibered over $\mathcal{P}$ in a way compatible with the twisting action of $\mathcal{W}$.

The groupoid of standard induction data $\mathcal{W}_\Xi$ is the translation groupoid arising from the action of $\mathcal{W}$ on Ξ. Explicitly, if $\xi = (P, \delta, t)$, $\xi' = (P', \delta', t') \in \Xi_u$ then the set of arrows $\mathcal{W}_{\xi,\xi'}$ in $\mathcal{W}_\Xi$ between these induction data consists of the set of $g = k \times w \in K_{P'} \times \mathfrak{W}_{P,P'}$ such that $P' = w(P)$, $\delta' = \delta^g$, and $t' = gt$. One easily verifies that this forms an orbifold groupoid in the sense of [50]. We remark that the action of $\mathcal{K}$ on Ξ is free. Thus the quotient $\mathcal{W}_\Xi \to \mathcal{K}\backslash\mathcal{W}_\Xi = \mathfrak{W}_{\mathcal{K}\backslash\Xi}$ is a Morita equivalence and defines the same orbifold structure on $|\Xi| = \mathcal{W}\backslash\Xi$.

We denote by $\mathcal{W}_{\Xi_u}$ the full subgroupoid whose set of objects Ξ_u consists of the unitary standard induction data, i.e. the induction data of the form (P, δ, t) with $t \in T_u^P$, the compact real form of T^P. Hence Ξ_u is a finite disjoint union of compact tori, and $\mathcal{W}_{\Xi_u}$ is a compact orbifold groupoid.

4.5. The induction-intertwining functor. *We choose explicit representatives* (V_δ, δ) *for the equivalence classes* $\delta \in \Delta = \coprod_{P\in\mathcal{P}} \Delta_P$. Given $\xi = (P, \delta, t) \in \Xi$ we denote by $\pi(\xi)$ the induced representation $\mathrm{Ind}_{\mathcal{H}^P}^{\mathcal{H}}(\delta_t)$, realized on the finite dimensional vector space

$$i(V_\delta) = \mathcal{H} \otimes_{\mathcal{H}^P} V_\delta = \bigoplus_{w\in W^P} N_w \otimes V_\delta \tag{4.9}$$

where W^P denotes the set of shortest length representatives in W_0 for the left cosets of $W_P = W(R_P)$. It is not very difficult to show (see [6] or [56]) that for $\xi \in \Xi_u$, the induced representation $\pi(\xi)$ is unitary with respect to the Hermitian inner product on $i(V_\delta)$ defined by (with $x, y \in W^P$ and $u, v \in V_\delta$)

$$\langle N_x \otimes u, N_y \otimes v\rangle = \delta_{x,y}\langle u, v\rangle. \tag{4.10}$$

Theorem 4.14 ([56, Theorem 4.38]). *The assignment* $\Xi_u \ni \xi \to \pi(\xi)$ *extends to a functor* π *(the "induction intertwining" functor) from* $\mathcal{W}_{\Xi_u}$ *to* $\mathbb{P}\,\mathrm{Rep}(\mathcal{H})_{\mathrm{unit}}$*, the category of unitary modules of* $\mathcal{H}$ *in which the morphisms are unitary* $\mathcal{H}$*-intertwiners modulo scalars. This functor assigns a projectively unitary intertwining isomorphism* $\pi(g, \xi)\colon \pi(\xi) \to \pi(\xi')$ *to each* $g \in \mathcal{W}_{\xi,\xi'}$*. For all* $h \in \mathcal{H}$*, the map* $\xi \to \pi(\xi)(h)$ *extends to a regular function on* Ξ*, and for all* $g \in \mathcal{W}_{\xi,\xi'}$ *the map* $\xi \to \pi(g, \xi)$ *is rational but regular at* Ξ_u*. The functor* π *is independent of the choices of the realizations* (V_δ, δ) *of the* $\delta \in \Delta$ *up to natural isomorphisms.*

Remark 4.15. In fact the representations $\pi(\xi)$ with $\xi \in \Xi_u$ are known to be tempered, see below (see [56, Proposition 4.20]).

The projective representation π of $\mathcal{W}_{\Xi_u}$ canonically determines a 2-cohomology class $[\eta] \in H^2(\mathcal{W}_{\Xi_u}, S^1)$ of the groupoid $\mathcal{W}_{\Xi_u}$, namely the pull back via π of the 2-cohomology class of the standard central extension of the category of finite dimensional projective Hilbert spaces by S^1. Notice that $[\eta]$ is obviously a torsion class since the dimensions of the representations $\pi(\xi)$ are bounded by $|W_0|$.

In fact we can be a bit more precise here. Let $\mathcal{W}_\Delta$ be the finite groupoid which is defined like $\mathcal{W}_\Xi$ but with the finite set of objects Δ instead of Ξ, and its morphisms given by twisting. Then the assignment $(P,\delta)\to V_\delta$ can be upgraded to a projective representation of $\mathcal{W}_\Delta$ by *choosing*, for each arrow $g\in\mathcal{W}_\Delta^1$ with source δ, unitary intertwining isomorphisms $\delta_g^i\colon V_\delta\to V_{\delta^g}$ such that for all $h\in\mathcal{H}_{P'}$:

$$\delta_g^i\circ\delta(\psi_g^{-1}h)=\delta^g(h)\circ\delta_g^i. \tag{4.11}$$

One easily checks that such a choice defines a 2-cocycle η_Δ with values in S^1 by

$$\delta_g^i\circ(\delta')_{g'}^i=\eta_\Delta(g,g')(\delta')_{gg'}^i \tag{4.12}$$

where g, g' are composable arrows of $\mathcal{W}_\Delta$. Its class $[\eta_\Delta]\in H^2(\mathcal{W}_\Delta,S^1)$ is independent of the chosen representatives and intertwining morphisms. Then the details of the construction of the projective representation π actually show that $[\eta]\in H^2(\mathcal{W}_{\Xi_u},S^1)$ is the pull back of $[\eta_\Delta]\in H^2(\mathcal{W}_\Delta,S^1)$ via the natural homomorphism of groupoids

$$\mathcal{W}_{\Xi_u}\to\mathcal{W}_\Delta,\quad (P,\delta,t)\mapsto(P,\delta). \tag{4.13}$$

Let D denote the order of $[\eta_\Delta]$. Then we can choose the 2-cocycle η_Δ so that it has its values in μ_D, the group of complex D-th roots of unity. Then the above amounts to

Proposition 4.16. *Let $\tilde{\mathcal{W}}_{\Xi_u}$ denote the central extension of $\mathcal{W}_{\Xi_u}$ by μ_D determined by $[\eta]$. The lifting $\tilde\pi$ to $\tilde{\mathcal{W}}_{\Xi_u}$ of the projective representation π of $\mathcal{W}_{\Xi_u}$ splits.*

4.6. The Plancherel decomposition of τ. We finally have everything in place to formulate the Plancherel theorem for the spectral decomposition of $L^2(\mathcal{H})$ as a (type I) representation of $\mathfrak{C}$. In order to describe the Plancherel density, we introduce relative c-functions for the spectral series of the form $\pi(\xi)$ with $\xi\in\Xi_{(P,\delta),u}:=\{(P,\delta,t)\mid \delta\in\Delta_P, t\in T_u^P\}$.

Definition 4.17. We adopt the notation (P,α) to denote the restriction of $\alpha\in R_0\backslash R_P$ to $T^P\subset T$. Let X^P denote the character lattice of T^P. We write $R^P\subset X^P\backslash\{0\}$ for the set of restrictions (P,α) of roots $\alpha\in R_0\backslash R_P$ which are in addition primitive in the sense that if $\beta\in R_0\backslash R_P$ and $(P,\alpha)\in R^P$ such that (P,α) and (P,β) are proportional, then $(P,\beta)=c(P,\alpha)$ with $c\in\mathbb{Z}$. We write R_+^P for the primitive restrictions corresponding to the positive roots $\alpha\in R_{0,+}\backslash R_{P,+}$. An element (P,α) is called *simple* if (P,α) is indecomposable in $\mathbb{Z}_+R_+^P$. This is equivalent to saying that (P,α) is the restriction of an element of $F_0\backslash P$. To each $(P,\alpha)\in R^P$ we denote by $(P,H_\alpha)\subset T^P$ the connected component of e of $\mathrm{Ker}(P,\alpha)\subset T^P$. It is a codimension 1 subtorus of T^P. The real hyperplanes $(P,H_\alpha)\cap T_{\mathrm{rs}}^P$ are called the *walls* in T_{rs}^P. The positive chamber $T_{\mathrm{rs}}^{P,+}$ is the connected component of the complement of the walls on which $(P,\alpha)>1$ for all $(P,\alpha)\in R_+^P$.

Let $(P, \alpha) \in R^P$. Then the rational function on T defined by

$$c_{(P,\alpha)}(t) := \prod_{\beta \in R_{0,+} \setminus R_P : (P,\beta) \in \mathbb{Z}_+(P,\alpha)} c_\beta(t) \tag{4.14}$$

is clearly $W_P = W(R_P)$-invariant. Hence it can be viewed as a rational function on $W_P \backslash T$. We compose this rational function with the algebraic central character map $z_P \colon \mathrm{Irr}(\mathcal{H}^P) \to W_P \backslash T$ and write $c_{(P,\alpha)}(\sigma)$ for any $\sigma \in \mathrm{Irr}(\mathcal{H}^P)$. We define a rational function $c_{(P,\alpha)}$ on $\Xi_{(P,\delta)}$ by putting $c_{(P,\alpha)}(\xi) := c_{(P,\alpha)}(\delta_t)$. Observe that its poles and zeroes are orbits of (P, H_α) acting on $\Xi_{(P,\delta)}$.

Definition 4.18. (i) We define the c-function on $\xi \in \Xi_{(P,\delta)}$ by means of the formula $c(\xi) = \prod_{(P,\alpha) \in R_+^P} c_{(P,\alpha)}(\xi)$.

(ii) We put $\mu_{(P,\alpha)}(\xi) = (c_{(P,\alpha)}(\xi) c_{(P,-\alpha)}(\xi))^{-1} = |c_{(P,\alpha)}(\xi)|^{-2}$ (see Remark 4.8).

(iii) If $\xi \in \Xi_{(P,\delta)}$ we put $\mu(\xi) = \prod_{(P,\alpha) \in R_+^P} \mu_{(P,\alpha)}(\xi) = (c(\xi) c(w^P \xi))^{-1}$ (where w^P denotes the longest element in W^P).

The following main theorem of [56] makes the abstract Plancherel formula (3.3) almost (up to the constants $d_\delta \in \mathbb{R}_+$ for $\delta \in \Delta$) explicit.

Theorem 4.19 ([56, Theorem 4.39, Proposition 4.42, Theorem 4.43]). (i) *For all $(P, \alpha) \in R_+^P$ the functions $\mu_{(P,\alpha)}$ are smooth and nonnegative on $\Xi_{(P,\delta),u}$. Moreover μ is $\mathcal{W}$-invariant on Ξ.*

(ii) *The function $\Delta \ni (P, \delta) \to \mu_{(\mathcal{R}_P, q_P), \mathrm{Pl}}(\{\delta\})$ (given by the product formula (4.4) applied to $\mathcal{H}(\mathcal{R}_P, q_P)$) is $\mathcal{W}$-invariant on Δ.*

(iii) *Outside a $\mathcal{W}$-invariant subset Ξ_u^{reg} whose complement in Ξ_u consists of finitely many components of codimension at least 1, the representations $\pi(\xi)$ are irreducible. This defines a homeomorphism $[\xi] \to [\pi(\xi)]$ from $|\Xi_u^{\mathrm{reg}}| := \mathcal{W} \backslash \Xi_u^{\mathrm{reg}}$ onto a subset of $\hat{\mathfrak{C}}$ whose complement has measure zero.*

(iv) *For ξ in the compact torus $\Xi_{(P,\delta),u}$, let $d\xi$ denote the normalized Haar measure on $\Xi_{(P,\delta)}$. The Plancherel measure μ_{Pl} is the push forward to the quotient $|\Xi_u| = \mathcal{W} \backslash \Xi_u$ of the absolutely continuous, $\mathcal{W}$-invariant measure on Ξ_u given by (with $\xi = (P, \delta, t) \in \Xi_{(P,\delta),u}$)*

$$d\mu_{\mathrm{Pl}}(\pi(\xi)) = q(w^P)^{-1} |\mathfrak{W}_P|^{-1} \mu_{(\mathcal{R}_P, q_P), \mathrm{Pl}}(\{\delta\}) \mu(\xi) d\xi \tag{4.15}$$

where $\mathfrak{W}_P$ denotes the set $\{w \in W_0 \mid w(P) \subset F_0\}$.

5. The structure of the Schwartz algebra $\mathcal{S}$

In joint work with Patrick Delorme [22], [23] we studied the refinement of the Fourier isomorphism where the L^2-functions are replaced by smooth functions. Following Harish-Chandra and Langlands this step miraculously leads to deep insights in the structure of $\hat{\mathfrak{C}}$ and of $\mathrm{Irr}(\mathcal{H})$. It also brings into play methods from noncommutative geometry.

5.1. The Schwartz algebra $\mathcal{S}$. We define a sub-multiplicative function $\mathcal{N}: W \to \mathbb{R}_+$ as follows. Let $Z = X^+ \cap X^- \subset X$ be the lattice of central translations in W. Given $v \in \mathfrak{a}^*$ we denote by $\overline{v} \in \mathbb{R} \otimes Z$ the projection of v onto $\mathbb{R} \otimes Z$ along $\mathbb{R} \otimes Q(R_0)$. We choose a Euclidean norm $\| \cdot \|$ on $\mathbb{R} \otimes Z$ and put for any $w \in W$:

$$\mathcal{N}(w) := l(w) + \|\overline{w(0)}\|. \tag{5.1}$$

Now we come to the definition of the Schwartz space completion $\mathcal{S}$ of $\mathcal{H}$.

Definition 5.1. The Schwartz space completion $\mathcal{S} \subset L^2(\mathcal{H})$ of $\mathcal{H}$ is the nuclear Fréchet space consisting of the elements $\sum_{w \in W} c_w N_w \in L^2(\mathcal{H})$ such that $w \to |c_w|$ is of rapid decay with respect to the function $\mathcal{N}$.

As an application of the explicit knowledge on $\hat{\mathfrak{C}}$ we obtained in the previous section one can actually prove that

Theorem 5.2 ([56, Theorem 6.5]). *The multiplication of $\mathcal{H}$ extends continuously to $\mathcal{S}$, giving $\mathcal{S}$ the structure of a nuclear Fréchet algebra. Moreover, matrix coefficients of discrete series representations are elements of $\mathcal{S}$.*

5.2. Tempered representations

Definition 5.3. A finite dimensional representation (V, π) of $\mathcal{H}$ is called tempered if it extends continuously to $\mathcal{S}$. Equivalently, (V, π) is tempered if χ_π extends continuously to $\mathcal{S}$.

The next theorem explains the relation of tempered representations with L^2-theory:

Theorem 5.4 ([22, Theorem 3.19]). *If $\xi \in \Xi_u$ then $\pi(\xi)$ is unitary and tempered. Conversely, let (V, π) be an irreducible tempered $\mathcal{H}$ representation. Then there exists a $\xi \in \Xi_u$ such that (V, π) is a direct summand of $\pi(\xi)$.*

Corollary 5.5. *Irreducible tempered representations of $\mathcal{H}$ are unitarizable. The set $\hat{\mathcal{S}}$ of irreducible tempered representations is equal to the support $\hat{\mathfrak{C}}$ of the Plancherel measure.*

5.3. The Fourier isomorphism. Let us denote by $\mathcal{V}_{\Xi_u}$ the trivial fibre bundle over Ξ_u whose fibre at $\xi = (P, \delta, t) \in \Xi_u$ is $V_\xi := i(V_\delta)$ (the representation space of $\pi(\xi)$), thus

$$\mathcal{V}_{\Xi_u} := \coprod_{(P,\delta)} \Xi_{(P,\delta),u} \times i(V_\delta). \tag{5.2}$$

We denote by $\mathrm{End}(\mathcal{V}_{\Xi_u})$ the corresponding bundle of endomorphism algebras. Let $\mathrm{Pol}(\Xi_u, \mathrm{End}(\mathcal{V}_{\Xi_u}))$ denote the algebra of polynomial sections in $\mathrm{End}(\mathcal{V}_{\Xi_u})$, i.e. sections such that the matrix coefficients are Laurent polynomials on each component $\Xi_{(P,\delta),u}$ of Ξ_u.

There is a natural action of $\mathcal{W}$ on $\mathrm{End}(\mathcal{V}_{\Xi_u})$ by algebra homomorphisms as follows. Suppose that $\xi \in \Xi_u$ and that $A \in \mathrm{End}(V_\xi)$. Given $g \in \mathcal{W}_{\xi,\xi'}$ we define $g(A) := \pi(g,\xi)\circ A\circ\pi(g,\xi)^{-1} \in \mathrm{End}(V_{\xi'})$. A section of f of $\mathrm{End}(\mathcal{V}_\Xi)$ is called $\mathcal{W}$-equivariant if we have $f(g(\xi)) = g(f(\xi))$ for all $\xi \in \Xi_u$ and all $g \in \mathcal{W}_{\Xi_u}$ with source ξ.

Observe that for all $h \in \mathcal{H}$, the polynomial section $\xi \to \pi(\xi)(h)$ on Ξ_u is $\mathcal{W}$-equivariant. Let us denote the algebra of $\mathcal{W}$-equivariant polynomial sections by $\mathrm{Pol}(\Xi_u, \mathrm{End}(\mathcal{V}_\Xi))^{\mathcal{W}}$. The Fourier transform on $\mathcal{H}$ is the canonical algebra homomorphism

$$\begin{aligned} \mathcal{F}_{\mathcal{H}} &: \mathcal{H} \to \mathrm{Pol}(\Xi_u, \mathrm{End}(\mathcal{V}_\Xi))^{\mathcal{W}}, \\ &\quad h \mapsto \{\xi \to \pi(\xi)(h)\}. \end{aligned} \tag{5.3}$$

The image of $\mathcal{F}_{\mathcal{H}}$ is difficult to describe. But it turns out that the situation becomes very intelligible upon extension to $L^2(\mathcal{H})$ or to $\mathcal{S}$.

Let $L^2(\Xi_u, \mathrm{End}(\mathcal{V}_{\Xi_u}), d\mu_{\mathrm{Pl}})$ denote the Hilbert space of L^2-sections of $\mathrm{End}(\mathcal{V}_{\Xi_u})$ with respect to the inner product

$$\langle \sigma, \tau \rangle = \int_{\Xi_u} \mathrm{trace}(\sigma(\xi)^*\tau(\xi)) d\mu_{\mathrm{Pl}}(\pi(\xi)). \tag{5.4}$$

Let the Fréchet algebra of smooth sections of $\mathrm{End}(\mathcal{V}_{\Xi_u})$ on Ξ_u be denoted by $C^\infty(\Xi_u, \mathrm{End}(\mathcal{V}_{\Xi_u}))$.

Theorem 5.6 ([56, Theorem 4.43], [22, Theorem 5.3]). (i) *The Fourier transform $\mathcal{F}_{\mathcal{H}}$ extends to an isometric isomorphism*

$$\mathcal{F} : L^2(\mathcal{H}) \to L^2(\Xi_u, \mathrm{End}(\mathcal{V}_{\Xi_u}), d\mu_{\mathrm{Pl}})^{\mathcal{W}}. \tag{5.5}$$

(ii) *The Fourier transform $\mathcal{F}$ restricts to an isomorphism $\mathcal{F}_{\mathcal{S}}$ of Fréchet algebras*

$$\mathcal{F}_{\mathcal{S}} : \mathcal{S} \to C^\infty(\Xi_u, \mathrm{End}(\mathcal{V}_{\Xi_u}))^{\mathcal{W}}. \tag{5.6}$$

5.4. The center of $\mathcal{Z}_{\mathcal{S}}$ of $\mathcal{S}$. As a consequence of Theorem 5.6 we see:

Corollary 5.7. *The center $\mathcal{Z}_{\mathcal{S}}$ of $\mathcal{S}$ is, via the Fourier Transform $\mathcal{F}_{\mathcal{S}}$, isomorphic to the algebra $C^\infty(\Xi_u)^{\mathcal{W}}$ of $\mathcal{W}$-invariant C^∞-functions on Ξ_u. In particular the algebra $\mathcal{S}$ is a $\mathcal{Z}_{\mathcal{S}}$-algebra of finite type.*

This gives, for irreducible tempered representations, a finer notion of central character which we call the *tempered central character*.

Definition 5.8. We denote by $\hat{\mathcal{S}}$ the set of irreducible tempered representations, equipped with its Jacobson topology.

It is easy to see that in our situation $\hat{\mathcal{S}}$ is naturally in bijection with the set $\mathrm{Prim}(\mathcal{S})$ if primitive ideals of $\mathcal{S}$. In view of Corollary 5.5 we have a bijection $\hat{\mathcal{S}} \to \hat{\mathfrak{C}}$, and it is not difficult to show that this bijection is in fact a homeomorphism.

Proposition 5.9. *We have a surjective, finite, continuous map*

$$z_{\mathcal{S}}\colon \hat{\mathcal{S}} \to |\Xi_u| = \mathcal{W}\backslash\Xi_u. \tag{5.7}$$

We call this map the tempered central character. *The irreducible summands of* $\pi(\xi)$ $(\xi \in \Xi_u)$ *all have central character* $[\xi] = \mathcal{W}_\xi \xi$.

5.5. Analytic R-groups. The structure of the fibres of the tempered central character map $z_{\mathcal{S}}$ is completely determined by the geometry of the orbifold $\mathcal{W}_{\Xi_u}$ in combination with the behaviour of the Plancherel density μ and the cohomology class η. This is revealed by studying the explicit inversion of the Fourier isomorphism $\mathcal{F}_{\mathcal{S}}$ by means of the wave packet operator $\mathcal{J}_{\mathcal{S}}$. Let $\mathcal{J}$ be the adjoint of $\mathcal{F}$ defined on the space $L^2(\Xi_u, \mathrm{End}(\mathcal{V}_{\Xi_u}), d\mu_{\mathrm{Pl}})$ of non-invariant L^2-sections. Then $p_{\mathcal{W}} := \mathcal{F} \circ \mathcal{J}$ is equal to taking the $\mathcal{W}$-average, and [22, Theorem 5.3] shows that $p_{\mathcal{W}}$ maps the subspace of $L^2(\Xi_u, \mathrm{End}(\mathcal{V}_{\Xi_u}), d\mu_{\mathrm{Pl}})$ consisting of sections of the form $c\sigma$ (with c the c-function and $\sigma \in C^\infty(\Xi_u, \mathrm{End}(\mathcal{V}_{\Xi_u}))$ to the space $C^\infty(\Xi_u, \mathrm{End}(\mathcal{V}_{\Xi_u}))^{\mathcal{W}}$ of *smooth* invariant sections.

Definition 5.10. We call the connected components of the poles of $c_{(P,\alpha)}$ on $\Xi_{(P,\delta),u}$ the set of (P,α)-mirrors (since a root (P,α) is real, this set is empty or of codimension one in $\Xi_{(P,\delta),u}$). We define the set of mirrors on Ξ_u to be the union of all (P,α)-mirrors (with $P \in \mathcal{P}$ and $(P,\alpha) \in R^P$). This set is $\mathcal{W}$-invariant.

Using the above properties of $p_{\mathcal{W}}$ one shows that:

Proposition 5.11. (i) *For any* (P,α)*-mirror* $M \subset \Xi_{(P,\delta)}$ *there exists a mirror reflection* $\mathfrak{s}_M \in \mathcal{W}_{(P,\delta),(P,\delta)}$*, i.e. an involution in* $\mathcal{W}_{P,P}$ *fixing* δ *such that* $\mathfrak{s}_M$ *fixes* M *pointwise.*

(ii) *Let* $\xi \in \Xi_u$*, say* $\xi = (P,\delta,t)$*. The set* R_ξ *of roots* $(P,\alpha) \in R^P$ *such that* ξ *lies in a* (P,α)*-mirror is a reduced integral root system. We denote by* $R_{\xi,+}$ *the set of roots in* R_ξ *which are element of* $(P,\alpha) \in R^P_+$.

(iii) *For each mirror* $M \in \Xi_u$ *and for all* $\xi \in M$*, the intertwining operator* $\pi(\mathfrak{s}_M, \xi)$ *is scalar.*

Definition 5.12. Denote by $\mathcal{W}^m_\xi = W(R_\xi) \subset \mathcal{W}_{\xi,\xi}$ the normal reflection subgroup generated by the reflections in the mirrors through ξ. The analytic R-group $\mathfrak{R}_\xi$ at ξ is the group of $\mathfrak{r} \in \mathcal{W}_{\xi,\xi}$ such that $\mathfrak{r}(R_{\xi,+}) = R_{\xi,+}$. Then $\mathcal{W}_{\xi,\xi} = \mathcal{W}^m_\xi \rtimes \mathfrak{R}_\xi$.

The above implies that the restriction η_ξ of the 2-cocycle η to $\mathcal{W}_{\xi,\xi}$ is cohomologous to the pull-back of a 2-cocycle (also denoted η_ξ) of $\mathfrak{R}_\xi$. We have the following analog of results of Harish-Chandra ([25], [26]), Knapp–Stein ([36]) and Silberger [61] on analytic R-groups.

Theorem 5.13 ([22], [23]). *The restriction of the induction-intertwining functor* π *to* $\mathfrak{R}_\xi$ *gives rise to an isomorphism* $\mathrm{End}_{\mathcal{H}} V_\xi \simeq \mathbb{C}[\mathfrak{R}_\xi, \eta]$*, the* η_ξ*-twisted group ring of* $\mathfrak{R}_\xi$*. In particular, the functor* E_ξ *defined by* $\psi \to \mathrm{Hom}_{\mathbb{C}[\mathfrak{R}_\xi,\eta]}(\psi, V_\xi)$ *defines*

an equivalence between the category of $\mathbb{C}[\mathfrak{R}_\xi, \eta]$-modules and the category of finite dimensional unitary tempered $\mathcal{H}$-modules with tempered central character $\mathcal{W}\xi$.

Corollary 5.14. *Let $w \in \mathcal{W}_\xi$. There is a unique decomposition $w = xm$ with $m \in \mathcal{W}_\xi^m$ and $x(R_{\xi,+}) = R_{w\xi,+}$. Hence $x\mathfrak{R}_\xi x^{-1} = \mathfrak{R}_{w\xi}$. Consider the isomorphism of algebras $c_w : \mathbb{C}[\mathfrak{R}_\xi, \eta] \to \mathbb{C}[\mathfrak{R}_{w\xi}, \eta]$ defined by η-twisted conjugation with x, i.e. $c_w(r) = \eta(x, r)\eta(xr, x^{-1})\eta(x, x^{-1})^{-1} xrx^{-1}$. For any $\mathbb{C}[\mathfrak{R}_\xi, \eta]$-module ρ we have $E_\xi(\rho) = E_{w\xi}(\rho^w)$ where $\rho^w = \rho \circ c_w^{-1}$.*

Recall that the action of $\mathcal{K}$ on Ξ_u is free. We identify the R-groups $\mathfrak{R}_{k\xi}$ ($k \in \mathcal{K}$) via conjugation by k, and write $\mathfrak{R}_{\mathcal{K}\xi}$. We identify via the twisted conjugations c_k ($k \in \mathcal{K}$) the rings $\mathbb{C}[\mathfrak{R}_{k\xi}, \eta]$ ($k \in \mathcal{K}$) and write $\mathbb{C}[\mathfrak{R}_{\mathcal{K}\xi}, \eta_{\mathcal{K}}]$. We consider the sheaf $\mathrm{G}(\mathfrak{R}, \eta)$ on Ξ_u whose fiber at ξ is the complex representation space $\mathrm{G}(\mathfrak{R}_\xi, \eta)$ of $\mathbb{C}[\mathfrak{R}_\xi, \eta_\xi]$ (the argument that this defines a sheaf is the same as for the usual representation ring sheaf of the orbifold $\mathcal{W}_{\Xi_u}$, see [7]). By the above there exists a $\mathcal{W}$-sheaf $\underline{\mathrm{G}}(\mathfrak{R}, \eta)$ of complex vector spaces on Ξ_u (we identify $\mathfrak{R}_\xi$ with the quotient $\mathcal{W}_{\xi,\xi}/\mathcal{W}_\xi^m$, so that the action on characters by conjugation with $w \in \mathcal{W}_\xi$ is equal to c_w as in Proposition 5.14):

Definition 5.15. The $\mathcal{W}$-sheaf $\mathrm{G}(\mathfrak{R}, \eta)$ on Ξ_u descends to a sheaf of complex vector spaces on $|\Xi_u|$ denoted by $\underline{\mathrm{G}}(\mathfrak{R}, \eta)$, and to a sheaf $\mathrm{G}(\mathfrak{R}_{\mathcal{K}}, \eta_{\mathcal{K}})$ on $\mathcal{K}\backslash\Xi_u$.

6. Smooth families of tempered representations

We investigate the geometry of the orbifold structure of $|\Xi_u|$ in relation to the structure of the Grothendieck group of (finite dimensional) tempered representations of $\mathcal{H}$ in this subsection. The approach is comparable with [12] (but working with $\mathcal{S}$ instead of $\mathcal{H}$). Much of the material in this section and the next is joint work in progress with Maarten Solleveld.

As was explained by Arthur [3], it is a basic fact that the functor E_ξ is compatible with the geometric structure of $\mathcal{W}_{\Xi_u}$ in the following sense. The same arguments apply in the present situation. Let $\xi = (P, \delta, t)$ and let $P \subset Q$. Let $\mathfrak{R}_\xi^Q$ be the subgroup of elements of $\mathfrak{R}_\xi$ which pointwise fix the T_u^Q-orbit through ξ. Let π^Q denote the induction-intertwining functor of the Hecke algebra $\mathcal{H}^Q = \mathcal{H}(\mathcal{R}^Q, q^Q) \subset \mathcal{H}$, and let E_ξ^Q be the corresponding equivalence. Let Ξ_u^Q denote the space of unitary standard induction data for $\mathcal{H}^Q$. Then $\mathfrak{R}_\xi^Q$ is the R-group at $\xi \in \Xi_u^Q \subset \Xi_u$ for induction to $\mathcal{H}^Q$.

Proposition 6.1 ([3], [23]). *We have the following equality of functors:*

$$\mathrm{Ind}_{\mathcal{H}^Q}^{\mathcal{H}} \circ E_\xi^Q = E_\xi \circ \mathrm{Ind}_{\mathbb{C}[\mathfrak{R}_\xi^Q, \eta]}^{\mathbb{C}[\mathfrak{R}_\xi, \eta]}. \tag{6.1}$$

For any $\mathfrak{r} \in \mathfrak{R}_\xi$ the set of fixed points is of the form $T_u^Q \xi$ for some parabolic subsystem R_Q where Q is not necessarily standard, but *compatible* in the sense that there exists a $w \in \mathcal{W}_\xi$ such that $w(Q)$ is standard and $w(R_{\xi,+}) = R_{w\xi,+}$ (compare with [3, Section 2]). In combination with basic aspects of the structure theory of the (analytic or formal) completion of $\mathcal{H}$ at an algebraic central character (see [39] or [56]) we can draw several conclusions. Let $\mathrm{G}(\mathcal{S}_{\mathcal{W}\xi})$ denote the Grothendieck group of $\mathcal{S}$-modules with tempered central character $\mathcal{W}\xi$ where $\xi = (P, \delta, t)$, and let $\mathrm{G}^{\mathbb{Q}}(\mathcal{S}_{\mathcal{W}\xi}) = \mathbb{Q} \otimes_{\mathbb{Z}} \mathrm{G}(\mathcal{S}_{\mathcal{W}\xi})$ (viewed as virtual tempered characters of $\mathcal{H}$).

Corollary 6.2. *Let $\chi \in \mathrm{G}^{\mathbb{Q}}(\mathcal{S}_{\mathcal{W}\xi})$ where $\xi = (P, \delta, t) \in \Xi_{(P,\delta),u}$, and let $Q \in \mathcal{P}$ be such that $P \subset Q$. The following are equivalent:*

(i) *$\chi = E_\xi(\rho)$ with ρ induced from $\mathbb{C}[\mathfrak{R}_\xi^Q, \eta]$.*

(ii) *$\chi = E_\xi(\rho)$ with ρ supported on the $\mathfrak{R}_\xi$-conjugacy classes meeting $\mathfrak{R}_\xi^Q$.*

(iii) *χ is induced from a virtual tempered character of $\mathcal{H}^Q$.*

(iv) *$\chi = (\chi_t)|_{t=1}$ for a (weakly) smooth family $T_u^Q \ni t \to \chi_t \in \mathrm{G}^{\mathbb{Q}}(\mathcal{S}_{\mathcal{W}(t\xi)})$.*

Proof. It is elementary (using the formula for induced characters in twisted group rings) that (i) $\Leftrightarrow$ (ii) and (i) $\Leftrightarrow$ (iii) follows from (6.1). It is trivial that (iii) $\Rightarrow$ (iv). The step (iv) $\Rightarrow$ (iii) needs explanation. By the (weak) smoothness of the family it enough to prove that χ_t is induced from $\mathcal{H}^Q$ for generic $t \in T_u^Q$. For generic $t \in T_u^Q$ the algebraic central character $z(\chi_t)$ is "R_Q-generic" in the sense of [56, Definition 4.12]. By [56, Corollary 4.15] all characters with an R^Q-generic central character are induced from $\mathcal{H}^Q$. □

Definition 6.3. We say that $\chi \in \mathrm{G}^{\mathbb{Q}}(\mathcal{S}_{\mathcal{W}\xi})$ is *d-smooth and pure* if there exists an open neighborhood $U \subset \Xi_u$ of ξ, a d-dimensional smooth submanifold $S \subset U$ with $\xi \in S$, and a weakly smooth family $S \ni s \to \chi_s \in \mathrm{G}^{\mathbb{Q}}(\mathcal{S}_{\mathcal{W}s})$ (weakly smooth means that $S \ni s \to \chi_s(h)$ is smooth for all $h \in \mathcal{H}$) such that the tempered central character of χ_s equals $\mathcal{W}s$ and $\chi = \chi_\xi$. We say that χ is *d-smooth* if χ is a $\mathbb{Q}$-linear combination of pure d-smooth characters.

We obtain a descending filtration $F^i_{\mathcal{W}\xi} = \mathbb{C} \otimes_{\mathbb{Q}} \{\chi \in \mathrm{G}^{\mathbb{Q}}(\mathcal{S}_{\mathcal{W}\xi}) \mid \chi \text{ is } i\text{-smooth}\}$ of $\mathrm{G}^{\mathbb{C}}(\mathcal{S}_{\mathcal{W}\xi})$. Observe that the filtration is stationary at least until the rank i_Z of the central lattice $Z \subset X$ of $\mathcal{R}$.

Definition 6.4. The vector space $\mathrm{Ell}^{\mathrm{temp}}_{\mathcal{W}\xi}$ of *elliptic tempered characters* of $\mathcal{S} = \mathcal{S}(\mathcal{R}, q)$ with tempered central character $\mathcal{W}\xi$ (with $\xi \in \Xi_u$) is defined as $F^0_{\mathcal{W}\xi}/F^1_{\mathcal{W}\xi}$. We call an irreducible tempered representation (with tempered central character $\mathcal{W}\xi$) elliptic if its character has a nonzero image in $\mathrm{Ell}^{\mathrm{temp}}_{\mathcal{W}\xi}$.

Proposition 6.5. *The complex vector space* $\mathrm{Ell}^{\mathrm{temp}}_{\mathcal{W}\xi}$ *is zero for all but finitely many orbits* $\mathcal{W}\xi \in |\Xi_u|$. *There exist orbits* $\mathcal{W}\xi \in |\Xi_u|$ *such that* $\mathrm{Ell}^{\mathrm{temp}}_{\mathcal{W}\xi} \neq 0$ *only if* $\mathcal{R}$ *is semisimple.*

One can show the following result:

Proposition 6.6. *Let* $F^d(\mathfrak{R}^Q_\xi, \eta)$ *denote the complex vector space of virtual* η*-twisted characters of* $\mathfrak{R}^Q_\xi$ *whose support consists of elements* $\mathfrak{r} \in \mathfrak{R}^Q_\xi$ *whose fixed point set in* $T_{Q,u}$ *has dimension at least* d. *In the case* $Q = F_0$ *this defines a filtration of* $\underline{\mathrm{G}}^{\mathbb{C}}_{\mathcal{W}\xi}(\mathfrak{R}, \eta)$ (*the complex span of irreducible* η*-twisted characters of* $\mathfrak{R}_\xi$). *Put* $I^Q_\xi := \mathrm{Ind}^{\mathbb{C}[\mathfrak{R}_\xi,\eta]}_{\mathbb{C}[\mathfrak{R}^Q_\xi,\eta]}$ *and define* $\mathrm{Ell}(\mathfrak{R}^Q_\xi, \eta) = F^0(\mathfrak{R}^Q_\xi, \eta)/F^1(\mathfrak{R}^Q_\xi, \eta)$. *We have an isomorphism of graded vector spaces*

$$\bigoplus_Q I^Q_\xi : \bigoplus_Q \mathrm{Ell}(\mathfrak{R}^Q_\xi, \eta) \xrightarrow{\sim} \mathrm{gr}(\underline{\mathrm{G}}^{\mathbb{C}}_{\mathcal{W}\xi}(\mathfrak{R}, \eta)) \tag{6.2}$$

where Q *runs over a complete set of representatives of the* $\mathcal{W}$*-association classes of compatible parabolic subgroups, and the degree of* $\mathrm{Ell}(\mathfrak{R}^Q_\xi, \eta)$ *is defined as the depth of* Q. *The functor* E_ξ *induces an isomorphism of graded vector spaces* $\mathrm{gr}(\underline{\mathrm{G}}^{\mathbb{C}}_{\mathcal{W}\xi}(\mathfrak{R}, \eta)) \to \mathrm{gr}(\underline{\mathrm{G}}^{\mathbb{C}}(\mathcal{S}_{\mathcal{W}\xi}))$. *If* $w \in \mathcal{W}_{\xi,\xi}$ *satisfies* $w(Q) = Q$ *then twisting by* w *acts trivially on* $\mathrm{Ell}(\mathfrak{R}^Q_\xi, \eta)$.

7. K-theory of the Schwartz algebra $\mathcal{S}$

In the last two sections we will discuss results and conjectures for the K-theory and noncommutative geometry of affine Hecke algebras and we indicate some of the evidence in support of these conjectures. These conjectures are not new, certainly not their analogues in the context of reductive algebraic groups. The point is however that these conjectures give a detailed guideline for representation theory of affine Hecke algebras with (unequal) continuous positive real parameters. In this sense the discussion below is a natural extension of the harmonic analysis questions that have been studied in this paper.

First of all recall the following result.

Proposition 7.1 (Corollary 5.9, [22]). *The dense* $*$*-subalgebra* $\mathcal{S} \subset \mathfrak{C}$ *is closed for holomorphic functional calculus. Hence the inclusion* $i : \mathcal{S} \to \mathfrak{C}$ *induces an isomorphism* $\mathrm{K}_*(\mathcal{S}) \xrightarrow{\sim} \mathrm{K}_*(\mathfrak{C})$.

7.1. The Chern character for $\mathcal{S}$. The result in this subsection is due to Maarten Solleveld. Proposition 7.1 shows that we can study the K-theory of the reduced C^*-algebra $\mathfrak{C}$ of $\mathcal{H}$ in terms of $\mathcal{S}$. By Theorem 5.6(ii) it follows easily that $\mathcal{S}$ is a Fréchet m-algebra, and for this type of topological algebras Cuntz [20] has shown the

existence of a unique functorial Chern character map $\mathrm{ch}\colon \mathrm{K}_* \to \mathrm{HP}_*$ with values in Connes' periodic cyclic homology HP_* and which is subject to certain natural compatibility properties. In [64] it is shown for a quite general class of Fréchet m-algebras that the Chern character becomes a natural isomorphism after tensoring with $\mathbb{C}$. Theorem 5.6(ii) shows that the Schwartz algebra $\mathcal{S}$ of $\mathcal{H}$ always falls in the class of algebras to which Solleveld's Theorem applies. Thus we have

Theorem 7.2 (Corollary 9, [64]). *The abelian group* $\mathrm{K}_*(\mathcal{S})$ *is finitely generated, and upon tensoring by* $\mathbb{C}$ *the Chern character* $\mathrm{Id}\otimes \mathrm{ch}\colon \mathrm{K}_*^{\mathbb{C}}(\mathcal{S}) \to \mathrm{HP}_*(\mathcal{S})$ *becomes an isomorphism, where we have used the notation* $\mathrm{K}_*^{\mathbb{C}}(\mathcal{S}) := \mathbb{C}\otimes_{\mathbb{Z}} \mathrm{K}_*(\mathcal{S})$.

7.2. Comparison between $\mathcal{S}$ and $\mathcal{H}$. The material this subsection is joint work in progress with Maarten Solleveld.

Conjecture 1 (Conjecture 8.9, [9]). The inclusion homomorphism $i\colon \mathcal{H} \to \mathcal{S}$ induces an isomorphism $\mathrm{HP}_*(\mathcal{H}) \to \mathrm{HP}_*(\mathcal{S})$.

There is quite solid evidence in support of this conjecture. Under certain additional assumptions we in fact have a proof of the statement (in fact, Solleveld has recently announced a general proof (private communication)). This proof is based on the philosophy explained in the important paper [35] and the Langlands classification for general affine Hecke algebras [23].

7.3. Independence of the parameters. Let us introduce the notation $\mathcal{S}(\boldsymbol{q}) := \mathcal{S}(\mathcal{R}, q)$ to stress the dependence on the base $\boldsymbol{q} > 1$ of the function q defined by $q(s) = \boldsymbol{q}^{f_s}$ while keeping the $f_s \in \mathbb{R}$ fixed. (In the terminology of Remark 2.3, we vary q in a half-line.) Let $\mathcal{S}_W = \mathcal{S}(1)$ denote the limiting case, the Schwartz algebra of functions $f\colon W \to \mathbb{C}$ of rapid decay. Observe that the Fréchet space $\mathcal{S}_W$ is isomorphic to $\mathcal{S}(\boldsymbol{q})$ as a Fréchet space via the naive linear isomorphism $f \to \sum_{w\in W} f(w)N_w$.

Solleveld has shown that there exists a family of isomorphisms (unique up to homotopy) $\psi_\varepsilon\colon \mathcal{S}(\boldsymbol{q}) \to \mathcal{S}(\boldsymbol{q}^\varepsilon)$ of pre C^*-algebras depending continuously on $\varepsilon \in (0, 1]$ such that $\psi_1 = \mathrm{id}_{\mathcal{S}}$. Now consider the family of linear isomorphisms $\phi_\varepsilon\colon \mathcal{S}_W \to \mathcal{S}(\boldsymbol{q})$ (with $\varepsilon \in (0, 1]$) consisting of the composition of the naive linear isomorphism $\mathcal{S}_W \to \mathcal{S}(\boldsymbol{q}^\varepsilon)$ with the inverse of ψ_ε. Solleveld has shown that the family ϕ_ε behaves as an asymptotic morphism $\mathcal{S}_W \to \mathcal{S}(\boldsymbol{q})$ as $\varepsilon \downarrow 0$ and defines a homomorphism $\mathrm{K}_*(\phi)\colon \mathrm{K}_*(\mathcal{S}_W) \to \mathrm{K}_*(\mathcal{S}(\boldsymbol{q}))$.

Conjecture 2. The map $\mathrm{K}_*^{\mathbb{Q}}(\phi)$ is an isomorphism.

This conjecture is the natural extension of [8, Conjecture 6.21] in the present context (after throwing away torsion), and in this sense it is entirely in the spirit of the Baum–Connes–Kasparov conjecture for p-adic reductive groups. In our situation (working with general continuous, unequal Hecke algebra parameters) it would be a very powerful principle for understanding the geometry of the irreducible spectrum

and the tempered irreducible spectrum of affine Hecke algebras, especially in combination with certain geometric refinements to be described below (see Conjectures 2b and 2c).

Let us first consider a weaker statement and the evidence in support of it:

Conjecture 2a (weaker version). $\dim(\mathrm{K}_*^{\mathbb{Q}}(\mathcal{S}(\boldsymbol{q}))) = \dim(\mathrm{K}_*^{\mathbb{Q}}(\mathcal{S}_W))$.

By Solleveld's Theorem 7.2 this statement is equivalent to $\dim(\mathrm{HP}_*(\mathcal{S}(\boldsymbol{q}))) = \dim(\mathrm{HP}_*(\mathcal{S}_W))$, and thus in cases where Conjecture 1 is known (certainly including the split case $f_s = 1, \forall s \in S^{\mathrm{aff}}$) it is equivalent to $\dim(\mathrm{HP}_*(\mathcal{H}(\boldsymbol{q}))) = \dim(\mathrm{HP}_*(\mathbb{C}[W]))$. In the split case this is a theorem of Baum and Nistor [10]. The proof in [10] is very interesting and is based on Lusztig's asymptotic morphism in combination with techniques from [35]. For unequal label Hecke algebras one may connect this with Lusztig's conjectures from [43], see [4].

7.4. Equivariant K-theory. The conjecture 2 can be expressed more geometrically in terms of equivariant K-theory using well known results (see [7], [10], [67]). First of all $\mathcal{S}_W = C^\infty(T_u) \rtimes W_0$, and this gives the identification $\mathrm{K}_*(\mathcal{S}_W) = \mathrm{K}_{W_0}^*(T_u)$. Recall that for any finite group G acting on a compact topological space X the equivariant Chern character defines an isomorphism $\mathrm{Id} \otimes \mathrm{ch}_{\mathrm{G}} : \mathbb{C} \otimes_{\mathbb{Z}} \mathrm{K}_G^*(X) \xrightarrow{\sim} \mathrm{H}^{[*]}(G\backslash\hat{X}, \mathbb{C})$ where $\hat{X} = \cup_{g\in G}(g, X^g)$ is the disjoint union of the fixed point spaces X^g of the elements of G, and where $\mathrm{H}^{[*]}$ denotes the $\mathbb{Z}/2\mathbb{Z}$-periodic Čech cohomology groups (see [7]). The topological space $G\backslash\hat{X}$ is called the extended quotient of X. It is the orbit space of the inertia orbifold $\Lambda(G_X) := G_{\hat{X}}$ of the translation orbifold $G_X = X \rtimes G$. In this geometric form the conjecture gives rise to a natural refinement of the conjecture for $\mathrm{K}_0(\mathcal{S})$ which is the main reason for this reformulation.

Definition 7.3. Given $\xi \in \mathcal{W}\backslash\Xi_u$ we have a quotient homomorphism $\pi_\xi : \mathcal{S} \to \mathcal{S}/m_\xi\mathcal{S}$ where m_ξ denotes the maximal ideal of $\mathcal{Z}_\mathcal{S}$ at ξ (the ring $\mathcal{S}/m_\xi\mathcal{S}$ is finite dimensional and semisimple by Theorem 5.6). For $\alpha \in \mathrm{K}_0(\mathcal{S})$ we define $\mathrm{Supp}(\alpha) = \{\mathcal{W}\xi \in \mathcal{W}\backslash\Xi_u \mid \mathrm{K}_0(\pi_\xi)(\alpha) \neq 0\}$ (a closed set in $\mathcal{W}\backslash\Xi_u$, as one checks easily).

Conjecture 2b (geometric refinement). There exists a natural isomorphism (take $\mathrm{K}_*^{\mathbb{C}}(\phi)$ composed with the inverse of the equivariant Chern character for the action of W_0 on T_u):

$$\kappa : \mathrm{H}^{[*]}(W_0\backslash\widehat{T_u}, \mathbb{C}) \xrightarrow{\sim} \mathrm{K}_*^{\mathbb{C}}(\mathcal{S}(\boldsymbol{q})). \tag{7.1}$$

The ascending filtration $F_i(\mathrm{K}_0^{\mathbb{C}}(\mathcal{S}(\boldsymbol{q}))) = \{\alpha \mid \dim(\mathrm{Supp}(\alpha)) \leq i\}$ of $\mathrm{K}_0^{\mathbb{C}}(\mathcal{S}(\boldsymbol{q}))$ coincides via this isomorphism with the filtration of the left hand side whose i-th filtered piece consist of the sum of the even cohomologies of the components of the extended quotient $W_0\backslash\widehat{T_u}$ of dimension at most i.

