(ii) $\int_0^{\ell(Q)}\int_Q |\theta_t b_Q(x)|^2 \frac{dxdt}{t} \le C_0|Q|$,

(iii) $\delta|Q| \le \left|\int_Q b_Q\right|$.

Then we have the square function bound

$$\iint_{\mathbb{R}^{n+1}_+} |\theta_t f(x)|^2 \frac{dxdt}{t} \le C\|f\|_2^2.$$

Proof. The proof combines the ideas of [S] and [AT] with those of [Ch], [HMc], [HLMc] and [AHLMcT]. (Actually, the argument below preceded the subsequent matrix-valued versions used in [HMc], [HLMc] and [AHLMcT] to solve the Kato problem, but the author never published it in this scalar-valued form; see also Auscher's lecture notes on the Kato problem [A], where the present formulation is given explicitly). We begin by recalling the following well-known fact, due explicitly to Christ and Journé [CJ], but also at least implicit in the work of Coifman and Meyer [CM].

Proposition 2.2 ([CJ])**.** *Let $\theta_t f(x) \equiv \int_{\mathbb{R}^n} \psi_t(x, y) f(y)dy$, where $\psi_t(x, y)$ satisfies* (2.1)*. Suppose that we have the Carleson measure estimate*

$$\sup_Q \frac{1}{|Q|}\int_0^{\ell(Q)}\int_Q |\theta_t 1(x)|^2 \frac{dxdt}{t} \le C. \tag{2.2}$$

Then we have the square function estimate

$$\iint_{\mathbb{R}^{n+1}_+} |\theta_t f(x)|^2 \, \frac{dxdt}{t} \leq C\|f\|_2^2. \tag{2.3}$$

Remark 2.3. The converse direction (i.e. that (2.3) implies (2.2)) is essentially due to Fefferman and Stein [FS].

Thus, to prove Theorem 2.1, it suffices to verify that $|\theta_t 1|^2 \, dxdt/t$ is a Carleson measure, given the existence of a family $\{b_Q\}$ satisfying hypotheses (i), (ii) and (iii) of the theorem. To this end, we first observe that, as in [S] and [AT], it is enough to verify that for $\{b_Q\}$ as in the theorem, we have the bound

$$\sup_Q \frac{1}{|Q|} \iint_{R_Q} |\theta_t 1|^2 \, \frac{dxdt}{t} \leq C \sup_Q \frac{1}{|Q|} \iint_{R_Q} |(\theta_t 1)(P_t b_Q)|^2 \, \frac{dxdt}{t} + C, \tag{2.4}$$

where $R_Q \equiv Q \times (0, \ell(Q))$ is the "Carleson box" above Q, and where P_t is a nice approximate identity, whose kernel satisfies, say, (2.1). Indeed, suppose momentarily that (2.4) holds. Then to obtain (2.2) (and thus also the conclusion of the theorem), it suffices to show that the right hand side of (2.4) is bounded. Following [CM], we write

$$\begin{aligned}(\theta_t 1) P_t b_Q &= [(\theta_t 1) P_t b_Q - \theta_t b_Q] + \theta_t b_Q \\ &= R_t b_Q + \theta_t b_Q.\end{aligned}$$

The contribution of $\theta_t b_Q$ is bounded, by hypothesis (ii) of the theorem. Moreover, by (2.1) and the fact that $R_t 1 = 0$, it follows by a well-known orthogonality argument that

$$\iint_{\mathbb{R}^{n+1}_+} |R_t f(x)|^2 \, \frac{dxdt}{t} \leq C\|f\|_2^2.$$

Thus, by (i), the contribution of $R_t b_Q$ is also bounded.

Therefore, to finish the proof of the theorem, it remains to verify (2.4). In fact, it suffices to proof that (2.4) holds with P_t replaced by the dyadic averaging operator A_t, defined by

$$A_t f(x) \equiv A_t^Q f(x) \equiv \frac{1}{|Q(x,t)|} \int_{Q(x,t)} f(y)\, dy,$$

where $Q(x,t)$ denotes the minimal dyadic subcube of Q containing x, with side length at least t. Indeed, a standard orthogonality argument yields the fact that

$$\iint_{R_Q} |(A_t - P_t) f(x)|^2 \, \frac{dxdt}{t} \leq C\|f\|_2^2,$$

so that the error is bounded.

Now, by a well-known "John–Nirenberg" type lemma for Carleson measures (see, e.g. [AHLT, Lemma 3.3]), in order to establish (2.6) (or rather its analogue with A_t

in place of P_t), it suffices to show that there is a positive constant $\eta > 0$ such that for each Q, there is a dyadic sawtooth region

$$E_Q^* \equiv R_Q \setminus (\cup R_{Q_j}), \tag{2.5}$$

where $\{Q_j\}$ are non-overlapping dyadic sub-cubes of Q, with

$$|Q \setminus (\cup Q_j)| > \eta |Q|$$

and

$$\iint_{E_Q^*} |\theta_t 1(x)|^2 \, \frac{dxdt}{t} \leq C \iint_{E_Q^*} |(\theta_t 1(x))(A_t b_Q(x))|^2 \, \frac{dxdt}{t}. \tag{2.6}$$

We establish (2.6) via a stopping time argument as in [HMc], [HLMc] and [AHLMcT] (but see also [Ch], where a similar idea had previously appeared). Our starting point is (iii). Dividing by an appropriate complex constant, we may suppose that

$$\frac{1}{|Q|} \int_Q b_Q = 1. \tag{2.7}$$

We then sub-divide Q dyadically, to select a family of non-overlapping cubes $\{Q_j\}$ which are maximal with respect to the property that

$$\Re e \, \frac{1}{|Q_j|} \int_{Q_j} b_Q \leq 1/2. \tag{2.8}$$

If E_Q^* is defined as in (2.5) with respect to this family $\{Q_j\}$, then by construction, if $(x, t) \in E_Q^*$, it follows that

$$\frac{1}{2} \leq \Re e \, A_t b_Q(x),$$

so that (2.6) holds with $C = 4$. It remains only to verify that there exists $\eta > 0$ such that

$$|E| > \eta |Q|, \tag{2.9}$$

where $E \equiv Q \setminus (\cup Q_j)$. By (2.7) we have that

$$\begin{aligned} |Q| = \int_Q b_Q = \Re e \int_Q b_Q = \Re e \int_E b_Q + \Re e \sum_j \int_{Q_j} b_Q \\ \leq |E|^{\frac{1}{2}} \left(\int_Q |b_Q|^2 \right)^{\frac{1}{2}} + \frac{1}{2} \sum |Q_j|, \end{aligned}$$

when in the last step we have used (2.8). From hypothesis (i) of Theorem 2.1, we then obtain that

$$|Q| \leq C |E|^{\frac{1}{2}} |Q|^{\frac{1}{2}} + \frac{1}{2} |Q|,$$

and (2.9) now follows readily. This concludes the proof of Theorem 2.1. □

As alluded to above, the previous theorem has an extension to the matrix valued setting. We shall explain momentarily why this is interesting. Let $\mathbb{M}^N$ denote the space of $N \times N$ matrices with complex entries.

Theorem 2.4. *Suppose that* $\mathbf{\Psi}_t : \mathbb{R}^n \times \mathbb{R}^n \to \mathbb{C}^N$ *satisfies* (2.1). *For* $\boldsymbol{f} : \mathbb{R}^n \to \mathbb{C}^N$ *define the operator*

$$\mathbf{\Theta}_t \cdot \boldsymbol{f}(x) \equiv \int \mathbf{\Psi}_t(x, y) \cdot \boldsymbol{f}(y)\, dy. \tag{2.10}$$

Suppose also that there are constants $\delta > 0$, $C_0 < \infty$ *and a system of matrix valued functions* $\boldsymbol{b}_Q : \mathbb{R}^n \to \mathbb{M}^N$, *indexed on the dyadic cubes, such that*

(i) $\int_{\mathbb{R}^n} |\boldsymbol{b}_Q|^2 \leq C_0 |Q|$,

(ii) $\int_0^{\ell(Q)} \int_Q |\mathbf{\Theta}_t \boldsymbol{b}_Q(x)|^2 \, \frac{dxdt}{t} \leq C_0 |Q|$,

(iii) $\delta |\xi|^2 \leq \Re e\ \xi \cdot \big(|Q|^{-1} \int_Q \boldsymbol{b}_Q\big)\overline{\xi}$.

where the ellipticity condition (iii) *holds for all* $\xi \in \mathbb{C}^N$, *and where the action of* $\mathbf{\Theta}_t$ *on the matrix valued function* $\boldsymbol{b}_Q$ *is defined in the obvious way as in* (2.10) *by viewing the kernel* $\mathbf{\Psi}_t(x, y)$ *as a* $1 \times N$ *matrix which multiplies the* $N \times N$ *matrix* $\boldsymbol{b}_Q$. *Then*

$$\iint_{\mathbb{R}^{n+1}_+} |\mathbf{\Theta}_t \cdot \boldsymbol{f}|^2 \, \frac{dxdt}{t} \leq C \|\boldsymbol{f}\|_2^2.$$

It turns out that a variant of this theorem lies at the heart of the solution of the Kato problem [HMc], [HLMc], [AHLMcT] (see also [AT]). We now sketch the proof, which is essentially the same as the argument used to establish the Kato conjecture. Let $\mathbf{1}$ denote the $N \times N$ identity matrix. Since

$$\mathbf{\Theta}_t \mathbf{1} = (\theta_t^1 1, \theta_t^2 1, \ldots, \theta_t^N 1),$$

Proposition 2.3 therefore implies that it is enough to show that $|\mathbf{\Theta}_t \mathbf{1}|^2 \, t^{-1} dxdt$ is a Carleson measure. For ε small, but fixed, we cover $\mathbb{C}^N$ by cones of aperture ε. Enumerating these cones as $\Gamma_1^\varepsilon, \ldots, \Gamma_K^\varepsilon,$, where $K = K(\varepsilon, N)$, we see that

$$\int_0^{\ell(Q)} \int_Q |\mathbf{\Theta}_t \mathbf{1}|^2 \, \frac{dxdt}{t} = \sum_{k=1}^K \int_0^{\ell(Q)} \int_Q |\mathbf{\Theta}_t \mathbf{1}|^2 \, 1_{\Gamma_k^\varepsilon}(\mathbf{\Theta}_t \mathbf{1}) \, \frac{dxdt}{t}.$$

Thus, it is enough to show that there is a uniform constant

$$C_1 = C_1(\varepsilon, \delta, C_0, n, N)$$

such that, for each fixed cone Γ^ε with ε small enough,

$$\sup_Q |Q|^{-1} \int_0^{\ell(Q)} \int_Q |\mathbf{\Theta}_t \mathbf{1}|^2 \, 1_{\Gamma^\varepsilon}(\mathbf{\Theta}_t \mathbf{1}) \, \frac{dxdt}{t} \leq C_1.$$

To this end, normalizing so that $\delta = 1$, and fixing Q, we follow the stopping time argument of the previous theorem, in the present case extracting dyadic subcubes $Q_j \subset Q$ which are maximal with respect to the property that at least one of the following holds:

$$\int_{Q_j} |\boldsymbol{b}_Q| \geq \frac{1}{4\varepsilon} \tag{2.11}$$

or

$$\Re e\, \nu \cdot \left(|Q_j|^{-1} \int_{Q_j} \boldsymbol{b}_Q \right) \overline{\nu} \leq \frac{3}{4}, \tag{2.12}$$

where $\nu \in \mathbb{C}^N$ is the unit normal in the direction of the central axis of Γ^ε, i.e.,

$$\Gamma^\varepsilon = \left\{ z \in \mathbb{C}^N : \left| \frac{z}{|z|} \right| - \nu \right| < \varepsilon \right\}.$$

As in the proof of the previous theorem, one may check that

$$|E| \equiv |Q \setminus (\cup Q_j)| \geq \eta |Q|,$$

for some fixed $\eta > 0$. Moreover, for $(x,t) \in E_Q^* \equiv R_Q \setminus \left(\bigcup R_{Q_j} \right)$, (we recall that $R_Q \equiv Q \times (0, \ell(Q)$ is the Carleson box above Q) and for $z \in \Gamma^\varepsilon$, we claim that

$$|z \cdot A_t \boldsymbol{b}_Q(x) \overline{\nu}| \geq \frac{1}{2} |z|, \tag{2.13}$$

where again A_t denotes the dyadic averaging operator with respect to the dyadic grid of Q. Indeed, since the opposite inequalities to (2.14) and (2.15) hold in E_Q^*, we have that

$$|\omega \cdot A_t \boldsymbol{b}_Q(x) \overline{\nu}| \geq |\nu \cdot A_t \boldsymbol{b}_Q(x) \overline{\nu}| - |(\omega - \nu) \cdot A_t \boldsymbol{b}_Q(x) \overline{\nu}| \geq \frac{3}{4} - \frac{1}{4} = \frac{1}{2}$$

whenever $|\omega - \nu| < \varepsilon$ and $(x,t) \in E_Q^*$. Taking $\omega = z/|z|$, with $z \in \Gamma^\varepsilon$, we obtain (2.16).

Consequently, we have that

$$\iint_{E_Q^*} |\boldsymbol{\Theta}_t \mathbf{1}|^2 \, 1_{\Gamma^\varepsilon}(\boldsymbol{\Theta}_t \mathbf{1}) \, \frac{dxdt}{t} \leq 4 \iint_{E_Q^*} |\boldsymbol{\Theta}_t \mathbf{1} \cdot A_t \boldsymbol{b}_Q \overline{\nu}|^2 \, \frac{dxdt}{t},$$

and the rest of the proof follows as in the previous theorem.

As mentioned above, a variant of this last theorem leads to the solution of the Kato problem. We recall the statement of the problem. Let B be an $n \times n$ matrix of complex, L^∞ coefficients, defined on $\mathbb{R}^n$, and satisfying the ellipticity (or "accretivity") condition

$$\lambda |\xi|^2 \leq \Re e \, \langle B\xi, \xi \rangle \equiv \Re e \sum_{i,j} B_{ij}(x) \, \xi_j \, \overline{\xi}_i, \quad \|B\|_\infty \leq \Lambda, \tag{2.14}$$

for $\xi \in \mathbb{C}^n$ and for some λ, Λ such that $0 < \lambda \leq \Lambda < \infty$. We define a divergence form operator

$$Ju \equiv -\operatorname{div}(B(x)\nabla u), \tag{2.15}$$

which we interpret in the usual weak sense via a sesquilinear form. The accretivity condition (2.14) enables one to define an accretive square root $\sqrt{J} \equiv J^{1/2}$ (see [K1], [K2]), and the "Kato problem", or "square root problem", is to establish the estimate

$$\|\sqrt{J} f\|_{L^2(\mathbb{R}^n)} \leq C\|\nabla f\|_{L^2(\mathbb{R}^n)}, \tag{2.16}$$

with C depending only on n, λ and Λ. The latter estimate is connected with the question of the analyticity of the mapping $B \to J^{\frac{1}{2}}$, which in turn has applications to the perturbation theory for certain classes of hyperbolic equations (see [Mc]). We remark that (2.16) is equivalent to the opposite inequality for the square root of the adjoint operator J^* (which amounts to the L^2 boundedness of the Riesz transforms $\nabla(J^*)^{-1/2}$). In [HMc], [HLMc], [AHLMcT], (but see also [AT]), estimate (2.16) was deduced, in effect, from a variant of Theorem 2.12, with $N = n$, in which the matrix $\boldsymbol{b}_Q$ is the derivative matrix of a carefully chosen $\mathbb{C}^n$-valued solution F_Q of an appropriate PDE. For example, one can take F_Q to be a certain $W^{1,2}$ solution of the parabolic equation $\frac{\partial u}{\partial t} + Ju = 0$, with t frozen at the scale $t = (\varepsilon \ell(Q))^2$ (ε chosen small, but fixed depending on n, λ and Λ), or it could be a solution of the resolvent equation $(1 + (\varepsilon \ell(Q))^2 J)F_Q = x$. In the case of the Kato problem, the operators $\boldsymbol{\Theta}_t$ which arise do not satisfy the kernel conditions (2.1), but they do posses some extra structure inherited from the operator J, which suffices to carry through the same argument sketched above in the proof of Theorem 2.12.

3. Local *Tb* theorems for singular integrals and applications

To help motivate our next application, we discuss the Kato problem from the perspective of elliptic boundary value problems. Consider the Dirichlet problem

$$\begin{cases} u_{tt} + \operatorname{div}_x B(x)\nabla_x u = 0 \text{ in } \mathbb{R}^{n+1}_+ = \{(x,t) \in \mathbb{R}^n \times (0,\infty)\} \\ u(x,0) = f(x) \in L^2(\mathbb{R}^n). \end{cases} \tag{D}$$

Then a solution u is given in terms of the Poisson semigroup: $u(x,t) = e^{-t\sqrt{J}} f(x)$. Note that the outward normal derivative is given by

$$\frac{\partial u}{\partial \nu} = -\frac{\partial u}{\partial t} = \sqrt{J} u,$$

and that the tangential gradient is simply

$$\nabla_{\tan} u = \nabla_x u.$$

Thus the Kato estimate (2.16), together with the reverse inequality for the Riesz transforms $\nabla J^{-1/2}$, can be thought of as a "Rellich identity"

$$\|\frac{\partial u}{\partial \nu}\|_2 \approx \|\nabla_{\tan} u\|_2 \tag{3.1}$$

for solutions of the boundary value problem (D). The Rellich identity, in turn, plays a vital role in the solution of the Neumann and regularity problems with L^2 estimates (see, e.g., Jerison and Kenig [JK2], Verchota [V] and Kenig and Pipher [KP]); moreover, a local scale invariant Rellich identity can be used to establish L^2 estimates for solutions of the Dirichlet problem [JK1], [JK3]. We observe that the equation

$$u_{tt} + \operatorname{div}_x B(x)\nabla_x u = 0$$

can be written in the form

$$\operatorname{div}_{x,t} A(x)\nabla_{x,t} u = 0, \tag{3.2}$$

where A is the $(n+1)\times(n+1)$ matrix

$$\left[\begin{array}{c|c} & 0 \\ B & \vdots \\ & 0 \\ \hline 0\cdots 0 & 1 \end{array}\right]. \tag{3.3}$$

The question then naturally arises whether the special "semi-group structure" (3.3) is needed to establish the "Rellich identity" (3.1) (and more generally, to obtain L^2 estimates for the Dirichlet, Neumann and regularity problems). Perhaps one might be able to consider equations of the type (3.2) with a "full" $(n+1)\times(n+1)$ elliptic coefficient matrix $A(x)$ (still independent of the t variable). Indeed, for real symmetric coefficients, this is the case [JK3], [KP], [Ke]. Unfortunately, the analogous statement fails for coefficients which are real, but non-symmetric (let alone complex): solvability with L^2 estimates does not hold in general if the non-symmetry is sufficiently severe [KKPT]. On the other hand, it turns out that the magnitude of the non-symmetry matters. Suppose that $A_1(x)$ is a complex, L^∞ elliptic matrix (in the sense of (2.17), but now with $\xi \in \mathbb{C}^{n+1}$), and that $\|A_1 - A_0\|_{L^\infty(\mathbb{R}^n)} \leq \varepsilon$, where $A_0(x)$ is real, symmetric, L^∞ and elliptic, and where ε depends only on dimension and the ellipticity parameters for A_0. Then the Rellich identity (3.1) holds for solutions of the equation

$$L_1 u = -\operatorname{div} A_1(x)\nabla u = 0$$

(in (3.1), $\frac{\partial u}{\partial \nu}$ now denotes the "co-normal" derivative), and one has solvability with L^2 estimates for the Dirichlet, Neumann and Regularity problems [AAAHK]. The proof entails establishing an analytic perturbation result for the layer potentials associated to operators close to $L_0 = -\operatorname{div} A_0(x)\nabla$, and therefore the first step requires that we obtain L^2 boundedness (and invertibility) of the layer potentials associated to L_0. We remark here that since L_0 has real, symmetric, t-independent coefficients, the

solvability, with L^2 estimates, of the Dirichlet [JK1], [JK3], [Ke, pp. 63–64] and Neumann and Regularity [KP] problems for the equation $L_0 u = 0$ was already known, but the layer potential theory is new, and is used to jump start the perturbation scheme. This first step brings us back to the subject of local *Tb* theorems, this time for singular integrals rather than for square functions. (Actually, the subsequent analytic perturbation step also uses local *Tb* technology, in the spirit of the proof of the Kato problem, but this aspect of the theory is rather involved, and we shall not discuss it here).

The following theorem was (essentially) proved in [AHMTT].

Theorem 3.1. *Let T be a singular integral operator associated to a kernel K satisfying the Calderón–Zygmund kernel conditions* (1.1) *and* (1.2)*, as well as the generalized truncation condition $K(x, y) \in L^\infty(\mathbb{R}^n \times \mathbb{R}^n)$. Suppose also that there exist pseudo-accretive systems $\{b_Q\}$, $\{b_Q^*\}$ such that* $\operatorname{supp} b_Q$, $\operatorname{supp} b_Q^* \subseteq Q$, *and*

(i) $\int_Q (|b_Q|^{2+\varepsilon} + |b_Q^*|^{2+\varepsilon}) \leq C|Q|$, *for some $\varepsilon > 0$,*

(ii) $\int_Q (|Tb_Q|^2 + |T^* b_Q^*|^2) \leq C|Q|$,

(iii) $\frac{1}{C}|Q| \leq \min(|\int_Q b_Q|, |\int_Q b_Q^*|)$.

Then $T: L^2(\mathbb{R}^n) \to L^2(\mathbb{R}^n)$, with bound independent of $\|K\|_\infty$.

Remark. This theorem was proved in [AHMTT] for so-called "perfect dyadic" singular integral operators, which are associated to a kernel for which the smoothness condition (1.2) is replaced by the condition that

$$K(x, y) - K(x', y) = 0, \tag{3.4}$$

whenever $x, x' \in Q$ and $y \in Q^c$, where Q is a dyadic cube. In that case, one can take ε to be 0 in condition (i). The proof of the present theorem is essentially the same as that in [AHMTT] except that one is forced to treat several error terms caused by the decaying tail in (1.2), which are absent when one has the perfect localization (3.5) (see [AAAHK] for details). We will not give the proof of this theorem here (it is a bit complicated), although we shall briefly discuss some of the ideas involved in its proof. First however, we describe how one may use this theorem to deduce boundedness of the layer potentials associated to a divergence form elliptic operator in $\mathbb{R}^{n+1}_+$, with real symmetric t-independent coefficients.

Suppose now that

$$Lu = -\operatorname{div} A(x)\nabla u,$$

is defined in $\mathbb{R}^{n+1} = \{(x, t) \in \mathbb{R}^n \times (-\infty, \infty)\}$ (so that div, ∇ are taken in all $n+1$ variables x and t), where $A(x)$ is real, symmetric, elliptic and L^∞. There is a global fundamental solution

$$\Gamma(x, t, y, s) = \Gamma(x, t - s, y, 0)$$

associated to L, which by De Giorgi–Nash–Moser estimates satisfies

$$|\Gamma(x,t,y,0)| \leq C(|t|+|x-y|)^{1-n} \tag{3.5}$$

$$\left|\frac{\partial}{\partial t}\Gamma(x,t,y,0)\right| \leq C(|t|+|x-y|)^{-n}, \tag{3.6}$$

$$\left|\frac{\partial}{\partial t}\left(\Gamma(x+h,t,y,0)-\Gamma(x,t,y,0)\right)\right| + \left|\frac{\partial}{\partial t}\left(\Gamma(x,t,y+h,0)-\Gamma(x,t,y,0)\right)\right| \leq C\frac{|h|^{\alpha}}{(|t|+|x-y|)^{n+\alpha}}, \tag{3.7}$$

whenever $|h| \leq \frac{1}{2}|x-y|$ or $|h| \leq |t|/2$, for some $\alpha > 0$. We define as usual the single layer potential operator

$$S_t f(x) \equiv \int_{\mathbb{R}^n} \Gamma(x,t,y,0) f(y)\, dy,$$

and also singular integrals

$$T_t f(x) \equiv \frac{\partial}{\partial t} S_t f(x) = \int_{\mathbb{R}^n} \frac{\partial}{\partial t}\Gamma(x,t,y,0) f(y)\, dy.$$

We observe that, by virtue of (3.7) and (3.8), the kernel of the latter operator satisfies the hypotheses of Theorem 3.4, uniformly in $t > 0$. Thus, the estimate

$$\sup_{t>0} \|T_t f\|_{L^2(\mathbb{R}^n)} \leq C\|f\|_2 \tag{3.8}$$

will follow immediately if we can produce pseudo-accretive systems $\{b_Q\}$, $\{b_Q^*\}$ satisfying the conditions (i),(ii) and (iii). Given (3.9), bounds for the tangential derivatives of $S_t f$ will follow from the estimate

$$\|\nabla_x S_t f\|_2 \leq C\|\frac{\partial}{\partial t} S_t f\|_2,$$

which in turn is easily obtained for real, symmetric coefficients via integration by parts (indeed, it is a consequence of the Rellich identity). The invertibility of the appropriate boundary integral operators is also then obtainable from the Rellich identity. Let us now indicate how one may deduce (3.9) from Theorem 3.4. We shall only produce a pseudo-accretive system for the operator T_t; one may treat T_t^* by a transparent variation of the same method. We recall the following fundamental result of Jerison and Kenig [JK3] (see also [Ke, pp. 63–64]):

Theorem 3.2 ([JK3]). *Suppose that $L = -\operatorname{div} A\nabla$, where A is real, symmetric, $(n+1)\times(n+1)$, t-independent, L^∞ and uniformly elliptic. Then the elliptic-harmonic measure associated to L, in the lower half-space $\mathbb{R}^{n+1}_-$, is absolutely continuous with respect to n-dimensional Lebesgue measure on the boundary $\{t = 0\}$. Moreover,*

if $k^{A_Q^-}(y)$ denotes the Poisson kernel, at the point $A_Q^- = (x_Q, -\ell(Q))$, where Q is a cube on the boundary with center x_Q, then we have the scale invariant estimate

$$\int_{\mathbb{R}^n} (k^{A_Q^-}(y))^{2+\varepsilon}\, dy \leq C|Q|^{-1-\varepsilon}, \tag{3.9}$$

for some $\varepsilon > 0$ depending only on dimension and ellipticity.

We now set

$$b_Q \equiv |Q| 1_Q\, k^{A_Q^-}. \tag{3.10}$$

Observe that condition (i) of Theorem 3.4 follows immediately from Theorem 3.10. Moreover (iii) is an immediate consequence of the following well-known estimate of Caffarelli, Fabes, Mortola and Salsa [CFMS] (see also [Ke, Lemma 1.3.2, p. 9]):

$$\int_Q k^{A_Q^-}(y)\, dy \geq \frac{1}{C}. \tag{3.11}$$

It remains to establish condition (ii). We consider first

$$\begin{aligned} \partial_t S_t \tilde{b}_Q(x) &= |Q| \int_{\mathbb{R}^n} \partial_t \Gamma(x, t, y, 0) k^{A_Q^-}(y)\, dy \\ &= |Q| \partial_t \Gamma(x, t, A_Q^-), \end{aligned}$$

where $\tilde{b}_Q$ is defined as in (3.10) (except that we have dropped the indicator function of the cube Q), and where we have used that for $(x, t) \in \mathbb{R}^{n+1}_+$ fixed, the function $\partial_t \Gamma(x, t, \cdot, \cdot)$ solves $Lu = 0$ in $\mathbb{R}^{n+1}_-$. Since $t > 0$, we then have by (3.5) and translation invariance in t that

$$|\partial_t S_t b_Q(x)| \leq C,$$

uniformly in $(x, t) \in \mathbb{R}^{n+1}_+$. It is not hard to use integration by parts, coupled again with the fact that $\partial_t \Gamma(x, t, \cdot, \cdot)$ is a solution in the lower half-space to obtain a similar estimate for $\partial_t S_t(\eta_Q \tilde{b}_Q)(x)$, where $\eta_Q \in C_0^\infty$, $\eta_Q \equiv 1$ on $5Q$, $\operatorname{supp} \eta_Q \leq 6Q$, with $\|\nabla \eta_Q\|_\infty \leq C/\ell(Q)$. One then obtains the L^2 bound (ii) for $\partial_t S_t b_Q$ by using (i) and the kernel estimate (3.7) to handle the error $\partial_t S_t \left((\eta_Q - 1_Q) b_Q\right)(x)$. We omit the details (the interested reader may consult [AAAHK]).

Let us conclude the article by sketching some of the ideas involved in the proof of Theorem 3.4. We begin by trying to mimic, as far as possible, the proof of Theorem 2.2. By the $T1$ theorem, it is enough to show that $T1 \in \mathrm{BMO}$ (we ignore the matter of establishing WBP – it turns out that there is a local version of the $T1$ condition, in which 1 is replaced by 1_Q, that yields weak boundedness also, and in practice, it is this local condition that one establishes). By [FS], it would be enough to verify the Carleson measure estimate

$$\sup_Q |Q|^{-1} \int_0^{\ell(Q)} \int_Q |\Delta_t T1(x)|^2\, \frac{dxdt}{t} < \infty, \tag{3.12}$$

where

$$\Delta_t f(x) \equiv \int t^{-n} \psi\left(\frac{x-y}{t}\right) f(y)\, dy,$$

and $\psi \in C_0^\infty(\{|x| < 1\})$ is radial with

$$\int_0^\infty |\hat{\psi}(t)|^2 \frac{dt}{t} = 1.$$

We attempt to proceed as in the proof of Theorem 2.2, but now with $\Delta_t T$ in place of θ_t. As before, we use conditions (i) and (iii) to produce a dyadic sawtooth region E_Q^*, with $|\partial E_Q^* \cap Q| > \eta |Q|$, on which

$$|\Delta_t T 1| \leq C |(\Delta_t T 1)(P_t b_Q)|$$

(modulo acceptable errors). It is then enough to control

$$\iint_{E_Q^*} |(\Delta_t T 1)(P_t b_Q)|^2 \frac{dx\,dt}{t}.$$

Again following the idea of [CM], we write

$$(\Delta_t T 1)(P_t b_Q) = \left[(\Delta_t T 1)(P_t b_Q) - \Delta_t T b_Q\right] + \Delta_t T b_Q \equiv \Lambda_t b_Q + \Delta_t T b_Q.$$

The contribution of the second summand can be handled using condition (ii) and the boundedness of the square function

$$f \to \left(\int_0^\infty |\Delta_t f|^2 \frac{dt}{t}\right)^{1/2}.$$

It is the first summand which causes problems. In contrast to the situation in Theorem 2.2, in which the kernel of the operator $R_t = (\theta_t 1) P_t - \theta_t$ gave rise to a bounded square function, the contribution of $\Lambda_t b_Q$ is now problematic, owing to the failure of the estimates (2.1) for the kernel of Λ_t. Let us try to isolate the difficulty, by writing

$$\Lambda_t = [(\Delta_t T 1) P_t - \Delta_t T P_t] + \Delta_t T (P_t - I) \equiv \tilde{R}_t + \tilde{\Lambda}_t.$$

Then we can at least handle $\tilde{R}_t$ exactly as we did R_t in Theorem 2.2: it is not hard to show that its kernel satisfies (2.1) (I am cheating a bit here – the bound for the kernel of $\Delta_t T P_t$ uses WBP) and clearly $\tilde{R}_t 1 = 0$. It is the term $\tilde{\Lambda}_t$ which now causes problems. If $T^* 1 = 0$, or even if $T^* 1 \in \mathrm{BMO}$, then one can prove square function bounds for the contribution of $\tilde{\Lambda}_t$ (this is easiest to do when the Littlewood–Paley operators Δ_t have been discretized, and when T is of "perfect dyadic" type; see the "one-sided *Tb* theorem" in [AHMTT]). In the absence of this "one-sided" condition, the idea is to build discretized Δ_t operators which are adapted to b_Q^* (as in [CJS]), to take advantage of the fact that we can control (locally) $T^* b_Q^*$ in place of $T^* 1$. The difficulty is that these adapted Δ_t operators are now well behaved only

in sawtooth regions on which b_Q^* is non-degenerate, and therefore there is a stopping time construction needed just to reach the analogue of (3.14), which now, for a given cube Q, becomes an estimate over a sawtooth adapted to b_Q^*. Morally speaking, one then proceeds more or less as I have described above. In practice, this is a bit delicate. We refer the interested reader to [AHMTT] and [AAAHK] for details.

Almost everywhere convergence and divergence of Fourier series

Sergey V. Konyagin*

Abstract. The aim of this expository paper is to demonstrate that there are several challenging problems concerning the behavior of trigonometric Fourier series almost everywhere.

Mathematics Subject Classification (2000). Primary 42A20; Secondary 42A24, 42B05, 42C10.

Keywords. Trigonometric Fourier series, Walsh system, partial sums, convergence, almost everywhere.

1. Introduction

We write $\mathbb{T} = \mathbb{R}/2\pi\mathbb{Z}$ for the one-dimensional torus considered as the real line with $x+2\pi$ identified with x. Let $L(\mathbb{T})$ denote the class of all Lebesgue integrable functions $\mathbb{T} \to \mathbb{C}$. We associate with any function $f \in L(\mathbb{T})$ its Fourier series

$$f \sim \sum_{k=-\infty}^{\infty} \hat{f}(k) e^{ikx},$$

where

$$\hat{f}(k) = \frac{1}{2\pi} \int_{\mathbb{T}} f(x) \exp(-ikx)\, dx,$$

The m-th partial sum of the trigonometric Fourier series of f is

$$S_m(f, x) = \sum_{k=-m}^{m} \hat{f}(k) \exp(ikx).$$

Unfortunately, the Fourier series of f does not necessarily converge to f. It is known from Du Bois-Reymond [8] that the Fourier series of a continuous function can unboundedly diverge at some point. Fejér [10] and Lebesgue [27] constructed other examples of such functions. Almost one century ago it was proven that a trigonometric series with coefficients tending to 0 can diverge everywhere. Lusin [30] constructed

*The author was supported by the Grant 05-01-00066 from the Russian Foundation for Basic Research.

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

such a series of power type $\sum_{k=0}^{\infty} c_k e^{ikx}$, and Steinhaus [38] gave an example of everywhere divergent real series

$$\sum_{k=1}^{\infty}(a_k \cos(kx) + b_k \sin(kx))$$

such that $a_k \to 0, b_k \to 0$ as $k \to \infty$. The central problem was: can the Fourier series of an integrable function diverge almost everywhere (everywhere)? G. H. Hardy [13] proved that if it is the case the divergence is not too fast:

$$S_m(f, x) = o(\log m) \quad (m \to \infty) \quad \text{almost everywhere.} \tag{1}$$

A. N. Kolmogoroff [17] constructed his famous example of a function $f \in L(\mathbb{T})$ such that $S_m(f, x)$ diverges unboundedly almost everywhere. In another paper [19] he constructed an everywhere divergent Fourier series.

These prominent results caused two type of problems.

I. To find a large class of functions with almost everywhere convergent Fourier series.

II. To show that a Fourier series of every integrable function converges in some sense to the function.

Some versions of these problems are discussed in the paper. We will deal not only with the trigonometric system but also with the Walsh system. The Walsh system is the following system of functions defined on [0, 1):

$$w_0(x) = 1, \quad w_k(x) = \prod_{j=0}^{r} \left(\operatorname{sign} \sin 2^{j+1}\pi x\right)^{\varepsilon_j} \quad (k \in \mathbb{N}),$$

where $\varepsilon_0, \dots, \varepsilon_r$ are the digits in the representation of k in the dyadic system

$$k = \sum_{j=0}^{r} \varepsilon_j 2^j, \quad \varepsilon_j \in \{0, 1\},\ \varepsilon_r = 1. \tag{2}$$

This is a complete orthonormal functional system, and any function $f \in L[0, 1)$ has the Fourier–Walsh representation

$$f \sim \sum_{k=0}^{\infty} \hat{f}(k) w_k(x), \quad \hat{f}(k) = \int_0^1 f(x) w_k(x)\, dx.$$

The Fourier–Walsh partial sums are defined as

$$S_m(f, x) = \sum_{k=0}^{m-1} \hat{f}(k) w_k(x).$$

The theory and the history of Fourier–Walsh series can be found in [11].

The author is grateful to A. V. Rozhdestvenskii for a careful reading of the paper. Due to his remarks, some shortcomings have been corrected.

2. Convergence of the sequence of all partial sums

Let $\phi\colon [0,+\infty)\to[0,+\infty)$ be a nondecreasing function, $\phi(0)=0$. Denote

$$\phi(L)=\Big\{f\in L(\mathbb{T}):\int_{\mathbb{T}}\phi(|f(x)|)\,dx<\infty\Big\}.$$

For example, if $\phi(u)=u$, then $\phi(L)=L(\mathbb{T})$; if $\phi(u)=u^2$, then $\phi(L)=L^2(\mathbb{T})$.

Problem 2.1. For what functions ϕ the trigonometric Fourier series of any function $f\in\phi(L)$ converges almost everywhere?

In particular, it was not clear whether the Fourier series of a continuous function can diverge everywhere. Carleson [6] showed that if $f\in L^2(\mathbb{T})$ (i.e., f is measurable and $\int_{\mathbb{T}}|f^2(x)|dx<\infty$), then $S_m(f,x)\to f(x)$ as $m\to\infty$ almost everywhere. The condition $f\in L^2(\mathbb{T})$ in the Carleson theorem was weakened by Hunt [15], Sjölin [36]. Antonov [2] proved that if f is a measurable function and

$$\int_{\mathbb{T}}|f(x)|\log^+|f(x)|\log^+\log^+\log^+|f(x)|\,dx<\infty,$$

then $S_m(f,x)\to f(x)$ as $m\to\infty$ for almost all $x\in\mathbb{T}$. (We denote $\log^+u=\log u$ if $u\ge 1$ and $\log^+u=0$ if $u<1$.) The results in [36] were proven for Fourier–Walsh series, but the proofs can be rewritten for trigonometric series as well. The analog of Antonov's result for Fourier–Walsh series was established by Sjölin and Soria [37]. Arias-de-Reyna [1] constructed a rearrangement invariant space QA of functions with almost everywhere convergent Fourier series such that QA strictly contains Antonov's space $L\log^+L\log\log\log^+L$.

On the other hand, Körner [26] proved that if

$$\phi(u)=o(u\log\log u)\quad(u\to\infty)\tag{3}$$

then there is a function $f\in\phi(L)$ such that $\limsup_{m\to\infty}|S_m(f,x)|=\infty$ for all $x\in\mathbb{T}$. This result was improved by the author [22], [23].

Theorem 2.2. *If*

$$\phi(u)=o(u\sqrt{\log u/\log\log u})\quad(u\to\infty)$$

then there is a function $f\in\phi(L)$ such that

$$\limsup_{m\to\infty}S_m(f,x)=\infty\quad\textit{for all } x\in\mathbb{T}.$$

Also, in [22] and [23] it was proven the existence of a function $f\in L(\mathbb{T})$ satisfying

$$S_m(f,x)>\psi(m)\quad\text{for all } x \text{ and infinitely many } m$$

provided that

$$\psi(m)=o(\sqrt{\log m/\log\log m})\quad(m\to\infty).$$

This improved the result of Chen [7] asserting the existence of such a function f under a stronger supposition

$$\psi(m) = o(\log\log m) \quad (m \to \infty).$$

However, it is still unknown whether Hardy's inequality (1) can be improved. More precisely: does there exist a function $\psi(u) = o(u)$ as $u \to \infty$ such that for any $f \in L(\mathbb{T})$ the inequality

$$S_m(f, x) = o(\psi(\log m)) \quad (m \to \infty)$$

holds everywhere?

Conjecture 2.3. For any $f \in L(\mathbb{T})$

$$S_m(f, x) = o(\sqrt{\log m}) \quad (m \to \infty) \quad \text{almost everywhere.}$$

Due to Bochkarev, we know the existence of a function with almost everywhere divergent Fourier–Walsh series from a smaller functional class $\phi(L)$ than in the case of trigonometric Fourier series. In fact, the following result was proven in [5].

Theorem 2.4. *If*

$$\phi(u) = o(u\sqrt{\log u}) \quad (u \to \infty)$$

then there is a function $f \in L[0, 1)$ such that

$$\int_0^1 \phi(|f(x)|)dx < \infty$$

and the Fourier–Walsh partial sums of f unboundedly diverge almost everywhere.

Antonov extended his result to convergence of cubic partial sums for multiple trigonometric Fourier series ([3], [4]; see also [37]). An extension of Körner's result to multiple trigonometric Fourier series was made in [21].

3. Convergence of subsequences of the sequence of partial sums

Gosselin [12] proved that for any increasing sequence $\{m_j\}$ there is $f \in L(\mathbb{T})$ such that

$$\sup_j |S_{m_j}(f, x)| = \infty \tag{4}$$

for almost all $x \in \mathbb{T}$. Totik [39] established the existence of f such that (4) holds for all $x \in \mathbb{T}$.

The problem is to determine under which conditions on a sequence $\{m_j\}$ and a function ϕ the partial sums $S_{m_j}(f)$ converge to f almost everywhere for any function $f \in \phi(L)$. In particular, is it true that for enough sparse sequence $\{m_j\}$ we can claim

the almost everywhere convergence of $S_{m_j}(f)$ to f for a wider functional class $\phi(L)$ than in the case of taking the full sequence of the partial sums?

Let $\{m_j\}$ be a lacunary sequence, that is, $\inf_j m_{j+1}/m_j > 1$. If the Fourier series of a function g is a power-type series, namely,

$$g \sim \sum_{k=0}^{\infty} \hat{g}(k) \exp(ikx),$$

then the sequence $\{S_{m_j}(g)\}$ converges to g almost everywhere ([42], Chapter 15, Theorem 5.11). Combining the last result with Theorem 5.11 of Chapter 7 from [42] we get that if a measurable function f satisfies the condition

$$\int_{\mathbb{T}} |f(x)| \log^+ |f(x)| \, dx < \infty, \tag{5}$$

and $\{m_j\}$ is a lacunary sequence, then $\{S_{m_j}(f)\}$ converges to f almost everywhere. Let us recall that we do not know whether (5) is sufficient for the almost everywhere convergence of the Fourier series of the function f.

The following theorem [25] contains the above-mentioned results of [26] and [39].

Theorem 3.1. *For any increasing sequence $\{m_j\}$ of positive integers and any nondecreasing function $\phi\colon [0, +\infty) \to [0, +\infty)$ satisfying condition* (3)*, there is a function $f \in \phi(L)$ such that*

$$\sup_j |S_{m_j}(f, x)| = \infty \quad \textit{for all } x \in \mathbb{T}.$$

For the proof the construction suggested by Heladze [14] is used.

However, the technique of [22] and [23] employed the partial sums S_{m_j} for a quite rich subsequence $\{m_j\}$ and did not allow to weaken condition (3) in Theorem 3.1. Moreover, it is quite possible that this condition is sharp.

Conjecture 3.2. For any lacunary increasing sequence $\{m_j\}$ of positive integers and any measurable function f such that

$$\int_{\mathbb{T}} |f(x)| \log^+ \log^+ |f(x)| \, dx < \infty,$$

we have $S_{m_j}(f, x) \to f(x)$ as $j \to \infty$ for almost all $x \in \mathbb{T}$.

There is no a direct analog of Gosselin's theorem for Fourier–Walsh series. For a positive integer k denote

$$s(k) = 1 + \sum_{j=0}^{r-1} |\varepsilon_j - \varepsilon_{j+1}|,$$

where $\varepsilon_0, \ldots, \varepsilon_r$ are defined by (2). It is well-known that if $\{m_j\}$ is an increasing sequence of positive integers and

$$\sup_j s(m_j) < \infty, \tag{6}$$

then the Fourier–Walsh sums $S_{m_j}(f)$ converge to f almost everywhere for any $f \in L[0, 1)$. In particular, this holds for $m_j = 2^j$. Moreover, condition (6) is not necessary for almost everywhere convergence of $S_{m_j}(f)$ to f for all functions $f \in L[0, 1)$ [20].

Problem 3.3. Find a necessary and sufficient condition on a sequence $\{m_j\}$ of positive integers under which the partial Fourier–Walsh sums $S_{m_j}(f)$ converge to f almost everywhere for every function $f \in L[0, 1)$.

One of the most remarkable results in this subject belongs to Lukomskij [29] who settled the problem for multiple Fourier–Walsh series of any dimension greater than one [29].

4. Ul'yanov's problem

Kolmogoroff [18] established the weak-type estimate for conjugate functions. One of the corollaries of his result is the convergence of trigonometric Fourier series of any integrable function in $L^p (0 < p < 1)$ and, therefore, in measure. Hence, for any function $f \in L(\mathbb{T})$ there exists an increasing sequence $\{m_j\}$ of positive integers such that the partial sums $S_{m_j}(f)$ converge to f almost everywhere. Gosselin's theorem demonstrates that such a sequence $\{m_j\}$ must depend on a function f.

Ul'yanov [40] asked the following question.

Problem 4.1. Does there exist a sequence $\{M_j\}$ such that the Fourier series of any $f \in L(\mathbb{T})$ possesses a subsequence $\{S_{m_j}(f)\}$ of its partial sums converging almost everywhere to f such that $m_j \le M_j$ for all j?

The following results have been proven in [24].

Theorem 4.2. *If $\phi(u)/u \to \infty$ as $u \to \infty$ then there exists a sequence $\{M_j\}$ such that for every function $f \in \phi(L)$ there is an increasing sequence $\{m_j\}$ such that $m_j \le M_j$ for all j and $S_{m_j}(f) \to f$ almost everywhere.*

Theorem 4.3. *There exists a sequence $\{M_j\}$ such that for every function $f \in L(\mathbb{T})$ there is an increasing sequence $\{m_j\}$ such that $m_j \le M_j$ for infinitely many j and $S_{m_j}(f) \to f$ almost everywhere.*

The sequence $\{M_j\}$ from Theorem 4.3 must grow very rapidly, faster than any multiple iteration of the exponent. Define the function $\exp^*(k)$, $k \in \mathbb{N}$, as the following: $\exp^*(0) = 0$, $\exp^*(k) = e^{\exp^*(k-1)}$ $(k \ge 1)$. It turns out that for any $\varepsilon > 0$ any sequence $\{M_j\}$ with

$$M_j = O\left(\exp^*([(\log\log j)^{1-\varepsilon}])\right) \quad (j \ge 20)$$

does not satisfy the requirements of Theorem 4.3. (Here $[u]$ is the greatest integer not exceeding u.)

Now we consider Ul'yanov's problem for measures. Let μ be a Borel measure on $\mathbb{T}$ with $\int_{\mathbb{T}} |\,d\mu| < \infty$. Denote

$$\hat{\mu}(k) = \frac{1}{2\pi} \int_{\mathbb{T}} \exp(-ikx) d\mu(x), \quad S_m(\mu, x) = \sum_{k=-m}^{m} \hat{\mu}(k) \exp(ikx).$$

In general, one cannot find an increasing sequence $\{m_j\}$ such that for almost all $x \in \mathbb{T}$ a sequence $\{S_{m_j}(\mu, x)\}$ converges, but, as follows from [18], the latter sequence is bounded for some $\{m_j\}$ and for almost all $x \in \mathbb{T}$. Ul'yanov's problem for measures can be formulated as follows.

Problem 4.4. Does there exist a sequence $\{M_j\}$ such that for any measure μ there is an increasing sequence $\{m_j\}$ such that $m_j \le M_j$ and for almost all $x \in \mathbb{T}$ the sequence $\{S_{m_j}(\mu, x)\}$ is bounded?

Let $\{x_k\}_{k\in\mathbb{N}}$ be a sequence of points in $\mathbb{T}$ and $\{a_k\}_{k\in\mathbb{N}}$ be a sequence of positive numbers satisfying the conditions $a_1 \ge a_2 \ge \cdots$, and $\sum_k a_k < \infty$. Let $\sigma = \{\sigma_k\}_{k\in\mathbb{N}}$ be a sequence of independent (real or complex) uniformly bounded random variables with the zero expectations. We define the random measure $\mu = \sum_k \sigma_k a_k \delta_{x_k}$, where δ_x is the Dirac unit point mass at x. The following assertion has been proved by the author and F. L. Nazarov.

Theorem 4.5. *Let $\eta > 0$ and $M_{\eta,j} = M_j = \exp^*[\eta \log\log(j+2))]$ for $j \in \mathbb{N}$. Then for any sequences $\{x_k\}$ and $\{a_k\}$ there exists an increasing sequence $\{m_j\}$ such that $m_j \le M_j$ for all sufficiently large j and, moreover, for any σ, almost all $\omega \in \Omega$ the inequality $\sup_j |S_{m_j}(d\mu(\omega))| < \infty$ holds almost everywhere on $\mathbb{T}$.*

I can prove that in general the estimate for the growth of $\{M_j\}$ in the theorem is sharp.

5. Strong summability

There are several ways to reconstruct the values of an integrable function via its partial Fourier sums almost everywhere. By the classical theorem of Lebesgue [28], the Fejér means $\frac{1}{M+1}\sum_{m=0}^{M} S_m(f)$ converge to f almost everywhere for every integrable f. This fact can be rewritten as

$$\lim_{M\to\infty} \frac{1}{M+1} \sum_{m=0}^{M} (S_m(f,x) - f(x)) = 0$$

almost everywhere. Marcienkiewicz [31] discovered that the convergence is not connected with oscillation of positive and negative terms, but reflects the fact that for most values m the difference $S_m(f,x) - f(x)$ is small. He proved that

$$\lim_{M\to\infty} \frac{1}{M+1} \sum_{m=0}^{M} |S_m(f,x) - f(x)|^2 = 0$$

holds almost everywhere and thus created the theory of strong summability. Let $\phi\colon [0,+\infty) \to [0,+\infty)$ be a nondecreasing function, $\phi(0) = 0$. There was a problem: for which ϕ we have

$$\lim_{M\to\infty} \frac{1}{M+1} \sum_{m=0}^{M} \phi(|S_m(f,x) - f(x)|) = 0 \tag{7}$$

almost everywhere for all $f \in L(\mathbb{T})$? As faster the growth of ϕ, as stronger the result. Thus, Marcienkiewicz [31] proved (7) for $\phi(u) = u^2$, and Zygmund [41] extended it to $\phi(u) = u^p$ for any $p > 0$.

If, moreover, $\phi(u) > 0$ for $u > 0$, then (7) implies the following property of the sequence $\{s_m\} = \{S_m(f,x)\}$ and the number $s = f(x)$: there exists an increasing sequence $\{m_j\}$ such that $\lim_j m_j/j = 1$ and $\lim_{j\to\infty} s_{m_j} = s$. This property is called almost everywhere ([42], Chapter 13, (9.1)), or statistical, convergence. There are many recent papers on statistical convergence; see, e.g., [32] and [33].

So, for almost all $x \in \mathbb{T}$ there exists an increasing sequence $\{m_j\}$ with $m_j = O(j)$ such that $\lim_{j\to\infty} S_{m_j}(f,x) = f(x)$. Recall that if we are looking for the same $\{m_j\}$ for almost all $x \in \mathbb{T}$ then in general its growth must be much faster.

To describe the contemporary approach to the strong summability, we recall the notion of the bounded mean oscillation (BMO); see, e.g., ([9], Chapter 6, §2). For a nondegenerate interval $I \subset \mathbb{R}$ and a function $f \in L(I)$ denote $f_I = |I|^{-1} \int_I f(x)dx$. The set BMO$[0,\infty)$ is defined as the class of all locally integrable on $[0,\infty)$ functions f such that

$$\|f\|_* = \sup_{I\subset[0,\infty)} \left\{ |I|^{-1} \int_I |f(x) - f_I|\, dx \right\} < \infty.$$

Next, for a function $f \in L(\mathbb{T})$, $x \in \mathbb{T}$, $t \in [0,\infty)$ denote

$$g_x(t) = S_{[t]}(f,x) - f(x).$$

Let $\mu(E)$ be the Lebesgue measure of a set E. The following result was proven by Rodin in [34], [35].

Theorem 5.1. *For any function $f \in L(\mathbb{T})$ and for almost all $x \in \mathbb{T}$ we have $g_x \in$ BMO$[0,\infty)$. Moreover, there exists an absolute constant $C > 0$ such that for any $\alpha > 0$ the following inequality holds*

$$\mu\left\{ x \in \mathbb{T} :\ \|g_x\|_* > \alpha \int_{\mathbb{T}} |f(y)|\, dy \right\} \le C\alpha^{-1}.$$

Corollary 5.2. *Let $\lambda > 0$ and $\phi(u) = \exp(\lambda u) - 1$. Then equality* (7) *holds almost everywhere for all $f \in L(\mathbb{T})$.*

Corollary 5.2 easily follows from Theorem 5.1 and the John–Nirenberg inequality ([9], Chapter 6, §4).

The condition on the function ϕ in Corollary 5.2 is sharp. Karagulyan [16] proved that if

$$\limsup_{u\to\infty} \log \phi(u)/u = \infty$$

then (7) fails for some $f \in L(\mathbb{T})$ for all $x \in \mathbb{T}$.

Iterated Segre mappings of real submanifolds in complex space and applications

Linda Preiss Rothschild*

Abstract. This article is a survey of various applications of the method of iterated Segre mappings obtained by a number of mathematicians, including the author, over the past decade. This method is applied to various problems involving real submanifolds in complex space and their mappings. The article begins with a description of the iterated Segre mappings associated to generic submanifolds. The problems addressed concern transversality of holomorphic mappings, finite jet determination, local stability groups, and algebraicity of holomorphic mappings between real-algebraic manifolds.

Mathematics Subject Classification (2000). Primary 32H02, 32H35, 32V40; Secondary 14P20.

Keywords. Generic submanifolds, holomorphic mappings, Segre mappings, finite determination.

1. Introduction and notation

In this survey we consider real submanifolds $M \subset \mathbb{C}^N$ and $M' \subset \mathbb{C}^{N'}$ through p and p' respectively and study local properties of germs of holomorphic mappings $H\colon (\mathbb{C}^N, p) \to (C^{N'}, p')$ such that $H(M) \subset M'$. The questions we consider are the following:

1. When is H determined by finitely many derivatives at p?
2. If $M = M'$ and $p = p'$, when does the set of all such H form a finite dimensional Lie group?
3. If M and M' are real-algebraic manifolds, when does it follow that H is necessarily an algebraic mapping?
4. When is H transversal to M' at p'?

The common thread of the approach to these problems is the use of the iterated Segre mappings, which represent a kind of blow-up of the complexification of a real submanifold. These mappings first appeared in the joint work of the author with

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

Baouendi and Ebenfelt [2]. In what follows I shall assume, without loss of generality, that p and p' are both the origin. Then the real submanifold M is given near 0 by the vanishing of a system of equations $\rho = (\rho_1, \ldots, \rho_d) = 0$, where d is the codimension of M and the ρ_j are real-valued functions with linearly independent differentials at 0. If, in addition, the complex vectors $\left(\frac{\partial \rho_j}{\partial Z_1}, \ldots, \frac{\partial \rho_j}{\partial Z_N}\right)(0)$, $1 \leq j \leq d$, are also linearly independent, the real submanifold M is called *generic*. In particular, the condition that M is generic insures that M is a *CR manifold*, i.e. that the space $T_q^{0,1}M$ of complex $(0, 1)$ vectors at q that are tangent to M at q is of constant dimension for $q \in M$ near 0. The assumption that a CR submanifold of $\mathbb{C}^N$ is generic is not very restrictive, since any such manifold can be locally embedded as a generic submanifold in some complex manifold, possibly of lower dimension (see e.g. [6]).

For quite some time an important tool in the study of holomorphic mappings has been the complexification of the real manifolds M and M' (see e.g. Webster [48], [49], Diederich-Webster [25], Baouendi–Jacobowitz–Treves [12], Diederich–Pinchuk [24], Chern–Ji [19]). To simplify notation and statements, I shall assume, unless stated otherwise, that the real submanifolds M and M' are real-analytic, and hence their defining functions can be assumed to be real-analytic. Then we may regard the real vector valued function ρ as a convergent power series, $\rho(Z, \bar{Z})$, in Z and $\bar{Z}$, which may be complexified as a (germ at 0 of a) convergent power series $\rho(Z, \zeta)$ in $2N$ complex variables. The *complexification* $\mathcal{M}$ of M is defined to be the (germ at 0 of a) complex manifold $\mathcal{M}$ defined near $(0, 0) \in \mathbb{C}^N \times \mathbb{C}^N$ by

$$\mathcal{M} = \{(Z, \zeta) \in \mathbb{C}^N \times \mathbb{C}^N : \rho(Z, \zeta) = 0\}. \tag{1.1}$$

(Here the real-analyticity of M and ρ allows the local complexification of ρ. By abuse of notation, I shall denote both ρ and its local complexification by the same letter.) Similarly, I denote by $\mathcal{M}'$ the complexification of M'. For $H\colon (\mathbb{C}^N, 0) \to (\mathbb{C}^{N'}, 0)$ denote by $\mathcal{H} = (H, \overline{H})\colon (\mathbb{C}^N \times \mathbb{C}^N, 0) \to (\mathbb{C}^{N'} \times \mathbb{C}^{N'}, 0)$ the *complexification* of H. (Here $\overline{H}(\zeta) := \overline{H(\bar{\zeta})}$.) Using again real-analyticity, it is easy to see that

$$H(M) \subset M' \iff \mathcal{H}(\mathcal{M}) \subset \mathcal{M}'. \tag{1.2}$$

The submanifold M is said to be of *finite type* at 0 in the sense of Kohn [40] (and also of Bloom–Graham) if the (complex) Lie algebra $\mathfrak{g}_M$ generated by all smooth $(1, 0)$ and $(0, 1)$ vector fields tangent to M satisfies $\mathfrak{g}_M(0) = \mathbb{C}T_0M$, where $\mathbb{C}T_0M$ is the complex tangent space to M at 0. The method of Segre mappings is an important tool in the analysis of the equation on the right hand side of (1.2) in case M and M' are of finite type at the origin.

In this survey I shall focus mainly on results for the case $N = N'$. Also, for simplicity of notation, the (germ at 0 of a) holomorphic map $H\colon (\mathbb{C}^N, 0) \to (\mathbb{C}^N, 0)$ will be assumed to be finite, i.e. any $Z \in \mathbb{C}^N$ near 0 has only finitely many inverse images under H near 0. An equivalent algebraic condition is that the ideal $I(H)$ in $\mathbb{C}\{Z\}$ (the ring of convergent power series in $Z = (Z_1, \ldots, Z_N)$) generated by the

components, $H_1(Z), \dots, H_N(Z)$, of $H(Z)$ is of finite codimension, i.e. the vector space $\mathbb{C}\{Z\}/I(H)$ is finite dimensional.

2. Iterated Segre mappings

Following the approach of [8], I shall give here an outline of the definition and main properties of the iterated Segre mappings for a generic submanifold M of codimension d in $\mathbb{C}^N$. Let $n := N - d$ and $\gamma\colon (\mathbb{C}^N \times \mathbb{C}^n, 0) \to (\mathbb{C}^N, 0)$ be a (germ of a) holomorphic mapping such that

$$\rho(\gamma(\zeta, t), \zeta) \equiv 0, \quad \operatorname{rk} \frac{\partial \gamma}{\partial t}(0,0) = n, \tag{2.1}$$

where $\zeta = (\zeta_1, \dots, \zeta_N)$, $t = (t_1, \dots, t_n)$. By the implicit function theorem, the existence of such γ follows from the genericity assumption on M. We define a sequence of germs of holomorphic mappings $v^j\colon (\mathbb{C}^{nj}, 0) \to (\mathbb{C}^N, 0)$, $j \geq 0$, called *the iterated Segre mappings* of M at 0 (relative to γ), inductively as follows:

$$\begin{aligned} &v^0 = 0, \\ &v^1(t^1) := \gamma(0, t^1), \\ &v^{j+1}(t^1, \dots, t^{j+1}) := \gamma\big(\overline{v^j}(t^1, \dots, t^j), t^{j+1}\big). \end{aligned} \tag{2.2}$$

Here $\overline{v^j}$ denotes the vector-valued convergent power series obtained from v^j by conjugating its coefficients.

For a (germ of a) holomorphic mapping $v\colon (\mathbb{C}^k, 0) \to (\mathbb{C}^l, 0)$, we denote by $\operatorname{Rk} v$ the generic rank of any representative of v in a sufficiently small neighborhood of 0. Some of the main properties of the Segre mappings are summarized in the following theorem.

Theorem 2.1 ([8]). *Let $M \subset \mathbb{C}^N$ be a real-analytic generic submanifold through 0 of codimension d, and let γ, v^j be as above. Then:*

(i) *For $l = 1, 2, \dots$, the mapping $(v^l(t^1, \dots, t^l), \overline{v^{l-1}}(t^1, \dots, t^{l-1}))$ sends $\mathbb{C}^{nl}$ into $\mathcal{M}$.*

(ii) *There exists an integer k_0, $1 \leq k_0 \leq d+1$, such that $\operatorname{Rk} v^j = \operatorname{Rk} v^{j+1}$ for $j \geq k_0$, and if $k_0 > 1$, then $\operatorname{Rk} v^j < \operatorname{Rk} v^{j+1}$ for $1 \leq j \leq k_0 - 1$.*

If k_0 is as in (ii)*, the following hold.*

(iii) *The submanifold M is of finite type at 0 if and only if $\operatorname{Rk} v^{k_0} = N$.*

(iv) *There exists a (germ at 0 of a) submanifold $\Sigma \subset \mathbb{C}^{2nk_0}$, such that $v^{2k_0}(\Sigma) = \{0\}$ and v^{2k_0} achieves full rank (i.e. $\operatorname{Rk} v^{k_0}$) on some points on Σ (arbitrarily close to 0).*

Here are some observations about Theorem 2.1. Part (ii) shows that the generic ranks of the Segre mappings stabilize before $d+1$ iterations. Part (iii) gives a characterization of finite type in terms of the generic rank of the Segre mappings after stabilization. Part (iv) shows that after at most $2(d+1)$ iterations, the Segre mappings achieve maximal rank on a set that is mapped by v^{2k_0} to the origin in $\mathbb{C}^N$.

The Segre mappings can be used in conjunction with special choices of coordinates in $\mathbb{C}^N$ for a given generic submanifold M. The coordinates $(z, w) \in \mathbb{C}^N = \mathbb{C}^n \times \mathbb{C}^d$ are called *normal* if there exists a (germ of a) holomorphic mapping $Q(z, \chi, \tau)$, $Q\colon (\mathbb{C}^n \times \mathbb{C}^n \times \mathbb{C}^d, 0) \to (\mathbb{C}^d, 0)$, with $Q(z, 0, \tau) \equiv Q(0, \chi, \tau) \equiv \tau$, such that M is given near the origin by the vector equation

$$w = Q(z, \overline{z}, \overline{w}). \tag{2.3}$$

The existence of normal coordinates may be proved by the use of the implicit function theorem ([20], [6]). If $Z = (z, w)$ is a choice of normal coordinates for M given by (2.3), then the equation in (2.1) for $\gamma(\zeta, t) = (\gamma_1(\zeta, t), \gamma_2(\zeta, t)) \in \mathbb{C}^n \times \mathbb{C}^d$ becomes

$$\gamma_2(\zeta, t) \equiv Q(\gamma_1(\zeta, t), \zeta). \tag{2.4}$$

Hence we may choose

$$\gamma(\zeta, t) = ((\gamma_1(\zeta, t), \gamma_2(\zeta, t)) = (t, Q(t, \zeta)). \tag{2.5}$$

Now suppose $(z', w') \in \mathbb{C}^{N'} = (\mathbb{C}^{n'} \times \mathbb{C}^{d'})$ is a given set of normal coordinates for a generic submanifold $M' \subset \mathbb{C}^{N'}$ of codimension d'. Then if $H\colon (\mathbb{C}^N, 0) \to (\mathbb{C}^{N'}, 0)$ we may write

$$H(Z) = (F(Z), G(Z)), \quad \text{where } z' = F(Z),\ w' = G(Z). \tag{2.6}$$

By (1.2), $H(M) \subset M'$ is equivalent to the holomorphic vector equation

$$G(Z) = Q'(F(Z), \overline{F}(\zeta), \overline{G}(\zeta)) \quad \text{for all } (Z, \zeta) \in \mathcal{M}. \tag{2.7}$$

By (i) of Theorem 2.1, if (2.7) holds, then for any integer $k \geq 0$ we may take $(Z, \zeta) = (v^{k+1}(t^1, \ldots, t^{k+1}), \overline{v^k}(t^1, \ldots, t^k))$ in equation (2.7) to obtain

$$G \circ v^{k+1} = Q'\big(F \circ v^{k+1}, \overline{F \circ v^k}, \overline{G \circ v^k}\big), \tag{2.8}$$

yielding a holomorphic vector equation in $n(k+1)$ free complex parameters. If M is of finite type at 0 and (2.8) holds for $k \geq d+1$, then by Theorem 2.1 (iii) it follows that (2.7) also holds. Hence (2.8) is equivalent to (2.7) in this case.

A construction analogous to that of the iterated Segre mappings was developed independently by Christ–Nagel–Stein–Wainger [21] in a different context.

3. Nondegeneracy conditions for generic submanifolds

In order to formulate nontrivial results concerning the questions posed in Section 1, we recall some nondegeneracy conditions that may be imposed on generic submanifolds. The best known (and strongest) of these conditions is that of Levi-nondegeneracy for a real hypersurface in $\mathbb{C}^N$. If M is a hypersurface given in normal coordinates by the (scalar) equation (2.3), then M is *Levi-nondegenerate* at 0 if the quadratic form

$$\mathbb{C}^{N-1} \times \mathbb{C}^{N-1} \ni (z, \chi) \mapsto Q^{(2)}(z, \chi) \tag{3.1}$$

is nondegenerate, where $Q^{(2)}(z, \chi)$ is the quadratic part of the Taylor expansion at 0 of $Q(z, \chi, 0)$. (Equivalent definitions independent of the choice of coordinates can be given for Levi-nondegeneracy, as well as for the other nondegeneracy conditions to be discussed here.) Germs of Levi-nondegenerate hypersurfaces have been completely classified up to local equivalence in the celebrated work of Chern and Moser [20] in the 1970s.

For a generic submanifold M of any codimension, given in normal coordinates by (2.3), a number of weaker geometric conditions can be given in terms of the vector-valued function $Q(z, \chi, \tau)$. We write $Q = (Q_1, \ldots, Q_d)$. The strongest of these conditions is finite nondegeneracy: M is *ℓ-nondegenerate* at 0 if the set of vectors

$$\frac{\partial^\alpha}{\partial \chi^\alpha}\left(\frac{\partial Q_j}{\partial z_1}, \ldots, \frac{\partial Q_j}{\partial z_n}\right)(0), \quad j = 1, \ldots, d,\ \alpha \in \mathbb{N}^n,\ |\alpha| \le \ell, \tag{3.2}$$

spans $\mathbb{C}^n$, and ℓ is the smallest positive integer for which this is true. If M is ℓ-nondegenerate at 0 for some finite integer ℓ, then M is called *finitely nondegenerate*. A hypersurface is Levi-nondegenerate at 0 if and only if it is 1-nondegenerate.

A condition weaker than finite nondegeneracy is the following. Expand $Q(z, \chi, 0)$ as a Taylor series in χ,

$$Q(z, \chi, 0) = \sum Q^\alpha(z, 0, 0)\chi^\alpha, \tag{3.3}$$

and let I be the ideal in $\mathbb{C}\{z\}$ generated by all the $Q^\alpha(z, 0, 0)$. Then M is said to be *essentially finite* at 0 if the ideal I is of finite codimension in $\mathbb{C}\{z\}$. If so, the dimension of the vector space $\mathbb{C}\{z\}/I$ is called the *essential type* of M at 0, denoted $\mathrm{ess}_0 M$. It is easy to see that if M is finitely nondegenerate at 0, then it is essentially finite at 0. However, the converse is not true. For example, the hypersurface $M \subset \mathbb{C}^2$ given as $\{(z, w) \in \mathbb{C}\times\mathbb{C} : \mathrm{Im}\, w = |z|^4\}$ is essentially finite at 0, but not finitely nondegenerate. The precise relationship is the following (see [6], Proposition 11.8.27):

$$M \text{ is finitely nondegenerate at } 0 \iff M \text{ is essentially finite at } 0 \text{ with } \mathrm{ess}_0 M = 1. \tag{3.4}$$

The conditions of finite nondegeneracy and essential finiteness can be expressed invariantly, i.e. independently of any choice of defining function or coordinates (see [6], Chapter XI), but I shall not do so here. However, I want to point out that the

condition of finite type, as defined in Section 1, cannot be easily expressed in terms of an arbitrary defining function, except in the case of hypersurfaces. This is one reason that Theorem 2.1 (iii) and (iv) turns out to be useful for the study of generic submanifolds of finite type.

Another condition, which is weaker than essential finiteness, is most easily expressed in terms of $(1,0)$ vector fields, i.e. sections of the vector bundle $T^{1,0}\mathbb{C}^N$ of $(1,0)$ vectors on $\mathbb{C}^N$. The generic submanifold M is said to be *holomorphically nondegenerate* at 0 if there is no nonzero $(1,0)$ vector field with holomorphic coefficients that is tangent to M in a whole neighborhood of 0.

It can be shown (see e.g. [6], Corollary 11.7.28) that holomorphic degeneracy of a connected generic submanifold M can also be described in terms of finite nondegeneracy or essential finiteness. In fact, if M is a connected, real-analytic generic submanifold of $\mathbb{C}^N$ with $0 \in M$, then the following conditions are equivalent:

(i) M is holomorphically nondegenerate at 0.

(ii) M is holomorphically nondegenerate at all $p \in M$.

(iii) M is essentially finite at some point in M.

(iv) M is essentially finite at all points outside a proper real-analytic subset of M.

(v) M is finitely nondegenerate at some point in M.

(vi) M is finitely nondegenerate at all points outside a proper real-analytic subset of M.

(vii) There is an integer $\ell \leq N-1$ such that M is ℓ-nondegenerate at all points outside a proper real-analytic subset of M.

The relation of the above conditions with finite type is more complicated. If a hypersurface is essentially finite at 0, it is necessarily of finite type at 0, but no implication holds for generic submanifolds of higher codimension.

In view of the equivalence of (i) and (ii), if M is holomorphically nondegenerate at 0, one simply says that M is holomorphically nondegenerate. If M is not holomorphically nondegenerate, then it is not essentially finite at any point. In this sense, holomorphic nondegeneracy is the weakest condition that guarantees the existence of some "good" points.

The notion of essential finiteness has been implicitly used in the work of Diederich–Webster [25] and was defined first in the work of Baouendi–Jacobowitz–Treves [12]. Holomorphic nondegeneracy was first introduced for hypersurfaces by Stanton [47] and for higher codimension in [2]. Finite nondegeneracy was implicitly used by Han [34] for hypersurfaces and defined in joint work with Baouendi and Huang [10]. An invariant definition for CR manifolds, not necessarily embedded in complex space, is due to Ebenfelt (see [6]).

4. Transversality of mappings

The notion of transversality of real differentiable mappings has been central in differential geometry. Recall that if $f\colon (\mathbb{R}^k, 0) \to (\mathbb{R}^\ell, 0)$ is a germ of a smooth mapping, and if $E \subset \mathbb{R}^\ell$ is a smooth manifold through 0, then f is called *transversal* to E at 0 if

$$T_0 E + df(T_0\mathbb{R}^k) = T_0\mathbb{R}^\ell. \tag{4.1}$$

If $E \subset \mathbb{C}^\ell$ is a generic submanifold, and $H\colon (\mathbb{C}^k, 0) \to (\mathbb{C}^\ell, 0)$ is a (germ of a) holomorphic mapping, a stronger notion of transversality is needed, for example, to guarantee that $H^{-1}(E)$ is again a generic submanifold of $\mathbb{C}^k$. Also, for mappings in which the target is a real hypersurface, it is desirable to have a notion of transversality that guarantees the nonvanishing of a derivative of the transversal component. For generic submanifolds and holomorphic mappings as above, the appropriate notion is the following. The mapping H is said to be *CR transversal* to E at 0 if

$$T_0^{1,0} E + dH(T_0^{1,0}\mathbb{C}^k) = T_0^{1,0}\mathbb{C}^\ell. \tag{4.2}$$

Here $T_0^{1,0}E$ denotes the space of $(1, 0)$ vectors tangent to M at 0. It is not hard to see that CR transversality implies transversality, but the converse is not necessarily true. However, we shall restrict ourselves here to the case $k = \ell$ and assume that H maps one generic submanifold into another. In this context it can be shown that the two notions of transversality coincide (see [30]).

Recently Ebenfelt and the author have obtained the following result.

Theorem 4.1 ([30]). *Let $M, M' \subset \mathbb{C}^N$ be real-analytic generic submanifolds of the same dimension through 0 such that either M or M' is of finite type at 0. Then any finite holomorphic mapping $H\colon (\mathbb{C}^N, 0) \to (\mathbb{C}^N, 0)$ with $H(M) \subset M'$ is CR transversal to M' at 0.*

For the case where M and M' are assumed to be hypersurfaces, Theorem 4.1 was proved earlier by Baouendi and the author (see [14]). The case of generic submanifolds of higher codimension had remained an open problem since then.

Theorem 4.1 can be viewed as a kind of complex Hopf Lemma. For smooth mappings between hypersurfaces where the target has some convexity properties, results of this type were previously obtained by Fornaess [31], [32] for the case of pseudoconvex hypersurfaces (using the classical Hopf Lemma). Related results could also be found in the author's joint work with Baouendi [15], as well as with Baouendi and Huang [11].

I shall describe briefly here how the iterated Segre mappings can be used in the proof of Theorem 4.1. We begin with normal coordinates (z, w) and (z', w') for M and M' respectively, leading to the equation (2.7). The condition of CR transversality in these coordinates is equivalent to

$$\det \frac{\partial G}{\partial w}(0) \neq 0, \tag{4.3}$$

where $H = (F, G)$ as in (2.6). Now assume M is of finite type at 0 and let k_0 be given by Theorem 2.1 and take $k = 2k_0 - 1$ in (2.8) to obtain

$$G \circ v^{2k_0} = Q'\big(F \circ v^{2k_0}, \overline{F \circ v^{2k_0-1}}, \overline{G \circ v^{2k_0-1}}\big), \tag{4.4}$$

which is equivalent to (2.7) since M is of finite type at 0. Put $v^{2k_0}(t) = (t^{2k_0}, u^{2k_0}(t))$, with $t = (t^1, \dots, t^{2k_0}) = (t', t^{2k_0}) \in \mathbb{C}^{2nk_0-n} \times \mathbb{C}^n$. If $\Sigma \subset \mathbb{C}^{2nk_0}$ is a submanifold given by Theorem 2.1 (iv), then necessarily $\Sigma \subset \mathbb{C}^{2nk_0-n} \times \{0\}$. Taking $t^{2k_0} = 0$ in (4.4), differentiating in t', and evaluating at any $s \in \Sigma$ and using the chain rule, the left hand side of (4.4) becomes

$$\frac{\partial G}{\partial w}(0)\frac{\partial u^{2k_0}}{\partial t'}(s), \tag{4.5}$$

since $v^{2k_0} \equiv 0$ on Σ. Now if (4.3) fails, there is a nonzero constant vector $V \in \mathbb{C}^d$ such that $V^\tau \dfrac{\partial G}{\partial w}(0) = 0$. Our proof proceeds by multiplying both sides of (4.4) by V^τ, differentiating in t' and restricting to Σ. We then show that under the hypotheses of the theorem, the right hand side cannot vanish identically. The details can be found in [30].

By using formal power series, instead of convergent ones, we can also prove Theorem 4.1 when M and M' are merely assumed to be smooth and H is replaced by a CR mapping that is assumed to be "formally" finite.

One may ask also when a finite holomorphic mapping H satisfying $H(M) \subset M'$ is not only transversal to M', but actually is a diffeomorphism at 0. If M is essentially finite at 0, then we prove, using Theorem 4.1, that M' is also essentially finite at 0 and

$$\operatorname{ess}_0 M = \operatorname{mult}(H) \cdot \operatorname{ess}_0 M', \tag{4.6}$$

where ess_0 denotes the essential type at 0 and $\operatorname{mult}(H)$ denotes the multiplicity of H as a finite holomorphic mapping. If M is finitely nondegenerate at 0, then as noted in (3.4), it follows that it is essentially finite at 0 with $\operatorname{ess}_0 M = 1$. Since $\operatorname{ess}_0 M'$ is a positive integer, the equation (4.6) implies that $\operatorname{mult}(H) = 1$, i.e., H is a diffeomorphism. Hence we have the following consequence of Theorem 4.1:

Theorem 4.2 ([30]). *Let $M \subset \mathbb{C}^N$ be a real-analytic generic submanifold of finite type and finitely nondegenerate at 0. If $M' \subset \mathbb{C}^N$ is a real-analytic generic submanifold of the same dimension and $H\colon (\mathbb{C}^N, 0) \to (\mathbb{C}^N, 0)$ is a finite holomorphic mapping with $H(M) \subset M'$, then H is a local biholomorphism at 0.*

Although this paper is mostly focused on the case where the manifolds M and M' are equidimensional and contained in the same complex space, I should mention that in recent years there have been a number of related results for nonequidimensional hypersurfaces. In particular, without striving for completeness, I would like to mention the work of D'Angelo [23], Forstnerič [33], Huang [35], Huang–Ji [36], Ebenfelt–Huang–Zaitsev [27], Baouendi–Huang [9].

5. Finite jet determination

One of the most basic questions to be asked about a (germ of a) holomorphic mapping $H\colon (\mathbb{C}^N, 0) \to (\mathbb{C}^N, 0)$ is to find the least data to determine H. Clearly H is determined by $\partial^\alpha H(0)$ for all $\alpha \in \mathbb{Z}^N$. If $H(M) \subset M'$ for real analytic generic submanifolds M and M', then H also satisfies a system of real analytic equations when restricted to M, and under favorable circumstances may be determined by finitely many derivatives at the origin. We denote by $j^k_p H$ the *k-jet* of H at p, i.e.

$$j^k_p H := (\partial^\alpha H)(p)_{\{|\alpha|\le k\}}. \tag{5.1}$$

It follows from the work of Chern–Moser [20] that if H is a diffeomorphism and M and M' are both Levi-nondegenerate hypersurfaces in $\mathbb{C}^N$ through 0, then H is actually determined by $j^2_0 H$.

A striking theorem of finite determination for hypersurfaces in $\mathbb{C}^2$ is the following.

Theorem 5.1 (Ebenfelt–Lamel–Zaitsev, [29]). *Let $M \subset \mathbb{C}^2$ be a real-analytic hypersurface of finite type at 0. Then if $H^1, H^2\colon (\mathbb{C}^N, 0) \to (\mathbb{C}^N, 0)$ are (germs of) holomorphic diffeomorphisms both sending M into itself and satisfying $j^2_0 H^1 = j^2_0 H^2$, then $H^1 = H^2$.*

The weakest known conditions, for finite determination, that can be imposed on M and M' in higher codimenson is that of finite type and holomorphic nondegeneracy at 0. The following result is joint work with Baouendi and Mir [13].

Theorem 5.2 ([13]). *Let M and M' be real-analytic generic submanifolds of $\mathbb{C}^N$ through 0 of the same dimension, with M of finite type and holomorphically nondegenerate at 0. Let $H^0\colon (\mathbb{C}^N, 0) \to (\mathbb{C}^N, 0)$ be a finite holomorphic mapping with $H^0(M) \subset M'$. Then there exists an integer K such that if $H\colon (\mathbb{C}^N, 0) \to (\mathbb{C}^N, 0)$ is any finite holomorphic mapping sending M into M' with $j^K_0 H = j^K_0 H^0$, it follows that $H = H^0$.*

The techniques of the proof do not provide an explicit integer K nor give any kind of dependence of this integer on the base point. Theorem 5.2 can be strengthened by merely assuming M and M' to be smooth and by a slight weakening of the assumption that H be finite (see [13]).

For more explicit results in $\mathbb{C}^N$, $N > 2$, the condition of finite nondegeneracy might need to be imposed. This condition enters as follows. For simplicity, let us assume that $M = M'$. We wish to describe those mappings $H\colon (\mathbb{C}^N, 0) \to (\mathbb{C}^N, 0)$ that are diffeomorphisms at 0 and satisfy $H(M) \subset M$. If M is ℓ_0-nondegenerate at 0, by taking appropriate derivatives of (2.7) and applying the implicit function theorem, the following can be shown (see [6]). For $\ell \ge 0$, there exists a holomorphic mapping Ψ_ℓ defined in a neighborhood of $(0, 0, j^{\ell_0+\ell}_0 \mathrm{Id})$ in $\mathbb{C}^N \times \mathbb{C}^N \times \mathbb{C}^J$ (for an appropriate integer J) such that one has the following "basic identity". For every $(Z, \zeta) \in \mathcal{M}$

near 0 and every H sending M into itself with $j_0^{\ell_0+\ell}H$ sufficiently close to $j_0^{\ell_0+\ell}\mathrm{Id}$, the following holds:

$$(Z, j_Z^{\ell}H) = \Psi_\ell\big(Z, (\zeta, j_\zeta^{\ell_0+\ell}\overline{H})\big). \tag{5.2}$$

We now use (5.2), by taking $(Z,\zeta) = (v^k(t^1,\dots,t^k), \overline{v^{k-1}}(t^1,\dots,t^{k-1})) \in \mathcal{M}$ (as defined in Section 2). In this way, we express all derivatives of H of length $\le \ell$ on the image of v^k in terms of the derivatives of $\overline{H}$ of length $\le \ell_0+\ell$ on the image of $\overline{v^{k-1}}$. We begin by taking $(Z,\zeta) = (v^1(t^1), \overline{v^0}) = ((t^1,0),(0,0)) \in \mathcal{M}$ in (5.2) to obtain

$$\big((t^1,0), j^{\ell}_{(t^1,0)}H\big) = \Psi_\ell\big((t^1,0),((0,0), j_0^{\ell_0+\ell}\overline{H})\big). \tag{5.3}$$

Hence all derivatives of H up to order ℓ on v^1 are determined by the $\ell_0+\ell$ jet of $\overline{H}$ at 0. Taking $(Z,\zeta) = (v^2(t^1,t^2), \overline{v^1}(t^1))$, we find that all derivatives of H up to order ℓ on v^2 are determined by the $\ell_0+\ell$ jet of $\overline{H}$ on $\overline{v^1}$. Since the latter is determined by $j_0^{2\ell_0+\ell}H$ by the first step (after complex conjugation), we observe that $j^{\ell}_{v^2}H$ is determined by $j_0^{2\ell_0+\ell}H$. Now let k_0 be as in Theorem 2.1. By using inductively the above argument, we conclude that $j^0_{v^{k_0}(t)}H$ is determined by $j_0^{k_0\ell_0}H$. If M is of finite type at 0, then by Theorem 2.1 (iii), H is completely determined by the values of $j^0_{v^{k_0}(t)}H$ as t varies in $\mathbb{C}^{nk_0}$. Since $k_0 \le d+1$, the above argument gives an outline of a proof of the following.

Theorem 5.3 ([4]). *Let $M \subset \mathbb{C}^N$ be a real-analytic generic submanifold of finite type and ℓ_0-nondegenerate at 0. If $H^i\colon (\mathbb{C}^N,0) \to (\mathbb{C}^N,0)$, $i=1,2$ are holomorphic diffeomorphisms both sending M into itself and satisfying $j_0^{(d+1)\ell_0}H^1 = j_0^{(d+1)\ell_0}H^2$, it follows that $H^1 = H^2$.*

The results stated in this paper are given for (germs of) holomorphic mappings, but many can also be formulated for (germs of) smooth generic submanifolds and smooth CR mappings that are diffeomorphisms. Since the methods described above rely on unique determination by the Taylor series at 0, different techniques must be used to prove finite determination for mappings that are merely smooth. By using the method of complete systems, Ebenfelt [26] proved unique determination results for smooth CR mappings between finitely nondegenerate hypersurfaces. These were later generalized by Ebenfelt–Lamel [28]. General results for smooth CR diffeomorphisms between finitely nondegenerate smooth generic submanifolds of any codimension were recently obtained by Kim–Zaitsev [39]. The reader is referred to the survey article of Zaitsev [52] for a more detailed discussion of this topic.

6. Stability groups

In this section I shall discuss questions concerned with the structure of the group of holomorphic mappings that send a generic submanifold into itself. Let $M \subset \mathbb{C}^N$

be (the germ at 0 of) a real-analytic generic submanifold. The *holomorphic stability group*, $\mathrm{Hol}\,(M,0)$ of M at 0 is defined as the set of all (germs at 0) of holomorphic diffeomorphisms $H\colon (\mathbb{C}^N,0)\to(\mathbb{C}^N,0)$ such that $H(M)\subset M$, where the group structure is given by composition. The group $\mathrm{Hol}\,(M,0)$ is equipped with its natural inductive limit topology. In particular, a sequence $\{H^j\}$ in $\mathrm{Hol}\,(M,0)$ converges to H if there exists a compact neighborhood $\overline{U}$ of 0 such that each H^j has a representative holomorphic in an open neighborhood of $\overline{U}$ and H^j converges uniformly to H on $\overline{U}$.

One may ask whether $\mathrm{Hol}\,(M,0)$ may be given the structure of a finite dimensional Lie group compatible with its topology. For any integer $\ell\geq 0$, let $G^\ell(\mathbb{C}^N)$ denote the set of all ℓ-jets of invertible holomorphic mappings, i.e.

$$G^\ell(\mathbb{C}^N):=\{j_0^\ell H:\ H\colon(\mathbb{C}^N,0)\to(\mathbb{C}^N,0),\ H \text{ biholomorphic}\}. \tag{6.1}$$

The set $G^\ell(\mathbb{C}^N)$ has a finite dimensional Lie group structure with the multiplication defined by $(j_0^\ell H^1)\cdot(j_0^\ell H^2):=j_0^\ell(H^1\circ H^2)$. It is easy to check that this multiplication is independent of the choice of representatives H^1 and H^2. If M is holomorphically nondegenerate and of finite type at 0, then by taking $M=M'$ and $H^0=\mathrm{Id}$ in Theorem 5.2, it follows that there exists an integer $K>0$ such that the mapping $\mathrm{Hol}\,(M,0)\ni H\mapsto j_0^K H\in G^K(C^N)$ is continuous and injective. Hence $\mathrm{Hol}\,(M,0)$ may be identified with a subgroup of $G^K(\mathbb{C}^N)$ in this case. However, to show that $\mathrm{Hol}\,(M,0)$ is a Lie group one must show that its image is closed in $G^K(\mathbb{C}^N)$. This was proved for any finitely nondegenerate hypersurface M by the author with Baouendi and Ebenfelt [3] and later by Zaitsev [50] for any finitely nondegenerate generic submanifold of finite type in higher codimension. The following sharper result was given in [5].

Theorem 6.1 ([5]). *Let $M\subset\mathbb{C}^N$ be a real-analytic generic submanifold, which is ℓ_0-nondegenerate and of finite type at 0. Then the mapping*

$$\mathrm{Hol}\,(M,0)\ni H\mapsto j_0^{\ell_0(d+1)}H\in G^{\ell_0(d+1)}(\mathbb{C}^N),$$

taking a germ of a local biholomorphism at 0 to its $\ell_0(d+1)$-jet, gives a diffeomorphism of $\mathrm{Hol}\,(M,0)$ onto a real-algebraic Lie subgroup of $G^{\ell_0(d+1)}(\mathbb{C}^N)$.

It should be noted here that Theorem 6.1 for the case of a Levi-nondegenerate hypersurface (i.e. $\ell_0=d=1$) follows from the work of Chern–Moser [20] and Burns–Shnider [18].

Recent work of Kim–Zaitsev [38] gives a construction of a smooth hypersurface $M\subset\mathbb{C}^N$, finitely nondegenerate at 0, for which $\mathrm{Hol}\,(M,0)$ is not a Lie group, although it is contained as a subgroup of a finite dimensional Lie group. In attempting to generalize Theorem 6.1 in another direction, one may ask whether the condition that M be finitely nondegenerate can be weakened (see the equivalences (i)–(vii) in Section 3). As observed above, in the case of a holomorphically nondegenerate generic submanifold of finite type there is an integer K for which the mapping

$\mathrm{Hol}\,(M,0) \ni H \mapsto j_0^K H \in G^K(\mathbb{C})$ is an injection, but it is not known if its image is closed. However, very recently Lamel and Mir [42] gave a positive answer in the slightly more restrictive case of a real-analytic generic submanifold that is essentially finite and of finite type at 0.

Although global questions are outside the announced scope of this paper, I would like to mention here a recent result joint with Baouendi, Winkelmann, and Zaitsev [16] in which we prove that the global automorphism group of a CR manifold that is finitely nondegenerate and of finite type at every point has the structure of a finite dimensional Lie group. This work uses the above mentioned results of Kim–Zaitsev [39].