This form of the conjecture guides us to a further reduction to the discrete part $F_0(\mathrm{K}_0^{\mathbb{C}}(\mathcal{S}(\boldsymbol{q})))$ of the vector space $\mathrm{K}_0^{\mathbb{C}}(\mathcal{S}(\boldsymbol{q}))$. This is best understood in the context of a conjecture concerning index theory.

8. Index functions

The material in this section was shaped in its present form in the course of various conversations with Mark Reeder and Joseph Bernstein. I am much indebted for their insightful comments. The ideas in this section have their origin in the theory of the Selberg trace formula. We want to construct "index functions" using the Euler–Poincaré principle in K-theory (see e.g. [37], [59], [21]).

We assume throughout in this section that the root datum $\mathcal{R}$ is semisimple unless stated otherwise. Every finite dimensional tempered module π gives rise to a $\mathbb{Z}$-valued "local index" function Ind_π on $\mathrm{K}_0(\mathcal{S})$. Namely $\pi\colon \mathcal{S} \to \mathrm{End}_{\mathbb{C}}(V_\pi)$ is a continuous algebra homomorphism, and given $\alpha = [p] \in \mathrm{K}_0(\mathcal{S})$ (with $p \in M_N(\mathcal{S})$ an idempotent) we define $\mathrm{Ind}_\pi(\alpha) = \mathrm{rank}(\pi(p)) \in \mathbb{Z}$. This naturally descends to bilinear pairing $[\,\cdot\,,\cdot\,]\colon \mathrm{K}_0(\mathcal{S}) \times \mathrm{G}(\mathcal{S}) \to \mathbb{Z}$ given by $[\alpha, [\pi]] := \mathrm{Ind}_{[\pi]}(\alpha)$. Moreover, by the structure theory of $\mathcal{S}$ (Theorem 5.6), it is clear that if the local index function $[\pi] \to \mathrm{Ind}_{[\pi]}(\alpha)$ vanishes identically on $\mathrm{G}(\mathcal{S})$ then $\alpha = 0$.

Now suppose that $\alpha \in F_0(\mathrm{K}_0^{\mathbb{C}}(\mathcal{S}))$. By definition of the support of α and of our notion of smooth families this means that $\mathrm{Ind}_{[\pi]}(\alpha) = 0$ for all π which are 1-smooth (it must be constant along the family on the one hand, but on the other hand its support must be finite). Therefore $\pi \to \mathrm{Ind}_{[\pi]}(\alpha)$ factors through a function on $\mathrm{Ell}^{\mathrm{temp}}$, and $[\,\cdot\,,\cdot\,]$ factors through a bilinear pairing $[\,\cdot\,,\cdot\,]$ on $F_0(\mathrm{K}_0^{\mathbb{C}}(\mathcal{S})) \times \mathrm{Ell}^{\mathrm{temp}}$ which is non-degenerate on the left.

Next we consider the change of base ring homomorphism $\beta\colon \mathrm{K}_0(\mathcal{H}) \to \mathrm{K}_0(\mathcal{S})$ defined by $[P] \to [S \otimes_{\mathcal{H}} P]$ if P denotes a finitely generated projective $\mathcal{H}$-module. One would like to complement this base change homomorphism β with a base change homomorphism $\beta\colon \mathrm{K}(\mathrm{Mod}_{fg}(\mathcal{H})) \to \mathrm{K}(\mathrm{Mod}(\mathcal{S}))$ but there seems no obvious way to do this. First of all $\mathcal{S}$ is *not* flat over $\mathcal{H}$ (this problem already occurs in rank 1) and it is also not quite clear which category of $\mathcal{S}$-modules one should consider. The conjecture we are about to make precisely states that this can anyway be done if one restricts in some sense to the tempered modules of finite length. To this end we will first show that the projective dimension of $\mathcal{H}$-modules of finite length is bounded by the rank [3] (which is a joint result with Mark Reeder). Let (π, V) be an $\mathcal{H}$-module of finite length. Let $C \subset \mathfrak{a}^* = \mathbb{R} \otimes_{\mathbb{Z}} X$ be the fundamental alcove for the action of $W^a = W_0 \ltimes Q \lhd W$ (the normal subgroup generated by reflections in W). Let $\Omega \subset W$ be the finite abelian subgroup of elements of length 0, then $W = W^a \rtimes \Omega$. We denote by $\mathcal{H}^a \subset \mathcal{H}$ the unital subalgebra of $\mathcal{H}$ spanned by the elements $\{N_w\}_{w \in W^a}$, then $\mathcal{H} = \mathcal{H}^a \rtimes \Omega$ (a crossed product).

Given a nonempty facet $\emptyset \neq f \subset C$ of C we have the corresponding subset $S_f \subset S^{\mathrm{aff}}$ of affine simple reflections fixing f. Let $\mathcal{H}_f \subset \mathcal{H}^a$ be the finite type Hecke subalgebra $\mathcal{H}_f = \mathcal{H}(S_f, q_{S_f})$. For any subset $I \subset S^{\mathrm{aff}}$ we denote by $\mathbb{C}^I$ the

[3] One can deduce from this the fact that the category of $\mathcal{H}$-modules is of finite cohomological dimension, as was explained to me by Joseph Bernstein. One should compare this to Bernstein's result that the category of smooth representations of a reductive p-adic group has finite cohomological dimension, see [65, Prop. 37].

complex vector space which has as a basis the set I. Put

$$\tilde{C}_i(V) = \bigoplus_{f:\dim(f)=i} \mathcal{H} \otimes_{\mathcal{H}_f} (V|_{\mathcal{H}_f}) \otimes_{\mathbb{C}} \bigwedge^{n-i} \mathbb{C}^{S_f}. \tag{8.1}$$

Since $\mathcal{H}_f \subset \mathcal{H}$ is a finite dimensional semisimple subalgebra this is clearly a projective, finitely generated $\mathcal{H}$-module. We define $\mathcal{H}$-linear maps $\tilde{d}_i : \tilde{C}_i \to \tilde{C}_{i-1}$ by

$$\tilde{d}_i(h \otimes_{\mathcal{H}_f} v \otimes \lambda) := \bigoplus_{\substack{f' \subset f \\ \dim(f')=i-1}} h \otimes_{\mathcal{H}_{f'}} v \otimes (\lambda \wedge s_{f,f'}) \tag{8.2}$$

where $s_{f,f'} \in S^{\mathrm{aff}}$ is defined by $S_{f'} = S_f \cup \{s_{f,f'}\}$. Observe that there is a natural left Ω-action on $\tilde{C}_i(V)$ by means of $\mathcal{H}$-intertwining operators via

$$j_\omega(h \otimes_{\mathcal{H}_f} v \otimes \lambda) = h\omega^{-1} \otimes_{\mathcal{H}_{\omega(f)}} \pi(\omega)v \otimes \omega(\lambda). \tag{8.3}$$

This action commutes with the action of the operators $\tilde{d}_i$. Finally, we define $C_i(V) = (\tilde{C}_i(V))^{j(\Omega)}$ and we denote by d_i the restriction of $\tilde{d}_i$ to $C_i(V)$.

Proposition 8.1 (E. Opdam and M. Reeder, unpublished). *Let (V, π) be an $\mathcal{H}$-module of finite length. The graded $\mathcal{H}$-linear operator $d = \{d_i\}$ is a differential on $C_*(V)$, making $C_*(V)$ into a bounded complex of finitely generated projective $\mathcal{H}$-modules. The $\mathcal{H}$-linear map $d_0 : C_0(V) \to C_{-1}(V) \simeq V$ extends this to a finite projective resolution $0 \leftarrow V \xleftarrow{d_0} C_*(V)$ of V.*

The proof of this proposition reduces simply to the case $\mathcal{H} = \mathcal{H}^a$, and there the proof is a variation of Kato's proof [33] of a statement about a similar "restriction-induction" complex for finite type Hecke algebras.

Definition 8.2. By the previous result all $\mathcal{H}$-modules of finite length have finite projective dimension. Hence there is a well defined Euler–Poincaré homomorphism $\varepsilon : \mathrm{G}(\mathcal{H}) \to \mathrm{K}_0(\mathcal{H})$. It has an explicit realization $\varepsilon([V]) := \sum_i (-1)^i [C_i(V)]$.

Let $\rho : \mathrm{G}(\mathcal{S}) \to \mathrm{G}(\mathcal{H})$ be the homomorphism which corresponds to the forgetful functor (forgetting temperedness). We have now altogether constructed a homomorphism $\gamma = \beta \circ \varepsilon \circ \rho : \mathrm{G}(\mathcal{S}) \to \mathrm{K}_0(\mathcal{S})$. We extend this to an *anti-linear* map $\gamma : \mathrm{G}^{\mathbb{C}}(\mathcal{S}) \to \mathrm{K}_0^{\mathbb{C}}(\mathcal{S})$. It is not difficult to show that this map vanishes on modules induced from a proper parabolic subalgebra (e.g. by using the Koszul resolution for a regular sequence of parameters for the smooth family of induced representations). Thus we obtain an anti-linear map

$$\gamma : \mathrm{Ell}^{\mathrm{temp}} \to F_0(\mathrm{K}_0^{\mathbb{C}}(\mathcal{S})). \tag{8.4}$$

Using γ the previously defined bilinear pairing $[\,\cdot\,,\cdot\,]$ on $F_0(\mathrm{K}_0^{\mathbb{C}}(\mathcal{S})) \times \mathrm{Ell}^{\mathrm{temp}}$ gives rise to a sesquilinear form $\langle U, V\rangle_{\mathrm{ell}} := [\gamma(U), V]$ on $\mathrm{Ell}^{\mathrm{temp}}$. This is the

precise analog of the elliptic pairing of tempered characters as defined by Schneider and Stuhler [59]: suppose that U and V are finite dimensional tempered modules of $\mathcal{H}$, then

$$\langle U, V\rangle_{\mathrm{ell}} = [\gamma(U), V] = \sum_{i\geq 0}(-1)^i \dim \mathrm{Ext}^i_{\mathcal{H}}(U, V). \tag{8.5}$$

In this context we remark that the natural map $\mathrm{Ell}^{\mathrm{temp}} \to \mathrm{Ell}^{\mathrm{alg}}$ (the elliptic virtual representations of $\mathcal{H}$) is a linear isomorphism [23], by the Langlands parametrization [23] for affine Hecke algebras.

By the Euler–Poincaré principle applied to our standard resolution we can also express this explicitly (following [59], [58]) in terms of an "index function" for U. Let $\Omega_f \subset \Omega$ be the stabilizer of f in Ω, and let ε_f be the character of Ω_f on $\mathbb{C}^{S_f}$. We define the index function $f_U \in \mathcal{H}$ by

$$f_U = \sum_f (-1)^{\dim(f)} \sum_{\sigma \in \mathrm{Irr}(\mathcal{H}_f \rtimes \Omega_f)} \dim(\sigma)^{-1} [U|_{(\mathcal{H}_f \rtimes \Omega_f)} \otimes \varepsilon_f : \sigma] e_\sigma \in \mathcal{H} \tag{8.6}$$

where f runs over a complete set of representatives of the Ω-orbits of faces of C, and where $e_\sigma \in \mathcal{H}_f \rtimes \Omega_f$ denotes the central idempotent corresponding to σ in the finite dimensional complex semisimple algebra $\mathcal{H}_f \rtimes \Omega_f$. Then

$$\langle U, V\rangle_{\mathrm{ell}} = \chi_V(f_U) \tag{8.7}$$

By (8.5) it is clear that this pairing is Hermitian, and that (virtual) tempered representations U and V with distinct tempered central characters are orthogonal. Moreover, the pairing is integral with respect to the lattice generated by the elliptic (true) characters.

Conjecture 3. The pairing $\langle U, V\rangle_{\mathrm{ell}}$ on $\mathrm{Ell}^{\mathrm{temp}}_{W_\xi}$ corresponds, via the functor E_ξ of Theorem 5.13, with the elliptic paring on $\mathrm{Ell}(\mathfrak{R}_\xi, \eta)$ given by

$$\langle \phi, \chi\rangle_{\mathrm{ell}} = |\mathfrak{R}_\xi|^{-1} \sum_{\mathfrak{r}\in\mathfrak{R}_\xi} |\det(1-\mathfrak{r})| \overline{\phi(\mathfrak{r})} \chi(\mathfrak{r}) \tag{8.8}$$

(see [3] and [58]). In particular, this pairing is positive definite (since the support of the function $\det(1-\mathfrak{r})$ is exactly equal to the set of elliptic conjugacy classes of $\mathfrak{R}_\xi$).

This conjecture is the natural analog of results of Arthur in the theory of the local trace formula [3]. In the split case with $X = P$ it was shown by Mark Reeder [58] using the Kazhdan–Lusztig parameterization and a comparison between geometric and analytic R-groups. The formula (8.6) for the index functions f_U is due to Mark Reeder [57], based on work of Schneider and Stuhler [59]. Recently a related and very general result was obtained by R. Meyer [48] for Schwartz algebra's of reductive p-adic groups. In order to explain this, first observe that Theorem 5.6 implies that a discrete series representation (U, δ) of $\mathcal{S}$ is a projective $\mathcal{S}$-module. Therefore it

defines a class $[U]_{\mathcal{S}} \in K_0(\mathcal{S})$. On the other hand we have defined the class $\gamma([U]) \in K_0(\mathcal{S})$ above. In our context Meyer's result would mean that $[U]_{\mathcal{S}} = \gamma([U])$, and in particular that all higher extensions $\mathrm{Ext}^i_{\mathcal{H}}(U, V)$ $(i > 0)$ vanish if V is tempered (this is remarkable since $\mathcal{S}$ is not flat over $\mathcal{H}$). Meyer's Theorem actually implies the validity of this statement for all affine Hecke algebras which arise in connection with a reductive p-adic group G via the theory of types of equivalence classes of G-inertial cuspidal data (of course, we conjecture that it holds for general $\mathcal{H}$). This proves that in those cases Conjecture 3 holds for the discrete series representations of $\mathcal{H}$, thus providing strong evidence in support of this conjecture.

Corollary 8.3 (L^2-index for discrete series representations of $\mathcal{H}$). *We have the following explicit Euler–Poincaré formula for the formal dimension of a discrete series representation (U, δ) of $\mathcal{H}$, expressed in terms of its "K-types":*

$$\begin{aligned}\mu_{\mathrm{Pl}}(\{\delta(q)\}) &= \tau(f_U(q)) \\ &= \sum_f (-1)^{\dim(f)} \sum_{\sigma \in \mathrm{Irr}(\mathcal{H}_f \rtimes \Omega_f)} [U|_{(\mathcal{H}_f \rtimes \Omega_f)} \otimes \varepsilon_f : \sigma] d_\sigma(q) \end{aligned} \tag{8.9}$$

where f runs over a complete set of representatives of the Ω-orbits of faces of C, and where $d_\sigma(q)$ denotes the formal dimension of σ in the finite dimensional Hilbert algebra $\mathcal{H}_f \rtimes \Omega_f$ whose trace is the restriction of the trace τ of $\mathcal{H}$ (these are rational functions in the parameters $q_s^{1/2}$, $q_s^{-1/2}$ with rational coefficients).

Please compare this statement with the product formula (4.4) for the formal dimensions. Observe that the rationality of the constant d_δ in (4.4) is an immediate consequence. The Euler–Poincaré formula for f_U (as obtained by Schneider and Stuhler [59]) was used by Reeder [57] for the computation of all formal dimensions of the square integrable unipotent representations of Chevalley groups of exceptional type. The main computational work in [57] consists in the reduction of the Euler–Poincaré alternating sum to the product formula.

A second consequence of Conjecture 3 is:

Corollary 8.4. *The map $\gamma\colon \mathrm{Ell}^{\mathrm{temp}} \to F_0(\mathrm{K}_0^{\mathbb{C}}(\mathcal{S}))$ is an anti-linear isomorphism.*

Let us write $\mathrm{Ell}^{\mathrm{temp}}(q)$ in order to stress the dependence on q. Observe that $\mathrm{Ell}^{\mathrm{temp}}(q)$ is a semisimple $\mathcal{Z}$-module via the algebraic central character z map. The combination of Corollary 8.4 with Conjecture 2b implies that the dimension of the finite dimensional space (see Proposition 6.5) $\mathrm{Ell}^{\mathrm{temp}}(q)$ is independent of $q \in \mathcal{Q}$. We conjecture a stronger statement:

Conjecture 2c. The $\mathcal{Q}$-family of finite dimensional semisimple $\mathcal{Z}$-modules $q \to \mathrm{Ell}^{\mathrm{temp}}(q)$ is continuous (i.e. isomorphic to a direct sum of one-dimensional $\mathcal{Z}$-modules, each depending continuously on q).

Let us denote by $j\colon |\Xi_u| \to W_0\backslash T_u$ the map that sends $\mathcal{W}\xi$ (with $\xi = (P, \delta, t)$) to $W_0(|r|^{-1}rt)$ where $z_P(\delta) = W_P r$ is the central character of δ. Let $q = 1$ and let

$t \in T_u = \Xi_u(1)$. Then $\mathfrak{R}_t$ is the isotropy group $W_{0,t}$ of t in W_0. Using Proposition 6.6, Conjecture 2c implies an isomorphism of sheaves

$$j_*(\underline{\mathrm{G}}(\mathfrak{R}, \eta)) \simeq \underline{\mathrm{G}}(W_0) \tag{8.10}$$

on $W_0 \backslash T_u$, where the sheaf on the right hand side is the usual complex representation ring sheaf for the action of W_0 on T_u.

8.1. Discussion and examples. We discuss the implications of Conjecture 2c for the problem of understanding the tempered spectrum of non-simply laced affine Hecke algebras. The results in this section are joint with Maarten Solleveld. In these cases, Proposition 4.7, Theorem 4.9 and Conjecture 2c suggest to use deformations to generic points $q \in \mathcal{Q}$ in order to approach this problem.

Let us consider the three parameter case $\mathcal{R} = (\mathbb{Z}^n, B_n, \mathbb{Z}^n, C_n, F_0)$ with $F_0 = \{e_1 - e_2, \ldots, e_{n-1} - e_n, e_n\}$ (thus $Q(B_n) = \mathbb{Z}^n$; we refer to this case as "type C_n^{aff}") with parameters $q_0 = q(s_0)$, $q_1 = q(s_{e_i})$, $q_2 = q(s_{e_i - e_{i+1}})$. The case $n = 1$ will be considered as a special case (but with two parameters q_0, q_1); the discussion below applies to this degenerate case without modifications). The set of distinct W_0-orbits of generic residual points is easily seen to be parametrized (using [56, Appendix A]) by ordered pairs (μ, ν) of partitions of total weight n. The orbit of the unitary part of (μ, ν) only depends on $i := |\mu| \in \{0, 1, \ldots, n\}$. Let $W_0 s_i$ denote this orbit. The orbits $W_0 s_i \in W_0 \backslash T_u$ are mutually distinct, and the stabilizer group of s_i is isomorphic to the Weyl group of type $B_i \times B_{n-i}$.

We see that for each i the cardinality of the set of orbits of generic residual points whose corresponding orbit of unitary parts equals $W_0 s_i$ is precisely equal to the number of elliptic conjugacy classes of the stabilizer group $W(B_i) \times W(B_{n-i})$ of s_i, which is the R-group $\mathfrak{R}_{s_i}$ for $\mathcal{S}_W = \mathcal{S}(1)$. By Theorem 4.9 each orbit $W_0 r$ of residual points carries *at least one* discrete series representation of $\mathcal{H}$. We call $q \in \mathcal{Q}$ *generic* if $q \in \cap \mathcal{Q}_r$ (intersection over all $r \in \mathrm{Res}$) and if for all $r, r' \in \mathrm{Res}$: $W_0 r(q) = W_0 r'(q) \Rightarrow W_0 r = W_0 r'$. By Conjecture 2c and the above description of the set of orbits of generic residual points we conclude that for a generic parameter q each residual orbit $W_0 r(q)$ must carry *precisely one* discrete series representation. So for generic $q \in \mathcal{Q}$ the discrete series characters are separated by their algebraic central character. Moreover, the complex linear span of these discrete series characters is isomorphic to the space $\mathrm{Ell}^{\mathrm{temp}}(q)$.

By the continuity aspect of Conjecture 2c we are now in principle able to understand the spaces $\mathrm{Ell}^{\mathrm{temp}}(q_0)$ for an *arbitrary* parameter $q_0 \in \mathcal{Q}$ by deformation to the generic case. The central support of the discrete series representations of $\mathcal{H}(q_0)$ is given by Theorem 4.9. For a given orbit of residual points $W_0 r$ for $\mathcal{H}(q_0)$ the set of discrete series representations which it carries is, in view of the above, parametrized by the set of orbits of generic residual points $\mathcal{W}_0 r(q)$ such that $W_0 r(q_0) = W_0 r$. This determines the set $\Delta_{F_0}(q_0)$, with complete information about the action of $\mathcal{Z}$. We can repeat this for any standard parabolic subset P, since the associated affine Hecke

algebra $\mathcal{H}_P$ is a tensor product of at most one factor of type C_m^{aff} (with $m \leq n$) (which we can handle as above) and factors of type $A_{\lambda_j - 1}$ (with lattice $X_j = P(A_{\lambda_j - 1})$, the corresponding weight lattice) such that $\sum \lambda_j = n - m$. The group K_P is a product of cyclic groups C_{λ_j} of order λ_j. We also get complete information on the action of $\mathcal{W}$ on Δ : $\mathcal{W}$ is generated by permutations of the type A-factors, by twisting with $-w$ if w is the longest element in the Weyl group of one of the type A-factors, and by twisting of one of the type A factors A_{k-1} by the corresponding cyclic group C_k. Observe that the action of $\mathcal{W}$ only affects the type A-factors of $\mathcal{H}_P$.

From this information we can reconstruct $\mathcal{W}_{\Xi_u}$, and we can verify directly that the cocycle η_Δ (and thus η itself) *is in fact always trivial*. Using Theorem 4.19 we can in principle compute the R-groups (this was actually carried out by Klaas Slooten [63] in the case of real central characters for all $q_0 \in \mathcal{Q}$). By Theorem 5.13 this gives essentially complete information about the structure of the tempered dual $\hat{\mathcal{S}}$.

If $q \in \cap \mathcal{Q}_r$ (intersection over all $r \in \text{Res}$) it is not hard to show that the R-groups are all trivial. This implies that $\mathcal{S}(q)$, in view of Theorem 5.13 and Theorem 5.11, is Morita equivalent to the algebra of $\mathcal{W}$-invariant C^∞-functions on $\Xi_u(q)$. We see that the components of $|\Xi_u(q)|$ are parametrized by the set of ordered triples of partitions (λ, μ, ν) of total weight n. If $\lambda = (1^{m_1}, 2^{m_2}, \ldots, k^{m_k})$ then the component corresponding to (λ, μ, ν) is the product of the quotients $W_0(B_{m_i})\backslash(S^1)^{m_i}$ $(i = 1, \ldots, k)$, and thus homeomorphic to $[0, 1]^{|\lambda|}$. Hence $\mathrm{K}_1(\mathcal{S}(q)) = 0$, and $\mathrm{K}_0(\mathcal{S}(q))$ is the free abelian group generated by the above set of components.

Let us compare this result with the other extreme case $q = 1$. Now $\mathcal{S}(1) = \mathcal{S}_W \simeq C^\infty(T_u) \rtimes W_0$ and thus $\mathrm{K}_*(\mathcal{S}(1)) \simeq \mathrm{K}^*_{W_0}(T_u)$. Application of the equivariant Chern character [7] to this last group yields an isomorphism (after killing torsion) with the periodized cohomology of the extended quotient $W_0\backslash\widehat{T_u}$ of T_u with respect to the action of $W_0 = W(B_n)$. The extended quotient $W_0\backslash\widehat{T_u}$ can be computed directly in this case. It turns out that this space is actually homeomorphic to the orbit space $|\Xi_u(q)|$ which we have just computed in the case where $q \in \cap \mathcal{Q}_r$. This is in complete accordance with Conjecture 2b (but of course, we already used the "discrete part" of this conjecture in order to conclude that each generic residual orbit carries precisely one discrete series representation).

Conjecture 2c gives in this example complete information on the classification problem of the irreducible tempered representations, but not on the internal structure of these representations. In the case of type C_n^{aff} Klaas Slooten [62] defined (for real central character) a "generalized Springer correspondence" in terms of certain symbols (in the sense of Malle [45]) and conjectured that the restriction of these tempered representations to $\mathcal{H}(W_0)$ is precisely given by the generalized Green functions [40], [60] attached to these symbols. These conjectures were verified for $n = 3, 4$.

Continuous representation theory of p-adic Lie groups

Peter Schneider

Abstract. In this paper we give an overview over the basic features of the continuous representation theory of p-adic Lie groups as it has emerged during the last five years. The main motivation for developing such a theory is a possible extension of the local Langlands program to p-adic Galois representations. This is still very much in its infancy. But in the last section we will describe a first approximation to an extended Langlands functoriality principle for crystalline Galois representations.

Mathematics Subject Classification (2000). Primary 11S37, 22E50; Secondary 11F70.

Keywords. Lie groups, representation theory, Langlands functoriality.

1. Motivation

Throughout the paper we fix a finite extension $L/\mathbb{Q}_p$ and let q denote the cardinality of its residue field. One object of major interest is the absolute Galois group $\mathcal{G}_L := \mathrm{Gal}(\bar{L}/L)$ where $\bar{L}/L$ is an algebraic closure. One obtains a first very coarse idea of its structure by looking at the tower of fields $L \subseteq L^{\mathrm{nr}} \subseteq L^{\mathrm{tr}} \subseteq \bar{L}$ where L^{nr}, resp. L^{tr}, denotes the maximal unramified, resp. tamely ramified, extension of L. Correspondingly we have the subgroups

$$\mathcal{P}_L := \mathrm{Gal}(\bar{L}/L^{\mathrm{tr}}) \subseteq \mathcal{I}_L := \mathrm{Gal}(\bar{L}/L^{\mathrm{nr}}) \subseteq \mathcal{G}_L.$$

All the complication of $\mathcal{G}_L$ is contained in the pro-p-group $\mathcal{P}_L$. The quotient $\mathcal{I}_L/\mathcal{P}_L$ is pro-cyclic of a pro-order prime to p. The quotient $\mathcal{G}_L/\mathcal{I}_L$ even has the natural Frobenius generator ϕ which makes $\mathcal{G}_L/\mathcal{I}_L$ naturally isomorphic to $\hat{\mathbb{Z}}$. In particular, this allows to introduce the Weil group

$$\mathcal{W}_L := \{g \in \mathcal{G}_L : g \equiv \phi^{\alpha(g)} \mathrm{mod}\ \mathcal{I}_L \text{ for some } \alpha(g) \in \mathbb{Z}\};$$

it is topologized by declaring the inertia subgroup $\mathcal{I}_L$ to be open.

Throughout the paper K will denote the coefficient field of whatever kind of representation we like to consider. It always will have characteristic zero and, most of the time, will carry a topology. This introductory section is about representations of the Weil group $\mathcal{W}_L$ by which we mean a continuous homomorphism

$$\rho\colon \mathcal{W}_L \longrightarrow \mathrm{GL}(E)$$

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

where E is a finite dimensional K-vector space. In the case that K is an abstract field, i.e., that $\mathrm{GL}(E)$ carries the discrete topology, we will speak of a smooth representation. Of course, then $\rho(\mathcal{I}_L)$ is a finite group. Even if we take $K = \mathbb{C}$ to be the field of complex numbers with its natural topology we still have, since $\mathcal{I}_L$ is totally disconnected, that $\rho(\mathcal{I}_L)$ is a finite group.

The setting becomes richer if we choose a prime number ℓ different from p and take for $K = \overline{\mathbb{Q}}_\ell$ an algebraic closure of $\mathbb{Q}_\ell$ with its ℓ-adic topology. Then $\mathrm{GL}(E)$ contains an open subgroup which is pro-ℓ. This means that only the image $\rho(\mathcal{P}_L)$ is finite. Nevertheless this setting still can be made "smooth" in the following way. By abuse of language we mean by a Weil–Deligne group representation a pair (ρ', N) consisting of a smooth representation $\rho' \colon \mathcal{W}_L \longrightarrow \mathrm{GL}(E)$ in a finite dimensional K-vector space E and a (nilpotent) endomorphism $N \colon E \longrightarrow E$ such that

$$g \circ N \circ g^{-1} = q^{\alpha(g)} \cdot N \quad \text{for any } g \in \mathcal{W}_L.$$

The point is that by deriving the action (via ρ) on E of the group $\mathcal{I}_L / \ker(\rho)$ one obtains an endomorphism N of E and that dividing ρ through the exponential of N in an appropriate way results in a smooth representation ρ'. In fact, by Grothendieck's abstract monodromy theorem, this construction sets up a natural bijection

$$\begin{array}{l}\text{isomorphism classes of continuous}\\ \text{representations } \rho \colon \mathcal{W}_L \to \mathrm{GL}(E)\end{array} \quad \longleftrightarrow \quad \begin{array}{l}\text{isomorphism classes of Weil–Deligne}\\ \text{group representations } (\rho', N).\end{array}$$

For a more detailed description we refer to [28]. The representation ρ is called Frobenius semisimple if the lifts in $\mathcal{W}_L$ of the Frobenius ϕ act semisimply on E. For the corresponding Weil–Deligne group representation (ρ', N) this amounts to the semisimplicity of the smooth representation ρ'.

In order to state the local Langlands correspondence we let G be the group of L-rational points of some connected reductive group over L. It naturally is a locally compact and totally disconnected group. Similarly as before a representation of G in a K-vector space V (but which here usually will be infinite dimensional) is called smooth if the corresponding map $G \times V \to V$ is continuous with respect to the discrete topology on V. The local Langlands correspondence asserts ([15], [16]) the existence of a distinguished bijection

$$\begin{array}{l}\text{isomorphism classes of } n\text{-dimensional}\\ \text{Frobenius semisimple continuous}\\ \text{representations } \rho \colon \mathcal{W}_L \longrightarrow \mathrm{GL}(E)\end{array} \quad \longleftrightarrow \quad \begin{array}{l}\text{isomorphism classes of irreducible}\\ \text{smooth representation of } \mathrm{GL}_n(L)\end{array}$$

for any $n \geq 1$ (and where the coefficient field still is $K = \overline{\mathbb{Q}}_\ell$). In fact, there is a much more general but conjectural local Langlands functoriality principle. The Langlands dual group ${}^L G$ of G is a semidirect product

$${}^L G = {}^L G^\circ \rtimes \mathcal{G}_L$$

where ${}^L G^\circ$ is the group of K-rational points of the connected reductive group over K whose root datum is dual to the root datum of G (over $\bar{L}$). The functoriality principle asserts that the set $\Pi(G)$ of isomorphism classes of irreducible smooth representations of G has a distinguished partitioning into finite subsets $\Pi_{\rho'}$ which are indexed by equivalence classes of certain Weil–Deligne group representations ρ' with values in ${}^L G$.

There is a particularly simple special case of this functoriality principle which is the unramified correspondence. An irreducible smooth representation of G is called unramified if it has a nonzero vector fixed by a good maximal compact subgroup. Suppose for simplicity that G is L-split. The Satake isomorphism for the Hecke algebra of this maximal compact subgroup produces from an unramified representation of G an orbit of unramified characters of a maximal split torus T in G and hence an orbit of points in ${}^L T^\circ(K)$ where ${}^L T^\circ \subseteq {}^L G^\circ$ is the dual torus. This means one has a natural bijection

$$\begin{array}{l}\text{isomorphism classes of unramified irreducible smooth representations of } G\end{array} \quad \longleftrightarrow \quad \begin{array}{l}\text{semisimple conjugacy classes in } {}^L G^\circ.\end{array}$$

Moreover the semisimple conjugacy class of an $s \in {}^L G^\circ$ corresponds to the equivalence class of the unramified Weil–Deligne group representation $\mathcal{W}_L \longrightarrow \mathcal{W}_L / \mathcal{I}_L \longrightarrow {}^L G^\circ$ which sends the Frobenius ϕ to s. For more details about the functoriality conjecture we refer to [3].

In this paper we are interested in the case $K = \overline{\mathbb{Q}}_p$. Then there is no obvious restriction on the image $\rho(\mathcal{P}_L)$ any more. This means that the p-adic representation theory of $\mathcal{W}_L$ is drastically more complicated than the previous ℓ-adic one. There is a natural functor, constructed by Fontaine ([13]), which associates with any continuous representation $\rho\colon \mathcal{W}_L \longrightarrow \mathrm{GL}(E)$ a Weil–Deligne group representation $Fon(\rho)$ in a free $\hat{\mathbb{Q}}_p^{\mathrm{nr}} \otimes_{\mathbb{Q}_p} K$-module of finite rank; here $\hat{\mathbb{Q}}_p^{\mathrm{nr}}$ denotes the completion of $\mathbb{Q}_p^{\mathrm{nr}}$. It should be viewed as a replacement for the monodromy theorem in the ℓ-adic case. But its construction is much more involved. Moreover, for most ρ one in fact has $Fon(\rho) = 0$. The rich theory of p-adic Galois representations which has evolved during the last twenty years therefore is largely restricted to the so called potentially semistable ones, i.e., to those for which ρ and $Fon(\rho)$ have the same rank. The author nevertheless is very much convinced that there is an extension of the Langlands functoriality principle which takes into account all p-adic representations of $\mathcal{W}_L$. Of course, it should be compatible with the traditional functoriality conjecture via the functor *Fon*.

Since the category of p-adic representations of $\mathcal{W}_L$ is so much richer and more complicated than the category of ℓ-adic representations it is clear that the author's conviction only has a chance if also on the side of the reductive group G we will be able to introduce a much richer but still reasonable category of representations of G than the category of smooth representations. The purpose of this paper is to report on such a construction which was developed in joint work with J. Teitelbaum. At the

end we will come back to Galois representations and will briefly discuss a possible extension of the unramified correspondence.

2. Banach space representations

From now on we always assume K to be a finite extension of $\mathbb{Q}_p$ and we let o denote the ring of integers in K. At first we let G be an arbitrary locally compact and totally disconnected group. Smoothness for a linear G-action on a K-vector space means continuity with respect to the discrete topology on the vector space. It therefore is a rather obvious idea to enrich the picture by considering continuous linear G-actions on some class of topological K-vector spaces.

A reasonable framework for topological K-vector spaces is provided by the notion of a locally convex topology. Such topologies on a K-vector space are defined by a family of nonarchimedean seminorms (cf. [21], §4). The open convex neighborhoods of the zero vector in a locally convex K-vector space are lattices, i.e. o-submodules which generate the vector space.

The most straightforward class of locally convex K-vector spaces is the class of K-Banach spaces. A K-Banach space is complete and its topology can be defined by a single nonarchimedean norm. A K-Banach space representation of G is a linear G-action on a K-Banach space V such that the corresponding map $G \times V \to V$ is continuous. Unfortunately this definition is much too general in order to lead to a reasonable category. We mention only two pathological phenomena:

- There can exist nonzero G-equivariant continuous linear maps between two nonisomorphic topologically irreducible Banach space representations.

- Already such a simple group as the additive group of p-adic integers $G = \mathbb{Z}_p$ has infinite dimensional topologically irreducible Banach space representations ([8]).

The challenge is to impose an additional "finiteness" condition leading to a category of representations which at the same time is rich enough and still is manageable.

To prepare the subsequent definition taken from [23] we point out the following. Let V be any K-Banach space representation of G. Given any compact open subgroup $H \subseteq G$ and any open lattice $M \subseteq V$ the o-submodule $\cap_{g \in H} gM$ is an H-invariant open lattice in V. We also recall that an o-module N is called of cofinite type if its Pontrjagin dual $\mathrm{Hom}_o(N, K/o)$ is a finitely generated o-module.

Definition 2.1. A K-Banach space representation V of G is called admissible if for any compact open subgroup $H \subseteq G$, for any bounded H-invariant open lattice $M \subseteq V$, and for any open subgroup $H' \subseteq H$ the o-submodule $(V/M)^{H'}$ of H'-invariant elements in the quotient V/M is of cofinite type.

We let $\mathrm{Ban}^a_G(K)$ denote the category of all admissible K-Banach space representations of G with continuous linear G-equivariant maps.

A first justification for this definition might be the following observation. We recall that a smooth representation of G is called admissible if the subspace of H'-fixed vectors, for any compact open subgroup $H' \subseteq G$, is finite dimensional. Let V be a K-Banach space representation of G, let $H \subseteq G$ be a compact open subgroup, and let $M \subseteq V$ be a bounded H-invariant open lattice. Then $M/\pi M$, where π is a prime element in o, evidently is a smooth representation of H over the residue field of K. If V is admissible then $M/\pi M$ is an admissible smooth representation of H.

In which sense is this category $\mathrm{Ban}^a_G(K)$ manageable? In order to answer this question we have to assume that G is a locally $\mathbb{Q}_p$-analytic group, i.e., a p-adic Lie group. Moreover, since the definition of admissibility is in terms of compact open subgroups it suffices to discuss this issue for compact groups. In the following we therefore let H be a compact p-adic Lie group. The completed group ring of H is defined to be

$$o[[H]] := \varprojlim o[H/H']$$

where H' runs over all open normal subgroups of H. This is a compact linear-topological o-algebra. The H-action on any K-Banach space representation extends uniquely to a separately continuous $o[[H]]$-module structure. We have the following crucial fact due to Lazard ([18], V.2.2.4).

Theorem 2.2. *For any compact p-adic Lie group H the ring $o[[H]]$ is noetherian.*

To understand how we will explore this fact let us look at the vector space $C(H, K)$ of all K-valued continuous functions on H. This is a K-Banach space representation of H for the sup-norm and the left translation action of H. But it is difficult to say anything straightforward about the corresponding $o[[H]]$-module $C(H, K)$. Instead, let us pass to the continuous dual

$$D^c(H, K) := C(H, K)'.$$

First of all $D^c(H, K)$ is a K-algebra with respect to the convolution product of continuous linear forms – the algebra of continuous distributions on H. Secondly, sending an element $g \in H$ to the Dirac distribution $\delta_g \in D^c(H, K)$ extends to an embedding of o-algebras

$$o[[H]] \hookrightarrow D^c(H, K)$$

whose image is a lattice so that, in fact, $K \otimes_o o[[H]] \cong D^c(H, K)$. Thirdly, via the latter isomorphism, the $K \otimes_o o[[H]]$-module structure on $C(H, K)'$ induced by functoriality from the $o[[H]]$-module structure on $C(H, K)$ simply corresponds to the action of $D^c(H, K)$ on itself by multiplication. Quite generally, the continuous dual V' of a K-Banach space representation V of H, by functoriality, is a module over the K-algebra $D^c(H, K)$. The main result (Thm. 3.5) of [23] now is the following.

Theorem 2.3. *Let* $\mathrm{Mod}_{fg}(D^c(H,K))$ *denote the category of finitely generated* $D^c(H,K)$*-modules. The functor*

$$\begin{aligned}\mathrm{Ban}^a_H(K) &\xrightarrow{\sim} \mathrm{Mod}_{fg}(D^c(H,K)),\\ V &\longmapsto V'\end{aligned}$$

is an anti-equivalence of categories.

By Theorem 2.2 the ring $D^c(H,K)$ is noetherian. Hence with $\mathrm{Mod}_{fg}(D^c(H,K))$ also $\mathrm{Ban}^a_G(K)$ is an abelian category. We mention that the underlying vector space of the kernel, image, and cokernel of a morphism in $\mathrm{Ban}^a_G(K)$ is the kernel, image, and cokernel, respectively, of the underlying linear map. We also emphasize that the above result completely algebraizes the theory of admissible K-Banach space representations.

As evidence for the category $\mathrm{Ban}^a_G(K)$ being rich enough we will discuss the continuous principal series of the group G of L-rational points of a connected reductive group over L. Let $P \subseteq G$ be a parabolic subgroup and $\chi : P \to K^\times$ be a continuous character. We put

$${}^c\mathrm{Ind}_P^G(\chi) := \{f : G \to K \text{ continuous: } f(gb) = \chi(b)^{-1} f(g) \text{ for } g \in G,\ b \in P\}$$

on which G acts by left translations. If $G_0 \subseteq G$ is a good maximal compact subgroup then we have the Iwasawa decomposition $G = G_0 P$. Hence taking the supremum over G_0 defines a norm on ${}^c\mathrm{Ind}_P^G(\chi)$. A different choice of G_0 leads to an equivalent norm.

Proposition 2.4. ${}^c\mathrm{Ind}_P^G(\chi)$ *is an admissible* K*-Banach space representation of the reductive group* G*.*

Proof. We only indicate the argument for the admissibility. Restricting functions to G_0 defines a topological embedding ${}^c\mathrm{Ind}_P^G(\chi) \to C(G_0, K)$. Dually this exhibits the continuous dual ${}^c\mathrm{Ind}_P^G(\chi)'$ as a quotient of $D^c(G_0, K)$. □

It seems likely that the representation ${}^c\mathrm{Ind}_P^G(\chi)$ always has a finite composition series. We want to state a precise irreducibility conjecture. To avoid technicalities we assume that $L \subseteq K$, that G is L-split, semisimple, and simply connected, and that P is a Borel subgroup. Let $T \subseteq P$ be a maximal L-split torus. Then χ can be viewed as a continuous character $\chi : T \to K^\times$. Let $X^*(T)$ resp. $X_*(T)$, denote as usual the group of rational characters, resp. cocharacters, of T. In $X^*(T)$ we have the subsets $\Delta \subseteq \Phi^+$ of simple and of positive roots with respect to P, respectively. For any $\alpha \in \Phi^+$ there is the corresponding coroot $\check{\alpha} \in X_*(T)$. By our assumption on G any fundamental weight ω_α, for $\alpha \in \Delta$, and hence their sum $\delta := \sum_{\alpha\in\Delta} \omega_\alpha$ lie in $X^*(T)$. The character $\chi : T \to K^\times$ is called anti-dominant if $\chi\delta \circ \check{\alpha} \neq (\ )^m$ for any integer $m \geq 1$ and any $\alpha \in \Phi^+$. Here $(\ )^m : L^\times \to K^\times$, for any $m \in \mathbb{Z}$, is the continuous character sending a to a^m.

Conjecture 2.5. The G-representation ${}^c\mathrm{Ind}_P^G(\chi)$ is topologically irreducible if χ^{-1} is anti-dominant.

Proposition 2.6. *Suppose that $L = \mathbb{Q}_p$. We then have:*

i. *The above conjecture holds true for the group $G = \mathrm{GL}_2(\mathbb{Q}_p)$.*

ii. *If the anti-dominance condition for χ^{-1} continues to hold after restriction to an arbitrary small open subgroup of $\mathbb{Q}_p^\times$ then the continuous dual ${}^c\mathrm{Ind}_P^G(\chi)'$ is simple as a $D^c(G_0, K)$-module and ${}^c\mathrm{Ind}_P^G(\chi)$, in particular, is topologically irreducible as a G_0-representation.*

The proof of this result is highly indirect. It requires corresponding facts for the locally analytic principal series (see Section 3) and the density of analytic vectors in admissible Banach space representations (see Section 4).

Breuil has introduced the notion of a unitary Banach space representation of G which means that the Banach space topology can be defined by a G-invariant norm. In recent work Berger and Breuil ([2]) and Colmez ([5]) construct, by very sophisticated methods, a series of topologically irreducible, admissible, and unitary Banach space representations of the group $\mathrm{GL}_2(\mathbb{Q}_p)$. In fact, they put this series into correspondence with certain two dimensional Galois representations of $\mathcal{G}_{\mathbb{Q}_p}$ called trianguline by Colmez.

We also point out that in a unitary Banach space representation V of G we find a G-invariant open lattice $M \subseteq V$. If V is admissible then $M/\pi M$, with $\pi \in o$ a prime element, is an admissible smooth representation of G over the residue field of K. As to be expected, the theory described in this section therefore is closely related to the smooth representation theory of p-adic groups with characteristic p coefficients (cf. [29]).

3. Locally analytic representation

Many continuous representations of p-adic Lie groups in locally convex K-vector spaces which naturally arise in geometric situations are not Banach space representations. One basic example is the following. Let $G = \mathrm{GL}_2(L)$ and let $\mathcal{X}_L := \mathbb{P}^1(\bar{L})\backslash\mathbb{P}^1(L)$ be the p-adic upper half plane over L. The rigid analytic variety $\mathcal{X}_L$ carries an obvious G-action. The vector space $\Omega^1(\mathcal{X}_L)$ of global holomorphic 1-forms on $\mathcal{X}_L$ is an L-Fréchet space with a natural continuous G-action. By a theorem of Morita ([19]) its continuous dual is isomorphic to the quotient $C^{\mathrm{an}}(\mathbb{P}^1(L), L)/L$ of the vector space $C^{\mathrm{an}}(\mathbb{P}^1(L), L)$ of L-valued locally L-analytic functions on the projective line $\mathbb{P}^1(L)$ by the subspace of constant functions. Clearly, $C^{\mathrm{an}}(\mathbb{P}^1(L), L)$ is not a Banach space. In fact, its natural locally convex topology is rather complicated. But in return it has good properties like being reflexive.

This observation leads to the concept of a locally analytic representation of a locally L-analytic group G. For the rest of the paper we assume that $L \subseteq K$. We first

remark that for any paracompact locally L-analytic manifold X and any Hausdorff locally convex K-vector space V the K-vector space $C^{\mathrm{an}}(X, V)$ of V-valued locally analytic functions on X is well defined. It carries a natural Hausdorff locally convex topology for whose rather technical construction we refer to [12].

Definition 3.1. A locally analytic representation V of G (over K) is a barrelled locally convex Hausdorff K-vector space V equipped with a G-action by continuous linear endomorphisms such that, for each $v \in V$, the map $g \mapsto gv$ lies in $C^{\mathrm{an}}(G, V)$.

The requirement that V is barrelled (i.e., that each closed lattice in V is open) is a convenient (and mild) technical restriction which makes applicable the Banach–Steinhaus theorem ([21], Prop. 6.15). It implies that the map $G \times V \to V$ describing the G-action is continuous and that the Lie algebra $\mathfrak{g}$ of G acts continuously on V by

$$\begin{aligned} \mathfrak{g} \times V &\longrightarrow V, \\ (\mathfrak{x}, v) &\longmapsto \mathfrak{x}v := \frac{d}{dt} \exp(t\mathfrak{x}) v_{|t=0}. \end{aligned}$$

The next step is, as in the previous section, to pass from the G-action to a module structure. The strong dual

$$D(G, K) := C^{\mathrm{an}}(G, K)'_b$$

is called the locally convex vector space of K-valued locally analytic distributions on G.

Proposition 3.2. i. *The convolution on $D(G, K)$ is well defined, is separately continuous, and makes $D(G, K)$ into an associative K-algebra with the Dirac distribution δ_1 in $1 \in G$ as the unit element.*

ii. *The map*

$$\begin{aligned} \mathfrak{g} &\longrightarrow D(G, K), \\ \mathfrak{x} &\longmapsto [f \mapsto ((-\mathfrak{x})f)(1)] \end{aligned}$$

extends to a monomorphism of K-algebras $U(\mathfrak{g}) \otimes_L K \longrightarrow D(G, K)$ where $U(\mathfrak{g})$ denotes the universal enveloping algebra of $\mathfrak{g}$.

iii. *The G-action on any locally analytic representation V of G extends uniquely to a separately continuous action of the algebra $D(G, K)$ on V.*

Proof. i. [11], 4.4.1 and 4.4.4, or [26], Remark A.1. ii. [24], p. 450. iii. [24], Prop. 3.2. □

It is important to notice ([24], Lemma 2.1) that for a compact group G the locally convex topology on $C^{\mathrm{an}}(G, K)$ is of compact type ([24], §1, and [21], §16). In particular, $D(G, K)$ then is a Fréchet algebra. Locally convex topologies of compact type are rather complicated but have the remarkable property that they can be characterized by their strong dual being nuclear and Fréchet. This leads to the following result ([24], Cor. 3.4).