7. Algebraicity of mappings

Recall that a real submanifold is *real-algebraic* if it is contained in a real-algebraic subset of the same dimension. A (germ at 0 of a) holomorphic mapping $H\colon (\mathbb{C}^N,0) \to (\mathbb{C}^N,0)$ is *complex-algebraic* if its graph is a (germ at 0 of a) complex algebraic variety of $\mathbb{C}^N \times \mathbb{C}^N$. One may ask under what conditions a mapping that sends one real-algebraic generic submanifold into another is necessarily complex-algebraic. Very early results on this question are contained in the work of Poincaré [46], who proved that a local biholomorphism between two pieces of spheres in $\mathbb{C}^2$ must be a rational mapping. In 1977 Webster [48] solved the above problem for the case when M and M' are algebraic hypersurfaces that are Levi-nondegenerate, proving that any such local biholomorphism is necessarily complex-algebraic. The following result for higher codimensional submanifolds was obtained in joint work of the author with Baouendi and Ebenfelt [2].

Theorem 7.1 ([2]). *Let $M, M' \subset \mathbb{C}^N$ be two real-algebraic generic submanifolds of the same dimension through 0. Assume that M is connected and of finite type and holomorphically nondegenerate at some point. Then if $H\colon (\mathbb{C}^N,0) \to (\mathbb{C}^N,0)$ is a germ of a holomorphic mapping with $H(M) \subset M'$ satisfying $\mathrm{Jac}\, H \not\equiv 0$ then H is complex-algebraic.*

If the condition that $\mathrm{Jac}\, H \not\equiv 0$ is not assumed, or if M and M' are generic submanifolds in complex spaces of different dimensions, a stronger assumption must be imposed on the target space. For the case of strongly pseudoconvex hypersurfaces of different dimensions, see the work of Huang [37], see also [10]. One of the most general results in this direction is due to Zaitsev:

Theorem 7.2 (Zaitsev [51]). *Let $M \subset \mathbb{C}^N$ and $M' \subset \mathbb{C}^{N'}$ be real-algebraic submanifolds through 0. Then all (germs at 0 of) local holomorphic maps $H\colon (\mathbb{C}^N,0) \to (\mathbb{C}^{N'},0)$ with $H(M) \subset M'$ are complex-algebraic if and only if the following are satisfied:*

(i) *M is generic and of finite type on a dense subset;*

(ii) *M' contains no analytic discs.*

8. Concluding remarks

Although I have attempted to survey a number of recent results in CR geometry that make use of the Segre mappings (as defined in Section 2), I have omitted a number of other interesting questions to which this method has also been applied. In particular, I would like to mention one such area of current research, namely the study of the convergence of formal mappings sending one generic submanifold into another. Here "formal" means that the mappings consist of formal power series, rather than convergent ones. In addition to the method of Segre mappings, the celebrated Artin Approximation Theorem [1] has been an important tool in this area of research. For some recent results in this direction I refer the reader to [7], [44], [45], [41], [13], [17], [43]. With these references, as well as with all the other references given here, I apologize in advance for any omissions.

Towards conformal invariance of 2D lattice models

Stanislav Smirnov

Abstract. Many 2D lattice models of physical phenomena are conjectured to have conformally invariant scaling limits: percolation, Ising model, self-avoiding polymers, etc. This has led to numerous exact (but non-rigorous) predictions of their scaling exponents and dimensions. We will discuss how to prove the conformal invariance conjectures, especially in relation to Schramm–Loewner evolution.

Mathematics Subject Classification (2000). Primary 82B20; Secondary 60K35, 82B43, 30C35, 81T40.

Keywords. Statistical physics, conformal invariance, universality, Ising model, percolation, SLE.

1. Introduction

For several 2D lattice models physicists were able to make a number of spectacular predictions (non-rigorous, but very convincing) about exact values of various scaling exponents and dimensions. Many methods were employed (Coulomb gas, Conformal Field Theory, Quantum Gravity) with one underlying idea: that the model at criticality has a continuum scaling limit (as mesh of the lattice goes to zero) and the latter is conformally invariant. Moreover, it is expected that there is only a one-parameter family of possible conformally invariant scaling limits, so universality follows: if the same model on different lattices (and sometimes at different temperatures) has a conformally invariant scaling limit, it is necessarily the same. Indeed, the two limits belong to the same one-parameter family, and usually it directly follows that the corresponding parameter values coincide.

Recently mathematicians were able to offer different, perhaps better, and certainly more rigorous understanding of those predictions, in many cases providing proofs. The point which is perhaps still less understood both from mathematics and physics points of view is why there exists a universal conformally invariant scaling limit. However such behavior is supposed to be typical in 2D models at criticality: Ising, percolation, self-avoiding polymers; with universal conformally invariant curves arising as scaling limits of the interfaces.

Until recently this was established only for the scaling limit of the 2D random walk, the 2D Brownian motion. This case is easier and somehow exceptional because of the Markov property. Indeed, Brownian motion was originally constructed

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

by Wiener [43], and its conformal invariance (which holds in dimension 2 only) was shown by Paul Lévy [24] without appealing to random walk. Note also that unlike interfaces (which are often simple, or at most "touch" themselves), Brownian trajectory has many "transversal" self-intersections.

For other lattice models even a rigorous formulation of conformal invariance conjecture seemed elusive. Considering percolation (a model where vertices of a graph are declared open independently with equal probability p – see the discussion below) at criticality as an example, Robert Langlands, Philippe Pouliot and Yvan Saint-Aubin in [20] studied numerically crossing probabilities (of events that there is an open crossing of a given rectangular shape). Based on experiments they concluded that crossing probabilities should have a universal (independent of lattice) scaling limit, which is conformally invariant (a conjecture they attributed to Michael Aizenman). Thus the limit of crossing probability for a rectangular domain should depend on its conformal modulus only. Moreover an exact formula (5) using hypergeometric function was proposed by John Cardy in [9] based on Conformal Field Theory arguments. Later Lennart Carleson found that the formula has a particularly nice form for equilateral triangles, see [38]. These developments got many researchers interested in the subject and stimulated much of the subsequent progress.

Rick Kenyon [16], [17] established conformal invariance of many observables related to dimer models (domino tilings), in particular to uniform spanning tree and loop erased random walk, but stopped short of constructing the limiting curves.

In [32], Oded Schramm suggested to study the scaling limit of a single interface and classified all possible curves which can occur as conformally invariant scaling limits. Those turned out to be a universal one-parameter family of SLE(κ) curves, which are now called *Schramm–Loewner evolutions*. The word "evolution" is used since the curves are constructed dynamically, by running classical Loewner evolution with Brownian motion as a driving term. We will discuss one possible setup, chordal SLE(κ) with parameter $\kappa \in [0, \infty)$, which provides for each simply-connected domain Ω and boundary points a, b a measure μ on curves from a to b inside Ω. The measures $\mu(\Omega, a, b)$ are conformally invariant, in particular they are all images of one measure on a reference domain, say a half-plane $\mathbb{C}_+$. An exact definition appears below.

In [37], [38] the conformal invariance was established for critical percolation on triangular lattice. Conformally invariant limit of the interface was identified with SLE(6), though its construction does not use SLE machinery. See also Federico Camia and Charles Newman's paper [8] for the details on subsequent construction of the full scaling limit.

In [23] Greg Lawler, Oded Schramm and Wendelin Werner have shown that a perimeter curve of the uniform spanning tree converges to SLE(8) (and the related loop erased random walk – to SLE(2)) on a general class of lattices. Unlike the proof for percolation, theirs utilizes SLE in a substantial way. In [35], Oded Schramm and Scott Sheffield introduced a new model, Harmonic Explorer, where properties needed for convergence to SLE(4) are built in.

Despite the results for percolation and uniform spanning tree, the problem remained open for all other classical (spin and random cluster) 2D models, including percolation on other lattices. This was surprising given the abundance of the physics literature on conformal invariance. Perhaps most surprising was that the problem of a conformally invariant scaling limit remained open for the Ising model, since for the latter there are many exact and often rigorous results – see the books [27], [6].

Recently we were able to work out the Ising case [39]:

Theorem 1. *As lattice step goes to zero, interfaces in Ising and Ising random cluster models on the square lattice at critical temperature converge to* SLE(3) *and* SLE(16/3) *correspondingly.*

Computer simulations of these interfaces (Figures 2, 4) as well as the definition of the Ising models can be found below. Similarly to mentioned experiments for percolation, Robert Langlands, Marc André Lewis and Yvan Saint-Aubin conducted in [21] numerical studies of crossing probabilities for the Ising model at critical temperature. A modification of the theorem above relating interfaces to SLE's (with drifts) in domains with five marked boundary points allows a rigorous setup for establishing their conjectures.

The proof is based on showing that a certain Fermionic lattice observable (or rather two similar ones for spin and random cluster models) is discrete analytic and solves a particular covariant Riemann Boundary Value Problem. Hence its limit is conformally covariant and can be calculated exactly. The statement is interesting in its own right, and can be used to study spin correlations. The observable studied has more manifest physics meaning than one in our percolation paper [38].

The methods lead to some progress in fairly general families of random cluster and $O(n)$ models, and not just on square lattices. In particular, besides Ising cases, they seem to suggest new proofs for all other known cases (i.e. site percolation on triangular lattice and uniform spanning tree).

In this note we will discuss this proof and general approach to scaling limits and conformal invariance of interfaces in the SLE context. We will also state some of the open questions and speculate on how one should approach other models.

We omit many aspects of this rich subject. We do not discuss the general mathematical theory of SLE curves or their connections to physics, for which interested reader can consult the expository works [5], [10], [15], [41] and the book [22]. We do not mention the question of how to deduce the values of scaling exponents for lattice models with SLE help once convergence is known. It was explored in some detail only for percolation [40], where convergence is known and the required (difficult) estimates were already in place thanks to Harry Kesten [19]. We also restrict ourselves to one interface, whereas one can study the collection of all loops (cf. exposition [42]), and many of our considerations transfer to the loop soup observables. Finally, there are many other open questions related to conformal invariance, some of which are discussed in Oded Schramm's paper [34] in these proceedings.

2. Lattice models

We focus on two families of lattice models which have nice "loop representations". Those families include or are closely related to most of the "important" models, including percolation, Ising, Potts, spherical (or $O(n)$), Fortuin–Kasteleyn (or random cluster), self-avoiding random walk, and uniform spanning tree models. For their interrelations and for the discussion of many other relevant models one can consult the books [6], [12], [26], [27]. We also omit many references which can be found there.

There are various ways to understand the existence of the scaling limit and its conformal invariance. One can ask for the full picture, which can be represented as a loop collection (representing all cluster interfaces), random height function (changing by ± 1 whenever we cross a loop), or some other object. It however seems desirable to start with a simpler problem.

One can start with observables (like correlation functions, crossing probabilities), for which it is easier to make sense of the limit: there should exist a limit of a number sequence which is a conformal invariant. Though a priori it might seem to be a weaker goal than constructing a full scaling limit, there are indications that to obtain the full result it might be sufficient to analyze just one observable.

We will discuss an intermediate goal to analyze the law of just one interface, explain why working out just one observable would be sufficient, and give details on how to find an observable with a conformally invariant limit. To single out one interface, we consider a model on a simply connected domain with Dobrushin boundary conditions (which besides many loop interfaces enforce existence of an interface joining two boundary points a and b). We omit the discussion of the full scaling limit, as well as models on Riemann surfaces and with different boundary conditions.

2.1. Percolation. Perhaps the simplest model (to state) is Bernoulli percolation on the triangular lattice. Vertices are declared open or closed (grey or white in Figure 1) independently with probabilities p and $(1-p)$ correspondingly. The critical value is $p = p_c = 1/2$ – see [18], [11], in which case all colorings are equally probable.

Then each configuration can be represented by a collection of interfaces – loops which go along the edges of the dual hexagonal lattice and separate open and closed vertices.

We want to distinguish one particular interface, and to this effect we introduce Dobrushin boundary conditions: we take two boundary points a and b in a simply connected Ω (or rather its lattice approximation), asking the counterclockwise arc ab to be grey and the counterclockwise arc ba to be white. This enforces existence of a single non-loop interface which runs from a to b. The "loop gas" formulation of our model is that we consider all collections of disjoint loops plus a curve from a to b on hexagonal lattice with equal probability.

For each value of the lattice step $\varepsilon > 0$ we approximate a given domain Ω by a lattice domain, which leads to a random interface, that is a probability measure μ_ε

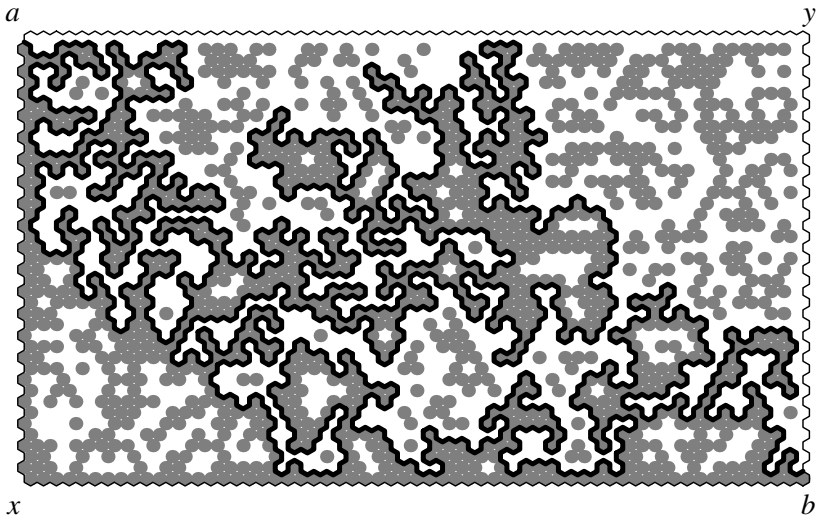

Figure 1. Critical site percolation on triangular lattice superimposed over a rectangle. Every site is grey or white independently with equal probability 1/2. Dobrushin boundary conditions (grey on lower and left sides, white on upper and right sides) produce an interface from the upper left corner a to the lower right corner b. The law of the interface converges to SLE(6) when lattice step goes to zero, while the rectangle is fixed.

on curves (broken lines) running from a to b. The question is whether there is a limit measure $\mu = \mu(\Omega, a, b)$ on curves and whether it is conformally invariant. To make sense of the limit we consider the curves with uniform topology generated by parameterizations (with distance between γ_1 and γ_2 being $\inf \|f_1 - f_2\|_\infty$ where the infimum is taken over all parameterizations f_1, f_2 of γ_1, γ_2), and ask for weak-$*$ convergence of the measures μ_ε.

2.2. $O(n)$ and loop models. Percolation turns out to be a particular case of the *loop gas* model which is closely related (via high-temperature expansion) to $O(n)$ (spherical) model. We consider configurations of non-intersecting simple loops and a curve running from a to b on *hexagonal lattice* inside domain Ω as for percolation in Figure 1. But instead of asking all configurations to be equally likely, we introduce two parameters: loop-weight $n \geq 0$ and edge-weight $x > 0$, and ask that probability of a configuration is proportional to

$$n^{\#\text{ loops}}\, x^{\text{length of loops}}.$$

The vertices not visited by loops are called monomers. Instead of weighting edges by x one can equivalently weight monomers by $1/x$.

We are interested in the range $n \in [0, 2]$ (after certain modifications $n \in [-2, 2]$ would work), where conformal invariance is expected (other values of n have different

behavior). It turns out that there is a critical value $x_c(n)$, such that the model exhibits one critical behavior at $x_c(n)$ and another on the interval $(x_c(n), +\infty)$, corresponding to "dilute" and "dense" phases (when in the limit the loops are simple and non-simple correspondingly).

Bernard Nienhuis [28], [29] proposed the following conjecture, supported by physics arguments:

Conjecture 2. The critical value is given by

$$x_c(n) = \frac{1}{\sqrt{2+\sqrt{2-n}}}.$$

Note that though for all $x \in (x_c(n), \infty)$ the critical behavior (and the scaling limit) are conjecturally the same, the related value $\tilde{x}_c(n) = 1/\sqrt{2-\sqrt{2-n}}$ turns out to be distinguished in some ways.

The criticality was rigorously established for $n = 1$ only, but we still may discuss the scaling limits at those values of x. It is widely believed that at the critical values the model has a conformally invariant scaling limit. Moreover, the corresponding criticalities under renormalization are supposed to be unstable and stable correspondingly, so for $x = x_c$ there should be one conformally invariant scaling limit, whereas for the interval $x \in (x_c, \infty)$ another, corresponding to $\tilde{x}_c$. The scaling limit for low temperatures $x \in (0, x_c)$, a straight segment, is not conformally invariant.

Plugging in $n = 1$ we obtain weight

$$x^{\text{length of loops}}.$$

Assigning the spins ± 1 (represented by grey and white colors in Figure 1) to sites of triangular lattice, we rewrite the weight as

$$x^{\#\text{ pairs of neighbors of opposite spins}}, \tag{1}$$

obtaining the Ising model (where the usual parameterization is $\exp(-2\beta) = x$). The critical value is known to be $\beta_c = \log 3/4$, so one gets the Ising model at critical temperature for $n = 1$, $x = 1/\sqrt{3}$. A computer simulation of the Ising model on the square lattice at critical temperature, when the probability of configuration is proportional to (1), is shown in Figure 2.

For $n = 1$, $x = 1$ we obtain critical site percolation on triangular lattice. Taking $n = 0$ (which amounts to considering configurations with no loops, just a curve running from a to b), one obtains for $x_c = 1/\sqrt{2+\sqrt{2}}$ a version of the self-avoiding random walk.

The following conjecture (see e.g. [15]) is a direct consequence of physics predictions and SLE calculations:

Conjecture 3. For $n \in [0, 2]$ and $x = x_c(n)$, as lattice step goes to zero, the law of the interface converges to Schramm–Loewner evolution with

$$\kappa = 4\pi/(2\pi - \arccos(-n/2)).$$

For $n \in [0, 2]$ and $x \in (x_c, \infty)$ (in particular for $x = \tilde{x}_c$), as lattice step goes to zero, the law of the interface converges to Schramm–Loewner evolution with

$$\kappa = 4\pi / \arccos(-n/2).$$

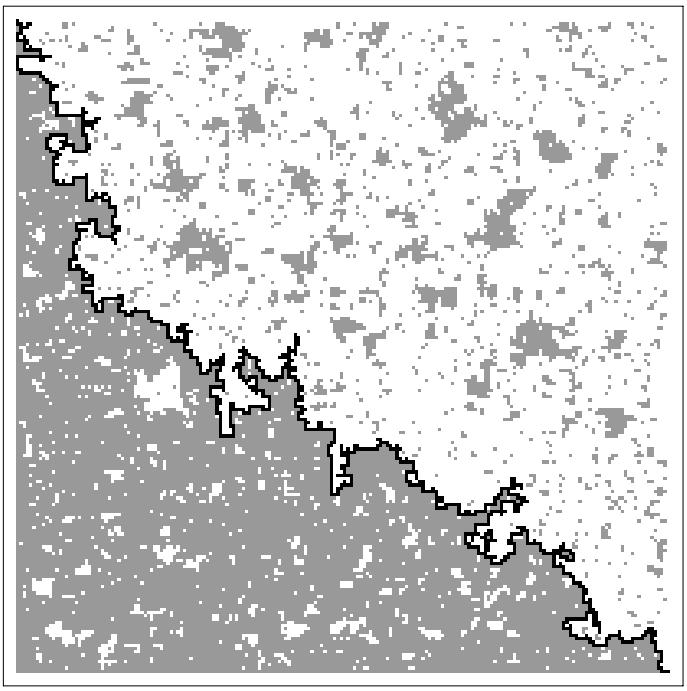

Figure 2. The Ising model at critical temperature on a square. White and grey sites represent ± 1 spins. Dobrushin boundary conditions (grey on lower and left sides, white on upper and right sides) produce, besides loop interfaces, an interface from the upper left to the lower right corner, pictured in black. When lattice step goes to zero, the law of the interface converges to SLE(3), which is a conformally invariant random curve, almost surely simple and of Hausdorff dimension 11/8.

Note that to address this question one does not need to prove that the Nienhuis temperature is indeed critical (Conjecture 2).

We discussed loops on the hexagonal lattice, since it is a trivalent graph and so at most one interface can pass through a vertex. One can engage in similar considerations on the square lattice with special regard to a possibility of two interfaces passing through the same vertex, in which case they can be split into loops in two different ways (with different configuration weights). In the case of Ising ($n = 1$) this poses less of a problem, since number of loops is not important. For $n = 1$ and $x = 1$ we get percolation model with $p = 1/2$, but for a general lattice this p need not be critical, so e.g. critical site percolation on the square lattice does not fit directly into this framework.

2.3. Fortuin–Kasteleyn random cluster models. Another interesting class is Fortuin–Kasteleyn models, which are random cluster representations of q-state Potts model. The random cluster measure on a graph (a piece of the *square lattice* in our case) is a probability measure on edge configurations (each edge is declared either open or closed), such that the probability of a configuration is proportional to

$$p^{\#\text{ open edges}}\,(1-p)^{\#\text{ closed edges}}\,q^{\#\text{ clusters}},$$

where clusters are maximal subgraphs connected by open edges. The two parameters are edge-weight $p \in [0,1]$ and cluster-weight $q \in (0,\infty)$, with $q \in [0,4]$ being interesting in our framework (similarly to the previous model, $q > 4$ exhibits different behavior). For a square lattice (or in general any planar graph) to every configuration one can prescribe a cluster configuration on the dual graph, such that every open edge is intersected by a dual closed edge and vice versa. See Figure 3 for a picture of two dual configurations with respective open edges. It turns out that the probability of a dual configuration becomes proportional to

$$p_*^{\#\text{ dual open edges}}\,(1-p_*)^{\#\text{ dual closed edges}}\,q^{\#\text{ dual clusters}},$$

with the dual to p value $p_* = p_*(p)$ satisfying $p_*/(1-p_*) = q(1-p)/p$. For $p = p_{\mathrm{sd}} := \sqrt{q}/(\sqrt{q}+1)$ the dual value coincides with the original one: one gets $p_{\mathrm{sd}} = (p_{\mathrm{sd}})_*$ and so the model is self-dual. It is conjectured that this is also the critical value of p, which was only proved for $q = 1$ (percolation), $q = 2$ (Ising) and $q > 25.72$.

Again we introduce Dobrushin boundary conditions: wired on the counterclockwise arc ab (meaning that all edges along the arc are open) and dual-wired on the counterclockwise arc ba (meaning that all dual edges along the arc are open, or equivalently all primal edges orthogonal to the arc are closed) – see Figure 3. Then there is a unique interface running from a to b, which separates cluster containing the arc ab from the dual cluster containing the arc ba.

We will work with the loop representation, which is similar to that in 2.2. The cluster configurations can be represented as Hamiltonian (i.e. including all edges) non-intersecting (more precisely, there are no "transversal" intersections) loop configurations on the medial lattice. The latter is a square lattice which has edge centers of the original lattice as vertices. The loops represent interfaces between cluster and dual clusters and turn by $\pm\frac{\pi}{2}$ at every vertex – see Figure 3. It is well-known that probability of a configuration is proportional to

$$\left(\frac{p}{1-p}\frac{1}{\sqrt{q}}\right)^{\#\text{ open edges}} \cdot \left(\sqrt{q}\right)^{\#\text{ loops}},$$

which for the self-dual value $p = p_{\mathrm{sd}}$ simplifies to

$$\left(\sqrt{q}\right)^{\#\text{ loops}}. \tag{2}$$

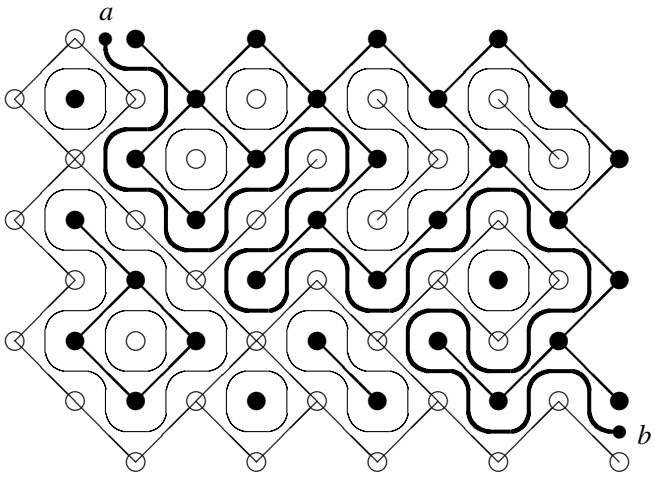

Figure 3. Loop representation of the random cluster model. The sites of the original lattice are colored in black, while the sites of the dual lattice are colored in white. Clusters, dual clusters and loops separating them are pictured. Under Dobrushin boundary conditions besides a number of loops there is an interface running from a to b, which is drawn in bold. Weight of the configuration is proportional to $(\sqrt{q})^{\#\text{ loops}}$.

Dobrushin boundary conditions amount to introducing two vertices with odd number of edges: a source a and a sink b, which enforces a curve running form a to b (besides loops) – see Figure 3 for a typical configuration.

Conjecture 4. For all $q \in [0, 4]$, as the lattice step goes to zero, the law of the interface converges to Schramm–Loewner evolution with $\kappa = 4\pi/\arccos(-\sqrt{q}/2)$.

The conjecture was proved by Greg Lawler, Oded Schramm and Wendelin Werner [23] for the case of $q = 0$, when they showed that the perimeter curve of the uniform spanning tree converges to SLE(8). Note that with Dobrushin boundary conditions loop representation still makes sense for $q = 0$. In fact, the formula (2) means that we restrict ourselves to configurations with no loops, just a curve running from a to b (which then necessarily passes through all the edges), and all configurations are equally probable.

Below we will outline our proof [39] that for the Ising parameter $q = 2$ the interface converges to SLE(16/3), see Figure 4. It almost directly translates into a proof that the interface of the spin cluster for the Ising model on the square lattice at the critical temperature (which can be rewritten as the loop model in 2.2 for $n = 1$, only on the square lattice) converges to SLE(3), as shown in Figure 2. It seems likely that it will work in the $n = 1$ case for the loop model on hexagonal lattice described above, providing convergence to SLE(3) for $x = x_c$ and (a new proof of) convergence to SLE(6) for $x = \tilde{x}_c$ (and possibly for all $x > x_c$).

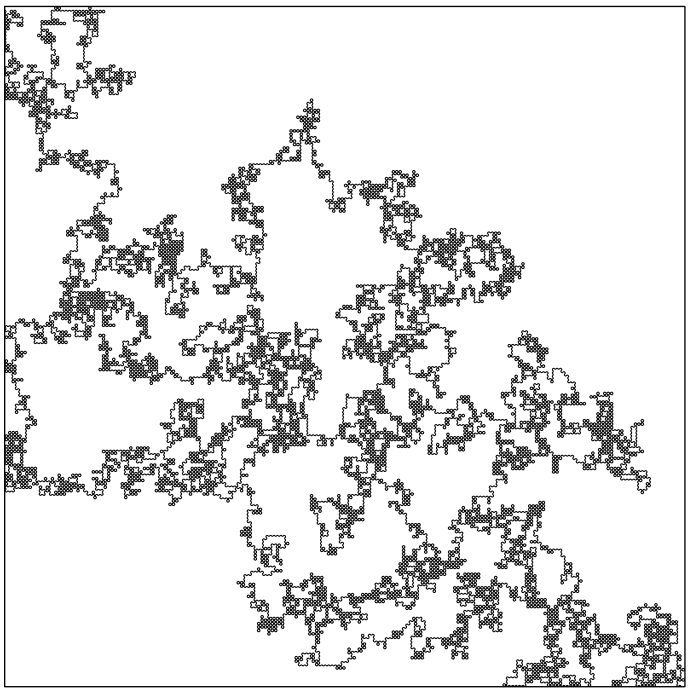

Figure 4. Interface in the random cluster Ising model at critical temperature with Dobrushin boundary conditions (loops not pictured). The law converges to SLE(16/3) when mesh goes to zero, so in the limit it has Hausdorff dimension $5/3$ and touches itself almost surely. The random cluster is obtained by deleting some bonds from the spin cluster, so the interfaces are naturally different. Indeed, they converge to different SLE's and have different dimensions. However they are related: conjecturally, the outer boundary of the (non-simple) pictured curve and the (simple) spin interface in Figure 2 have the same limit after appropriate conditioning.

Summing it up, Conjecture 3 was proved earlier for $n = 1$, $x = \tilde{x}_c$, see [38], [37], whereas Conjecture 4 was established for $q = 0$, see [23]. We outline a technique, which seems to prove conformal invariance in two new cases, and provide new proofs for the only cases known before, making Conjecture 4 solved for $q = 0$ and $q = 2$, and Conjecture 3 for $n = 1$. The method also contributes to our understanding of universality phenomenon.

Much of the method works for general values of n and q. The most interesting values of the parameters (where it does not yet work all the way) are $n = 0$, related to the self-avoiding random walk, and $q = 1$, equivalent to the critical bond percolation on the square lattice (in the latter case some progress was achieved by Vincent Beffara by a different method). Hopefully the lemma (essentially the discrete analyticity statement – see below) required to transfer our proof to other models will be worked out someday, leading to full resolution of these conjectures.

3. Schramm–Loewner evolution

3.1. Loewner evolution. Loewner evolution is a differential equation for a Riemann uniformization map for a domain with a growing slit. It was introduced by Charles Loewner in [25] in his work on Bieberbach's conjecture.

In the original work, Loewner considered slits growing towards interior point. Though such *radial* evolution (along with other possible setups) is also important in the context of lattice models and fits equally well into our framework, we will restrict ourselves to the *chordal* case, when the slit is growing towards a point on the boundary.

In both cases we choose a particular Riemann map by fixing its value and derivative at the target point. *Chordal Loewner evolution* describes uniformization for the upper half-plane $\mathbb{C}_+$ with a slit growing from 0 to ∞ (one deals with a general domain Ω with boundary points a, b by mapping it to $\mathbb{C}_+$ so that $a \mapsto 0$, $b \mapsto \infty$).

Loewner only considered slits given by smooth simple curves, but more generally one allows any set which grows continuously in conformal metric when viewed from ∞. We will omit the precise definition of *allowed slits* (more extensive discussion in this context can be found in [22]), only noting that all simple curves are included. The random curves arising from lattice models (e.g. cluster perimeters or interfaces) are simple (or can be made simple by altering them on the local scale). Their scaling limits are not necessarily simple, but they have no "transversal" self-intersections. For such a curve to be an allowed slit it is sufficient if it touches itself to never venture into the created loop. This property would follow if e.g. a curve visits no point thrice.

Parameterizing the slit γ in some way by time t, we denote by $g_t(z)$ the conformal map sending $\mathbb{C}_+ \setminus \gamma_t$ (or rather its component at ∞) to $\mathbb{C}_+$ normalized so that at infinity $g_t(z) = z + \alpha(t)/z + \mathcal{O}(1/|z|^2)$, the so called *hydrodynamic normalization*. It turns out that $\alpha(t)$ is a continuous strictly increasing function (it is a sort of capacity-type parameter for γ_t), so one can change the time so that

$$g_t(z) = z + \frac{2t}{z} + \mathcal{O}\left(\frac{1}{|z|^2}\right). \tag{3}$$

Denote by $w(t)$ the image of the tip $\gamma(t)$. The family of maps g_t (also called a *Loewner chain*) is uniquely determined by the real-valued *"driving term"* $w(t)$. The general Loewner theorem can be roughly stated as follows:

Loewner's theorem. *There is a bijection between allowed slits and continuous real valued functions $w(t)$ given by the ordinary differential equation*

$$\partial_t g_t(z) = \frac{2}{g_t(z) - w(t)}, \quad g_0(z) = z. \tag{4}$$

The original Loewner equation is different since he worked with smooth radial slits and evolved them in another (but related) way.

3.2. Schramm–Loewner evolution. While a deterministic curve γ corresponds to a deterministic driving term $w(t)$, a random γ corresponds to a random $w(t)$. One obtains SLE(κ) by taking $w(t)$ to be a Brownian motion with speed κ:

Definition 5. *Schramm–Loewner evolution*, or SLE(κ), is the Loewner chain one obtains by taking $w(t) = \sqrt{\kappa} B_t$, $\kappa \in [0, \infty)$. Here B_t denotes the standard (speed one) Brownian motion (Wiener process).

The resulting slit will be almost surely a continuous curve. So we will also use the term SLE for the resulting random curve, i.e. a probability measure on the space of curves (to be rigorous one can think of a Borel measure on the space of curves with uniform norm). Different speeds κ produce different curves: we grow the slit with constant speed (measured by capacity), while the driving term "wiggles" faster. Naturally, the curves become more "fractal" as κ increases: for $\kappa \leq 4$ the curve is almost surely simple, for $4 < \kappa < 8$ it almost surely touches itself, and for $\kappa \geq 8$ it is almost surely space-filling (i.e. visits every point in $\mathbb{C}_+$) – see [22], [30] for these and other properties. Moreover, Vincent Beffara [7] has proved that the Hausdorff dimension of the SLE(κ) curve is almost surely $\min(1 + \kappa/8, 2)$.

3.3. Conformal Markov property. Suppose we want to describe the scaling limits of cluster perimeters, or interfaces for lattice models assuming their existence and conformal invariance. We follow Oded Schramm [32] to show that Brownian motion as the driving force arises naturally. Consider a simply connected domain Ω with two boundary points, a and b. Superimpose a lattice with mesh ε and consider some lattice model, say critical percolation with the Dobrushin boundary conditions, leading to an interface running from a to b, which is illustrated by Figure 1 for a rectangle with two opposite corners as a and b. So we end up with a random simple curve (a broken line) connecting a to b inside Ω. The law of the curve depends of course on the lattice superimposed. If we believe the physicists' predictions, as mesh tends to zero, this measure on broken lines converges (in an appropriate weak-$*$ topology) to some measure $\mu = \mu(\Omega, a, b)$ on continuous curves from a to b inside Ω.

In this setup the conformal invariance prediction can be formulated as follows:

(A) Conformal invariance. *For a conformal map ϕ of the domain Ω one has*

$$\phi\left(\mu(\Omega, a, b)\right) = \mu(\phi(\Omega), \phi(a), \phi(b)).$$

Here a bijective map $\phi : \Omega \to \phi(\Omega)$ induces a map acting on the curves in Ω, which in turn induces a map on the probability measures on the space of such curves, which we denote by the same letter. By a conformal map we understand a bijection which locally preserves angles.

Moreover, if we start drawing the interface from the point a, we will be walking around the grey cluster following the right-hand rule – see Figure 1. If we stop at some point a' after drawing the part γ' of the interface, we cannot distinguish the boundary of Ω from the part of the interface we have drawn: they both are colored grey on the

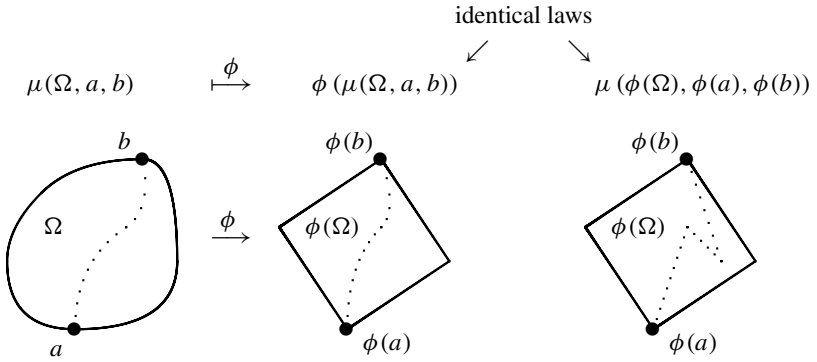

Figure 5. (A) Conformal invariance: conformal image of the law of the curve γ (dotted) in Ω coincides with the law of the curve γ in the image domain $\phi(\Omega)$.

(counterclockwise) arc $a'b$ and white on the arc ba' of the domain $\Omega \setminus \gamma'$. So we can say that the conditional law of the interface (conditioned on it starting as γ') is the same as the law in a new domain with a slit. We expect the limit law μ to have the same property:

(B) Markov property. *The law conditioned on the interface already drawn is the same as the law in the slit domain:*

$$\mu\,(\Omega, a, b)\,|\gamma' = \mu(\Omega \setminus \gamma', a', b).$$

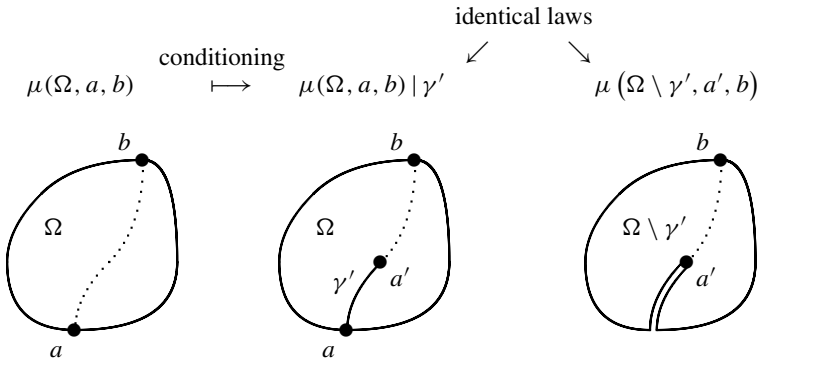

Figure 6. (B) Markov property: The law conditioned on the curve already drawn is the same as the law in the slit domain. In other words when drawing the curve we do not distinguish its past from the boundary.

If one wants to utilize these properties to characterize μ, by (A) it is sufficient to study some reference domain (to which all others can be conformally mapped), say

the upper half-plane $\mathbb{C}_+$ with a curve running from 0 to ∞. Given (A), the second property (B) is easily seen to be equivalent to the following:

(B′) Conformal Markov property. *The law conditioned on the interface already drawn is a conformal image of the original law. Namely, for any conformal map $G = G_{\gamma'}$ from $\mathbb{C}_+ \setminus \gamma'$ to $\mathbb{C}_+$ preserving ∞ and sending the tip of γ' to 0, we have*

$$\mu\,(\mathbb{C}_+, 0, \infty)\,|\gamma' = G^{-1}(\mu\,(\mathbb{C}_+, 0, \infty)).$$

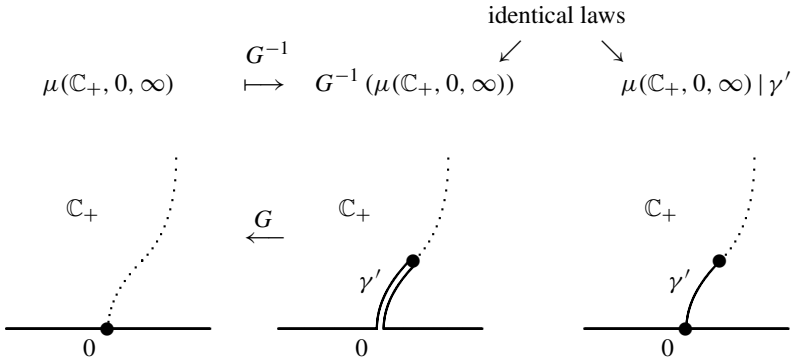

Figure 7. (B′) Conformal Markov property: The law conditioned on the curve already drawn is a conformal image of the original law. In other words the curve has "Markov property in conformal coordinates".

Remark 6. Note that property (B′) is formulated for the law μ for one domain only, say $\mathbb{C}_+$ as above. If we extend μ to other domains by conformal maps, it turns out that (A) and (B) are equivalent to (B′) together with scale invariance (under maps $z \mapsto kz, k > 0$).

To use the property (B′), we describe the random curve by the Loewner evolution with a certain random driving force $w(t)$ (we assume that the curve is almost surely an allowed slit). If we fix the time t, the property (B′) with the slit $\gamma[0, t]$ and the map $G_t(z) = g_t(z) - w(t)$ can be rewritten for random conformal map $G_{t+\delta}$ conditioned on G_t (which is the same as conditioning on $\gamma[0, t]$) as

$$G_{t+\delta}|G_t = G_t(G_\delta).$$

Expanding G's near infinity we obtain

$$\begin{aligned} z - w(t+\delta) + \cdots |G_t &= (z - w(t) + \cdots) \circ (z - w(\delta) + \cdots) \\ &= z - (w(t) + w(\delta)) + \cdots, \end{aligned}$$

concluding that

$$w(t+\delta) - w(t)|G_t = w(\delta).$$

This means that $w(t)$ is a continuous (by Loewner's theorem) stochastic process with independent stationary increments. Thus for *a random curve satisfying* (B′) the driving force $w(t)$ has to be a Brownian motion with a certain speed $\kappa \in [0, \infty)$ and drift $\alpha \in \mathbb{R}$:

$$w(t) = \sqrt{\kappa} B_t + \alpha t.$$

Applying (A) with anti-conformal reflection $\phi(u + iv) = -u + iv$ or with stretching $\phi(z) = 2z$ shows that α vanishes. So one logically arrives at the definition of SLE and the following

Schramm's principle. *A random curve satisfies* (A) *and* (B) *if and only if it is given by* SLE(κ) *for some* $\kappa \in [0, \infty)$.

The discussion above is essentially contained in Oded Schramm's paper [32] for the radial version, when slit is growing towards a point inside and the Loewner differential equation takes a slightly different form. To make this principle a rigorous statement, one has to require the curve to be almost surely an allowed slit.

4. SLE as a scaling limit

4.1. Strategy. In order to use the above principle one still has to show the *existence* and *conformal invariance* of the scaling limit, and then calculate some observable to pin down the value of κ. For percolation one can employ its locality or Cardy's formula for crossing probabilities to show that $\kappa = 6$. Based on this observation Oded Schramm concluded in [32] that *if* percolation interface has a conformally invariant scaling limit, it must be SLE(6).

But it is probably difficult to show that some interface has a conformally invariant scaling limit without actually identifying the latter.

To identify a random curve in principle one needs "infinitely many observables," e.g. knowing for any finite number of points the probability of passing above them. This seems to be a difficult task, which is doable for percolation since the locality allows us to create many observables from just one (crossing probability), see [38].

Fortunately it turns out that even in the general case if an observable has a limit satisfying analogues of (A) and (B), one can deduce convergence to SLE(κ) (with κ determined by the values of the observable).

This was demonstrated by Greg Lawler, Oded Schramm and Wendelin Werner in [23] in establishing the convergence of two related models: of loop erased random walk to SLE(2) and of uniform spanning tree to SLE(8).

They described the discrete curve by a Loewner evolution with unknown random driving force. Stopping the evolution at times t and s and comparing the values of the observable, one deduces (approximate) formulae for the conditional expectation and variance of the increments of the driving force. Skorokhod embedding theorem is then used to show that driving force converges to the Brownian motion. Finally

one has to prove a (stronger) convergence of the measures on curves. The trick is that knowing just one observable (but *for all domains*) after conditioning translates to a continuum of information about the driving force.

We describe a different approach with the same general idea, which is perhaps more transparent, separating "exact calculations" from "a priori estimates". The idea is to first get a priori estimates, which imply that collection of laws is precompact in a suitable space of allowed slits. Then to establish the convergence it is enough to show that limit of any converging subsequence coincides with SLE. To do that we describe the subsequential limit by Loewner evolution (with unknown random driving force $w(t)$) and extract from the observable enough information to evaluate expectation and quadratic variation of increments of $w(t)$. Lévy's characterization implies that $w(t)$ is the Brownian motion with a particular speed κ and so our curves converge to SLE(κ).

As an example we discuss below an alternative proof of convergence to SLE(6) in the case of percolation, which uses crossing probability as an observable. For a domain Ω with boundary points a, b superimpose triangular lattice with mesh ε and Dobrushin boundary conditions. We obtain an interface γ_ε (between open vertices on one side and closed on another) running from a to b, see Figure 1, i.e. a measure μ_ε on random curves running from a to b.

4.2. Compactness. First we note that the collection $\{\mu_\varepsilon\}$ is precompact (in weak-$*$ topology) in the space of continuous curves that are Loewner allowed slits.

The necessary framework for precompactness in the space of continuous curves was suggested by Michael Aizenman and Almut Burchard [2]. It turns out that appropriate bounds for probability of an annulus being traversed k times imply tightness: a curve has a Hölder parameterization with stochastically bounded norm. Hence $\{\mu_\varepsilon\}$ is precompact by Prokhorov's theorem: a (uniformly controlled) part of μ_ε is supported on a compact set (of curves with norm bounded by M), and so such parts are weakly precompact by Banach–Alaoglu theorem, whereas the mass of the remainder tends uniformly to zero as $M \to \infty$.