Proposition 3.3. *If G is compact then the functor*

$$\begin{array}{ll} \textit{locally analytic representations of } G & \textit{continuous } D(G,K)\textit{-modules on} \\ \textit{on } K\textit{-vector spaces of compact type} & \xrightarrow{\sim} \quad \textit{nuclear Fréchet spaces with} \\ \textit{with continuous linear } G\textit{-maps} & \textit{continuous } D(G,K)\textit{-module maps} \end{array}$$

which sends V to its strong dual V_b' is an anti-equivalence of categories.

This last result means that in the context of locally analytic representations we now have singled out the correct type of locally convex topology to which we should restrict our attention. But we are still lacking the equivalent of the algebraic finiteness condition which we have imposed in the last section. The situation is considerably complicated by the fact that even for compact G the algebra $D(G, K)$ is far from being noetherian. As a remedy for this we develop in [25], §3, the following axiomatic framework.

Suppose that A is a K-Fréchet algebra. For any continuous algebra seminorm q on A the completion A_q of A with respect to q is a K-Banach algebra. For any two such seminorms $q' \leq q$ the identity on A extends to a continuous K-algebra homomorphism $\phi_q^{q'} : A_q \to A_{q'}$.

Definition 3.4. A K-Fréchet algebra A is called a Fréchet–Stein algebra if there is a sequence $q_1 \leq \cdots \leq q_n \leq \cdots$ of continuous algebra seminorms on A which define the Fréchet topology and such that

(i) A_{q_n} is (left) noetherian, and

(ii) A_{q_n} is flat as a right $A_{q_{n+1}}$-module (via $\phi_{q_{n+1}}^{q_n}$)

for any $n \in \mathbb{N}$.

Suppose that A is a Fréchet–Stein algebra as in the above definition. We have the obvious isomorphism of Fréchet algebras

$$A \xrightarrow{\cong} \varprojlim_n A_{q_n}.$$

Definition 3.5. A (left) A-module N is called coadmissible if

(i) $A_{q_n} \otimes_A N$ is finitely generated over A_{q_n} for any $n \in \mathbb{N}$, and

(ii) the natural map $N \xrightarrow{\cong} \varprojlim_n (A_{q_n} \otimes_A N)$ is an isomorphism.

We let $\mathcal{C}_A$ denote the full subcategory of all coadmissible modules in the category $\mathrm{Mod}(A)$ of all left A-modules. By a cofinality argument it is independent of the particular choice of the sequence of seminorms q_n.

Proposition 3.6. *$\mathcal{C}_A$ is an abelian subcategory of* $\mathrm{Mod}(A)$ *containing all finitely presented A-modules.*

Over a noetherian Banach algebra every finitely generated module carries a unique Banach space topology which makes the module structure continuous. Using its representation as a projective limit in Definition 3.5 (ii) we therefore see that any coadmissible A-module carries a distinguished Fréchet topology which will be called its canonical topology.

In [25], Thm. 5.1, we give the following justification for introducing these definitions.

Theorem 3.7. *For any compact locally L-analytic group G the Fréchet algebra $D(G, K)$ is a K-Fréchet–Stein algebra.*

If $G_{\mathbb{Q}_p}$ denotes the locally $\mathbb{Q}_p$-analytic group which underlies G then one has a natural continuous surjection

$$D(G_{\mathbb{Q}_p}, K) \longrightarrow D(G, K).$$

By a general argument with Fréchet–Stein algebras ([25], Prop. 3.7) this allows to reduce the proof of the theorem to the case $L = \mathbb{Q}_p$. Furthermore it is easy to see that it suffices to prove the theorem for a conveniently chosen open normal subgroup of G. To avoid technicalities we assume in the following that $p \neq 2$. Let ω_p denote the additive p-adic valuation on $\mathbb{Z}_p$. Lazard in [18], III.2.1.2, has introduced the notion of a p-valuation on a group H which is a real valued function $\omega\colon H\backslash\{1\} \longrightarrow (1/(p-1), \infty)$ such that

$$\omega(gh^{-1}) \geq \min(\omega(g), \omega(h)),$$
$$\omega(g^{-1}h^{-1}gh) \geq \omega(g) + \omega(h),$$

and

$$\omega(g^p) = \omega(g) + 1.$$

Our proof of the above theorem very much relies on the techniques and results in [18]. First of all we may assume, by the above reductions and [9], Cor. 8.34 (ii), that G is a compact p-adic Lie group which has an (ordered) set of topological generators $h_1, \ldots, h_d$ such that:

(i) The map

$$\mathbb{Z}_p^d \xrightarrow{\sim} G,$$
$$(x_1, \ldots, x_d) \longmapsto h_1^{x_1} \ldots h_d^{x_d}$$

is a global chart of the manifold G.

(ii) The function

$$\omega(h_1^{x_1} \ldots h_d^{x_d}) := \min_{1 \leq i \leq d} (1 + \omega_p(x_i))$$

is a p-valuation on G.

(iii) Every $g \in G$ such that $\omega(g) \geq 2$ is a p-th power in G.

We define $b_i := \delta_{h_i} - 1$ and, for any multi-index $\alpha = (\alpha_1, \ldots, \alpha_d) \in \mathbb{N}_0^d$,

$$\boldsymbol{b}^\alpha := b_1^{\alpha_1} \ldots b_d^{\alpha_d} \in D(G, K)$$

(which does depend on the ordering of the generators h_i!). Using the global chart in (i) we may identify $D(G, K)$ as a Fréchet space with $D(\mathbb{Z}_p^d, K)$. The latter, by Amice's p-adic Fourier isomorphism ([1]), is naturally isomorphic to the ring of power series with coefficients in K converging on the open unit polydisk. It follows that any distribution $\lambda \in D(G, K)$ has a unique convergent expansion

$$\lambda = \sum_{\alpha \in \mathbb{N}_0^d} d_\alpha \boldsymbol{b}^\alpha$$

where the set $\{|d_\alpha| r^{\alpha_1 + \cdots + \alpha_d}\}_{\alpha \in \mathbb{N}_0^d}$, for any $0 < r < 1$, is bounded. Moreover, the family of norms

$$\|\lambda\|_r := \sup_{\alpha \in \mathbb{N}_0^d} |d_\alpha| r^{\alpha_1 + \cdots + \alpha_d}$$

defines the Fréchet topology on $D(G, K)$. Lazard in [18] investigates the norm $\| \ \|_{\frac{1}{p}}$.

Lemma 3.8. *For each $\frac{1}{p} \leq r < 1$ the norm $\| \ \|_r$ is submultiplicative.*

The completion $D_r(G, K)$ of $D(G, K)$ with respect to the norm $\| \ \|_r$ for $\frac{1}{p} \leq r < 1$, is a K-Banach algebra and

$$D(G, K) = \varprojlim_{\frac{1}{p} \leq r < 1} D_r(G, K).$$

Proposition 3.9. *For $\frac{1}{p} < r' \leq r < 1$ in $p^{\mathbb{Q}}$ we have:*

i. *$D_r(G, K)$ is noetherian with multiplicative norm $\| \ \|_r$.*

ii. *The homomorphism $D_r(G, K) \longrightarrow D_{r'}(G, K)$ is flat.*

This is proved in [25], following the model for $\| \ \|_{\frac{1}{p}}$ in [18], by explicitly computing the associated graded ring for the filtration on $D_r(G, K)$ defined by the norm $\| \ \|_r$. Philosophically this technique means to view the noncommutative ring $D_r(G, K)$ as a deformation quantization of the commutative ring $D_r(\mathbb{Z}_p^d, K)$ which allows to transfer many ring theoretic properties from the latter to the former.

For later purposes we mention the following important additional result in [14], §1.4, Cor. 2.

Theorem 3.10 (Frommer). *Suppose that G is as above and that $\frac{1}{p} < r < 1$ in $p^{\mathbb{Q}}$. Then $D_r(G, K)$ is finitely generated free as a module over the closure of the universal enveloping algebra $U(\mathfrak{g}) \otimes_L K$.*

By [17], Thm. 1.4.2, this result continues to hold for $L \neq \mathbb{Q}_p$ but the precise conditions on the compact locally L-analytic group G are a little too technical to be formulated here. Having Theorem 3.7 at our disposal we now make the following definition where G again is a general locally L-analytic group.

Definition 3.11. A locally analytic representation of G on a K-vector space of compact type V is called admissible if its strong dual V_b' as a $D(H, K)$-module, for some (or equivalently any) compact open subgroup $H \subseteq G$, is coadmissible with its canonical topology.

Using Proposition 3.6 we obtain the following facts about the category $\mathrm{Rep}_G^a(K)$ of all admissible locally analytic representations of G ([25], Prop. 6.4).

Proposition 3.12. i. $\mathrm{Rep}_G^a(K)$ *is an abelian category; kernel and image of a morphism in* $\mathrm{Rep}_G^a(K)$ *are the algebraic kernel and image with the subspace topology.*

ii. *Any morphism in* $\mathrm{Rep}_G^a(K)$ *is strict and has closed image.*

iii. *The category* $\mathrm{Rep}_G^a(K)$ *is closed with respect to the passage to closed G-invariant subspaces.*

A first evidence that this category $\mathrm{Rep}_G^a(K)$ is not too small is provided by the following result ([25], Thm. 6.6). Let $\mathrm{Rep}_G^{\infty,a}(K)$ denote the abelian category of admissible smooth representations of G in K-vector spaces as recalled in Section 2.

Theorem 3.13. *The functor* $\mathrm{Rep}_G^{\infty,a}(K) \longrightarrow \mathrm{Rep}_G^a(K)$ *of equipping an admissible smooth representation with the finest locally convex topology is a fully faithful embedding; its image is characterized by the condition that the Lie algebra* $\mathfrak{g}$ *acts trivially* (*i.e.,* $\mathfrak{g}V = 0$).

This says that the representation theory appearing in the Langlands functoriality conjecture is fully contained in the new admissible locally analytic theory. It is rather obvious that in case G is an algebraic group also every rational representation of G is admissible locally analytic. Similarly as in the previous section there is a locally analytic principal series for any connected reductive group G over L. Let $P \subseteq G$ be a parabolic subgroup and $\chi : P \longrightarrow K^\times$ be a locally L-analytic character. Then

$$\mathrm{Ind}_P^G(\chi) := \{f : G \to K \text{ locally analytic: } f(gb) = \chi(b)^{-1} f(g) \text{ for } g \in G,\ b \in P\}$$

with G acting by left translations is an admissible locally analytic representation of G. This is proved quite similarly as in the Banach space case. Again we expect that $\mathrm{Ind}_P^G(\chi)$ always has a finite composition series. But there are important differences. For example, if χ is locally constant then the smooth induction ${}^\infty\mathrm{Ind}_P^G(\chi)$ is a proper closed subspace of $\mathrm{Ind}_P^G(\chi)$ but is dense in ${}^c\mathrm{Ind}_P^G(\chi)$. At the moment the deepest result about the locally analytic principal series is the following. If $\mathfrak{p}$ denotes the Lie algebra of P then we have the derived character $d\chi : \mathfrak{p} \longrightarrow K$ and we may form the Verma module $\mathcal{V}_{d\chi} := U(\mathfrak{g}) \otimes_{U(\mathfrak{p})} K_{d\chi}$ of $U(\mathfrak{g}) \otimes_L K$.

Theorem 3.14 (Frommer). *Suppose that $L = \mathbb{Q}_p$ and that G is $\mathbb{Q}_p$-split; if $\mathcal{V}_{-d\chi}$ is a simple module for $U(\mathfrak{g}) \otimes_L K$ then $\mathrm{Ind}_P^G(\chi)$ is topologically irreducible as a representation of G*

It is his Theorem 3.10 which allows Frommer to make this close connection to Verma modules. In view of Kohlhaase's generalization of Theorem 3.10 it seems very likely that Theorem 3.14 holds for any L-split group G where L is arbitrary. Without recalling the details we mention that the simplicity of Verma modules is decided by anti-dominance properties of the inducing character. In [22], §4, we determine, in the case of the group $G = \mathrm{SL}_2(\mathbb{Q}_p)$, a complete composition series for the reducible locally analytic principal series; its length is two or three.

We want to briefly mention three further results in the locally analytic theory. Extending Harish Chandra's computation of the center of $U(\mathfrak{g})$ Kohlhaase determines in [17] the center of $D(G, K)$. His result is particularly simple to formulate in the following case ([17], Thms. 2.1.6 and 2.4.2).

Theorem 3.15 (Kohlhaase). *Suppose that G is an L-split connected reductive group with maximal L-split torus T and corresponding Weyl group W. There is a canonical isomorphism*

$$\text{center of } D(G, K) \cong D(T, K)_Z^W$$

where the right hand side denotes the subalgebra of $D(T, K)$ consisting of all W-invariant distributions supported on the center Z of G. Furthermore, if in addition $Z = \{1\}$ then $D(T, K)_Z^W$ is isomorphic to the ring of entire functions on the rigid analytic affine space over K of dimension equal to the rank of T.

A very basic construction in representation theory is the construction of the contragredient representation. But in the present context the strong dual V_b' of a K-vector space of compact type V is a Fréchet space and hence rarely is again of compact type. The naive method to define the contragredient representation therefore does not work in the locally analytic theory. Perhaps this is not too surprising since we already have used up, so to speak, the strong dual to define the notion of admissibility. In [26] we construct in case $L = \mathbb{Q}_p$, as a replacement for the contragredient, a natural auto-antiequivalence of a certain derived category of $\mathrm{Rep}_G^a(K)$. This is based on the fact that the rings $D_r(G, K)$, for a p-valued Lie group G as discussed above, are Auslander regular, hence that the category $\mathcal{C}_G$ in an appropriate sense is Auslander regular, and it then uses the derived functor of the functor $\mathrm{Hom}_{D(G,K)}(\,.\,, D(G, K))$ on $\mathcal{C}_G$. The restriction to the case $L = \mathbb{Q}_p$ will be removed in the forthcoming thesis of T. Schmidt.

As exemplified by the various principal series, a very important method to construct representations is, in the case of a reductive group G, the induction from the Levi quotient of a parabolic subgroup. In the smooth theory this functor, called parabolic induction, has an adjoint functor in the opposite direction, called parabolic restriction or Jacquet functor. In [10] Emerton constructs by rather sophisticated techniques a

generalization of the Jacquet functor to locally analytic representations. Although no longer adjoint to parabolic induction it is doubtlessly an important construction which must be investigated further.

4. Analytic vectors

In order to describe the connection between Banach space and locally analytic representations we let V be a K-Banach space representation of the locally L-analytic group G.

Definition 4.1. A vector $v \in V$ is called analytic if the (continuous) map $\rho_v(g) := g^{-1}v$ lies in $C^{\mathrm{an}}(G, V)$.

Obviously $V_{\mathrm{an}} := \{v \in V : v \text{ is analytic}\}$ is a G-invariant subspace of V. But we always equip V_{an} with the subspace topology with respect to the G-equivariant embedding

$$\begin{aligned} V_{\mathrm{an}} &\longrightarrow C^{\mathrm{an}}(G, V), \\ v &\longmapsto \rho_v. \end{aligned}$$

One checks that V_{an} is closed in $C^{\mathrm{an}}(G, V)$. Of course, in this generality the subspace V_{an} might very well be zero. But in [25], Thm. 7.1, the following is shown.

Theorem 4.2. *Suppose that $L = \mathbb{Q}_p$; if V is admissible then V_{an} is dense in V and is an admissible locally analytic representation of G; moreover the functor*

$$\begin{aligned} \mathrm{Ban}^a_G(K) &\longrightarrow \mathrm{Rep}^a_G(K), \\ V &\longmapsto V_{\mathrm{an}} \end{aligned}$$

is exact.

The key reason for this result is the following purely algebraic fact ([25], Thm. 5.2).

Theorem 4.3. *Suppose that $L = \mathbb{Q}_p$ and that G is compact; then the natural ring homomorphism*

$$D^c(G, K) \longrightarrow D(G, K)$$

is faithfully flat.

In the case of the principal series for a locally L-analytic character χ we, of course, have

$${}^c\mathrm{Ind}_P^G(\chi)_{\mathrm{an}} = \mathrm{Ind}_P^G(\chi).$$

It is a remarkable fact that ${}^c\mathrm{Ind}_P^G(\chi)$ and $\mathrm{Ind}_P^G(\chi)$ can have different length. In particular, the former can be topologically irreducible and the latter not.

5. Unramified p-adic functoriality

For the simplicity of the presentation we assume in this section that the base field is $L = \mathbb{Q}_p$. As before $K/\mathbb{Q}_p$ is a finite extension of which we assume that it contains a square root $p^{1/2}$ of p. The group G is assumed to be $\mathbb{Q}_p$-split. We let $T \subseteq G$ be a maximal split torus and we fix a maximal compact subgroup $U \subseteq G$ which is special for T. The Satake–Hecke algebra $\mathcal{H}(G, 1_U)$ is the convolution algebra of K-valued U-bi-invariant compactly supported functions on G. By the Satake isomorphism this algebra is commutative and its characters ζ into $\overline{K}$ are in natural bijection with the semisimple conjugacy classes $s(\zeta)$ in ${}^L G^\circ(\overline{K})$. Representation theoretically the Satake–Hecke algebra can be described as the algebra of endomorphisms of the smooth G-representation $\mathrm{ind}_U^G(1_U)$ over K obtained by compact induction from the trivial representation 1_U of U. Any character ζ of $\mathcal{H}(G, 1_U)$ therefore gives rise, by specialization, to the smooth G-representation

$$\mathrm{ind}_U^G(1_U) \underset{\mathcal{H}(G,1_U)}{\otimes} \overline{K}_\zeta$$

which has a unique irreducible quotient V_ζ. The correspondence $V_\zeta \longleftrightarrow s(\zeta)$ is the unramified (smooth) Langlands functoriality we have alluded to already in the first section. We also repeat that $s(\zeta)$ should be viewed as the Weil–Deligne group representation $\mathcal{W}_{\mathbb{Q}_p} \to \mathcal{W}_{\mathbb{Q}_p}/\mathcal{I}_{\mathbb{Q}_p} \to {}^L G^\circ(\overline{K})$ which sends the Frobenius ϕ to $s(\zeta)$ (and with $N = 0$).

We now broaden the picture by bringing in an irreducible $\mathbb{Q}_p$-rational representation σ of G of highest weight $\xi \in X^*(T)$. The corresponding Satake–Hecke algebra $\mathcal{H}(G, \sigma_U)$ is the convolution algebra over K of all compactly supported functions $\psi : G \to \mathrm{End}_K(\sigma)$ satisfying

$$\psi(u_1 g u_2) = \sigma(u_1) \circ \psi(g) \circ \sigma(u_2) \quad \text{for any } u_1, u_2 \in U \text{ and } g \in G.$$

Again the algebra $\mathcal{H}(G, \sigma_U)$ can naturally be identified with the algebra of endomorphisms of the compact induction $\mathrm{ind}_U^G(\sigma_U)$ of the restriction $\sigma_U := \sigma|U$. In fact, since σ is a representation of the full group G the algebras $\mathcal{H}(G, \sigma_U)$ and $\mathcal{H}(G, 1_U)$ are isomorphic. But fixing once and for all a U-invariant norm $\| \ \|$ on the K-vector space which underlies σ we may equip $\mathcal{H}(G, \sigma_U)$ with the sup-norm

$$\|\psi\|_\xi := \sup_{g \in G} \|\psi(g)\|$$

where on the right hand side $\| \ \|$ refers to the operator norm on $\mathrm{End}_K(\sigma)$. Since $\| \ \|_\xi$ obviously is submultiplicative the algebra $\mathcal{H}(G, \sigma_U)$ gives rise, by completion with respect to $\| \ \|_\xi$, to a K-Banach algebra $\mathcal{B}(G, \sigma_U)$. Clearly, $\mathcal{B}(G, \sigma_U)$ is very far from being isometrically isomorphic to $\mathcal{B}(G, 1_U)$. Correspondingly we have a sup-norm on $\mathrm{ind}_U^G(\sigma_U)$ which by completion leads to a unitary Banach space representation $B_U^G(\sigma_U)$ of G.

Lemma 5.1. *$\mathcal{B}(G, \sigma_U)$ is isometrically isomorphic to the algebra of continuous G-equivariant endomorphisms of the Banach space $B_U^G(\sigma_U)$.*

Proof. [27], Lemma 1.3. □

As the completion of a commutative algebra $\mathcal{B}(G, \sigma_U)$ of course is commutative as well. For any K-valued (continuous) character ζ of $\mathcal{B}(G, \sigma_U)$ we obtain, by specialization, the unitary Banach space representation

$$B_{\xi,\zeta} := B_U^G(\sigma_U) \hat{\otimes}_{\mathcal{B}(G,\sigma_U)} K_\zeta$$

of G (where $\hat{\otimes}$ denotes the completed tensor product). Unfortunately the following conjecture seems to be a very difficult problem.

Conjecture 5.2. $B_{\xi,\zeta}$ always is nonzero.

On the other hand it is not to be expected that the Banach space representations $B_{\xi,\zeta}$ are admissible in general. One of the main results in [27] is the explicit computation of the Banach algebra $\mathcal{B}(G, \sigma_U)$. For this we let $\omega_p \colon K^\times \to \mathbb{R}$ denote the unique additive valuation such that $\omega_p(p) = 1$ and we introduce the map

$$\mathrm{val} : {}^L T^\circ(K) = \mathrm{Hom}(T/U \cap T, K^\times) \xrightarrow{\omega_{p^\circ}} \mathrm{Hom}(T/U \cap T, \mathbb{R}) =: V_{\mathbb{R}}.$$

We note that via the isomorphism

$$\begin{aligned} X^*(T) \otimes \mathbb{R} &\xrightarrow{\cong} V_{\mathbb{R}}, \\ \chi \otimes a &\longmapsto a \cdot \omega_p \circ \chi \end{aligned}$$

we may view $V_{\mathbb{R}}$ as the root space of G with respect to T. In particular we may consider the highest weight ξ as well as half the sum of the positive roots η as elements of $V_{\mathbb{R}}$. Let $\leq$ denote the usual partial order on $V_{\mathbb{R}}$. Finally let W be, as before, the Weyl group of T and let z^{dom}, for any point $z \in V_{\mathbb{R}}$, be the unique dominant point in the W-orbit of z. We put

$${}^L T^\circ_{\xi,\mathrm{norm}} := \{\zeta \in {}^L T^\circ : \mathrm{val}(\zeta)^{\mathrm{dom}} \leq \eta + \xi\}.$$

Theorem 5.3. i. *${}^L T^\circ_{\xi,\mathrm{norm}}$ is an open K-affinoid subdomain of the dual torus ${}^L T^\circ$ which is preserved by the action of W.*

ii. *The Banach algebra $\mathcal{B}(G, \sigma_U)$ is naturally isomorphic to the ring of analytic functions on the quotient affinoid $W\backslash {}^L T^\circ_{\xi,\mathrm{norm}}$.*

Proof. [27], Prop. 2.4, Lemma 2.7, and the discussion before the remark in §6. □

For any given highest weight ξ the parameter space for our family of Banach space representations $B_{\xi,\zeta}$ therefore is $W\backslash {}^L T^\circ_{\xi,\mathrm{norm}}$. We emphasize that the pair

(ξ, ζ) should be viewed as consisting of a K-rational cocharacter $\xi \in X_*({}^L G^\circ)$ and a semisimple conjugacy class ζ in ${}^L G^\circ$.

In a second step we have to recognize this parameter space on the Galois side. This has its origin in a fundamental theorem about p-adic Galois representations ([6]) which asserts the existence of an equivalence of categories

$$\begin{array}{lll} \textit{Fon}: & K\text{-linear crystalline representations of } \mathrm{Gal}(\overline{\mathbb{Q}}_p/\mathbb{Q}_p) & \xrightarrow{\sim} \quad \text{weakly admissible filtered } K\text{- isocrystals.} \end{array}$$

A filtered K-isocrystal is a triple $(D, \varphi, \mathrm{Fil}^\cdot D)$ consisting of a finite dimensional K-vector space D, a K-linear automorphism φ of D – the "Frobenius" –, and an exhaustive and separated decreasing filtration $\mathrm{Fil}^\cdot D = (\mathrm{Fil}^i D)_{i\in\mathbb{Z}}$ on D by K-subspaces. Note that the pair (D, φ) can be viewed as a Weil–Deligne group representation $\mathcal{W}_{\mathbb{Q}_p} \to \mathcal{W}_{\mathbb{Q}_p}/\mathcal{I}_{\mathbb{Q}_p} \to \mathrm{GL}(D)$ sending ϕ to φ. Let FIC_K denote the additive tensor category of filtered K-isocrystals. Weak admissibility is a certain condition on the relation between the filtration $\mathrm{Fil}^\cdot D$ and the eigenvalues of the Frobenius φ which we will not recall here.

Let $\mathrm{REP}_K({}^L G^\circ)$ denote the Tannakian category of all K-rational representations of ${}^L G^\circ$. Consider now any pair (ν, b) consisting of a K-rational cocharacter $\nu \in X_*({}^L G^\circ)$ and an element $b \in {}^L G^\circ$. We then have the tensor functor

$$\begin{aligned} I_{(\nu,b)} : \mathrm{REP}_K({}^L G^\circ) &\longrightarrow \mathrm{FIC}_K \\ (\tau, D) &\longmapsto (D, \tau(b), \mathrm{Fil}^\cdot_{\tau\circ\nu} D) \end{aligned}$$

with the filtration

$$\mathrm{Fil}^i_{\tau\circ\nu} D := \bigoplus_{j\geq i} D_j$$

defined by the weight spaces D_j of the cocharacter $\tau \circ \nu$. Borrowing a terminology from [20], Chap. 1, we make the following definition.

Definition 5.4. The pair (ν, b) is called weakly admissible if the filtered K-isocrystal $I_{(\nu,b)}(\tau, D)$, for any (τ, D) in $\mathrm{REP}_K({}^L G^\circ)$, is weakly admissible.

Suppose that (ν, b) is weakly admissible. Then we may compose $I_{(\nu,b)}$ with the inverse of the functor *Fon* and obtain a faithful tensor functor

$$\Gamma_{(\nu,b)} : \mathrm{REP}_K({}^L G^\circ) \longrightarrow \mathrm{Rep}_K^{\mathrm{con}}(\mathrm{Gal}(\overline{\mathbb{Q}}_p/\mathbb{Q}_p))$$

into the Tannakian category of all finite dimensional K-linear continuous representations of $\mathrm{Gal}(\overline{\mathbb{Q}}_p/\mathbb{Q}_p)$. By the general formalism of neutral Tannakian categories ([7]) the functor $\Gamma_{(\nu,b)}$ gives rise to a continuous homomorphism of groups

$$\gamma_{\nu,b} := \mathrm{Gal}(\overline{\mathbb{Q}}_p/\mathbb{Q}_p) \longrightarrow {}^L G^\circ(\overline{K})$$

which is unique up to conjugation in ${}^L G^\circ(\overline{K})$. Hence any weakly admissible pair (ν, b) determines an isomorphism class of "Galois parameters" $\gamma_{\nu,b}$. The connection to our parameter space from the first step is provided by [27], Prop. 6.1, as follows.

Theorem 5.5. *Suppose that $\eta \in X^*(T)$, let $\xi \in X^*(T)$ be dominant, and let $\zeta \in {}^L T^\circ(K)$; then there exists a weakly admissible pair (ν, b) such that ν lies in the ${}^L G^\circ(K)$-orbit of $\xi\eta$ and b has semisimple part ζ if and only if $\zeta \in {}^L T^\circ_{\xi,\mathrm{norm}}(K)$.*

We see that, given a pair (ξ, ζ) with $\xi \in X^*(T)$ dominant and $\zeta \in {}^L T^\circ_{\xi,\mathrm{norm}}(K)$ and assuming that $\eta \in X^*(T)$, we have on the one hand the conjecturally nonzero unitary Banach space representation $B_{\xi,\zeta}$ of G. On the other hand we have the Galois parameters $\gamma_{\nu,b}$ into ${}^L G^\circ(\overline{K})$ for all weakly admissible (ν, b) such that ν is conjugate to $\xi\eta$ and b has semisimple part ζ. This is the basis for our belief that these Galois parameters $\gamma_{\nu,b}$ essentially classify the topologically irreducible "quotient" representations of $B_{\xi,\zeta}$ (the quotation marks indicate that we want to allow for the possibility that the quotient map only has dense image). This would constitute an unramified p-adic Langlands functoriality principle. The technical assumption that $\eta \in X^*(T)$ is satisfied if G is semisimple and simply connected. But it is interesting to realize that it can be altogether avoided by working with a modification of the Galois group $\mathrm{Gal}(\overline{\mathbb{Q}}_p/\mathbb{Q}_p)$. By local class field theory the group $\mathrm{Gal}(\overline{\mathbb{Q}}_p/\mathbb{Q}_p)$ has a (up to isomorphism) unique nontrivial central extension of the form

$$1 \longrightarrow \{\pm 1\} \longrightarrow \mathrm{Gal}(\overline{\mathbb{Q}}_p/\mathbb{Q}_p)^{(2)} \longrightarrow \mathrm{Gal}(\overline{\mathbb{Q}}_p/\mathbb{Q}_p) \longrightarrow 1.$$

We now impose on our coefficient field K the slightly stronger condition that $\mathbb{Q}_p^\times \subseteq (K^\times)^2$. If $\varepsilon\colon \mathrm{Gal}(\overline{\mathbb{Q}}_p/\mathbb{Q}_p) \to \mathbb{Z}_p^\times$ denotes the cyclotomic character then we have a cartesian square

$$\begin{array}{ccc} \mathrm{Gal}(\overline{\mathbb{Q}}_p/\mathbb{Q}_p)^{(2)} & \longrightarrow & \mathrm{Gal}(\overline{\mathbb{Q}}_p/\mathbb{Q}_p) \\ \downarrow{\scriptstyle \varepsilon_2} & & \downarrow{\scriptstyle \varepsilon} \\ K^\times & \xrightarrow{(\cdot)^2} & K^\times. \end{array}$$

The important point is that on $\mathrm{Gal}(\overline{\mathbb{Q}}_p/\mathbb{Q}_p)^{(2)}$ the cyclotomic character ε has the square root ε_2. If $\mathbb{D}$ denotes the protorus with character group $\mathbb{Q}$ then η always can be viewed as a K-rational cocharacter $\eta\colon \mathbb{D} \to {}^L T^\circ$ such that $\eta^2 \in X_*({}^L T^\circ)$.

The notion of weak admissibility extends to filtered K-isocrystals where the filtration is indexed by $\frac{1}{2}\mathbb{Z}$. As a consequence we may define weak admissibility for any pair (ν, b) where $\nu\colon \mathbb{D} \to {}^L G^\circ$ is a K-rational cocharacter such that $\nu^2 \in X_*({}^L G^\circ)$ and $b \in {}^L G^\circ$. Theorem 5.5 without the restriction on η remains true in this more general setting ([27], end of §6). Moreover, it is shown in [4] that the above construction of Galois parameters extends in the sense that any weakly admissible pair (ν, b) (of this more general kind) such that ν is conjugate to $\xi\eta$ gives rise to an isomorphism class of "Galois parameters"

$$\gamma_{\nu,b}\colon \mathrm{Gal}(\overline{\mathbb{Q}}_p/\mathbb{Q}_p)^{(2)} \longrightarrow {}^L G^\circ(\overline{K}).$$

The picture can be made somewhat more precise in the case of the group $\mathrm{GL}_{d+1}(\mathbb{Q}_p)$. But first we remark that the reason for our assumption that $p^{1/2} \in K$

is to make the affinoid ${}^L T^\circ_{\xi,\mathrm{norm}}$ functorial on the category $\mathrm{REP}_K({}^L G^\circ)$. Even for an arbitrary group G the Satake isomorphism can be renormalized in such a way that it is defined over any finite extension $K/\mathbb{Q}_p$. The Banach algebra $\mathcal{B}(G, \sigma_U)$ then becomes isomorphic to the ring of analytic functions on the quotient by W of the affinoid

$$ {}^L T^\circ_\xi := \{\zeta \in {}^L T^\circ : (\mathrm{val}(\zeta) + \eta)^{\mathrm{dom}} \leq \eta + \xi\}. $$

Of course, the W-action now is a twisted version of the natural action. If the derived group of G is simply connected then one can go one step further and make, in addition, the point η integral. In the following we describe this in the case of the general linear group.

For the rest of this section $K/\mathbb{Q}_p$ is an arbitrary finite extension, and we let $G = \mathrm{GL}_{d+1}(\mathbb{Q}_p)$. We also let $U := \mathrm{GL}_{d+1}(\mathbb{Z}_p)$ and T be the torus of diagonal matrices. Our preferred choice of positive roots corresponds to the Borel subgroup of lower triangular matrices. For any $1 \leq i \leq d+1$ we let $\lambda_i \in T/U \cap T$ be the coset of the diagonal matrix having p at the place i and 1 elsewhere. We make the identification

$$ \begin{aligned} V_{\mathbb{R}} = \mathrm{Hom}(T/U \cap T, \mathbb{R}) &\longrightarrow \mathbb{R}^{d+1} \\ z &\longmapsto (z_1, \ldots, z_{d+1}) \text{ with } z_i := z(\lambda_i). \end{aligned} $$

The dominant weight $\xi \in X^*(T)$ is given by

$$ \begin{pmatrix} g_1 & & 0 \\ & \ddots & \\ 0 & & g_{d+1} \end{pmatrix} \longmapsto \prod_{i=1}^{d+1} g_i^{a_i} $$

for an increasing sequence $a_1 \leq \cdots \leq a_{d+1}$ of integers. In fact, $(a_1, \ldots, a_{d+1})$ is the point in $\mathbb{R}^{d+1}$ which corresponds to ξ under the above identification. Our other point η corresponds to

$$ \frac{1}{2}(-d, -(d-2), \ldots, d-2, d). $$

We now note that the point

$$ \tilde{\eta} := (0, \ldots, d) = \eta + \frac{1}{2}(d, \ldots, d) $$

is integral with a correcting summand which is fixed by W. Hence we may rewrite the definition of ${}^L T^\circ_\xi$ as

$$ {}^L T^\circ_\xi = \{\zeta \in {}^L T^\circ : (\mathrm{val}(\zeta) + \tilde{\eta})^{\mathrm{dom}} \leq \tilde{\eta} + \xi\}. $$

Finally, for ${}^L T^\circ(K) = \mathrm{Hom}(T/U \cap T, K^\times)$ we use the coordinates

$$ \begin{aligned} {}^L T^\circ &\longrightarrow (K^\times)^{d+1} \\ \zeta &\longmapsto (\zeta_1, \ldots, \zeta_{d+1}) \text{ with } \zeta_i := p^{i-1}\zeta(\lambda_i). \end{aligned} $$

With these identifications our map val corresponds to the map

$$\begin{aligned}(K^\times)^{d+1} &\longrightarrow \mathbb{R}^{d+1}\\ (\zeta_1,\dots,\zeta_{d+1}) &\longmapsto (\omega_p(\zeta_1),\dots,\omega_p(\zeta_{d+1})) - (0,\dots,d)\end{aligned}$$

and ${}^L T^\circ_\xi$ corresponds to the subdomain

$$\{(\zeta_1,\dots,\zeta_{d+1}) \in (K^\times)^{d+1} : (\omega_p(\zeta_1),\dots,\omega_p(\zeta_{d+1}))^{\mathrm{dom}} \le (a_1, a_2+1,\dots,a_{d+1}+d)\}$$

where now $(\,\cdot\,)^{\mathrm{dom}}$ simply means rearrangement in increasing order. Theorem 5.5 in this case amounts to the following.

Proposition 5.6. *For any $(\zeta_1,\dots,\zeta_{d+1}) \in (K^\times)^{d+1}$ the following are equivalent:*

i. *There is a weakly admissible filtered K-isocrystal of the form*

$$(K^{d+1}, \varphi, \mathrm{Fil}^\cdot K^{d+1})$$

such that $\zeta_1,\dots\zeta_{d+1}$ are the eigenvalues of φ and $(a_1, a_2+1,\dots,a_{d+1}+d)$ are the break points of the filtration $\mathrm{Fil}^\cdot K^{d+1}$.

ii. $(\omega_p(\zeta_1),\dots,\omega_p(\zeta_{d+1}))^{\mathrm{dom}} \le (a_1, a_2+1,\dots,a_{d+1}+d)$.

For any K-linear crystalline representation ρ of $\mathrm{Gal}(\overline{\mathbb{Q}}_p/\mathbb{Q}_p)$ we call the break points of the filtration on $Fon(\rho)$ the Hodge–Tate coweights of ρ. Moreover, we say that ρ is K-split if all eigenvalues of the Frobenius on $Fon(\rho)$ are contained in K. Using the Colmez–Fontaine equivalence of categories we deduce from Proposition 5.6 the existence of a natural map

$$\begin{array}{l}\text{set of isomorphism classes of } (d+1)\text{-dimensional}\\ K\text{-split crystalline representations of } \mathrm{Gal}(\overline{\mathbb{Q}}_p/\mathbb{Q}_p)\\ \text{all of whose Hodge–Tate coweights have multiplicity one}\end{array} \longrightarrow \dot{\bigcup_\sigma} \begin{array}{l}\text{set of } K\text{-valued}\\ \text{characters of}\\ \mathcal{B}(G,\sigma_U).\end{array}$$

In the limit with respect to K this map is surjective. Our earlier speculation means that the fiber in a point (ξ,ζ) in the right hand side should essentially parametrize the topologically irreducible "quotients" of $B_{\xi,\zeta}$.

For the group $G = \mathrm{GL}_2(\mathbb{Q}_p)$ the above picture was the original and basic insight of Breuil. The drastic simplification which occurs in this case is that the fibers of the above map have at most two elements and, in fact, only one element most of the time (whereas these fibers are infinite in general). Later Breuil and Berger were able in [2] to actually prove that the Banach space representations $B_{\xi,\zeta}$ in the case where the corresponding two dimensional crystalline Galois representation is irreducible indeed are nonzero, topologically irreducible, and admissible.

We finish by remarking that the content of this section can be developed for any base field L finite over $\mathbb{Q}_p$. We refer to [22] and [4] for the details.

The algebraization of Kazhdan's property (T)

Yehuda Shalom*

Abstract. We present the surge of activity since 2005, around what we call the algebraic (as contrasted with the geometric) approach to Kazhdan's property (T). The discussion includes also an announcement of a recent result (March 2006) regarding property (T) for linear groups over arbitrary finitely generated rings.

Keywords. Property (T), spectral gap, cohomology of unitary representations, bounded generation, stable range, expanders, sum–product phenomena, finite simple groups.

1. Introduction

I. The objectives and setting. A discrete group is said to have *property* (T) if every isometric action of it on a Hilbert space has a global fixed point. This property (in an equivalent characterization), was introduced by Kazhdan in 1967 [62], as a means to establish its two consequences: being *finitely generated* and having *finite abelianization*, for lattices in "higher rank" simple algebraic groups. While originally property (T) appeared unexpectedly, during the 70s–80s it found various surprising applications, e.g., to the first explicit construction of expander graphs (Margulis), the solution to the so-called Banach–Ruziewicz problem (Rosenblatt, Margulis, Sullivan), and in operator algebras, to the first constructions of type II_1 factors with a countable fundamental group (Connes). Since the 90s, and particularly during this decade, the study of property (T) has seen further rapid developments, both in theory and in applications, and its perception has substantially been transformed. It is now a fundamental notion and a powerful tool in diverse areas of mathematics, ranging from representation theory (where it was born), ergodic theory and geometric group theory, to operator algebras and descriptive set theory.

An excellent account of the 70s–80s theory can be found in de la Harpe–Valette's influential book [50]; the developments of the 90s are presented in Valette's Bourbaki [104], and a comprehensive up-to-date exposition of the subject can be found in the outstanding forthcoming book by Bekka, de la Harpe and Valette [11]. Consequently, our purpose is not to present another general exposition. Rather, we discuss two different, rather opposite trends in the study of property (T), *geometric* and *algebraic* which, we believe, can be detected quite clearly in retrospect. Following a brief historical account of the former, we focus our attention here mainly on recent exciting developments of the latter, and announce the following new result:

*Supported by the Israeli Science Foundation.

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

Theorem 1.1. *Let R be any finitely generated commutative ring with* 1. *Denote by* $\mathrm{EL}_n(R) < \mathrm{GL}_n(R)$ *the group generated by the elementary matrices over R. Then for all* $n \geq 2 + \mathrm{Krull\,dim} R$, *the group* $\mathrm{EL}_n(R)$ *has Kazhdan's property* (T).

In particular, it follows from a non-trivial "$\mathrm{EL}_n = \mathrm{SL}_n$" result of Suslin [101], that for any $m \geq 0$, the group $\mathrm{SL}_n(\mathbb{Z}[x_1, \ldots, x_m])$ has property (T) when $n \geq m+3$. These groups are the first known *linear* Kazhdan groups outside the family of lattices. In fact a better result holds, covering non commutative rings as well, in which Bass' ring theoretic notion of the *stable range* of R replaces the Krull dimension. The proof of the theorem also reduces to a new treatment of the "classical" case, $R = \mathbb{Z}$. The reader interested primarily in Theorem 1.1 may wish to skip to Section 4 on first reading, where a sketch of its proof is presented.

II. The geometrization of property (T). As is well known by now, a lattice Γ in a simple algebraic group G over a local field k has property (T), unless k-rank $G = 1$, but including $G = F_4^{-20}$, $\mathrm{Sp}(n, 1)$ when $k = \mathbb{R}$ – cf. [11], [50]. Due to the celebrated results of Margulis (rank > 1) and Corlette and Gromov–Schoen (rank 1), these simple algebraic groups turn out to be also the ones whose lattices enjoy *super-rigidity*, hence a fortiori, these lattices are *arithmetic groups* (with $\Gamma = \mathrm{SL}_{n\geq 3}(\mathbb{Z})$ serving as outstanding examples). For a long time, the simultaneous appearance of property (T) and superrigidity–arithmeticity was only empirical, having very different origin. However during the 90s, beginning with the breakthrough of Corlette [31], it has become evident that the theory of harmonic maps should provide a unified explanation for the two phenomena, even though in practice this has been carried out primarily for archimedean k and co-compact Γ. Be that as it may, for two decades following Kazhdan's discovery, essentially no new constructions of Kazhdan groups were found, and the proofs of property (T) for the *arithmetic groups* were depending crucially on their being *lattices*. As the latter are intimately related with the special geometry of symmetric spaces or Bruhat–Tits buildings, as well as with arithmetic-algebraic objects, this highly rigid framework was naturally projected back to the general perception of property (T).

The first new constructions of Kazhdan groups were put forward in Gromov's seminal work [46], as quotients of co-compact lattices in the rank one Kazhdan Lie groups. Although this geometric method gave rise to a continuum of Kazhdan groups, it is above all an achievement of Gromov's hyperbolic group theory; from the point of view of property (T), the implicit constructions are "deformations" of existing ones. It is only in 1994 that the first explicit constructions of entirely new Kazhdan groups appeared, in a remarkable work of Cartwright, Młotkowski and Steger [26]. The groups constructed there act simply transitively on the vertices of certain "exotic $\tilde{A}_2$ buildings" introduced in [25], and for a natural generating subset, the *best* Kazhdan constant was computed. At the time, these groups seemed to form a "singular" class of "cousins" of standard lattices, and their original treatment was quite algebraic. However, it is now understood that they are outstanding representatives of the "geometrization of property (T)", an approach going back to Garland's seminal paper [44].

In 1973, Garland [44] established the first general results in what has later developed to become the "vanishing below the rank" principle. Loosely speaking, this asserts that for a simple algebraic group G over a local field k, the cohomology $H^i(G,\pi)$ vanishes for a wide class of representations π, as long as $i < k - \text{rank}G$. A similar statement is inherited by the discrete co-compact subgroups $\Gamma < G$. Although soon a complete algebraic theory had been established in this setting (cf. [13], [27], [64], [107]), it is the geometric approach of Garland that has lent itself to broad generalizations outside the linear framework, thereby giving birth, a decade ago, to the "geometrization of property (T)". At the heart of Garland's approach lies the idea that an appropriate bound on the norm of a *local* Laplacian, defined on the links of a complex on which Γ acts, leads to vanishing of cohomology. Since the above definition of property (T) is tautologically equivalent to the vanishing of $H^1(\Gamma,\pi)$ for any unitary Γ-representation π, this can be used to give an extremely useful, geometric criterion for the presence of property (T). An illuminating account of the remarkable path from the classical Hodge theory and Matsushima and Bochner type formulae in the theory of harmonic maps, through Garland's work, to Kazhdan's property (T), can be found in Pansu's [84]. As was pointed out to us by Lior Silberman, one can now present a particularly simple proof of the following resulting local criterion for property (T) (due to Ballmann–Świątkowski [8], Pansu [84], Żuk [111]), using the most basic Poincaré type inequality for Hilbert space valued functions on finite graphs:

Theorem 1.2. *Let X be a 2-dimensional simplicial complex on which the group Γ acts properly and co-finitely by automorphisms. Assume that each vertex and each edge of X is contained in some triangle. If for any vertex x, its link is a connected graph whose first positive eigenvalue is $> 1/2$, then Γ has property* (T).

See also [11, Ch. 5], [82], [108], and particularly [53, Theorem 6.4]. All of the aforementioned works, as well as [35], [36], furnish us with a rich and wild family of Kazhdan groups, well beyond the original distinguished class of arithmetic groups. Last, but not least in this direction, is Gromov's "random groups" paper [47], in which the geometrization approach to fixed point properties of groups culminates in the construction of remarkable groups, having property (T) among other important features; see also the related elaborations [45], [81], [100].

III. From geometrization to algebraization of property (T). The geometrization of property (T), when it applies, is a powerful tool. It is so sweeping that it typically yields a much stronger fixed point property, covering at least all isometric actions on non-positively curved manifolds (as in Theorem 1.2 above – cf. [53, Theorem 6.4]). Thus, it *intrinsically* cannot apply when dealing with such interesting groups as $\text{SL}_n(\mathbb{Z})$. Moreover, so far it has not produced a single example of a *linear* group which is not a standard arithmetic lattice. Related to this, the crude scissors of the geometric approach are currently helpless in dealing with delicate questions regarding expanding properties of *infinite families of finite groups*. It is exactly for these problems that

we shall see the advantages of the recent *algebraic approach* to property (T). Unlike the geometric one, which looks at the group "locally", and essentially as a purely geometric object, the algebraic approach relies heavily on precise global algebraic structure. It applies a finer spectral analysis, and generally offers a more individual, less collective treatment. Our main purpose in this exposition is to describe its recent developments and achievements.

Trying to "geometrize the algebraization" – a failure report. Before proving Theorem 1.1 above, an attempt was made, together with Donald Cartwright, Lior Silberman, and Tim Steger, to find a computer assisted proof of some cases treated by Theorem 1.1, using Theorem 1.2 applied to Cayley complexes associated with the group. More precisely, going over $\sim 10^6$ generating subsets, the computer tested Żuk's-"$\lambda_1 > 1/2$" criterion for property (T) in an improved version, taking generating subsets invariant under conjugation by a finite subgroup, and applying a corrected variation of Żuk's Theorem 8 in [112]. While as explained, the condition inherently cannot hold over rings like $\mathbb{Z}$ or $\mathbb{Z}[x]$, a priori there seems to be no reason why it should not be satisfied when working with $R = \mathbb{F}_p[x, y]$, let alone with $R = \mathbb{F}_p[x]$ (for which $\mathrm{SL}_3(R)$ is a lattice on a $\tilde{A}_2$ building, and has property (T)). The attempts (with $p = 2, 3$) failed. There indeed seems to be little intersection between the two approaches to property (T).

Acknowledgments. Thanks to J. Bourgain, P. de la Harpe, H. Helfgott, M. Kassabov, A. Lubotzky, A. Valette, and particularly to T. Steger, for helpful remarks and discussions on this exposition. Being completed essentially on our wedding anniversary March 30, the paper is dedicated to my wife Marina, with my love and appreciation.

2. First algebraization results: bounded generation and general rings

I. Kazhdan constants. One driving force in the study of property (T) is the determination of *explicit Kazhdan constants*. Recall (the well known Delorme–Guichardet theorem, cf. [50]) that a finitely generated group Γ has property (T) iff for every finite generating subset $S \subseteq \Gamma$ there exists some $\varepsilon > 0$, such that the following is satisfied: *If $\pi : \Gamma \to U(V)$ is any unitary Γ-representation on a Hilbert space V, for which there is some $v \in V$ with $\|\pi(g)v - v\| < \varepsilon\|v\|$ (such v is called (S, ε)-invariant), then there is some $0 \neq u \in V$ which is Γ-invariant.* Any $\varepsilon > 0$ is referred to as a *Kazhdan constant* for Γ, with respect to (and usually depending on) S.

Besides serving as a natural challenge, determining explicit Kazhdan constants makes quantitative many of the applications of property (T). It also makes available the next qualitative problem of *uniformity* of property (T) (more precisely, of the Kazhdan constant) over a family of groups, which reduces to the important theme of expander Cayley graphs for finite groups (discussed in Section 3 below). The particularly natural, intriguing case of $\mathrm{SL}_{n\geq 3}(\mathbb{Z})$, with its "canonical" generating subset of $n^2 - n$

unit elementary matrices, was a problem raised by Serre in the 80s – see also the problem list in [50].

In [94] it was realized that Kazhdan's original proof of property (T) for higher rank algebraic groups, actually is (or can be made) effective. Thus, explicit and even optimal Kazhdan constants can be obtained for these groups (see also [10], [12], [80] in this direction). From there, by making quantitative Kazhdan's original argument that any lattice in a Kazhdan group is Kazhdan, explicit Kazhdan constants for each lattice can be obtained, based on some (soft) information on a fundamental domain of it. The latter being handled by standard reduction theory, this settles the issue *in principle*. In practice, however, matters are not quite as simple, and many basic questions regarding the asymptotic behavior of the Kazhdan constants are difficult to understand from this viewpoint. Although this is the solution one can hope for when dealing with the *family* of all lattices, for many individual arithmetic groups, such as $\mathrm{SL}_{n\geq 3}(\mathbb{Z})$, it yields Kazhdan constants for generating sets of "geometric" rather than "algebraic" nature. From the more general perspective we are trying to pursue here, this is far from being the "right" solution, as it continues to treat the arithmetic groups as *lattices*, rather than approaching them as independent groups. Such an approach was indeed accomplished in [96], providing a solution to Serre's question above for $\mathrm{SL}_{n\geq 3}(\mathbb{Z})$. In that paper a systematic use of two tools was initiated: the group theoretic notion of *bounded generation*, and the passage from standard rings like $\mathbb{Z}$, to *arbitrary* finitely generated rings, like $\mathbb{Z}[x]$, via a general relative property (T) result. The next two subsections introduce these two ingredients, and some of their earlier (yet still quite recent) combined applications. Further recent developments follow in subsequent sections.

II. Bounded generation

Definition 2.1. Let G be a group, and $\{H_i\}$ be a finite family of subgroups. We say that G is *boundedly generated* by $\{H_i\}$, if there exists some $M < \infty$, such that every $g \in G$ is a product of at most M elements, each belonging to some H_i. If the H_i are cyclic subgroups, we simply say that G is boundedly generated.

This notion, and the first non-trivial examples of it, came with the work of Carter–Keller [24], who showed that for the ring of integers $\mathcal{O}$ of any number field k, $\mathrm{SL}_{n\geq 3}(\mathcal{O})$ is boundedly generated. More precisely, they showed that this group is boundedly generated by the family of its $(n^2 - n)$ *elementary subgroups*, a property which makes sense when working over *any* ring R, and is then termed *bounded elementary generation*. Carter–Keller's result uses Dirichlet's theorem on primes in arithmetic progressions, and gives an explicit bound on M in terms of n and the discriminant ($2n^2 + 50$ works for $\mathrm{SL}_{n\geq 3}(\mathbb{Z})$ – see also the friendlier account in [1], still not avoiding Dirichlet's theorem, where matters stand as of today). Bounded generation has since been studied further, especially for arithmetic groups and in relation to the congruence subgroup property (cf. [85], [109] and the references therein). Although it certainly deserves more attention, we shall not be able to discuss it out-

side the framework of property (T), except to mention the fundamentally important problem of deciding whether it is shared by any single *co-compact* lattice in a higher rank simple Lie group.

The relevance of bounded generation to questions around property (T) was first demonstrated by Colin de Verdière (cf. [30, Theorem 3.9]), and independently in [96]. The idea can be easily explained through the following simple, yet remarkably useful observation:

Lemma 2.2 (Bounded Generation Lemma). *Assume that G is boundedly generated by $\{H_i\}$. If an isometric G-action on a Hilbert space admits a fixed point for each H_i separately, then it admits a global fixed point.*

Proof. The existence of a fixed point for one H_i, implies that all its orbits are norm bounded (as the action is isometric). Therefore the G-action has bounded orbits, and the unique circumcenter of one such orbit is fixed by all of G. □

In reality, one often tries to argue more quantitatively, at the level of the *unitary representation*, in order to get an *explicit Kazhdan constant* for the group G. The general scheme goes as follows:

(i) Show that for any unitary G-representation with almost invariant vectors, there is an H_i-invariant vector for each i. Quantitatively, any ε-invariant vector v (with respect to a fixed generating set), is ε' close to an H_i-invariant vector, for each i separately.

(ii) Deduce from (i) that *the same* v is $2\varepsilon'$-invariant under *all* of H_i.

(iii) By choosing $\varepsilon > 0$ small enough, make $2\varepsilon' < 1/M$, where M is the bounded generation constant. Hence all of G moves the unit vector v by less than unit distance, and the circumcenter of Gv is a *non-zero* vector, invariant under all of G.

As we shall see, this scheme (with small variations) turns out to be extremely useful even when all the groups involved are *finite*, enabling one to "lift" Kazhdan constants from "smaller" to "larger" groups, upon having a precise structural algebraic information. The main spectral analysis lies in part (i), and it is this *relative property* (T) (of G with respect to H_i), to which we now turn our attention.

III. The relative property (T) over general rings. The relative property (T) is an important variant which is implicit in Kazhdan's original paper, and was first introduced by Margulis (cf. [74], [75]). In analogy with Delorme–Guichardet's equivalent characterization of property (T), Julissaint [54] established the following (see also de Cornulier's extension of this notion in [32]):

Definition 2.3. Let Γ be a discrete group and $N < \Gamma$ a subgroup. We say that the pair (Γ, N) has the *relative property* (T), if either one of the following equivalent conditions is satisfied:

(i) Any isometric Γ-action on a Hilbert space admits a fixed point for N.

(ii) There exists a finite subset $S \subseteq \Gamma$ and $\varepsilon > 0$ ("Kazhdan constants"), so that any unitary Γ-representation containing a (S, ε)-invariant vector, admits a non-zero vector invariant under N.

The outstanding example, used by Margulis in his first explicit construction of expanders [74], is the semi-direct product $\Gamma = \mathrm{SL}_2(\mathbb{Z}) \ltimes \mathbb{Z}^2$, with $N = \mathbb{Z}^2$. In the course of computing explicit Kazhdan constants for the finite representations of $\mathrm{SL}_3(\mathbb{Z})$, Burger [21] found explicit Kazhdan constants for this pair. While his method used, by means of unitary induction, the co-compact embedding $\mathbb{Z}^2 < \mathbb{R}^2$, a variant avoiding it was found in [96]. This seemingly technical issue turned out to be of importance, as it triggered the passage to working with *general finitely generated commutative rings*, thereby releasing a part of the theory from the burden of an ambient locally compact group. Kassabov observed that the commutativity of the ring multiplication operation is not required in the proof, and consequently we have [58], [96]:

Theorem 2.4. *Let R be any finitely generated ring with* 1. *Then* $(\mathrm{EL}_2(R) \ltimes R^2, R^2)$ (*and* $(\mathrm{SL}_2(R) \ltimes R^2, R^2)$ *when R is commutative*)*, has the relative property* (T)*, with explicit Kazhdan constants available, depending only on the number of generators of R.*

The main tool in the proof of the result is the spectral theorem for representations of abelian groups. By taking the spectral measure on the Pontrjagin dual $\widehat{R^2}$, corresponding to almost $\mathrm{EL}_2(R)$-invariant vectors, one gets a sequence of almost $\mathrm{EL}_2(R)$-invariant measures with respect to the dual action on $\widehat{R^2}$. It is then shown that such a sequence of measures cannot exist when they have "most" of their support "close" to (but excluding) $0 \in \widehat{R^2}$. That, however, would have been the case if the vectors in consideration were taken to be also *almost R^2-invariant*. The whole proof can be made quantitative, leading to explicit Kazhdan constants for the relative property (T). Without getting more technical, we note (anticipating the sum–product results to be discussed in Section 3.III below), the tension used here between the two algebraic operations of the ring.

IV. Bounded generation + relative (T) approach: first applications. It was shown in [96] that when $R = \mathbb{Z}$ in Theorem 2.4, one can take $\varepsilon = 1/10$ in Definition 2.3 (ii), for the generating set S consisting of the unit elementary matrices of $\mathrm{SL}_2(\mathbb{Z})$ and the standard basis of $\mathbb{Z}^2$. It is easy to see that every elementary subgroup $H_i \cong \mathbb{Z}$ of $\mathrm{SL}_{n\geq 3}(\mathbb{Z})$ can be placed in a copy of $\mathbb{Z}^2$, which is normalized by some embedding of $\mathrm{SL}_2(\mathbb{Z})$ in $\mathrm{SL}_n(\mathbb{Z})$. Thus, the relative property (T) for $(\mathrm{SL}_2(\mathbb{Z}) \ltimes \mathbb{Z}^2, \mathbb{Z}^2)$ gives the explicit $\varepsilon = 1/10$ in step (i) of the quantitative scheme described following Lemma 2.2, for the generating set of $n^2 - n$ unit elementary matrices. Taking the Carter–Keller bounded generation estimate, one completes the last two steps of the scheme to get explicit Kazhdan constants for $\mathrm{SL}_{n\geq 3}(\mathbb{Z})$, which decrease quadratically in n. Later, Kassabov realized in [56] that with additional effort, one can execute this scheme "more efficiently" for large n, to obtain Theorem 2.5 below. It is quite remarkable that while the unitary dual of $\mathrm{SL}_n(\mathbb{Z})$ (or any non-virtually abelian group for that matter), is entirely out of reach, ultimately these ideas give rise to an *explicit* determination of the *precise asymptotic behavior* of the Kazhdan constants of these groups, over all n:

Theorem 2.5. *Let ε_n denote the largest Kazhdan constant of the group* $\mathrm{SL}_{n\geq 3}(\mathbb{Z})$ *w.r.t. the set of $n^2 - n$ unit elementary matrices. Then* $10^{-3}n^{-\frac{1}{2}} < \varepsilon_n < 2n^{-\frac{1}{2}}$.

A more careful analysis reduces the ratio between the two bounds to 60 as $n \to \infty$.

The successful treatment of $\mathrm{SL}_{n\geq 3}(\mathbb{Z})$, together with the generality of Theorem 2.4, suggests that one should aim higher, at property (T) for other groups of similar type, notably $\mathrm{SL}_{n\geq 3}(\mathbb{Z}[x_1, \ldots, x_m])$. These groups are called "universal lattices" in [96], as they naturally surject onto many standard arithmetic lattices over both zero and positive characteristic local fields. Property (T) for them would thus account in a uniform manner for Kazhdan's property of very different arithmetic groups. Notice that if we knew that for $n \geq 3$ they were *boundedly elementary generated*, then the same strategy as for $\mathrm{SL}_n(\mathbb{Z})$ would establish property (T) for them as well. It was conjectured in [96] that property (T) should indeed be present among these groups, even though the question of bounded elementary generation has been open since its introduction in the context of K-theory by van der Kallen, in 1982 [55] (where it was also shown that bounded elementary generation over the ring $\mathbb{C}[x]$ does not hold). As will be seen in Section 4 below, the proof of Theorem 1.1 circumvents this delicate, still unsettled issue, by using a different cohomological proof which requires a more modest bounded generation property (which shows up when n is larger than the dimension of the ring $+1$).

The following variation on the same general scheme enables one to get other interesting consequences, where bounded elementary generation is less elusive. It is implicit in the proof of [96, Corollary 4], and subsumes the previous discussion as well, when the ring is taken with its discrete topology.

Theorem 2.6. *Fix $n \geq 3$. Assume that for some finitely generated ring R with* 1*, the group* $\mathrm{EL}_n(R)$ *is embedded* densely *in a topological group G, and the group G is boundedly generated by the* closure *of the embeddings of the elementary subgroups of* $\mathrm{EL}_n(R)$*. Then every* continuous *unitary G-representations with almost invariant vectors for* $\mathrm{EL}_n(R)$*, has a non-zero vector invariant under* all *of G. Moreover, an explicit bound on the Kazhdan constant and size of the Kazhdan set is available, depending only on the number of generators of R as a ring, and on the bounded generation estimate.*

We conclude this section with two rather different applications of this result.

Theorem 2.7. *For $n \geq 3$, the infinite dimensional loop group $G = L(\mathrm{SL}_n(\mathbb{C}))$ of all continuous maps from the circle to* $\mathrm{SL}_n(\mathbb{C})$*, has property* (T)*. More precisely, there is a finite subset $S \subseteq G$ and $\varepsilon > 0$, so that every continuous unitary G-representation with an (S, ε)-invariant vector, admits a non-zero invariant vector.*

This result from [96] is the first construction of an infinite dimensional Lie group, and in fact of any *non locally compact* topological group, with property (T) (more recent ones can be found in [9], [33], [78]). The second application of Theorem 2.6 is the following deeper result of Kassabov and Nikolov [61], giving the first positive

result towards Theorem 1.1 above. The relevant ambient topological group G here, is the profinite completion.

Theorem 2.8. *Fix $n \geq 3$. Then for any finitely generated commutative ring R, the group* $\mathrm{EL}_n(R)$ *has property* (τ)*, namely, the family of all its* finite *representations not containing an invariant vector, does not contain any (S, ε)-invariant vector (for an explicit finite subset S and $\varepsilon > 0$). In particular, property (τ) holds for the groups* $\mathrm{SL}_{n\geq 3}(\mathbb{Z}[x_1, \ldots, x_m])$.

The bounded generation result needed for Theorem 2.8 controls the "failure of the congruence subgroup property" over higher dimensional rings. This is obtained by proving a result of independent interest, on the bounded generation of $K_2(R)$ by products of Steinberg symbols $\{a, b\}$.

3. The algebraization of property (T) for finite groups: expanders

The general theme of expanders, which has attracted much attention and interest in computer science, combinatorics and group theory, needs by now no introduction (cf. [69], [90] and references therein, for more information, particularly in the directions we shall follow). When dealing with Cayley graphs, the relation to property (T) is fundamental: *A family of finite groups, each equipped with a generating set of uniformly bounded size, is an* expander*, iff their Kazhdan constants are all uniformly bounded away from* 0. For our purposes, and for the benefit of the interested non-specialist, we may simply regard the latter as our definition of expanders in the framework of Cayley graphs. The main general group theoretic problems in this setting can be put into two related, yet independent directions:

1. Existence. Given a family of finite groups G_i, can one find for each i a generating set $S_i \subseteq G_i$, making $\mathrm{Cay}(G_i, S_i)$ an expander family?

2. Independence. Given a family G_i for which 1 is answered positively, is it an expander family with respect to *all* generating subsets? *Random* ones?

Implicit here is the natural question (due to Lubotzky–Weiss [73]), settled *positively* only in recent work of Alon–Lubotzky–Wigderson [3] (following [86]), of whether being an expander family *depends in general* on the choice of generating subsets. This makes any positive results towards 2 of substantial interest. For completeness, we mention that Alon–Roichman [4] showed that any family of finite groups can be made expander using generating subsets of logarithmic size, and that some families, e.g. consisting of abelian groups, *cannot* be made expanders. A completely positive answer to 2 is still unknown for any infinite family of groups; an empirical support towards it for the family $\{\mathrm{SL}_2(\mathbb{F}_p)\}$ was provided by Lafferty–Rockmore in [65], [66].

In this section we describe the remarkable progress made on these two problems *during the last year* (2005), which turns out to be very closely related to the previously

discussed algebraization approach to property (T). Before getting into more details, we discuss briefly some relevant background, which shows striking parallelism to the early slow developments in constructing new Kazhdan groups (as discussed in the introduction), and may help to put this exciting progress in perspective.

I. Some background. Margulis' 1973 first explicit construction of expander graphs gives rise to a general class of so-called *"mother group expanders"*: Take a finitely generated ("mother"-)group Γ generated by a finite (symmetric) subset $S \subseteq \Gamma$, an infinite sequence of finite index normal subgroups $N_i \lhd \Gamma$, and consider $\mathrm{Cay}(\Gamma/N_i, \bar{S})$ (where $\bar{S}$ is the canonical projection of S). This automatically yields expanders when Γ has property (T) (interestingly, Gromov's recent random constructions [47] mark a way back from expanders to property (T)). However different, even "better" constructions can be obtained, by using other mother groups such as free groups. The necessary spectral gap property is always a highly non-trivial matter, and for more than two decades after Margulis' construction, the only known approach besides property (T) relied on deep number theoretic tools, around Selberg ("$\lambda_1 \geq 3/16$")–Ramanujan type estimates. All the groups Γ which were known to become mother groups for expanders, were *arithmetic lattices* (with subgroups $N_i \lhd \Gamma$ taken to be *congruence*). As outstanding examples, one should keep in mind the two families $\mathrm{SL}_2(\mathbb{F}_p)$ and $\mathrm{SL}_{n\geq 3}(\mathbb{F}_p)$, *always taken with the projection of a generating set of the corresponding mother group:* $\mathrm{SL}_2(\mathbb{Z})$ (the number theoretic approach), or $\mathrm{SL}_{n\geq 3}(\mathbb{Z})$ (the property (T) approach).

As will become clear, it is not a coincidence that the prolonged lack of progress here was so reminiscent of the one described in the Introduction, concerning new constructions of Kazhdan groups. Besides the little flexibility available by choosing the generators for the quotients Γ/N_i as projections of a subset $S_0 \subseteq \Gamma$ generating a *finite index* subgroup $\Gamma_0 < \Gamma$, no single other construction was known until a decade ago. See Lubotzky's "frustrated account" of this state of affairs in [70]. There the "1–2–3" test case problem was suggested, of proving that $\mathrm{SL}_2(\mathbb{F}_p)$ are expanders with respect to the projection of the set S_0 of elementary 2×2 matrices with ± 3 off the diagonal (while the usual mother group generators yield expanders only for ± 1 or ± 2).

In [92] and [93] appeared the first new constructions of subsets S_0 of the mother group Γ, generating an *infinite index* subgroup, whose projections to Γ/N_i remain expanders. The general principle put forward there, was that one can retain the expanding property when $\langle S_0 \rangle = \Gamma_0 < \Gamma$ has *infinite index*, as long as Γ_0 is "*close enough*" to Γ, in terms of a comparison between the spectral gaps of $(\ell^2-)\Gamma/\Gamma_0$ and $(\ell^2_0-)\Gamma/N_i$. The spectral gap here can be measured by means of norms of convolution operators in $\mathbb{C}[\Gamma]$, or by comparing the Riemannian λ_0 vs λ_1 eigenvalues in geometric settings. For example, one can always remain with expanders, when using $S_0 \subseteq \Gamma$ generating a *co-amenable* subgroup $\Gamma_0 < \Gamma$ (e.g. Γ_0 is normal, and $\Gamma/\Gamma_0 \cong \mathbb{Z}$, cf. the concrete example in [93], computationally analyzed in [67]). A more interesting implementation of this principle can be obtained when Γ is a (necessarily) free group for

which Γ/N_i are *Ramanujan graphs* à la Lubotzky–Phillips–Sarnak–Margulis. Their optimal spectral gap property alone, implies that one can find (non-constructively, though) in *every non-trivial normal subgroup* $\Gamma_0 < \Gamma$, a finite subset S_0 whose projection to the finite quotients Γ/N_i (whatever groups they are), is an expander. The approach to these results is functional analytic, applying such tools as compactness in weak topologies, and the Krein–Milman theorem. It is based on an intimate connection with the Banach–Ruziewicz type problem on the profinite completion of Γ. Similarly to Gromov's constructions of Kazhdan groups as quotients of hyperbolic Kazhdan groups, this approach suffers from the fundamental drawback of introducing only a "deformation" of previously existing constructions. It is in itself incapable of providing expanders independently.

A second class of new, self contained constructions, came later in Gamburd's [40], where the same direction of taking $S_0 \subseteq \mathrm{SL}_2(\mathbb{Z})$ generating an infinite index "large" subgroup, is pursued. Here "largeness" is interpreted by the Hausdorff dimension (at least $5/6$) of the limit set on the boundary. The result still fell short of dealing with the "1–2–3" question of Lubotzky mentioned earlier. Gamburd's work relied on previous ideas of Sarnak and Xue [91] (see also [34]), which, as explained in Subsection III below, play a fundamental role in the recent far reaching work of Bourgain–Gamburd [15]. The latter, which concerns the independence problem 2, together with the work discussed in the next subsection regarding the existence problem 1, changed dramatically the poor progress made around the group theoretical aspects of expanders, by the end of the last century.

II. Making the finite simple groups into expanders. The first "new generation" Cayley graph expanders, i.e., ones not obtained via the previously discussed "mother group" approach, were established in [96]: *For any fixed $n \geq 3$ and $m > 0$, when R varies over all the commutative finite rings generated by at most m elements, the family* $\mathrm{SL}_n(R)$ *forms an expander family*. This immediately follows from Theorem 2.6, as it is a simple matter to give a uniform bounded elementary generation estimate for these rings, depending only on n. For example, all finite fields are generated as a ring by one element, hence $\{\mathrm{SL}_n(F)\}$, for any fixed $n \geq 3$, is an expander.

A major bridge was, however, yet to be crossed: obtaining a uniform Kazhdan constant for SL_n over a fixed finite field, but with *n growing*. At first glance, this seems quite unapproachable by the methods discussed earlier. However, using a fundamental clever variation, Kassabov showed [58] that one can extend the existing technique to encompass the latter as well, by taking appropriate *non-commutative rings R* in Theorem 2.6. More precisely, if F is a finite field, and if we let $R_d = \mathrm{Mat}_d(F)$ be the standard $d \times d$ matrix ring, then it can be shown that R_d is generated by 3 elements for all d, that $\mathrm{EL}_3(R_d)$ have a uniform bounded elementary generation property over all d, and that $\mathrm{EL}_3(R_d) = \mathrm{EL}_3(\mathrm{Mat}_d(F)) \cong \mathrm{SL}_{3d}(F)$. Hence, by Theorem 2.6 the latter form an expander family. Since it is easy to see that for all n and all finite fields F, $\mathrm{SL}_n(F)$ is uniformly boundedly generated by embeddings of $\mathrm{SL}_{3d}(F)$ for $d = [n/3]$, the quantitative version of the Bounded Generation Lemma 2.2 establishes

the following result of Kassabov [58]:

Theorem 3.1. *$\{\mathrm{SL}_n(F) \mid n \geq 3,\ F$ is a finite field$\}$ can be made an expander.*

We shall next formulate a considerably more general statement (whose proof uses this result), however we mark Theorem 3.1 as the first significant indication that one might hope to cover essentially all finite simple groups (at least those of Lie type). This was accomplished very recently as an accumulation of works by Kassabov, Lubotzky and Nikolov (cf. [60] and its references):

Theorem 3.2. *Excluding the Suzuki groups, the family of all finite* (*non-abelian*) *simple groups can be made an expander.*

The result was conjectured in [6] without the exception of the Suzuki groups. By the classification of finite simple groups, the proof amounts to dealing with the family of alternating groups A_n, and with the groups of Lie type (the finitely many sporadic groups are of course negligible in such asymptotic questions). An illuminating account of the work towards the proof of this theorem can be found in the joint announcement [60] of the three authors; we shall only present here some highlights, emphasizing the intimate relations with the main theme of this exposition.

Finite simple groups of Lie type. To complete first the family $\{\mathrm{SL}_n(\mathbb{F}_q)\}$ for all n and $q = p^k$, we are left, by Theorem 3.1 above, with the case $n = 2$. This is done by Lubotzky [71] in the following way: in [72] these groups are made Ramanujan with respect to sets $S_k^{(p)} \subseteq \mathrm{SL}_2(\mathbb{F}_{p^k})$ of (unbounded !) size $p + 1$. The Ramanujan spectral gap enters only is showing that they yield uniform Kazhdan constants for $\mathrm{SL}_2(\mathbb{F}_{p^k})$, over all k and p (yet with unbounded size of generating sets). However the specific construction in [72] is of use, in showing that for any p and k there is an element $g_k^{(p)} \in \mathrm{SL}_2(\mathbb{F}_{p^k})$ so that $S_k^{(p)} \subseteq \mathrm{SL}_2(\mathbb{F}_p) \cdot g_k^{(p)} \cdot \mathrm{SL}_2(\mathbb{F}_p)$. Since all the $\mathrm{SL}_2(\mathbb{F}_p)$'s can be made uniformly expanders with two generators, adding to those the $g_k^{(p)}$ and using the quantitative version of the Bounded Generation Lemma 2.2, yields expanding generating sets of three elements.

Once the case of $\{\mathrm{SL}_n(\mathbb{F}_q)\}$ has been settled, the quantitative version of the Bounded Generation Lemma 2.2 completes the treatment of all finite simple groups of Lie type, excluding the Suzuki groups, using the following two results:

Theorem 3.3. (1) (Nikolov [79]). *Every finite simple group G of* classical *type is a product of at most $M = 200$ conjugates of a subgroup H which is a* (*central*) *quotient of $\mathrm{SL}_n(\mathbb{F}_q)$, for some n and q.*

(2) (Lubotzky [71]). *Excluding the Suzuki family, for any family $X_r(q)$ of finite simple groups associated with a group X of* Lie type (*twisted or untwisted*) *and fixed rank r, there exists a constant M such that the statement in* (1) *holds* (*with $H \cong (P)\,\mathrm{SL}_2(\mathbb{F}_q)$*).

Since there are only finitely many families of finite simple groups not covered by (1), together with (2) Theorem 3.2 follows, excluding the alternating groups. The

difficulty in treating the Suzuki groups arises from the fact that the only simple groups they contain belong to that same family. The proof of (1) involves a detailed analysis of the subgroup structure of these groups. Although it seems that a more delicate treatment in this spirit should cover (2) as well, Lubotzky appeals instead to a model theoretic approach developed by Hrushovski and Pillay [52], which enables one to deduce the result by a kind of dimension argument, as if working over an algebraically closed field. However, we note that one can prove this result with less sophisticated model theoretic tools, by appealing to the *first order logic compactness theorem*. See [109] for a different useful relation between the latter theorem and bounded generation.

Symmetric groups. For the proof of Theorem 3.2 we are left with the family A_n (or equivalently S_n), which is the most intriguing and challenging among the groups covered in Theorem 3.2. One reason is that unlike the other families $X_r(q)$, it is easy to find (natural) bounded generating subsets for S_n, which make them *non-expanders*. Additionally, a simple cardinality computation, coupled with some basic knowledge of the subgroup structure of S_n, shows that a similar bounded generation strategy, using embeddings of $\mathrm{SL}_n(F)$, will not work here. Unfortunately, in this confined exposition we cannot do justice to the brilliant (and quite technical) work of Kassabov [57], who showed that S_n can be made an expander. Besides the original paper [57], see also the announcement [59] (an elaborate account), or the previously mentioned [60] (a less technical one). Below are only some highlights.

Kassabov proves his theorem by dividing the irreducible representations of S_n into two classes, according to whether the corresponding partition of n has the first row "small" (first class), or "large" (second class), and showing the uniform spectral gap in each class independently. This method is inspired by similar previous ideas of Roichman [89], whose work [88] is also applied in the analysis of the first class, to show that the Kazhdan constant of large (unbounded) sets $F_n \subseteq S_n$, consisting of "nearly all" elements in a suitable conjugacy class of S_n, is uniform. Although the sizes of these F_n are unbounded, Kassabov is able to confine them in a bounded product of uniformly expanding subgroups ($\cong$ products of $\mathrm{SL}_d(\mathbb{F}_2)$). Thus, using the quantitative version of the Bounded Generation Lemma 2.2, he obtains bounded Kazhdan sets for the representations in the first class. The argument for the second is entirely different: those representations are contained in $\ell^2(S_n/S_m)$, for appropriate m which is "close enough" to n, in order to imply strong transitivity (or fast mixing) for the action in that space. The precise argument yields uniform Kazhdan constants only for the family S_k with $k \sim 2^{18l}$, $l = 1, 2 \ldots$. The general case follows by showing that one can *uniformly boundedly generate* each S_n by embeddings of S_k for k of this type.

III. Uniform expansion over different generating sets. In a recent impressive achievement [15], Bourgain and Gamburd established the following:

Theorem 3.4. (1) *For any subset* $S \subseteq \mathrm{SL}_2(\mathbb{Z})$ *not generating a virtually cyclic subgroup,* $\mathrm{Cay}(\mathrm{SL}_2(\mathbb{F}_p), \overline{S})$ *is an expander family* (*for p large enough*).

(2) *Fix $k \geq 2$. As $p \to \infty$, an independent uniform random choice of k elements in each* $\mathrm{SL}_2(\mathbb{F}_p)$ *makes with probability* $\to 1$ *the* (*undirected*) *Cayley graphs into an expander.*

(3) *Fix any $c > 0$. If for every p a symmetric generating set $S_p \subseteq \mathrm{SL}_2(\mathbb{F}_p)$ is chosen, so that girth* $\mathrm{Cay}(\mathrm{SL}_2(\mathbb{F}_p), S_p) \geq c \cdot \log p$, *then these graphs form an expander.*

The heart of the result lies in part (3), which easily implies (1), and using the "random logarithmic girth" result established in [41], immediately implies (2). The proof of the theorem borrows key ideas from the approach introduced by Sarnak and Xue [91], incorporating two main ingredients: I. High multiplicity of the (bad) eigenvalues in the regular representation of $\mathrm{SL}_2(\mathbb{F}_p)$, stemming from Frobenius' classical result that the smallest dimension of a non-trivial representation of this group ($\frac{p-1}{2}$), is large relative to its size ($\sim p^3$) – i.e., there is a uniformly positive logarithmic ratio between the two (unlike the symmetric groups, for example). II. An upper bound on the number of returns to the identity for random walks of length up to logarithmic order of the group.

While previously, the upper bound in II was obtained by translating the problem into a Diophantine one, the generality of the Bourgain–Gamburd result is made possible by using instead tools from *additive combinatorics*. These include a non-commutative version of the Balog–Szemeredi–Gowers Lemma due to Tao [102], and notably Helfgott's recent breakthrough, discussed below, which capitalizes on *sum–product* results. Other aspects of Bourgain–Gamburd's work involve algebraic inputs, such as Frobenius' result above, and the precise subgroup structure of $\mathrm{SL}_2(\mathbb{F}_p)$. However, it is actually in the fascinating theme of sum–product phenomena, that one finds a rather striking similarity with previously discussed algebraization methods for property (T), and a conceptual explanation of how rich algebraic structure may lead to expansion properties. We shall try to shed some light on this fundamental ingredient, beginning with the recent pioneering result of Helfgott [51]:

Theorem 3.5. *Let $S \subseteq \mathrm{SL}_2(\mathbb{F}_p)$ be any generating set. Then* $\mathrm{Cay}(\mathrm{SL}_2(\mathbb{F}_p), S)$ *has diameter $\leq K(\log p)^c$, where the constants K, c are absolute.*

This result is weaker than "expansion" (in which case $c = 1$), and a similar statement (with $\log p$ replaced by $\log |G|$) is conjectured by Babai [5] to hold uniformly over all finite simple groups. However, it is here that for the first time, the barrier of handling uniformly independent generating subsets is crossed. The proof of Theorem 3.5 is a direct consequence of the following:

Key Proposition. *Let p be a prime and $A \subseteq \mathrm{SL}_2(\mathbb{F}_p)$. Then:*

(a) (Small sets) *If A is not contained in a proper subgroup, and $|A| < p^{3-\delta}$ with $\delta > 0$, then $|A \cdot A \cdot A| > c|A|^{1+\varepsilon}$, where $c, \varepsilon > 0$ depend only on δ.*

(b) (Large sets) *Assume A is not contained in any proper subgroup, and $|A| > p^{\delta}$, $\delta > 0$. Then there is an integer k depending only on δ, such that $(A \cup A^{-1})^k = \mathrm{SL}_2(\mathbb{F}_p)$.*

Theorem 3.5 follows immediately by first applying a constant number of set multiplications (depending only on c, ε), so that (a) starts giving exponential growth, and then applying (a) followed by (b). The latter is a major ingredient in Bourgain–Gamburd's work. Its proof when δ is close to 3 (e.g. $\delta > 8/3$) requires soft Fourier analysis, hence matters rest primarily on (a). We next discuss it, remarking first that the appearance of $|A \cdot A \cdot A|$ rather than $|A \cdot A|$ is necessary; consider e.g. $A = H \cup \{g_0\}$, where H is a subgroup.

Sum–product phenomena and expansion. Besides standard (by now) tools from additive combinatorics, such as the Balog–Szemeredi–Gowers theorem, and properties of Ruzsa distances, the proof of (a) in the Key Proposition makes crucial use of powerful *sum–product phenomena*. These arise in works of Bourgain, Glibichuk, Katz, Konyagin, Tao, and originally involved also subtle arithmetic techniques originated from (Stepanov's elementary proof of) Weil's work on the Riemann hypothesis over finite fields (the latter part is relevant only to Helfgott's and not to Bourgain–Gamburd's work, due to their logarithmic girth assumption). See [14], [18], [19], [63], Section 2.8 in [103], and the references therein, for further details, including the interesting intimate connections with work (notably by Bourgain), on the ring conjecture, Kakeya problem, and exponential sum estimates. For our purposes, it suffices to state the following (cf. [51]):

Theorem 3.6 (Sum–Product). *Fix $\delta > 0$. Then for any subset $A \subseteq \mathbb{F}_p - \{0\}$ with $C < |A| < p^{1-\delta}$, we have*

$$\max\{|A \cdot A|, |A + A|\} > |A|^{1+\varepsilon}$$

where $C, \varepsilon > 0$ depend only on δ.

An analogous result over the integers was first established by Erdös–Szemeredi [37]. Very recently, a simplified proof of the theorem was found by Tao (see Theorem 2.52, Corollary 2.55 in [103]). A similar statement holds for an arbitrary finite field F (taking into account the presence of subfields). Results accounting for a small growth of a set under applying internal arithmetic operations by an obvious algebraic structure (arithmetic progression, subring, subfield) capturing most of its mass, go back to Friemann's classical theorem (cf. [103, Ch. 2]). In fact, under the same heading one can also include the recent far reaching uniform exponential growth results of Eskin–Mozes–Oh [38], and Breuillard–Gelander [20], for infinite, finitely generated linear groups. In the latter, as in the proof of Theorem 3.6, one first shows that some algebraic operation on the set A yields a set with the desired growth property, and then deduces the result back for A itself. However, quite surprisingly, in the proof of Theorem 3.6 it is actually the *latter* step which is *trickier* (for instance, it can happen that $|A \cdot A + A \cdot A| \sim |A|^2$, but $|A \cdot A|, |A + A| < 2|A|$). Returning to Helfgott's Theorem 3.5 above, since matrix multiplication in $\mathrm{SL}_2(\mathbb{F}_p)$ encodes the addition and multiplication in $\mathbb{F}_p$ together, the relevance of sum–product results to Theorem 3.5 is not a surprise *a posteriori*. In practice, the proof applies Theorem 3.6

to the traces of the elements of a set, showing that the sizes of a set and its set of traces "keep track of one another".

If one wants to pin down the source of the expansion in both Bourgain–Gamburd and Helfgott results, it is the sum–product phenomenon which gives the best quick answer. It is quite interesting to examine in this light the proof of relative property (T) for general rings (Theorem 2.4 above), which is the departure point for most results in the algebraization of property (T). Its proof capitalizes on the same ring theoretic phenomenon, where sets (or measures) which are "almost invariant" under the combined ring operations, must be "degenerate" (e.g., must assign mass to 0).

The Archimedean spectral gap analogue. In this exposition we can only mention the second companion work by Bourgain–Gamburd [16], which also deals with establishing a uniform spectral gap, and involves some similar ingredients, this time working over $\mathbb{R}$ or $\mathbb{C}$. It is shown there that a certain "non-commutative Diophantine condition" on (the group generated by) a finite set $S \subseteq \mathrm{SU}(2)$, implies that its induced action on the zero mean functions $L^2_0(\mathrm{SU}(2))$ has a spectral gap. This Diophantine condition was introduced in previous (weaker) results in this direction by Gamburd–Jakobson–Sarnak [42], who also showed that it is automatically satisfied if all elements in S have algebraic traces. See these two papers, as well as [69], [90], for more on the history of the problem, which may be viewed as a quantitative version of the (positive solution to the) Banach–Ruziewicz problem, pertaining to a certain uniqueness property of the Lebesgue measure on the 2-sphere.

The bulk of this companion work by Bourgain–Gamburd consists in establishing a "statistical" analogue of Helfgott's Key Proposition above [16, Proposition 1]. Its proof replaces the sum–product Theorem 3.6 by an approach originating from (and improving on) Bourgain's work [14, Theorem 0.3], towards the ring problem. This work of Bourgain–Gamburd turns out to be more involved than the one on expanders, a fact which may seem surprising in view of past experience with these parallel problems. There are, however, two conceptual explanations why, when dealing with more "generic" (or less "special") finite subsets, one should expect more difficulties here. Firstly, while in the real topology "bad" sets can be continuously approached by "good" ones, such phenomenon cannot occur in the non-archimedean case. Even more importantly, the right analogue of the (ideal) SU(2) result, would be showing a uniform expansion for (topologically generating) finite subsets of the compact group $\mathrm{SL}_2(\mathbb{Z}_p)$ (p-adic integers), which, in return, is *equivalent* (see [92]) to showing that for any fixed k, *all* choices of k-generator subsets, independently in each $\mathrm{SL}_2(\mathbb{Z}/p^i\mathbb{Z})$, form expanders. Now, it may be expected that the latter property turns out more subtle than making $\mathrm{SL}_2(\mathbb{F}_p)$ with varying p into expanders. In the latter case, it is not a priori clear if and how the questions over different primes p relate. One may hope (perhaps naively though), that as it often happens, the "right" solution (spectral gap here) for one prime, would work uniformly over all primes. In contrast, in the case of $\mathrm{SL}_2(\mathbb{Z}/p^i\mathbb{Z})$ with i increasing, establishing a spectral gap bound for a given i automatically yields the same bound for smaller i's (as the canonical quotient map induces an inclusion at the L^2 level). Hence one faces more difficult tasks as i grows.

In fact, remarking on the preceding paragraph (in a previous draft of this paper), Jean Bourgain has informed us of substantial progress achieved recently towards a generalization of Theorem 3.4, covering uniformly essentially all $\mathrm{SL}_2(\mathbb{Z}/q\mathbb{Z})$. He noted that the method when $q = p^i$ is indeed closer to the one in the SU(2) case, and may be viewed as its p-adic analogue – see below, and [17], where this generalization is involved. The higher rank cases $\mathrm{SL}_{n\geq 3}$ should naturally be addressed as well. Whether they turn out to be as demanding, remains to be seen.

Finally, we remark that Theorem 3.4 (with its extension mentioned above) has very recently been applied by Bourgain–Gamburd–Sarnak, to develop a combinatorial sieve method for primes and almost primes, on orbits of various subgroups of $\mathrm{GL}_n(\mathbb{Z})$ as they act on $\mathbb{Z}^n$. Unlike the more familiar case of sieving in $\mathbb{Z}^n$, in this setting the expander property plays a critical role. See the announcement [17] for further details.

4. Reduced cohomology and property (T) for elementary linear groups

I. Definition and basic properties of reduced cohomology. The study and use of reduced cohomology in relation to property (T) was first pursued in [95], motivated by establishing rigidity results for lattices in products of groups. We shall need it in Subsection III for the proof of Theorem 1.1, and in the next subsection some previous applications of it are mentioned. Recall first the basic correspondence between (affine) isometric actions of a group Γ on a Hilbert space V, and first cohomology. Any such action is of the form $\rho(\gamma)v = \pi(\gamma)v + b(\gamma)$, where π is a unitary Γ-representation on V, and the affine part $b\colon \Gamma \to V$ satisfies the 1-cocycle identity corresponding to π (the identity sufficient and necessary to make ρ an *action*). Fixing π, the set of all such b is a vector space, denoted $Z^1(\Gamma, \pi)$, and those "trivial" elements of the form $b_v(\gamma) = v - \pi(\gamma)v$, the coboundaries, form a subspace denoted $B^1(\Gamma, \pi)$. It is immediate that the Γ-action on V has a fixed point (v_0) iff the corresponding 1-cocycle b is a coboundary (b_{v_0}). We define the quotient space $H^1(\Gamma, \pi) = Z^1(\Gamma, \pi)/B^1(\Gamma, \pi)$, and can now consider also the topological version of it. Namely, fixing π, introducing the topology of pointwise convergence on the space $Z^1(\Gamma, \pi)$ makes it a Frechet space, in which B^1 is not always closed. Forming its closure, the first *reduced cohomology* $\overline{H}^1(\Gamma, \pi)$ can now be defined as $Z^1/\overline{B}^1$. The following analogous relation between fixed points of affine actions and coboundaries, can be verified easily:

Lemma 4.1. *Given $b \in Z^1(\Gamma, \pi)$, we have $b \in \overline{B}^1(\Gamma, \pi)$ iff the corresponding affine action $\rho(\gamma)v = \pi(\gamma)v + b(\gamma)$ has almost fixed points in the metric sense, namely, for every finite $S \subseteq \Gamma$, and $\varepsilon > 0$, there is $v \in V$ with $\|\rho(\gamma)v - v\| < \varepsilon$ for all $\gamma \in S$.*

All the notions and results here extend naturally to the class of second countable locally compact groups. The discussion above shows that the characterization of property (T) in terms of vanishing of usual cohomology is a tautology if one takes the fixed point property as a definition. However, the following characterization in

terms of the (generally smaller) reduced cohomology is less transparent, and holds only under the assumption of finite generation (or compact generation, in the locally compact setting):

Theorem 4.2 ([95]). *Let Γ be a finitely generated group without property* (T). *Then there exists some unitary Γ-representation π, with $\overline{H}^1(\Gamma, \pi) \neq 0$. Moreover, one can find such π which is irreducible.*

II. Some applications of the reduced cohomology

(1) Theorem 4.2 implies the existence of an irreducible π with $H^1(\Gamma, \pi) \neq 0$, as conjectured by Vershik–Karpushev [106]. Together with [106, Theorem 2] (see Louvet's [68] for a detailed exposition) it implies: *A discrete group Γ has property* (T) *iff it is finitely generated, has finite abelianization, and it does not admit any non-trivial irreducible unitary representation not separated* (*in the Fell topology*) *from the trivial representation*.

(2) As an application of the proof of Theorem 4.2, it is shown in [95] that every finitely generated Kazhdan group is a quotient of a *finitely presented* Kazhdan group (answering questions of Grigorchuk and of Żuk; the result is generalized by Fisher–Margulis [39] to locally compact groups). However, the existence seems entirely non-constructive, and there are concrete interesting groups which would be of interest to understand in this regards – see II in Section 5 below.

(3) Although in general, the existence of the *irreducible* cohomological π in Theorem 4.2 is non-constructive, somewhat surprisingly, in many cases one can actually classify all such π, and show that there are only *finitely many* of them. It may seem particularly unexpected that this finiteness phenomenon appears among *amenable* groups. For example, this is the case for all polycyclic (or lamplighter) groups, a result from [98] shown there to have applications in geometric group theory (e.g., any group quasi-isometric to a polycyclic group has a finite index subgroup with infinite abelianization). Martin [77] showed that all connected locally compact groups also have only finitely many such representations π.

(4) Inspired by Margulis' remarkable strategy in proving the normal subgroup theorem for higher rank lattices, as well as by more recent beautiful work of Burger–Mozes (cf. [22]), the following result was completed very recently: over sufficiently large finite fields, *any irreducible Kac–Moody group of non-affine* (*and non-spherical*) *type, has a finite index commutator subgroup, which is a* (*finitely generated*) *simple group, modulo its finite center*. Building on fundamental work of Rémy, the proof consists of three entirely independent results on any quotient of the simple group by a non-trivial normal subgroup: it is *Kazhdan* [95], *amenable* (Bader–Shalom [7]), and *infinite* (Caprace–Rémy [23]), classes of groups which do not intersect. The proof of the first relies crucially on the reduced cohomology of (infinite dimensional) unitary representations. Incidentally, we remark that while in virtually all of the applications of property (T), an appropriate Kazhdan group comes to the rescue, the ones made through normal subgroup theorems are of quite unique nature, as throughout the proof

no (non-trivial) Kazhdan group appears.

III. Sketch of proof of Theorem 1.1. Fix $n \geq 3$ (note that if $\dim R = 0$, by finite generation R must be finite). We proceed via the following steps:

1. Setting and notation. Set $\Gamma = \mathrm{EL}_n(R)$, and define the following subgroups: $\Lambda =$ matrices whose first row and first column begin with 1 and have 0s elsewhere, $N_1, N_2 \cong R^{n-1}$ the subgroups sitting in the upper row and left column with a "common" 1 at the upper left corner. Notice that Λ normalizes each one of the N_i's. The standard Steinberg commutator relations show that N_1 and N_2 together generate Γ. In fact, letting $r_1 = 1, r_2, \ldots, r_k$ be generators of R as a ring, the set S of all elementary matrices belonging to one of the two N_i's, having one of the r_j as the only non-zero element off the diagonal, forms a finite generating set for Γ.

Finally, for an isometric Γ-action ρ on a Hilbert space V_ρ and $v \in V_\rho$, denote

$$\delta_S(v) = \max\{\|\rho(s)v - v\| \mid s \in S\}, \quad \delta_S(\rho) = \inf\{\delta_S(v) \mid v \in V_\rho\}.$$

2. Reduced cohomology. Assume that Γ does not have property (T). We argue to get a contradiction. By Theorem 4.2 and Lemma 4.1 above, there exists some isometric Γ-action ρ on a Hilbert space V_ρ, with $\delta_S(\rho) > 0$. By rescaling we may assume that $\delta_S(\rho) \geq 1$. Denote by $\mathcal{A}$ the set of all isometric Γ-actions ρ with $\delta_S(\rho) \geq 1$.

3. Relative property (T) – the spectral ingredient. By (an obvious extension of) Theorem 2.4, for each i the pair $(\Lambda \ltimes N_i, N_i)$ has the relative property (T). Consequently, by the equivalence in Definition 2.3, the following infimum is not taken over the empty set:

$$d = \inf\{\|v^1 - v^2\| \mid v^i \in V_\rho \text{ with } \rho \in \mathcal{A}, \text{ and } \rho(N_i)v^i = v^i \text{ for } i = 1, 2\}.$$

4. Attaining d through a limiting process. Let $\rho_n \in \mathcal{A}$ and $v_n^i \in V_{\rho_n}^{N_i}$ with $\|v_n^1 - v_n^2\| = d_n \to d$. We may assume that $d_n < d + 1$, and this gives for all n $\delta_S(v_n^1) < 2(d+1)$, since v_n^1 is fixed by the N_1-generators of S, and a vector of distance at most $d + 1$ from it is fixed by the N_2-generators of S. This uniform bound implies (using an ultra-product argument as in [39], or a negative definite kernel argument as in [95]), that a subsequence of the actions (ρ_n, V_{ρ_n}), pointed at v_n^1, converges to an isometric Γ-action on a Hilbert space (ρ_∞, V_∞), with two points $v^i \in V_\infty^{N_i}$ satisfying $\|v^1 - v^2\| = d$. One shows that indeed $\rho_\infty \in \mathcal{A}$, hence d defined in step 3 is attained. Notice that $d \neq 0$, for otherwise v^1 is fixed by Γ, contradicting $\rho \in \mathcal{A}$.