The curves on the lattice are simple, so they cannot have transversal self-intersections even after passing to the limit. So to check that for any weak limit of μ_ε's almost every curve is an allowed slit, one has to check that as we grow it the tip is always visible and moves continuously when viewed from infinity. Essentially, one has to rule out two scenarios: that the curve passes for a while inside already visited set, and that the curve closes a loop, and then travels inside before exiting. Both are reduced to probabilities of annuli traversing.

In the case of percolation one uses the Russo–Seymour–Welsh theory [31], [36] together with Michael Aizenman's observation [1] (that in the limit interface can visit no point thrice – "no 6 arms") to obtain the required estimates.

Since the collection of interface laws $\{\mu_\varepsilon\}$ is precompact (in weak-$*$ topology) in the space of continuous curves that are Loewner allowed slits, to show that as mesh goes to zero the interface law converge to the law of SLE(6), it is sufficient to show

that the limit of any converging subsequence is in fact SLE(6).

Take some subsequence converging to a random curve in the domain Ω from a to b. We map conformally to a half-plane $\mathbb{C}_+$, obtaining a curve γ from 0 to ∞ with law μ. We must show that μ is given by SLE(6).

By a priori estimates γ is almost surely an allowed slit. So we can describe γ by a Loewner evolution with a (random) driving force $w(t)$. It remains to show that $w(t) = \sqrt{6}B_t$. Note that at this point we only know that $w(t)$ is an almost surely continuous random function – we do not even have a Markov property.

4.3. Martingale observable. Given a topological rectangle (a simply connected domain Ω with boundary points a, b, c, d) one can superimpose a lattice with mesh ε onto Ω and study the probability $\Pi_\varepsilon(\Omega, [a, b], [c, d])$ that there is an open cluster joining the arc $[a, b]$ to the arc $[c, d]$ on the boundary of Ω. It is conjectured that there is a limit $\Pi := \lim_{\varepsilon\to 0} \Pi_\varepsilon$, which is conformally invariant (depends only on the conformal modulus of the configuration Ω, a, b, c, d), and satisfies Cardy's formula (predicted by John Cardy in [9] and proved in [37]) in half-plane:

$$\Pi(\mathbb{C}_+, [1-u, 1], [\infty, 0]) = \frac{\Gamma(2/3)}{\Gamma(1/3)\Gamma(4/3)}\, u^{1/3}\, {}_2F_1\left(\frac{1}{3}, \frac{2}{3}; \frac{4}{3}; u\right) =: F(u). \quad (5)$$

Above ${}_2F_1$ is the hypergeometric function, so one can alternatively write

$$F(u) = \int_0^u (v(1-v))^{-2/3}\, dv \Big/ \int_0^1 (v(1-v))^{-2/3}\, dv.$$

Particular nature of the function is not important, we rather use the fact that there is an explicit formula for half-plane with four marked boundary points and hence by conformal invariance for an arbitrary topological rectangle. The value $\kappa = 6$ will arise later from some expression involving derivatives of F.

Assume that for some percolation model we are able to prove the above conjecture (for critical site percolation on the triangular lattice it was proved in [37], [38]).

Add two points on the boundary, making Ω a topological rectangle $axby$ and consider the crossing probability $\Pi_\varepsilon(\Omega, [a, x], [b, y])$ (from the arc ax to the arc by on a lattice with mesh ε).

Parameterize the interface γ_ε in some way by time, and draw the part $\gamma_\varepsilon[0, t]$. Note that it has open vertices on one side (arc $\gamma_\varepsilon(t)a$) and closed on another (arc $a\gamma_\varepsilon(t)$). Then any open crossing from the arc by to the arc ax inside Ω is either disjoint from $\gamma_\varepsilon[0, t]$, or hits its "open" arc $\gamma_\varepsilon(t)a$. In either case it produces an open crossing from the arc by to the arc $\gamma_\varepsilon(t)x$ inside $\Omega \setminus \gamma_\varepsilon[0, t]$, and converse also holds. Therefore one sees that for every realization of $\gamma_\varepsilon[0, t]$ the crossing probability conditioned on $\gamma_\varepsilon[0, t]$ coincides with crossing probability in the slit domain $\Omega \setminus \gamma_\varepsilon[0, t]$:

$$\Pi_\varepsilon(\Omega, [a, x], [b, y] | \gamma_\varepsilon[0, t]) = \Pi_\varepsilon(\Omega \setminus \gamma_\varepsilon[0, t], [\gamma_\varepsilon(t), x], [b, y]), \quad (6)$$

an analogue of the Markov property (B). Alternatively this follows from the fact that Π can be understood in terms of the interface as the probability that it touches the

arc xb before the arc by. For example, in Figure 1 there is no horizontal grey (open) crossing (there is a vertical white crossing instead), and interface traced from the left upper corner a touches the lower side xb before the right side by.

Stopping the curve at times $t < s$ and using (6) we can write by the total probability theorem for every realization of $\gamma_\varepsilon[0,t]$

$$\begin{aligned}&\Pi_\varepsilon\left(\Omega \setminus \gamma_\varepsilon[0,t], [\gamma_\varepsilon(t), x], [b, y]\right)\\ &\quad = \mathbb{E}_{\gamma_\varepsilon[t,s]}\left(\Pi_\varepsilon\left(\Omega \setminus \gamma_\varepsilon[0,s], [\gamma_\varepsilon(s), x], [b, y]\right) | \gamma[0,t]\right).\end{aligned} \tag{7}$$

The same a priori estimates as in the previous subsection show that the identity (7) also holds for the (subsequential) scaling limit μ (strictly speaking there is an error term in case the interface touches the arcs $[ax]$ or $[ya]$ before time s, but it decays very fast as we move x and y away from a). We know that the scaling limit $\Pi := \lim_{\varepsilon\to 0} \Pi_\varepsilon$ of the crossing probabilities exists and is conformally invariant, so we can rewrite (7) for the curve γ with Loewner parameterization as

$$\begin{aligned}&\Pi\left(\mathbb{C}_+ \setminus \gamma[0,t], [\gamma(t), x], [\infty, y]\right)\\ &\quad = \mathbb{E}_{\gamma[t,s]}\left(\Pi\left(\mathbb{C}_+ \setminus \gamma[0,s], [\gamma(s), x], [\infty, y]\right) | \gamma[0,t]\right),\end{aligned} \tag{8}$$

for almost every realization of $\gamma[0,t]$. Moreover we can plug in exact values of the crossing probabilities, given by the Cardy's formula. Recall that the domain $\mathbb{C}_+ \setminus \gamma[0,t]$ is mapped to half-plane by the map $g_t(z)$ with $\gamma(t) \mapsto w(t)$. Then the map $z \mapsto \frac{g_t(z)-g_t(y)}{g_t(x)-g_t(y)}$ also maps it to half-plane with $\gamma(t) \mapsto \frac{w(t)-g_t(y)}{g_t(x)-g_t(y)}$, $y \mapsto 0$, $x \mapsto 1$. Using conformal invariance and applying Cardy's formula we write

$$\begin{aligned}\Pi\left(\mathbb{C}_+ \setminus \gamma[0,t], [\gamma(t), x], [\infty, y]\right) &= \Pi\Big(\mathbb{C}_+, \Big[-\frac{g_t(y)-w(t)}{g_t(x)-g_t(y)}, 1\Big], [\infty, 0]\Big)\\ &= F\Big(\frac{g_t(x)-w(t)}{g_t(x)-g_t(y)}\Big),\end{aligned} \tag{9}$$

for Cardy's hypergeometric function F.

4.4. Conformally invariant martingale. Plugging (9) into both sides of (8) we arrive at

$$F\Big(\frac{g_t(x)-w(t)}{g_t(x)-g_t(y)}\Big) = \mathbb{E}_{\gamma[t,s]}\Big(F\Big(\frac{g_s(x)-w(s)}{g_s(x)-g_s(y)}\Big) | \gamma[0,t]\Big). \tag{10}$$

Remark 7. Denote by $x_t := g_t(x) - w(t)$ and $y_t := g_t(y) - w(t)$ trajectories of x and y under the random Loewner flow. Then (10) essentially means that $F\big(\frac{x_t}{x_t-y_t}\big)$ is a martingale.

Since we want to extract the information about $w(t)$, we fix the ratio $x/(x-y) := 1/3$ (anything not equal to $1/2$ would do) and let x tend to infinity: $y := -2x$, $x \to +\infty$. Using the normalization $g_t(z) = z + 2t/z + \mathcal{O}(1/z^2)$ at infinity, writing

Taylor expansion for F, and plugging in values of derivatives of F at $1/3$, we obtain the following expansion for the right-hand side of (10):

$$\begin{aligned}
\cdots &= F\left(\frac{x - w(t) + 2t/x + \mathcal{O}(1/x^2)}{(x + 2t/x + \mathcal{O}(1/x^2)) - (-2x + 2t/(-2x) + \mathcal{O}(1/x^2))}\right) \\
&= F\left(\frac{1}{3} - \frac{w(t)}{3}\frac{1}{x} + \frac{t}{3}\frac{1}{x^2} + \mathcal{O}\left(\frac{1}{x^3}\right)\right) \\
&= F\left(\frac{1}{3}\right) - \frac{w(t)}{3}F'\left(\frac{1}{3}\right)\frac{1}{x} + \left(\frac{t}{3}F'\left(\frac{1}{3}\right) + \frac{w(t)^2}{3^2\cdot 2}F''\left(\frac{1}{3}\right)\right)\frac{1}{x^2} + \mathcal{O}\left(\frac{1}{x^3}\right) \\
&= F\left(\frac{1}{3}\right) - \frac{1}{x}\frac{\Gamma(2/3)}{\Gamma(1/3)\Gamma(4/3)}\frac{3^{1/3}}{2^{2/3}}\mathbb{E}\, w(t) \\
&\qquad - \frac{1}{x^2}\frac{\Gamma(2/3)}{\Gamma(1/3)\Gamma(4/3)}\frac{1}{3^{2/3}2^{5/3}}\mathbb{E}\left(w(t)^2 - 6t\right) + \mathcal{O}\left(\frac{1}{x^3}\right) \\
&=: A - \frac{1}{x}B\,\mathbb{E}\, w(t) - \frac{1}{x^2}C\,\mathbb{E}\left(w(t)^2 - 6t\right) + \mathcal{O}\left(\frac{1}{x^3}\right),
\end{aligned}$$

where we plugged in values of the derivative for hypergeometric function. Using similar reasoning for the right-hand side of (10) we arrive at the following identity:

$$\begin{aligned}
&A - \frac{1}{x}B\,\mathbb{E}\, w(t) - \frac{1}{x^2}C\,\mathbb{E}\left(w(t)^2 - 6t\right) + \mathcal{O}\left(\frac{1}{x^3}\right) \\
&\quad = A - \frac{1}{x}B\,\mathbb{E}_{\gamma[t,s]}\left(w(s)|\gamma[0,t]\right) - \frac{1}{x^2}C\,\mathbb{E}_{\gamma[t,s]}\left(w(s)^2 - 6s|\gamma[0,t]\right) + \mathcal{O}\left(\frac{1}{x^3}\right).
\end{aligned}$$

Equating coefficients in the series above, we conclude that

$$\mathbb{E}_{w[t,s]}\left(w(s)|w[0,t]\right) = 0, \quad \mathbb{E}_{w[t,s]}\left(w(s)^2 - 6s|w[0,t]\right) = w(t)^2 - 6t. \tag{11}$$

Thus $w(t)$ is a continuous (by Loewner's theorem) process such that both

$$w(t) \quad \text{and} \quad w(t)^2 - 6t$$

are martingales so by Lévy's characterization of the Brownian motion $w(t) = \sqrt{6}B_t$, and therefore SLE(6) is the scaling limit of the critical percolation interface.

The argument will work wherever Cardy's formula and a priori estimates are available, particularly for triangular lattice. More generally, any conformally invariant martingale will do, with value of κ arising from its Taylor expansion.

Remark 8. The scheme can also be reversed to do calculations for SLE's, if an observable is a martingale (e.g. crossing probability). Indeed, writing the same formulae with $x/(x-y) = a$ we conclude that the coefficient by $\frac{1}{x^2}$, namely

$$\frac{2a(1-2a)}{1-a}tF'(a) + \frac{a}{2}\mathbb{E}\left(w(t)^2\right)F''(a)$$

vanishes. Since for $w(t) = \sqrt{6}B(t)$ one has $\mathbb{E}\left(w(t)^2\right) = 6t$, we arrive at the differential equation

$$\frac{2(1-2a)}{3(1-a)}F'(a) + F''(a) = 0.$$

With the given boundary data it has a unique solution, which is Cardy's hypergeometric function.

5. Ising model and beyond

The martingale method as described above shows that to construct a conformally invariant scaling limit for some model we need a priori estimates and a non-trivial martingale observable with a conformally invariant scaling limit.

5.1. A priori estimates. A priori estimates are necessary to show that collection of interface laws is precompact in weak-$*$ topology (on the space of measures on continuous curves which are allowed slits).

If we follow the same route as for percolation (via the work [2] of Michael Aizenman and Almut Burchard), we only need to evaluate probabilities of traversals of an annulus in terms of its modulus. For percolation such estimates are (almost) readily available from the Russo–Seymour–Welsh theory. For uniform spanning tree and loop erased random walk one can derive the estimates using random walk connection and the known estimates for the latter (a "branch" of a uniform spanning tree is a loop erased random walk), see [3], [32].

For the Ising model the required estimates do not seem to be readily available, but a vast arsenal of methods is at hand. Essentially all we need can be reduced by monotonicity arguments to spin correlation estimates of Bruria Kaufman, Lars Onsager and Chen Ning Yang [14], [44].

For general random cluster or loop models such exact results are not available, but we actually need much weaker statements, and many of the techniques used by us for the Ising model (like FKG inequalities) are well-known in the general case.

So this part does not seem to be the main obstacle to construction of scaling limits, though it might require very hard work. Moreover, following the proposed approach we actually get that interfaces have a Hölder parameterization with uniformly stochastically bounded norm. Thus rather weak kinds of convergence of interfaces would lead to convergence in uniform norm (or rather weak-$*$ convergence of measures on curves with uniform norm).

It also appears that the same a priori estimates can be employed to show observable convergence in the cases concerned, and hopefully they will be sufficient for other models. So a more pressing question is how to construct a martingale observable.

5.2. Conformally covariant martingales. Suppose that for every simply connected domain Ω with a boundary point a we have defined a random curve γ starting from a.

Mark several points $b, c, \dots$ in Ω or on the boundary. Remark 7 suggests the following definition:

Definition 9. We say that a function (or rather a *differential*) $F(\Omega, a, b, c, \dots)$ is a *conformal* (*covariant*) *martingale* for a random curve γ if

F is conformally covariant:

$$F(\Omega, a, b, c, \dots) = F(\phi(\Omega), \phi(a), \phi(b), \phi(c), \dots) \cdot \phi'(b)^{\alpha} \bar{\phi}'(b)^{\beta} \phi'(c)^{\gamma} \bar{\phi}'(c)^{\delta} \dots, \tag{12}$$

and

$$F(\Omega \setminus \gamma[0, t], \gamma(t), b, c, \dots) \text{ is a martingale} \tag{13}$$

with respect to the random curve γ drawn from a (with Loewner parameterization).

Introducing covariance at $b, c, \dots$ we do not ask for covariance at a, since it always can be rewritten as covariance at other points. And applying factor at a would be troublesome: once we started drawing a curve the domain becomes non-smooth in its neighborhood, creating problems with the definition.

If the exponents $\alpha, \beta, \dots$ vanish, we obtain an invariant quantity. While the crossing probability for the percolation was invariant, many quantities of interest in physics are covariant differentials, e.g. open edge density at c would scale as a lattice step to some power (depending on the model), so we would arrive at a factor

$$|\phi'(c)|^{\delta} = \phi'(c)^{\delta/2} \bar{\phi}'(c)^{\delta/2}.$$

There are other possible generalisations, e.g. one can add the Schwarzian derivative of ϕ to (12).

The two properties in Definition 9 are analogues of (A) and (B), and similarly combined they show that for the curve γ mapped to half-plane from any domain Ω so that $a \mapsto 0$, $b \mapsto \infty$, $c \mapsto x$ (note that the image curve in $\mathbb{C}_+$ might depend on Ω – we only know the conformal invariance of an observable, not of the curve itself) we have an analogue of (B′), which was already mentioned in Remark 7 for percolation. Namely

$$F(\mathbb{C}_+, 0, \infty, g_t(x), \dots) \cdot g_t'(x)^{\gamma} \bar{g}_t'(x)^{\delta} \dots,$$

is a martingale with respect to the random Loewner evolution (covariance factor at $b = \infty$ is absent, since $g_t'(\infty) = 1$).

The equation (10) can be written for this F, and if we can evaluate F exactly, the same machinery as one used by Greg Lawler, Oded Schramm and Wendelin Werner in [23] or as the one discussed above for percolation proves that our random curve is SLE. So one arrives at a following generalization of Oded Schramm's principle:

Martingale principle. *If a random curve γ admits a* (*non-trivial*) *conformal martingale F, then γ is given by* SLE *with κ* (*and drift depending on modulus of the configuration*) *derived from F.*

Remark 10. In chordal situation we consider curves growing from a towards another boundary point b in a simply connected domain. But the same conclusion would hold on general domains or Riemann surfaces with boundary once we find a covariant martingale (for appropriate generalizations of Loewner evolutions see e.g. the book [4]). The only difference is that driving force of the corresponding Loewner evolution will be a Brownian motion with drift depending on conformal modulus of the configuration $\Omega, a, b, c, \dots$, leading to SLE generalizations. Starting from lattice models with various boundary conditions and conditioned on various events, one can see which drifts will be of interest for SLE generalizations.

5.3. Discrete analyticity. Passing to the lattice model, we want to find a discrete object, which in the limit becomes a conformally covariant martingale.

Martingale property is actually more accessible in the discrete setting. For example, functions which are defined as observables (like probability of the interface going through a vertex, edge density for the model, etc.) have the martingale property built in, and so only conformal covariance must be established.

Alternatively, one can work with a discrete function $F(\Omega, a, b, c)$ (a priori not related to lattice models) which has a conformally covariant scaling limit by construction. Then we need to connect it to a particular lattice model, establishing a martingale property (13). In the discrete case it is sufficient to check the latter for a curve advanced by one step. Assume that once we have drawn the part γ' of the interface from the point a to point a', it turns left with probability $p = p(\Omega, \gamma', a', b)$ creating a curve $\gamma_l = \gamma \cup \{a_l\}$ or right with probability $(1 - p)$ creating a curve $\gamma_r = \gamma \cup \{a_r\}$. Then it is enough to check the identity

$$F(\Omega \setminus \gamma', a', b, c) = pF(\Omega \setminus \gamma_l, a_l, b, c) + (1 - p)F(\Omega \setminus \gamma_r, a_r, b, c), \qquad (14)$$
$$p = p(\Omega, \gamma', a', b).$$

Actually our proof for the Ising model can be rewritten that way, with F defined as a solution of an appropriate discretization of the Riemann Boundary Value Problem (17) – the observable nature of F never comes up.

Moreover, starting with F one can define a random curve by choosing "turning probabilities" p so that identity (14) is satisfied, obtaining a model with conformally invariant scaling limit by "reverse engineering." For example, starting with a harmonic function of c with boundary values 1 on the arc ba and 0 on the arc ab, one obtains a unique discrete random curve, which has it as a martingale. Note that such a function is a particular case $\alpha = 1$ of the martingale (15) below, corresponding to $\kappa = 4$ (or rather its integral). In [35] Oded Schramm and Scott Sheffield introduced this curve with a nicer "Harmonic Explorer" definition, and utilizing the mentioned observable showed that it indeed converges to SLE(4). It seems that in this way one can use the solutions to the problem (17) to construct models converging to arbitrary SLE's, however it is not clear though whether they would similarly have "nicer" definitions.

Anyway, for either approach to work we need a *discrete conformal covariant* with a scaling limit. We have tried discretizations of many conformally invariant

objects (extremal length, capacity, solutions to variational problems, …) and the most promising in this context seem to be discrete harmonic or analytic functions in additional variable(s) (in $c, \dots$). Firstly, all other invariants can be rewritten in this way. Secondly, discretization of harmonic and analytic functions is a nice and very well studied (especially in the case of harmonic ones) object. Thirdly, one can obtain very non-trivial invariants by just checking local conditions: harmonicity or analyticity inside plus some boundary conditions (Dirichlet, Neumann, Riemann–Hilbert, etc.). The most natural candidate would be a harmonic function solving some Dirichlet problem.

Note that such an observable is known for the Brownian motion. A classical theorem [13] of Shizuo Kakutani states that in a domain Ω exit probabilities for Brownian motion started at z are harmonic functions in z with easily determinable boundary values. Though Kakutani works directly with Brownian motion, one can do the same for the random walk (which is actually much easier, since discrete Laplacian of the exit probability is trivially zero), and then passing to a limit deduce statements about Brownian motion, including its conformal invariance.

5.4. Classification of conformal martingales. Before we start working in the discrete setting, we might want to investigate which functions are conformal martingales for SLE curves, and so can arise as scaling limits of martingale observables for lattice models.

As discussed in Remark 8, one can write partial differential equations for SLE conformal martingales. For small number of points those equations can be solved, and in such a way one computes dimensions, scaling exponents and other quantities of interest. For any particular value of κ we can see which martingales have the simplest form and so are probably easier to work with. Also if they have a geometric SLE interpretation (like probability of SLE curve going to one side of a point, etc.) we can study similar quantities for the lattice model.

It turns out that only for $\kappa = 4$ one obtains a nice harmonic martingale with Dirichlet boundary conditions. In that case the probability of SLE(4) passing to one side of a point z is harmonic in z and has boundary conditions 0 and 1, see [33]. Oded Schramm and Scott Sheffield [35] constructed a model which has this property on discrete level built in. Unfortunately the property was not yet observed in any of the classical models conjecturally converging to SLE(4), though results of Kenyon [16] show it holds for double-domino curves in Temperley domains (i.e. a domain with the boundary satisfying a certain local condition).

In the case of mixed Dirichlet–Neumann conditions, it becomes possible to work with some other values of κ, including uniform spanning tree $\kappa = 8$, which is exploited in [23]. There are also covariant candidates for a few other values of κ (notably $8/3$ which corresponds to self-avoiding random walk), but they were not yet observed in lattice models.

Thus to study general models, one is forced to utilize more general boundary value problems with a Riemann(–Hilbert) Boundary Value Problem being the natural

candidate. Besides harmonic function it involves its harmonic conjugate, and so is better formulated in terms of analytic functions. Moreover, discrete analyticity involves a first order Cauchy–Riemann operator, rather than a second order Laplacian, and so it should be easier to deal with than harmonicity.

As discussed above, we can classify all analytic martingales. For chordal SLE and F with three points a, b, z as parameters we discover two particularly nice families. The following proposition will be discussed in [39] and our subsequent work:

Proposition 11. *Let Ω be a simply connected domain with boundary points a, b. Let $\Phi(z) = \Phi(\Omega, a, b, z)$ be a mapping of Ω to a horizontal strip $\mathbb{R} \times [0, 1]$, such that a and b are mapped to $\mp\infty$. Then*

$$F(\Omega, a, b, z) = \Phi'(z)^\alpha \quad \text{with } \alpha = \frac{8}{\kappa} - 1, \tag{15}$$

is a martingale for SLE(κ). *Let $\Psi(z) = \Psi(\Omega, a, b, z)$ be a mapping of Ω to a half-plane $\mathbb{C}_+$, such that a and b are mapped to ∞ and 0 correspondingly. Then*

$$G(\Omega, a, b, z) = \Psi'(z)^\alpha \Psi'(b)^{-\alpha} \quad \text{with } \alpha = \frac{3}{\kappa} - \frac{1}{2}, \tag{16}$$

is a martingale for SLE(κ).

These martingales make most sense for $\kappa \in [4, 8]$ and $\kappa \in [8/3, 8]$ correspondingly, and are related to observables of interest in Conformal Field Theory (which was part of our motivation to introduce them). Note that both functions are covariant with power α (which is the spin in physics terminology), and solve the Riemann boundary value problems

$$\operatorname{Im}\left(F(z)\tau(z)^\alpha\right) = 0, \quad z \in \partial\Omega, \tag{17}$$

where $\tau(z)$ is the tangent vector to $\partial\Omega$ at z.

The problem is to observe these functions in the discrete setting, and some intuition can be obtained from their geometric meaning for SLE's. For example, F is roughly speaking (one has to consider an intermediate scale to make sense of it) an expectation of SLE curve passing through z taken with some complex weight depending on the winding.

5.5. Height models and Coulomb gas. The above-mentioned expectation actually makes more sense (and is immediately well-defined) in the discrete setting and one arrives at the same object with the same complex weight via several different approaches.

One way is to consider the Coulomb gas arguments (cf. [29] by Bernard Nienhuis) for the loop representation. In the random cluster case at criticality, the weight of a loop is $\sqrt{q}$ – recall (2). We randomly and independently orient the loops, and introduce the height function h which whenever a loop is crossed changes by ± 1 (depending on loop direction – think of a topographic map). One could weight oriented loops by

$\sqrt{q}/2$, obtaining essentially the same model. However it makes sense to consider a complex weight instead. When q is in the $[0, 4]$ range, there is a complex unit number $\mu = \exp(k \cdot 2\pi i)$ such that

$$k = \frac{1}{2\pi}\arccos\left(\sqrt{q}/2\right) \text{ or } \mu + \bar{\mu} = \sqrt{q}. \tag{18}$$

We (independently and randomly) orient all loops, prescribing weight μ per counter-clockwise and $\bar{\mu}$ per clockwise loop.

Forgetting orientation of loops reconstructs the original model. Unfortunately the new partition function is complex and no longer leads to a probability measure (moreover, its variation blows up as the lattice step goes to zero), but it can be defined locally, making it much more accessible.

Indeed, going around a cycle, and turning by Δ_z at vertex z, the total sum of turns $\sum_{z\in\text{cycle}} \Delta_z$ is $\pm 2\pi$ depending on whether the cycle is counter or clockwise. So the weight per cycle can be written as $\prod_{z\in\text{cycle}} \exp(ik \cdot \Delta_z)$ and the total weight of the configuration is $\prod_{z\in\Omega} \exp(ik \cdot \Delta_z)$, which can be computed locally (without reference to the global order of cycles). The same weight can also be written in terms of the gradient of height function.

The interface is always oriented from a to b, so that the height function is always equal to 0 on the arc ab and to 1 on the arc ba. From physics arguments the interface curve (being "attached" to the boundary on both sides) should be weighted differently from loops, namely by $\exp(i(2k - 1/2) \cdot \Delta_z)$ per turn. When interface runs between two boundary points (being oriented from a to b), these factors do not matter, since total turn from a to b is independent of the configuration.

However, if we choose a point z on an interface and reverse the orientation of one of its halves (so that it is oriented from a to z and from z to b), the interface inputs a non-constant complex factor. This orientation reversal has a nice meaning: after it the height function acquires a $+2$ monodromy at z: when we go around z we cross two curves (halves of the interface) incoming into it.

All the loops (when we forget their orientation) still contribute the same $\sqrt{q}$ per loop, and the complex weight can be expressed in terms of the interface winding (total turn expressed in radians) from b to z, denoted by $w(\gamma, b \to z)$. So one logically arrives at the partition function Z for our model with $+2$ monodromy at z:

$$F(\Omega, a, b, z) := Z_{+2 \text{ monodromy at } z} = \mathbb{E}\chi_{z\in\gamma} \exp\left(i(4k - 1)w(\gamma, b \to z)\right). \tag{19}$$

This function is clearly a martingale, and there are strong indications (both from mathematics and physics points of view) that it is discrete analytic.

This follows from the fact that the interface can arrive at a boundary point z from b with a unique winding equal to the winding of the boundary from b to z, so we can express it in terms of the tangent vector $\tau(z)$. Writing this down, we discover that the function F solves a discrete version of the Riemann Boundary Value Problem (17) with $\alpha = 1 - 4k$.

Remark 12. The continuum problem was solved by the function (15), so if we establish discrete analyticity it only remains to show that a solution to a discrete Riemann Boundary Value Problem converges to its continuum counterpart. Moreover, combining identity $\alpha = 1 - 4k$ with (15) and (18) we obtain the relation between κ and q stated in Conjecture 4.

This convergence problem seems to be difficult (and open in the general case). The way we solve it in the Ising case is sketched below.

There are other indications that this function is nice to work with. Indeed, the easiest form of discrete analyticity involves local partial difference relations, and to prove those we should count configurations included into our expectation. To obtain relations, we need some bijections in the configuration space, and the easiest ones are given by local rearrangements (we worked with global rearrangements for percolation [37], but such work must be more difficult for non-local models).

The easiest rearrangement involves redirecting curves passing through z, see Figure 8, and we have a good control over relative weights of configurations whenever they are defined through windings. Counting how much a pair of configurations contributes to values of F at neighbors of z, we get some relations. Moreover, a careful analysis shows that the maximal number of relations is attained with the complex weight (19).

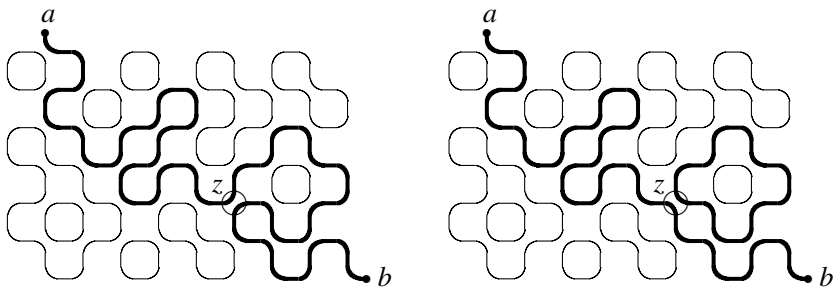

Figure 8. Rearrangement at a point z: we only change connections inside a small circle marking z. Either interface does not pass through z in both configurations, or it passes in a way similar to the pictured above. On the left the interface (in bold) passes through z twice, on the right (after the rearrangement) it passes once, but a new loop through z appears (also in bold). The loops not passing through z remain the same, so the weights of configurations differ by a factor of $\sqrt{q}$ because of the additional loop on the right. To get some linear relation on values of F, it is enough to check that any pair of such configurations makes equal contributions to two sides of the relation.

5.6. Ising model. We finish with a sketch of our proof for the random cluster representation of the Ising model (i.e. $q = 2$) on the square lattice $\varepsilon\mathbb{Z}^2$ at the critical temperature. As before consider loop representation in a simply connected domain Ω with two boundary points a and b and Dobrushin boundary conditions.

Consider function $F = F_\varepsilon(\Omega, a, b, z)$ given by (19) which is the expectation that interface from a to b passes through a vertex z taken with appropriate unit complex weight. Note that for Ising $q = 2$, so $k = 1/8$ and the weight is Fermionic (which of course was expected): a passage in the same direction but with a 2π twist has a relative weight -1, whereas a passage in the opposite direction with a counterclockwise π twist has a relative weight $-i$.

As discussed F automatically has the martingale property when we draw γ starting from a, so only conformal invariance in the limit has to be checked.

Color lattice vertices in chessboard fashion, and to each edge e prescribe orientation such that it points from a black vertex to a white one, turning it into a vector, or equivalently a complex number e. Denote by $\ell(e)$ the line passing through the origin and $\sqrt{\bar{e}}$ – the square root of the complex conjugate to e (the choice of the square root is not important). Careful analysis of the rearrangement in Figure 8 shows that F satisfies the following relation: for every edge $e \in \Omega$ orthogonal projections of the values of F at its endpoints on the line $\ell(e)$ coincide. We denote this common projection by $F(e)$ as it would also be given by the same formula (19) with z taken on the edge e (to be exact one has to divide by $2\cos(\pi/8)$ to arrive at the same normalization).

It turns out to be a form of *discrete analyticity*, and implies (but does not follow from) the common definition. The latter asks for the discrete version of the Cauchy–Riemann equations $\partial_{i\alpha} F = i\partial_\alpha F$ to be satisfied. Namely for every lattice square the values of F at four corners (denoted u, v, w, z in the counter-clockwise direction) should obey

$$F(z) - F(v) = i(F(w) - F(u)).$$

Remark 13. In the complex plane *holomorphic* (i.e. having a complex derivative) and *analytic* (i.e. admitting a power series expansion) functions are the same, so the terms are often interchanged. Though the term *discrete analytic* is in wide use, in discrete setting there are no power expansions, so it would be more appropriate to speak of *discrete holomorphic* (or *discrete regular*) functions.

As discussed above, F solves a discrete version of the Riemann Boundary Value Problem (17) with $\alpha = 1 - 4k = 1/2$, which was solved in the continuum case by $\sqrt{\Phi'}$. It remains to show that as the lattice step goes to zero, properly normalized F converges to the latter.

A logical thing to do is to integrate F^2 to retrieve Φ. Unfortunately, the square of a discrete analytic function is no longer discrete analytic and so cannot be integrated. However it turns out that there is a unique function $H = \operatorname{Im} \int F^2 dz$, which is defined on the dual lattice by

$$H(b) - H(w) = |F(e)|^2, \tag{20}$$

where edge e separates the centers of two adjacent squares, black b and white w.

After writing (20), one checks that

1. H is well defined and unique up to an additive constant,
2. H restricted to white (black) squares is super (sub) harmonic,

3. $H = 1$ on (counterclockwise) boundary arc ba and $H = 0$ on (counterclockwise) boundary arc ab,
4. The (local) difference between H restricted to white and to black squares tends uniformly to zero.

The properties 1, 2 are consequences of discrete analyticity: 1 a rather direct one, while 2 follows from the identity

$$\Delta H(u) = \pm |F(x) - F(y)|^2 ,$$

where u is a center of white (black) square with two opposite corner vertices x and y (particular choice is unimportant). Definition of F implies the property 3. The property 4 easily follows from a priori estimates (namely Kaufman–Onsager–Yang results [14], [44]). In principle it should also directly follow from the discrete analyticity of F and the property 3.

We immediately infer that H converges to $\mathrm{Im}\Phi$, and after differentiating and taking a square root we obtain the following:

Proposition 14. *Suppose that the lattice mesh ε_j goes to zero and a lattice domain Ω_j with boundary points a_j, b_j converges (in a weak sense, e.g. in Carathéodory metric) to a domain Ω with boundary points a, b as $j \to \infty$. Then away from the boundary there is a uniform convergence:*

$$\frac{1}{\sqrt{\varepsilon_j}} F(\Omega_j, a_j, b_j, z) \rightrightarrows \sqrt{\Phi'(\Omega, a, b, z)}$$

Since by Proposition 11 the function on the right is a martingale for SLE(16/3), convergence of the interface to the Schramm–Löwner evolution with $\kappa = 16/3$ follows.

6. Conclusion

At the moment the approach discussed above works only for a (finite) number of models. Another notable case when it works is the usual spin representation of the Ising model at critical temperature on the square lattice, pictured in Figure 2, where considering a similar observable (partition function with $+1$ monodromy, cf. (19)) leads to the martingale (16) and to Schramm–Loewner evolution with $\kappa = 3$. Interestingly, exactly the same definition of discrete analyticity arises.

Analogously, examination of partition function with $+1$ monodromy at z for hexagonal loop models (for all values of n at criticality) suggests its convergence to conformal martingale (16). These considerations lead to a new explanation of the Nienhuis' Conjecture 2 for the critical value of x. In this case we firmly believe that our method works all the way for $n = 1$ constructing conformally invariant scaling limits for the $O(1)$ model, but convergence estimates still have to be verified.

Two parallel methods, with observables related to (15) and (16), seem specially adapted to the square lattice and the hexagonal lattice correspondingly. However, the main arguments work for a large family of four- and trivalent graphs correspondingly. So we advance towards establishing the universality conjectures.

Though only for a few models the conformal invariance was proved, the only essential missing step for the remaining ones is discrete analyticity, and it can be attacked in a large number of ways.

So from our point of view, the perspectives for establishing conformal invariance of classical 2D lattice models are quite encouraging. Moreover, we can start discussing reasons for universality, and try to construct the full loop ensemble starting from the discrete picture. The approach discussed above is rigorous, but what makes it (and the whole SLE subject) even more interesting is that while borrowing some intuition from physics, it gives a new way to approach these phenomena.

Acknowledgments. Much of the work was completed while the author was a Royal Swedish Academy of Sciences Research Fellow supported by a grant from the Knut and Alice Wallenberg Foundation. The author also gratefully acknowledges support of the Swiss National Science Foundation.

Existence of a discrete analytic function in the Ising spin model which has potential to imply convergence of interfaces to SLE(3) was first noticed by Rick Kenyon and the author based on the dimer techniques applied to the Fisher lattice. However at the moment the Riemann Boundary Value Problem seemed beyond reach. John Cardy independently observed that (the classical version) of discrete analyticity holds for the function (19) restricted to edges.

I would like to thank Lennart Carleson for introducing me to this area, as well as for constant encouragement and advice. Most of what I know about lattice models was learnt from others, and I am especially grateful to Michael Aizenman, John Cardy and Rick Kenyon for numerous inspiring conversations on the subject. Much of the SLE considerations discussed above are due to Greg Lawler, Oded Schramm and Wendelin Werner. Finally I wish to thank Dmitri Beliaev, Ilia Binder and Geoffrey Grimmett for helpful comments on this note.

Aspects of the L^2-Sobolev theory of the $\bar\partial$-Neumann problem

Emil J. Straube*

Abstract. The $\bar\partial$-Neumann problem is the fundamental boundary value problem in several complex variables. It features an elliptic operator coupled with non-coercive boundary conditions. The problem is globally regular on many, but not all, pseudoconvex domains.

We discuss several recent developments in the L^2-Sobolev theory of the $\bar\partial$-Neumann problem that concern compactness and global regularity.

Mathematics Subject Classification (2000). Primary 32W05; Secondary 35N15.

Keywords. $\bar\partial$-Neumann problem, regularity in Sobolev spaces, compactness, pseudoconvex domains.

1. Introduction

The $\bar\partial$-Neumann problem was formulated in the fifties by D. C. Spencer as a means to generalize the theory of harmonic integrals (i.e. Hodge theory) to non-compact complex manifolds. For domains in $\mathbb{C}^n$, which is the context we will restrict ourselves to almost exclusively in this paper, the problem can be formulated as follows. Denote by Ω a pseudoconvex domain in $\mathbb{C}^n$, and by $L^2_{(0,q)}(\Omega)$ the space of $(0,q)$-forms on Ω with square integrable coefficients. Each such form can be written uniquely as a sum

$$u = {\sum_J}' u_J d\bar z_J, \tag{1.1}$$

where $J = (j_1, \dots, j_q)$ is a multi-index with $j_1 < j_2 < \cdots < j_q$, $d\bar z_J = d\bar z_{j_1} \wedge \cdots \wedge d\bar z_{j_q}$, and the $'$ indicates summation over increasing multi-indices. The inner product

$$(u, v) = \Big({\sum_J}' u_J d\bar z_J, \, {\sum_J}' v_J d\bar z_J \Big) = {\sum_J}' \int_\Omega u_J \bar v_J \tag{1.2}$$

turns $L^2_{(0,q)}(\Omega)$ into a Hilbert space. Set

$$\bar\partial\Big({\sum_J}' u_J d\bar z_J \Big) = \sum_{j=1}^n {\sum_J}' \frac{\partial u_J}{\partial \bar z_j} d\bar z_j \wedge d\bar z_J, \tag{1.3}$$

of Mathematicians, Madrid, Spain, 2006

where the derivatives are computed as distributions, and the domain of $\bar\partial$ is defined to consist of those $u \in L^2_{(0,q)}(\Omega)$ where the result is a $(0, q+1)$-form with square integrable coefficients. Then $\bar\partial = \bar\partial_q$ is a closed, densely defined operator from $L^2_{(0,q)}(\Omega)$ to $L^2_{(0,q+1)}(\Omega)$, and as such has a Hilbert space adjoint. This adjoint is denoted by $\bar\partial^*_q$. (We will not use the subscripts when the form level at which the operators act is clear or not an issue.) One can check that $\bar\partial\bar\partial = 0$, so that we arrive at a complex, the $\bar\partial$ (or Dolbeault)-complex:

$$L^2(\Omega) \xrightarrow{\bar\partial} L^2_{(0,1)}(\Omega) \xrightarrow{\bar\partial} L^2_{(0,2)}(\Omega) \xrightarrow{\bar\partial} \cdots \xrightarrow{\bar\partial} L^2_{(0,n)}(\Omega) \xrightarrow{\bar\partial} 0.$$

In analogy to the Laplace–Beltrami operator associated to the DeRham complex on a Riemannian manifold, one forms the complex Laplacian

$$\Box_q = \bar\partial_{q-1}\bar\partial^*_{q-1} + \bar\partial^*_q\bar\partial_q, \tag{1.4}$$

with domain so that the compositions are defined. The $\bar\partial$-complex is elliptic. The $\bar\partial$-Neumann problem is the problem of inverting $\Box_q$; that is, given $v \in L^2_{(0,q)}(\Omega)$, find $u \in \mathrm{Dom}(\Box_q)$ such that $\Box_q u = v$. Note that $\mathrm{Dom}(\Box_q)$ involves the two boundary conditions $u \in \mathrm{Dom}(\bar\partial^*)$ and $\bar\partial u \in \mathrm{Dom}(\bar\partial^*)$; these are the $\bar\partial$-Neumann boundary conditions. The condition $u \in \mathrm{Dom}(\bar\partial^*)$ is equivalent to a Dirichlet condition for the (complex) normal component of u. Similarly, the condition $\bar\partial u \in \mathrm{Dom}(\bar\partial^*)$ is equivalent to a Dirichlet condition on the normal component of $\bar\partial u$, that is, a *complex (or $\bar\partial$-) Neumann condition* for u.

From the point of view of partial differential equations, the $\bar\partial$-Neumann problem represents the prototype of a problem where the operator is elliptic, but the boundary conditions are not coercive, so that the classical elliptic theory does not apply. From the point of view of several complex variables, the importance of the problem stems from the fact that its solution provides a Hodge decomposition in the context of the $\bar\partial$-complex, together with the attendant elegant machinery (as envisioned by Spencer). For example, such a decomposition readily produces a solution to the inhomogeneous $\bar\partial$ equation, as follows. Assume for the moment that $\Box_q$ has a (bounded) inverse in $L^2_{(0,q)}(\Omega)$, say N_q. Then we have the orthogonal decomposition

$$u = \bar\partial\bar\partial^* N_q u + \bar\partial^*\bar\partial N_q u, \quad u \in L^2_{(0,q)}(\Omega). \tag{1.5}$$

If $\bar\partial u = 0$, then $\bar\partial^*\bar\partial N_q u$ is $\bar\partial$-closed as well (from (1.5)). Consequently, $\bar\partial^*\bar\partial N_q u = 0$ (since it is also orthogonal to $\mathrm{Ker}(\bar\partial)$), and

$$u = \bar\partial\big(\bar\partial^* N_q u\big), \tag{1.6}$$

with $\|\bar\partial^* N_q u\|^2 = (\bar\partial\bar\partial^* N_q u, N_q u) \le C\|u\|^2$. Thus the operator $\bar\partial^* N$ provides an L^2-bounded solution operator to $\bar\partial$. In fact, this operator gives the (unique) solution

orthogonal to $\mathrm{Ker}(\bar{\partial})$ (equivalently: the solution with minimal norm). This solution is called the canonical (or Kohn) solution.

That $\Box_q$ *does* have a bounded inverse N_q on bounded pseudoconvex domains was known by the mid sixties. Kohn ([64], [65], [66]) solved the $\bar{\partial}$-Neumann problem for strictly pseudoconvex domains, showing that in this case, not only is there an L^2-bounded inverse, but N_q exhibits a subelliptic gain of one derivative as measured in the L^2-Sobolev scale. Another interesting approach was given by Morrey in [79]. Hörmander ([58], see also Andreotti–Vesentini [1] for similar techniques) proved certain Carleman type estimates which in the case of bounded pseudoconvex domains imply the existence of N_q as a bounded self-adjoint operator on $L^2_{(0,q)}(\Omega)$. Early applications included embedding of real analytic manifolds ([78], [79]), a new solution of the Levi problem ([65]), a new proof of the Newlander–Nirenberg theorem on integrable almost complex manifolds ([65]), and in general, an approach to several complex variables which takes advantage of the then newly developed $\bar{\partial}$-methods ([58], [59]). Interesting 'eyewitness' accounts of this foundational period by two of the principals appear in [60] and [69], respectively.