5. Can assume π_∞ has no invariant vectors. Write $\rho_\infty(\gamma)v = \pi_\infty(\gamma)v + b_\infty(\gamma)$, where π_∞ is the (unitary) linear part (see the discussion at the beginning of the previous subsection). Decompose orthogonally $\pi_\infty = \pi_0 \oplus \pi_1$ where $\pi_0 = \pi^\Gamma$, and correspondingly, $b_\infty = b_0 + b_1$. Being a 1-cocycle for a trivial Γ-action, b_0 is an additive character, and since Γ is perfect (as it is generated by commutators), $b_0 = 0$. Replacing ρ_∞ by $\rho'_\infty(\gamma)v := \pi_1(\gamma)v + b_1(\gamma)$ yields the required reduction.

6. A fixed point for Λ via a geometric argument. Assume that for some $\lambda_0 \in \Lambda$, $w^1 := \rho_\infty(\lambda_0)v^1 \neq v^1$, and denote $w^2 = \rho_\infty(\lambda_0)v^2$. We will show this to be impossible. As Λ normalizes N_i, we have $v^i, w^i, u^i := \frac{1}{2}(v_i + w_i) \in V_\infty^{N_i}$, for $i = 1, 2$. Because λ_0 is an isometry, $\|v^1 - v^2\| = \|w^1 - w^2\| = d$, while by the definition of d as infimum, $\|u^1 - u^2\| \geq d$. By a standard convexity argument this is possible only if $v^1 - v^2 = w^1 - w^2$, and hence $v^1 - w^1 = v^2 - w^2 \neq 0$. But since v^1, w^1 are N_1-fixed, the left hand side is a non-zero *vector* invariant under the *linear* action of N_1, and similarly for $v^2 - w^2$ w.r.t. N_2. Since $\langle N_1, N_2 \rangle = \Gamma$, it follows that this common non-zero vector is Γ-invariant, contradicting the reduction made in step 5. Thus, $\rho(\Lambda)v^1 = v^1$.

7. Finishing with bounded generation and the stable range. A fundamental result of Bass (cf. Theorem 4.1.14 in [49]), asserts that if R is a commutative Noetherian (in particular, by Hilbert's basis theorem, if it is a finitely generated) ring, then for any $n \geq 2 + \text{Krull dim} R$, the ring R satisfies the following property: For every $a_1, \ldots, a_n \in R$ such that $a_1 R + \cdots + a_n R = R$ (such an n-tuple is called *unimodular*), there exist $\alpha_2, \ldots, \alpha_n \in R$, such that $(a_2 + \alpha_2 a_1)R + \cdots + (a_n + \alpha_n a_1)R = R$. The minimal n satisfying this property is called the *stable range* of R, denoted $\text{sr}(R)$ (so $\text{sr}(R) \leq \dim R + 2$ – strict inequality can hold. Note also that there is "inconsistency up to ± 1" in the literature regarding the definition of the stable range). This property enables one to reduce any $\gamma \in \Gamma$ to $\lambda \in \Lambda$, using a bounded number of elementary operations. Indeed, notice that since all matrices in Γ are invertible, the first row of γ is unimodular. Then, by performing $n - 1$ elementary operations we may create a unimodular $(n-1)$-tuple in the last entries of the first row, and since $1 \in R$, proceed to place 1 in the upper left corner, and use it to annihilate all of the rest of the first row and column. In group theoretic terms, since all the elementary subgroups are conjugate, and any elementary operation is obtained as multiplication by an elementary matrix, this means that Γ is *boundedly generated* by finitely many conjugates of Λ. Like Λ, all of these conjugate fix some point in V_∞, and the Bounded Generation Lemma 2.2 yields a fixed point for Γ, a contradiction which finishes the proof.

It is clear that all that was really relevant to the proof was the stable range of R. Moreover, this notion is similarly defined for *any* ring, not necessarily commutative, only that here one has to distinguish between left and right ideals (although the left and right stable ranges were shown by Vaserstein to be equal [105]). After stating the condition on n in Theorem 1.1 in terms of the stable range in place of dim R, the above proof goes through in this general setting. See [99] for the complete details.

5. Some concluding remarks, questions, and speculations

I. More on Theorem 1.1. The following arises immediately from Theorem 1.1: *Given a finitely generated commutative ring R, when does* $\text{EL}_n(R)$ *begin to have property* (T)? By that theorem the answer lies between $n = 3$ and $n = 2 + \dim R$.

In fact, the proof gives the generally better upper bound $\mathrm{sr}(R)$ (which we suspect is not always optimal). It seems that to address this issue, one should understand better the relation between bounded generation and property (T). We next speculate about a possible strategy.

The proof of Theorem 1.1 actually establishes the following result for any finitely generated ring R and every $n \geq 3$: if $\mathrm{EL}_n(R)$ is boundedly generated by conjugates of $\mathrm{EL}_n(R) \cap \mathrm{GL}_{n-1}(R)$ ($= \Lambda$ in our previous notation), then $\mathrm{EL}_n(R)$ has property (T). The purely algebraic assumption involved here is satisfied when $n \geq \dim R + 2$, and it seems that a full understanding of when it happens (in terms of n as a function of R), takes one beyond the "property (T) territory". However, an attempt at understanding its inverse relation to property (T) should be made: can one show that its failure reflects back on the failure of property (T)? The only device which currently seems available towards such a result, is that of "spaces with walls" defined in [48] (whose more general measurable counterpart is known to capture the lack of property (T) [87]; see also [28]). This setting enables one to construct a negative definite kernel on a group, out of its action on ("half spaces" of) a discrete set, satisfying simple axioms. For our purposes, a natural strategy would thus be to "encode" the algebraic framework into such a set, where the value of the negative definite kernel at $\gamma \in \mathrm{EL}_n(R)$ corresponds to the number of multiplications needed to generate it.

II. Quantifying the robustness of property (T). As mentioned is Section 4.II (2), one of the consequences of the reduced cohomology approach is that any finitely generated Kazhdan group Γ is a quotient of a *finitely presented* Kazhdan group. An intriguing example to which this applies is the group $\Gamma = \mathrm{SL}_3(\mathbb{F}_p[t])$ (which has property (T) because $3 > 2$, and is not finitely presented because $3 < 4$ – see the first mention of the group in this context on [76, p. 134]). Thus, finitely many among the well understood infinite sequence of relations in this group, already suffice to define a Kazhdan group. However, even in this particular case (where explicit Kazhdan constants are known), it is an open problem to *make the existence proof effective*.

The question can in fact be seen as merely one instance of trying to *quantify the robust behavior of property* (T), a phenomenon which was applied in Fisher–Margulis local rigidity results [39]. If Γ has property (T), then for some $\varepsilon > 0$ there is a fixed point for any ε-isometric action of it on a Hilbert space. Moreover, it is actually enough to impose this condition on a generating set only, and for spaces which are Hilbert only locally (on some $1/\varepsilon$ ball). Even further, the action may be well defined only on elements inside a $1/\varepsilon$-ball of Γ, and a moment reflection shows that the latter yields the previously mentioned result about the existence of a finitely presented Kazhdan cover. In fact, one may go further, in assuming the latter action to be only a *near* (ε-)action. In short, by appropriately using a (rather standard by now) limiting argument as needed in the proof of Theorem 1.1, essentially everything in the characterizations of property (T) can be perturbed, yet there is no single non-trivial case when it is known how to do this effectively. To put matters in perspective, we remark that a similar robustness phenomenon *does not* hold for the "opposite" fixed

point property – amenability. Notice also that the proof of Theorem 1.1 *does not yield any explicit Kazhdan constants*. While we believe that some new ideas are needed for the previous questions, it may be that a variation on the proof of Theorem 1.1 will make this an easier task.

III. Property (τ) for irreducible lattices. Although Clozel's recent property (τ) paper [29] largely closes a chapter on the study of property (τ) for arithmetic groups, the story is not quite over as might be perceived. What Clozel actually establishes is the *Selberg property*, and the precise semantics here is important exactly because the congruence subgroup property for many arithmetic groups (e.g., co-compact irreducible lattices in $\mathrm{SL}_2(\mathbb{R}) \times \mathrm{SL}_2(\mathbb{R})$) is only conjectured. While Selberg's property, just like his original $\lambda_1 \geq 3/16$ result for $\mathrm{SL}_2(\mathbb{Z})$, yields a spectral gap over the *congruence subgroups*, property (τ) seeks a spectral gap over *all* finite index subgroups. We remark that the incompleteness of property (τ) becomes worse for arithmetic groups over local fields of *positive characteristic*, which were not treated by Clozel.

For higher rank lattices in *simple* algebraic groups, property (T) automatically takes care of property (τ), hence all the unsettled cases lie in a general setting which was extensively and successfully studied in recent years; that of an irreducible lattice Γ in a product $G = G_1 \times G_2$. We believe that under fairly general conditions, certainly ones satisfied when each G_i is a simple algebraic group over a local field, one should be able to get a "softer" proof (certainly avoiding number theory, or a subtle identification of the finite index subgroups), that Γ has property (τ). While as explained, this would have some advantages compared to Clozel's theorem, we note that such a general approach cannot compete with Clozel's: his theorem gives *explicit* spectral bounds on the spectrum of $L^2_0(G/\Gamma_n)$, when restricting to *each simple factor* G_i. Property (τ) is equivalent to the existence of some bound on the joint spectrum of the G_i's.

It may be that there is actually a deeper, more interesting representation theoretic phenomenon underlying the conjectural property (τ) for irreducible lattices: *Is it true that whenever π is a unitary Γ-representation, possibly infinite dimensional, which admits almost invariant vectors, then π has some subrepresentation which extends to G*? Obviously, this would immediately imply property (τ) for Γ (using only that G_i have no non-trivial finite dimensional unitary representations). Such a result would be extremely useful. Some support may be provided by the superrigidity for reduced cohomology in [95], as the failure of property (T) for Γ is always detected by representations with reduced cohomology (Theorem 4.2 above), which in return, *must come from the ambient group G* [95, Theorem 3.1].

IV. Burnside groups and Zelmanov's theorem. The existence of infinite Burnside groups, i.e., finitely generated groups of bounded torsion (first established by Adyan and Novikov, see also [83] and the references therein), is still one of the impressive achievements of infinite group theory. Even harder non-finiteness results are non-amenability of such groups [2]. It is an extremely intriguing question, to which we believe the answer is positive, *whether all Burnside groups should have property* (T). One of the puzzling features of the problem is that it is unclear if it should be attacked

within a *geometric*, or an *algebraic* approach. While serious attempts in the negative have been made within the former direction, we believe that it is actually the latter which should be used, and that reduced cohomology may again become useful. Of course, one of the rewards of establishing property (T) for Burnside groups would be an immediate "size dichotomy" of independent interest: either they are *finite*, or *non-amenable*. There is no known counterexample to this plausible statement.

With the hope of establishing property (T) for Burnside groups in mind, one can wildly speculate further, about a possible approach to reproving Zelmanov's celebrated positive solution to the restricted Burnside problem (cf. [110]): A *residually finite Burnside group is finite*. The idea is to try to adapt Margulis' "(T) ∩ (amenable) = (finite)" strategy in proofs of normal subgroup theorems, to this setting. More precisely, assume that Γ is a Burnside group and $N_i \lhd \Gamma$ is a decreasing sequence of finite index normal subgroups. If Γ was shown to have (T), we would know that Γ/N_i are expanders. On the other hand, a reduction (due to Hall and Higman, already used by Zelmanov) enables one to assume that Γ has prime power torsion, in which case all the finite quotients would have a similar property (and are hence nilpotent). While nilpotency may hint (although in itself is not enough to show) that the quotients should not be expanders, the additional uniform torsion may be sufficient to establish this opposite behavior. Its contrast with the first, property (T) part, would then imply Zelmanov's theorem.

Rankin–Selberg integrals, the descent method, and Langlands functoriality

David Soudry

Abstract. In this article I survey the descent method of Ginzburg, Rallis and Soudry and its main applications to the Langlands functorial lift of automorphic, cuspidal, generic representations on a classical group to (appropriate) GL_n, and to establishing a local Langlands reciprocity law for (split) SO_{2n+1} (joint work with D. Jiang). The descent method arises when we consider certain residues of special cases of a family of global integrals, attached to pairs of automorphic, cuspidal representations, one on a classical group G and one on GL_n. The last part of this article focuses on the case $G = \mathrm{SO}_m$ (split), and the progress made in a joint work with S. Rallis, towards establishing, via the converse theorem, the functorial lift from any automorphic, cuspidal representation on G to $\mathrm{GL}_{2[\frac{m}{2}]}$.

Mathematics Subject Classification (2000). Primary 11F70; Secondary 11R39.

Keywords. L-functions, functorial lift, descent method, Gelfand–Graev models.

1. Introduction

Let F be a number field, and let $\mathbb{A}$ be its ring of Adeles. I will start with a general family of global integrals of Rankin–Selberg type or of Shimura type for $G \times \mathrm{GL}_n$, where G is an orthogonal group, a unitary group, a symplectic group, or a metaplectic group defined over F. This family contains, at one end, the integrals studied by Shahidi, giving rise to the Langlands–Shahidi method, and at another end, this family contains the global integrals, giving rise to the descent method of Ginzburg, Rallis and Soudry. In this section, I sketch the structure of these integrals, and in the next section I report on my joint work with D. Ginzburg and S. Rallis on the descent method and its many applications, and on my joint work with D. Jiang on the local Langlands reciprocity law for the split group SO_{2n+1}. In the third section I report on a joint work in progress with S. Rallis towards the (weak) functorial lift from SO_m to $\mathrm{GL}_{2[\frac{m}{2}]}$.

a. Let E be either F or a quadratic extension of F. Let V and V' be vector spaces over E of dimensions m and m' equipped with non-degenerate bilinear forms b and b', respectively, which are symmetric if $E = F$ and Hermitian (with respect to the Galois conjugation "-" of E over F) otherwise. Let $G = U(V)$ and $G' = U(V')$ be the isometry groups of (V, b) and (V', b'), respectively. Denote by X_i the (orthogonal) direct sum of i hyperbolic planes, where, in the second case, we mean two

Proceedings of the International Congress of Mathematicians, Madrid, Spain, 2006

dimensional spaces over E with Hermitian form (according to some basis) given by $b((x_1, x_2), (y_1, y_2)) = x_1\bar{y}_2 + x_2\bar{y}_1$. Fix a decomposition $X_n = X_n^+ + X_n^-$, where $X_n^{\pm}$ are transversal n-dimensional totally isotropic subspaces. Assume that m and m' have different parities and that one of the following holds.

(1) There is an orthogonal decomposition of the form $V = X_j \oplus Y$ and there is a non-isotropic vector $y_0 \in Y$ such that $V' = Y \cap y_0^{\perp}$, and b' is the restriction of b to $V' \times V'$.

(2) The same as in (1), but reversing the roles of V and V', i.e. $V' = X_j \oplus Y'$ and there is a non-isotropic $y_0' \in Y'$ such that $V = Y' \cap y_0'^{\perp}$, and b is the restriction of b' to $V \times V$.

Let $W = X_n \oplus V'$ and $H = U(W)$. Let π, ρ, τ be irreducible, automorphic, cuspidal representations of $G_{\mathbb{A}}$, $G'_{\mathbb{A}}$, $\mathrm{GL}_n(\mathbb{A}_E)$, respectively. Let P be the parabolic subgroup of H which preserves X_n^+; its Levi part M is isomorphic to $\mathrm{Res}_{E/F}\,\mathrm{GL}_n \times G'$. Thus we may view $\tau|\det|^{s-\frac{1}{2}} \otimes \rho = \tau_s \otimes \rho$ as a representation of $M_{\mathbb{A}}$ and consider its parabolic induction $I(\tau_s, \rho)$ to $H_{\mathbb{A}}$. Let $E(h, f_{\tau_s,\rho})$ be an Eisenstein series corresponding to an analytic section $f_{\tau_s,\rho}$ in $I(\tau_s, \rho)$. Now we distinguish three cases.

(i) $m' < m < 2n + m'$.

(ii) $2n + m' < m$.

(iii) $m < m'$.

In cases (i) and (iii) we apply to $E(h, f_{\tau_s,\rho})$ a Fourier coefficient of Gelfand–Graev type stabilized by G; let us denote it by $E^{\psi,G}(h, f_{\tau_s,\rho})$, where ψ is a non-trivial character of $F\backslash\mathbb{A}$. We pair this coefficient with cusp forms φ_π in π,

$$\mathcal{L}(\varphi_\pi, f_{\tau_s,\rho}) = \int_{G_F\backslash G_{\mathbb{A}}} \varphi_\pi(g) E^{\psi,G}(g, f_{\tau_s,\rho})\, dg. \tag{1.1}$$

In case (ii) we apply to φ_π a Fourier coefficient of Gelfand–Graev type stabilized by H, and pair it with $E(h, f_{\tau_s,\rho})$,

$$\mathcal{L}(\varphi_\pi, f_{\tau_s,\rho}) = \int_{H_F\backslash H_{\mathbb{A}}} \varphi_\pi^{\psi,H}(h) E(h, f_{\tau_s,\rho})\, dh. \tag{1.2}$$

For the general notion of a Fourier coefficient of Gelfand–Graev type see [29]. The integrals above, in this generality, appear in [9] for orthogonal groups. See also [34]. These integrals are meromorphic in the whole plane, and their poles are included in the set of poles of the Eisenstein series involved. They can be unwinded for $\mathrm{Re}(s) \gg 0$ and can be shown to depend, through an inner integration, on an invariant bilinear pairing $b_{\pi,\rho}(\varphi_\pi, \varphi_\rho)$, where, in cases (i) and (ii),

$$b_{\pi,\rho}(\varphi_\pi, \varphi_\rho) = \int_{G'_F\backslash G'_{\mathbb{A}}} \varphi_\pi^{\psi,G'}(g)\varphi_\rho(g)\, dg, \tag{1.3}$$

and, in case (iii),

$$b_{\pi,\rho}(\varphi_\pi, \varphi_\rho) = \int_{H_F \backslash H_{\mathbb{A}}} \varphi_\pi(h) \varphi_\rho^{\psi, G}(h)\, dh. \tag{1.4}$$

In particular, if $b_{\pi,\rho}(\varphi_\pi, \varphi_\rho) = 0$ (identically), then the integrals (1.1), (1.2) are (identically) zero. The integrals above have easy variants when G, G' are special orthogonal groups.

b. Let now (V, b), (V', b') be symplectic spaces over F, and let X_j be a symplectic space of dimension $2j$ over F with two transversal Lagrangians $X_j^{\pm}$. Let $W = X_n \oplus V'$. Let G, G', H be the symplectic groups of V, V', W, respectively. Let P be the parabolic subgroup of H which preserves X_n^+. Denote by $\tilde{H}_{\mathbb{A}}$ the metaplectic cover of $H_{\mathbb{A}}$, and similarly for G, G'. Let π, ρ, τ be irreducible, automorphic, cuspidal representations of $G_{\mathbb{A}}$, $\tilde{G}'_{\mathbb{A}}$, $\mathrm{GL}_n(\mathbb{A})$, respectively. We assume that ρ is genuine. Consider the Eisenstein series $E(h, f_{\tau_s,\rho})$ on $\tilde{H}_{\mathbb{A}}$ corresponding to parabolic induction from $\tau_s \otimes \rho$ (we have to multiply τ_s by a Weil factor corresponding to ψ). Now we can either apply a Fourier–Jacobi coefficient, stabilized by G, to the Eisenstein series and pair it, as above, along $G_F \backslash G_{\mathbb{A}}$ with cusp forms φ_π, or apply such a coefficient, stabilized by H, to φ_π and pair it along $H_F \backslash H_{\mathbb{A}}$ with the Eisenstein series. In this way we get global integrals $\mathcal{L}(\varphi_\pi, \phi, f_{\tau_s,\rho})$; here ϕ is a Schwartz function in the space of the Weil representation, which occurs in the Fourier–Jacobi coefficients above. As before these integrals are meromorphic, can be unwinded, and depend through inner integrations on invariant bilinear pairings, which define a Fourier–Jacobi model of π with respect to ρ or vice-versa. Similar integrals can be written for π on $\tilde{G}_{\mathbb{A}}$, ρ on $G'_{\mathbb{A}}$, and τ as before (with $H_{\mathbb{A}}$ instead of $\tilde{H}_{\mathbb{A}}$). Finally, similar integrals can also be written when (V, b), (V', b') are Hermitian spaces over F. For more details see [29], [15], [34].

c. Two extreme cases

1. Assume that G is trivial. Also assume that when b' is symmetric, then G' is a special orthogonal group. Then, in all cases above, one can see that G' must be quasi-split, and the global integrals above are nothing but applications of a Whittaker coefficient to the Eisenstein series $E(h, f_{\tau_s,\rho})$, and using (1.4) and its analog in (b) above, we see that (for the global integrals to be non-trivial) ρ must be globally generic. This is the well-known Langlands–Shahidi method. It is worked out in a long series of papers (see [7] for a survey) by Shahidi and constitutes a beautiful chapter in mathematics. In particular, he established the complete theory of the standard L-functions $L(\rho \times \tau, s)$ (except the metaplectic case) and of $L(\tau, \wedge^2, s)$, $L(\tau, \mathrm{sym}^2, s)$, $L(\tau, \mathrm{Asai}, s)$. Together with the converse theorem of Cogdell and Piatetski–Shapiro [3] it yields the existence of the weak functorial lift from cuspidal generic representations of $G'_{\mathbb{A}}$ to automorphic representations of $\mathrm{GL}_N(\mathbb{A}_E)$ (appropriate N) [1], [2], [26].

2. Assume that G' is trivial. Also assume that when b is symmetric, then G is a special orthogonal group. Then the Levi part of the parabolic subgroup P is isomorphic to $\mathrm{Res}_{E/F}\,\mathrm{GL}_n$. The global integrals, in this case, were studied by many authors; see, for example, [8], [15], [6], [34], [35], [36]. As before, using (1.3) and its analog in (b) above, we see that π must be generic (or else, the global integrals are trivial). These integrals yield (up to a controllable factor) the quotient of the partial L-function $L^S(\pi \times \tau, s)$ by the following denominator. It is $L^S(\tau, r_G, 2s)$, by which we mean $L^S(\tau, \wedge^2, 2s)$ (G odd orthogonal), or $L^S(\tau, \mathrm{sym}^2, 2s)$ (G even orthogonal or symplectic), or $L^S(\tau, \mathrm{Asai}, 2s)$ (G odd unitary); it is $L^S\big(\tau, s+\frac{1}{2}\big)L^S(\tau, \wedge^2, 2s)$ if π is on a metaplectic group, and finally, if G is even unitary, the denominator is the partial Asai L-function of τ at $2s$, but in this case the numerator is $L^S(\pi \times \tau\gamma^{-1}, s)$, where we twist τ by a character γ^{-1}, which enters in the choice of the Weil representation defining the Fourier–Jacobi coefficient in this case. We remark that in the metaplectic case $L^S(\pi \times \tau, s)$ depends also on ψ. The descent method of Ginzburg, Rallis and Soudry is derived when we analyze the existence of a pole at $s = 1$ for the global integrals $\mathcal{L}(\varphi_\pi, f_{\tau_s})$, $\mathcal{L}(\varphi_\pi, \phi, f_{\tau_s})$. The descent method allows us to give a complete description of the image of the weak functorial lift from cuspidal generic representations of $G_{\mathbb{A}}$ to $\mathrm{GL}_N(\mathbb{A}_E)$, to prove the existence and give a description of endoscopic lifts to G (from generic cuspidal representations), to obtain a full local Langlands reciprocity law for generic representations of SO_{2n+1} (joint work with D. Jiang), and much more. I survey some of these applications in the next section.

The general case (G, G' non-trivial) was considered mainly for orthogonal groups in [9], where it is shown that the integrals $\mathcal{L}(\varphi_\pi, f_{\tau_s,\rho})$ yield the quotient

$$\frac{L^S(\pi \times \tau, s)}{L^S\big(\rho \times \tau, s+\frac{1}{2}\big)L^S(\tau, r, 2s)},$$

where $r = r_G = \wedge^2$ or sym^2, depending on G. See also [4] for local analogs in case $m < m'$.

In the third section, I report on the progress in a joint work with S. Rallis towards the existence of a weak functorial lift of cuspidal (not necessarily generic) representations of $\mathrm{SO}_m(\mathbb{A})$ to $\mathrm{GL}_{2[\frac{m}{2}]}(\mathbb{A})$.

2. The descent method and applications

We retain the notation from part c.2 of the previous section. So we have to assume that π is (globally) generic. We assume for simplicity that if G is even (special) orthogonal, then it is split. We also assume, as we may, that τ is unitary such that its central character ω_τ is trivial on the positive real numbers, embedded diagonally at all archimedean primes in the Idele group. The material in Section 2.1–2.3 is part of a long-term joint work with Ginzburg and Rallis [10]–[14], [34].

2.1.

Theorem 2.1. *$L^S(\pi \times \tau, s)$ is holomorphic for* $\mathrm{Re}(s) > 1$ *except when $n = 1$, τ is trivial, and π is on a metaplectic group; in this case the only such pole may occur at $s = \frac{3}{2}$. If $L^S(\pi \times \tau, s)$ has a pole at s_0 with* $\mathrm{Re}(s_0) = 1$, *then $s_0 = 1$. In this case $L^S(\tau, r_G, s)$ has a pole at $s = 1$, when G is orthogonal, symplectic, or odd unitary; if π is on a metaplectic group, then $L^S(\tau, \wedge^2, s)$ has a pole at $s = 1$ and $L\left(\tau, \frac{1}{2}\right) \neq 0$. Finally, if G is even unitary, then $L^S(\hat{\tau} \times \gamma, \mathrm{Asai}, s)$ has a pole at $s = 1$.*

This follows from the fact that the analysis of poles of the integrals $\mathcal{L}(\varphi_\pi, f_{\tau_s})$, $\mathcal{L}(\varphi_\pi, \phi, f_{\tau_s})$ reduces to that of the Eisenstein series $E(h, f_{\tau_s})$ induced from τ.

In a similar way we get that if τ is the (standard) weak functorial lift of π, then τ is self-conjugate, and its central character is trivial on $\mathbb{A}^* = \mathbb{A}_F^*$, and the results of Theorem 2.1 hold for τ. The reason for this is that $L^S(\pi \times \hat{\tau}, s)$ has a pole at $s = 1$. Moreover, for the residue of the global integrals at $s = 1$ to be non-trivial, the L^2-pairing between π and $\mathrm{Span}\{\mathrm{Res}_{s=1} E^{\psi^{-1}, G}(\cdot, f_{\tilde{\tau}_s \gamma})_{|G_{\mathbb{A}}}\} := \sigma_\psi(\tau)$ is non-trivial; in case π is on a metaplectic group, then, in the definition of $\sigma_\psi(\tau)$, we have to take restrictions to $\tilde{G}_{\mathbb{A}}$. Here γ is trivial except when G is even unitary. Note also that starting with τ, G (resp. $\tilde{G}$) is determined by n and the precise data about the pole at $s = 1$ related to τ. We keep all this implicit in the notation $\sigma_\psi(\tau)$. One of our main theorems is

Theorem 2.2. *Let τ be an irreducible, automorphic, cuspidal representation of* $\mathrm{GL}_n(\mathbb{A}_E)$ *such that ω_τ is trivial on $\mathbb{A}^*$. Assume that the results of Theorem* 2.1 *about the pole at $s = 1$ are satisfied for τ. Then $\sigma_\psi(\tau)$ is a non-trivial, automorphic, cuspidal, multiplicity free representation of $G_{\mathbb{A}}$ (respectively of $\tilde{G}_{\mathbb{A}}$ if H is symplectic). All irreducible summands of $\sigma_\psi(\tau)$ are (ψ-)generic and lift at almost all finite places to τ. Each such representation has a non-trivial L^2-pairing with $\sigma_\psi(\tau)$.*

2.2. We call $\sigma_\psi(\tau)$, for τ as in the last theorem, the descent of τ to G (resp. to $\tilde{G}$). Theorem 2.2 describes the cuspidal part of the weak functorial lift from generic cuspidal representations on G (resp. $\tilde{G}$) to GL_n, without knowing that such a lift exists in the sense that we know which cuspidal τ can occur in the image, and moreover, we do construct in a direct manner for such τ irreducible, cuspidal, (ψ-)generic representations which lift to τ; these are the summands of $\sigma_\psi(\tau)$.

When we analyze non-cuspidal τ on $\mathrm{GL}_n(\mathbb{A})$ which may be obtained as a weak lift from cuspidal generic representations of $G_{\mathbb{A}}$ (resp. a metaplectic group), we get that the central character of τ is trivial on $\mathbb{A}^*$, and, by successive applications of Theorem 2.1, we get that, except in the metaplectic case, τ must have the form $\tau = \tau_1 \times \cdots \times \tau_l$, where the τ_i are pairwise inequivalent, irreducible, unitary, self-conjugate automorphic representations of $\mathrm{GL}_{n_i}(\mathbb{A}_E)$, cuspidal when $n_i > 1$; each one satisfying the results of Theorem 2.1 about the pole at $s = 1$. In the metaplectic case τ may also have the form above, with an added "tail" of the form $|\cdot|^{\frac{1}{2}} \times |\cdot|^{-\frac{1}{2}}$.

Thus, for such τ, except in the last case, we form $\sigma_\psi(\tau)$ as before by replacing the residue of the Eisenstein series at $s = 1$, with the multi-residue at $(1, \dots, 1)$ of the Eisenstein series induced from $\tau_{1,s_1} \times \cdots \times \tau_{l,s_l}$. We prove

Theorem 2.3. *Let τ be an irreducible automorphic representation of $\mathrm{GL}_n(\mathbb{A}_E)$ as in the last paragraph (except the additional possibility in the metaplectic case). Then $\sigma_\psi(\tau)$ satisfies the conclusions of Theorem 2.2.*

Again, the descent $\sigma_\psi(\tau)$ of τ constructs cuspidal, generic representations of $G_\mathbb{A}$ (resp. $\tilde{G}_\mathbb{A}$) which lift to τ. Since all cuspidal, generic representations of $G_\mathbb{A}$ do lift to $\mathrm{GL}_n(\mathbb{A}_E)$, by [2] (recall again that n and G are related) we get the description of the image of this lift and that the descent is an explicit inverse map of this lift to the set of near equivalence classes of irreducible, cuspidal, generic representations of $G_\mathbb{A}$. Moreover, since each factor τ_i of τ, as above, satisfies the assumptions of Theorem 2.2, it determines a corresponding group G_i (or $\tilde{G}_i$) and a cuspidal, generic representation on it, π_i, which lifts to τ_i. Thus we establish the endoscopic lift from cuspidal, generic representations on $G_{1,\mathbb{A}} \times \cdots \times G_{l,\mathbb{A}}$ to automorphic representations on $G_\mathbb{A}$. In particular, if τ is non-cuspidal and in the image of the weak lift above, say, lifted from π (cuspidal, generic), then π is in the image of an endoscopic lift which can be described precisely.

Example. Let $G = \mathrm{Sp}_{2k}$ or SO_{2k} (split). In the first case $n = 2k + 1$, and in the second case $n = 2k$. Let π be an irreducible, automorphic, cuspidal, generic representation of $G_\mathbb{A}$. Assume that the lift τ of π to $\mathrm{GL}_n(\mathbb{A})$ is non-cuspidal. Then $\tau = \tau_1 \times \cdots \times \tau_l$, as above. Assume, for simplicity, that all $\omega_{\tau_i} = 1$. Then all partial L-functions $L^S(\tau_i, \mathrm{sym}^2, s)$ have a pole at $s = 1$. Let $G_i = \mathrm{Sp}_{2k_i}$ if $n_i = 2k_i + 1$ is odd, and $G_i = \mathrm{SO}_{2k_i}$ (split) if $n_i = 2k_i$ is even; $n = n_1 + \cdots + n_l$. Let π_i be an irreducible summand of the descent $\sigma_\psi(\tau_i)$ to G_i. Then π is a weak (generalized endoscopic) lift of $\pi_1 \otimes \cdots \otimes \pi_l$ from $G_1 \times \cdots \times G_l$.

2.3. The descent has a local analog, which was developed in [11], [12] for the target group $\tilde{G} = \tilde{\mathrm{Sp}}_{2k}$. We proved

Theorem 2.4. *Let K be a local non-archimedean field of characteristic zero. Let $\tau_1, \dots, \tau_l$ be pairwise inequivalent, irreducible, supercuspidal representations of $\mathrm{GL}_{2k_1}(K), \dots, \mathrm{GL}_{2k_l}(K)$, respectively, such that each local L-function $L(\tau_i, \wedge^2, s)$ has a pole at $s = 0$. Let $\tau = \tau_1 \times \cdots \times \tau_l$ be the corresponding parabolic induction to $\mathrm{GL}_{2k}(K)$, where $k = k_1 + \cdots + k_l$. Then there is a unique (up to isomorphism) irreducible, supercuspidal, ψ-generic representation π of $\tilde{\mathrm{Sp}}_{2k}(K)$ such that the local gamma factor $\gamma(\pi \times \tau, s, \psi)$ has a pole of order l at $s = 1$. The representation π is obtained by a local analogue, applied to τ, of the descent construction.*

For the local analogue of the descent construction, we induce, as in the global set-up, $\tau = \tau_{1,s_1} \times \cdots \times \tau_{l,s_l}$ at the point $s_1 = \cdots = s_l = 1$ from the Siegel parabolic subgroup P to $H = \mathrm{Sp}_{4k}(K)$, and we consider the corresponding Langlands quotient,

call it e_τ; this is the analogue to the multi-residue at $(1, \dots 1)$ of the Eisenstein series in the global case. Then we apply to e_τ a Jacquet module, analogous to the Fourier–Jacobi coefficient, that we apply in the global case to the multi-residue of the Eisenstein series.

2.4. The local descent from $\mathrm{GL}_{2k}(K)$ to $\mathrm{SO}_{2k+1}(K)$ yields powerful results, among which are the local converse theorem for generic representations of $\mathrm{SO}_{2k+1}(K)$, a full local Langlands reciprocity law for generic representations of $\mathrm{SO}_{2k+1}(K)$, a rigidity property (strong multiplicity one, up to isomorphism) of irreducible, cuspidal generic representations of $\mathrm{SO}_{2k+1}(\mathbb{A})$, and more.... These are results of my joint work with D. Jiang and can all be found in [23], [24]. I survey this work in this subsection.

Consider the representations τ and π as in Theorem 2.4. Using the local Howe duality from $\tilde{\mathrm{Sp}}_{2k}(K)$ to $\mathrm{SO}_{2k+1}(K)$, we lift π to an irreducible, supercuspidal, generic representation σ of $\mathrm{SO}_{2k+1}(K)$. It is unique, up to isomorphism, with the property that the local gamma factor $\gamma(\sigma \times \tau, s, \psi)$ has a pole of order l at $s = 1$. Using the existence of the weak lift of [1] we prove

Theorem 2.5 (The local converse theorem). *Let σ and σ' be two irreducible generic representations of $\mathrm{SO}_{2k+1}(K)$ such that, for all $j < 2k$ and all irreducible generic representations ρ of $\mathrm{GL}_j(K)$,*

$$\gamma(\sigma \times \rho, s, \psi) = \gamma(\sigma' \times \rho, s, \psi).$$

Then σ and σ' are isomorphic.

The idea is to reduce the proof to supercuspidal representations σ and σ', lift them locally to $\mathrm{GL}_{2k}(K)$, and use Henniart's local converse theorem for $\mathrm{GL}_n(K)$ [18] to conclude that both representations lift to the same representation τ of $\mathrm{GL}_{2k}(K)$. We prove that τ has the form as in Theorem 2.4, and then we conclude that both gamma factors of σ, twisted by τ, and of σ', twisted by τ, have a pole of order l at $s = 1$. Using the uniqueness mentioned in the last paragraph, we conclude that σ and σ' are isomorphic. As a result from this we prove

Theorem 2.6. *There is a one-to-one correspondence t between the isomorphism classes of irreducible, supercuspidal, generic representations of $\mathrm{SO}_{2k+1}(K)$ and the isomorphism classes of irreducible, generic representations of $\mathrm{GL}_{2k}(K)$, as in Theorem 2.4, such that if $\tau = t(\sigma)$, then for all irreducible generic representations ρ of $\mathrm{GL}_j(K)$, $j > 0$,*

$$\begin{aligned} \gamma(\sigma \times \rho, s, \psi) &= \gamma(\tau \times \rho, s, \psi), \\ L(\sigma \times \rho, s) &= L(\tau \times \rho, s). \end{aligned} \tag{2.1}$$

See [2] for partial results for the other groups G. Let us outline some applications.

Theorem 2.7 (Rigidity theorem). *Let σ and σ' be two irreducible, automorphic, cuspidal, generic representations of $\mathrm{SO}_{2k+1}(\mathbb{A})$ which are isomorphic, at almost all*

unramified places. Then σ and σ' are isomorphic. In particular, the weak lift from cuspidal, generic representations of $\mathrm{SO}_{2k+1}(\mathbb{A})$ *to* $\mathrm{GL}_{2k}(\mathbb{A})$ *is injective.*

The point is that, by the strong multiplicity one theorem of Jacquet and Shalika [21] for GL_n, we know that both σ and σ' lift, following [1], to the same automorphic representation τ on $\mathrm{GL}_{2k}(\mathbb{A})$. Now it follows from [1], p. 26, that all twisted local gamma factors of our two representations are the same at all finite places and hence, by Theorem 2.6, they are isomorphic at all finite places. Since the local lift is already prescribed at the archimedean places, σ and σ' are isomorphic at all places. From Theorem 2.6 we derive

Theorem 2.8. *Let τ be in the domain of the descent map σ_ψ from* GL_{2k} *to* SO_{2k+1}. *Then $\sigma_\psi(\tau)$ is irreducible.*

This follows from the fact that $\sigma_\psi(\tau)$ is multiplicity free and all its summands are cuspidal, generic and nearly equivalent, and hence by the rigidity theorem they are all isomorphic and we conclude that $\sigma_\psi(\tau)$ is irreducible.

Let us return to Theorem 2.5. Using the local Langlands reciprocity law for $\mathrm{GL}_n(K)$ proved by Harris–Taylor [17] and Henniart [19], and a theorem of Henniart on the compatibility of the exterior square local L and ε-factors for $\mathrm{GL}_n(K)$ with their corresponding local exterior square Artin factors [20], we obtain

Theorem 2.9. *There exists a unique bijection, preserving twisted ε-factors, between the conjugacy classes of $2k$-dimensional admissible, absolutely irreducible, multiplicity free symplectic representations of the Weil group W_K of K and the isomorphism classes of irreducible, supercuspidal, generic representations of* $\mathrm{SO}_{2k+1}(K)$.

In [24] we extend Theorem 2.8 to a full local Langlands reciprocity law, using Muić's description of all generic representations of $\mathrm{SO}_{2k+1}(K)$ [30].

Theorem 2.10. *For each local Langlands parameter φ of* $\mathrm{SO}_{2k+1}(K)$ (*i.e. a conjugacy class of admissible homomorphisms from $W_K \times \mathrm{SL}_2(\mathbb{C})$ to* $\mathrm{Sp}_{2k}(\mathbb{C})$), *there is a unique, up to isomorphism, irreducible representation $\sigma(\varphi)$ of* $\mathrm{SO}_{2k+1}(K)$ *which is the Langlands subquotient of a parabolic induction of the form $\Sigma(\varphi) = \delta(\Sigma_1) \times \cdots \times \delta(\Sigma_f) \rtimes \sigma^{(t)}$, where $\sigma^{(t)}$ is tempered generic* (*on appropriate* $\mathrm{SO}_{2k'+1}(K)$) *and $\delta(\Sigma_i)$ is an essentially square integrable representation of* $\mathrm{GL}_{n_i}(K)$ *associated to an imbalanced segment Σ_i* (*in the sense of* [37]). *The map $\varphi \mapsto \sigma(\varphi)$ preserves local twisted L and ε-factors. Moreover, $\sigma(\varphi)$ is generic if and only if $\Sigma(\varphi)$ is irreducible.*

As a corollary, we get that, for each tempered local Langlands parameter φ for $\mathrm{SO}_{2k+1}(K)$, the representation $\sigma(\varphi)$ is generic; it will eventually be "the generic member of the tempered local L-packet $\prod(\varphi)$". This is the case of SO_{2k+1} of a conjecture of Shahidi [33]. We also get, as another corollary, a conjecture of Gross–Prasad [16] and of Rallis [27] for $\mathrm{SO}_{2k+1}(K)$.

Theorem 2.11. *With notation as above, $\sigma(\varphi)$ is generic if and only if the local adjoint L-function $L(\mathrm{Ad}_{\mathrm{Sp}_{2k}} \circ \varphi, s)$ is regular at $s = 1$.*

Finally, we get the following applications to automorphic representations.

Theorem 2.12. 1. *Let τ be an irreducible, automorphic, cuspidal representation of* $\mathrm{GL}_{2k}(\mathbb{A})$ *such that $L(\tau, \wedge^2, s)$ has a pole at $s = 1$. Then the local components τ_v are symplectic at all places v.*

2. *The weak lift from irreducible, automorphic, cuspidal, generic representations of* $\mathrm{SO}_{2k+1}(\mathbb{A})$ *to automorphic representations of* $\mathrm{GL}_{2k}(\mathbb{A})$ *is compatible with the local Langlands functorial lift at all places.*

3. *L*-functions for orthogonal groups; non-generic representations

In this section I report on a joint work in progress with S. Rallis towards establishing the existence of a weak functorial lift from irreducible, automorphic, cuspidal representations on a split special orthogonal group, $G_m = \mathrm{SO}_m$ (regarded over F) in m variables, to $\mathrm{GL}_{2[\frac{m}{2}]}$.

Let π be an irreducible, automorphic, cuspidal representation of $G_m(\mathbb{A})$. Consider the Fourier coefficients of Gelfand–Graev type of the form φ_π^{ψ, G'_i} as in Section 1.a, where $G'_i = G_{m-2i-1}$ and φ_π varies in the space of π. These generate, upon restriction to $G'_i(\mathbb{A})$, a space of automorphic functions on $G'_i(\mathbb{A})$, which is invariant to right translations by $G'_i(\mathbb{A})$; denote this space by π^{ψ, G'_i}. Note that the last space is non-trivial for $i = 0$, and if it is non-trivial for $i = \left[\frac{m-1}{2}\right]$, then π is generic. Otherwise let i_1 be the largest index such that $\pi^{\psi, G'_{i_1}}$ is non-trivial. We prove that $\pi^{\psi, G'_{i_1}}$ is cuspidal on $G'_{i_1}(\mathbb{A})$. Choose an irreducible, cuspidal summand of $\pi^{\psi, G'_{i_1}}$ and let ρ_0 be its conjugate representation. Then the $G'_{i_1}(\mathbb{A})$-invariant bilinear pairing $b_{\pi,\rho_0}(\varphi_\pi, \varphi_{\rho_0})$ in (1.3) is non-trivial. We may consider the integrals of the form (1.2),

$$\int_{G_{m-1}(F)\backslash G_{m-1}(\mathbb{A})} \varphi_\pi(g) E(g, f_{s_1,\ldots,s_{i_1};\rho_0})\, dg, \tag{3.1}$$

where $E(g, f_{s_1,\ldots,s_{i_1};\rho_0})$ is an Eisenstein series on $G_{m-1}(\mathbb{A})$ corresponding to the parabolic induction from $|\cdot|^{s_1} \otimes \cdots \otimes |\cdot|^{s_{i_1}} \otimes \rho_0$ on the parabolic subgroup P_1 whose Levi part is isomorphic to $\mathrm{GL}_1^{i_1} \times G_{m-2i_1-1}$. (The difference from (1.2) is that the cuspidal representation τ on GL_{i_1} is replaced by the Eisenstein series induced from the Borel subgroup and its character $|\cdot|^{s_1} \otimes \cdots \otimes |\cdot|^{s_{i_1}}$.) The methods of [9] apply here, as well, and (3.1) is non-trivial and meromorphic. Let us choose and fix $s_1, \ldots, s_{i_1}$ purely imaginary such that (3.1) is non-trivial and $\mathrm{Ind}_{P_1(\mathbb{A})}^{G_{m-1}(\mathbb{A})} |\cdot|^{s_1} \otimes \cdots \otimes |\cdot|^{s_{i_1}} \otimes \rho_0$ is in general position. Denote by ρ the automorphic representation of $G_{m-1}(\mathbb{A})$ generated by the Eisenstein series corresponding to this induced representation. Denote

$$b_{\pi,\rho}(\varphi_\pi, \xi_\rho) = \int_{G_{m-1}(F)\backslash G_{m-1}(\mathbb{A})} \varphi_\pi(g)\xi_\rho(g)\, dg, \tag{3.2}$$

where ξ_ρ is in the space of ρ. Let τ be an irreducible, automorphic, cuspidal representation of $\mathrm{GL}_n(\mathbb{A})$. We consider the integrals (1.1) $\mathcal{L}(\varphi_\pi, f_{\tau_s,\rho})$, even when $i_1 > 0$, in which case ρ is not cuspidal. The methods of [9] still apply, and so we have, for $\mathrm{Re}(s) \gg 0$, the following "Eulerian" expression

$$\mathcal{L}(\varphi_\pi, f_{\tau_s,\rho}) = \int_{G_{m-1}(\mathbb{A})\backslash G_m(\mathbb{A})} \int_{U'_{\mathbb{A}}} b_{\pi,\rho}(\pi(g)\varphi_\pi, f_{\tau_s,\rho}(ug))\psi_{U'}(u)\,du dg, \quad (3.3)$$

where U' is a certain F-unipotent subgroup and $\psi_{U'}$ is a certain character of $U'(\mathbb{A})$, trivial on $U'(F)$. We can find data such that

$$\mathcal{L}(\varphi_\pi, f_{\tau_s,\rho}) = \mathcal{L}_{S_\infty}(\varphi_\pi, f_{\tau_s,\rho}) \frac{L^Z(\pi \times \tau, s)}{L^Z\left(\rho \times \tau, s + \frac{1}{2}\right) L^Z(\tau, r, 2s)}, \quad (3.4)$$

where Z is any finite set of places, including those at infinity, outside which π, ρ_0, τ are all unramified; $r = \wedge^2$ (resp. sym^2) if m is odd (resp. m is even). We denote by S_∞ the set of archimedean primes. $\mathcal{L}_{S_\infty}(\varphi_\pi, f_{\tau_s,\rho})$ is the integral, as in the right-hand side of (3.3), where we replace $\mathbb{A}$ by $\mathbb{A}_{S_\infty}$; it can be chosen to be holomorphic and non-zero at any given point s_0. Fix a finite set of finite places S such that π, ρ_0 are unramified outside $S_\infty \cup S$.

Let τ belong to the twisting set $\mathcal{T}(S, \chi)$ of the converse theorem [3], i.e. χ is a character of $F^*\backslash\mathbb{A}^*$ such that at the places ν of S, χ_ν is highly ramified, and τ_ν is χ_ν times an unramified representation.

Let us define now the (standard) local factors $L(\pi_\nu \times \tau_\nu, s)$ and $\gamma(\pi_\nu \times \tau_\nu, s, \psi_\nu)$ at all places. Let S_τ be a finite set of finite places disjoint from S such that τ is unramified outside $S' = S_\infty \cup S \cup S_\tau$. The definition of the local factors is clear outside S' via the unramified parameters. At the places of S_τ the definition is by multiplicativity of the local factors in the first variable π which is unramified, where for a character μ the local factors for $\mu \times \tau$ are the ones for GL_n. At the places of S we define $L(\pi_\nu \times \tau_\nu, s) = 1$, and we define the local gamma factor by multiplicativity in the second variable τ which is induced from the Borel subgroup, and for a character μ we define $\gamma(\pi_\nu \times \mu, s, \psi_\nu)$ by the doubling method [31], [28]. Finally, at S_∞ we define the local factors through the Langlands classification. We have similar definitions of local factors for $\rho \times \tau$. Denote by $\mathcal{T}_0(S, \chi)$ the subset of elements τ of $\mathcal{T}(S, \chi)$ which are unitary, with central character, which is trivial on the positive real numbers and diagonally embedded inside $\mathbb{A}^*_{S_\infty}$. We prove:

Theorem 3.1. *For $\tau \in \mathcal{T}_0(S, \chi)$, $L^{S_\infty}(\pi \times \tau, s)$ is holomorphic for* $\mathrm{Re}(s) \geq \frac{1}{2}$.