It is not hard to see that Kohn's results for strictly pseudoconvex domains are optimal: N can never gain more than one derivative, and it can gain one derivative only when the domain is strictly pseudoconvex. However, under what circumstances subellipticity with a fractional gain of less than one derivative holds was not understood until the early eighties. Kohn gave sufficient conditions in [67], satisfied for example when the boundary is real-analytic [40]. In deep work, his students Catlin ([18], [19], [21]) and D'Angelo ([28], [29], [30]) resolved this question: on a smooth bounded pseudoconvex domain in $\mathbb{C}^n$, the $\bar{\partial}$-Neumann problem is subelliptic if and only if each boundary point is of finite type,that is, the order of contact, at the point, of complex varieties with the boundary is finite. For more on these ideas, see [32], [34], [33], [70].

When N_q does not gain derivatives, but is still compact (as an operator on $L^2_{(0,q)}(\Omega)$), it follows from work of Kohn and Nirenberg ([71]) that N_q preserves the Sobolev spaces $W^s_{(0,q)}(\Omega)$ for all $s \geq 0$. In particular, N_q preserves $C^\infty_{(0,q)}(\overline{\Omega})$ (it is globally regular). Work of Catlin ([20], compare also Takegoshi [95]) and Sibony ([84]) shows that compactness provides indeed a viable route to global regularity: the compactness condition can be verified on large classes of domains. We refer the reader to [47] for a survey of compactness in the $\bar{\partial}$-Neumann problem. In Section 2 below, we will discuss some developments that have occurred since the publication of [47].

In addition to the 'usual' (pde) reasons for studying regularity properties of a differential operator, there are, in the case of the $\bar{\partial}$-Neumann problem, the implications global regularity of the $\bar{\partial}$-Neumann operator has for several complex variables. Chief among these is the relevance for boundary behavior of biholomorphic or proper holomorphic maps. Namely, if Ω_1 and Ω_2 are two bounded pseudoconvex domains in $\mathbb{C}^n$ with smooth boundaries, such that the $\bar{\partial}$-Neumann operator on $(0, 1)$-forms (i.e. N_1)

on Ω_1 is globally regular, then any proper holomorphic map from Ω_1 to Ω_2 extends smoothly to the boundary of Ω_1 ([7], [41]). This is a highly nontrivial result: in contrast to the one variable situation, where the result is classical, the general case in higher dimensions, even for biholomorphic maps, is open. An exposition of the ideas and issues involved here can be found in [6], [72], [23].

That global regularity holds on large classes of pseudoconvex domains where local regularity or compactness fail was shown in the early nineties by Boas and the author ([11], [13]). They proved in [11] that if Ω admits a defining function whose complex Hessian is positive semi-definite at points of the boundary (a condition slightly more restrictive than pseudoconvexity), then the $\bar\partial$-Neumann problem is globally regular (for all q). This class of domains includes in particular all (smooth) convex domains. The proof is based on the existence of certain families of vector fields which have good approximate commutator properties with $\bar\partial$. In [13], the authors studied the situation when the boundary points of infinite type form a complex submanifold (with boundary) of the boundary of the domain. They identified a DeRham cohomology class associated to the submanifold as the obstruction to the existence of the vector fields needed. In particular, a simply connected complex manifold in the boundary is benign for global regularity of the $\bar\partial$-Neumann problem. It is noteworthy that this cohomology class also plays a role in deciding whether or not the closure of the domain admits a Stein neighborhood basis ([5]).

The question whether global regularity holds on general pseudoconvex domains turned out to be very difficult and was resolved only in the mid nineties. Barrett ([3], see also [2] and [63] for predecessors) showed that on the worm domains of Diederich and Fornæss ([38]), N_1 does not preserve $W^s_{(0,1)}(\Omega)$ for s sufficiently large, depending on the winding (that is, exact regularity fails). Christ ([24], see also [25], [26]) resolved the question by proving certain a priori estimates for N_1 on these domains that would imply exact regularity in Sobolev spaces (and thus would contradict Barrett's result) if N_1 were to preserve the space of forms smooth up to the boundary.

In Section 3, we will discuss some recent developments. In [93] and [45], the authors consider the case where the boundary is finite type except for a Levi-flat piece which is 'nicely' foliated by complex hypersurfaces. Whether or not the families of vector fields with good approximate commutator properties with $\bar\partial$ exist turns out to be equivalent to a property of the Levi foliation much studied in foliation theory, namely whether or not the foliation can be defined globally by a closed one-form. Sucheston and the author showed in [92] that the approaches via plurisubharmonic defining functions and vector fields with good approximate commutator properties with $\bar\partial$ are actually equivalent, when suitably reformulated. This left two main avenues to global regularity: compactness and plurisubharmonic defining functions and/or good vector fields. These two approaches were unified by the author in [91], via a new sufficient condition for global regularity.

Detailed accounts of the $\bar\partial$-Neumann theory, from different points of view, may be found in [43], [59], [72], [23], [73], [81]. Developments up to about ten years ago

are covered in [14] (for compactness, see [47]). Two recent informative surveys that concentrate on topics not covered here are the following: [83] deals with estimates on Lipschitz domains, and [77] discusses applications obtained by inserting a so called twisting factor into the $\bar\partial$-complex.

Although this paper concentrates on aspects of the $\bar\partial$-Neumann problem on domains in $\mathbb{C}^n$, we wish to mention a very important and fruitful development, namely the application of L^2-methods to algebraic and complex geometry, and vice versa. For expositions of this very active area of research, we refer the reader to [35], [36], [86], [87].

2. Compactness

It is of interest in several contexts to know whether or not the $\bar\partial$-Neumann operator is, or is not, compact. Examples include global regularity ([71]), the Fredholm theory of Toeplitz operators(see e.g. [54]), and existence or non-existence of Henkin–Ramirez type kernels for solving $\bar\partial$ ([51]). A fairly comprehensive discussion of compactness, up to about 1999, is in [47]. There one also finds complete proofs and/or references for background material. In this section, we review some recent developments.

2.1. Sufficient conditions for compactness. In [20] Catlin introduced a sufficient condition for compactness which he called property (P). The boundary of a domain is said to satisfy property (P) if for every positive number M there are an open neighborhood U_M of $b\Omega$ and a plurisubharmonic function $\lambda_M \in C^2(U_M \cap \Omega)$ with $0 \le \lambda_M \le 1$, such that for all $z \in U_M \cap \Omega$,

$$\sum_{j,k}^{n} \frac{\partial^2 \lambda_M}{\partial z_j \partial \overline{z}_k}(z) w_j \overline{w}_k \ge M|w|^2. \tag{2.1}$$

(This is somewhat more general than the formulation given in [20], but see also [47].) Property (P) can be very nicely reformulated, on Lipschitz domains, in the spirit of Oka's lemma: the boundary satisfies property (P) if and only if it locally admits functions ρ comparable to minus the boundary distance, such that the complex Hessian of $-\log(-\rho)$ tends to infinity upon approach to the boundary ([50]). If the boundary of the bounded pseudoconvex domain satisfies property (P), then the $\bar\partial$-Neumann operator N_q on Ω is compact, $1 \le q \le n$ ([20], [88] when no boundary regularity is assumed). There are natural versions of property (P) for $(0, q)$-forms, see [47]: (2.1) is replaced by the requirement that the sum of the smallest q eigenvalues of the complex Hessian of λ_M should be at least M. Note that then $P = P_1 \Rightarrow P_2 \Rightarrow \cdots \Rightarrow P_n$. This is appropriate, since compactness of N_q likewise percolates up the complex: if N_q is compact, then so is N_{q+1} (an observation due to McNeal ([76]), see also the proof of Lemma 2 in [91]). A detailed study of property (P_1) is in [84],where various equivalent characterizations are given (with some minimal boundary regularity required for

equivalence to the definition we have adopted here, see [47], section 3). In particular, $b\Omega$ satisfies property (P_1) if and only if every continuous function on $b\Omega$ can be approximated uniformly on $b\Omega$ by functions plurisubharmonic in a neighborhood of $b\Omega$.

In $\bar\partial$-problems, the condition that a function be bounded can sometimes be replaced by the condition that the gradient of the function be bounded in the metric induced by the complex Hessian of the function (compare [9] and the references there). In the present context, this was realized by McNeal ([75]). Say that the boundary of the domain Ω satisfies condition $(\tilde P_q)$ if, for every $M > 0$, there exists $\lambda_M \in C^2(U_M \cap \Omega)$, where U_M is an open neighborhood of $b\Omega$, such that the sum of any q eigenvalues of its complex Hessian is at least M, and

$$\sum_K{}' \Big| \sum_{j=1}^n \frac{\partial \lambda_M}{\partial z_j}(z) w_{jK} \Big|^2 \le C \sum_K{}' \sum_{j,k=1}^n \frac{\partial^2 \lambda_M}{\partial z_j \partial \bar z_k}(z) w_{jK} \bar w_{kK} \tag{2.2}$$

for all $w \in \Lambda_z^{(0,q)}$ and $z \in U_M \cap \Omega$, where $\Lambda_z^{(0,q)}$ denotes the space of $(0,q)$-forms at z. (Actually, for $q > 1$, this definition is slightly more general than McNeal's; in particular, it does not force λ_M to be plurisubharmonic.) McNeal ([75]) proved the following theorem.

Theorem 2.1. *Let Ω be a bounded pseudoconvex domain in $\mathbb{C}^n$, $1 \le q \le n$. If Ω satisfies condition $(\tilde P_q)$, then N_q is compact.*

Again note that $\tilde P_1 \Rightarrow \tilde P_2 \Rightarrow \cdots \Rightarrow \tilde P_n$ (compare the proof of Lemma 2 in [91].) Also, there is a weak formulation of (2.2) in terms of currents which is sufficient for Theorem 2.1, see [75] for details.

To prove Theorem 2.1, one uses that compactness of N_q is equivalent to compactness of the canonical solution operators $\bar\partial^* N_q$ and $\bar\partial^* N_{q+1}$ (or their adjoints, see e.g. [47], Lemma 1.1). Since $(\tilde P_q) \Rightarrow (\tilde P_{q+1})$, it suffices to establish compactness of $\bar\partial^* N_q$. We sketch an argument (slightly different from McNeal's) to show how the hypotheses of the theorem enter (as well as for use in Remark 2.2 below). We only consider $(0,1)$-forms for simplicity. Also, we assume that Ω is smooth and that λ_M is smooth up to the boundary (see [88] and [47] for the regularization procedure in the non-smooth case). We may extend λ_M smoothly to all of Ω (by shrinking U_M, where the estimates hold). The starting point is the classical Morrey–Kohn–Hörmander inequality ([23], Proposition 4.3.1, and the density Lemma 4.3.2). Taking the weight function to be λ_M and computing the adjoint of $\bar\partial^*$ in the weighted metric in terms of $\bar\partial^*$ and terms of order zero in u gives for $u \in \mathrm{Ker}(\bar\partial) \cap \mathrm{Dom}(\bar\partial^*)$

$$\int_\Omega \sum_{j,k} \frac{\partial^2 \lambda_M}{\partial z_j \partial \bar z_k} u_j \bar u_k e^{-\lambda_M} \lesssim \|\bar\partial^*(e^{-\lambda_M/2} u)\|^2 + \Big\| e^{-\lambda_M/2} \sum_j \frac{\partial \lambda_M}{\partial z_j} u_j \Big\|^2. \tag{2.3}$$

The constant in (2.2) may be assumed as small as we wish (by scaling $\lambda \to t\lambda$, see [75], p. 199). Therefore, the last term in (2.3) can be absorbed into the left hand side,

for $z \in U_M$. The result is, upon also applying (2.1), using interior elliptic regularity to estimate $\|e^{-\lambda_M/2}u\|^2_{\Omega\setminus\bar U_M}$ (this term controls the various error terms), and absorbing terms:

$$\|e^{-\lambda_M/2}u\|^2 \lesssim \frac{1}{M}\|\bar\partial^*(e^{-\lambda_M/2}u)\|^2 + C_M\|e^{-\lambda_M/2}u\|^2_{-1}, \tag{2.4}$$

when $u \in \mathrm{Ker}(\bar\partial) \cap \mathrm{Dom}(\bar\partial^*)$. Denote by B the standard Bergman projection, and by B_φ the Bergman projection in the weighted space with weight e^φ. Let $v \in \mathrm{Ker}(\bar\partial)$. Then $v = B(e^{-\lambda_M/2}u)$, with $u = B_{-\lambda_M/2}(e^{\lambda_M/2}v) \in \mathrm{Ker}(\bar\partial)$. We obtain

$$\|v\|^2 \lesssim \frac{1}{M}\|\bar\partial^* v\|^2 + C_M\|e^{-\lambda_M/2}B_{-\lambda_M/2}(e^{\lambda_M/2}v)\|^2_{-1}. \tag{2.5}$$

For M fixed, the norm in the last term on the right hand side of (2.5) is compact with respect to $\|v\|$, hence with respect to $\|\bar\partial^* v\|$ (the canonical solution operator to $\bar\partial^*$ is continuous in L^2). Since M is arbitrary, this implies that $(\bar\partial^* N_1)^*$, the canonical solution operator to $\bar\partial^*$, is compact (see e.g [22], Lemma 1, [75], Lemma 2.1). This concludes the (sketch of) proof of Theorem 2.1.

It is easy to see that P_q implies $\tilde P_q$, by considering the family $\mu_M := e^{\lambda_M}$, $M > 0$ (see [75] for details). The exact relationship is however not understood. But there are two classes of domains where property (P_q) is known to be equivalent to compactness of N_q, and hence condition $(\tilde P_q)$ is also equivalent to both compactness of N_q and property (P_q). These are the bounded locally convexifiable domains (with no boundary smoothness assumptions assumed beyond what is implied by local convexifiability (Lipschitz), [46], [47]) and the smooth bounded Hartogs domains in $\mathbb{C}^2$ ([27]). In addition, (P) and $(\tilde P)$ are known to agree for planar domains ([48], Lemma 7). Although condition $(\tilde P_1)$ also appears naturally in connection with another important question in several complex variables, namely with that of the existence of a Stein neighborhood basis for the closure of the domain ([84], (4.4) on p. 317), it is not well studied at all. This is in stark contrast to property (P_q), where we have Sibony's theory ([84], see also [47] when $q > 1$). It would be very interesting to have an analogous treatment of condition $(\tilde P_q)$. Finally, its connection with Stein neighborhoods suggests studying what the implications of compactness in the $\bar\partial$-Neumann problem are for the existence of a Stein neighborhood basis for the closure.

Compactness can be viewed as a limiting case of subellipticity. Subellipticity is equivalent to having a bounded plurisubharmonic function, near the boundary, whose Hessian blows up like a power of the reciprocal of the boundary distance ([21], [88], compare also [50], [55]). The only way to show the direction *subellipticity* $\Rightarrow$ *good plurisubharmonic functions* that the author is aware of is via finite type of the boundary. It would be very interesting to have a direct proof of this fact, arguing directly from the subelliptic estimates and bypassing the geometric arguments related to finite type. If there is a reasonable characterization of compactness in terms of (potential theoretic) properties of the boundary (such as $P/\widetilde{P}$ or a slightly weaker

property), it should emerge from such a proof when one extracts the features that remain valid in the limiting case.

Remark 2.2. Takegoshi gives a sufficient condition for compactness in [95] which is a precursor to condition $(\tilde{P}_1)$, in the sense that it replaces the uniform boundedness condition on the functions in property (P_1) by a boundedness condition on the gradients. In fact, Takegoshi's condition implies $(\tilde{P}_1)$, but with (2.2) only for complex tangential w's. But this is enough to prove Theorem 2.1, because the forms to which one needs to apply the estimates are in the domain of $\bar{\partial}^*$ (see (2.3) above), so they are complex tangential (at points of the boundary, but the normal component of a form satisfies a subelliptic estimate, and so terms caused by it are under control).

We next want to describe a technique for establishing compactness that does not rely on (P)/$(\tilde{P})$, introduced recently by the author ([90]). Such a technique is of interest because it is not understood how much stronger (if at all) $(\tilde{P})$ is than compactness. Also, as will be seen, for domains in $\mathbb{C}^2$, this technique yields a sufficient condition that modulo a certain (albeit crucial) lower bound on certain radii is also necessary.

Let Ω be a smooth bounded pseudoconvex domain in $\mathbb{C}^2$. If Z is a (real) vector field defined in some open subset of $b\Omega$ (or of $\mathbb{C}^2$), we denote by $\mathcal{F}_Z^t$ the flow generated by Z. In $\mathbb{C}^2$, the various notions of finite type coincide (see [32]), so we do not need to specify which notion we mean. Recall that the set of infinite type points in the boundary is compact. Finally, $B(P, r)$ denotes the open ball of radius r centered at P. The following theorem is the main result in [90].

Theorem 2.3. *Let Ω be a smooth bounded pseudoconvex domain in $\mathbb{C}^2$. Denote by K the set of boundary points of infinite type. Assume there exist constants C_1, $C_2 > 0$, and C_3 with $1 \leq C_3 < 3/2$, and a sequence $\{\varepsilon_j > 0\}_{j=1}^{\infty}$ with $\lim_{j\to\infty} \varepsilon_j = 0$ so that the following holds. For every $j \in \mathbb{N}$ and $P \in K$ there is a (real) complex tangential vector field $Z_{P,j}$ of unit length defined in some neighborhood of P in $b\Omega$ with $\max |\operatorname{div} Z_{P,j}| \leq C_1$ such that $\mathcal{F}_{Z_{P,j}}(B(P, C_2(\varepsilon)^{C_3}) \cap K) \subseteq b\Omega \setminus K$. Then the $\bar{\partial}$-Neumann operator on Ω is compact.*

The assumptions in the theorem quantify the notion that at points of K, there should exist a (real) complex tangential direction transversal to K in which $b\Omega \setminus K$ (the good set) is 'thick' enough. A geometrically very simple special case occurs when $b\Omega \setminus K$ satisfies a complex tangential cone condition (that is, the axis of the cone at a point P lies in a complex tangential direction). In this case, the assumptions in the theorem are satisfied with $C_3 = 1$ (see [90] for details).

Corollary 2.4. *Let Ω be a smooth bounded pseudoconvex domain in $\mathbb{C}^2$. Denote by K the set of boundary points of infinite type. Assume that $b\Omega \setminus K$ satisfies a complex tangential cone condition (as an open subset of $b\Omega$). Then the $\bar{\partial}$-Neumann operator is compact.*

The main idea of the proof of Theorem 2.3 is very simple. In order to derive a compactness estimate, what needs to be estimated is the L^2-norm of a form u near K.

To do this near a point P in K, we express u near P in terms of u in a patch which meets the boundary in a relatively compact subset of $b\Omega \setminus K$, plus the integral of the derivative of u in the direction $Z_{P,j}$. The first contribution is easily handled by subelliptic estimates, while the second is dominated by the length of the curve (which is ε_j) times the L^2-norm of $Z_{P,j}u$ on a certain subset of the boundary. But in $\mathbb{C}^2$, this norm is dominated by $\|\bar{\partial}u\| + \|\bar{\partial}^* u\|$, because $Z_{P,j}$ is complex tangential (so called maximal estimates hold, c.f. [37]). When one sums up over the various patches (for a fixed j), overlap as well as divergence issues arise. These are handled by the uniformity built into the assumptions.

The conditions in Theorem 2.3 are natural, and, in fact, modulo the size of the lower bound $C_2(\varepsilon_j)^{C_3}$ on the radius of the balls, necessary. Indeed, if N_1 is compact, the boundary contains no analytic discs (since we are in $\mathbb{C}^2$, see [47] for a proof). This implies, by a result of Catlin ([16], Proposition 3.1.12, see also [82], Lemma 3) that for each point $P \in K$ and for every $\varepsilon > 0$, there is a complex tangential vectorfield $Z_{P,\varepsilon}$ (of unit length) near P so that on the integral curve of $Z_{P,\varepsilon}$ through P there is a strictly pseudoconvex point at distance (measured along the curve) less than ε. Then there is a ball $B(P, r)$ which is transported, for $t = \varepsilon$, by the flow generated by $Z_{P,\varepsilon}$, into the points of finite type: it suffices to take r small enough. Since there are smooth bounded pseudoconvex domains in $\mathbb{C}^2$ without discs in their boundaries, but whose $\bar{\partial}$-Neumann operator is not compact ([74], [47]), this discussion also shows that without a lower bound on r, the conclusion of the theorem does not hold. The lower bound given in Theorem 2.3 is probably not optimal. An 'optimal' bound (if one exists), in a sense to be made precise, would be of great interest: in light of the above discussion, such a bound essentially amounts to a characterization of compactness in the $\bar{\partial}$-Neumann problem on domains in $\mathbb{C}^2$.

Theorem 2.3 does not hold in dimension $n > 2$. Consider a convex domain with a disc in its boundary. When $n > 2$, there is an additional complex tangential direction in which to flow, so that the assumptions in Theorem 2.3 can be satisfied. Yet such domains have noncompact $\bar{\partial}$-Neumann operator ([46]). Since the only place where the proof uses that the domain is in $\mathbb{C}^2$ is the invocation of maximal estimates, an obvious generalization to $\mathbb{C}^n$ is to require the domain to satisfy maximal estimates (equivalently: all the eigenvalues of the Levi form are comparable, see [37]).There is, however, a more interesting generalization in [80]. It suffices to be able to flow into the set of finite type points along curves whose tangents lie in a complex tangential direction associated with the smallest eigenvalue of the Levi form.

The author does not know examples of domains that satisfy the assumptions in Theorem 2.3, but do not satisfy condition $(\tilde{P})$. As far as just asserting compactness of the $\bar{\partial}$-Neumann problem on the domains in the theorem is concerned, it does not matter whether or not these domains always satisfy $(\tilde{P})$: we have, in any case, a simple geometric proof of compactness for these domains. However, from the point of view of understanding to what extent $(\tilde{P})$ is necessary for compactness, this question is obviously very important.

2.2. Obstructions to compactness. An analytic disc in the boundary constitutes the most blatant violation of condition $(\tilde{P})$ (on domains whose boundaries are locally the graph of a continuous function) as well as of the condition in Theorem 2.3. This is obvious for the condition in Theorem 2.3 (recall that the setup is in $\mathbb{C}^2$). For condition $(\tilde{P})$, this can be seen by pulling back (suitable translates of) the plurisubharmonic functions to the unit disc D in the plane: there do not exist subharmonic functions in D satisfying (2.1) and (2.2) for arbitrarily large M (compare Appendix A in [47]). Indeed, integration by parts and (2.2) give for $u \in C_0^\infty(D)$

$$\begin{aligned}\int_D \frac{\partial^2\lambda}{\partial z\partial\bar z}|u|^2 = \int_D \frac{\partial^2\lambda}{\partial z\partial\bar z}u\bar u &\le \left|\int_D \frac{\partial\lambda}{\partial\bar z}\frac{\partial u}{\partial z}\bar u\right| + \left|\int_D \frac{\partial\lambda}{\partial\bar z}u\frac{\partial\bar u}{\partial z}\right| \\ &\le \int_D \left|\frac{\partial\lambda}{\partial\bar z}\right|^2|u|^2 + \int_D\left|\frac{\partial u}{\partial z}\right|^2 \le C\int_D \frac{\partial^2\lambda}{\partial z\partial\bar z}|u|^2 + \int_D\left|\frac{\partial u}{\partial z}\right|^2,\end{aligned} \tag{2.6}$$

where C is the constant from (2.2). We have used here that $\|\partial u/\partial\bar z\|^2 = \|\partial u/\partial z\|^2$. As pointed out earlier, C may be taken as small as we wish. Taking a family with $C = 1/4$ in (2.2) (hence in (2.6)) and combining with (2.1) gives

$$\frac{M}{4} \le \inf_{u\in C_0^\infty(D)} \frac{\int_D \left|\frac{\partial u}{\partial z}\right|^2}{\int_D |u|^2}. \tag{2.7}$$

(The infimum on the right hand side of (2.7) is (up to a factor $1/4$) the smallest eigenvalue of the Dirichlet realization of $-\Delta$ on D.) In the case of property (P), this is of course also an obvious consequence of its characterization (see above) by the approximation property by continuous functions. A disc in the boundary is also known to be an obstruction to hypoellipticity of $\bar\partial$ ([17], [42]). It is therefore very natural to ask whether such a disc is an obstruction to compactness of the $\bar\partial$-Neumann operator.

An old folklore result, usually attributed to Catlin, says that this is indeed the case for sufficiently regular domains in $\mathbb{C}^2$. A proof for the case of Lipschitz boundary may be found in [47]. There, a simple example (the unit ball in $\mathbb{C}^2$ minus the variety $\{z_1 = 0\}$) is given that shows that some boundary regularity is needed. Whether for domains in $\mathbb{C}^2$ there can be other obstructions to compactness was resolved only surprisingly recently. Matheos ([74]) showed that there are indeed more subtle obstructions:

Theorem 2.5. *Let K be a compact subset of the complex plane with non-empty fine interior, but empty Euclidean interior. There exists a smooth bounded complete pseudoconvex Hartogs domain in $\mathbb{C}^2$ with the following properties:* (i) *its set of weakly pseudoconvex boundary points projects onto K;* (ii) *it contains no analytic discs in its boundary;* (iii) *its $\bar\partial$-Neumann operator is not compact.*

For properties of the fine topology, see e.g. [53], [48], section 3; in particular, there do exist (many) sets K as in the theorem (an explicit construction of such sets may also

be found in section 4 of [27]). The version of the theorem given here comes from [47], to where we refer the reader for details (compare also [27]). Note in particular that this also means that there are more subtle obstructions to property (P)/condition $(\tilde P)$ than discs in the boundary. This was known before, see [84].

Remark 2.6. It is easy to see that on a smooth bounded complete pseudoconvex Hartogs domain in $\mathbb{C}^2$, there is no disc in the boundary if and only if the projection of the weakly pseudoconvex boundary points has empty Euclidean interior. It will be seen in Subsection 2.3 below that the $\bar\partial$-Neumann operator is compact if and only if this set has empty fine interior (as a compact subset of $\mathbb{C}$); see the discussion following Theorem 2.11.

Remark 2.7. Whether on a smooth bounded pseudoconvex domain in $\mathbb{C}^2$ the absence of discs from the boundary implies global regularity is open.

It is folklore that the methods that work in $\mathbb{C}^2$ can be used in $\mathbb{C}^n$ to show that when the $\bar\partial$-Neumann operator N_1 is compact, the boundary cannot contain an $(n-1)$-dimensional complex manifold. However, whether a disc is necessarily an obstruction is open in general, and is arguably the most important problem concerning compactness. Şahutoğlu and the author recently showed that when the disc contains a point at which the boundary is strictly pseudoconvex in the directions transverse to the disc ([82]), then compactness does fail. This holds more generally for complex submanifolds of the boundary of arbitrary (positive) dimension.

Theorem 2.8. *Let Ω be a smooth bounded pseudoconvex domain in $\mathbb{C}^n$, $n \geq 2$. Let $p \in b\Omega$ and assume that the Levi form of $b\Omega$ at P has the eigenvalue zero with multiplicity at most k, $1 \leq k \leq n-1$ (i.e. the rank is at least $n-1-k$). If the $\bar\partial$-Neumann operator on $(0,1)$-forms is compact, then $b\Omega$ does not contain a k-dimensional complex manifold through P.*

It follows immediately from the theorem that if the set K of weakly pseudoconvex boundary points has nonempty relative interior in the boundary, then the $\bar\partial$-Neumann operator (on $(0,1)$-forms) is not compact ([82]). It suffices to observe that near a relative interior point of K where the Levi form attains its maximal rank (among points of the relative interior of K), say m, the rank has to be constant, so that the boundary is foliated there by complex manifolds of dimension $n-1-m$. Note that in general, K is considerably bigger than the set of Levi *flat* points.

The proof of Theorem 2.8 results from the following ideas. Compactness is a local property (see [47], Lemma 1.2). Therefore, it suffices to argue locally. Assume the boundary contains a complex manifold, say M. There is a holomorphic change of coordinates near P so that in the new coordinates M is affine, and the real normal to the boundary of Ω is constant on M. This is always possible ([82], Lemma 1). Next, consider a section Ω_1 of Ω through P, perpendicular to M. If Ω_1 has a subdomain Ω_2, whose boundary shares P with $b\Omega$ and such that (i) the restriction operator from the Bergman space of Ω_1 to the Bergman space of Ω_2 is not compact, and (ii) the product

$\Omega_2 \times M$ is contained in Ω (near P), then the arguments from [46] (which in turn are based on ideas from [17], [42]) carry over to produce a contradiction to the existence of a compact solution operator to $\bar\partial$ (which would be a consequence of compactness of N_1). In the situation of Theorem 2.8, any smooth subdomain Ω_2 will do, because Ω_1 is strictly pseudoconvex at P ([82], Lemma 2). If we take for Ω_2 a ball with small radius and tangent to $b\Omega_1$ at P, (ii) also holds (because the real normal to $b\Omega$ is constant along M).

Experience indicates that a flatter boundary should be even more favorable to noncompactness of the $\bar\partial$-Neumann operator. In other words, the extra assumption that the boundary is strictly pseudoconvex in the directions transverse to M should not be needed. However, the present methods do not seem to yield this. An interesting recent contribution to this circle of ideas, involving the Kobayashi metric of the domain, is in [62].

The above proof of Theorem 2.8 also raises a question of independent interest. Namely given a domain Ω and a subdomain Ω_1, when is the restriction operator from the Bergman space of Ω to that of Ω_1 compact? Of course, this happens when Ω_1 is relatively compact in Ω, so the case of interest is that where the domains share a boundary point. As mentioned above, this restriction is known not to be compact when Ω is smooth near a strictly pseudoconvex boundary point P and $b\Omega_1$ shares P with $b\Omega$ and is smooth there ([82], Lemma 2). In addition, this restriction is known not to be compact when Ω is convex, $P = 0 \in b\Omega$, and $\Omega_1 = r\Omega$, for $r < 1$ ([46]). The general situation is not understood.

2.3. Hartogs domains in $\mathbb{C}^2$ and semi-classical analysis of Schrödinger operators. It is well known that $\bar\partial$ and related operators on Hartogs domains can be studied by means of weighted operators on the base domain. In the sequel, the base domain U will be a planar domain (i.e. the Hartogs domain is in $\mathbb{C}^2$). The resulting weighted problems lead to Schrödinger operators on U, see for example [8] and the references there.

Let U be a bounded domain in $\mathbb{C}$, $\phi(z) \in C^2(\overline{U})$. Denote by S_ϕ the Schrödinger operator with magnetic potential $A = -(\partial\phi/\partial y)dx + (\partial\phi/\partial x)dy$, magnetic field $dA = \Delta\phi(dx \wedge dy)$, and electric potential $V = \Delta\phi$. That is, S_ϕ is given by (the Dirichlet realization of)

$$S_\phi = -\left[(\partial/\partial x + i\partial\phi/\partial y)^2 + (\partial/\partial y - i\partial\phi/\partial x)^2\right] + \Delta\phi. \tag{2.8}$$

Denote by S_ϕ^0 the corresponding nonmagnetic Schrödinger operator, given by (the Dirichlet realization of)

$$S_\phi^0 = -\Delta + \Delta\phi. \tag{2.9}$$

For (very) brief introductions to Schrödinger operators, we refer the reader to [48], section 2 or [27], section 2.3. For a detailed treatment in the context of semi-classical analysis relevant here, see [52].

Let Ω be a bounded complete pseudoconvex Hartogs domain in $\mathbb{C}^2$ given by $\Omega = \{(z, w) \in \mathbb{C}^2 : z \in U, |w| < e^{-\phi(z)}\}$, where U is a domain in $\mathbb{C}$. Note that

pseudoconvexity forces ϕ to be plurisubharmonic. Also, smoothness of Ω means that ϕ is smooth on U, but not on $\overline{U}$, but the notions needed here are still well defined, compare [48], [27]. The rotation invariance in the w variable brings a discrete Fourier variable into play, and so what one actually has when analyzing the $\bar{\partial}$ and related problems on Hartogs domains are sequences of Schrödinger operators of the form $\{S_{n\phi}\}_{n=1}^{\infty}$ and $\{S^0_{n\phi}\}_{n=1}^{\infty}$, respectively (see [48] for details). Compactness of the $\bar{\partial}$-Neumann operator on Ω is closely linked to the behavior of the sequence of lowest eigenvalues $\{\lambda_{n\phi}\}_{n=1}^{\infty}$ (the ground state energies) of the magnetic Schrödinger operators, while property (P) of $b\Omega$ is similarly linked to the behavior of the sequence $\{\lambda^0_{n\phi}\}_{n=1}^{\infty}$ of lowest eigenvalues of their nonmagnetic counterparts. The former idea originates with [74], the latter with [48]. The precise relationships are given in the following theorem ([48]).

Theorem 2.9. *Let $\Omega = \{(z, w) \in \mathbb{C}^2 : |w| < e^{-\phi(z)}, z \in U\}$ be a smooth bounded complete pseudoconvex Hartogs domain. Suppose that $b\Omega$ is strictly pseudoconvex on $b\Omega \cap \{w = 0\}$. Then*

(1) *$b\Omega$ satisfies property (P) if and only if $\lambda^0_{n\phi} \to \infty$ as $n \to \infty$.*

(2) *The $\bar{\partial}$-Neumann operator on Ω is compact if and only if $\lambda_{n\phi} \to \infty$.*

We remark that for the domains in Theorem 2.9, property (P) and property $(\tilde{P})$ are equivalent ([48], Lemma 6). It was already noted in [48] that for some of the implications, regularity of the boundary is not needed. For a version of Theorem 2.9 that assumes very little regularity of ϕ, see [27].

It is the limit in part (2) of Theorem 2.9 that gives rise to the terminology used in the title of this subsection. Note that $S_{n\phi} = -n^2[((1/n)(\partial/\partial x) + i(\partial\phi/\partial y))^2 + ((1/n)(\partial/\partial y) - i(\partial\phi/\partial x))^2] + n\Delta\phi$. Understanding the behavior of the ground state energy as n tends to infinity is thus analogous to understanding (modulo the factor n^2) what happens when 'Planck's constant' $h = 1/n$ tends to zero. This situation is typically referred to as semi-classical analysis in the mathematical physics literature. Mathematical physics also has its own version of (1) $\Rightarrow$ (2): Simon's diamagnetic inequality asserts that $\lambda^0_{n\phi} \leq \lambda_{n\phi}$ ([85], see also [61]). Reverse relationships, when there is some kind of domination of the magnetic eigenvalues by the nonmagnetic ones, obviously of interest in our context, are known in the physics literature as paramagnetism. For more thorough discussions of these topics, we refer again to [52], [48], and [27], and their references.

This point of view has allowed to clarify the relationship between property (P) and compactness of the $\bar{\partial}$-Neumann operator on the (special) class of Hartogs domains in $\mathbb{C}^2$. Namely, Christ and Fu recently established the paramagnetic property required for the implication (2) $\Rightarrow$ (1) in Theorem 2.9.

Theorem 2.10. *Let ϕ be subharmonic on the domain $U \subseteq \mathbb{C}$, and let $\Delta\phi$ be Hölder continuous of some positive order. If $\sup_n \lambda^0_{n\phi} < \infty$ then $\liminf_{n\to\infty} \lambda_{n\phi} < \infty$.*

Since the sequence $\{\lambda^0_{n\phi}\}_{n=1}^{\infty}$ is increasing (this is obvious from (2.9); ϕ is subharmonic), we immediately get the corollary that on the domains from Theorem 2.9, property (P) and compactness of the $\bar\partial$-Neumann operator are equivalent. In fact, combining this with some additional work, Christ and Fu ([27]) were able to handle general (not necessarily complete) Hartogs domains, thus establishing the following equivalence.

Theorem 2.11. *Let $\Omega \subseteq \mathbb{C}^2$ be a smooth bounded pseudoconvex Hartogs domain. The $\bar\partial$-Neumann operator on Ω is compact if and only if $b\Omega$ satisfies property (P).*

While we have not made an effort to state Theorem 2.11 with optimal boundary smoothness assumptions (see [27]), we point out that in view of the example mentioned before the statement of Theorem 2.5, some boundary regularity is needed for the equivalence in Theorem 2.11 to hold. If the Hartogs domain is complete, then the two properties in Theorem 2.11 are also equivalent to the set K (as defined above) having empty fine interior, by work of Sibony. Namely, $b\Omega$ satisfies property (P) if and only if K does (as a subset of $\mathbb{C}$, [84], p. 310). In turn, K satisfies property (P) if and only if it has empty fine interior ([84], Proposition 1.11).

3. Global regularity

The $\bar\partial$-Neumann operator N_q is said to be globally regular if it maps $C^\infty(0,q)(\overline{\Omega})$ (necessarily continuously) into itself. It is said to be exactly regular if it maps $W^s_{(0,q)}(\Omega)$ into itself for $s \geq 0$. Exact regularity implies of course global regularity. So far, in all instances where one can prove global regularity, one actually proves exact regularity. On the worm domains, failure of global regularity ([24]) is proved via failure of exact regularity ([3]): for most s, exact a priori estimates hold in $W^s(\Omega)$, and global regularity would then give exact regularity. It is consistent with what is known that such a priori estimates might hold on all domains (they are also known to hold on the nonpseudoconvex counterexample domains from [2], see [12]).

For a survey of results up to about ten years ago, we refer he reader to [14]. In this section, we first discuss regularity on domains whose boundary contains an open patch foliated by complex hypersurfaces ([93], [45]. In Subsection 3.2, we describe a unified approach to global regularity ([92], [91]).

We recall the following important 1-form on the boundary of a domain. Let Ω be a smooth bounded pseudoconvex domain. Denote by η a purely imaginary nowhere vanishing 1-form on $b\Omega$ that annihilates the complex tangent space and its conjugate. Let T denote the purely imaginary vector field on $b\Omega$ orthogonal to the complex tangent space and its conjugate and such that $\eta(T) \equiv 1$. The real 1-form α is defined by $\alpha = -\mathcal{L}_T\eta$, the Lie derivative of η in the direction of T (compare [31], [32]). The form arises naturally in the computation of (normal components of) commutators of vector fields; indeed, if $\eta = \partial\rho - \bar\partial\rho$, and $\overline{X}$ is a local section of $T^{0,1}(b\Omega)$,

then $\alpha(\overline{X}) = 2\partial\rho([L_n, \overline{X}])$ (L_n is the complex normal). The cohomology class on complex submanifolds of the boundary mentioned in the introduction in connection with [13] is the class of α.

3.1. A foliation in the boundary. Background on foliation theory and notions used here can be found in [15] and [96], as well as in [93], [45], and their references. Assume now there is a codimension one foliation in the boundary, say the relative interior of the set K of weakly pseudoconvex points is foliated by complex manifolds of dimension $n-1$. Note that such a foliation is always transversely orientable (by the vector field T defined on all of $b\Omega$). In order to run the machinery from [11], [13], one needs a function h smooth in a relative neighborhood of K, satisfying

$$dh|_L = \alpha|_L, \quad \text{for all leaves } L. \tag{3.1}$$

For details, see [93]. Of course, this requires that the restriction of α to a leaf is closed. This does indeed hold: $d\alpha|_{\mathcal{N}_P} = 0$ always, where $\mathcal{N}_P$ is the null space of the Levi form at P, see the lemma in section 2 of [13]. Thus solving (3.1) is always possible locally. Globally, topological constraints arise. Also, the boundary behavior of h on K needs to be controlled.

It turns out that these issues are very much related to ones studied in foliation theory. Note that the foliation can be defined by η: the tangent planes to the leaves are given by the null space of η. Then the Frobenius condition reads $d\eta \wedge \eta = 0$. Hence $d\eta = \beta \wedge \eta$ for some 1-form β. α is such a form, that is

$$d\eta = \alpha \wedge \eta \quad \text{on } K \tag{3.2}$$

([96], Proposition 2.2). With (3.2), solving (3.1) is easily tied to an important property in foliation theory ([93]).

Lemma 3.1. (3.1) *can be solved* (*say on the relative interior of* K) *if and only if the Levi foliation of* K *can be defined* globally *by a* closed 1*-form.*

Indeed, if ω is a 1-form defining the foliation, then $\omega = e^{-h}\eta$, and

$$d\omega = d(e^{-h}\eta) = e^{-h}(-dh \wedge \eta + d\eta) = e^{-h}(-dh + \alpha) \wedge \eta. \tag{3.3}$$

Therefore,

$$d\omega = 0 \Leftrightarrow (-dh + \alpha) \wedge \eta = 0 \Leftrightarrow -dh|_L + \alpha|_L = 0. \tag{3.4}$$

In addition to closedness of $\alpha|_L$, solvability of (3.1) also requires that the De Rham cohomology class of $\alpha|_L$ vanishes. This again fits nicely into the foliation framework: this cohomology class coincides with the infinitesimal holonomy of L ([93], Remark 2, [15], Example 2.3.15).

We first present a result in $\mathbb{C}^2$ from [93]. The relative boundary of K in $b\Omega$, say Γ, is assumed smooth, and so is a smooth compact orientable surface embedded in $\mathbb{C}^2$.

Recall that a complex tangency at a point of Γ is called generic if it is either elliptic or hyperbolic (see [93] for more information). Note that at a hyperbolic point there are locally two leaves that meet.

Theorem 3.2. *Let Ω be a smooth bounded pseudoconvex domain in $\mathbb{C}^2$. Suppose that the set K of infinite type points of $b\Omega$ is smoothly bounded (in $b\Omega$) and that its boundary Γ is connected and has only isolated generic complex tangencies. Assume that the two leaves meeting at a hyperbolic point are distinct globally and that they have no other hyperbolic points in their closure (in K). If each leaf of the Levi foliation is closed (in the relative interior of K) and has trivial infinitesimal holonomy, then the $\bar\partial$-Neumann operator on Ω is continuous on $W^s_{(0,1)}(\Omega)$ for $s \geq 0$.*

If one assumes that the Levi foliation of K is part of a foliation of a bigger smooth Levi flat hypersurface M, with $M \cap \overline{\Omega} = K$, then boundary behavior of the leaves is easier to control, and one needs no conditions on the boundary of K. This results in a geometrically appealing sufficient condition. The following theorem is from [45]. A codimension one foliation is called simple if through every point there exists a local transversal (a line) that meets each leaf at most once.

Theorem 3.3. *Let $\Omega \subseteq \mathbb{C}^n$ be a smooth bounded pseudoconvex domain such that the set K of all boundary points of infinite D'Angelo-type is the closure of its relative interior in $b\Omega$. Assume K is contained in a smooth Levi-flat (open) hypersurface $M \subset \mathbb{C}^n$, whose Levi foliation satisfies one (hence both) of the following equivalent conditions:* (i) *the leaves of the restriction of the foliation to a neighborhood of K are topologically closed;* (ii) *the foliation is simple in a neighborhood of K. Then the $\bar\partial$-Neumann operators N_q on Ω are continuous in $W^s_{(0,q)}(\Omega)$ for $s \geq 0$, $1 \leq q \leq n$.*

Very roughly speaking, in both Theorems 3.2 and 3.3, one would like to obtain a closed form that defines the foliation by pulling back from the leaf space (which is one dimensional) a form roughly like dx. One then has to deal with the non-Hausdorff nature of this space. In Theorem 3.2, one also has to control the boundary behavior.

It is interesting to note that the main concern in [45] is not the $\bar\partial$-Neumann problem, but rather holomorphic convexity properties of compact subsets of M. The authors use asymptotically pluriharmonic defining functions for M (near a compact subset) for constructing Stein neighborhoods, and whether such defining functions exist leads precisely to the question whether the foliation, near the compact set (globally), can be defined by a closed 1-form. In view of Lemma 3.1, this is related to the equivalence between 'pluriharmonic defining functions' and 'exactness of α' in [92] (see Theorem 3.4 below). In a local context, compare also [4].

The two equivalent conditions in Lemma 3.1 are equivalent to a third one, given in terms of the flow generated by T ([93], Proposition 2). This is at least potentially of interest because the condition is in terms of T, (rather than the Levi foliation), which is well defined on the boundary of any smooth domain. Furthermore, this leads to a homological necessary and sufficient condition for the existence of a function

$h \in C^\infty(K)$ as above ([93], Theorem 3), in terms of foliation currents ([94], [15]) associated to T.

3.2. Sufficient conditions for global regularity. In [13], Remark 3 in section 4, the authors point out that the families of vector fields with good approximate commutator conditions with $\bar\partial$, required in their approach to global regularity ([11], [13]) can exist in situations where the domain does not admit (even a local) plurisubharmonic defining function. On the other hand, they had noted in [11] that it suffices to have the commutator conditions with components of $\bar\partial$ in directions that lie in the null space of the Levi form. For this, positivity of the Hessian of a defining function at a boundary point is needed only on the span of the null space of the Levi form and the complex normal. The situation was cleared up in [92]: the authors showed that the vector fields and the plurisubharmonic defining functions approaches can be reformulated naturally and then become equivalent.