Indeed, taking the (highly ramified at S) character χ as in [1], p. 12, we get that τ is not self-dual, and we conclude as in loc. cit. that $\mathcal{L}(\varphi_\pi, f_{\tau_s,\rho})$ is holomorphic for $\mathrm{Re}(s) \geq \frac{1}{2}$. As in (3.4) we obtain that

$$\mathcal{L}_{S'}(\varphi_\pi, f_{\tau_s,\rho}) \frac{L^{S'}(\pi \times \tau, s)}{L^{S'}\left(\rho \times \tau, s + \frac{1}{2}\right) L^{S'}(\tau, r, 2s)}$$

is holomorphic for $\mathrm{Re}(s) \geq \frac{1}{2}$. Here $\mathcal{L}_{S'}$ is as in the right-hand side of (3.3), with $\mathbb{A}$ replaced by $\mathbb{A}_{S'}$. Next we can find data such that

$$\mathcal{L}_{S'}(\varphi_\pi, f_{\tau_s,\rho}) = \mathcal{L}_{S_\infty \cup S}(\varphi_\pi, f_{\tau_s,\rho}) \prod_{\nu \in S_\tau} \frac{L(\pi_\nu \times \tau_\nu, s)}{L\big(\rho_\nu \times \tau_\nu, s + \frac{1}{2}\big) L(\tau_\nu, r, 2s)}. \tag{3.5}$$

Finally we can find data such that $\mathcal{L}_{S_\infty \cup S}(\varphi_\pi, f_{\tau_s,\rho}) = \mathcal{L}_{S_\infty}(\varphi_\pi, f_{\tau_s,\rho})$. Thus, $\frac{L^{S_\infty}(\pi \times \tau, s)}{L^{S_\infty}(\rho \times \tau, s+\frac{1}{2}) L^{S_\infty}(\tau, r, 2s)}$ is holomorphic, for $\mathrm{Re}(s) \geq \frac{1}{2}$. Since $L^{S_\infty}(\tau, r, 2s)$ is holomorphic for $\mathrm{Re}(2s) \geq 1$, we conclude that $\frac{L^{S_\infty}(\pi \times \tau, s)}{L^{S_\infty}(\rho \times \tau, s+\frac{1}{2})}$ is holomorphic for $\mathrm{Re}(s) \geq \frac{1}{2}$. By induction on m, $L^{S_\infty}(\rho \times \tau, s + \frac{1}{2})$ is holomorphic for $\mathrm{Re}(s) \geq \frac{1}{2}$, and hence so is $L^{S_\infty}(\pi \times \tau, s)$. Note that S can be enlarged so that the process above can be repeated for a finite sequence $\pi, \rho_0, \rho_1, \ldots, \rho_l$ of irreducible cuspidal representations of $G_m(\mathbb{A}), G_{m-2i_1-1}(\mathbb{A}), G_{m-2(i_1+i_2)-2}(\mathbb{A}), \ldots$ such that they are all unramified outside $S_\infty \cup S$ and ρ_i appears in the space of Gelfand–Graev coefficients of ρ_{i-1}. The basic case of induction is when π is generic, and then the theorem is known by [1].

Let M be the intertwining operator corresponding to a Weyl element of $H = G_{2n+m-1}$, which flips X_n^+ and X_n^-. Then we have a functional equation

$$\mathcal{L}(\varphi_\pi, f_{\tau_s,\rho}) = \mathcal{L}(\varphi_\pi, M(f_{\tau_s,\rho})),$$

which unfolds to

$$\begin{aligned} &\mathcal{L}_{S_\infty \cup S}(\varphi_\pi, f_{\tau_s,\rho}) \prod_{\nu \in S_\tau} \mathcal{L}_\nu(\varphi_\pi, f_{\tau_s,\rho}) L^{S'}(\pi \times \tau, s) \\ &\qquad = \tilde{\mathcal{L}}_{S_\infty \cup S}(\varphi_\pi, M_{S_\infty \cup S}(f_{\tau_s,\rho})) \prod_{\nu \in S_\tau} \tilde{\mathcal{L}}_\nu(\varphi_\pi, M_\nu(f_{\tau_s,\rho})) \\ &\qquad\quad \cdot \frac{L^{S'}\big(\rho \times \tau, s - \frac{1}{2}\big) L^{S'}(\tau, r, 2s-1)}{L^{S'}\big(\rho \times \hat{\tau}, \frac{3}{2} - s\big) L^{S'}(\hat{\tau}, r, 2-2s)} L^{S'}(\pi \times \hat{\tau}, 1-s), \end{aligned} \tag{3.6}$$

where at the places $\nu \in S_\tau$, $\mathcal{L}_\nu$ are local analogs of the right-hand side of (3.3) and $\tilde{\mathcal{L}}_\nu$ are obtained from these after a slight modification. Here we use the uniqueness theorem of [25]; for unramified representations π_ν, ρ_ν the space $\mathrm{Hom}_{G_{m-1}(F_\nu)}(\pi_\nu, \hat{\rho}_\nu)$ is one-dimensional. Recall that π_ν and ρ_ν are unramified for $\nu \in S_\tau$. Using this result again, we also prove a local functional equation and compute the proportionality factor at the places of S_τ.

Theorem 3.2. *For $\nu \in S_\tau$ we have*

$$\frac{\gamma(\pi_\nu \times \tau_\nu, s, \psi_\nu)}{\gamma\big(\rho_\nu \times \tau_\nu, s - \frac{1}{2}, \psi_\nu\big) \gamma(\tau_\nu, r, 2s-1, \psi_\nu)} \mathcal{L}_\nu(\varphi_\pi, f_{\tau_s,\rho}) = \tilde{\mathcal{L}}_\nu(\varphi_\pi, M_\nu(f_{\tau_s,\rho})). \tag{3.7}$$

Note that all the local gamma factors in the left-hand side of (3.7) are well defined. We can also prove (3.7) for the places of S, but we prove it as an identity for each local pairing $b_\nu \in \mathrm{Hom}_{G_{m-1}(F_\nu)}(\pi_\nu \otimes \rho_\nu, 1)$, and local integrals $\mathcal{L}_\nu$, and $\tilde{\mathcal{L}}_\nu$, defined using this pairing b_ν. The point is that at S the representation τ is induced from the Borel subgroup, and we have a way to factorize the local integrals, "one GL_1-twist at a time", and then relate the local integrals above for $G_m \times \mathrm{GL}_1$ to the local integrals arising in the doubling method. Thus we get

$$\begin{aligned}\prod_{\nu\in S} \frac{\gamma(\pi_\nu \times \tau_\nu, s, \psi_\nu)}{\gamma\big(\rho_\nu \times \tau_\nu, s-\frac{1}{2}, \psi_\nu\big)\gamma(\tau_\nu, r, 2s-1, \psi_\nu)} \mathcal{L}_{S_\infty \cup S}(\varphi_\pi, f_{\tau_s,\rho}) \\ = \mathcal{L}^{\sim}_{S_\infty \cup S}(\varphi_\pi, M_S(f_{\tau_s,\rho})).\end{aligned} \tag{3.8}$$

Here $\mathcal{L}^{\sim}$ refers to the modification $\sim$ taking place only at S. Note again that all local gamma factors which appear in the left-hand side of (3.8) are well defined. The formal steps of the proof of (3.8) carry on for S_∞ as well. They yield, in the left-hand side of (3.8), the product over all of $S_\infty \cup S$, where, in the case of S_∞, the local factors are the corresponding Artin local gamma factors, and in the right-hand side of (3.8) we have to replace M_S by $M_{S_\infty \cup S}$ and $\mathcal{L}^{\sim}_{S_\infty \cup S}$ by $\tilde{\mathcal{L}}_{S_\infty \cup S}$. However, there are fine details which need to be taken care of in order to justify the formal steps of the proof; this has to do with analytic continuation (in general) of the local integrals. Let us assume that (3.8) is valid, with $S_\infty \cup S$ replacing S, as we just explained, so that we can continue and point out what we have at present, and what is still missing towards a proof of existence of a weak functorial lift from SO_m (split) to $\mathrm{GL}_{2\lfloor \frac{m}{2} \rfloor}$. With this assumption, (3.6)–(3.8) imply that

$$\begin{aligned}L(\pi \times \tau, s) = \varepsilon(\pi \times \tau, s) L(\pi \times \hat{\tau}, 1-s) \frac{L(\tau, r, 2s-1)}{\varepsilon(\tau, r, 2s-1) L(\hat{\tau}, r, 2-2s)} \\ \cdot \frac{L\big(\rho \times \tau, s-\frac{1}{2}\big)}{\varepsilon\big(\rho \times \tau, s-\frac{1}{2}\big) L\big(\rho \times \hat{\tau}, \frac{3}{2}-s\big)}.\end{aligned} \tag{3.9}$$

By the functional equation for $L(\tau, r, s)$, the first quotient in the right-hand side of (3.9) is 1. By induction on m, the second quotient is also 1, the basic case being that where ρ is generic (or just take the trivial cases $m = 0, 1$). This will prove

Theorem 3.3. *Let $\tau \in \mathcal{T}(S, \chi)$ (notation as above). Assume that* (3.8) *is valid , with $S_\infty \cup S$ replacing S (as explained above). Then*

$$L(\pi \times \tau, s) = \varepsilon(\pi \times \tau, s) L(\pi \times \hat{\tau}, 1-s). \tag{3.10}$$

As in [1], define an irreducible representation $\Pi = \otimes \Pi_\nu$ of $\mathrm{GL}_{2\lfloor \frac{m}{2} \rfloor}(\mathbb{A})$ as follows. For $\nu \notin S_\infty \cup S$, Π_ν is the unramified representation (of $\mathrm{GL}_{2\lfloor \frac{m}{2} \rfloor}(F_\nu)$) obtained from π_ν by the local unramified functorial lift. Similarly, for $\nu \in S_\infty$, Π_ν is obtained from π_ν via the Langlands classification. For $\nu \in S$ choose any irreducible, generic, self-dual representation Π_ν of $\mathrm{GL}_{2\lfloor \frac{m}{2} \rfloor}(F_\nu)$ which has a trivial central character. In particular, Π has a trivial central character.

Theorem 3.4. *Assume that χ is highly ramified at S (depending on π only). Then, for all places ν,*

$$L(\Pi_\nu \times \tau_\nu, s) = L(\pi_\nu \times \tau_\nu, s), \tag{3.11}$$

$$\gamma(\Pi_\nu \times \tau_\nu, s, \psi_\nu) = \gamma(\pi_\nu \times \tau_\nu, s, \psi_\nu), \tag{3.12}$$

Similar identities apply to $\hat{\tau}$.

By construction, (3.11) and (3.12) are clear for all ν outside S. For $\nu \in S$, since χ_ν is highly ramified, both sides of (3.11) are 1. As for (3.12), let us write τ_ν as the representation, induced from the Borel subgroup and a character $\mu_{1,\nu}\chi_\nu \otimes \cdots \otimes \mu_{n,\nu}\chi_\nu$, where $\mu_{1,\nu}, \ldots, \mu_{n,\nu}$ are unramified. Then we need to prove

$$\prod_{i=1}^{n} \gamma(\Pi_\nu \times \mu_{i,\nu}\chi_\nu, s, \psi_\nu) = \prod_{i=1}^{n} \gamma(\pi_\nu \times \mu_{i,\nu}\chi_\nu, s, \psi_\nu).$$

For this it is enough to prove

$$\gamma(\Pi_\nu \times \chi_\nu, s, \psi_\nu) = \gamma(\pi_\nu \times \chi_\nu, s, \psi_\nu). \tag{3.13}$$

Recall again that the right-hand side of (3.13) is defined via the doubling method. Both sides of (3.13) are stable for sufficiently ramified χ_ν. See [22] for the stability of the left-hand side, and [32] for the stability of the right-hand side. Thus we may replace π_ν and Π_ν with a pair of unramified representations, which correspond without changing their local gamma factors (twisted by χ_ν). This proves (3.13).

The main property which is missing at this stage is the holomorphicity of the full L-function $L(\pi \times \tau, s)$ for $\mathrm{Re}(s) \geq \frac{1}{2}$. Recall from Theorem 3.1 that we know that $L^{S_\infty}(\pi \times \tau, s)$ is holomorphic for $\mathrm{Re}(s) \geq \frac{1}{2}$, when $\tau \in \mathcal{T}_0(S, \chi)$. Assume, for example, that π is tempered at S_∞. Then $\prod_{\nu \in S_\infty} L(\pi_\nu \times \tau_\nu, s)$ is holomorphic for $\mathrm{Re}(s) \geq \frac{1}{2}$, and hence so is $L(\pi \times \tau, s)$. In such a case Theorem 3.3 (where we assumed that (3.8) is valid for $S_\infty \cup S$ as well) will imply that $L(\pi \times \tau, s)$ is entire. Once we have this, we see that by Theorem 2 in [5], $L(\pi \times \tau, s)$ is an entire function of finite order, and we can conclude that it is bounded in vertical strips (and similarly for $\hat{\tau}$). Then we can apply the converse theorem and obtain an automorphic representation of $\mathrm{GL}_{2[\frac{m}{2}]}(\mathbb{A})$ which is isomorphic to Π at all places outside S. Finally, let us mention that the ideas of the descent method can be applied here as well, and moreover, cuspidal representations on any orthogonal group (split or otherwise) can be considered along similar lines. These topics are the subject of current work in progress, which we hope to report on in future times.

Representation theory and the cohomology of arithmetic groups

Birgit Speh*

Abstract. Let G be a semisimple Lie group with finitely many connected components and Lie algebra $\mathfrak{g}$, K a maximal compact subgroup of G, and $X = G/K$ a symmetric space. A torsion free discrete subgroup Γ of G and a finite dimensional real or complex linear representation (ρ, E) of G define a locally symmetric space $X_\Gamma = \Gamma\backslash G/K$ with a local system $\tilde{E}$. Then $H^*(\Gamma, E) = H^*(\Gamma\backslash X, \tilde{E})$ is isomorphic to $H^*(\mathfrak{g}, K, C^\infty(\Gamma\backslash G) \otimes E)$. If Γ is an arithmetic group, then $H^*(\mathfrak{g}, K, C^\infty(\Gamma\backslash G) \otimes E)$ is isomorphic to the $(\mathfrak{g}, K)$-cohomology with coefficients in $\mathcal{A}(\Gamma\backslash G) \otimes E$ where $\mathcal{A}(\Gamma\backslash G)$ is the space of automorphic forms. Using representation theory and the theory of automorphic forms a large amount of information about $H^*(\Gamma, E)$ can be deduced.

Mathematics Subject Classification (2000). Primary 22E40; Secondary 22E46.

Keywords. Cohomology, arithmetic groups, unitary representations, reductive Lie groups.

1. Introduction

Let $\boldsymbol{G}$ be a semi-simple simply connected algebraic group over $\mathbb{Q}$, K be a maximal compact subgroup of its real points $G = \boldsymbol{G}(\mathbb{R})$ and $X = G/K$ the global symmetric space. Assume that $\Gamma \subset \boldsymbol{G}(\mathbb{Q})$ is a torsion-free congruence subgroup. Then $S(\Gamma) = \Gamma\backslash X$ is a manifold with finite volume under the G-invariant metric and volume form on $X = G/K$.

Suppose that $\boldsymbol{H}$ is a $\mathbb{Q}$-rational reductive subgroup with real points H such that $K \cap H = K_H$ is maximal compact in H. Then the inclusion

$$X_H := H/K_H \to X$$

induces a map

$$j\colon \Gamma \cap H\backslash X_H \longrightarrow \Gamma\backslash X.$$

We assume from now on that $\Gamma\backslash X$ and $S_H(\Gamma) := \Gamma \cap H\backslash X_H$ are not compact.

Let $[\phi]$ be an element in the i-th cohomology with compact support $H^i_c(S(\Gamma), \mathbb{C})$ represented by a closed compactly supported i-form ϕ and that $i + k =$

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

$\dim(X_H)$. Then $[\phi]$ determines a map

$$(\phi, S_H)\colon H^k(S(\Gamma), \mathbb{C}) \to \mathbb{C},$$
$$[\omega] \mapsto \int_{\Gamma\cap H\backslash X_H} \phi \wedge j^*\omega.$$

We call this map the modular symbol attached to $([\phi], S_H)$. If we can find $[\omega] \in H^*(S(\Gamma), \mathbb{C})$ such that $([\phi], H)([\omega]) \neq 0$ then $([\phi], S_H)$ is a nontrivial modular symbol. If $S(\Gamma)$ is oriented we use Poincaré duality and identify $([\phi], S_H)$ with an element in $H_c^*(S(\Gamma), \mathbb{C})$.

On the other hand if $[\psi] \in H^i(\Gamma \cap H\backslash X_H, \mathbb{C})$ and $i + k = \dim(X_H)$ the map

$$([\psi], S_H)\colon H_c^k(\Gamma\backslash X, \mathbb{C}) \to \mathbb{C},$$
$$[\omega] \mapsto \int_{\Gamma\cap H\backslash X_H} \psi \wedge j^*\omega$$

can be identified with an element in $H^*(\Gamma\backslash X, \mathbb{C})$ which we also call a modular symbol attached to $([\psi], S_H)$. If the degree of ψ is 0 then we say that the fundamental class $[S_H(\Gamma)]$ is a modular symbol in $H^{\dim X - \dim X_H}(S(\Gamma), \mathbb{C})$.

The Hecke algebra acts on $H^*(S(\Gamma), \mathbb{C})$ and on $H_c^*(S(\Gamma), \mathbb{C})$ and one may consider the span of Hecke translates of the modular symbols $([\psi], S_H)$ and in particular $[S_H(\Gamma)]$, where H ranges over all groups H. It is unknown, how much of the cohomology of $S(\Gamma)$ may be captured by nonzero modular symbols and their Hecke translates.

The cohomology $H^*(\Gamma\backslash X, \mathbb{C})$ of the locally symmetric space $\Gamma\backslash X$ can be identified with the $(\mathfrak{g}, K)$-cohomology of the G-module $\mathcal{A}(\Gamma\backslash G)$ of automorphic functions on $\Gamma\backslash G$. Thus it is determined by representation theoretic and arithmetic data. Understanding the relationship between nontrivial modular symbols attached to a subgroup $\boldsymbol{H}$ and the subrepresentations of $\mathcal{A}(\Gamma\backslash G)$ gives important arithmetic information, since many of the integrals $\int_{\Gamma\cap H\backslash X_H} \psi \wedge j^*\omega$ are period integrals or are related to special values of L-functions. This is discussed in [7], [11], [12], [4] and the recent work of S. Kudla [8].

For some compact locally symmetric spaces Kudla and Millson [9], by Clozel and Venkataranama [4] and by Tong and Wang [19], have obtained results relating some special $[S_H(\Gamma)]$ to cohomology classes defined by automorphic representations. I will discuss here some connections between cohomology classes defined using automorphic representations and nontrivial modular symbols for noncompact locally symmetric spaces.

2. The cohomology $H^*(S(\Gamma), \mathbb{C})$ and automorphic representations

We denote the Lie algebra by gothic letters and write $\mathfrak{g} = \mathfrak{k} + p$ for the Cartan decomposition of the Lie algebra $\mathfrak{g}$. The complex of the differential forms on $S(\Gamma)$ is

isomorphic to

$$\mathrm{Hom}_K(\wedge^*\mathfrak{g}/\mathfrak{k}, C^\infty(\Gamma\backslash G))$$

(see [3]). Here consider $C^\infty(\Gamma\backslash G)$ as a left $\mathfrak{g}$-module and

$$df(x_0,\dots x_q) = \sum_i x_i f(x_0,\dots,\hat{x}_i,\dots x_q) + \sum_{i<j}(-1)^{i+j} f([x_i,x_j],x_0,\dots,\hat{x}_i,\dots,\hat{x}_j,\dots,x_q).$$

We denote its cohomology by $H^*(S(\Gamma),\mathbb{C}) = H^*(\mathfrak{g},K,C^\infty(\Gamma\backslash G))$. Similarly we define for an admissible representation π of G the $(\mathfrak{g},K)$-cohomology $H^*(\mathfrak{g},K,\pi)$.

We denote the space of automorphic functions on $\Gamma\backslash G$ by $\mathcal{A}(\Gamma\backslash G)$. An admissible $(\mathfrak{g},K)$-module, which is isomorphic to a subrepresentation of $\mathcal{A}(\Gamma\backslash G)$, is called an automorphic representation. The space of square integrable automorphic functions is a direct sum of $\mathcal{A}_{\mathrm{res}}(\Gamma\backslash G)$, the space of residual automorphic functions and $\mathcal{A}_{\mathrm{cusp}}(\Gamma\backslash G)$, the space of the cuspidal automorphic functions [10]. An irreducible unitary $(\mathfrak{g},K)$-submodule of $\mathcal{A}_{\mathrm{res}}(\Gamma\backslash G)$, respectively of $\mathcal{A}_{\mathrm{cusp}}(\Gamma\backslash G)$ is called a residual, respectively cuspidal $(\mathfrak{g},K)$-module.

As a $(\mathfrak{g},K)$-module

$$\mathcal{A}_{\mathrm{cusp}}(\Gamma\backslash G) = \oplus_{U\in\hat{G}_u} m(\Gamma,U)U.$$

Here $\hat{G}_u$ denotes the set of all unitary irreducible $(\mathfrak{g},K)$-modules and

$$m(\Gamma,U) = \dim \mathrm{Hom}_{\mathfrak{g},K}(U,\mathcal{A}_{\mathrm{cusp}}(\Gamma\backslash G)).$$

A result by A. Borel [2] states that if π is a cuspidal $(\mathfrak{g},K)$-module then

$$H^*(\mathfrak{g},K,\pi) \hookrightarrow H^*(\mathfrak{g},K,C^\infty(\Gamma\backslash G)) = H^*(S(\Gamma),\mathbb{C}). \tag{1}$$

In particular, if $S(\Gamma)$ is compact, then

$$\mathcal{A}_{\mathrm{cusp}}(\Gamma\backslash G) = \mathcal{A}(\Gamma\backslash G)$$

and hence

$$H^*(S(\Gamma),\mathbb{C}) = H_c^*(S(\Gamma),\mathbb{C}) = \oplus_{U\in\hat{G}_u} m(\Gamma,U)H^*(\mathfrak{g},K,U).$$

See [3] for details.

If $\Gamma\backslash G$ and hence $S(\Gamma)$ are not compact a result of Franke [5] shows that

$$H^*(S(\Gamma),\mathbb{C}) = H^*(\mathfrak{g},K,\mathcal{A}(\Gamma\backslash G)).$$

In contrast to (1)

$$H^*(\mathfrak{g},K,\mathcal{A}_{\mathrm{res}}(\Gamma\backslash G)) \not\hookrightarrow H^*(\mathfrak{g},K,C^\infty(\Gamma\backslash G))$$

as the following example illustrates.

The trivial representation I of G is an automorphic representation satisfying $H^*(\mathfrak{g}, K, I) \neq 0$. Let G_u be the compact subgroup of $\boldsymbol{G}(\mathbb{C})$ with Lie algebra $\mathfrak{k} \oplus ip$ and write $\hat{X} = G_u/K$ for the compact dual of X. We identify $H^*(\hat{X})$ with $H^*(\mathfrak{g}, K, I)$. The Borel map j from the cohomology $H^*(\hat{X})$ into the cohomology $H^*(S(\Gamma), \mathbb{C})$ is defined by the inclusion of the constant functions $\mathbb{C}$ in the space $\mathcal{A}(\Gamma\backslash G)$. The classes in the image of $H^*(\mathfrak{g}, K, I)$ in $H^*(S(\Gamma), \mathbb{C})$ are represented by invariant differential forms. If D is the dimension of $S(\Gamma)$ then $\dim H^D(\mathfrak{g}, K, I) = 1$. On the other hand $H^D(S(\Gamma), \mathbb{C}) = 0$ since $S(\Gamma)$ is not compact.

The kernel of the Borel map $j\colon H^*(\mathfrak{g}, K, I) \to H^*(S(\Gamma), \mathbb{C})$ is determined in [6].

According to Parthasaraty, Kumaresan and Vogan–Zuckerman the irreducible unitary representations π with $H^*(\mathfrak{g}, K, \pi) \neq 0$ are classified as follows: let $\mathfrak{h} = \mathfrak{t} \oplus \mathfrak{a}$ be a θ-stable fundamental Cartan subalgebra and $\mathfrak{q}_{\mathbb{C}} = \mathfrak{l}_{\mathbb{C}} \oplus \mathfrak{n}_{\mathbb{C}}$ a θ-stable parabolic subgroup of $\mathfrak{g} \otimes \mathbb{C}$ containing $\mathfrak{h} \otimes \mathbb{C}$. Then $\mathfrak{l}_{\mathbb{C}}$, $\mathfrak{l}$ and L are the centralizers of an element $X \in i\mathfrak{t}$ in $\mathfrak{g}_{\mathbb{C}}$, $\mathfrak{g}$ and G respectively. Associated to $\mathfrak{q}$ is an irreducible unitary $(\mathfrak{g}, K)$-modules $A_{\mathfrak{q}}$ and an irreducible finite dimensional representation $V(\mathfrak{q}) \subset \wedge^{\dim(p \cap \mathfrak{n})} p$ of K so that

$$H^{\dim(p \cap \mathfrak{n})}(\mathfrak{g}, KA_{\mathfrak{q}}) \cong \mathrm{Hom}(V(\mathfrak{q}), A_{\mathfrak{q}}) \cong \mathbb{C},$$

and we obtain forms representing all other nontrivial cohomology classes as the wedge product of $0 \neq \omega_{\mathfrak{q}} \in \mathrm{Hom}(V(\mathfrak{q}), A_{\mathfrak{q}})$ with forms representing classes in $H^*(\mathfrak{l}, L \cap K, I)$. Every irreducible unitary representation with nontrivial $(\mathfrak{g}, K)$-cohomology is isomorphic to a representation $A_{\mathfrak{q}}$.

Suppose that $\boldsymbol{P}$ is a rational parabolic subgroup and that $A_{\mathfrak{q}}$ is the Langlands quotient of $I(\boldsymbol{P}(\mathbb{R}), \pi, \nu)$. Assume furthermore that there is a map

$$E_{\mathrm{res}}\colon I(\boldsymbol{P}(\mathbb{R}), \pi, \nu) \to \mathcal{A}_{\mathrm{res}}(\Gamma\backslash G)$$

which defines a $(\mathfrak{g}, K)$-map $J\colon A_{\mathfrak{q}} \hookrightarrow \mathcal{A}_{\mathrm{res}}(\Gamma\backslash G)$ into the residual spectrum. It extends to a map

$$J^*\colon \mathrm{Hom}_K(\wedge^* p, A_{\mathfrak{q}}) \to \mathrm{Hom}_K(\wedge^* p, \mathcal{A}_{\mathrm{res}}(\Gamma\backslash G)).$$

One can show that $[J^*(\omega_{\mathfrak{q}}] \neq 0$.

I expect the following generalization of Franke's result to hold.

Conjecture. Let $[\omega_L] \in H^*(\mathfrak{l}, K \cap L, I)$ be in the kernel of the Borel map for L. Then

$$[J^*(\omega_{\mathfrak{q}} \wedge \omega_L)] = 0.$$

The contribution to $H^*(S(\Gamma), \mathbb{C})$ by representations with nontrivial $(\mathfrak{g}, K)$-cohomology which are induced from parabolic subgroups and which are embedded via Eisenstein series into $\mathcal{A}(\Gamma\backslash G)$ has been considered by G. Harder and J. Schwermer [15].

3. Locally symmetric spaces in the adelic language

Let $\boldsymbol{A}$ be the adeles of $\mathbb{Q}$ and $\boldsymbol{A}_f$ the finite adeles. For a linear algebraic semi-simple simply connected group $\boldsymbol{G}$ defined over $\mathbb{Q}$ we define $\boldsymbol{G}(\boldsymbol{A})$, $\boldsymbol{G}(\mathbb{Q})$, $\boldsymbol{G}(\boldsymbol{A}_f)$ and a compact group

$$K_{\boldsymbol{A}} = K_\infty \prod_p \boldsymbol{G}(\mathcal{O}_p) = K_\infty K_{\boldsymbol{A}_f},$$

where K_∞ is the maximal compact subgroup of $G = \boldsymbol{G}(\mathbb{R})$. We have a locally symmetric space

$$S(K_{\boldsymbol{A}_f}) = \boldsymbol{G}(\mathbb{Q})\backslash X \times \boldsymbol{G}(\boldsymbol{A}_f)/K_{\boldsymbol{A}_f}.$$

For each subgroup $K'_{\boldsymbol{A}_f} \subset K_{\boldsymbol{A}_f}$ of finite index we also define a locally symmetric space $S(K'_{\boldsymbol{A}}) = \boldsymbol{G}(\mathbb{Q})\backslash X \times \boldsymbol{G}(\boldsymbol{A}_f)/K'_{\boldsymbol{A}_f}$. If K'_f is sufficiently small then

$$S(K'_f) = \bigcup_{i=1}^{h} \Gamma_i \backslash X$$

is a finite disjoint union of locally symmetric spaces $\Gamma_i\backslash X$, where the $\Gamma_i \subset G(\mathbb{Q})$ are congruence subgroups. Furthermore

$$H^*(S(K'_f), \mathbb{C}) \cong H^*(\mathfrak{g}, K_\infty, \mathcal{A}(\boldsymbol{G}(\mathbb{Q})\backslash G(\boldsymbol{A}))^{K'_f}.$$

We give $\boldsymbol{G}(\boldsymbol{A}_f)$ the topology induced by the topology of $\boldsymbol{A}_f$ and define $X_{\boldsymbol{A}} := X \times \boldsymbol{G}(\boldsymbol{A}_f)$. Then $X_{\boldsymbol{A}}$ with the product topology is the *adelic symmetric space* attached to $\boldsymbol{G}$. The group $\boldsymbol{G}(\mathbb{Q})$ of $\mathbb{Q}$-rational points of $\boldsymbol{G}$ acts by left translation freely and discontinuously on $X_{\boldsymbol{A}}$. The space $\boldsymbol{G}(\mathbb{Q})\backslash X_{\boldsymbol{A}} =: S_G$ with the quotient topology is called the *adelic locally symmetric space* attached to $\boldsymbol{G}$.

Let $\tilde{\mathbb{C}}$ be a locally constant sheaf S_G. By $H^*(S_G, \tilde{\mathbb{C}})$ we denote the smooth sheaf cohomology of S_G with coefficients $\tilde{\mathbb{C}}$. The group $\boldsymbol{G}(\boldsymbol{A}_f)$ acts by right translation on S_G and $H^j(S_G, \tilde{\mathbb{C}})$ is a smooth $\boldsymbol{G}(\boldsymbol{A}_f)$-module, i.e. if K_f runs in the set of compact open subgroups of $\boldsymbol{G}(\boldsymbol{A}_f)$ and if $H^j(S_G, \tilde{\mathbb{C}})^{K_f}$ denotes the K_f-invariants in $H^j(S_G, \tilde{\mathbb{C}})$ then

$$\bigcup_{K_f} H^j(S_G, \tilde{\mathbb{C}})^{K_f} = H^j(S_G, \tilde{\mathbb{C}}).$$

Moreover

$$H^j(S_G, \tilde{\mathbb{C}})^{K_f} = H^j(S_G/K_f, \tilde{\mathbb{C}})$$

where $S_G/K_f = S(K_f)$ is the topological quotient of S_G by the K_f-action, and $H^j(S_G/K_f, \tilde{\mathbb{C}})$ is the sheaf-cohomology of S_G/K_f with coefficients in the sheaf $\tilde{\mathbb{C}}$.

A finite dimensional representation $\rho\colon G \to \mathrm{End}(V)$ of G defines a locally constant sheaf $\tilde{V}$ on S_G and we have similar formulas for the sheaf $\tilde{V}$.

4. Modular symbols and automorphic representations

Consider first the trivial representation I which is in the residual spectrum of $\mathcal{A}(\boldsymbol{G}(\mathbb{Q})\backslash\boldsymbol{G}(\boldsymbol{A}))$.

For a subgroup $\boldsymbol{H}$ define the compact dual $\hat{X}_H$ of X_H analogously. One has an embedding of $\hat{X}_H$ in $\hat{X}$, and the fundamental class of $[\hat{X}_H]$ is a cohomology class in $H^*(\hat{X})$.

Put $\Gamma_0 = \boldsymbol{G}(\mathbb{Q}) \cap \prod_p \boldsymbol{G}(\mathcal{O}_p)$ and let $\mathcal{H}_0$ to be the space of complex valued compactly supported $K_f = \prod_p \boldsymbol{G}(\mathcal{O}_p)$-bi-invariant functions on the finite adelic group $G(\boldsymbol{A}_f)$. This is the Hecke algebra corresponding to K_f under convolutions and acts on the cohomology group $H^*(S(\Gamma_0), \mathbb{C}) = H^*(S_G, \tilde{\mathbb{C}})^{K_f}$.

Theorem ([17]). *Suppose that $\boldsymbol{G}$ is a simply connected group which has no $\mathbb{R}$-anisotropic factors defined over $\mathbb{Q}$. Then, the class $j([\hat{X}_H])$ is a linear combination of Hecke translates of the generalized modular symbol $[S_H(\Gamma')] \in H^*(S(\Gamma'), \mathbb{C})$ for some congruence subgroup Γ' of Γ_0.*

In particular, if $j([\hat{X}_H]) \neq 0$, then the modular symbol $[S_H(\Gamma')]$ does not vanish.

Since the kernel of the Borel map j has been determined in [6], this result is used to exhibit many modular symbols in [17] related to the trivial representation.

We now consider representations with nontrivial $(\mathfrak{g}, K)$-cohomology which are induced from parabolic subgroups and which are considered as subrepresentations of $\mathcal{A}(\boldsymbol{G}(\mathbb{Q})\backslash\boldsymbol{G}(\boldsymbol{A}))$ via Eisenstein series. Let $\boldsymbol{P} \supset \boldsymbol{B}$ be a standard parabolic subgroup of $\boldsymbol{G}$ with standard Levi part $\boldsymbol{L}_P$. Let $x_0 = K\,e \in X$. The orbit of x_0 under $L_P(\boldsymbol{A})$ in the globally symmetric space $X_{\boldsymbol{A}}$ is isomorphic to $\boldsymbol{L}_P(\mathbb{R})/(\boldsymbol{L}_P(\mathbb{R}) \cap K)) \times \boldsymbol{L}_P(\boldsymbol{A}_f)$. We have a symmetric space $\boldsymbol{L}_P(\mathbb{R})/(\boldsymbol{L}_P(\mathbb{R}) \cap K)$ and

$$S^{\natural}_{L_P} := \boldsymbol{L}_P(\mathbb{Q})\backslash\boldsymbol{L}_P(\mathbb{R})/(\boldsymbol{L}_P(\mathbb{R}) \cap K)) \times \boldsymbol{L}_P(\boldsymbol{A}_f)$$

is a locally symmetric space and we have a continuous injection $S^{\natural}_{L_P} \hookrightarrow S_G$, which identifies it with a closed subspace of S_G. We call $S^{\natural}_{L_P}$ the *modular manifold* attached to P.

In [14] we consider the covering space $S_P := \boldsymbol{P}(\mathbb{Q})\backslash X_{\boldsymbol{A}}$. One can see that

$$H^*(S_P, \mathbb{C}) = H^*(\boldsymbol{P}(\mathbb{Q}), C^\infty(\boldsymbol{G}(\boldsymbol{A}_f), \mathbb{C})).$$

Using the Steinberg representation we define the Poincaré dual $H^*_c(S_P, \mathbb{C})$. In [13] we attach to a class $[\phi] \in H^j_c(S_P, \mathbb{C})$ a class

$$\mathrm{cor}_P([\phi]) \in H^j_c(S_G, \tilde{V}).$$

The classes are in a sense the Poincaré dual to Eisenstein classes defined by embeddings of representations induced from $\boldsymbol{P}(\boldsymbol{A})$ into the space of automorphic functions [15]. In [14] we obtain formulas for a restriction map res_c of the classes $\mathrm{cor}_P([\phi])$

to $H^*(S^{\natural}_{L_P}, \mathbb{C})$, thus obtaining modular symbols. As a special case we prove that the fundamental class $[S^{\natural}_{L_P}]$ defines a nontrivial modular symbol generalizing a result by Ash and Borel [1].

For $G = \mathrm{Gl}(2n, \mathbb{R})$ there is a unique unitary irreducible representation $J(n)$ with

$$H^{n(n+1)/2}(\mathfrak{g}, K, J(n)) \neq 0$$

and

$$H^j(\mathfrak{g}, K, J(n)) = 0 \quad \text{for } j < n(n+1)/2.$$

By Poincaré duality $H^{(n+1)(3n-2)/2}(\mathfrak{g}, K, J(n)) \neq 0$.

If Γ is a small congruence subgroup the residues of Eisenstein series define an embedding

$$E\colon J(n) \to \mathcal{A}_{\mathrm{res}}(\Gamma\backslash G)$$

in the residual spectrum and a nonzero class in $H^{n(n+1)/2}(S(\Gamma), \mathbb{C})$ [16]. By Poincaré duality we have a nonzero class in $H_c^{(n+1)(3n-2)/2}(S(\Gamma), \mathbb{C})$ which can be represented by a pseudo Eisenstein form ω_{sp} [13].

Now let $H = \mathrm{Sp}(n, \mathbb{R}) \subset \mathrm{Gl}(2n, \mathbb{R})$ be defined by the skew symmetric form $\left(\begin{smallmatrix} 0 & I \\ -I & 0 \end{smallmatrix}\right)$. The work of Jacquet and Rallis implies that $J(n)$ admits an H-invariant linear functional and no other irreducible unitary infinite dimensional representation with nontrivial $(\mathfrak{g}, K)$-cohomology admits an H-invariant linear functional.

Proposition. *Suppose that $n = 2$. If Γ is a sufficiently small congruence subgroup, then $\int_{S_H(\Gamma)} \omega_{\mathrm{sp}} \neq 0$ and so the modular symbol $[S_H(\Gamma)]$ is not zero.*

Suppose that $n > 2$. Then the Oda restriction of $[\omega_{\mathrm{sp}}]$ to $S(\Gamma)$ is zero.

5. A conjecture

These examples support the conjecture that understanding the automorphic representations with nontrivial $(\mathfrak{g}, K)$-cohomology as H- modules and their $(\mathfrak{h}, K_H)$-quotients, respectively subrepresentations, is crucial to understanding their relationship to modular symbols. In general the restriction of π to $\mathfrak{h}$ is not a direct sum of unitary irreducible $(\mathfrak{h}, K_H)$-modules and so we have to consider its irreducible quotients.

Suppose that $j\colon H \hookrightarrow G$ is a subgroup, π an irreducible unitary automorphic representation with $H^*(\mathfrak{g}, K, \pi) \neq 0$. Let $0 \neq [\omega] \in H^*(\mathfrak{g}, K, \pi)$. Assume also that there exists an irreducible $(\mathfrak{h}, K_H)$-module π_H and $Q \in \mathrm{Hom}_H(\pi, \pi_H)$ and $0 \neq [Q^*\omega] \in H^*(\mathfrak{h}, K \cap H, \pi_H)$.

Let

$$E\colon \pi \hookrightarrow \mathcal{A}_{\mathrm{res}}(\Gamma\backslash G) \oplus \mathcal{A}_{\mathrm{cusp}}(\Gamma\backslash G)$$

be an embedding.

Conjecture. Suppose that $[E^*(\omega)] \neq 0$. For sufficiently small congruence subgroup Γ' the Oda restriction of $[E^*\omega]$ to $H^*(S_H(\Gamma'), \mathbb{C})$ is non trivial.

By duality we have a map

$$E_c\colon H_c^*(S(\Gamma),\mathbb{C}) \to H^*(\mathfrak{g}, K, \pi).$$

Suppose again that $0 \neq [Q^*\omega] \in H^*(\mathfrak{h}, K \cap H, \pi_H)$.

Conjecture. Suppose that $[Q^* E_c^* \omega] \neq 0$. Then for sufficiently small Γ there exists a "restriction" map

$$\mathrm{res}_c\colon H^*(S(\Gamma),\mathbb{C}) \to H_c^*(S_H(\Gamma'),\mathbb{C})$$

so that $\mathrm{res}_c[\omega] \neq 0$.

If the restriction of π to $\mathfrak{h}$ is a direct sum of unitary irreducible representations, the first conjecture is true.

Some results on compactifications of semisimple groups

Tonny A. Springer

Abstract. This paper deals with recent results involving a compactification X of a semisimple group G. The emphasis is on the case that G is adjoint and X is its wonderful compactification. Group theoretical constructions in G have repercussions in X. The paper describes a number of them.

Mathematics Subject Classification (2000). Primary 14M17; Secondary 14M15.

Keywords. Semisimple groups, compactifications.

1. Introduction

1.1. Notations. G is a connected semisimple linear algebraic group over the algebraically closed field k of characteristic $p \geq 0$. Fix a maximal torus T of G and a Borel subgroup $B = T.U$, where U is the unipotent subgroup of B. The Weyl group $N_G(T)/T$ is denoted by W. It acts on T.

For $w \in W$ we denote by $\dot{w}$ a representative of $w \in N_G(T)$, not necessarily always the same.

R is the root system of (G, T) and $R^+ \subset R$ the system of positive roots defined by B. Its set of simple roots is denoted by I. We identify it with the set of simple reflections. l is the corresponding length function on W.

For $J \subset I$, W_J is the subgroup of W generated by J and W^J the set of minimal length coset representatives for W/W_J. The longest element of W_J is $w_{0,J}$.

1.2. Compactification. $G \times G$ acts on G by $(x, y).z = xyz^{-1}$ $(x, y, z \in G)$. By a *compactification* of G we mean an irreducible normal projective $G \times G$-variety, containing G as an open $G \times G$-stable subvariety. The theory of embeddings of spherical varieties (due to Luna and Vust, see [Kn]) can be applied to the $G \times G$-variety G to analyze such compactifications.

We shall be concerned here mainly with the particular case that G is adjoint and X is the wonderful compactification of G. This was first constructed for $k = \mathbb{C}$ by De Concini and Procesi in [DP1]. The case of an arbitrary algebraically closed k was dealt with in [St]. (See also [DS], where fields of definition are also taken into account).

In the construction given in these papers one uses a suitable finite-dimensional projective representation $\rho\colon G \to \mathrm{PGL}(V)$ of G and X is defined to be the closure in

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

$\mathbb{P}(\mathrm{End}(V))$ of the image $\rho(G)$ (this turns out to be independent of the choice of ρ).

Then X is a compactification of G. It is a smooth projective $G \times G$-variety. A key property is that X contains a unique closed $G \times G$-orbit, isomorphic to $G/B^- \times G/B$, where B^- is the opposite of B (see Lemma 1 below). The complement $X - G$ is a union of smooth divisors D_i indexed by the simple roots $i \in I$, with normal crossings.

For $J \subset I$ let $X_J \subset \bigcap_{i \in I-J} D_i$ be the set of points not lying in a smaller intersection of the same kind. The X_J $(J \subset I)$ are the $G \times G$-orbits in X. Then $X_I = G$, $X_{I-\{i\}}$ is the orbit which is open in D_i and $X_\emptyset$ is the closed orbit.

[DP2] analyzes general smooth compactifications of G. The wonderful one is shown to be "minimal".

There are other constructions of X:

(a) as the closure of the $G \times G$-orbit of the diagonal in the variety of Lie subalgebras of $\mathrm{Lie}(G \times G)$ (see [DP1, sect. 6]),

(b) as the closure of the $G \times G$-orbit of the diagonal of $G/B \times G/B$, viewed as a point of the Hilbert scheme of $G/B \times G/B$ (see [B2]).

If G is arbitrary there does not seem to be a canonical smooth compactification. One can construct a not necessarily smooth one in the following manner.

Let G_{ad} be the corresponding adjoint group and X_{ad} its wonderful compactification. Let X be the normalization of X_{ad} in the function field $k(G)$ (a finite extension of $k(G_{\mathrm{ad}})$).

Then X is a compactification of G. The homomorphism $G \to G_{\mathrm{ad}}$ extends to a $G \times G$-morphism $X \to X_{\mathrm{ad}}$. It induces a bijection of the sets of $G \times G$-orbits.

We recall some facts, to be elaborated on later in the context of compactifications.

1.3. Bruhat's Lemma. G is the disjoint union of the locally closed subsets $G_w = B\dot{w}B$. In other words: $B \times B$ acts on G with finitely many orbits, indexed by the elements of W.

There is an order $\leq$ on W (the Bruhat–Chevalley order) such that for $x, w \in W$ the orbit G_x lies in the closure $\overline{G_w}$ if and only if $x \leq w$.

The flag variety G/B is a smooth projective G-variety. The closed subvarieties $S_w = \overline{G_w}/B$ $(w \in W)$ are the Schubert varieties.

1.4. Conjugation action. Let $G_{\mathrm{d}} \simeq G$ be the diagonal subgroup of $G \times G$. The restriction to G_{d} of the $G \times G$-action on G is the conjugation action of G on itself.

We have a partition of G into G_{d}-stable closed subsets, each of which consists of the elements whose semisimple part lies in a given conjugacy class. We call these subsets *Steinberg fibers*. Regular semisimple conjugacy classes are examples.

The Steinberg fibers are the fibers of a flat morphism $G \to W\backslash T$.

1.5. Character sheaves. There is a geometric character theory for G, embodied in Lusztig's theory of character sheaves (see [L1]). Character sheaves are certain

conjugation-equivariant irreducible perverse sheaves on G. Ingredients in their construction are $B \times B$-equivariant perverse sheaves on G, supported by the closure of some G_w.

2. $B \times B$-action on a compactification

2.1. The $B \times B$-orbits. G is assumed to be adjoint and X is its wonderful compactification. The question of extending Bruhat's Lemma to X, i.e. of describing the $B \times B$-action on X arises naturally. It was studied in [B1], [Sp1] and more recently in [HT2]. The last paper also deals with non-adjoint groups.

We first describe in more detail the $G \times G$-orbits X_J in X.

For $J \subset I$ denote by $P_J \supset B$ the corresponding standard parabolic subgroup and by $P_J^- \supset B^-$ its opposite. We denote by L_J the Levi subgroup of P_J and P_J^- containing T and by G_J the adjoint group of L_J. The image of T in G_J is a maximal torus denoted by T_J.

Let λ be a cocharacter of T (a homomorphism $\lambda\colon \mathbb{G}_m \to T$). Then $\lambda(0) = \lim_{\xi \to 0} \lambda(\xi)$ is a well-defined point of X, as X is complete. λ also defines a linear function on the character group of T, denoted by the same symbol.

The $G \times G$-orbits X_J ($J \subset I$) in X can be described as follows.

Lemma 1. (i) *There is a unique base point $h_J \in X_J$ such that for all cocharacters λ with $\lambda(\alpha) = 0$ for $\alpha \in J$ and $\lambda(\alpha) > 0$ for $\alpha \in I - J$ we have $\lambda(0) = h_J$.*

(ii) *The orbit map $(x, y) \mapsto (x, y).h_J$ induces an isomorphism of the quotient variety $(G \times G) \times_{P_J^- \times P_J} G_J$ onto X_J.*

For (i) see [DS, sect. 3]. The quotient of (ii) is relative to the right action of $P_J^- \times P_J$ on $G \times G$ and the left action on G_J given by $(x, y).z = \bar{x} z \bar{y}^{-1}$, the bars denoting projection on G_J in P_J, respectively P_J^-. See [Sp1, p. 73].

By (ii) the closed orbit $X_\emptyset$ is isomorphic to $G/B^- \times G/B$ (as was already mentioned).

Proposition 1. (i) *A $B \times B$-orbit in X_J is of the form*

$$[J, x, w] = (B \times B).(\dot{x}, \dot{w}).h_J,$$

with unique $w \in W$, $x \in W^J$.

(ii) $\dim[J, x, w] = l(w_{0,J}) - l(x) + l(w) + |J|$.

See [Sp1, p. 74]. The result is due to Brion [B1]. $[I, 1, w]$ is the set G_w of 1.3.

The next result describes the closure relations between the $[I, x, w]$.