Let Ω be a smooth bounded pseudoconvex domain. Say that Ω admits a family of essentially pluriharmonic defining functions if there exists a family $\{\rho_\varepsilon\}_{\varepsilon>0}$ of defining functions with gradients bounded and bounded away from zero on $b\Omega$ uniformly in ε, such that the complex Hessian of ρ_ε is $O(\varepsilon)$ on the span, over $\mathbb{C}$, of $\mathcal{N}_P$ and $L_n(P)$, for all $P \in b\Omega$. We emphasize that this notion is indeed a generalization of the notion of a pluri*sub*harmonic defining function (see [92]). We say that the form α (see above) is approximately exact on the null space of the Levi form if there exists a family $\{h_\varepsilon\}_{\varepsilon>0}$ of functions smooth in neighborhoods U_ε of the set K of boundary points of infinite D'Angelo type, bounded uniformly in ε, such that $dh|_{\mathcal{N}_P} = \alpha|_{\mathcal{N}_P} + O(\varepsilon)$ for all $P \in K$. A family of conjugate normals which are approximately holomorphic in weakly pseudoconvex directions is defined similarly; see [92], where Sucheston and the author established the following equivalence (compare also the remarks in section 5 of [91] concerning (iii)).

Theorem 3.4. *Let Ω be a smooth bounded pseudoconvex domain in $\mathbb{C}^n$. The following are equivalent:*

(i) *Ω admits a family of essentially pluriharmonic defining functions.*

(ii) *Ω admits a family of conjugate normals which are approximately holomorphic in weakly pseudoconvex directions.*

(iii) *Ω admits a family of vector fields as in* [13].

(iv) *The form α is approximately exact on the null space of the Levi form.*

The equivalence to condition (ii) is of interest because the existence of such a family leads, under favorable circumstances (K is uniformly H-convex), to the existence of transverse vector fields *holomorphic in a neighborhood of K*, and these lead to Stein neighborhood bases for $\overline{\Omega}$ and to Mergelyan type approximation ([44], [92], [45]).

Theorem 3.4 shows that the approaches to global regularity in the $\bar\partial$-Neumann problem through plurisubharmonic defining functions and through good vector fields

are really equivalent. Left unanswered was the question of how to unify this approach with that via compactness. This is achieved in the following theorem from [91].

Theorem 3.5. *Let Ω be a smooth bounded pseudoconvex domain in $\mathbb{C}^n$, ρ a defining function for Ω. Let $1 \leq q \leq n$. Assume that there is a constant C such that for all $\varepsilon > 0$ there exists a defining function ρ_ε for Ω and a constant C_ε with*

$$1/C < |\nabla \rho_\varepsilon| < C \quad \text{on } b\Omega, \tag{3.5}$$

and

$$\Big\| \sum_{|K|=q-1}{}' \Big(\sum_{j,k=1}^{n} \frac{\partial^2 \rho_\varepsilon}{\partial z_j \partial \overline{z}_k} \frac{\partial \rho}{\partial \overline{z}_j} \bar{u}_{kK} \Big) d\overline{z}_K \Big\|^2 \leq \varepsilon \big(\|\bar{\partial} u\|^2 + \|\bar{\partial}^* u\|^2 \big) + C_\varepsilon \|u\|_{-1}^2 \tag{3.6}$$

for all $u \in C^\infty_{(0,q)}(\overline{\Omega}) \cap \mathrm{Dom}(\bar{\partial}^*)$. Then

$$\|N_q u\|_s \leq C_s \|u\|_s, \tag{3.7}$$

for $s \geq 0$ and all $u \in W^s_{(0,q)}(\Omega)$.

Notice that the assumptions in Theorem 3.5 are for q-forms, q fixed. It is not hard to see that when they are satisfied at level q, then they are satisfied at level $q+1$ ([91], Lemma 2). It would be interesting to know whether global regularity similarly moves up to higher form levels (recall from Section 2 that subellipticity and compactness do).

The simplest situation occurs when there is one defining function, say ρ, that works for all ε. This covers the case when N_q is compact: the left hand side is in this case bounded by $\|u\|^2$ independently of ε, and compactness says precisely that $\|u\|^2$ can be bounded in the manner required by the right hand side of (3.6) (this is the right hand side of a compactness estimate).

When Ω admits a defining function ρ that is plurisubharmonic at the boundary, $\rho_\varepsilon = \rho$ for all ε also works. Assume $q = 1$ for the moment. Applying the Cauchy-Schwarz inequality to the left hand side of (3.6) at boundary points gives that this left hand side is dominated by $\sum(\partial^2 \rho / \partial z_j \partial \overline{z}_k) u_j \bar{u}_k$ plus a term of order ρ plus a compactly supported term. The latter two are benign for (3.6). Estimating the former in the way required in (3.6) can be done via subelliptic multiplier properties of the Levi matrix ([34], Lemma 4.1), or via the Kohn–Morrey formula (see [91] for details). When $q > 1$, one can reformulate (3.6) so that the left hand side of the inequality involves a pairing between q-forms ([91], Lemma 1), and the above argument works under the weaker assumption that the sum of any q eigenvalues of the Hessian of ρ is nonnegative. In view of the equivalence results in [10], this recovers, in the pseudoconvex case, a recent result of Herbig–McNeal ([56]), where the authors prove Sobolev estimates for the Bergman projection on j-forms, $q-1 \leq j \leq n$, under this weaker assumption.

More generally, the sufficient conditions for global regularity from Theorem 3.4 imply those in Theorem 3.5:

Proposition 3.6. *Let Ω be a smooth bounded pseudoconvex domain in $\mathbb{C}^n$. Assume that Ω satisfies one (hence all) of the equivalent conditions in Theorem* 3.4. *Then the assumptions in Theorem* 3.5 *are satisfied for $q = 1, 2, \ldots, n$.*

We indicate what is involved, details are in [91], Proposition 1. Assume (i) in Theorem 3.4. It suffices to consider the case $q = 1$. Fix ε. Then $L_{\rho_\varepsilon}(z)(w) = O(\varepsilon)|w|^2$ when (z, w) is in a neighborhood U_ε of the compact subset $\{(z, w) : w \in \mathcal{N}_z\}$ of the unit sphere bundle in $T^{1,0}(b\Omega)$. Here, L_g denotes the complex Hessian of a function g. There is a constant C_ε such that $|w|^2 \le C_\varepsilon L_{\rho_\varepsilon}(z)(w)$ when $(z, w) \notin U_\varepsilon$. This implies the estimate, when $z \in b\Omega$, $w \in T^{1,0}(b\Omega)$:

$$\Big| \sum_{j,k=1}^{n} \frac{\partial^2 \rho_\varepsilon}{\partial z_j \partial \bar z_k}(z) \frac{\partial \rho}{\partial \bar z_j}(z) \bar w_k \Big|^2 \le C\varepsilon |w|^2 + \widetilde{C_\varepsilon} \sum_{j,k=1}^{n} \frac{\partial^2 \rho_\varepsilon}{\partial z_j \partial \bar z_k}(z) w_j \bar w_k \tag{3.8}$$

(since both terms on the right are nonnegative). By continuity and homogeneity, (3.8) holds near (depending on ε) the boundary. To verify (3.6) for $u \in C^\infty_{(0,1)}(\overline{\Omega})$, it suffices to apply (3.8) to u pointwise, near the boundary (the normal component of u is zero only on the boundary, but it satisfies a subelliptic estimate, so is under control). In view of the discussion preceding the statement of Proposition 3.6, integration over Ω now gives (3.6).

It should not be surprising that condition (3.6) has a potential theoretic flavor: global regularity probably is not determined by geometric conditions alone (unlike the much stronger property of subellipticity). However, it is not hard to extract a geometric sufficient condition from (3.6), compare [91], section 2. What one arrives at is precisely condition (i) in Theorem 3.4. In other words, *the vector field approach constitutes* what might be called *the geometric content of Theorem* 3.5.

It is noteworthy that whether or not a family of defining functions satisfies (3.5) and (3.6) is determined entirely by the interplay of the gradients with the boundary. That is, if a family $\{\rho_\varepsilon\}_{\varepsilon>0}$ satisfies (3.5) and (3.6), and $\{\widetilde{\rho_\varepsilon}\}_{\varepsilon>0}$ is another family such that $\nabla(\widetilde{\rho_\varepsilon}) = \nabla(\rho_\varepsilon)$ for all ε and all $z \in b\Omega$, then $\{\widetilde{\rho_\varepsilon}\}_{\varepsilon>0}$ also satisfies (3.5) and (3.6) (possibly after rescaling). For details, see [91], Remark 2.

At the level of a priori estimates, a proof of Theorem 3.5 follows from a small modification of the ideas in [11], [13]. We briefly indicate what changes, keeping the general setup from [11]. This will show how (3.6) enters into the estimates. Set $X_\varepsilon = e^{-h_\varepsilon} \sum (\partial\rho/\partial\bar z_j)(\partial/\partial z_j)$, where h_ε is defined by $\rho_\varepsilon = e^{h_\varepsilon}\rho$, and ρ is a defining function with normalized gradient (all of this is near $b\Omega$, away from $b\Omega$, any smooth continuation will do). For the Bergman projection P, the key quantity to be estimated is

$$\|\varphi(X_\varepsilon - \overline{X}_\varepsilon)Pf\|^2 \lesssim \big(N_1 \bar\partial f, \varphi^2 (X_\varepsilon - \overline{X}_\varepsilon)[\bar\partial, X_\varepsilon - \overline{X}_\varepsilon]Pf\big) + \text{o.k.}, \tag{3.9}$$

where 'o.k.' stands for terms that are under control or can be absorbed, and φ is a smooth cutoff function supported near the boundary (see [11], p. 83–84). One needs to control the normal component of the commutator in (3.9). In contrast to [11], we

do not have a pointwise estimate on this normal component. But there is some slack built into the argument in [11], in that there the contribution from the commutator of $X_\varepsilon - \overline{X}_\varepsilon$ with each component of $\bar\partial$ is estimated separately. If one takes this into account, computing the commutator gives the main term (after integrating $X_\varepsilon - \overline{X}_\varepsilon$ back to the left)

$$\Big(\sum_{j,k=1}^{n} \frac{\partial^2 \rho_\varepsilon}{\partial z_j \partial \overline{z}_k} \big((X_\varepsilon - \overline{X}_\varepsilon) N_1 \bar\partial f \big)_j \frac{\partial \rho}{\partial z_k},\ X_\varepsilon P f \Big) \tag{3.10}$$

(as opposed to estimating $\sum_{k=1}^n \cdots$ for each j, $j = 1, \ldots, n$). The term in the left hand side of this inner product is now (the conjugate of) one to which (3.6) can be applied. (As usual, we let $X_\varepsilon - \overline{X}_\varepsilon$ act in special boundary charts so that it preserves $\mathrm{Dom}(\bar\partial^*)$.) Note that $X_\varepsilon = e^{h_\varepsilon} L_n$, and that e^{h_ε} is bounded independently of ε. Consequently (by (3.6)), the square of the L^2-norm of this term is dominated by

$$\begin{aligned} \varepsilon \big(\|\bar\partial (L_n - \overline{L_n}) N_1 \bar\partial f\|^2 + \|\bar\partial^* (L_n - \overline{L_n}) N_1 \bar\partial f\|^2 \big) + C_\varepsilon \|(L_n - \overline{L_n}) N_1 \bar\partial f\|_{-1}^2 \\ \lesssim \varepsilon \big(\|N_1 \bar\partial f\|_1^2 + \|\bar\partial^* N_1 \bar\partial f\|_1^2 \big) + C_\varepsilon \|f\|^2. \end{aligned} \tag{3.11}$$

From here on, the argument proceeds as in [11]; in particular, in the setup of the downward induction on q there, $N_1 \bar\partial$ is 'as good as' P. Absorbing terms, one arrives at the required a priori estimate (compare p. 84–85 in [11]).

The situation changes rather markedly with regard to genuine estimates. In [11], the authors simply observe that the estimates can be carried out uniformly on suitable approximating strictly pseudoconvex subdomains, by using the same family of vector fields. By contrast, the assumptions in Theorem 3.5 do not seem strong enough to be inherited by these approximating subdomains. Therefore, one has to employ some other regularization procedure, such as elliptic regularization. This makes the argument considerably more involved, and the author derives in [91] certain needed new estimates for the regularized operators. This is also in contrast to [23], where the results of [11] are proved working directly with the $\bar\partial$-Neumann operator and using elliptic regularization. There too it is the strength of the pointwise estimates on the size of the normal component of the commutators that makes elliptic regularization routine (once the derivation of the a priori estimates is in place).

Note that to get estimates at a fixed Sobolev level k, it suffices to have (3.6) in Theorem 3.5 for some $\varepsilon = \varepsilon(k)$. Kohn ([68]) has proved estimates where the level in the Sobolev scale up to which estimates hold is tied to the Diederich–Fornæss exponent ([39]) of the domain. The discussion above of Proposition 3.6, combined with [89], where the plurisubharmonicity of $-\log(-\rho)$ is exploited, suggests that it should be possible to obtain results of this type by the methods in [91].

Remark 3.7. Consider the operator A_ρ from $\mathrm{Dom}(\bar\partial) \cap \mathrm{Dom}(\bar\partial^*)$, provided with the graph norm, to $L^2(\Omega)$, given by

$$A_\rho(u) = \sum_{j,k=1}^{n} \frac{\partial^2 \rho}{\partial z_j \partial \bar z_k} \frac{\partial \rho}{\partial \bar z_j} \bar u_k, \quad u \in \mathrm{Dom}(\bar\partial) \cap \mathrm{Dom}(\bar\partial^*). \tag{3.12}$$

Then (3.6) holds with $\rho_\varepsilon = \rho$ for all ε precisely when A_ρ is compact (see e.g. [22], Lemma 1, [75], Lemma 2.1). The form of A_ρ suggests that one study sesquilinear forms that produce compact operators via (3.12). It is possible that there is a theory of 'compactness multipliers'. We mention that compactness of A_ρ for a suitable defining function ρ is considerably weaker than compactness of N_1. It holds on all convex domains (since they admit a plurisubharmonic defining function), yet N_1 is compact (if and) only if the boundary of the domain contains no analytic disc ([46]).

Greedy approximations with regard to bases

Vladimir N. Temlyakov

Abstract. This paper is a survey of recent results on greedy approximations with regard to bases. The theory of greedy approximations is a part of nonlinear approximations. The standard problem in this regard is the problem of m-term approximation where one fixes a basis and seeks to approximate a target function by a linear combination of m terms of the basis. When the basis is a wavelet basis or a basis of other waveforms, then this type of approximation is the starting point for compression algorithms. We are interested in the quantitative aspects of this type of approximation. Introducing the concept of best m-term approximation we obtain a lower bound for the accuracy of any method providing m-term approximation. It is known that a problem of simultaneous optimization over many parameters (like in best m-term approximation) is a very difficult problem. We would like to have an algorithm for constructing m-term approximants that adds at each step only one new element from the basis and keeps elements of the basis obtained at the previous steps. The primary object of our discussion is the Thresholding Greedy Algorithm (TGA) with regard to a given basis. The TGA, applied to a function f, picks at the mth step an element with the mth biggest coefficient (in absolute value) of the expansion of f in the series with respect to the basis. We show that this algorithm is very good for a wavelet basis and is not that good for the trigonometric system. We discuss in detail the behavior of the TGA with regard to the trigonometric system. We also discuss one example of an algorithm from a family of very general greedy algorithms that works in the case of a redundant system instead of a basis. It turns out that this general greedy algorithm is very good for the trigonometric system.

Mathematics Subject Classification (2000). Primary 41A25; Secondary 41A46.

Keywords. Nonlinear approximation, greedy algorithm, convergence, best m-term approximation, greedy basis.

1. Introduction. Historical remarks

In order to give the reader some ideas for comparing the quality of approximation methods we now discuss some classical results in approximation of periodic functions. In this section we briefly discuss various classical approaches, created in linear approximation, for the estimation of the quality of a method of approximation. We will use and refine these approaches in nonlinear approximation. We confine our discussion to the case of approximation of periodic functions of a single variable. The two main parameters of a method of approximation are accuracy and complexity. These concepts may be treated in various ways depending on the particular problems involved. Here we will start from the classical idea about approximation of functions by polynomials. After Fourier's article (1807) the representation of a 2π-periodic

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

function by its Fourier series became natural. In other words, the function $f(x)$ is approximately represented by a partial sum $S_n(f,x)$ of its Fourier series.

We will be interested in the approximation of a function f by a polynomial $S_n(f)$ in some L_p-norm, $1 \le p \le \infty$. In the case $p = \infty$ we will assume that we deal with the uniform norm. As accuracy of the method of approximating a periodic function by its Fourier partial sum we will consider the quantity $\|f - S(f)\|_p$. The complexity of this method of approximation contains the two following characteristics. The order of the trigonometric polynomial $S_n(f)$ is the quantitative characteristic. The following observation gives us the qualitative characteristic. The coefficients of this polynomial are found by the Fourier formulas which means that the operator S_n is the orthogonal projection onto the subspace of trigonometric polynomials of order n.

In 1854 Chebyshev suggested to represent a continuous function f by its polynomial of best approximation, namely by the polynomial $t_n(f)$ such that

$$\|f - t_n(f)\|_\infty = E_n(f)_\infty := \inf_{\alpha_k,\beta_k} \left\| f(x) - \sum_{k=0}^{n} (\alpha_k \cos kx + \beta_k \sin kx) \right\|_\infty .$$

He proved the existence and uniqueness of such a polynomial. We will consider this method of approximation not only in the uniform norm, but in all L_p-norms, $1 \le p < \infty$. The accuracy of the Chebyshev method can be easily compared with the accuracy of the Fourier method:

$$E_n(f)_p \le \|f - S_n(f)\|_p.$$

The quantitative characteristics of complexity coincide for the two methods but the qualitative characteristics are different (for example, it is not difficult to understand that for $p = \infty$ the mapping $f \to t_n(f)$ is not a linear operator). The du Bois-Reymond example (1873) of a continuous function f such that $\|f - S_n(f)\|_\infty \to \infty$ when $n \to \infty$, and the Weierstrass theorem which says that for each continuous function f we have $E_n(f)_\infty \to 0$ as $n \to \infty$, showed the advantage of the Chebyshev method in comparison with the Fourier method from the point of view of accuracy. It is known that for each $f \in L_2(\mathbb{T})$ the approximation with the error $E_n(f)_2$ can be realized by the operator S_n of orthogonal projection onto the space of trigonometric polynomials of order n. The performance of the operator S_n was studied thoroughly in all L_p spaces, $1 \le p \le \infty$. It was proved that S_n provides almost optimal or close to optimal approximation for each $f \in L_p(\mathbb{T})$:

$$\|f - S_n(f)\|_p \le C(p) E_n(f)_p, \qquad 1 < p < \infty,$$
$$\|f - S_n(f)\|_p \le C \ln(n+2) E_n(f)_p, \quad p = 1, \infty.$$

The desire to construct methods of approximation which have the advantages of the Fourier and Chebyshev methods led to the study of various methods of summation of the Fourier series. The most important among them from the point of view of approximation are the de la Vallée Poussin, Fejér and Jackson methods which were

constructed early in the 20th century. All these methods are linear. For example, the de la Vallée Poussin method is the method of approximation of a function f by the polynomial

$$V_n(f) = \frac{1}{n} \sum_{l=n}^{2n-1} S_l(f)$$

of order $2n - 1$.

From the point of view of accuracy this method is close to the Chebyshev method; de la Vallée Poussin proved that

$$\|f - V_n(f)\|_p \le 4E_n(f)_p, \quad 1 \le p \le \infty.$$

From the point of view of complexity it is close to the Fourier method, and the property of linearity essentially distinguishes it from the Chebyshev method.

We see that common to all these methods is the approximation by means of trigonometric polynomials; however, the ways of constructing these polynomials differ: orthogonal projections on the subspace of trigonometric polynomials of fixed order, the operator of best approximation, and linear operators.

In 1936 Kolmogorov introduced the concept of width $d_n(F, X)$ of a class F in a Banach space X:

$$d_n(F, X) = \inf_{\{\phi_j\}_{j=1}^n} \sup_{f \in F} \inf_{\{c_j\}_{j=1}^n} \left\| f - \sum_{j=1}^n c_j \phi_j \right\|_X.$$

This concept is designed to find for a fixed n and for a class F a subspace of dimension n, optimal with respect to the construction of an approximating element as the element of best approximation. In other words, the Kolmogorov width gives the lower bound for accuracy of Chebyshev's methods, having the same quantitative characteristic of complexity (the dimension of the approximating subspace). In analogy to the concept of the Kolmogorov width, that is, to the problem concerning the best Chebyshev method, the problems concerning the best linear method and the best Fourier method were considered. Tikhomirov ([51]) introduced the concept of linear width

$$\lambda_n(F, X) = \inf_{A:\operatorname{rank} A \le n} \sup_{f \in F} \|f - Af\|_X.$$

The concept of orthowidth (Fourier width) was introduced in [38]:

$$\varphi_n(F, X) := d_n^{\perp}(F, X) := \inf_{\substack{\text{orthonormal} \\ \text{system } \{u_i\}_{i=1}^n}} \sup_{f \in F} \left\| f - \sum_{i=1}^n \langle f, u_i \rangle u_i \right\|_X.$$

We discuss these widths in more detail later in this section. We present here some well-known results for the Sobolev classes

$$W_q^r := \{f : f^{(r-1)} \text{ is absolutely continuous, } \|f^{(r)}\|_q \le 1\}.$$

The first result about widths, namely Kolmogorov's result (1936)

$$d_{2n+1}(W_2^r, L_2) = (n+1)^{-r},$$

showed that the best subspace of dimension $2n+1$ for approximation of classes of periodic functions is the subspace of trigonometric polynomials of order n. This result confirmed that the approximation of functions in the class W_2^r by trigonometric polynomials is natural. Further estimates of the widths $d_{2n+1}(W_q^r, L_p)$, $1 \le q$, $p \le \infty$, some of which are discussed here, showed that for some values of the parameters q, p the subspace of trigonometric polynomials of order n is optimal (in the sense of order) but for other values of q, p this subspace is not optimal.

The Ismagilov estimate [20] for the quantity $d_n(W_1^r, L_\infty)$ gave the first example where the subspace of trigonometric polynomials of order n is not optimal. This phenomenon was thoroughly studied by Kashin [22]. We remark that from the point of view of orthowidth the Fourier operator S_n is optimal (in the sense of order of approximation in the L_p-norm) for all Sobolev classes W_q^r with $1 \le q$, $p \le \infty$ with the exception of the two cases $q = p = 1$ and $q = p = \infty$.

All the above defined widths have as a starting point a function class F. Thus in this setting we choose a priori a function class F and look for optimal subspaces for approximation of a given class. The following results are well known [39]. We present these results for r a positive integer. In the case $q = 1$, $p = \infty$ we assume $r > 1$. For a number a we denote $(a)_+ := \max(a, 0)$.

A. In the case $1 \le p \le q \le \infty$ or $1 \le q \le p \le 2$ one has

$$\varphi_n(W_q^r, L_p) \asymp \lambda_n(W_q^r, L_p) \asymp d_n(W_q^r, L_p) \asymp n^{-r+(1/q-1/p)_+}. \tag{1.1}$$

B. In the case $1 \le q < p \le \infty$, $p > 2$, one has

$$d_n(W_q^r, L_p) \asymp n^{-r+(1/q-1/2)_+},$$
$$\lambda_n(W_q^r, L_p) \asymp n^{-r+\max(1/q-1/2,1/2-1/p)},$$
$$\varphi_n(W_q^r, L_p) \asymp n^{-r+1/q-1/p}.$$

In case A the classical trigonometric system provides the optimal orders for all widths, except for φ_n for $q = p = 1, \infty$. Let us discuss the more interesting case B for the particular choice $q = 2$ and $p = \infty$. We have

$$d_n(W_2^r, L_\infty) \asymp n^{-r}, \tag{1.2}$$
$$\lambda_n(W_2^r, L_\infty) \asymp \varphi_n(W_2^r, L_\infty) \asymp n^{-r+1/2}. \tag{1.3}$$

These relations show that if we drop the linearity requirement for the approximation method we gain in accuracy a factor $n^{-1/2}$. However, there is a big difficulty in realization of the estimate (1.2). We know by Kashin's result that there exists a subspace realizing (1.2) but we do not know a way to construct it. Thus it is only an existence theorem for now.

Let us discuss one more special case: $q = 1$ and $p = \infty$. In this case we have

$$d_n(W_1^r, L_\infty) \asymp \lambda_n(W_1^r, L_\infty) \asymp n^{-r+1/2} \tag{1.4}$$

and

$$\varphi_n(W_1^r, L_\infty) \asymp n^{-r+1}. \tag{1.5}$$

Therefore, by (1.4) the best possible approximation (in the sense of order) can be realized by a linear method, say, A_n. However, by (1.5) this linear method A_n is certainly not an orthogonal projector. Moreover, by [39] it cannot satisfy even the following much weaker restriction $\|A_n(e^{ikx})\|_2 \le C, k \in \mathbb{Z}$. This means that the optimal linear operator A_n is unstable. A small change in some of the Fourier coefficients of f may result in a big change of $\|A_n(f)\|_2$.

Let us make some conclusions now. In linear approximation of W_q^r in L_p the bottom line is given by $\varphi_n(W_q^r, L_p)$ where the approximation method is the simplest, namely orthogonal projection. Partial sums with regard to classical systems provide an optimal error of approximation for this width. The trigonometric system works for all $1 \le q, p \le \infty$ except for $(q, p) = (1, 1), (\infty, \infty)$. The wavelet systems (see [1]) work for all $1 \le q, p \le \infty$. In the example of the pair (W_1^r, L_∞) we have seen that we need to sacrifice important and convenient properties of the approximating operator in order to achieve better accuracy. In the example of (W_2^r, L_∞) we have seen that we need to pay even a bigger price for better accuracy in a form of proving only an existence theorem instead of providing a constructive method of approximation.

Our main interest in this paper is nonlinear approximation. We begin our discussion with the trigonometric system. Let $\mathcal{T}$ be the complex trigonometric system $\{e^{ikx}\}_{k\in\mathbb{Z}}$. Denote for $f \in L_p(\mathbb{T})$

$$\sigma_m(f, \mathcal{T})_p := \inf_{c_1,\dots,c_m;\phi_1,\dots,\phi_m\in\mathcal{T}} \left\| f - \sum_{j=1}^m c_j\phi_j \right\|_p$$

the best m-term trigonometric approximation of f in the L_p-norm. It is clear that one can get an upper estimate for $\sigma_{2m+1}(f, \mathcal{T})_p$ by approximating f by trigonometric polynomials of order m. Denote $\mathcal{T}(m)$ the subspace of trigonometric polynomials of order m and define

$$E_m(f, \mathcal{T})_p := \inf_{t\in\mathcal{T}(m)} \|f - t\|_p.$$

The first result that indicated an advantage of m-term approximation over approximation by trigonometric polynomials of order m is due to Ismagilov [20]:

$$\sigma_m(|\sin x|, \mathcal{T})_\infty \le C_\epsilon m^{-6/5+\epsilon}, \quad \text{for any } \epsilon > 0. \tag{1.6}$$

Let us compare it with the well-known result due to de la Vallée Poussin and Bernstein:

$$E_m(|\sin x|, \mathcal{T})_\infty \asymp m^{-1}. \tag{1.7}$$

Maiorov [35] improved the estimate (1.6):

$$\sigma_m(|\sin x|, \mathcal{T})_\infty \asymp m^{-3/2}. \tag{1.8}$$

In [11] we proved the following rate of best m-term approximation of the Sobolev classes W_q^r in L_p, $1 \le q, p \le \infty$:

$$\sigma_m(W_q^r, \mathcal{T})_p := \sup_{f \in W_q^r} \sigma_m(f, \mathcal{T})_p \asymp m^{-r+(1/q-\max(1/p,1/2))_+}. \tag{1.9}$$

Comparing (1.9) with the above bounds for the Kolmogorov width we conclude that

$$\sigma_m(W_q^r, \mathcal{T})_p \asymp d_m(W_q^r, L_p).$$

In particular, this means, that in the case (W_2^r,L_∞) the nonlinear m-term approximations provide much better accuracy than the trigonometric polynomials of order m. The best m-term approximations $\sigma_m(f, \mathcal{T})_p$ may be considered as a nonlinear analogue (counterpart) of the best approximations $E_m(f, \mathcal{T})_p$. The main goal of this paper is to discuss a nonlinear analogue (counterpart) of the operator $S_n(f)$. We consider the greedy approximant to be a nonlinear analogue of the partial sum. In Sections 2 and 3 we discuss the general theory of greedy approximation with regard to bases. Our primary object of discussion is the Thresholding Greedy Algorithm (TGA). We return to a discussion of nonlinear approximations with regard to the trigonometric system in Sections 4 and 5. In Section 6 we deviate from the main stream of the paper of studying the TGA and discuss one example of a family of greedy algorithms that works in a very general situation. The most important feature of this algorithm is that it provides m-term approximation with regard to a very general system that may be redundant (overcomplete). It turns out (this will be seen from the discussion in Section 6) that this general approximation method is very good for the trigonometric system.

2. Greedy algorithms with regard to bases

Let X be a Banach space with a given basis $\Psi = \{\psi_k\}_{k=1}^\infty$. We assume that $\|\psi_k\| \ge C > 0$, $k = 1, 2, \dots$, and consider the following theoretical greedy algorithm. For a given element $f \in X$ we consider the expansion

$$f = \sum_{k=1}^\infty c_k(f, \Psi)\psi_k. \tag{2.1}$$

For an element $f \in X$ we call a permutation ρ, $\rho(j) = k_j$, $j = 1, 2, \dots$, of the positive integers decreasing and write $\rho \in D(f)$ if

$$|c_{k_1}(f, \Psi)| \ge |c_{k_2}(f, \Psi)| \ge \cdots. \tag{2.2}$$

In the case of strict inequalities here $D(f)$ consists of only one permutation. We define the m-th greedy approximant of f with regard to the basis Ψ corresponding to a permutation $\rho \in D(f)$ by the formula

$$G_m(f) := G_m(f, \Psi) := G_m(f, \Psi, \rho) := \sum_{j=1}^{m} c_{k_j}(f, \Psi)\psi_{k_j}.$$

We note that there is another natural greedy type algorithm based on ordering $\|c_k(f, \Psi)\psi_k\|$ instead of ordering absolute values of coefficients. In this case we do not need the restriction $\|\psi_k\| \geq C > 0$, $k = 1, 2, \ldots$. Denote by $\Lambda_m(f)$ a set of indices such that

$$\min_{k \in \Lambda_m(f)} \|c_k(f, \Psi)\psi_k\| \geq \max_{k \notin \Lambda_m(f)} \|c_k(f, \Psi)\psi_k\|.$$

We define $G_m^X(f, \Psi)$ by the formula

$$G_m^X(f, \Psi) := S_{\Lambda_m(f)}(f, \Psi), \quad \text{where } S_E(f) := S_E(f, \Psi) := \sum_{k \in E} c_k(f, \Psi)\psi_k.$$

It is clear that in the case of the normalized basis ($\|\psi_k\| = 1$, $k = 1, 2, \ldots$) the above two greedy algorithms coincide.

In the case $X = L_p$ we will write p instead of L_p in notations. It is a simple algorithm which describes the theoretical scheme for m-term approximation of an element f. We call this algorithm the Thresholding Greedy Algorithm (TGA). In order to understand the efficiency of this algorithm we compare its accuracy with the best possible when an approximant is a linear combination of m terms from Ψ. We define the best m-term approximation with regard to Ψ as follows:

$$\sigma_m(f) := \sigma_m(f, \Psi)_X := \inf_{c_k, \Lambda} \left\| f - \sum_{k \in \Lambda} c_k \psi_k \right\|_X,$$

where inf is taken over coefficients c_k and sets of indices Λ with cardinality $|\Lambda| = m$. The best we can achieve with the algorithm G_m is

$$\|f - G_m(f, \Psi, \rho)\|_X = \sigma_m(f, \Psi)_X,$$

or, a little weaker,

$$\|f - G_m(f, \Psi, \rho)\|_X \leq G\sigma_m(f, \Psi)_X \tag{2.3}$$

for all elements $f \in X$ with a constant $G = C(X, \Psi)$ independent of f and m. It is clear that in the case $X = H$ is a Hilbert space and Ψ is an orthonormal basis we have

$$\|f - G_m(f, \Psi, \rho)\|_H = \sigma_m(f, \Psi)_H.$$

Let us begin our discussion with an important class of bases: wavelet type bases. Denote $\mathcal{H} := \{H_k\}_{k=1}^{\infty}$ the Haar basis on $[0, 1)$ normalized in $L_2(0, 1)$: $H_1 = 1$ on $[0, 1)$ and for $k = 2^n + l$, $n = 0, 1, \dots$, $l = 1, 2, \dots, 2^n$,

$$H_k(x) = \begin{cases} 2^{n/2}, & x \in [(2l-2)2^{-n-1}, (2l-1)2^{-n-1}) \\ -2^{n/2}, & x \in [(2l-1)2^{-n-1}, 2l2^{-n-1}) \\ 0, & \text{otherwise.} \end{cases}$$

We denote by $\mathcal{H}_p := \{H_{k,p}\}_{k=1}^{\infty}$ the Haar basis $\mathcal{H}$ renormalized in $L_p(0, 1)$. We will use the following definition of the L_p-equivalence of bases. We say that $\Psi = \{\psi_k\}_{k=1}^{\infty}$ is L_p-equivalent to $\Phi = \{\phi_k\}_{k=1}^{\infty}$ if for any finite set Λ and any coefficients c_k, $k \in \Lambda$, we have

$$C_1(p, \Psi, \Phi)\Big\| \sum_{k\in\Lambda} c_k\phi_k \Big\|_p \le \Big\| \sum_{k\in\Lambda} c_k\psi_k \Big\|_p \le C_2(p, \Psi, \Phi)\Big\| \sum_{k\in\Lambda} c_k\phi_k \Big\|_p$$

with two positive constants $C_1(p, \Psi, \Phi), C_2(p, \Psi, \Phi)$ which may depend on p, Ψ, and Φ. For sufficient conditions on Ψ to be L_p-equivalent to $\mathcal{H}$ see [16] and [10]. In particular, it is known that all reasonable univariate wavelet type bases are L_p-equivalent to $\mathcal{H}$ for $1 < p < \infty$. We proved the following theorem in [40].

Theorem 2.1. *Let $1 < p < \infty$ and let a basis Ψ be L_p-equivalent to the Haar basis $\mathcal{H}$. Then for any $f \in L_p(0, 1)$ we have*

$$\|f - G_m^p(f, \Psi)\|_p \le C(p, \Psi)\sigma_m(f, \Psi)_p$$

with a constant $C(p, \Psi)$ independent of f and m.

By a simple renormalization argument one obtains the following version of Theorem 2.1.

Theorem 2.2. *Let $1 < p < \infty$ and let a basis Ψ be L_p-equivalent to the Haar basis $\mathcal{H}_p$. Then for any $f \in L_p(0, 1)$ and any $\rho \in D(f)$ we have*

$$\|f - G_m(f, \Psi, \rho)\|_p \le C(p, \Psi)\sigma_m(f, \Psi)_p$$

with a constant $C(p, \Psi)$ independent of f, ρ, and m.

We note that [40] also contains a generalization of Theorem 2.1 to the multivariate Haar basis obtained by the multiresolution analysis procedure. These theorems motivated us to consider the general setting of greedy approximation in Banach spaces. We concentrated on studying bases which satisfy (2.3) for all individual functions. The following Definitions 2.1, 2.2 and 2.3 are from [27].

Definition 2.1. We call a basis Ψ a *greedy basis* if for every $f \in X$ there exists a permutation $\rho \in D(f)$ such that

$$\|f - G_m(f, \Psi, \rho)\|_X \le G\sigma_m(f, \Psi)_X \tag{2.4}$$

holds with a constant independent of f, m.

The following proposition has been proved in [27].

Proposition 2.1. *If Ψ is a greedy basis, then inequality* (2.4) *holds for any permutation $\rho \in D(f)$.*

Theorem 2.2 shows that each basis Ψ which is L_p-equivalent to the univariate Haar basis $\mathcal{H}_p$ is a greedy basis for $L_p(0,1)$, $1 < p < \infty$. We note that in the case of Hilbert space each orthonormal basis is a greedy basis with a constant $G = 1$ (see (2.4)).

We give now the definitions of unconditional and democratic bases.

Definition 2.2. A basis $\Psi = \{\psi_k\}_{k=1}^{\infty}$ of a Banach space X is said to be *unconditional* if for every choice of signs $\theta = \{\theta_k\}_{k=1}^{\infty}$, $\theta_k = 1$ or -1, $k = 1, 2, \dots$, the linear operator M_θ defined by $M_\theta\big(\sum_{k=1}^{\infty} a_k \psi_k\big) = \sum_{k=1}^{\infty} a_k \theta_k \psi_k$ is a bounded operator from X into X.

Definition 2.3. We say that a basis $\Psi = \{\psi_k\}_{k=1}^{\infty}$ is a *democratic basis* for X if there exists a constant $D := D(X, \Psi)$ such that for any two finite sets of indices P and Q with the same cardinality $|P| = |Q|$ we have $\big\| \sum_{k\in P} \psi_k \big\| \le D \big\| \sum_{k\in Q} \psi_k \big\|$.

We proved in [27] the following theorem.

Theorem 2.3. *A basis is greedy if and only if it is unconditional and democratic.*

This theorem gives a characterization of greedy bases. Further investigations ([41], [6], [25], [18], [21]) showed that the concept of greedy bases is very useful in direct and inverse theorems of nonlinear approximation and also in applications in statistics. The papers [27], [40] contain other results on greedy bases.

Let us discuss a question of weakening the property of a basis of being a greedy basis. We begin with the concept of quasi-greedy basis introduced in [27].

Definition 2.4. We call a basis Ψ a *quasi-greedy basis* if for every $f \in X$ and every permutation $\rho \in D(f)$ we have

$$\|G_m(f, \Psi, \rho)\|_X \le C \|f\|_X \tag{2.5}$$

with a constant C independent of f, m, and ρ.

It is clear that (2.5) is weaker then (2.4). P. Wojtaszczyk [53] proved the following theorem.

Theorem 2.4. *A basis Ψ is quasi-greedy if and only if for any $f \in X$ and any $\rho \in D(f)$ we have*

$$\|f - G_m(f, \Psi, \rho)\| \to 0 \quad \text{as } m \to \infty. \tag{2.6}$$

We proceed to an intermediate concept of almost greedy basis. This concept has been introduced and studied in [14]. Let

$$f = \sum_{k=1}^{\infty} c_k(f)\psi_k.$$

We define the following expansional best m-term approximation of f:

$$\tilde{\sigma}_m(f) := \tilde{\sigma}_m(f, \Psi) := \inf_{\Lambda, |\Lambda|=m} \Big\| f - \sum_{k\in\Lambda} c_k(f)\psi_k \Big\|.$$

It is clear that

$$\sigma_m(f, \Psi) \le \tilde{\sigma}_m(f, \Psi).$$

It is also clear that for an unconditional basis Ψ we have

$$\tilde{\sigma}_m(f, \Psi) \le C\sigma_m(f, \Psi).$$

Definition 2.5. We call a basis Ψ *almost greedy* if for every $f \in X$ there exists a permutation $\rho \in D(f)$ such that

$$\|f - G_m(f, \Psi, \rho)\|_X \le C\tilde{\sigma}_m(f, \Psi)_X \tag{2.7}$$

holds with a constant independent of f, m.

The following proposition follows from the proof of Theorem 3.3 of [14] (see Theorem 2.5 below).

Proposition 2.2. *If Ψ is an almost greedy basis then* (2.7) *holds for any permutation $\rho \in D(f)$.*

The following characterization of almost greedy bases has been obtained in [14].

Theorem 2.5. *Suppose Ψ is a basis of a Banach space. The following are equivalent:*

A. *Ψ is almost greedy.*

B. *Ψ is quasi-greedy and democratic.*

C. *For any (respectively, every) $\lambda > 1$ there is a constant $C = C_\lambda$ such that*

$$\|f - G_{[\lambda m]}(f, \Psi)\| \le C_\lambda \sigma_m(f, \Psi).$$

We now proceed to a generalization of the concept of greedy bases from [26] that is useful in statistical applications. Let Ψ be a basis for X. If $\inf_k \|\psi_k\| > 0$ then $c_k(f) \to 0$ as $k \to \infty$, where

$$f = \sum_{k=1}^{\infty} c_k(f)\psi_k.$$

Then we can rearrange the coefficients $\{c_k(f)\}$ in the decreasing way

$$|c_{k_1}(f)| \geq |c_{k_2}(f)| \geq \cdots$$

and define the mth greedy approximant as

$$G_m(f, \Psi) := \sum_{j=1}^{m} c_{k_j}(f)\psi_{k_j}. \tag{2.8}$$

In the case $\inf_k \|\psi_k\| = 0$ we define $G_m(f, \Psi)$ by (2.8) for f of the form

$$f = \sum_{k \in Y} c_k(f)\psi_k, \quad |Y| < \infty. \tag{2.9}$$

Let a weight sequence $w = \{w_k\}_{k=1}^{\infty}$, $w_k > 0$, be given. For $\Lambda \subset \mathbb{N}$ denote $w(\Lambda) := \sum_{k \in \Lambda} w_k$. For a positive real number $v > 0$ define

$$\sigma_v^w(f, \Psi) := \inf_{\{b_k\}, \Lambda : w(\Lambda) \leq v} \|f - \sum_{k \in \Lambda} b_k \psi_k\|,$$

where the sets Λ are finite.

Definition 2.6. We call a basis Ψ a *weight-greedy basis* (w-greedy basis) if for any $f \in X$ in the case $\inf_k \|\psi_k\| > 0$ or for any $f \in X$ of the form (2.9) in the case $\inf_k \|\psi_k\| = 0$ we have

$$\|f - G_m(f, \Psi)\| \leq C_G \sigma^w_{w(\Lambda_m)}(f, \Psi),$$

where

$$G_m(f, \Psi) = \sum_{k \in \Lambda_m} c_k(f)\psi_k, \quad |\Lambda_m| = m.$$

Definition 2.7. We call a basis Ψ *weight-democratic* (w-democratic basis) if for any finite $A, B \subset \mathbb{N}$ such that $w(A) \leq w(B)$ we have

$$\|\sum_{k \in A} \psi_k\| \leq C_D \|\sum_{k \in B} \psi_k\|.$$

Recently, we proved in [26] the following criterion for w-greedy bases.

Theorem 2.6. *A basis Ψ is a w-greedy basis if and only if it is unconditional and w-democratic.*

The reader can find a further discussion in the surveys [8], [28], [46], [47].

3. Optimal methods in nonlinear approximation

In the widths problem of linear approximation (see Section 1) we were looking for an optimal n-dimensional subspace for approximating a given function class. A nonlinear analogue of this setting is the following. Let a function class F and a Banach space X be given. Assume that on the basis of some additional information we know that our basis for m-term approximation should satisfy some structural properties, for instance, it has to be orthogonal. Then similarly to the setting for the widths d_n, λ_n, φ_n we get the optimization problems for m-term nonlinear approximation. Let $\mathbb{B}$ be a collection of bases satisfying a given property.

I. Define an analogue of the Kolmogorov width

$$\sigma_m(F, \mathbb{B})_X := \inf_{\Psi \in \mathbb{B}} \sup_{f \in F} \sigma_m(f, \Psi)_X.$$

II. Define an analogue of the orthowidth

$$\gamma_m(F, \mathbb{B})_X := \inf_{\Psi \in \mathbb{B}} \sup_{f \in F} \|f - G_m(f, \Psi)\|_X.$$

We present here some results in the case $\mathbb{B} = \mathbb{O}$, the set of orthonormal bases, $F = W_q^r$, $X = L_p$, $1 \le q, p \le \infty$. First of all we formulate a result (see [24], [43]) that shows that in the case $p < 2$ we need some more restrictions on $\mathbb{B}$ in order to obtain meaningful results (lower bounds).

Proposition 3.1. *For any $1 \le p < 2$ there exists a complete in $L_2(0, 1)$ orthonormal system Φ such that for each $f \in L_p(0, 1)$ we have $\sigma_1(f, \Phi)_p = 0$.*

Let us restrict our further discussion to the case $p \ge 2$. This case was also more interesting in the linear approximation discussion (see Section 1). Kashin [23] proved that

$$\sigma_m(W_\infty^r, \mathbb{O})_2 \gg m^{-r}. \tag{3.1}$$

We proved (see [11]) that

$$\sigma_m(W_2^r, \mathcal{T})_\infty \ll m^{-r}. \tag{3.2}$$

The estimates (3.1) and (3.2) imply that for $2 \le q, p \le \infty$ we have

$$\sigma_m(W_q^r, \mathbb{O})_p \asymp \sigma_m(W_q^r, \mathcal{T})_p \asymp m^{-r}. \tag{3.3}$$

Let us compare this relation with (1.2). We see that the best m-term trigonometric approximation provides the same accuracy as the best approximation from an optimal m-dimensional subspace. An advantage of nonlinear approximation here is that we use a natural basis instead of an existing but nonconstructive subspace. However, we should note that the estimate (3.2) was proved in [11] as an existence theorem. We did not give an algorithm to get (3.2) in [11]. We gave such an algorithm in [49]

(see a further discussion in Section 6). The Thresholding Greedy Algorithm does not provide the estimate (3.2). We have (see [42])

$$\sup_{f\in W_2^r}\|f-G_m(f,\mathcal{T})\|_\infty \asymp m^{-r+1/2}.$$

It is known from different results (see [9], [8], [45]) that wavelets are well designed for nonlinear approximation.

In the multivariate periodic case the following basis $U^d := U\times\cdots\times U$ has approximation properties close to the corresponding properties of wavelets. We define the system $U := \{U_I\}$ in the univariate case. Denote

$$\begin{aligned}
U_n^+(x) &:= \sum_{k=0}^{2^n-1} e^{ikx} = \frac{e^{i2^nx}-1}{e^{ix}-1}, \qquad n=0,1,2,\dots;\\
U_{n,k}^+(x) &:= e^{i2^nx}U_n^+(x-2\pi k2^{-n}), \qquad k=0,1,\dots,2^n-1;\\
U_{n,k}^-(x) &:= e^{-i2^nx}U_n^+(-x+2\pi k2^{-n}), \quad k=0,1,\dots,2^n-1.
\end{aligned}$$

We normalize the system of functions $\{U_{n,k}^+, U_{n,k}^-\}$ in L_2 and enumerate it by dyadic intervals. We write

$$\begin{aligned}
U_I(x) &:= 2^{-n/2}U_{n,k}^+(x) \quad \text{with } I=[(k+1/2)2^{-n},(k+1)2^{-n});\\
U_I(x) &:= 2^{-n/2}U_{n,k}^-(x) \quad \text{with } I=[k2^{-n},(k+1/2)2^{-n});
\end{aligned}$$

and

$$U_{[0,1)}(x) := 1.$$

P. Wojtaszczyk [52] proved that the system U is an unconditional basis for $L_p(\mathbb{T})$, $1<p<\infty$.

We define the anisotropic multivariate periodic Hölder–Nikol'skii classes NH_p^R in the following way. The class NH_p^R, $R=(R_1,\dots,R_d)$ and $1\le p\le\infty$, is the set of periodic functions $f\in L_p([0,2\pi]^d)$ such that for each $l_j=[R_j]+1$, $j=1,\dots,d$, the following relations hold:

$$\|f\|_p\le 1, \quad \|\Delta_t^{l_j,j}f\|_p\le |t|^{R_j}, \quad j=1,\dots,d, \tag{3.4}$$

where $\Delta_t^{l,j}$ is the l-th difference with step t in the variable x_j. In the case $d=1$ NH_p^R coincides with the standard Hölder class H_p^R. For $R=(R_1,\dots,R_d)$, $R_j>0$, $j=1,\dots,d$, we define $g(R) := \left(\sum_{j=1}^d R_j^{-1}\right)^{-1}$. The following result has been proved in [45].

Theorem 3.1. *Let $1<q,p<\infty$. Then for R such that $g(R)>(1/q-1/p)_+$ we have*

$$\sup_{f\in NH_q^R}\|f-G_m^{L_p}(f,U^d)\|_p \ll m^{-g(R)}.$$

We also proved in [45] that the basis U^d is an optimal orthonormal basis for approximation of classes NH_q^R in L_p:

$$\sigma_m(NH_q^R, \mathbb{O})_p \asymp \sigma_m(NH_q^R, U^d)_p \asymp m^{-g(R)} \tag{3.5}$$

for $1 < q < \infty$, $2 \le p < \infty$, $g(R) > (1/q - 1/p)_+$. It is important to remark that Theorem 3.1 guarantees that the estimate in (3.5) can be realized by the TGA with regard to U^d.

4. The TGA with regard to the trigonometric system

Let us consider nonlinear approximation with regard to the trigonometric system $\mathcal{T}^d := \mathcal{T} \times \cdots \times \mathcal{T}$ (d times). The existence of best m-term trigonometric approximation was proved in [2] (see also [42]). The method $G_m(f) := G_m(f, \mathcal{T}^d)$ has an advantage over the traditional approximation by trigonometric polynomials in the case of approximation of functions of several variables. In this case ($d > 1$) there is no natural order of trigonometric system and the use of G_m allows us to avoid the problem of finding natural subspaces of trigonometric polynomials for approximation purposes. We proved in [42] the following results.

Theorem 4.1. *For each $f \in L_p(\mathbb{T}^d)$ we have*

$$\|f - G_m(f)\|_p \le (1 + 3m^{h(p)})\sigma_m(f)_p, \quad 1 \le p \le \infty,$$

where $h(p) := |1/2 - 1/p|$.

Remark 4.1. For all $1 \le p \le \infty$

$$\|G_m(f)\|_p \le m^{h(p)}\|f\|_p.$$

Remark 4.2. There is a positive absolute constant C such that for each m and $1 \le p \le \infty$ there exists a function $f \ne 0$ with the property

$$\|G_m(f)\|_p \ge Cm^{h(p)}\|f\|_p. \tag{4.1}$$

The above results show that the trigonometric system is not a quasi-greedy basis for L_p, $p \ne 2$. This leads to a natural attempt to consider some other algorithms that may have some advantages over the TGA in the case of $\mathcal{T}$. We discuss here the performance of the WCGA (see Section 6) with regard to $\mathcal{T}$.

Let us compare the rate of approximation of the TGA and the WCGA. Let $\mathcal{RT}$ denote the real trigonometric system $1/2, \sin x, \cos x, \dots$. We need to switch to this system from the complex trigonometric system because the algorithm WCGA is defined for the real Banach space. We note that the system $\mathcal{RT}$ is not normalized in L_p but quasinormalized: $C_1 \le \|t\|_p \le C_2$ for any $t \in \mathcal{RT}$ with absolute constants

C_1, C_2, $1 \le p \le \infty$. It is sufficient for the application of the general methods developed in Section 6. For a function f with absolutely convergent Fourier series

$$f(x) = a_0/2 + \sum_{k=1}^{\infty}(a_k \cos kx + b_k \sin kx)$$

denote

$$\|f\|_A := |a_0| + \sum_{k=1}^{\infty}(|a_k| + |b_k|).$$

Define the class

$$A := A(\mathcal{RT}) := \{f : \|f\|_A \le 1\}.$$

For a sequence $\tau := \{t_k\}$ with $t_k = t$, $k = 1, 2, \dots$, we replace τ by t in the notation. Theorem 6.1 and (6.2) imply the following result.

Theorem 4.2. *Let $0 < t \le 1$. For $f \in A$ we have*

$$\|f - G_m^{c,t}(f, \mathcal{RT})\|_p \le C(p,t)m^{-1/2}, \quad 2 \le p < \infty. \tag{4.2}$$

This estimate and Theorem 4.1 imply that for $f \in A$ we have

$$\|f - G_m(f, \mathcal{RT})\|_p \le C(p,t)m^{-1/p}, \quad 2 \le p < \infty, \tag{4.3}$$

which is weaker than (4.2). It is proved in [15] that (4.3) can not be improved. Thus the WCGA works better than the TGA for the class A. We note that the restriction $p < \infty$ in (4.2) is important. We gave a lower estimate for m-term approximation in L_∞ in [47].

Proposition 4.1. *For a given m define*

$$f := \sum_{k=0}^{2m} \cos 3^k x.$$

Then we have

$$\sigma_m(f, \mathcal{T})_\infty \ge m/8.$$

5. Convergence of the TGA with regard to the trigonometric system

We discuss in this section the following nonlinear method of summation of trigonometric Fourier series. Consider a periodic function $f \in L_p(\mathbb{T}^d)$, $1 \le p \le \infty$, $(L_\infty(\mathbb{T}^d) = C(\mathbb{T}^d))$, defined on the d-dimensional torus $\mathbb{T}^d$. Take a number $t \in (0, 1]$. Let a number $m \in \mathbb{N}$ be given and Λ_m be a set of $k \in \mathbb{Z}^d$ with the properties

$$\min_{k \in \Lambda_m} |\hat{f}(k)| \ge t \max_{k \notin \Lambda_m} |\hat{f}(k)|, \quad |\Lambda_m| = m, \tag{5.1}$$

where

$$\hat{f}(k) := (2\pi)^{-d} \int_{\mathbb{T}^d} f(x) e^{-i(k,x)} dx$$

is a Fourier coefficient of f. We define

$$G_m^t(f) := G_m^t(f, \mathcal{T}^d) := S_{\Lambda_m}(f) := \sum_{k \in \Lambda_m} \hat{f}(k) e^{i(k,x)}$$

and call it an mth weak greedy approximant of f with regard to the trigonometric system $\mathcal{T}^d = \{e^{i(k,x)}\}_{k \in \mathbb{Z}^d}$. We write $G_m(f) = G_m^1(f)$ and call it an mth greedy approximant. Clearly, an mth weak greedy approximant and even an mth greedy approximant may not be unique. Here we do not impose any extra restrictions on Λ_m in addition to (5.1). Thus theorems formulated below hold for any choice of Λ_m satisfying (5.1) or, in other words, for any realization $G_m^t(f)$ of the weak greedy approximation.

There has recently been (see the surveys [8], [47], [28]) much interest in approximation of functions by m-term approximants with regard to a basis (or minimal system). In this section we will discuss in detail only results concerning the trigonometric system. Answering a question raised by Carleson and Coifman, T. W. Körner constructed in [31] a function from $L_2(\mathbb{T})$ and then in [32] a continuous function such that $\{G_m(f, \mathcal{T})\}$ diverges almost everywhere. It has been proved in [42] for $p \neq 2$ and in [7] for $p < 2$ that there exists an $f \in L_p(\mathbb{T})$ such that $\{G_m(f, \mathcal{T})\}$ does not converge in L_p. It was remarked in [47] that the method from [42] gives a little bit more: 1) There exists a continuous function f such that $\{G_m(f, \mathcal{T})\}$ does not converge in $L_p(\mathbb{T})$ for any $p > 2$; and 2) there exists a function f that belongs to any $L_p(\mathbb{T})$, $p < 2$, such that $\{G_m(f, \mathcal{T})\}$ does not converge in measure. Thus the above negative results show that the condition $f \in L_p(\mathbb{T}^d)$, $p \neq 2$, does not guarantee convergence of $\{G_m(f, \mathcal{T}^d)\}$ in the L_p-norm. The main goal of this section is to discuss an additional (to $f \in L_p$) condition on f to guarantee that $\|f - G_m(f, \mathcal{T}^d)\|_p \to 0$ as $m \to \infty$. Some results in this direction have been obtained in [29], [30]. In the case $2 < p \leq \infty$ we found in [29] necessary and sufficient conditions on a decreasing sequence $\{A_n\}_{n=1}^{\infty}$ to guarantee the L_p-convergence of $\{G_m(f)\}$ for all $f \in L_p$, satisfying $a_n(f) \leq A_n$, where $\{a_n(f)\}$ is a decreasing rearrangement of absolute values of the Fourier coefficients of f. We will formulate three theorems from [29].

For $f \in L_1(\mathbb{T}^d)$ let $\{\hat{f}(k(l))\}_{l=1}^{\infty}$ denote the decreasing rearrangement of $\{\hat{f}(k)\}_{k \in \mathbb{Z}^d}$, i.e.

$$|\hat{f}(k(1))| \geq |\hat{f}(k(2))| \geq \cdots . \tag{5.2}$$

Denote $a_n(f) := |\hat{f}(k(n))|$.

Theorem 5.1. *Let $2 < p < \infty$ and let a decreasing sequence $\{A_n\}_{n=1}^{\infty}$ satisfy the condition*

$$A_n = o(n^{1/p-1}) \quad \text{as } n \to \infty. \tag{5.3}$$

Then for any $f \in L_p(\mathbb{T}^d)$ *with the property* $a_n(f) \le A_n$, $n = 1, 2, \dots$, *we have*

$$\lim_{m\to\infty} \|f - G_m^t(f, \mathcal{T})\|_p = 0. \tag{5.4}$$

We also proved in [29] that for any decreasing sequence $\{A_n\}$ satisfying

$$\limsup_{n\to\infty} A_n n^{1-1/p} > 0$$

there exists a function $f \in L_p$ such that $a_n(f) \le A_n$, $n = 1, \dots$, with divergent in the L_p norm sequence of greedy approximants $\{G_m(f)\}$.

Theorem 5.2. *Let a decreasing sequence* $\{A_n\}_{n=1}^{\infty}$ *satisfy the following condition* $(\mathcal{A}_\infty)$*:*

$$\sum_{M<n\le e^M} A_n = o(1) \quad \text{as } M \to \infty. \tag{5.5}$$

Then for any $f \in C(\mathbb{T})$ *with the property* $a_n(f) \le A_n$, $n = 1, 2, \dots$, *we have*

$$\lim_{m\to\infty} \|f - G_m^t(f, \mathcal{T})\|_\infty = 0. \tag{5.6}$$

The following theorem from [29] shows that the condition $(\mathcal{A}_\infty)$ in Theorem 5.2 is sharp.

Theorem 5.3. *Assume that a decreasing sequence* $\{A_n\}_{n=1}^{\infty}$ *does not satisfy the condition* $(\mathcal{A}_\infty)$. *Then there exists a function* $f \in C(\mathbb{T})$ *with the property* $a_n(f) \le A_n$, $n = 1, 2, \dots$, *and such that we have*

$$\limsup_{m\to\infty} \|f - G_m(f, \mathcal{T})\|_\infty > 0$$

for some realization $G_m(f, \mathcal{T})$.

In [30] we concentrated on imposing extra conditions in the following form. We assume that for some sequence $\{M(m)\}$, $M(m) > m$, we have

$$\|G_{M(m)}(f) - G_m(f)\|_p \to 0 \quad \text{as } m \to \infty. \tag{5.7}$$

In the case that p is an even number or $p = \infty$ we found in [30] necessary and sufficient conditions on the growth of the sequence $\{M(m)\}$ to provide convergence $\|f - G_m(f)\|_p \to 0$ as $m \to \infty$. We proved the next theorem in [30].

Theorem 5.4. *Let* $p = 2q$, $q \in \mathbb{N}$, *be an even integer,* $\delta > 0$. *Assume that* $f \in L_p(\mathbb{T})$ *and there exists a sequence of positive integers* $M(m) > m^{1+\delta}$ *such that*

$$\|G_m(f) - G_{M(m)}(f)\|_p \to 0 \quad \text{as } m \to \infty.$$

Then we have

$$\|G_m(f) - f\|_p \to 0 \quad \text{as } m \to \infty.$$

In [30] we proved that the condition $M(m) > m^{1+\delta}$ cannot be replaced by the condition $M(m) > m^{1+o(1)}$.

Theorem 5.5. *For any $p \in (2, \infty)$ there exists a function $f \in L_p(\mathbb{T})$ with divergent in the $L_p(\mathbb{T})$ norm sequence $\{G_m(f)\}$ of greedy approximations with the following property. For any sequence $\{M(m)\}$ such that $m \le M(m) \le m^{1+o(1)}$ we have*

$$\|G_{M(m)}(f) - G_m(f)\|_p \to 0 \quad (m \to 0).$$

In [30] we also considered the case $p = \infty$. We proved there necessary and sufficient conditions for convergence of greedy approximations in the uniform norm. For a mapping $\alpha : W \to W$ we denote by α_k its k-fold iteration: $\alpha_k := \alpha \circ \alpha_{k-1}$.

Theorem 5.6. *Let $\alpha : \mathbb{N} \to \mathbb{N}$ be strictly increasing. Then the following conditions are equivalent:*

a) *For some $k \in \mathbb{N}$ and for any sufficiently large $m \in \mathbb{N}$ we have $\alpha_k(m) > e^m$.*

b) *If $f \in C(\mathbb{T})$ and*

$$\left\|G_{\alpha(m)}(f) - G_m(f)\right\|_\infty \to 0 \quad (m \to \infty)$$

then

$$\|f - G_m(f)\|_\infty \to 0 \quad (m \to \infty).$$

The proof of the necessary condition is based on the above Theorem 5.3 from [29]. In the proof of the sufficient condition we use the following special inequality (see [30]).

By $\Sigma_m(\mathcal{T})$ we denote the set of all trigonometric polynomials with at most m nonzero coefficients.

Theorem 5.7. *For any $h \in \Sigma_m(\mathcal{T})$ and any $g \in L_\infty$ one has*

$$\|h + g\|_\infty \ge K^{-2}\|h\|_\infty - e^{C(K)m}\|\{\hat{g}(k)\}\|_{\ell_\infty}, \quad K > 1. \tag{5.8}$$

We note that in the proof of the above inequality we used a deep result on the uniform approximation property of the space $C(X)$ (see [4]). The paper [30] contains some other inequalities in the style of (5.8).

6. General greedy algorithms

The purpose of this section is to discuss nonlinear m-term approximation and greedy algorithms with regard to a general system (dictionary). We concentrate here on a discussion of m-term approximation with regard to redundant dictionaries in Banach spaces. We will discuss only one example of an algorithm from the family of greedy

algorithms. The reader can find a further discussion of greedy approximation in Banach spaces in the survey [47]. This section is based on the paper [44] which in turn is a combination of ideas and methods developed for Banach spaces in a fundamental paper [13] with the approach used in [50] in the case of Hilbert spaces. The papers [13] and [50] contain detailed historical remarks and we refer the reader to those papers. Two greedy type approximation methods the Weak Chebyshev Greedy Algorithm (WCGA) and the Weak Relaxed Greedy Algorithm (WRGA) have been introduced and studied in [44]. These methods (WCGA and WRGA) are very general approximation methods that work well in an arbitrary uniformly smooth Banach space X for any dictionary $\mathcal{D}$ (see below). Surprisingly, it turned out that these general approximation methods are also very good for specific dictionaries. It has been observed in [15] that the WCGA provides constructive methods in m-term trigonometric approximation in L_p, $p \in [2, \infty)$, which realizes optimal rate of m-term approximation for different function classes. In [48] the WCGA and WRGA have been used in constructing deterministic cubature formulas for a wide variety of function classes with error estimates similar to those for the Monte Carlo Method. It looks like WCGA and WRGA can be considered as a constructive deterministic alternative to (substitute for) some powerful probabilistic methods. This observation encouraged us to continue thorough study of WCGA and WRGA.

In this section we discuss in detail only WCGA. In [44] we developed the theory of the Weak Chebyshev Greedy Algorithm in a general setting: X is an arbitrary uniformly smooth Banach space and $\mathcal{D}$ is any dictionary. We keep the term *greedy algorithm* in the name of this approximation method for two reasons. First, this term has been used in previous papers and has become a standard name for procedures like WCGA. For more discussion of the terminology see [47, Remark 1.1, p. 38]. Second, clearly, in the above general setting the term *algorithm* cannot be confused with the same term used in a more restricted sense, say, in computer science. We note that in the case of finite dimensional X and finite $\mathcal{D}$ the above methods are algorithms in a strict sense.

In this section we discuss the following two applications of general greedy algorithms from [49]. In [49] we used WCGA to build a constructive method for m-term trigonometric approximation in the uniform norm. It is known that the case of approximating by m-term trigonometric polynomials in the uniform norm is the most difficult. We note that in the case of L_p-norms with $p < \infty$ the corresponding constructive method has been provided in [15]. In [49] we also studied a slight modification of incremental type algorithm from [13]. We applied that algorithm for constructing deterministic sets of points with small L_p discrepancy and also with small symmetrized L_p discrepancy.

We now proceed to a systematic presentation of the mentioned above results. Let X be a Banach space with norm $\|\cdot\|$. We say that a set of elements (functions) $\mathcal{D}$ from X is a dictionary if each $g \in \mathcal{D}$ has norm less than or equal to one ($\|g\| \le 1$),

$$g \in \mathcal{D} \quad \text{implies} \quad -g \in \mathcal{D},$$

and $\overline{\operatorname{span}}\mathcal{D} = X$. We note that in [44] we required in the definition of a dictionary normalization of its elements ($\|g\| = 1$). However, it is pointed out in [49] that it is easy to check that the arguments from [44] work under the assumption $\|g\| \le 1$ instead of $\|g\| = 1$. In applications it is more convenient for us to have the assumption $\|g\| \le 1$ than normalization of a dictionary.

For an element $f \in X$ we denote by F_f a norming (peak) functional for f:

$$\|F_f\| = 1, \quad F_f(f) = \|f\|.$$

The existence of such a functional is guaranteed by the Hahn–Banach theorem. Let $\tau := \{t_k\}_{k=1}^{\infty}$ be a given sequence of nonnegative numbers $t_k \le 1$, $k = 1, \dots$. We define (see [44]) the Weak Chebyshev Greedy Algorithm (WCGA) which is a generalization for Banach spaces of the Weak Orthogonal Greedy Algorithm defined and studied in [50] (see also [12] for the Orthogonal Greedy Algorithm).

6.1. Weak Chebyshev Greedy Algorithm (WCGA). We define $f_0^c := f_0^{c,\tau} := f$. Then for each $m \ge 1$ we inductively define

1) $\varphi_m^c := \varphi_m^{c,\tau} \in \mathcal{D}$ is any element satisfying

$$F_{f_{m-1}^c}(\varphi_m^c) \ge t_m \sup_{g \in \mathcal{D}} F_{f_{m-1}^c}(g).$$

2) Define

$$\Phi_m := \Phi_m^{\tau} := \operatorname{span}\{\varphi_j^c\}_{j=1}^m,$$

and define $G_m^c := G_m^{c,\tau}$ to be the best approximant to f from Φ_m.

3) Denote

$$f_m^c := f_m^{c,\tau} := f - G_m^c.$$

The term "weak" in this definition means that at step 1) we do not shoot for the optimal element of the dictionary which realizes the corresponding supremum but are satisfied with the weaker property rather than being optimal. The obvious reason for this is that we do not know in general that the optimal one exists. Another practical reason is that, the weaker the assumption, the easier to satisfy it and, therefore, easier to realize in practice.

We consider here approximation in uniformly smooth Banach spaces. For a Banach space X we define the modulus of smoothness by

$$\rho(u) := \sup_{\|x\|=\|y\|=1} \left(\frac{1}{2}(\|x + uy\| + \|x - uy\|) - 1 \right).$$

The uniformly smooth Banach space is the one with the property

$$\lim_{u \to 0} \rho(u)/u = 0.$$

It is easy to see that for any Banach space X its modulus of smoothness $\rho(u)$ is an even convex function satisfying the inequalities

$$\max(0, u-1) \le \rho(u) \le u, \quad u \in (0, \infty). \tag{6.1}$$

It is well known (see for instance [13], Lemma B.1) that in the case $X = L_p$, $1 \le p < \infty$ we have

$$\rho(u) \le \begin{cases} u^p/p & \text{if} \quad 1 \le p \le 2, \\ (p-1)u^2/2 & \text{if} \quad 2 \le p < \infty. \end{cases} \tag{6.2}$$

It is also known (see [34], p. 63) that for any X with $\dim X = \infty$ one has

$$\rho(u) \ge (1+u^2)^{1/2} - 1$$

and for every X, $\dim X \ge 2$,

$$\rho(u) \ge Cu^2, \quad C > 0.$$

This limits power type moduli of smoothness of nontrivial Banach spaces to the case $1 \le q \le 2$. Denote by $A(\mathcal{D})$ the closure of the convex hull of $\mathcal{D}$. The following theorem from [44] gives the rate of convergence of the WCGA for f in $A(\mathcal{D})$.

Theorem 6.1. *Let X be a uniformly smooth Banach space with the modulus of smoothness $\rho(u) \le \gamma u^q$, $1 < q \le 2$. Then for a sequence $\tau := \{t_k\}_{k=1}^{\infty}$, $t_k \le 1$, $k = 1, 2, \dots$, we have for any $f \in A(\mathcal{D})$ that*

$$\|f - G_m^{c,\tau}(f, \mathcal{D})\| \le C(q, \gamma)\Big(1 + \sum_{k=1}^{m} t_k^p\Big)^{-1/p}, \quad p := \frac{q}{q-1},$$

with a constant $C(q, \gamma)$ which may depend only on q and γ.

In [49] we demonstrated the power of the WCGA in classical areas of harmonic analysis. The problem concerns the trigonometric m-term approximation in the uniform norm. Let $\mathcal{RT}(N)$ be the subspace of real trigonometric polynomials of order N. Both R. S. Ismagilov [20] and V. E. Maiorov [35] used constructive methods to get their estimates (1.6) and (1.8). V. E. Maiorov [35] applied a number theoretical method based on Gaussian sums. The key point of that technique can be formulated in terms of best m-term approximation of trigonometric polynomials. Using the Gaussian sums one can prove (constructively) the estimate

$$\sigma_m(t, \mathcal{RT})_\infty \le CN^{3/2}m^{-1}\|t\|_1, \quad t \in \mathcal{RT}(N). \tag{6.6}$$

Denote

$$\Big\|a_0/2 + \sum_{k=1}^{N}(a_k \cos kx + b_k \sin kx)\Big\|_A := |a_0| + \sum_{k=1}^{N}(|a_k| + |b_k|).$$

We note that by the simple inequality

$$\|t\|_A \le (2N+1)\|t\|_1, \quad t \in \mathcal{RT}(N),$$

the estimate (6.6) follows from the estimate

$$\sigma_m(t, \mathcal{RT})_\infty \le C(N^{1/2}/m)\|t\|_A, \quad t \in \mathcal{RT}(N). \tag{6.7}$$

Thus (6.7) is stronger than (6.6). The following estimate was proved in [11]:

$$\sigma_m(t, \mathcal{RT})_\infty \le Cm^{-1/2}(\ln(1+N/m))^{1/2}\|t\|_A, \quad t \in \mathcal{RT}(N). \tag{6.8}$$

In a way (6.8) is much stronger than (6.7) and (6.6). The proof of (6.8) from [11] is not constructive. The estimate (6.8) has been proved in [11] with the help of a nonconstructive theorem of Gluskin [17]. In [49] we gave a constructive proof of (6.8). The key ingredient of that proof is the WCGA. In the paper [15] we already pointed out that the WCGA provides a constructive proof of the estimate

$$\sigma_m(f, \mathcal{T})_p \le C(p)m^{-1/2}\|f\|_A, \quad p \in [2, \infty). \tag{6.9}$$

The known proofs (before [15]) of (6.9) were nonconstructive (see discussion in [15, Section 5]).

We formulate here a result from [49] (see Theorem 4.1).

Theorem 6.2. *There exists a constructive method $A(N, m)$ such that for any $t \in \mathcal{RT}(N)$ it provides an m-term trigonometric polynomial $A(N, m)(t)$ with the following approximation property:*

$$\|t - A(N, m)(t)\|_\infty \le Cm^{-1/2}(\ln(1+N/m))^{1/2}\|t\|_A$$

with an absolute constant C.

In [49] we applied greedy type algorithms for constructing points with small discrepancy and small symmetrized discrepancy. Let $1 \le p \le \infty$. We will define first the L_p discrepancy (the L_p-star discrepancy) of points $\{\xi^1, \dots, \xi^m\} \subset \Omega_d := [0,1]^d$. Let $\chi_{[a,b]}(\cdot)$ be a characteristic function of the interval $[a, b]$. Denote for $x, y \in \Omega_d$

$$B(x, y) := \prod_{j=1}^d \chi_{[0,x_j]}(y_j).$$

Then the L_p discrepancy of $\xi := \{\xi^1, \dots, \xi^m\} \subset \Omega_d$ is defined by

$$D(\xi, m, d)_p := \Big\| \int_{\Omega_d} B(x, y)dy - \frac{1}{m}\sum_{\mu=1}^m B(x, \xi^\mu) \Big\|_{L_p(\Omega_d)}.$$

We are interested in ξ with small discrepancy. Consider

$$D(m, d)_p := \inf_\xi D(\xi, m, d)_p.$$

The concept of discrepancy is a fundamental concept in numerical integration. There are many books and survey papers on discrepancy and related topics. We mention some of them as a reference for the history of the subject: [33], [3], [36], [5], [37], [48]. For $1 < p < \infty$ the following relation is known (see [3, p. 5]):

$$D(m,d)_p \asymp m^{-1}(\ln m)^{(d-1)/2} \tag{6.10}$$

with constants in $\asymp$ depending on p and d. The right order of $D(m,d)_p$, $p = 1, \infty$, for $d \geq 3$ is unknown. Recently, driven by possible applications (see [37]) in numerical integration the tendancy to control dependence of $D(m,d)_p$ on both variables m and d has appeared. Very interesting results in this direction have been obtained in [19]. The authors established the estimate

$$D(m,d)_\infty \leq Cd^{1/2}m^{-1/2} \tag{6.11}$$

with C an absolute constant. It is pointed out in [19] that (6.11) is only an existence theorem and even a constant C in (6.11) is unknown. The proof is a probabilistic one. There are also some other estimates in [19] with explicit constants. We mention one of them:

$$D(m,d)_\infty \leq C(d\ln d)^{1/2}((\ln m)/m)^{1/2} \tag{6.12}$$

with an explicit constant C. The proof of (6.12) is also probabilistic.

In [49] we gave constructive proofs of the following two upper estimates:

$$D(m,d)_p \leq C_1 p^{1/2}m^{-1/2}, \qquad p \in [2,\infty),$$

$$D(m,d)_\infty \leq C_2 d^{3/2}(\max(\ln d, \ln m))^{1/2}m^{-1/2}, \quad d,m \geq 2,$$

with effective absolute constants C_1 and C_2. The term *constructive proof* goes back to Kronecker who outlined the program of giving constructive proofs of theorems that were established as existence theorems. Following traditions of approximation theory we understand constructive proof as a proof that provides a construction of an object and this construction has a potential of being implemented numerically. For instance, a proof by contradiction or a probabilistic proof establishing existence of an object is not a constructive proof for us. In [49] we provided a method which consists of maximizing (approximately) certain functions of d variables at each step. For a given $p \in [2,\infty)$ after m steps of this method we obtain a set $\xi = \{\xi^1, \dots, \xi^m\} \subset \Omega_d$ of points with small L_p discrepancy

$$D(\xi, m, d)_p \leq C_1 p^{1/2}m^{-1/2}$$

with effective absolute constant C_1. The above method is a greedy type algorithm (see the IA(ϵ) below) which is a slight modification of the corresponding procedure from [13]. Here we do not assume that a dictionary $\mathcal{D}$ is symmetric: $g \in \mathcal{D}$ implies $-g \in \mathcal{D}$. To indicate this we will use the notation $\mathcal{D}^+$ for such a dictionary. We do not assume that elements of a dictionary $\mathcal{D}^+$ are normalized ($\|g\| = 1$ if $g \in \mathcal{D}^+$) we only assume that $\|g\| \leq 1$ if $g \in \mathcal{D}^+$. By $\mathcal{A}_1(\mathcal{D}^+)$ we denote the closure of the convex hull of $\mathcal{D}^+$. Let $\epsilon = \{\epsilon_n\}_{n=1}^\infty$, $\epsilon_n > 0$, $n = 1, 2, \dots$.

6.2. Incremental algorithm with schedule ϵ (IA(ϵ)). Let $f \in \mathcal{A}_1(\mathcal{D}^+)$. Denote $f_0^{i,\epsilon} := f$ and $G_0^{i,\epsilon} := 0$. Then for each $m \geq 1$ we inductively define

1. $\varphi_m^{i,\epsilon} \in \mathcal{D}^+$ is any element satisfying

$$F_{f_{m-1}^{i,\epsilon}}(\varphi_m^{i,\epsilon} - f) \geq -\epsilon_m.$$

2. Define

$$G_m^{i,\epsilon} := (1 - 1/m)G_{m-1}^{i,\epsilon} + \varphi_m^{i,\epsilon}/m.$$

3. Denote

$$f_m^{i,\epsilon} := f - G_m^{i,\epsilon}.$$

Analytic capacity, rectifiability, and the Cauchy integral

Xavier Tolsa*

Abstract. A compact set $E \subset \mathbb{C}$ is said to be removable for bounded analytic functions if for any open set Ω containing E, every bounded function analytic on $\Omega \setminus E$ has an analytic extension to Ω. Analytic capacity is a notion that, in a sense, measures the size of a set as a non removable singularity. In particular, a compact set is removable if and only if its analytic capacity vanishes. The so-called Painlevé problem consists in characterizing removable sets in geometric terms. Recently many results in connection with this very old and challenging problem have been obtained. Moreover, it has also been proved that analytic capacity is semiadditive. We review these results and other related questions dealing with rectifiability, the Cauchy transform, and the Riesz transforms.

Mathematics Subject Classification (2000). Primary 30C85; Secondary 42B20, 28A75.

Keywords. Analytic capacity, rectifiability, Cauchy transform, Riesz transform, singular integrals.

1. Introduction

In this paper we survey recent results in connection with analytic capacity, rectifiability and the Cauchy and Riesz transforms. We are specially interested in the interaction between analytic and geometric notions. Most of the results that we will review are a mixture of harmonic analysis and geometric measure theory. Some of them may have also some little amount of complex analysis.

Let us introduce some notation and definitions. A compact set $E \subset \mathbb{C}$ is said to be removable for bounded analytic functions if for any open set Ω containing E, every bounded function analytic on $\Omega \setminus E$ has an analytic extension to Ω. In order to study removability, in the 1940s Ahlfors [Ah] introduced the notion of analytic capacity. The *analytic capacity* of a compact set $E \subset \mathbb{C}$ is

$$\gamma(E) = \sup |f'(\infty)|, \tag{1}$$

where the supremum is taken over all analytic functions $f : \mathbb{C} \setminus E \to \mathbb{C}$ with $|f| \leq 1$ on $\mathbb{C} \setminus E$, and $f'(\infty) = \lim_{z\to\infty} z(f(z) - f(\infty))$.

In [Ah], Ahlfors showed that E is removable for bounded analytic functions if and only if $\gamma(E) = 0$.

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

Painlevé's problem consists in characterizing removable singularities for bounded analytic functions in a metric/geometric way. By Ahlfors' result this turns out to be equivalent to describing compact sets with positive analytic capacity in metric/geometric terms.

Vitushkin in the 1950s and 1960s showed that analytic capacity plays a central role in problems of uniform rational approximation on compact sets of the complex plane. Because of its applications to this type of problems he raised the question of the semiadditivity of γ. Namely, does there exist an absolute constant C such that

$$\gamma(E \cup F) \leq C(\gamma(E) + \gamma(F))\,?$$

It has recently been proved [To5] that analytic capacity is indeed semiadditive. Moreover, a characterization of removable sets for bounded analytic functions in terms of the so-called curvature of measures is also given in [To5]. In Section 2 of the present paper we will review these results and other recent advances in connection with analytic capacity and Painlevé's problem. We will describe some of the ideas involved in their proofs. In particular, we will see that L^2 estimates for the Cauchy transform play a prominent role in most of these results.

Recall that if ν is a finite complex Borel measure on $\mathbb{C}$, the *Cauchy transform* (or *Cauchy integral*) of ν is defined by

$$\mathcal{C}\nu(z) = \int \frac{1}{\xi - z} d\nu(\xi).$$

Although the integral above is absolutely convergent a.e. with respect to Lebesgue measure, it does not make sense, in general, for $z \in \operatorname{supp}(\nu)$. This is the reason why one considers the *truncated Cauchy transform* of ν, which is defined as

$$\mathcal{C}_\varepsilon \nu(z) = \int_{|\xi - z| > \varepsilon} \frac{1}{\xi - z} d\nu(\xi),$$

for any $\varepsilon > 0$ and $z \in \mathbb{C}$.

In Section 3 we will survey several results about the μ-almost everywhere (a.e.) existence of the principal value

$$\text{p.v.}\mathcal{C}\mu(z) = \lim_{\varepsilon \to 0} \mathcal{C}_\varepsilon \mu(z),$$

where μ is some positive finite Borel measure on $\mathbb{C}$, and its relationship with rectifiability.

Section 4 deals with the natural generalization of analytic capacity to higher dimensions, the so-called Lipschitz harmonic capacity. The role played by the Cauchy transform in connection with analytic capacity corresponds to the Riesz transforms in the case of Lipschitz harmonic capacity. See Section 4 for more details.

In the final section of the paper we recall some open problems related to analytic capacity, the Cauchy and Riesz transforms, and rectifiability. This is a rather short list

which reflects our personal interests and it is not intended to be a complete account of open problems in the area.

Some comments about the notation used in the paper: as usual, the letter 'C' stands for an absolute constant which may change its value at different occurrences. The notation $A \lesssim B$ means that there is a positive absolute constant C such that $A \leq CB$. Also, $A \approx B$ is equivalent to $A \lesssim B \lesssim A$.

2. Analytic capacity and the Cauchy transform

2.1. Basic properties of analytic capacity. In a sense, analytic capacity measures the size of a set as a non removable singularity for bounded analytic functions. A direct consequence of the definition is that for all $\lambda \in \mathbb{C}$ and $E \subset \mathbb{C}$ compact one has $\gamma(\lambda + E) = \gamma(E)$ and $\gamma(\lambda E) = |\lambda|\gamma(E)$. Further, if E is connected, then

$$\operatorname{diam}(E)/4 \leq \gamma(E) \leq \operatorname{diam}(E).$$

The second inequality (which holds for any compact set E) follows from the fact that the analytic capacity of a ball coincides with its radius, and the first one is a consequence of Koebe's $1/4$ theorem (see [Gam, Chapter VIII] or [Gar2, Chapter I] for the details, for example). Thus if E is connected and different from a point, then it is non removable. This implies that any removable compact set must be totally disconnected.

The relationship between analytic capacity and Hausdorff measure is as follows:

- If $\dim_H(E) > 1$ (here $\dim_H$ stands for the Hausdorff dimension) then $\gamma(E) > 0$. This result is an easy consequence of Frostman's Lemma.
- $\gamma(E) \leq \mathcal{H}^1(E)$, where $\mathcal{H}^s$ is the s-dimensional Hausdorff measure, or length when $s = 1$. This follows from Cauchy's integral formula, and it was proved by Painlevé about one hundred years ago. In particular, notice that if $\dim_H(E) < 1$ then $\gamma(E) = 0$.

By the statements above, one infers that dimension 1 is the critical dimension in connection with analytic capacity. It turns out that some sets of positive length and dimension 1 have positive analytic capacity (for example, a segment), while others have vanishing analytic capacity. The latter assertion was proved by Vitushkin [Vi1]. Later on, an easier example of a set with positive length and zero analytic capacity was found by Garnett [Gar1] and Ivanov [Iv].

2.2. The Cauchy transform and the capacity γ_+. Recall that given a positive Borel measure μ on the complex plane, $\mathcal{C}\mu$ stands for the Cauchy transform of μ. If f is a μ-measurable function f on $\mathbb{C}$, we denote $\mathcal{C}_\mu f(z) := \mathcal{C}(f\,d\mu)(z)$ for $z \notin \operatorname{supp}(f)$, and $\mathcal{C}_{\mu,\varepsilon} f(z) := \mathcal{C}_\varepsilon(f\,d\mu)(z)$ for any $\varepsilon > 0$ and $z \in \mathbb{C}$. We say that $\mathcal{C}_\mu$ is bounded on $L^2(\mu)$ if the operators $\mathcal{C}_{\mu,\varepsilon}$ are bounded on $L^2(\mu)$ uniformly on $\varepsilon > 0$.

Let us denote by $M_+(\mathbb{C})$ the set of finite (positive) Borel measures on $\mathbb{C}$. The capacity γ_+ of a compact set $E \subset \mathbb{C}$ is

$$\gamma_+(E) := \sup\{\mu(E) : \mu \in M_+(\mathbb{C}), \operatorname{supp}(\mu) \subset E, \ \|\mathcal{C}\mu\|_{L^\infty(\mathbb{C})} \leq 1\}. \qquad (2)$$

That is, γ_+ is defined as γ in (1) with the additional constraint that f should coincide with $\mathcal{C}\mu$, where μ is some positive Borel measure supported on E (observe that $(\mathcal{C}\mu)'(\infty) = -\mu(\mathbb{C})$ for any Borel measure μ). Moreover, there is another slight difference: in (1) we required $\|f\|_{L^\infty(\mathbb{C}\setminus E)} \leq 1$, while in (2), $\|f\|_{L^\infty(\mathbb{C})} \leq 1$ (for $f = \mathcal{C}\mu$). Trivially, we have $\gamma_+(E) \leq \gamma(E)$.

We introduce now some additional notation. A Borel measure μ on $\mathbb{R}^d$ has growth of degree n if there exists some constant C such that $\mu(B(x, r)) \leq Cr^n$ for all $x \in \mathbb{R}^d$, $r > 0$. When $n = 1$, we say that μ has linear growth. If μ satisfies $\mu(B(x, r)) \approx r^n$ for all $x \in \operatorname{supp}(\mu)$, $0 < r \leq \operatorname{diam}(\operatorname{supp}(\mu))$, we say that μ is n-Ahlfors–David (n-AD) regular, or abusing language, AD regular. A set $E \subset \mathbb{C}$ is called n-AD regular (abusing language, AD regular) if $\mathcal{H}^n|_E$ is AD regular. We say that μ is doubling if there exists some constant C such that $\mu(B(z, 2r)) \leq C\mu(B(z, r))$ for all $z \in \operatorname{supp}(\mu)$, $r > 0$. In particular, AD regular measures are doubling.

The next theorem shows why L^2 estimates for the Cauchy transform are useful in connection with analytic capacity.

Theorem 2.1. *Let μ be a measure with linear growth on $\mathbb{C}$. Suppose that the Cauchy transform is bounded in $L^2(\mu)$. Then, for any compact $E \subset \mathbb{C}$ there exists a function h supported on E with $0 \leq h \leq 1$ such that $\int h\, d\mu \approx \mu(E)$, with $\|\mathcal{C}_\varepsilon(h\, d\mu)\|_\infty \leq C$ for all $\varepsilon > 0$, and $\|\mathcal{C}(h\, d\mu)\|_{\infty,\mathbb{C}\setminus E} \leq C$. All the constants depend only on the linear growth of μ and on $\|\mathcal{C}\|_{L^2(\mu),L^2(\mu)}$.*

In the statement above, $\|\mathcal{C}_\mu\|_{L^2(\mu),L^2(\mu)}$ stands for the operator norm of $\mathcal{C}_\mu$ on $L^2(\mu)$. That is, $\|\mathcal{C}_\mu\|_{L^2(\mu),L^2(\mu)} = \sup_{\varepsilon>0} \|\mathcal{C}_{\mu,\varepsilon}\|_{L^2(\mu),L^2(\mu)}$.

From the preceding result one infers that if E supports a non zero measure μ with linear growth such that the Cauchy transform $\mathcal{C}_\mu$ is bounded on $L^2(\mu)$, then $\gamma(E) \geq \gamma_+(E) > 0$.

Theorem 2.1 is from Davie and Øksendal [DØ] and it follows from the fact that the L^2 boundedness of the Cauchy transform implies weak (1, 1) estimates. Theorem 2.1 is obtained by a suitable dualization of these weak (1, 1) estimates. See [Uy] for a connected result prior to [DØ] which also involves a dualization of a weak (1, 1) inequality.

2.3. Menger curvature and rectifiability. Given three pairwise different points $x, y, z \in \mathbb{C}$, their *Menger curvature* is

$$c(x, y, z) = \frac{1}{R(x, y, z)},$$

where $R(x, y, z)$ is the radius of the circumference passing through x, y, z. If two among these points coincide, we let $c(x, y, z) = 0$. For a positive Borel measure μ,

we define the *curvature of* μ as

$$c^2(\mu) = \iiint c(x, y, z)^2 \, d\mu(x) d\mu(y) d\mu(z). \tag{3}$$

Given $\varepsilon > 0$, $c_\varepsilon^2(\mu)$ stands for the ε-truncated version of $c^2(\mu)$, defined as in the right hand side of (3), but with the triple integral over $\{(x, y, z) \in \mathbb{C}^3 : |x - y|, |y - z|, |x - z| > \varepsilon\}$.