Proposition 2. *Let $J, J' \subset I$, $x \in W^J$, $x' \in W^{J'}$, $w, w' \in W$. Then $[J', x', w'] \subset \overline{[J, x, w]}$ if and only if $J' \subset J$ and there exists $u \in W_J$ such that $xu \leq x'$, $w' \leq wu$.*

See [HT2, Prop. 6.3]. [Sp1, Prop. 2.4] gives a somewhat more complicated description.

The closures $\overline{G_w}$ (in X) are the *large Schubert varieties*, first studied in [BP]. The large Schubert variety of minimal dimension is the closure $\overline{B}$. It follows from Proposition 2 that it is the union of the $[J, x, w]$ with $w \leq x$.

In [BP] it is shown how the geometry of $\overline{B}$ can be used to understand a result about the simply connected cover G_{sc} of G, namely van der Kallen's filtration (see [Kal]) of the coordinate algebra $k[B_{\mathrm{sc}}]$ of the preimage B_{sc} of B in G_{sc}.

More generally, for each J there is a unique $B \times B$-orbit of minimal dimension in X_J, viz. $[J, w_{0,I} w_{0,J}, 1]$.

In the present case there is also a version of the Bott–Samelson–Demazure–Hansen variety. To formulate it succinctly write $B \times B = \boldsymbol{B}$ and denote by $\boldsymbol{P}_h$ minimal parabolic subgroups of $G \times G$ containing $\boldsymbol{B}$ (so $\boldsymbol{P}_h/\boldsymbol{B} = \mathbb{P}^1$). For $\boldsymbol{h} = (h_1, \ldots, h_s)$ put

$$Z_{\boldsymbol{h}} = \boldsymbol{B}^s \backslash (\boldsymbol{P}_{h_1} \times \cdots \times \boldsymbol{P}_{h_s} \times \overline{[J, w_{0,I} w_{0,J}, 1]}),$$

the quotient for the $\boldsymbol{B}^s$-action (with obvious notations)

$$(b_1, \ldots, b_s).(p_1, \ldots, p_s, x) = (p_1 b_1^{-1}, b_1 p_2 b_2^{-1}, \ldots, b_{s-1} p_s b_s^{-1}, b_s.x).$$

The $G \times G$-action on X defines a morphism $\phi_{\boldsymbol{h}} \colon Z_{\boldsymbol{h}} \to X$.

Proposition 3. *Given $x \in W^J$, $w \in W$ there exist $\boldsymbol{h}$ such that $\phi_{\boldsymbol{h}}$ is a proper birational morphism of $Z_{\boldsymbol{h}}$ onto $\overline{[J, x, w]}$.*

The proof is along familiar lines, it uses reduced decompositions of w and of $w_{0,J} w_{0,I} x$. However, one cannot claim that $\phi_{\boldsymbol{h}}$ is a resolution, as the varieties $\overline{[J, w_{0,I} w_{0,J}, 1]}$ are usually not smooth.

For example, if G is simple and of rank > 1, $\overline{B}$ is not smooth, see [Sp1, Cor. 4.8]. The following problem arises naturally.

Problem 1. Construct a $B \times B$-equivariant resolution of $\overline{[J, w_{0,I} w_{0,J}, 1]}$, in particular of $\overline{B}$.

Proposition 4. *A large Schubert variety admits a cellular decomposition* (*paving by affine spaces*).

See [Sp1, p. 81]. The cells can be described explicitly, which leads to a description of the cohomology groups of large Schubert varieties. In particular, their odd cohomology vanishes (see [loc. cit., 2.11]).

Problem 2. Do all $B \times B$-orbit closures have cellular decompositions?

Proposition 5. *The odd* (*global*) *intersection cohomology of a $B \times B$-orbit closure vanishes.*

See [loc. cit., Thm. 4.11]. The local intersection cohomology of orbit closures will appear in Section 4.

2.2. Algebro-geometric properties of orbit closures. In this subsection G is an arbitrary semisimple group and X is a compactification of G, as in 1.2. For Frobenius splittings and their various refinements we refer to [BK].

Theorem 1. *Let $p > 0$. X admits a $B \times B$-canonical Frobenius splitting which compatibly splits the closures of all $B \times B$-orbits.*

This is [HT2, Prop. 7.1], where it is deduced from the slightly weaker result in [BK, Thm. 6.1.12].
The theorem has the following corollaries, in any characteristic. They are proved by familiar arguments. Let $Z \subset X$ be a $B \times B$-orbit closure.

Corollary 1. *Let $\mathcal{L}$ be an ample line bundle on Z.*

(i) $H^i(Z, \mathcal{L}) = 0$ *for* $i > 0$.

(ii) *If $Z' \subset Z$ is another orbit closure then the restriction map*

$$H^i(Z, \mathcal{L}) \to H^i(Z', \mathcal{L})$$

is surjective.

Corollary 2. *Z is normal and Cohen–Macaulay.*

In fact, more is proved in [loc. cit.], namely that all $B \times B$-orbit closures are globally F-regular. This property also entails the two Corollaries (and more). We will not go into this.

Corollary 2 was first proved by Brion in [B3].

Let $\mathcal{L}$ be an ample line bundle on X. Chirivì and Maffei in [CM] constructed a "standard monomial basis" of the space of global sections $H^0(X, \mathcal{L})$. K. Appel recently showed (see [A]) that this basis is compatible with the $B \times B$-orbit closures.

3. The G_d-action

In this section G is adjoint and X is its wonderful compactification. This section discusses results about the G_{d}-action on X. Notations are as in Section 2.

If σ is an automorphism of G we have a σ-twisted $G \times G$-action on X: $(x, y).{}_\sigma z = (x, \sigma y).z$. The induced G_{d}-action on G is σ-twisted conjugacy: $(x, y) \mapsto xy(\sigma x)^{-1}$. Several of the results of this section extend to twisted actions.

3.1. A partition of X. The partition to be described is essentially due to Lusztig (see [L2, 12.3]). The present formulation was given by He (in [H1, sect. 2]). A similar result also occurs in [EL].

For $J \subset I$ and $W \in W^J$ put

$$X_{J,w} = G_{\mathrm{d}}.[J, w, 1]. \tag{1}$$

Theorem 2. (i) *X_J is the disjoint union of the $X_{J,w}$ ($w \in W^J$).*

(ii) *$X_{J,w}$ is locally closed and irreducible, of dimension* $\dim G - l(w) - |I - J|$.

(iii) *For $w \in W^J$ there exist a connected reductive group G_w and an automorphism σ_w of it such that there is a bijection of the set of G_{d}-orbits in $X_{J,w}$ onto the set of σ_w-twisted conjugacy classes of G_w.*

The proofs of (i) in [L] and [H1] use a combinatorial machinery. (ii) and (iii) are also due to Lusztig (see [L2, sect. 8]).

Remark. For $J = \emptyset$ part (i) of the theorem is a familiar variant of Bruhat's lemma.

We next describe the closure relations between the $X_{J,w}$, following [H2]. Let $\mathcal{I}$ be the set of pairs (J, x) with $J \subset I,\ x \in W^J$. Define a relation $\leq$ on $\mathcal{I}$ by

$$(J, x) \leq (K, y) \text{ if and only if } J \subset K \text{ and } x \geq z^{-1} y z \text{ for some } z \in W_K.$$

Theorem 3. (i) *$\leq$ defines an order on $\mathcal{I}$.*

(ii) *If $(J, x),\ (K, y) \in \mathcal{I}$ then $X_{J,w} \subset \overline{X_{K,y}}$ if and only if $(J, x) \leq (K, y)$.*

See [H2, sect. 3, 4].

Proposition 6. *If $\overline{X_{K,y}}$ contains only finitely many G_{d}-orbits then it has a cellular decomposition.*

See [loc. cit., sect. 5].

3.2. The closure of Steinberg fibers. Let $F \subset G$ be a Steinberg fiber (see 1.4). Its closure $\overline{F}$ is an irreducible closed G_{d}-stable subset of X. An example is the unipotent variety of X, the closure of the unipotent variety G_u of G.

Lemma 2. *There is $t \in T$ such that $\overline{F} = G_{\mathrm{d}}.t\overline{U}$*

See [Sp2, Lemma 1.4].

This leads to the problem of describing $\overline{U}$. Some partial results are given in [loc. cit.]. They use the fact (a consequence of completeness) that a point of $\overline{U}$ can be obtained by "specializing ξ to 0" from a point of $U(K)$ where $K = k((\xi))$, the field of formal Laurent series.

Let again G_{sc} be the simply connected cover of G, with Borel group $B_{\mathrm{sc}} = T_{\mathrm{sc}}.U_{\mathrm{sc}}$, B_{sc} and T_{sc} lying over B and T. Then $U_{\mathrm{sc}} \simeq U$.

Put

$$H = \{g \in G_{\mathrm{sc}}(k[[\xi]]) \mid g(0) \in B_{\mathrm{sc}}\}.$$

This is the Iwahori subgroup of $G(K)$ defined by B_{sc}. Let W_a be the affine Weyl group associated to T_{sc}. Then we have the Bruhat decomposition $G(K) = HW_aH$. whence a map $G(K) \to W_a$.

Problem 3. Determine the image in W_a of $U_{\mathrm{sc}}(K)$.

A solution of this problem will be useful for describing of $\overline{U}$, see [loc. cit.].

The main fact about the closures $\overline{F}$ is that they all intersect the boundary $X - G$ of X in the same set. More precisely, we have the following result. For $w \in W$ we denote by $\mathrm{supp}(w) \subset I$ the set of simple reflections occurring in a reduced decomposition of w.

Theorem 4.

$$\overline{F} - F = \coprod_{J \neq I} \coprod_{\substack{w \in W^J \\ \mathrm{supp}(w) = I}} X_{J,w}$$

This was first proved by He in [H1, Thms. 4.3, 4.5], via a laborious case by case check. In [HT1] a shorter proof is given and the result is extended to the σ-twisted case.

3.3. We sketch a simplified version of the proof of the theorem. It uses the following steps. F is a Steinberg fiber.

(a) $\overline{F} \cap X_\emptyset \neq \emptyset$.

By Lemma 2 it suffices to show that $\overline{U} \cap X_\emptyset \neq \emptyset$. This follows from the results of [Sp2, sect. 3], for example from [loc. cit., Cor. 3.8] with $w = w_{0,I}$.

(b) If $J \neq I$ and $X_{J,w} \cap \overline{F} \neq \emptyset$ then $\mathrm{supp}(w) = I$.

This is established using an argument from the proof of [H1, Thm. 4.3]. Assume that $i \notin \mathrm{supp}(w)$. Let ϖ_i be the fundamental weight associated to i and let (ρ, V) be an irreducible representation of G with lowest weight $-n\varpi_i$ $(n > 0)$. Then ρ extends to a G_{d}-equivariant morphism $X \to \mathbb{P}(\mathrm{End}(V))$ (see [DS, 3.15]). The image $\rho(\overline{F} - F)$ consists of nilpotent lines in $\mathrm{End}(V)$. On the other hand a lowest weight vector is an eigenvector of $\rho(\dot{w})$ with a nonzero eigenvalue and $\rho(h_J)$ is projection on the line of lowest weight vectors. Using (1) and Proposition 1 (i) one sees that this contradicts nilpotency.

(c) $\overline{F}$ and X_J intersect properly if $J \neq I$.

It suffices to prove this for $J = \emptyset$. From (a) it follows that $\dim \overline{F} \cap X_\emptyset \geq \dim F - |I|$. (b) implies, on the other hand, that the intersection has dimension $\leq \dim F - |I|$.

(d) Let $i \in I$. By (c) $\dim(\overline{F} \cap X_{I-\{i\}}) = \dim F - 1$. By Theorem 2 (i) there must be a set $X_{J,w}$ whose intersection with $\overline{F} \cap X_{I-\{i\}}$ is dense in $X_{I-\{i\}}$. Then $J \subset I - \{i\}$ and

$$\dim G - l(w) - |I - J| = \dim X_{J,w} \geq \dim F - 1 = \dim G - |I| - 1,$$

and $l(w) \leq |J| + 1$. But by (b) $l(w) \geq |I|$. We conclude that $|J| = |I| - 1$ and $l(w) = |I|$. We then must have $J = I - \{i\}$. Moreover, w is a Coxeter element i.e., $\mathrm{supp}(w) = I$ and $l(w) = |I|$.

(e) $W^{I-\{i\}}$ contains a unique Coxeter element c_i.

This is proved by induction on $|I|$.

(f) We conclude from (d) that $\overline{F} \cap X_{I-\{i\}} = \overline{X_{I-\{i\},c_i}}$ for all $i \in I$. Since for $J \neq I$

$$X_J = \bigcap_{i \notin J} X_{I-\{i\}}$$

this implies that the intersection $\overline{F} \cap (X - G)$ is independent of F. With a little more work the theorem follows.

3.4. Algebro-geometric properties. Let X_{sc} be a compactification of the simply connected cover G_{sc}. Let X_i $(1 \leq i \leq n)$ be the irreducible components of $X_{\mathrm{sc}} - G_{\mathrm{sc}}$. They all have codimension 1.

Proposition 7. *Let $p > 0$. Let F be a Steinberg fiber in G_{sc}.*

(i) *X_{sc} admits a Frobenius splitting which compatibly splits $\overline{F}$ and the X_i $(1 \leq i \leq n)$.*

(ii) *$\overline{F}$ is normal and Cohen–Macaulay.*

For (a somewhat stronger version of) (i) see [T, Thm. 8.2] and for (ii) [loc. cit., Thm. 10.2].

Notice that this result covers the wonderful compactification X of G if G has trivial center. For arbitrary adjoint G a partial result is proved in [LT]. For $i \in I$ let χ_i be the fundamental character of G_{sc} associated to i. Put

$$\tilde{F}_0 = \{g \in G_{\mathrm{sc}} \mid \chi_i(g) = 0 \text{ for all } i\},$$

this is a Steinberg fiber in G_{sc}. Its image in G is a Steinberg fiber F_0 in G, the zero fiber.

Proposition 8. *Let $p > 0$. X admits a Frobenius splitting which compatibly splits F_0 and the components of $X - G$.*

See [loc. cit., Thm. 8.1]. It is also pointed out that the result cannot be true for arbitrary Steinberg fibers in G.

Remark. The appearance of the zero fiber is somewhat curious. Over $\mathbb{C}$ it appears in [Ka] in another context. I learned from J.-P. Serre (private communication) that for a quasi-simple group over $\mathbb{C}$, F_0 has been determined (case by case). Its elements are regular and have finite order. The characteristic p case does not seem to have been analyzed.

Problem 4. $(p > 0)$ Does X admit a Frobenius splitting which compatibly splits an arbitrary $\overline{F}$?

Problem 5. Is $\overline{F}$ normal and Cohen–Macaulay?

Problem 6. Does $\overline{F}$ admit a cellular decomposition?

An example given in [Sp2, 4.3] with $G = \mathrm{PGL}_3$ shows that $\overline{F}$ need not be smooth.

Problem 7. Determine the intersection cohomology (local and global) of $\overline{F}$.

4. Character sheaves on X

In this section G is an adjoint group and X is its wonderful compactification.

4.1. $B \times B$-equivariant perverse sheaves. The definition of character sheaves on X uses certain $B \times B$-equivariant perverse sheaves on X, which we first have to introduce.

If S is a torus let $C(S)$ be its character group and put

$$\hat{C}(S) = C(S) \otimes (\mathbb{Z}_{(p)}/\mathbb{Z}),$$

where $\mathbb{Z}_{(p)}$ is the localization of $\mathbb{Z}$ at the prime ideal (p). The elements of $\hat{C}(S)$ parametrize tame rank one local systems on S (also called Kummer local systems). We work in l-adic cohomology, with a coefficient field E (e.g. $\overline{\mathbb{Q}_l}$).

Let $v = [J, x, w]$ be a $B \times B$-orbit in X, as in Proposition 1. Using that it is a homogeneous space for $B \times B$ one constructs a morphism $\phi\colon v \to T_J$, where T_J is the maximal torus of G_J of 2.1 (see [H3, 3.1]). For $\xi \in \hat{C}(T_J)$ we have a local system $\mathcal{L}_{\xi,v} = \phi^*\xi$ on v. Let $\mathcal{I}_{\xi,v}$ be its perverse extension, a perverse sheaf on X (for l-adic cohomology) supported by $\bar{v}$, whose restriction to v is $\mathcal{L}_{\xi,v}[\dim v]$.

[Sp1, sect. 5] deals with these perverse sheaves. It is shown that they are even, i.e. that their cohomology sheaves are zero in dimensions $\not\equiv \dim v \pmod 2$.

In the next lemma one uses that $\hat{C}(T_J)$ can be viewed as a subset of $\hat{C}(T)$ (see [loc. cit., 1.7]) and that W acts on $\hat{C}(T)$.

Lemma 3. *If $x.\xi = w.\xi$ then $\mathcal{I}_{\xi,v}$ is a B_{d}-equivariant irreducible perverse sheaf on X.*

See [H3, 3.1].

4.2. Character sheaves. Character sheaves on a reductive group were introduced by G. Lusztig in the 1980s, in a long series of papers. [L1] gives a brief exposition of the results of these papers. [MS] is a report on part of the results. The definition of character sheaves used there is slightly different from Lusztig's.

In [L2] Lusztig defines character sheaves on the compactification X. I noticed (unpublished) that the approach of [MS] could also be followed to do this. But it is not obvious that the two definitions of character sheaves on X are equivalent.

Independently, Xuhua He also came to the definition based on [MS]. He proved in [H3] the equivalence with Lusztig's definition. I shall not go into Lusztig's definition. I will only report on the other one.

B acts on $G \times X$ by $b.(g, x) = (gb^{-1}, (b, b).x)$. Let $G \times_B X$ be the quotient and $\alpha\colon G \times X \to G \times_B X$ the quotient map. The G_{d}-action on X induces a proper morphism $\mu\colon G \times_B X \to X$.

Let $\mathcal{I}_{\xi,v}$ be as in Lemma 3. Then $A = E[\dim G] \boxtimes \mathcal{I}_{\xi,v}$ is an irreducible perverse sheaf on $G \times X$ and there is an irreducible perverse sheaf $\tilde{A}$ on $G \times_B X$ with $A = \alpha^*\tilde{A}$.

Put $C_{\xi,v} = \mu_! \tilde{A}$. By the decomposition theorem this is a semisimple complex on X, i.e. a direct sum of shifted irreducible perverse sheaves on X. The perverse sheaves occurring in the $C_{\xi,v}$ (if ξ and v vary) are the character sheaves on X. They are G_{d}-equivariant.

The nonzero restrictions of these character sheaves to the open subvariety G of X are Lusztig's original character sheaves. More generally, for $J \subset D$ we call character sheaf on X_J the restriction to X_J of a character sheaf on X which is obtained as above from an orbit $v \subset X_J$.

The character sheaves on X deserve a further study. Here are a few problems.

Problem 8. Analyze the restriction of a character sheaf on X to a $G \times G$-orbit X_J. Can such restrictions be described in terms of character sheaves on X_J?

Problem 9. Are character sheaves on X even?

4.3. Finite ground fields. Now let k be an algebraic closure of the finite field $\mathbb{F}_q$ and let $F\colon a \mapsto a^q$ be the Frobenius automorphism of k. Assume that G is defined over k. Then so is X, by [DS, Prop. 3.11].

Let A be a character sheaf on G whose support is not contained in $X - G$. The restriction of A to G is a character sheaf on G. Assume that A "comes from $\mathbb{F}_q$", meaning that $F^*A \simeq A$. Fix an isomorphism $\phi\colon F^*A \simeq A$. It can be normalized such as to be unique up to a root unity (see [L1, p. 178]).

$x \in X^F = X(\mathbb{F}_q)$ being an $\mathbb{F}_q$-rational point of X, ϕ defines linear maps ϕ_x^i of the cohomology stalks $H^i(A)_x$. Define a function χ_ϕ on X^F by

$$\chi_\phi(x) = \Sigma_i (-1)^i \operatorname{Tr}(\phi_x^i, H^i(A)_x).$$

For $x \in G$ one obtains a class function on the finite Lie group G^F, which can be viewed as a generalized character of G^F. This function on G^F has boundary values, viz. the values of χ_ϕ on points of $X^F - G^F$.

Problem 10. Can one define and compute boundary values of irreducible characters of G^F?

Quasiconformal geometry of fractals

Mario Bonk*

Abstract. Many questions in analysis and geometry lead to problems of quasiconformal geometry on non-smooth or fractal spaces. For example, there is a close relation of this subject to the problem of characterizing fundamental groups of hyperbolic 3-orbifolds or to Thurston's characterization of rational functions with finite post-critical set.

In recent years, the classical theory of quasiconformal maps between Euclidean spaces has been successfully extended to more general settings and powerful tools have become available. Fractal 2-spheres or Sierpiński carpets are typical spaces for which this deeper understanding of their quasiconformal geometry is particularly relevant and interesting.

Mathematics Subject Classification (2000). Primary 30C65; Secondary 20F67.

Keywords. Quasiconformal maps, analysis on fractals.

1. Introduction

A homeomorphism on $\mathbb{R}^n$ is called *quasiconformal* if it maps infinitesimal balls to infinitesimal ellipsoids with uniformly controlled eccentricity. While in its substance this notion (for $n = 2$) was introduced by Grötzsch in the late 1920s (see [Kü] for an account of Grötzsch's work), the term "quasiconformal" was first used by Ahlfors in 1935 [Ah, p. 213 and p. 242].

The importance of planar quasiconformal mappings was only fully realized after Teichmüller had published his groundbreaking work on the classical moduli problem for Riemann surfaces around 1940. It took another two decades after the foundational issues of the theory of quasiconformal mappings had been clarified. A great subtlety here is what a priori smoothness assumption to impose on a quasiconformal map in order to get a theory with the desired compactness properties under limits. It turned out that some requirement of Sobolev regularity is appropriate.

Nowadays planar quasiconformal maps are recognized as a standard tool in various areas of complex analysis such as Teichmüller theory, Kleinian groups, and complex dynamics. One of the main reasons for this is that in the plane a flexible existence theorem for quasiconformal maps is available in the Measurable Riemann Mapping Theorem.

*Supported by NSF grants DMS-0200566 and DMS-0244421. The author would like to thank J. Heinonen, B. Kleiner and S. Merenkov for useful discussions and help with this survey.

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

In higher dimensions there is no such existence theorem putting severe limitations to the theory. Accordingly, quasiconformal maps for $n \geq 3$ initially had a less profound impact than their planar relatives. This situation changed when Mostow used the theory of higher-dimensional quasiconformal maps in the proof of his celebrated rigidity theorems for rank-one symmetric spaces [Mo]. In this context it also became desirable to extend the classical theory of quasiconformal mappings on $\mathbb{R}^n$ to other settings such as Heisenberg groups which arise as boundaries of complex hyperbolic spaces [KR1], [KR2], [Pa1]. A continuation of this trend was a theory of quasiconformal maps in a general metric space context and recently led to Heinonen and Koskela's theory of quasiconformal maps on Loewner spaces and spaces satisfying a Poincaré inequality [HK].

In this survey we will focus on questions of quasiconformal geometry of low-dimensional fractals such as 2-spheres and Sierpiński carpets. In particular, we will discuss uniformization and rigidity theorems that are motivated by questions in geometric group theory and complex dynamics. For some additional topics not discussed here, we refer to B. Kleiner's article in these conference proceedings.

2. Quasiconformal and quasisymmetric maps

We first give a precise definition of various classes of maps that are related to the concept of quasiconformality (see [BI], [He], [Vä1] for more details).

A homeomorphism $f\colon \mathbb{R}^n \to \mathbb{R}^n$, $n \geq 2$, is called *quasiconformal*, if f belongs to the Sobolev space $W^{1,n}_{\mathrm{loc}}(\mathbb{R}^n, \mathbb{R}^n)$ and if there exists a constant $K \geq 1$ such that the inequality

$$\|Df(x)\|^n \leq K|J_f(x)| \tag{1}$$

is valid for almost every $x \in \mathbb{R}^n$. Here $\|Df(x)\|$ is the norm of the formal differential Df and $J_f = \det(Df)$ is the Jacobian determinant of f. If we want to emphasize K, then we say that f is *K-quasiconformal*. We will use similar language below for concepts that depend on parameters. We exclude $n = 1$ in the following, because in this case the theory of quasiconformal maps has somewhat different features than for $n \geq 2$. An important fact about quasiconformal maps is that they are differentiable almost everywhere. Hence we can replace the formal quantity Df in (1) by the classical derivative.

The "analytic" definition of quasiconformality above applies to more general smooth settings, for example, if f is a map between Riemannian n-manifolds. If one drops the requirement that f is a homeomorphism and allows branching, then one is led to the concept of a *quasiregular* map [Re], [Ri].

A general definition of a quasiconformal map in a metric space context (the "metric" definition) can be given as follows. Suppose $f\colon X \to Y$ is a homeomorphism between metric spaces (X, d_X) and (Y, d_Y). Then f is *quasiconformal* if there exists

a constant $H \geq 1$ such that

$$H_f(x) := \limsup_{r \to 0^+} \frac{\sup\{d_Y(f(x'), f(x)) : d_X(x, x') \leq r\}}{\inf\{d_Y(f(x'), f(x)) : d_X(x, x') \geq r\}} \leq H$$

for all $x \in X$. In $\mathbb{R}^n$, $n \geq 2$, this is equivalent to the analytic definition. In general, this concept is rather weak and does not lead to a useful theory, if one does not impose further restrictions on the spaces X and Y.

A related, but stronger concept is the notion of a quasisymmetric map [TV]. By definition a homeomorphism $f\colon X \to Y$ is called *quasisymmetric*, if there exists a homeomorphism $\eta\colon [0, \infty) \to [0, \infty)$ (which plays the role of a distortion function) such that

$$\frac{d_Y(f(x), f(y))}{d_Y(f(x), f(z))} \leq \eta\left(\frac{d_X(x, y)}{d_X(x, z)}\right),$$

whenever $x, y, z \in X$, $x \neq z$.

The geometric meaning of this condition is that balls are mapped to "round" sets with quantitative control for their "eccentricity". This is a global version of the geometric property of a quasiconformal map. In $\mathbb{R}^n$, $n \geq 2$, a map is quasiconformal if and only if it is quasisymmetric. Inverse maps or compositions of quasisymmetric maps are again quasisymmetric. So the quasisymmetric maps $f\colon X \to X$ on a metric space X form a group that we denote by $\mathrm{QS}(X)$.

In particular when a group action is present, the concept of a quasi-Möbius map is often more suitable than that of a quasisymmetry. Here a homeomorphism $f\colon X \to Y$ is called a *quasi-Möbius map* [Vä2] if there exists a homeomorphism $\eta\colon [0, \infty) \to [0, \infty)$ such that for every 4-tuple (x_1, x_2, x_3, x_4) of distinct points in X, we have the inequality

$$[f(x_1), f(x_2), f(x_3), f(x_4)] \leq \eta([x_1, x_2, x_3, x_4])$$

for the *metric cross-ratio*

$$[z_1, z_2, z_3, z_4] = \frac{d_X(z_1, z_3) d_X(z_2, z_4)}{d_X(z_1, z_4) d_X(z_2, z_3)}.$$

Every quasisymmetric map $f\colon X \to Y$ between metric spaces is also quasi-Möbius. This statement is "quantitative" in the following sense: If f is η-quasisymmetric, then f is $\tilde{\eta}$-quasi-Möbius with $\tilde{\eta}$ only depending on η. Conversely, every quasi-Möbius map between bounded metric spaces is quasisymmetric, but in contrast to the other implication this statement is not quantitative in general. One can also get a quantitative statement here if one assumes that the spaces are bounded and adds a normalization condition for the map.

There is a third way to characterize quasiconformal maps on $\mathbb{R}^n$ based on the concept of the modulus of a path family. We first review some definitions related to this.

Suppose (X, d, μ) is a metric measure space, i.e., (X, d) is a metric space and μ a Borel measure on X. Moreover, we assume that (X, d) is locally compact and that μ is locally finite and has dense support.

The space (X, d, μ) is called (*Ahlfors*) Q*-regular*, $Q > 0$, if the measure μ satisfies

$$C^{-1} R^Q \le \mu(\bar{B}(a, R)) \le C R^Q$$

for each closed ball $\bar{B}(a, R)$ of radius $0 < R \le \operatorname{diam}(X)$ and for some constant $C \ge 1$ independent of the ball. If the measure is not specified, then it is understood that μ is Q-dimensional Hausdorff measure. Note that a complete Ahlfors regular space X is *proper*, i.e., closed balls in X are compact.

A *density* on X is a Borel function $\rho\colon X \to [0, \infty]$. A density ρ is called *admissible* for a path family Γ in X, if

$$\int_\gamma \rho \, ds \ge 1$$

for each locally rectifiable path $\gamma \in \Gamma$. Here integration is with respect to arclength on γ.

If $Q \ge 1$, the Q*-modulus* of a family Γ of paths in X is the number

$$\operatorname{Mod}_Q(\Gamma) = \inf \int \rho^Q \, d\mu,$$

where the infimum is taken over all densities $\rho\colon X \to [0, \infty]$ that are admissible for Γ. If E and F are subsets of X with positive diameter, we denote by

$$\Delta(E, F) = \frac{\operatorname{dist}(E, F)}{\min\{\operatorname{diam}(E), \operatorname{diam}(F)\}}$$

the *relative distance* of E and F, and by $\Gamma(E, F)$ the family of all paths in X connecting E and F.

Suppose (X, d, μ) is a connected metric measure space. Then X is called a Q-*Loewner space*, $Q \ge 1$, if there exists a positive decreasing function $\Psi\colon (0, \infty) \to (0, \infty)$ such that

$$\operatorname{Mod}_Q(\Gamma(E, F)) \ge \Psi(\Delta(E, F)), \tag{2}$$

whenever E and F are disjoint continua in X.

Condition (2) axiomatizes a property of n-modulus in $\mathbb{R}^n$ relevant for quasiconformal geometry to a general metric space setting. Examples for Loewner spaces are $\mathbb{R}^n$, all compact Riemannian manifolds, Carnot groups (such as the Heisenberg group), and boundaries of some Fuchsian buildings. Equivalent to the Loewner property of a space is that it satisfies a Poincaré inequality (see [HK], [He] for more discussion on these topics).

The following theorem is a combination of results by Heinonen and Koskela [HK] and by Tyson [Ty], and characterizes quasiconformal maps on Loewner spaces by a distortion property for modulus.

Theorem 2.1. *Let X and Y be Q-regular Q-Loewner spaces, $Q > 1$, and $f : X \to Y$ a homeomorphism. Then f is quasiconformal if and only if there exists a constant $K \geq 1$ such that*

$$\frac{1}{K} \operatorname{Mod}_Q(\Gamma) \leq \operatorname{Mod}_Q(f(\Gamma)) \leq K \operatorname{Mod}_Q(\Gamma) \tag{3}$$

for every family Γ of paths in X, where $f(\Gamma) = \{f \circ \gamma : \gamma \in \Gamma\}$.

In $\mathbb{R}^n$ this characterization of a quasiconformal map is known as the "geometric" definition. The reason for this terminology is that (3) immediately leads to strong geometric consequences. For example, using this one can show that f is quasisymmetric.

The fact that the analytic, metric, and geometric definitions of a quasiconformal map on $\mathbb{R}^n$ are (quantitatively) equivalent is a rather deep fact. This has recently been generalized to the general Loewner space setting [HKST].

3. The quasisymmetric uniformization problem

The classical uniformization theorem implies that every Riemann surface is conformally equivalent to a "standard" surface carrying a metric of constant curvature. One can ask whether a general metric space version of this fact is true where the class of conformal maps is replaced by the more flexible class of quasisymmetric homeomorphisms.

Quasisymmetric uniformization problem. Suppose X is a metric space homeomorphic to some "standard" metric space Y. When is X quasisymmetrically equivalent to Y?

Here we call two metric spaces X and Y *quasisymmetrically equivalent* if there exists a quasisymmetric homeomorphism from X onto Y. Equivalently, one may ask for a quasisymmetric characterization of Y. Of course, it depends on the context how the term "standard" is precisely interpreted. This general question is motivated by problems in geometric group theory, for example (see Sections 5 and 7). One can also pose a similar uniformization problem for other classes of maps, for example bi-Lipschitz maps (recall that a homeomorphism between metric spaces is called *bi-Lipschitz* if it distort distances by at most a fixed multiplicative amount).

The prime instance for a quasisymmetric uniformization result is the following theorem due to Tukia and Väisälä that characterizes *quasicircles*, i.e., quasisymmetric images of the unit circle $\mathbb{S}^1$ [TV].

Theorem 3.1. *Let X be a metric space homeomorphic to $\mathbb{S}^1$. Then X is quasisymmetrically equivalent to $\mathbb{S}^1$ if and only if X is doubling and linearly locally connected.*

Here a metric space X is called *doubling* if there exists a number N such that every ball in X of radius R can be covered by N balls of radius $R/2$. A metric space X

is called *linearly locally connected* if there exists a constant $\lambda \geq 1$ satisfying the following conditions: If $B(a, r)$ is an open ball in X and $x, y \in B(a, r)$, then there exists a continuum in $B(a, \lambda r)$ connecting x and y. Moreover, if $x, y \in X \setminus B(a, r)$, then there exists a continuum in $X \setminus B(a, r/\lambda)$ connecting x and y. The geometric significance of this condition is that it rules out "cusps" of the space.

A quasisymmetric characterization of the standard $1/3$-Cantor set can be found in [DS]. Work by Semmes [Se1], [Se2] shows that the quasisymmetric characterization of $\mathbb{R}^n$ or the standard sphere $\mathbb{S}^n$ for $n \geq 3$ is a problem that seems to be beyond reach at the moment. The intermediate case $n = 2$ is particularly interesting.

For a metric 2-sphere X to be quasisymmetrically equivalent to the standard 2-sphere $\mathbb{S}^2$ it is necessary that X is linearly locally connected. This alone is not sufficient, but will be if a mass bound assumption is added [BK1].

Theorem 3.2. *Suppose X is a metric space homeomorphic to $\mathbb{S}^2$. If X is linearly locally connected and Ahlfors 2-regular, then X is quasisymmetrically equivalent to $\mathbb{S}^2$.*

This answers a question by Heinonen and Semmes [HS]. A similar result for other simply connected surfaces has been obtained by K. Wildrick [Wi].

The proof of Theorem 3.2 uses approximations of X by graphs that are combinatorially equivalent to triangulations of $\mathbb{S}^2$. Realizing such a triangulation as an incidence graph of a circle packing on $\mathbb{S}^2$, one finds a mapping of X to $\mathbb{S}^2$ on a coarse scale. The main difficulty is to show the subconvergence of this procedure. For this one controls the quasisymmetric distortion by modulus estimates. Incidentally, a very similar algorithm has recently been used to obtain mappings of the surface of the human brain [H-R].

The assumption of Ahlfors regularity for some exponent $Q \geq 2$ is quite natural, because it is satisfied in many interesting cases (for boundaries of Gromov hyperbolic groups for example; see Section 4). There are metric 2-spheres X though that are linearly locally connected and Q-regular with $Q > 2$, but are not quasisymmetrically equivalent to $\mathbb{S}^2$ [Vä3].

The following result can be proved similarly as Theorem 3.2 [BK1].

Theorem 3.3. *Let $Q \geq 2$ and Z be an Ahlfors Q-regular metric space homeomorphic to $\mathbb{S}^2$. If Z is Q-Loewner, then $Q = 2$ and Z is quasisymmetrically equivalent to $\mathbb{S}^2$.*

Note that an analog of this is false in higher dimensions. For example, one can equip $\mathbb{S}^3$ with a Carnot–Carathéodory metric d modeled on the geometry of the Heisenberg group. Then $(\mathbb{S}^3, d)$ is 4-regular and 4-Loewner, but not quasisymmetrically equivalent to standard $\mathbb{S}^3$ [Se1].

In [BK1] a necessary and sufficient condition was established for a metric 2-sphere to be quasisymmetrically equivalent to $\mathbb{S}^2$. This condition is in terms of the behavior of some combinatorially defined moduli of ring domains and too technical to be stated here. The usefulness of any such characterization depends on whether one

can verify its hypotheses in concrete situations such as for fractal 2-spheres coming from dynamical systems as considered in the following Sections 5 and 6.

4. Gromov hyperbolic spaces and quasisymmetric maps

As a preparation for the next sections, we quickly review some standard material on Gromov hyperbolic spaces and groups [GH], [Gr].

Let (X, d) be a metric space, and $\delta \geq 0$. Then X is called *δ-hyperbolic*, if the inequality

$$(x \cdot z)_p \geq \min\{(x \cdot y)_p, (y \cdot z)_p\} - \delta$$

holds for all $x, y, z, p \in X$, where

$$(u \cdot v)_p = \frac{1}{2}\big(d(u, p) + d(v, p) - d(u, v)\big)$$

for $u, v \in X$. If the space X is *geodesic* (this means that any two point in X can be joined by a path whose length is equal to the distance of the points), then the δ-hyperbolicity of X is equivalent to a thinness condition for geodesic triangles. We say that X is *Gromov hyperbolic* if X is δ-hyperbolic for some $\delta \geq 0$. Roughly speaking, this requires that the space is "negatively curved" on large scales. Examples for such spaces are simplicial trees, or Cartan–Hadamard manifolds with a negative upper curvature bound such as the real hyperbolic spaces $\mathbb{H}^n$, $n \geq 2$.

To each Gromov hyperbolic space one can associate a boundary at infinity $\partial_\infty X$ as follows. Fix a basepoint $p \in X$, and consider sequences of points $\{x_i\}$ in X *converging to infinity* in the sense that

$$\lim_{i,j\to\infty} (x_i \cdot x_j)_p = \infty.$$

We declare two such sequences $\{x_i\}$ and $\{y_i\}$ in X as *equivalent* if

$$\lim_{i\to\infty} (x_i \cdot y_i)_p = \infty.$$

Now the *boundary at infinity* $\partial_\infty X$ is defined as the set of equivalence classes of sequences converging to infinity. It is easy to see that the choice of the basepoint p does not matter here. If X is in addition proper and geodesic, then there is an equivalent definition of $\partial_\infty X$ as the set of equivalence classes of geodesic rays emanating from the basepoint p. One declares two such rays as equivalent if they stay within bounded Hausdorff distance. Intuitively, a ray represents its "endpoint" on $\partial_\infty X$. If $\mathbb{H}^n$ is given by the unit ball model, then from this point of view it is clear that $\partial_\infty \mathbb{H}^n = \mathbb{S}^{n-1}$.

The boundary $\partial_\infty X$ comes naturally equipped with a class of "visual" metrics. By definition a metric ρ on $\partial_\infty X$ is called *visual* if there exist $p \in X$, $C \geq 1$, and $\varepsilon > 0$ such that

$$\frac{1}{C} \exp(-\varepsilon(a \cdot b)_p) \leq \rho(a, b) \leq C \exp(-\varepsilon(a \cdot b)_p) \tag{4}$$

for all $a, b \in \partial_\infty X$. In this inequality we used the fact that a "product" $(a \cdot b)_p \in [0, \infty]$ can also be defined for points $a, b \in \partial_\infty X$ in a natural way. Here we have $(a \cdot b)_p = \infty$ if and only if $a = b \in \partial_\infty X$. If X is δ-hyperbolic, then there exists a visual metric ρ with parameter ε if $\varepsilon > 0$ is small enough depending on δ.

In the following we always think of $\partial_\infty X$ as a metric space by equipping it with a fixed visual metric. If ρ_1 and ρ_2 are two visual metrics on $\partial_\infty X$, then the identity map is a quasisymmetric map between (X, ρ_1) and (X, ρ_2) (the visual metrics form a *conformal gauge* – see [He, Ch. 15] for this terminology and further discussion). So the ambiguity of the visual metric is irrelevant if one wants to speak of quasisymmetric maps on $\partial_\infty X$. One should consider the space $\partial_\infty X$ equipped with such a visual metric ρ as very "fractal". For example, if the parameter ε in (4) is very small, then $(\partial_\infty X, \rho)$ will not contain any non-constant rectifiable curves.

Suppose (X, d_X) and (Y, d_Y) are metric spaces. A map $f\colon X \to Y$ is called a *quasi-isometry* if there exist constants $\lambda \geq 1$ and $k \geq 0$ such that

$$\frac{1}{\lambda} d_X(u, v) - k \leq d_Y(f(u), f(v)) \leq \lambda d_X(u, v) + k$$

for all $u, v \in X$ and if

$$\inf_{x \in X} d_Y(f(x), y) \leq k$$

for all $y \in Y$. The spaces X and Y are called *quasi-isometric* if there exists a quasi-isometry $f\colon X \to Y$.

Quasi-isometries form a natural class of maps in the theory of Gromov hyperbolic spaces. For example, Gromov hyperbolicity of geodesic metric spaces is invariant under quasi-isometries. The following fact links these concepts to quasisymmetric maps (see [BS] for more on this subject).

Proposition 4.1. *Let X and Y be proper and geodesic Gromov hyperbolic spaces. Then every quasi-isometry $f\colon X \to Y$ induces a natural quasisymmetric boundary map $\tilde{f}\colon \partial_\infty X \to \partial_\infty Y$.*

The boundary map $\tilde{f}$ is defined by assigning to a point $a \in \partial_\infty X$ represented by the sequence $\{x_i\}$ the point $b \in \partial_\infty Y$ represented by the sequence $\{f(x_i)\}$.

This proposition constitutes a core element in Mostow's proof of rigidity of rank-one symmetric spaces. The point is that a quasi-isometry may locally exhibit very irregular behavior, but gives rise to a quasisymmetric boundary map that can be analyzed by analytic tools.

Suppose G is a finitely generated group, and let S be a set of generators. We will always assume that S is finite and *symmetric* in the sense that if $s \in S$, then $s^{-1} \in S$. The *Cayley graph* $C(G, S)$ of G with respect to S is a graph that has G as its set of vertices. Moreover, we connect two distinct vertices $x, y \in G$ by an edge if there exists $s \in S$ such that $y = xs$. The graph $C(G, S)$ carries a natural path metric that assigns length 1 to each edge. By considering its Cayley graph, one can study properties of the group from a geometric point of view.

The group G is called *Gromov hyperbolic* if $C(G, S)$ is Gromov hyperbolic for some set S of generators of G. If this is the case, then $C(G, S')$ is Gromov hyperbolic for all generating sets S'. This essentially follows from the fact that $C(G, S)$ and $C(G, S')$ are bi-Lipschitz equivalent (and in particular quasi-isometric). This also implies that if we define $\partial_\infty G := \partial_\infty C(G, S)$, then by Proposition 4.1 the boundary at infinity of G is well-defined up to quasisymmetric equivalence. Examples of Gromov hyperbolic groups are free groups and fundamental groups of negatively curved manifolds.

Letting a group element $g \in G$ act on the vertices of $C(G, S)$ by left-translation, we get a natural action $G \curvearrowright C(G, S)$ by isometries. According to Proposition 4.1 this induces a group action $G \curvearrowright \partial_\infty G$, where each group element acts as a quasisymmetric map. In general the distortion function η will be different for different group elements. This changes if one uses the concept of quasi-Möbius maps. In this case the action $G \curvearrowright \partial_\infty G$ is *uniformly quasi-Möbius*, i.e., there exists a distortion function η such that every element $g \in G$ acts as an η-quasi-Möbius map on $\partial_\infty G$ [Pau].

Another important property of the action $G \curvearrowright \partial_\infty G$ is its "cocompactness on triples". Denote by $\mathrm{Tri}(X)$ the space of triples of distinct points in a space X. The action $G \curvearrowright \partial_\infty G$ induces an action $G \curvearrowright \mathrm{Tri}(\partial_\infty G)$. This action is discrete and cocompact, and Gromov hyperbolic groups are characterized by this property according to a theorem by Bowditch [Bow].

5. Cannon's conjecture and fractal 2-spheres

It is a natural question to what extent the structure of a Gromov hyperbolic group G is reflected in its boundary $\partial_\infty G$. For example, $\partial_\infty G$ is totally disconnected iff G is virtually free, i.e., it contains a free group of finite index. Similarly, $\partial_\infty G$ is a topological circle iff G is virtually Fuchsian (see [KB] for these and related results). The case where $\partial_\infty G$ is a topological 2-sphere is covered by the following conjecture [Ca].

Conjecture 5.1 (*Cannon's conjecture, Version* I). Suppose G is a Gromov hyperbolic group whose boundary at infinity $\partial_\infty G$ is homeomorphic to $\mathbb{S}^2$. Then there exists an action of G on hyperbolic 3-space $\mathbb{H}^3$ that is isometric, properly discontinuous, and cocompact.

If true, this conjecture would essentially give a characterization of fundamental groups of closed hyperbolic 3-orbifolds from the point of view of geometric group theory. The conjecture is equivalent to a quasisymmetric uniformization problem.

Conjecture 5.2 (*Cannon's conjecture, Version* II). Suppose G is a Gromov hyperbolic group whose boundary at infinity $\partial_\infty G$ is homeomorphic to $\mathbb{S}^2$. Then $\partial_\infty G$ is quasisymmetrically equivalent to $\mathbb{S}^2$.

Indeed, if Conjecture 5.2 holds, then we can conjugate the natural action of G on $\partial_\infty G$ to a uniformly quasiconformal action of G on $\mathbb{S}^2$. By a well-known theorem due

to Sullivan [Su1] and to Tukia [Tu] such an action is conjugate to an action of G on $\mathbb{S}^2$ by Möbius transformations. Considering $\mathbb{S}^2$ as the boundary at infinity of $\mathbb{H}^3$, we can extend this action to an isometric action of G on $\mathbb{H}^3$ with the desired properties.

Conversely, if G acts on $\mathbb{H}^3$ isometrically, properly discontinuously, and cocompactly, then the Cayley graph of G with respect to any (finite and symmetric) set of generators is quasi-isometric to $\mathbb{H}^3$. This quasi-isometry induces the desired quasisymmetric equivalence between $\partial_\infty G$ and $\partial_\infty \mathbb{H}^3 = \mathbb{S}^2$.

Cannon, Floyd, and Parry [CFP] have attempted to settle Conjecture 5.1 by using subdivision rules and Cannon's Combinatorial Riemann Mapping Theorem [Ca]. A different approach is due to B. Kleiner and the author. In [BK4] recently developed techniques from analysis on metric spaces were used and led to the following theorem.

Theorem 5.3. *Suppose G is a Gromov hyperbolic group whose boundary at infinity $\partial_\infty G$ is homeomorphic to $\mathbb{S}^2$. If the Ahlfors regular conformal dimension of $\partial_\infty G$ is attained as a minimum, then ∂G_∞ is quasisymmetrically equivalent to $\mathbb{S}^2$.*

Here the (*Ahlfors regular*) *conformal dimension* of a metric space X is defined as

$$\dim_{\mathrm{c}} X = \inf\{Q : \text{there exists an Ahlfors } Q\text{-regular metric space } Y \text{ that is quasisymmetrically equivalent to } X\}. \tag{5}$$

This concept was implicitly introduced by Bourdon and Pajot [BP]. Pansu [Pa2] has defined a related, but different concept of conformal dimension of a space. If $X = \partial_\infty G$, where G is a Gromov hyperbolic group, then the set over which the infimum in (5) is taken is nonempty, because the boundary of a Gromov hyperbolic group equipped with a visual metric is Ahlfors regular [Co].

In more intuitive terms, the above result can be formulated as follows: Let G be a Gromov hyperbolic group as in Cannon's conjecture. If a certain infimum for $\partial_\infty G$ is attained as a minimum (related to how much we can "squeeze" the space by a quasisymmetric map while retaining Ahlfors regularity for some exponent), then the desired conclusion holds.

The proof of this theorem depends on a recent result by Keith and Laakso [KL] which essentially says that if $Q > 1$ is the conformal dimension of a Q-regular space X, then X has a *weak tangent* (see [BBI, Ch. 8] for the definition and [BK2] for related discussions), carrying a family of non-constant paths with positive Q-modulus.

In our situation $X = \partial_\infty G$ is the boundary of a Gromov hyperbolic group G, and is equipped with a metric that comes from the minimizer in (5). Every weak tangent of X is quasisymmetrically equivalent to $\partial_\infty G$ minus a point [BK2]. Therefore, $\partial_\infty G$ itself carries a family of positive Q-modulus, where Q is the conformal dimension of $\partial_\infty G$. The main work now consists in showing that the natural group action $G \curvearrowright \partial_\infty G$ allows one to promote this to the stronger conclusion that $\partial_\infty G$ has families of non-constant paths with uniformly positive Q-modulus on all locations and scales; more precisely, that $X = \partial_\infty G$ is a Q-regular Q-Loewner space. Up to this point, the assumption that $\partial_\infty G$ is homeomorphic to $\mathbb{S}^2$ was not used. The proof

of the above statement is now finished by invoking Theorem 3.3 which shows that $\partial_\infty G$ is quasisymmetrically equivalent to $\mathbb{S}^2$.

Related to these questions is the following problem due to P. Papasoglu: Suppose that G is a Gromov hyperbolic group whose boundary $\partial_\infty G$ is homeomorphic to $\mathbb{S}^2$. Cannon's conjecture predicts that in this situation $\partial_\infty G$ is quasisymmetrically equivalent to $\mathbb{S}^2$; in particular, $\partial_\infty G$ should contain many quasicircles. While Cannon's conjecture is still open, can one at least prove that $\partial_\infty G$ contains a *single* quasicircle? The following result proved in [BK5] settles this in the affirmative.

Theorem 5.4. *The boundary of a Gromov hyperbolic group contains a quasicircle if and only if the group is not virtually free.*

In order to get a better understanding of the relevant issues in Cannon's conjecture, it seems natural to study uniformly quasi-Möbius actions on compact metric spaces X such that the induced action on the space $\mathrm{Tri}(X)$ of triples is discrete and cocompact. In addition to these assumptions it is reasonable to require that X is Ahlfors regular.

If a metric space X is Q-regular, then the exponent Q is at least as big as the topological dimension of X. The borderline case where Q equals the topological dimension of X is of particular interest. In [BK2] (for $n \geq 2$) and [BK3] (for $n = 1$) the following rigidity theorem was proved in all dimensions (see [Su2] and [Yu] for related results).

Theorem 5.5. *Let X be a compact, Ahlfors n-regular metric space of topological dimension $n \in \mathbb{N}$. Suppose that a group G acts on X by uniformly quasi-Möbius maps and that the induced action on* $\mathrm{Tri}(X)$ *is discrete and cocompact. Then the action $G \curvearrowright X$ is quasisymmetrically conjugate to a Möbius group action on the standard sphere $\mathbb{S}^n$.*

Note that we do not assume that X is homeomorphic to $\mathbb{S}^n$. We get the quasisymmetric equivalence of X and $\mathbb{S}^n$ as part of the conclusion.

6. Post-critically finite rational maps

Apart from Gromov hyperbolic groups, there are other dynamical systems where quasisymmetric uniformization problems arise. Interesting examples are provided by post-critically finite rational maps R on the Riemann sphere $\overline{\mathbb{C}}$ [DH].

Suppose $R\colon \overline{\mathbb{C}} \to \overline{\mathbb{C}}$ is a holomorphic map of $\overline{\mathbb{C}}$ onto itself, i.e., a rational function. Let Ω_R denote the set of critical points of R, and $P_R = \bigcup_{n\in\mathbb{N}} R^n(\Omega_R)$ be the set of post-critical points of R (here R^n denotes the n-th iterate of R). We make the following assumptions on R:

(i) R is post-critically finite, i.e., P_R is a finite set,

(ii) R has no periodic critical points; this implies that $\mathcal{J}(R) = \overline{\mathbb{C}}$ for the Julia set of R,

(iii) the orbifold $\mathcal{O}_R$ associated with R is hyperbolic (see [DH] for the definition of $\mathcal{O}_R$); this implies that the dynamics of R on the Julia set $\mathcal{J}(R) = \overline{\mathbb{C}}$ is expanding.

A characterization of post-critically finite rational maps is due to Thurston. The right framework is the theory of topologically holomorphic self-maps $f\colon \mathbb{S}^2 \to \mathbb{S}^2$ of the sphere. By definition these maps have the local form $z \mapsto z^n$ with $n \in \mathbb{N}$ in appropriate local coordinates, and one defines the critical set, the post-critical set, and the associated orbifold similarly as for rational maps. In our context, Thurston's theorem can be stated as follows [DH].

Theorem 6.1. *Let $f\colon \mathbb{S}^2 \to \mathbb{S}^2$ be a post-critically finite topologically holomorphic map with hyperbolic orbifold. Then f is equivalent to a rational map R if and only if f has no "Thurston obstructions".*

Equivalence has to be understood in an appropriate sense. If f and R are both expanding, this just means conjugacy of the maps.

A Thurston obstruction is defined as follows. A *multicurve* $\Gamma = \{\gamma_1, \dots, \gamma_n\}$ is a system of Jordan curves in $\mathbb{S}^2 \setminus P_f$ with the following properties: the curves have pairwise empty intersection, are pairwise non-homotopic in $\mathbb{S}^2 \setminus P_f$, and non-peripheral (this means that each of the complementary components of a curve contains at least two points in P_f). A multicurve Γ is called *f-stable* if for all j every component of $f^{-1}(\gamma_j)$ is either peripheral or homotopic in $\mathbb{S}^2 \setminus P_f$ to one of the curves γ_i.

If Γ is an f-stable multicurve, fix i and j and label by α the components $\gamma_{i,j,\alpha}$ of $f^{-1}(\gamma_j)$ homotopic to γ_i in $\mathbb{S}^2 \setminus P_f$. Then f restricted to $\gamma_{i,j,\alpha}$ has a mapping degree $d_{i,j,\alpha} \in \mathbb{N}$. Let

$$m_{ij} = \sum_{\alpha} \frac{1}{d_{i,j,\alpha}}$$

and define the *Thurston matrix* $A(\Gamma)$ of the f-stable multicurve Γ by $A(\Gamma) = (m_{ij})$. This is a matrix with nonnegative coefficients; therefore, it has a largest eigenvalue $\lambda(f, \Gamma) \geq 0$. Then Γ is a *Thurston obstruction* if $\lambda(f, \Gamma) \geq 1$.

In Figure 1 we see topological 2-spheres obtained by gluing together 16 squares (colored black and white in an alternating fashion) for the surface on the left, and two large squares for the surface on the right. The map f is constructed by scaling a white square so that it corresponds to the top square on the right and extending the partially defined map to the whole surface by "Schwarz reflection". Then f is post-critically finite with a set of 4 post-critical points (the corners of the large squares). An f-stable multicurve Γ consisting of one Jordan curve γ is indicated on the right. It has 4 preimages on the left. Two of them are peripheral, and the other ones are homotopic to γ in the complement of P_f. Since the degree of the map on these curves is 2, the Thurston matrix is a (1×1)-matrix with the entry $1/2 + 1/2 = 1$. Hence Γ is a Thurston obstruction and f is not equivalent to a rational map.

Post-critically finite rational maps are related to *subdivision rules* [CFKP], [CFP]. For example, if R is a real rational map, i.e., $R(\overline{\mathbb{R}}) \subseteq \overline{\mathbb{R}} := \mathbb{R} \cup \{\infty\}$, satisfying

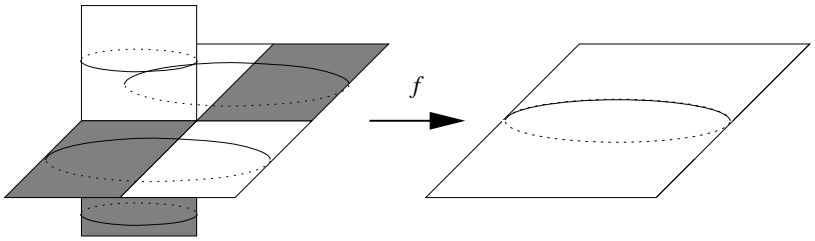

Figure 1. A post-critically finite topologically holomorphic map with a Thurston obstruction.

the above conditions (i)–(iii), and $P_R \subseteq \overline{\mathbb{R}}$, then $R^{-1}(\overline{\mathbb{R}})$ is a graph providing a subdivision of the upper and lower half-planes. It will give rise to a *one-tile subdivision rule*, because the upper and the lower half-planes are subdivided in the same way. The combinatorics of the graphs $R^{-n}(\overline{\mathbb{R}})$ with its corresponding tiles of level n (the closures of the complementary components of the graph $R^{-n}(\overline{\mathbb{R}})$) is determined by iterating the subdivision rule n times. Note that once the subdivision rule is given, the map R admits a completely combinatorial description as an "expanding map" of the subdivision rule by specifying which tiles on level n are mapped to which tiles on level $n-1$. The map f in Figure 1 is also associated with a one-tile subdivision rule which describes how the squares on the right are subdivided into 8 squares each to obtain the combinatorics of the squares on the surface on the left.

For general, not necessarily real rational functions, one expects at least two tile types. More precisely, one can ask whether every rational map satisfying (i)–(iii), or at least a sufficiently high iterate of such a map, is associated with a two-tile subdivision rule. This is indeed the case [BMy], showing that the behavior of the rational maps as discussed admits a combinatorial description.

Theorem 6.2. *Let R be a rational function satisfying* (i)–(iii). *Then there exists an iterate R^n and a quasicircle $C \subseteq \overline{\mathbb{C}}$ such that $P_{R^n} \subseteq C$ and $R^n(C) \subseteq C$.*

A related result has been announced by Cannon, Floyd, and Parry (unpublished).

Conversely, one can start with a two-tile subdivision rule of $\mathbb{S}^2$ (satisfying additional technical assumptions encoding the properties (i)–(iii)). One can associate a natural metric d_λ on $\mathbb{S}^2$ with such a subdivision rule. Roughly speaking, one fixes a parameter $\lambda < 1$ and declares tiles on level n to have size λ^n. The distance $d_\lambda(x, y)$ between two points $x, y \in \mathbb{S}^2$ is then defined as the infimum of all sums of tile-sizes in chains of tiles connecting x and y. Here one has to allow tiles of different levels in a chain. If $\lambda < 1$ is sufficiently close to 1, this gives a metric d_λ on $\mathbb{S}^2$ such that the diameter of a tile on level n is comparable to λ^n. The ambiguity in the parameter λ is not very serious and leads to quasisymmetrically equivalent metrics. These metrics d_λ form an analog of the visual metrics on the boundary of a Gromov hyperbolic group.

If we denote by X the sphere $\mathbb{S}^2$ equipped with this metric, then X is Ahlfors regular and linearly locally connected, and the subdivision rule produces a topologically holomorphic expanding map $f\colon X \to X$ which is post-critically finite, and which is "uniformly" quasiregular with respect to a suitable notion of quasiregularity in this metric space context. The question when the dynamical system $f\colon X \to X$ comes from a rational map can be formulated as a quasisymmetric uniformization problem. The following result is essentially contained in [My].

Theorem 6.3. *The map $f\colon X \to X$ is conjugate to a rational map $R\colon \overline{\mathbb{C}} \to \overline{\mathbb{C}}$ if and only if X is quasisymmetrically equivalent to $\mathbb{S}^2$.*

If f is not equivalent to a rational function, then it is natural to ask whether the dynamical system $f\colon X \to X$ is conjugate to a corresponding dynamical system on a better and less "fractal" space. More precisely, we want to replace X by a quasisymmetrically equivalent Ahlfors regular space of lower Hausdorff dimension. As in Theorem 5.3 discussed above, this leads to the problem of finding the conformal dimension $\dim_{\mathrm{c}} X$ of the self-similar space X. By Theorem 6.3 the conformal case is characterized by the fact that we can squeeze X to a 2-regular space (and hence to the standard sphere $\mathbb{S}^2$ according to Theorem 3.2) by a quasisymmetric map. So we have a situation that is very similar to Cannon's conjecture.

In discussions with L. Geyer and K. Pilgrim the following conjecture for $\dim_{\mathrm{c}} X$ in terms of dynamical data emerged. To state it, let $Q \geq 2$ and Γ be an f-stable multicurve, define the modified Thurston matrix $A(\Gamma, Q)$ as $A(\Gamma, Q) = (m_{ij}^Q)$, where

$$m_{ij}^Q = \sum_\alpha \frac{1}{d_{i,j,\alpha}^{Q-1}},$$

and let $\lambda(f, \Gamma, Q)$ be the largest nonnegative eigenvalue of $A(\Gamma, Q)$.

Conjecture 6.4. If X comes from a subdivision rule with associated expanding map f, then $\dim_{\mathrm{c}} X$ is the infimum of all $Q \geq 2$ such that $\lambda(f, \Gamma, Q) < 1$ for all f-stable multicurves Γ.

As in the proof of Theorem 6.1 (related to the necessity of the condition), there is one part of Conjecture 6.4 that seems to be rather easy to establish: If there exists an f-stable multicurve Γ with $\lambda(f, \Gamma, Q) \geq 1$, then $\dim_{\mathrm{c}} X \geq Q$. The idea for proving this is to find path families related to ring domains associated with Γ which have positive Q-modulus. Any such path family on an Ahlfors regular space provides an obstruction to lowering its dimension by a quasisymmetric map [He, Thm. 15.10].

For some nontrivial cases one can show that Conjecture 6.4 is true [BMy]. For example, if X is the fractal obtained from the subdivision rule suggested by Figure 1, then $\dim_{\mathrm{c}} X = 2$. This corresponds to the prediction of Conjecture 6.4 in this case. Note that here the infimum defining $\dim_{\mathrm{c}} X$ is not attained as a minimum; otherwise f would be equivalent to a rational map by Theorem 6.3. We have seen above that this is not the case.

7. Sierpiński carpets

Sierpiński carpets are fractal spaces with a very interesting quasiconformal geometry. Recall that the "standard" Sierpiński carpet is obtained as follows: Start with the closed unit square, and subdivide it into $9 = 3 \times 3$ equal subsquares. Remove the interior of the middle square, and repeat this procedure for each of the remaining 8 subsquares. The limiting object of this construction is the standard Sierpiński carpet.

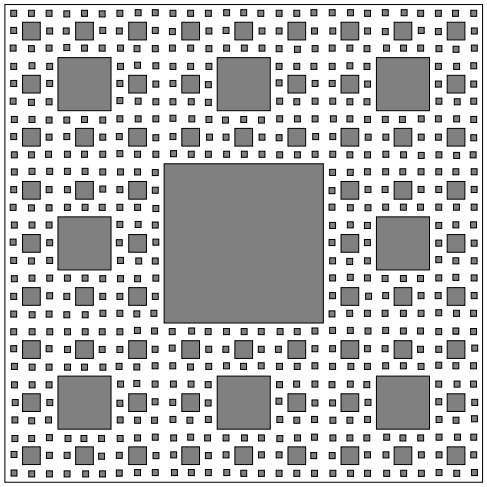

Figure 2. The standard Sierpiński carpet S_3.

One can run a similar construction, where one subdivides each square into $(p \times p)$-subsquares, p odd, and removes the middle square in each step. We denote the resulting space by S_p. So the standard Sierpiński carpet is S_3. We equip S_p with the restriction of the Euclidean metric on $\mathbb{R}^2$.

The spaces S_p are all homeomorphic to each other as follows from the following topological characterization theorems due to Whyburn [Wh].

Theorem 7.1. *Let X be a metric space. Then X is homeomorphic to the standard Sierpiński carpet if and only if X is a locally connected continuum, is topologically planar, has topological dimension* 1*, and has no local cut points.*

Here we call a set *topologically planar* if it is homeomorphic to a subset of the plane $\mathbb{R}^2$. A *local cut point* p of X is a point that has a connected neighborhood U such that $U \setminus \{p\}$ is not connected.

Theorem 7.2. *Let $X = \mathbb{S}^2 \setminus \bigcup_{i\in\mathbb{N}} D_i$ be the complement in $\mathbb{S}^2$ of countably many pairwise disjoint open Jordan regions D_i. Then X is homeomorphic to the standard Sierpiński carpet if and only if X has empty interior, $\partial D_i \cap \partial D_j = \emptyset$ for $i \neq j$, and* $\operatorname{diam}(D_i) \to 0$ *as* $i \to \infty$.

In the following we will call a metric space X a *carpet* if it is homeomorphic to S_3. A topological circle J in a carpet X is called a *peripheral circle* if J does not separate X, i.e., if $X \setminus J$ is connected. If X is a carpet as in Theorem 7.2, then the peripheral circles of X are precisely the Jordan curves ∂D_i, $i \in \mathbb{N}$. Note that every homeomorphism between two carpets X and Y has to map every peripheral circle of X to a peripheral circle of Y.

The deeper reason why all spaces as in Theorem 7.1 are homeomorphic to each other is that the homeomorphisms on a carpet form a rather large and flexible class. This is illustrated by the following transitivity result: If X is a carpet, $\{C_1, \dots, C_n\}$ and $\{C_1', \dots, C_n'\}$ are two collections of peripheral circles of X with n elements, then there exists a homeomorphism $f\colon X \to X$ such that $f(C_i) = C_i'$. In other words, the homeomorphism group of X acts n-transitively on the set of peripheral circles of X for every $n \in \mathbb{N}$. This changes drastically if one restricts attention to quasisymmetric homeomorphisms and surprising rigidity phenomena emerge (cf. the Three-Circle Theorem 8.3 below). To discuss instances of this we first introduce some more terminology.

We say that a carpet $X \subseteq \mathbb{S}^2$ is *round* if its peripheral circles are round circles, i.e., if X is as in Theorem 7.2, where the Jordan regions D_i are round disks. If X is a round carpet and $f\colon \mathbb{S}^2 \to \mathbb{S}^2$ is a (possibly orientation reversing) Möbius transformation, then $f(X)$ is also a round carpet. We say that a round carpet X is *rigid* if this is the only way to obtain another round carpet as a quasisymmetric image of X, i.e., if every quasisymmetric map $g\colon X \to Y$ to another round carpet Y is the restriction of a Möbius transformation. Rigid round carpets admit a simple characterization [BKM].

Theorem 7.3. *A round carpet X is rigid if and only if it has measure zero.*

Actually, in [BKM] a related rigidity result is proved in all dimensions. Call a subset $X \subseteq \mathbb{S}^n$, $n \geq 2$, a *Schottky set* if it is the complement of pairwise disjoint open balls, and call a Schottky set $X \subseteq \mathbb{S}^n$ *rigid* if every quasisymmetric map $f\colon X \to Y$ to another Schottky set $Y \subseteq \mathbb{S}^n$ is the restriction of a Möbius transformation. Then one can show that every Schottky set of measure zero is rigid. This is a strengthening of a result due M. Kapovich, B. Kleiner, B. Leeb, and R. Schwartz (unpublished).

A corollary of Theorem 7.3 is that the set of quasisymmetric equivalence classes of round carpets has the cardinality of the continuum. So even though topologically there is only one Sierpiński carpet, from the point of view of quasiconformal geometry, there are many different ones.

An important source of round carpets is the theory of Kleinian groups. Let M be a compact hyperbolic 3-orbifold with nonempty totally geodesic boundary. Its universal cover $\tilde{M}$ is isometric to a convex subset K of $\mathbb{H}^3$ bounded by a nonempty collection of pairwise disjoint hyperplanes. Then the boundary at infinity $\partial_\infty K \subseteq \partial_\infty \mathbb{H}^3 = \mathbb{S}^2$ of K is a round carpet. The fundamental group $G = \pi_1(M)$ of M acts in a natural way on K by isometries. This induces an action $G \curvearrowright \partial_\infty K$ of G on the round carpet $S = \partial_\infty K$ by Möbius transformations. The group G is Gromov hyperbolic and its boundary $\partial_\infty G$ is quasisymmetrically equivalent to S. Hence the group $\mathrm{QS}(S) \supseteq G$

of quasisymmetric self-maps of S is rather large, because it acts cocompactly on triples of S and so there are only finitely many distinct orbits of peripheral circles. Accordingly, one should think of these round carpets as particularly "symmetric" ones.

It is tempting to try to characterize this situation from the point of view of Gromov hyperbolic groups. An analog of Cannon's conjecture is the following conjecture due to Kapovich and Kleiner who studied Gromov hyperbolic groups with carpet boundaries [KK]: *Suppose G is a Gromov hyperbolic group such that $\partial_\infty G$ is a carpet. Then G admits a properly discontinuous, cocompact and isometric action on a convex subset of $\mathbb{H}^3$ with nonempty totally geodesic boundary.*

This can be reformulated as a quasisymmetric uniformization problem.

Conjecture 7.4 (*Kapovich–Kleiner conjecture).* Suppose G is a Gromov hyperbolic group with $\partial_\infty G$ homeomorphic to the standard Sierpiński carpet. Then $\partial_\infty G$ is quasisymmetrically equivalent to a round carpet.

We call a carpet a *group carpet* if it arises as (i.e., is quasisymmetrically equivalent to) a boundary of a Gromov hyperbolic group. So the Kapovich–Kleiner conjecture asks whether every group carpet is quasisymmetrically equivalent to a round carpet.

Group carpets X should be thought of as very self-similar fractal spaces. As in the Kleinian case, the group $\mathrm{QS}(X)$ of quasisymmetric self-maps of X is rather large. It acts cocompactly on triples, and so there are only finitely many distinct orbits of peripheral circles. In addition, the collection of peripheral circles of a group carpet has the following geometric properties:

(i) The peripheral circles are *uniform quasicircles*, i.e., each one is quasisymmetrically equivalent to $\mathbb{S}^1$ by an η-quasisymmetric map with η independent of the peripheral circle.

(ii) The peripheral circles are *uniformly separated*, i.e., there is a uniform positive lower bound for the relative distance

$$\frac{\mathrm{dist}(C, C')}{\min\{\mathrm{diam}(C), \mathrm{diam}(C)\}}$$

of two distinct peripheral circles C and C'.

(iii) The peripheral circles *occur on all locations and scales*, i.e., if B is a ball in the carpet, then there exists a peripheral circle that intersects B and has a size comparable to B.

In view of the Kapovich–Kleiner conjecture one can ask whether these conditions are sufficient for X to be quasisymmetrically equivalent to a round carpet. It turns out that this is true for carpets that can be quasisymmetrically embedded into $\mathbb{S}^2$. This is a consequence of the following uniformization result [Bo].

Theorem 7.5. *Let $X \subseteq \mathbb{S}^2$ be a carpet, and suppose that the peripheral circles of X are uniform quasicircles and are uniformly separated. Then there exists a quasisymmetric map $f\colon X \to Y$ to a round carpet $Y \subseteq \mathbb{S}^2$.*

This theorem applies for example to the carpets S_p. So they are quasisymmetrically equivalent to round carpets. Note that if X as in the theorem has measure zero in addition (which is true if X is quasisymmetrically equivalent to a group carpet), then the uniformizing map f is uniquely determined up to a post-composition by a Möbius transformation (this essentially follows from Theorem 7.3). This shows that one can expect very little flexibility in constructing the uniformizing map f.

Theorem 7.5 is an analog of Koebe's well-known result on uniformization by circle domains. It says that every region in $\mathbb{S}^2$ with finitely many complementary components is conformally equivalent to a *circle domain*, i.e., a region whose complementary components are round (possibly degenerate) disks. This statement is actually used in the proof of Theorem 7.5. One considers regions Ω_n obtained by removing from $\mathbb{S}^2$ the closures of n complementary components of the given carpet X. By circle uniformization one can map the regions Ω_n to circle domains by (suitably normalized) conformal maps f_n. The uniformizing map f of X to a round carpet is then obtained as a sublimit of the sequence of maps f_n. The main difficulty is to show that such a sublimit exists. For this one proves that the maps f_n are uniformly quasisymmetric, i.e., η-quasisymmetric with η independent of n. It is a standard idea to use modulus estimates to get the required uniform distortion estimates for the maps f_n. If X has measure zero, then X does not support path families of positive modulus. Accordingly, one cannot expect any control for the distortion coming from such estimates involving classical modulus. This situation is remedied by a new quasisymmetric invariant, the modulus of a path family with respect to a carpet, which is the main technical ingredient in the proof of Theorem 7.5.

Let $X \subseteq \mathbb{S}^2$ be a carpet with peripheral circles C_i, $i \in \mathbb{N}$, and Γ a family of paths in $\mathbb{S}^2$. Then the *modulus of* Γ *with respect to* X is defined as

$$M_X(\Gamma) = \inf\Big\{ \sum_{i\in\mathbb{N}} \rho_i^2 : \rho = \{\rho_i\} \text{ is admissible for } \Gamma \Big\}.$$

Here a sequence $\rho = \{\rho_i\}$ of nonnegative weights ρ_i is called *admissible for* Γ if there exists an exceptional path family $\Gamma_0 \subseteq \Gamma$ with $\operatorname{Mod}_2(\Gamma_0) = 0$ such that

$$\sum_{\gamma\cap C_i\neq\emptyset} \rho_i \geq 1$$

for all paths $\gamma \in \Gamma \setminus \Gamma_0$.

So in contrast to classical modulus where ρ is a density, the test function is an assignment of discrete weights ρ_i to the peripheral circles C_i. This is similar to Schramm's notion of "transboundary extremal length" [Sc], where the test function consists both of a density and a discrete part. In the definition of $M_X(\Gamma)$ one wants

to infimize the total mass $\sum_{i\in\mathbb{N}} \rho_i^2$ for all admissible sequences $\rho = \{\rho_i\}$. The admissibility requires that essentially every path picks up at least total weight 1 from all the peripheral circles that it meets. An important subtlety here is to allow the exceptional path family Γ_0. Otherwise, the quantity $M_X(\Gamma)$ would be infinite (and hence useless) for sufficiently large families Γ.

In contrast to classical modulus which is distorted by a multiplicative amount (cf. Theorem 2.1), the quantity $M_X(\Gamma)$ is invariant under quasisymmetric maps on $\mathbb{S}^2$.

Proposition 7.6. *Let $X \subseteq \mathbb{S}^2$ be a carpet, Γ a path family in $\mathbb{S}^2$, and $f : \mathbb{S}^2 \to \mathbb{S}^2$ a quasisymmetric map. Then*

$$M_X(\Gamma) = M_{f(X)}(f(\Gamma)).$$

The restriction to global maps f is not very serious here if one requires that the peripheral circles of X are uniform quasicircles. Then one can extend every quasisymmetric embedding of X into $\mathbb{S}^2$ to a quasisymmetric homeomorphism on $\mathbb{S}^2$.

As we remarked, Theorem 7.5 would settle the Kapovich–Kleiner conjecture if one could always quasisymmetrically embed a group carpet into $\mathbb{S}^2$. The conditions (i)–(iii) for the peripheral circles discussed above are not enough to guarantee this, because there are some carpets with these properties which do not admit such an embedding. In the positive direction one can show that if $\dim_{\mathrm{c}} X < 2$ for such a carpet X, then one gets the desired quasisymmetric embedding into $\mathbb{S}^2$. This was recently proved by B. Kleiner and the author [BK6]. The idea for the proof (due to J. Heinonen) is that each peripheral circle can be filled by a metric disk to obtain a sphere to which Theorem 3.2 can be applied. To get fillings of the right type one uses conformal densities as in [BHR].

8. Rigidity of square carpets

A carpet $X \subseteq \mathbb{R}^2$ is called a *square carpet* if its peripheral circles are boundaries of squares. Examples are the carpets $S_3, S_5, \ldots$ introduced in the previous section. Obviously, these carpets are very symmetric and self-similar, so one may wonder whether they are group carpets. If so, the groups $\mathrm{QS}(S_p)$ should be rather large, and in particular infinite. It turns out that this is not the case [BMe].

Theorem 8.1. *Suppose $f : S_3 \to S_3$ is a quasisymmetric map. Then f is an isometry.*

The only isometries of S_3 are the obvious symmetries given by reflections and rotations; so $\mathrm{QS}(S_3)$ is a dihedral group containing 8 elements. It is very likely that an analog of Theorem 8.1 is true for all carpets S_p, p odd. At the moment it is only known that $\mathrm{QS}(S_p)$ is always a finite dihedral group. This implies that no carpet S_p is a group carpet.

The proof of Theorem 8.1 is surprisingly difficult. To explain some of the ingredients, suppose $f : S_3 \to S_3$ is a quasisymmetric map. For simplicity assume that f

is orientation preserving. Denote by C_1 the boundary of the unit square, and by C_2 the boundary of the middle square that was deleted in the first step of the construction of S_3. So C_1 and C_2 are peripheral circles of S_3.

If C and C' are two distinct peripheral circles of S_3, let $\Gamma(C, C')$ be the family of all open paths $\gamma|_{(0,1)}$, where $\gamma\colon [0, 1] \to \mathbb{S}^2$ is a path connecting C and C' such that $\gamma(0) \in C$, $\gamma(1) \in C'$, and $\gamma(0, 1) \cap (C \cup C') = \emptyset$. Then the (unordered) pair $\{C_1, C_2\}$ is distinguished from all other pairs $\{C, C'\}$ due to the following fact.

Lemma 8.2. *If C and C' are two distinct peripheral circles of S_3, then*

$$M_{S_3}(\Gamma(C, C')) \le M_{S_3}(\Gamma(C_1, C_2))$$

with equality if and only if $\{C, C'\} = \{C_1, C_2\}$.

The proof crucially uses the self-similarity of S_3 combined with monotonicity properties of the modulus invariant $M_X(\Gamma)$ defined in the previous section.

An immediate consequence of Lemma 8.2 and Proposition 7.6 is that

$$\{f(C_1), f(C_2)\} = \{C_1, C_2\}.$$

In other words, f preserves the peripheral circles C_1 and C_2 setwise or exchanges them.

Let us again make a simplifying assumption, namely that $f(C_1) = C_1$ and $f(C_2) = C_2$. Now one analyzes the possibilities for the images of the eight peripheral circles of S_3 that constitute the boundaries of the squares deleted in the second step of the construction of S_3. These eight peripheral circles come in two groups: "corner" circles and "side" circles. Using ideas as in the proof of Lemma 8.2, one can show that at least one of these eight second-generation peripheral circles is mapped to another second-generation peripheral circle; say one of the corner circles C_3 is mapped to a corner circle or a side circle C_3'.

In the first case where C_3' is also a corner circle there exists a rotation R of S_3 such that $R(C_3) = C_3'$. Since R also preserves C_1 and C_2 setwise, we conclude that $f = R$ by the following theorem (applied to $g = R^{-1} \circ f$).

Theorem 8.3 (Three-circle theorem). *Let $X \subseteq \mathbb{S}^2$ be a carpet of measure zero whose peripheral circles are uniform quasicircles and are uniformly separated. Suppose C_1, C_2, C_3 are three distinct peripheral circles of X and $g\colon X \to X$ is an orientation preserving quasisymmetric map such that $g(C_i) = C_i$, $i = 1, 2, 3$. Then g is the identity on X.*

In other words, if an orientation preserving quasisymmetric map of the carpet fixes three peripheral circles setwise, then it is the identity. The same proof will show that if g fixes three points (instead of three peripheral circles), then the same conclusion holds, i.e., g is the identity.

Proof. By Theorem 7.5 there exists a quasisymmetric uniformization map $h\colon X \to Y$ to a round carpet $Y \subseteq \mathbb{S}^2$. One can show that the map h can be extended to a global quasiconformal map $H\colon \mathbb{S}^2 \to \mathbb{S}^2$. Since quasiconformal maps preserve sets of measure zero, the round carpet Y has measure zero. Hence Y is rigid by Theorem 7.3. Therefore, the quasisymmetric map $\tilde{g} = h \circ g \circ h^{-1}\colon Y \to Y$ is the restriction of an orientation-preserving Möbius transformation. Since it fixes the three round circles $h(C_i)$ setwise, it is the identity on Y. Hence g is the identity on X. □

The second case where the corner circle C_3 is mapped to a side circle C_3' does not occur. To rule out the existence of such a "ghost" map, one argues by contradiction. Suppose the situation is as represented in Figure 3. If R_D and R_M denote the reflections in the indicated symmetry lines D and M of S_3, respectively, one can show that

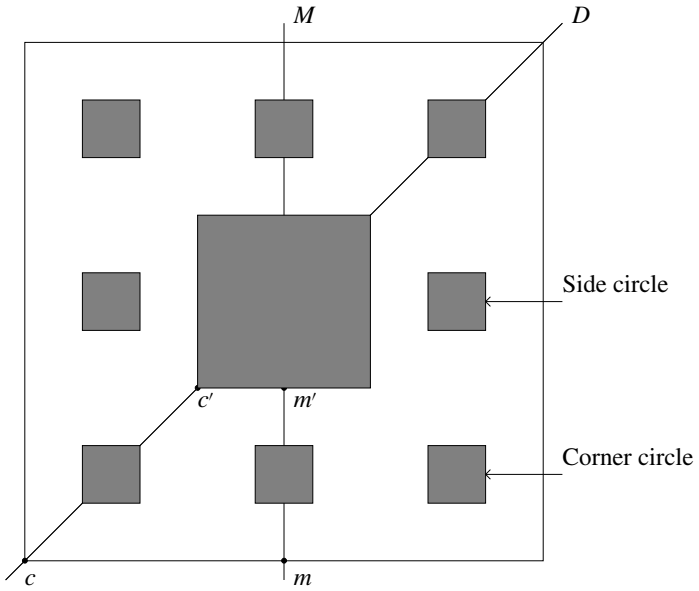

Figure 3. Corner and side circles of S_3.

$R_M \circ f = f \circ R_D$ by using the Three-Circle Theorem 8.3. This leads to $f(c) = m$ and $f(c') = m'$. Blowing up the carpet at c and m, the map f induces a quasisymmetric equivalence between the weak tangents W_c and W_m of S_3 at these points (with a suitable normalization these weak tangents are uniquely determined up to isometry). Similarly, the weak tangents $W_{c'}$ and $W_{m'}$ are quasisymmetrically equivalent. Since W_m and $W_{m'}$ are isometric, one concludes that W_c and $W_{c'}$ are quasisymmetrically equivalent. Since $W_{c'}$ essentially consists of three copies of W_c, one can get the desired contradiction by using the modulus invariant $M_X(\Gamma)$ and its monotonicity properties. The last step in the proof could be simplified, if one knew that W_c and W_m

are not quasisymmetrically equivalent. This is likely to be true, but an open problem at the moment.

The following result was also proved in [BMe].

Theorem 8.4. *Let $p, q \geq 3$ be odd integers. Then S_p and S_q are quasisymmetrically equivalent if and only if $p = q$.*

Using the known estimate

$$\dim_{\mathrm{c}} S_p \geq 1 + \frac{\log(p-1)}{\log p}$$

for the conformal dimension of S_p, it is not hard to see that S_p cannot be quasisymmetrically equivalent to S_q if p is much larger than q. The full result Theorem 8.4 is much harder to establish and uses ideas similar to the ones just described. An interesting open problem in this connection is to determine $\dim_{\mathrm{c}} S_p$.

9. Conclusion

It is evident from the preceding discussion that we are still far from a full understanding of the quasiconformal geometry of fractal 2-spheres and Sierpiński carpets. An obstacle in the solution of Cannon's conjecture is the lack of examples that could reveal some hidden structures. All known examples of Gromov hyperbolic groups with 2-sphere boundary arise from the standard Kleinian group situation, and Cannon's conjecture predicts that there are no others. In this sense the fractal 2-spheres that arise in the dynamics of post-critically finite maps exhibit more interesting phenomena, because sometimes they are quasisymmetrically equivalent to the standard 2-sphere and sometimes not. By investigating these spaces one may discover some general obstruction (formed by a "large" path family for example) that prevents a self-similar 2-sphere from obtaining a minimum for its conformal dimension. One may speculate that in the situation of Cannon's conjecture the group action prevents the existence of such an obstruction. This would lead to a solution of the conjecture according to Theorem 5.3.

The Kapovich–Kleiner conjecture looks somewhat more accessible due to the additional features given by the geometry of the peripheral circles of a group carpet. It has to be explored whether a modulus invariant similar to the invariant $M_X(\Gamma)$ for carpets in the plane can be used to prove general uniformization theorems for metric carpets.

The picture is sketchiest for the rigidity results on square carpets. Here it would be desirable to put isolated facts such as Theorems 8.1 and 8.4 into a general framework. A possible venue here is to develop an analytic theory of quasisymmetrically invariant "harmonic" functions. Similarly as in the definition of $M_X(\Gamma)$ this can be based on the minimization of energies of discrete weights $\rho = \{\rho_i\}$ which play the role of

"upper" gradients of the functions. Such a theory could also lead to the solution of problems about weak tangents of carpets such as the one mentioned in Section 8.

Local *Tb* theorems and applications in PDE

Steve Hofmann*

Abstract. A *Tb* theorem is a boundedness criterion for singular integrals, which allows the L^2 boundedness of a singular integral operator T to be deduced from sufficiently good behavior of T on some suitable non-degenerate test function b. However, in some PDE applications, including, for example, the solution of the Kato problem for square roots of divergence form elliptic operators, it may be easier to test the operator T locally (say on any given dyadic cube Q), on a test function b_Q that depends upon Q, rather than on a single, globally defined b. Or to be more precise, in the applications, it may be easier to find a family of b_Q's for which Tb_Q is locally well behaved, than it is to find a single b for which Tb is nice globally. In this lecture, we shall discuss some versions of local *Tb* theorems, as well as some applications to PDE.

Mathematics Subject Classification (2000). Primary 42B20, 42B25; Secondary 35J25, 35J55, 47F05, 47B44.

Keywords. *Tb* theorem, singular integrals, square functions, boundary value problems, Kato problem, layer potentials.

1. Introduction

The *Tb* theorem, and its predecessor, the $T1$ theorem, were introduced in large part to better understand the Cauchy integral operator on a Lipschitz curve, and the related Calderón commutators. In this note, we shall discuss more recent "local" versions of the *Tb* theorem, as well as the application of such theorems to some questions in PDE.

We begin by recalling the statements of the original $T1$ and *Tb* theorems. To this end, we require a few definitions.

We say that T is a singular integral operator (in the generalized sense of Coifman and Meyer), if T is a mapping from test functions $\mathcal{D}(\mathbb{R}^n)$ into distributions $\mathcal{D}'(\mathbb{R}^n)$, which is associated to a "Calderón–Zygmund kernel" $K(x, y)$, in the sense that

$$\langle T\varphi, \psi\rangle = \int\int \psi(x)K(x, y)\varphi(y)dxdy,$$

whenever $\varphi, \psi \in C_0^\infty(\mathbb{R}^n)$ with disjoint supports (the theory can be extended to settings other than Euclidean space, and there are worthwhile reasons for doing so,

*supported by NSF

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

but we shall not insist much on that point, for the sake of simplicity of exposition). A Calderón–Zygmund kernel is one which satisfies the "standard" bounds

$$|K(x, y)| \leq C|x - y|^{-n} \tag{1.1}$$

and

$$|K(x, y + h) - K(x, y)| + |K(x + h, y) - K(x, y)| \leq \frac{C|h|^{\alpha}}{|x - y|^{n+\alpha}}, \tag{1.2}$$

for some $\alpha \in (0, 1]$, whenever $|x - y| \geq 2|h|$. A singular integral operator T is said to satisfy the "Weak Boundedness Property" (WBP), if

$$\sup \left(R^{-n}|\langle T\varphi, \psi\rangle|\right) \leq C < \infty, \tag{1.3}$$

where the supremum runs over all $R > 0$, over all balls $B(x, R)$ of radius R and arbitrary center x, and over all test functions φ, ψ supported in $B(x, R)$, and normalized so that $\|\varphi\|_{\infty} + R\|\nabla\varphi\|_{\infty} \leq 1$ and $\|\psi\|_{\infty} + R\|\nabla\psi\|_{\infty} \leq 1$. In order to demystify this condition, we note that it holds automatically for any L^2 bounded operator (just apply Cauchy–Schwarz). Moreover, with just a small amount of work, it can be shown that, given an anti-symmetric kernel (i.e., one for which $K(x, y) = -K(y, x)$), which in addition satisfies the size condition (1), there is an associated "principal value" type singular integral operator for which WBP holds.

We recall that BMO is the space of locally integrable functions modulo constants for whom the norm

$$\|b\|_{*} = \sup |Q|^{-1} \int_{Q} |b(x) - [b]_{Q}|dx$$

is finite. Here, the supremum runs over all cubes (balls work just as well) with sides parallel to the co-ordinate axes, and

$$[b]_{Q} \equiv |Q|^{-1} \int_{Q} b(x)dx.$$

The $T1$ theorem of David and Journé [DJ] is the following:

Theorem 1.1. *Suppose that T is a singular integral operator associated to a standard kernel $K(x, y)$ satisfying* (1) *and* (2). *Then T extends to a bounded operator on L^2 if and only if T satisfies WBP, and $T1$, $T^*1 \in$ BMO.*

Here, T^* is the formal transpose of T. It is of course associated to the kernel $K^*(x, y) = K(y, x)$. One might ask whether T and T^* are well defined on constant functions, but it is not hard to show, using the kernel condition (2), that $T1$ and T^*1 exist as distributions modulo constants. This result may be understood as follows. If T is bounded on L^2, and its kernel satisfies the smoothness condition (1.2), then by a result obtained independently by Peetre [P], Spanne [Sp] and Stein [St] it follows

that $T: L^\infty \to \mathrm{BMO}$, and similarly for T^*. Conversely, if both T and T^* are bounded from $L^\infty \to \mathrm{BMO}$, then by duality and interpolation (using results of Fefferman and Stein [FS]), we have that T is bounded on L^2. The $T1$ theorem says that in order to obtain the latter conclusion, one need not test T on all of L^∞, but rather, only on a very special element of L^∞, namely the constant function 1.

The Tb theorem is an extension of the $T1$ theorem, in which the function 1 is replaced by a suitable function $b \in L^\infty$ (or, more generally, by two such functions b_1 and b_2: one for T, and one for T^*). One supposes that $b_2 T b_1$ is a mapping from test functions to distributions which satisfies WBP (in particular, principal value operators associated to anti-symmetric kernels have this property) and that $Tb_1, T^*b_2 \in \mathrm{BMO}$. Then, if b_1 and b_2 are sufficiently non-degenerate, one again deduces that T extends to a bounded operator on L^2. In the original versions of this theorem, b was assumed to be essentially bounded and "accretive", i.e., for some $\delta > 0$,

$$\Re e\ b \geq \delta,$$

or merely "pseudo-accretive":

$$\inf_Q \left|[b]_Q\right| \geq \delta,$$

or even "para-accretive", a relaxed version of pseudo-accretivity in which nondegeneracy of the average over each given cube is replaced by nondegeneracy of the average over some sub-cube of comparable size. The special case that $Tb_1 = 0 = T^*b_2$ (here 0 is meant in the sense of BMO, i.e., modulo constants) and b_1, b_2 are accretive, is due to McIntosh and Meyer [McM], the general case to David, Journé and Semmes [DJS].

The special case treated in [McM] already had a spectacular application: as a direct corollary, one obtains an alternative proof of the Cauchy integral theorem of Coifman, McIntosh and Meyer. Indeed, for a Lipschitz function A, the kernel $(x-y+i(A(x)-A(y))^{-1}$ is anti-symmetric and standard, so that L^2 boundedness of

$$T_A f(x) = p.v.\ \frac{1}{2\pi i} \int_{\mathbb{R}} \frac{f(y)}{x - y + i(A(x) - A(y)} \, dy$$

follows immediately from the theorem of [McM] and the observation that, at least formally, by the formula of Plemelj, $T_A b = 1/2$, where $b = 1 + iA'$. In practice, some care must be taken in interpreting the Plemelj formula on an infinite graph, but this can be managed.

In some applications, it may not be at all evident that there is an accretive (or pseudo-accretive) b for which Tb is well behaved. On the other hand, in such cases it is sometimes possible to find a family $\{b_Q\}$, indexed by dyadic cubes Q, such that Tb_Q behaves well locally on Q. This motivates the introduction of the notion of a "local Tb theorem", in which good local control of a singular integral operator T, on each member of a family of suitably non-degenerate functions b_Q (one for each dyadic cube Q), still suffices to deduce L^2 boundedness of T. The appropriate version of

non-degeneracy in this setting was introduced by M. Christ [Ch]: a "pseudo-accretive system" is a collection of functions $\{b_Q\}$, indexed on the dyadic cubes, with b_Q supported in Q and integrable, such that for some $\delta > 0$, we have that

$$\left| |Q|^{-1} \int_Q b_Q \right| \geq \delta. \tag{1.4}$$

The first local *Tb* theorem was proved by Christ:

Theorem 1.2 ([Ch]). *Suppose that T is a singular integral operator associated to a standard kernel K(x,y), which in addition we assume to be in L^∞. Suppose also that there are constants $\delta > 0$ and $C_0 < \infty$, and pseudo-accretive systems $\{b^1_Q\}$, $\{b^2_Q\}$, with* $\operatorname{supp} b^i_Q \subseteq Q$, $i = 1, 2$, *such that for each dyadic cube Q,*

(i) $\|b^1_Q\|_{L^\infty(Q)} + \|b^2_Q\|_{L^\infty(Q)} \leq C_0$,

(ii) $\|Tb^1_Q\|_{L^\infty(Q)} + \|T^* b^2_Q\|_{L^\infty(Q)} \leq C_0$,

(iii) $\delta|Q| \leq \min(\left|\int_Q b^1_Q\right|, \left|\int_Q b^2_Q\right|)$.

Then T extends to a bounded operator on L^2, with bound depending only on n, δ, C_0 and the kernel constants in (1.1) *and* (1.2)*, but not on the L^∞ norm of $K(x, y)$.*

A few remarks are in order. The assumption that $K \in L^\infty$ is merely qualitative, and is satisfied, e.g., by smooth truncations of a standard kernel. This assumption allows one to make certain formal manipulations with impunity, during the course of the proof. Christ actually proved this theorem in the setting of a space of homogeneous type (that is, a space endowed with a pseudo-metric and a doubling measure), which (as he demonstrated) possesses a suitable version of a "dyadic cube" structure. Christ's theorem and the technique of its proof are related to the solution of Painlevé's problem concerning the characterization of those compact sets $K \subset \mathbb{C}$ for which there exist non-constant bounded analytic functions on $\mathbb{C} \setminus K$. We will not discuss this aspect of the theory in detail, but we mention that extensions of either local or global *Tb* theorems to the non-doubling setting have been obtained by G. David [D1] and by Nazarov, Treil and Volberg [NTV1], [NTV2]; moreover, the circle of ideas involved in [Ch], [D1] and [NTV1], [NTV2] have played a crucial role in the solution of the Painlevé problem, see Mattila, Melnikov and Verdera [MMV], G. David [D1], [D2] and X. Tolsa [T], and also Volberg [Vo], where the higher dimensional version of this theory is treated. See also the article of Tolsa in these proceedings.

Instead, in this note we shall concentrate on extensions of Christ's result in another direction, in which L^∞ control of b_Q and Tb_Q is replaced by local, scale invariant L^2 control. These extensions have been useful in certain applications in PDE, including the solution of the Kato problem. In the next two sections, we discuss local *Tb* theorems for square functions, and for singular integrals, respectively.

Acknowledgements. Various portions of the material discussed in this paper were joint work with M. Alfonseca, P. Auscher, A. Axelsson, M. Lacey, S. Kim, A. McIntosh, C. Muscalu, T. Tao, P. Tchamitchian and C. Thiele. To all of them I express my deepest appreciation.

2. Local *Tb* theorems for square functions and applications

We begin with a local *Tb* theorem for square functions, which extends a global version due to Semmes [S]. Suppose that we have a family of kernels $\{\psi_t(x, y)\}_{t\in(0,\infty)}$, satisfying, for some exponent $\alpha > 0$,

$$\begin{aligned} |\psi_t(x, y)| &\le C\frac{t^\alpha}{(t + |x - y|)^{n+\alpha}}, \\ |\psi_t(x, y + h) - \psi_t(x, y)| &\le C\frac{|h|^\alpha}{(t + |x - y|)^{n+\alpha}} \end{aligned} \tag{2.1}$$

whenever $|h| \le \frac{1}{2}|x - y|$ or $|h| \le |t|/2$.

Theorem 2.1. *Let $\theta_t f(x) \equiv \int \psi_t(x, y) f(y)\, dy$, where $\psi_t(x, y)$ satisfies* (2.1)*. Suppose also that there exist constants $\delta > 0$, $C_0 < \infty$, and a system $\{b_Q\}$ of functions indexed by dyadic cubes $Q \subseteq \mathbb{R}^n$ such that for each dyadic cube Q*

(i) $\int_{\mathbb{R}^n} |b_Q|^2 \le C_0|Q|$,