The notion of curvature of a measure was introduced by Melnikov [Me] when he was studying a discrete version of analytic capacity, and it is one of the notions which is responsible of the big recent advances in connection with analytic capacity. The notion of curvature is connected to the Cauchy transform by the following result, proved by Melnikov and Verdera [MeV].

Proposition 2.2. *Let μ be a Borel measure on $\mathbb{C}$ with linear growth. We have*

$$\|\mathcal{C}_\varepsilon \mu\|_{L^2(\mu)}^2 = \frac{1}{6} c_\varepsilon^2(\mu) + O(\mu(\mathbb{C})), \tag{4}$$

where $|O(\mu(\mathbb{C}))| \leq C\mu(\mathbb{C})$.

Sketch of the proof of Proposition 2.2. If we do not worry about truncations and the absolute convergence of the integrals, we can write

$$\begin{aligned} \|\mathcal{C}\mu\|_{L^2(\mu)}^2 &= \int \left| \int \frac{1}{y - x} \, d\mu(y) \right|^2 d\mu(x) \\ &= \iiint \frac{1}{(y - x)(\overline{z - x})} \, d\mu(y) d\mu(z) d\mu(x). \end{aligned}$$

By Fubini (assuming that it can be applied correctly), permuting x, y, z, we get,

$$\|\mathcal{C}\mu\|_{L^2(\mu)}^2 = \frac{1}{6} \iiint \sum_{s \in S_3} \frac{1}{(z_{s_2} - z_{s_1})(\overline{z_{s_3} - z_{s_1}})} \, d\mu(z_1) d\mu(z_2) d\mu(z_3),$$

where S_3 is the group of permutations of three elements. An elementary calculation shows that

$$\sum_{s \in S_3} \frac{1}{(z_{s_2} - z_{s_1})(\overline{z_{s_3} - z_{s_1}})} = c(z_1, z_2, z_3)^2.$$

So we get

$$\|\mathcal{C}\mu\|_{L^2(\mu)}^2 = \frac{1}{6} \, c^2(\mu).$$

To argue rigorously, above we should use the truncated Cauchy transform $\mathcal{C}_\varepsilon \mu$ instead of $\mathcal{C}\mu$, and then we would obtain

$$\begin{aligned} \|\mathcal{C}_\varepsilon \mu\|_{L^2(\mu)}^2 &= \iiint_{\substack{|x-y|>\varepsilon \\ |x-z|>\varepsilon}} \frac{1}{(y - x)(\overline{z - x})} \, d\mu(y) d\mu(z) d\mu(x) \\ &= \iiint_{\substack{|x-y|>\varepsilon \\ |x-z|>\varepsilon \\ |y-z|>\varepsilon}} \frac{1}{(y - x)(\overline{z - x})} \, d\mu(y) d\mu(z) d\mu(x) + O(\mu(\mathbb{C})). \end{aligned} \tag{5}$$

By the linear growth of μ, it is easy to check that $|O(\mu(\mathbb{C}))| \leq \mu(\mathbb{C})$. As above, using Fubini and permuting x, y, z, one shows that the triple integral in (5) equals $c_\varepsilon^2(\mu)/6$. □

The identity (4) is remarkable because it relates an analytic notion (the Cauchy transform of a measure) with a metric/geometric one (curvature).

The above proposition was used in [MeV] to give a simple geometric proof of the L^2 boundedness of the Cauchy transform on a Lipschitz graph (the original proof is from Coifman, McIntosh and Meyer [CMM]). Indeed, using a Fourier type estimate, it was proved in [MeV] that if Γ is a Lipschitz graph, then $c^2(\mathcal{H}^1|_{\Gamma\cap B(z,r)} \lesssim r$ for all $z \in \Gamma$, $r > 0$. From (4) one infers that $\|\mathcal{C}_\varepsilon(b\,\chi_{B(z,r)}\mathcal{H}^1|_\Gamma)\|_{L^2(\mathcal{H}^1|\Gamma\cap B(z,r))} \lesssim \|b\|_\infty r^{1/2}$ for all $b \in L^\infty$, $z \in \Gamma$, and $r > 0$, uniformly on $\varepsilon > 0$. Now a simple argument shows that $\mathcal{C}_{\mathcal{H}^1|_\Gamma}$ sends boundedly L^∞ into $\mathrm{BMO}(\mathcal{H}^1|_\Gamma)$ and thus $H^1(\mathcal{H}^1|_\Gamma)$ into $L^1(\mathcal{H}^1|_\Gamma)$. Interpolating one gets the conclusion.

Let us turn our attention to rectifiability and its relationship with curvature of measures. A set is called rectifiable if it is $\mathcal{H}^1$-almost all contained in a countable union of rectifiable curves. On the other hand, it is called purely unrectifiable if it intersects any rectifiable curve at most in a set of zero length.

Now we wish to recall the traveling salesman theorem of P. Jones [Jo]. First we introduce some notation. Given $E \subset \mathbb{C}$ and a square Q, let V_Q be an infinite strip (or line in the degenerate case) of smallest possible width which contains $E \cap 3Q$, and let $w(V_Q)$ denote the width of V_Q. Then we set

$$\beta_E(Q) = \frac{w(V_Q)}{\ell(Q)},$$

where $\ell(Q)$ stands for the side length of Q. We denote by $\mathcal{D}$ the family of all dyadic squares in $\mathbb{C}$. In [Jo] the following result was proved:

Theorem 2.3. *A set $E \subset \mathbb{C}$ is contained in a rectifiable curve Γ (with finite length) if and only*

$$\sum_{Q\in\mathcal{D}} \beta_E(Q)^2 \ell(Q) < \infty. \tag{6}$$

Moreover, the length of the shortest curve Γ containing E satisfies

$$\mathcal{H}^1(\Gamma) \approx \mathrm{diam}(E) + \sum_{Q\in\mathcal{D}} \beta_E(Q)^2 \ell(Q),$$

with absolute constants.

The theorem also holds for sets E contained in $\mathbb{R}^d$. The proof of the "if" part of the theorem in [Jo] is also valid in this case. The "only if" part (for $\mathbb{R}^d$) was proved by Okikiolu [Ok]. Several versions of Jones' result which involve n-dimensional AD regular sets in $\mathbb{R}^d$ have been obtained by David and Semmes [DS1], [DS2]. In

fact, David and Semmes have developed a whole theory of the so-called "uniform rectifiability" for n-dimensional AD regular sets in $\mathbb{R}^d$.

The next result, proved by P. Jones (see [Pa, Chapter 3]), shows that there is a strong connection between curvature and the coefficients β in Jones' traveling salesman theorem.

Theorem 2.4. (a) *If $E \subset \mathbb{C}$ is 1-AD regular, then*

$$\sum_{Q \in \mathcal{D}} \beta_E(Q)^2 \ell(Q) \leq C\, c^2(\mathcal{H}^1|_E),$$

where C depends only on the AD regularity constant of E.

(b) *If μ is a measure with linear growth supported on a rectifiable curve $\Gamma \subset \mathbb{C}$, then*

$$c^2(\mu) \leq C \sum_{Q \in \mathcal{D}} \beta_\Gamma(Q)^2 \mu(Q),$$

where C depends only on the linear growth constant of μ.

From (a) in the preceding theorem and Theorem 2.3 it turns out that if $E \subset \mathbb{C}$ is AD regular and $c^2(\mathcal{H}^1|_E) < \infty$, then E is rectifiable. If one does not assume E to be AD regular, David and Léger [Lé] showed that the result still holds:

Theorem 2.5. *Let $E \subset \mathbb{C}$ be compact with $\mathcal{H}^1(E) < \infty$. If $c^2(\mathcal{H}^1|_E) < \infty$, then E is rectifiable.*

The proof of this result in [Lé] uses geometric techniques, in the spirit of the ones used by P. Jones for Theorem 2.3 in [Jo] and by David and Semmes in [DS1]. Recently, in [To9] a very different proof of Theorem 2.5 has been obtained. The new arguments are based on some kind of isoperimetric inequality involving analytic capacity and on the characterization of rectifiability in terms of densities.

From Theorem 2.5 and Proposition 2.2 one infers that if $\mathcal{H}^1(E) < \infty$ and the Cauchy transform is bounded on $L^2(\mathcal{H}^1|_E)$, then E must be rectifiable. A more quantitative version of this result proved by Mattila, Melnikov and Verdera [MMV] asserts that if E is AD regular and the Cauchy transform is bounded on $L^2(\mathcal{H}^1|_E)$, then E is contained in an AD regular curve Γ.

Recently, some of the results above dealing with rectifiability, β's, and curvature have been extended in different directions. For example, Lerman [Lr] has obtained a result analogous to Theorem 2.3 which involves very general Borel measures μ on $\mathbb{R}^d$ (instead of $\mathcal{H}^1|_E$) and $L^2(\mu)$ versions of Jones' β's. Ferrari, Franchi and Pajot [FFP] have extended the "if" part of the Theorem 2.3 to the Heisenberg group. Schul [Sch] has proved a version of the same theorem which is valid for Hilbert spaces. On the other hand, Hahlomaa [Hah] has obtained a version of Léger's Theorem 2.5 suitable for metric spaces.

2.4. Vitushkin's conjecture. For $\theta \in [0, \pi)$, let p_θ denote the orthogonal projection onto the line through the origin and direction $(\cos\theta, \sin\theta)$. Given a Borel set $E \subset \mathbb{C}$, its Favard length is

$$\mathrm{Fav}(E) = \int_0^\pi \mathcal{H}^1(p_\theta(E))\, d\theta. \tag{7}$$

Vitushkin conjectured in the 1960s that $\gamma(E) > 0$ if and only if $\mathrm{Fav}(E) > 0$. In 1986 Mattila [Ma1] showed that this conjecture is false. Indeed, he proved that the property of having positive Favard length is not invariant under conformal mappings while removability for bounded analytic functions remains invariant. Mattila's result did not tell which implication in the above conjecture was false. Later on, Jones and Murai [JM] constructed a set with zero Favard length and positive analytic capacity. An easier example using curvature was obtained more recently by Joyce and Mörters [JyM].

Although Vitushkin's conjecture is not true in full generality, it turns out that it holds in the particular case of sets with finite length. This was proved by G. David [Da] in 1998. Recall that when has E with finite length, by Besicovitch theorem, $\mathrm{Fav}(E) = 0$ if and only if E is purely unrectifiable.

The precise statement of David's result is the following.

Theorem 2.6. *Let $E \subset \mathbb{C}$ be compact with $\mathcal{H}^1(E) < \infty$. Then, $\gamma(E) = 0$ if and only if E is purely unrectifiable.*

This result is the solution of Painlevé's problem for sets with finite length. To be precise, let us remark that the "if" part of the theorem is not due to David. In fact, it follows from Calderón's theorem on the L^2 boundedness of the Cauchy transform on Lipschitz graphs with small Lipschitz constant and from Theorem 2.1. The "only if" part of the theorem, which is more difficult, is the one proved by David. Let us also mention that Mattila, Melnikov and Verdera [MMV] had proved previously the same result under the assumption that E is a 1-dimensional AD regular set.

The scheme of the proof of the "only if" part of Theorem 2.6 is the following. Let $E \subset \mathbb{C}$ be compact with $\gamma(E) > 0$ and finite length. Then there exists a function f analytic on $\mathbb{C} \setminus E$ such that $|f(z)| \leq 1$ on $\mathbb{C} \setminus E$ and $f'(\infty) = \gamma(E)$ (this is the so-called Ahlfors function, which maximizes $\gamma(E)$). Since $\mathcal{H}^1(E) < \infty$ it is not difficult to see that there exists some complex, bounded function g supported on E such that $f(z) = \mathcal{C}(g\, d\mathcal{H}^1|_E)(z)$ for $z \notin E$. Then it easily follows that $\|\mathcal{C}_\varepsilon(g\, d\mathcal{H}^1|_E)\|_{L^\infty} \leq C$ uniformly on $\varepsilon > 0$. On the other hand, g also satisfies $|\int g\, d\mathcal{H}^1|_E| = |f'(\infty)| = \gamma(E) > 0$. By a suitable $T(b)$ type theorem (which involves some delicate stopping time arguments, and non doubling measures) proved in [Da], one infers that there exists a subset $F \subset E$ with $\mathcal{H}^1(F) > 0$ such the Cauchy transform is bounded on $L^2(\mathcal{H}^1|_F)$. From Proposition 2.2 it follows that $c^2(\mathcal{H}^1|_F) < \infty$, and then by Theorem 2.5 F is rectifiable. So E cannot be purely unrectifiable.

Let us remark that the $T(b)$ theorem in [Da] uses a preliminary result from [DM]. A similar theorem had been previously obtained by Christ [Ch] in the AD regular case.

The result analogous to Theorem 2.6 for sets with infinite length is false. For this type of sets there is no such a nice geometric solution of Painlevé's problem, and we have to content ourselves with a characterization such as the one in Corollary 2.10 below (at least, for the moment).

2.5. Characterization of γ_+ in terms of curvature of measures and L^2 estimates for the Cauchy transform. The following theorem characterizes γ_+ in terms of curvature of measures and in terms of the L^2 norm of the Cauchy transform.

Theorem 2.7. *Let $\Sigma(E)$ denote class of Borel measures supported on E such that $\mu(B(x,r)) \leq r$ for all $x \in \mathbb{C}$, $r > 0$. For any compact set $E \subset \mathbb{C}$ we have*

$$\begin{aligned}\gamma_+(E) &\approx \sup\{\mu(E) :\ \mu \in \Sigma(E),\ c^2(\mu) \leq \mu(E)\} \\ &\approx \sup\{\mu(E) :\ \mu \in \Sigma(E),\ \|\mathcal{C}_\mu\|_{L^2(\mu),L^2(\mu)} \leq 1\}.\end{aligned} \tag{8}$$

Sketch of the proof of Theorem 2.7. Call S_1 and S_2 the first and second suprema on the right side of (8), respectively.

To see that $S_1 \gtrsim \gamma_+(E)$ take μ supported on E such that $\|\mathcal{C}\mu\|_\infty \leq 1$ and $\mu(E) \geq \gamma_+(E)/2$. One easily gets that $\|\mathcal{C}_\varepsilon \mu\|_\infty \lesssim 1$ on $\operatorname{supp}(\mu)$ for every $\varepsilon > 0$ and $\mu(B(x,r)) \leq Cr$ for all $r > 0$. From Proposition 2.2, it follows then that $c^2(\mu) \leq C\mu(E)$.

Consider now the inequality $S_2 \gtrsim S_1$. Let μ be supported on E with linear growth such that $c^2(\mu) \leq \mu(E)$ and $S_1 \leq 2\mu(E)$. We set

$$A := \left\{x \in E :\ \iint c(x,y,z)^2\, d\mu(y) d\mu(z) \leq 2\right\}.$$

By Tchebychev's inequality $\mu(A) \geq \mu(E)/2$. Moreover, for any set $B \subset \mathbb{C}$,

$$c^2(\mu|_{B\cap A}) \leq \iiint_{x\in B\cap A} c(x,y,z)^2\, d\mu(x) d\mu(y) d\mu(z) \leq 2\mu(B).$$

In particular, this estimate holds when B is any square in $\mathbb{C}$. Then, by the so-called $T(1)$ theorem (see [To1] or [NTV1]), one infers that $\mathcal{C}_{\mu|_A}$ is bounded on $L^2(\mu|_A)$. Thus $S_2 \gtrsim \mu(A) \approx S_1$.

Finally, the inequality $\gamma_+(E) \gtrsim S_2$ follows from Theorem 2.1. □

For the complete arguments of the preceding proof, see [To1] or [To4]. Notice that since the term

$$\sup\{\mu(E) :\ \mu \in \Sigma(E),\ \|\mathcal{C}_\mu\|_{L^2(\mu),L^2(\mu)} \leq 1\}$$

is countably semiadditive, from Theorem 2.7 one infers that γ_+ is also countably semiadditive.

Corollary 2.8. *The capacity γ_+ is countably semiadditive. That is, if E_i, $i = 1, 2, \ldots$, is a countable (or finite) family of compact sets, we have*

$$\gamma_+\Big(\bigcup_{i=1}^{\infty} E_i\Big) \leq C \sum_{i=1}^{\infty} \gamma_+(E_i).$$

2.6. Comparability between γ and γ_+. In [To5] the following result has been proved.

Theorem 2.9. *There exists an absolute constant C such that for any compact set $E \subset \mathbb{C}$ we have*

$$\gamma(E) \leq C\gamma_+(E).$$

As a consequence, $\gamma(E) \approx \gamma_+(E)$.

The comparability between γ and γ_+ had been previously proved by P. Jones for compact connected sets by geometric arguments, very different from the ones in [To5] (see [Pa, Chapter 3]). Also, in [MTV] it had already been shown that $\gamma \approx \gamma_+$ holds for a big class of Cantor sets. The proof of Theorem 2.9 in [To5] is inspired in part by the ideas in [MTV].

An obvious corollary of Theorem 2.9 and the characterization of γ_+ in terms of curvature in Theorem 2.7 is the following.

Corollary 2.10. *Let $E \subset \mathbb{C}$ be compact. Then, $\gamma(E) > 0$ if and only if E supports a non zero Borel measure with linear growth and finite curvature.*

Since we know that γ_+ is countably semiadditive, the same happens with γ:

Corollary 2.11. *Analytic capacity is countably semiadditive. That is, for any countable (or finite) family of compact sets E_i, $i = 1, 2, \ldots$, we have*

$$\gamma\Big(\bigcup_{i=1}^{\infty} E_i\Big) \leq C \sum_{i=1}^{\infty} \gamma(E_i).$$

Some few words about the proof of Theorem 2.7 are in order: it is enough to show that there exists some measure μ supported on E with linear growth, satisfying $\mu(E) \approx \gamma(E)$, and such that the Cauchy transform $\mathcal{C}_\mu$ is bounded on $L^2(\mu)$ with absolute constants. To this end, an important tool used in [To5] is the $T(b)$ theorem of Nazarov, Treil and Volberg in [NTV2], which is valid for non doubling measures. To apply this $T(b)$ theorem, one has to construct a suitable measure μ and a function $g \in L^\infty(\mu)$ fulfilling some precise conditions, similarly to the proof of Vitushkin's conjecture by David.

However, the situation now is more delicate because a direct application of that $T(b)$ theorem does not suffice. Indeed, let f be the Ahlfors function of E, so that f is analytic and bounded in $\mathbb{C} \setminus E$, with $f'(\infty) = \gamma(E)$. By a standard approximation

argument, it is not difficult to see that one can assume that $\mathcal{H}^1(E) < \infty$. Thus there exists some function g such that $f(z) = \mathcal{C}(g\, d\mathcal{H}^1|_E)(z)$ for $z \notin E$. If we argue like in [Da] (see Subsection 2.4 above), we will deduce that there exists a subset $F \subset E$ such that the Cauchy transform is bounded in $L^2(\mathcal{H}^1|_F)$. However, the size of F and the L^2 norm of the Cauchy transform $\mathcal{C}_{\mathcal{H}^1|_F}$ will depend strongly on the ratio $\mathcal{H}^1(E)/\gamma(E)$, which blows up as $\mathcal{H}^1(E) \to \infty$ or $\gamma(E) \to 0$. This difficulty is overcome in [To5] by using some ideas from potential theory and a suitable "induction on scales" argument.

Corollary 2.10 yields a characterization of removable sets for bounded analytic functions in terms of curvature of measures. Although this result has a definite geometric flavor, it is not clear if this is a really good geometric characterization. Nevertheless, in [To7] it has been shown that the characterization is invariant under bilipschitz mappings, using a corona type decomposition for non doubling measures. Previously, Garnett and Verdera [GV] had proved an analogous result for some Cantor sets. The problem about the behavior of removability and analytic capacity under bilipschitz mappings was raised by Verdera. See [Ve2].

2.7. Other results. In [To6], some results analogous to Theorems 2.7 and 2.9 have been obtained for the continuous analytic capacity α. This capacity is defined like γ in (1), with the additional requirement that the functions f considered in the sup should extend continuously to the whole complex plane. The capacity α is important because its many applications in connection with problems of uniform rational approximation in the complex plane, as shown by Vitushkin [Vi3]. In [To6] it is proved that α is semiadditive. This result has some nice consequences. For example, it implies the so-called *inner boundary conjecture*.

The inner boundary of a compact set $E \subset \mathbb{C}$, denoted by $\partial_i E$, is the set of boundary points of E which do not belong to the boundary of any connected component of $\mathbb{C} \setminus E$. The inner boundary conjecture (or theorem) says that if $\alpha(\partial_i E) = 0$, then any function analytic in $\overset{\circ}{E}$ and continuous on E can be approximated uniformly by functions which are analytic in neighborhoods of E (i.e. different neighborhoods for different functions).

The techniques for the proof of Theorem 2.9 have also been used by Prat [Pr] and Mateu, Prat and Verdera [MPV] to study the capacities γ_s associated to the s-dimensional signed Riesz kernel $k_s(x) = x/|x|^{s+1}$, with s non integer. Given a compact $E \subset \mathbb{R}^n$, the precise definition of $\gamma_s(E)$ is

$$\gamma_s(E) = \sup |\langle \nu, 1\rangle|, \tag{9}$$

where the supremum is taken over all distributions ν supported on E such that $K_s * \nu$ is an L^∞ function with $\|K_s * \nu\|_\infty \leq 1$.

The results in [Pr] and [MPV] show that the behavior of γ_s with s non integer is very different from the one with s integer. In [Pr] it is shown that sets with finite

s-dimensional Hausdorff measure have vanishing capacity γ_s when $0 < s < 1$. Moreover, for these s's it is proved in [MPV] that γ_s is comparable to the capacity $C_{\frac{2}{3}(n-s),\frac{3}{2}}$ from nonlinear potential theory. Recall that for $1 < p < \infty$ and $0 < tp \leq d$ the capacity $C_{t,p}$ of a compact set $E \subset \mathbb{R}^d$ is defined by

$$C_{t,p}(E) = \inf\bigl\{\|\varphi\|_p^p : \varphi \in \mathcal{C}_c^\infty(\mathbb{R}^d),\ \varphi * \tfrac{1}{|x|^{d-t}} \geq 1 \text{ on } E\bigr\}.$$

It is not known if the comparability $\gamma_s \approx C_{\frac{2}{3}(n-s),\frac{3}{2}}$ holds for non integers $s > 1$. This case seems much more difficult to study, although in the AD regular situation some results have been obtained in [Pr].

Using the corona type decomposition for measures with finite curvature and linear growth obtained in [To7], it has been proved in [To8] that if μ is a measure without atoms such that the Cauchy transform is bounded on $L^2(\mu)$, then any Calderón–Zygmund operator associated to an odd kernel sufficiently smooth is also bounded in $L^2(\mu)$.

3. Principal values for the Cauchy integral and related results

There is a strong relationship between rectifiability and the behavior of the Cauchy transform. Indeed, in Section 2 we saw that the L^2 boundedness of the Cauchy transform with respect to the arc length measure implies rectifiability. In this section we will describe some related results which involve the existence of principal values instead of L^2 boundedness.

Recall that given a Borel measure μ on $\mathbb{C}$, the principal of the Cauchy transform $\mathcal{C}\mu$ at $z \in \mathbb{C}$ is

$$\text{p.v.}\mathcal{C}\mu(z) = \lim_{\varepsilon \to 0} \mathcal{C}_\varepsilon \mu(z),$$

whenever the limit exists. The maximal Cauchy transform of μ is

$$\mathcal{C}_*\mu(z) = \sup_{\varepsilon>0}\left|\int_{|\xi - z|>\varepsilon} \frac{1}{\xi - z}\, d\mu(\xi)\right|.$$

Obviously, the existence of $\text{p.v.}\mathcal{C}\mu(z)$ implies that $\mathcal{C}_*\mu(z)$ is finite. The converse needs not to be true.

Recall also that the upper and lower linear densities of μ at z are defined, respectively, by

$$\Theta_\mu^*(z) = \limsup_{r\to 0} \frac{\mu(B(z,r))}{2r}, \quad \Theta_{*,\mu}(z) = \liminf_{r\to 0} \frac{\mu(B(z,r))}{2r}.$$

When both densities coincide one writes $\Theta_\mu(z) := \Theta_\mu^*(z) = \Theta_{*,\mu}(z)$ and calls it linear density. A Dirac delta on a point $z \in \mathbb{C}$ is denoted by δ_z.

Mattila and Melnikov proved in [MMe] that if $E \subset \mathbb{C}$ has finite length and is rectifiable, then $\text{p.v.}\mathcal{C}\mu(z)$ exists $\mathcal{H}^1$-a.e. on E, for any Borel measure μ (see [Ve1]

for an easier proof). Using this result and Léger's Theorem 2.5 it was shown later in [To3] that if σ is a measure with linear growth such that the Cauchy transform is bounded on $L^2(\sigma)$, then p.v.$\mathcal{C}\mu(z)$ exists σ-a.e. As a consequence, by Theorem 2.9, for any Borel measure μ on $\mathbb{C}$, p.v.$\mathcal{C}\mu(z)$ exists γ-a.e., that is to say, the set where p.v.$\mathcal{C}\mu(z)$ fails to exist has zero analytic capacity (this result answers a question from Verdera [Ve2]).

In the converse direction (existence of principal values implies rectifiability) the first result was obtained by Mattila [Ma3]: he proved that if $\Theta_{*,\mu}(z) > 0$ and p.v.$\mathcal{C}\mu(z)$ exists (and is finite) for μ-a.e. $z \in \mathbb{C}$, then μ is concentrated on a rectifiable set, that is μ vanishes out of a rectifiable set. Let us remark that this result was obtained before the proof of the identity (4) which relates the Cauchy transform and curvature. Mattila's techniques were based on the use of tangent measures. In [Huo], Huovinen extended Mattila's result to other kernels in the plane different from the Cauchy transform.

In [Ma3] Mattila wondered if the assumption $\Theta_{*,\mu}(z) > 0$ μ-a.e. might be replaced by $\Theta^*_\mu(z) > 0$ μ-a.e. In [To2] a partial answer was given: using the $T(b)$ theorem of Nazarov, Treil and Volberg in [NTV2] and the "curvature method" (identity (4) and Léger's Theorem 2.5 were used), it was shown that the main result in [Ma3] also holds for measures such that $0 < \Theta^*_\mu(z) < \infty$ μ-a.e. Also, it was proved that one can replace the assumption on the existence of principal values by finiteness of the maximal Cauchy transform. As a consequence, one deduces that if $E \subset \mathbb{C}$ has finite length and $\mathcal{C}_*\mathcal{H}^1|_E(z) < \infty$ $\mathcal{H}^1$-a.e. on E, then E must be rectifiable.

A complete answer to Mattila's question has been given in [To10] recently. The precise result is the following.

Theorem 3.1. *Assume that μ is a finite Radon measure on the complex plane and set $E = \{z \in \operatorname{supp}(\mu) : \mathcal{C}_*\mu(z) < \infty\}$. Then $\mu|_E$ can be decomposed as $\mu|_E = \mu_d + \mu_r + \mu_0$, where*

$$\mu_d = \sum_i a_i \delta_{z_i}$$

for some $a_i > 0$ and $z_i \in \mathbb{C}$,

$$\mu_r = \sum_i g_i \mathcal{H}^1|_{\Gamma_i}$$

for some rectifiable curves Γ_i and non negative functions $g_i \in L^1(\mathcal{H}^1|_{\Gamma_i})$, and

$$\mu_0 = \sum_i \sigma_i,$$

where σ_i are measures with finite curvature such that $\Theta_{\sigma_i}(z) = 0$ for σ_i-a.e. $z \in \mathbb{C}$.

Notice that the preceding result asserts that there is a kind of "dimensional gap" between 0 and 1 for the measures μ such that $\mathcal{C}_*\mu(z) < \infty$ μ-a.e. For instance, for $0 < s < 1$ there are no measures of the form $\mu = \mathcal{H}^s|_E$, with $0 < \mathcal{H}^s(E) < \infty$, such that $\mathcal{C}_*\mu(z) < \infty$ μ-a.e.

A straightforward corollary of the theorem above is the following.

Corollary 3.2. *Let μ be a finite Radon measure on the complex plane such that $\Theta^*_\mu(z) > 0$ for μ-a.e. $z \in \mathbb{C}$. If $\mathcal{C}_*\mu(z) < \infty$ at μ-a.e. $z \in \mathbb{C}$, then μ can be decomposed as $\mu = \mu_d + \mu_r$, where $\mu_d = \sum_i a_i \delta_{z_i}$ for some $a_i > 0$ and $z_i \in \mathbb{C}$, and $\mu_r = \sum_i g_i \mathcal{H}^1|_{\Gamma_i}$ for some rectifiable curves Γ_i and non negative functions $g_i \in L^1(\mathcal{H}^1|_{\Gamma_i})$.*

In particular, under the assumptions of the corollary, μ is concentrated on a countable union of rectifiable curves.

The main difficulty to prove Theorem 3.1 consists in proving that if $\mathcal{C}_*\mu(z) < \infty$ μ-a.e. on $\mathbb{C}$, then on the set $\{z : \Theta^*_\mu(z) = \infty\}$ μ must be discrete (i.e. the addition of countably many point masses). Once this is proved, one can argue as in [To2]. A basic tool for the proof is the identity (4) again. However, notice that (4) holds for measures with linear growth, and the measures μ considered in Theorem 3.1 may be very far from having this property. This is the main obstacle that is overcome in [To10].

Before [To10], Jones and Poltoratski proved in [JP], among other things, that if μ is supported on a line (and more generally on a $\mathcal{C}^1$ curve) and $\mathcal{C}_*\mu(z) < \infty$ μ-a.e., then μ equals a countable collection of point masses plus some measure absolutely continuous with respect to arc length. Observe that this result is implied by Corollary 3.2, because any measure μ supported on a line satisfies $\Theta^*_\mu(z) > 0$ μ-a.e. In [JP] it was also shown that if one does not assume μ to be supported on a line and instead one asks the same conditions as Mattila in [Ma3] (i.e. $\Theta_{*,\mu}(z) > 0$ and p.v.$\mathcal{C}\mu(z)$ exists μ a.e. on $\mathbb{C}$), then the conclusion of Corollary 3.2 holds: μ equals a countable collection of point masses plus some measure absolutely continuous with respect to arc length on a rectifiable set.

The same techniques used for Theorem 3.1 also yield the following result, proved previously by Jones and Poltoratski [JP] when μ is supported on a $\mathcal{C}^1$ curve.

Theorem 3.3. *Assume that μ is a finite Radon measure on the complex plane and set $E = \{x \in \operatorname{supp}(\mu) : \mathcal{C}_\varepsilon\mu(x) = o(\mu(B(x,\varepsilon)/\varepsilon)$ as $\varepsilon \to 0+\}$. Then $\mu|_E$ can be decomposed as $\mu|_E = \mu_d + \mu_r + \mu_0$, with μ_d, μ_r, and μ_0 as in Theorem* 3.1.

The arguments in [To10] rely on the relationship between the Cauchy transform and curvature and so they do not extend to higher dimensions (i.e. to Riesz transforms). This is not the case with the results in [Ma3] and [JP]. Mattila's results in [Ma3] have been extended to the case of Riesz transforms by Mattila and Preiss [MPr], while some theorems in [JP] deal both with Cauchy and Riesz transforms. See next section for the precise definition of Riesz transforms.

4. Lipschitz harmonic capacity and Riesz transforms

Let $E \subset \mathbb{R}^d$ be a compact set. Its Lipschitz harmonic capacity is

$$\kappa(E) = \sup |\langle \Delta f, 1\rangle|,$$

where Δ stands for the Laplacian in the distributional sense and the supremum is taken over all functions f which are harmonic in $\mathbb{R}^d \setminus E$ and Lipschitz on $\mathbb{R}^d$, with $\|\nabla f\|_\infty \leq 1$ and $\nabla f(\infty) = 0$. If, in addition, in the supremum above one asks f to be $\mathcal{C}^1$, then one obtains the so-called $\mathcal{C}^1$ harmonic capacity.

Given a distribution ν on $\mathbb{R}^d$, let $R(\nu) = \frac{y}{|y|^d} * \nu$ be its (vectorial) Riesz transform, so that when ν is a real measure,

$$R\nu(x) = \Big(\frac{y}{|y|^d} * \nu\Big)(x) = \int \frac{x-y}{|x-y|^d}\, d\nu(y). \tag{10}$$

If μ is a positive Borel measure and f a μ-measurable function, we consider the operator $R_\mu f := R(f\, d\mu)$. For $\varepsilon > 0$, the truncated Riesz transforms R_ε, $R_{\mu,\varepsilon}$ are defined analogously to $\mathcal{C}_\varepsilon$ and $\mathcal{C}_{\mu,\varepsilon}$. One says that R_μ is bounded on $L^2(\mu)$ if the operators $R_{\mu,\varepsilon}$ are bounded on $L^2(\mu)$ uniformly on $\varepsilon > 0$.

An equivalent definition of $\kappa(E)$ in terms of Riesz transforms is the following:

$$\kappa(E) = \sup \sigma_d^{-1} |\langle \nu, 1\rangle|, \tag{11}$$

where σ_d stands for the $(d-1)$-dimensional volume of the sphere $\{|x| = 1\}$ in $\mathbb{R}^d$ and the supremum is taken over all real distributions ν supported on E such that $R\nu$ is a bounded function on $\mathbb{R}^d$, with $\|R\nu\|_\infty \leq 1$. An analogous definition exists for the $\mathcal{C}^1$ harmonic capacity.

The notions of Lipschitz harmonic capacity and $\mathcal{C}^1$ harmonic capacity were introduced by Paramonov [Par] in order to study problems of approximation of harmonic functions in the $\mathcal{C}^1$ norm. These capacities can be considered as real versions of the analytic capacity γ and the continuous analytic capacity α in $\mathbb{R}^d$, $d \geq 2$, respectively. Indeed, in $\mathbb{R}^2$, κ coincides (modulo a multiplicative absolute constant) with the so-called real analytic capacity $\gamma_{\mathbb{R}}$:

$$\gamma_{\mathbb{R}}(E) = \sup |f'(\infty)|,$$

where the supremum is taken over all functions f analytic on $\mathbb{C} \setminus E$ with $\|f\|_\infty \leq 1$ which are Cauchy transforms of *real* distributions. Analogously with respect to the $\mathcal{C}^1$ harmonic capacity.

Some geometric properties of κ in $\mathbb{R}^d$ have been studied in [MPa]. In particular, the relationship with the $(d-1)$-dimensional Hausdorff measure. Analogously to the case of analytic capacity, $(d-1)$-dimensional rectifiability seems to play a key role in the understanding of κ. Recall that $E \subset \mathbb{R}^d$ is called n-rectifiable if there are

Lipschitz maps $f_i : \mathbb{R}^n \to \mathbb{R}^d$ such that

$$\mathcal{H}^n\Big(E \setminus \bigcup_{i=1}^{\infty} f_i(\mathbb{R}^n)\Big) = 0.$$

For example, if $\mathcal{H}^{d-1}(E) > 0$ and E is $(d-1)$-rectifiable, then $\kappa(E) > 0$. However, unlike in the case of analytic capacity, it is not known if the compact sets $E \subset \mathbb{R}^d$ with $\mathcal{H}^{d-1}(E) < \infty$ and $\kappa(E) = 0$ must be purely $(d-1)$-unrectifiable (recall Theorem 2.6). The main obstacle is the lack of a formula similar to (4) which relates the L^2 norm of the Riesz transforms with something which has some geometric meaning, or at least with something non negative, which may act as a square function for Riesz transforms. See [Fa] for this question.

Because of the same reason, many of the results in connection with the Cauchy transform which have been described in Sections 2 and 3 are missing in the case of Riesz transforms. See next section for some open questions.

On the other hand, although in the proof of the comparability between γ and γ_+ in [To5], curvature seems to play an important role, Volberg [Vo] has been able to show κ and κ_+ are also comparable (κ_+ is defined like κ in (11), but taking only the supremum over positive measures ν supported on E). As a consequence, κ is countably semiadditive, because κ_+ has the following characterization (compare with Theorem 2.7):

$$\kappa_+(E) \approx \sup\{\mu(E) : \operatorname{supp}(\mu) \subset E,\ \mu(B(x,r)) \leq r^{d-1} \text{ for all } x, r, \\ \|R_\mu\|_{L^2(\mu),L^2(\mu)} \leq 1\},$$

which is clearly subadditive. The main difference between the arguments used in [To5] for analytic capacity and ones in [Vo] for Lipschitz harmonic capacity stems from the choice of an appropriate potential useful for κ_+ which is very different from the one used for γ_+ in [To5].

Another paper concerning Lipschitz harmonic capacity is [MT]. In this article some Cantor sets in $\mathbb{R}^d$ are considered, and their Lipschitz harmonic capacity is estimated. The results are analogous to the ones in [MTV] for analytic capacity. The main difficulty in [MT] consists in estimating the L^2 norm of the Riesz transforms with respect to the natural probability measure associated to these Cantor sets.

5. Some open problems

In this section we collect some open problems related to analytic capacity, the Cauchy and Riesz transforms, and rectifiability. Most of them are well known, and there is no attempt at originality or completeness.

1. Subadditivity of analytic capacity. Is analytic capacity subadditive? That is to say, we are asking if γ is semiadditive with constant 1:

$$\gamma(E \cup F) \leq \gamma(E) + \gamma(F) \quad \text{for all compact sets } E, F \subset \mathbb{C}.$$

There are a couple of facts that suggest that this may be true: first, γ is *countably* semiadditive; and second, the above inequality holds when E and F are disjoint compact connected sets [Su].

Even when $\gamma(F) = 0$, the identity $\gamma(E \cup F) = \gamma(E)$ remains unproved.

2. The Cauchy capacity. Given $E \subset \mathbb{C}$ compact, consider the so-called *Cauchy capacity* of E:

$$\gamma_C(E) = \sup |\nu(E)|,$$

where the supremum is taken over all *complex measures* supported on E such that $|\mathcal{C}\nu(z)| \leq 1$ for $z \notin E$. This definition is similar to the one of analytic capacity, but now the supremum is restricted to Cauchy transforms of complex measures instead of distributions. Is it true that

$$\gamma(E) = \gamma_C(E)?$$

Notice that Theorem 2.9 implies that $\gamma(E) \approx \gamma_C(E)$. However, it is not known if the identity holds, except in some particular cases: for example, when E has finite length.

There exist compact sets E and functions f that are bounded and analytic on $\mathbb{C} \setminus E$ which are not the Cauchy transform of any complex measure ν. Nevertheless, the identity $\gamma(E) = \gamma_C(E)$ may still hold. See [Kha1] and [Kha2] for more information about this question.

3. Analytic capacity and Favard length. Recall the definition of Favard length in (7). We have already mentioned in Subsection 2.4 that Vitushkin's conjecture fails for sets with infinite length [Ma1]. In fact, Jones and Murai [JM] showed that there are sets with zero Favard length and positive analytic capacity.

So one of the implications in Vitushkin's conjecture is false. However the other implication is still open:

$$\text{Fav}(E) > 0 \quad \Rightarrow \quad \gamma(E) > 0?$$

Observe that by the characterization of γ in terms of curvature, this question can be restated in a more geometric way.

A related problem is the following. Let E be the so-called corner quarters Cantor set. This set is constructed as follows. Let $Q^0 = [0, 1] \times [0, 1]$. At the first step we take four closed squares inside Q^0 with side length $1/4$, with sides parallel to the coordinate axes, and so that each square contains a vertex of Q^0. At the second step we apply the preceding procedure to each of the four squares obtained in the first step,

so that we get 16 squares of side length $1/16$. Proceeding inductively, at each step we obtain 4^n squares Q_j^n, $j = 1, \ldots, 4^n$ with side length 4^{-n}. We denote

$$E_n = \bigcup_{j=1}^{4^n} Q_j^n,$$

and we define $E = \bigcap_{n=1}^{\infty} E_n$. This set has positive finite length and is purely unrectifiable, and so it has zero analytic capacity by David's theorem (this had been proved before David's result in [Gar1] and [Iv]). In fact, by [MTV] one has the asymptotic estimate $\gamma(E_n) \approx n^{-1/2}$. By Besicovitch theorem, we have $\mathrm{Fav}(E) = 0$. However, the asymptotic behavior of $\mathrm{Fav}(E_n)$ as $n \to \infty$ is not known. An interesting problem consists in finding more or less precise estimates for the asymptotic behavior of $\mathrm{Fav}(E_n)$.

From some results due to Mattila [Ma2] one gets the lower estimate $\mathrm{Fav}(E_n) \gtrsim 1/n$. Other recent results by Peres and Solomyak [PS] for random Cantor sets suggest that the estimate $\mathrm{Fav}(E_n) \approx 1/n$ may hold. However, up to now the best upper estimate is

$$\mathrm{Fav}(E_n) \lesssim \exp(-a \log_* n) \tag{12}$$

where C, a are positive absolute constants and $\log_*$ is the function

$$\log_* x = \min\Big\{n \in \mathbb{N} : \underbrace{\log \log \cdots \log}_{n} x \leq 1\Big\}.$$

Inequality (12) has been obtained in [PS]. It turns out that $\exp(-a \log_* n) \to 0$ extremely slowly, much more slowly than $1/n$.

Many difficulties that arise in connection with Favard length are related to the fact that there is no a *quantitative* proof of Besicovitch theorem. For more information concerning Favard length and projections we recommend to have a look at the nice survey [Ma4].

4. Vanishing Cauchy transforms. Let ν be a complex Borel measure on $\mathbb{C}$. Suppose that $\mathrm{p.v.}\mathcal{C}\nu(z)$ exists and vanishes $|\nu|$-a.e. on $\mathbb{C}$. Does this imply that ν is an atomic measure?

Notice that if ν is a positive measure, then Theorem 3.1 applies to ν and so in this case we know that $\nu = \nu_d + \nu_r + \nu_0$, where ν_d is discrete and ν_r, ν_0 are as in Theorem 3.1.

In [TVe] two particular cases have been studied. In the first one ν is absolutely continuous with respect to Lebesgue measure, and in the second one ν is a positive measure with linear growth and finite curvature. In both cases, if $\mathrm{p.v.}\mathcal{C}\nu(z)$ exists and vanishes $|\nu|$-a.e., then $\nu = 0$.

Let us remark that there are positive discrete (non zero) measures such that $\mathrm{p.v.}\mathcal{C}\nu(z)$ exists and vanishes ν-a.e. A trivial example is a single point mass. One can also construct other examples with countably many point masses.

5. Riesz transforms and rectifiability. Let $E \subset \mathbb{R}^d$ be a compact set with $0 < \mathcal{H}^n(E) < \infty$, for some integer $0 < n < d$. Take $\mu = \mathcal{H}^n|_E$ and consider the n-dimensional Riesz transform:

$$R_\mu^n f(x) = \int \frac{x-y}{|x-y|^{n+1}} f(y)\, d\mu(y),$$

for $f \in L^2(\mu)$, and $x \notin E$. As usual, we say that R_μ^n is bounded in $L^2(\mu)$ if the corresponding ε-truncated operators are bounded in $L^2(\mu)$ uniformly on $\varepsilon > 0$. If R_μ^n is bounded in $L^2(\mu)$, is then E n-rectifiable? The answer is known (and it is positive in this case) only for $n = 1$, because the curvature method works for $n = 1$. By [Vo], when $n = d - 1$ this question is equivalent to the following, which has already appeared in Section 4: is it true that $\kappa(E) = 0$ if and only if E is purely $(d-1)$-unrectifiable?

A variant of this problem consist in taking E AD regular and n-dimensional. If R_μ^n is bounded in $L^2(\mu)$, is then E uniformly n-rectifiable? For the definition of uniform rectifiability, see [DS1] and [DS2] (for the reader's convenience let us say that, roughly speaking, uniform rectifiability is the same as rectifiability plus some quantitative estimates). For $n = 1$ the answer is true again, because of curvature. The result is from Mattila, Melnikov and Verdera [MMV]. For $n > 1$, in [DS1] and [DS2] some partial answers are given. Let H_n be class of all the operators T defined as follows:

$$Tf(x) = \int k(x-y) f(y)\, d\mu(x),$$

where k is some odd kernel (i.e. $k(-x) = -k(x)$) smooth away from the origin such that $|x|^{n+j}|\nabla^j k(x)| \in L^\infty(\mathbb{R}^d \setminus \{0\})$ for $j \geq 0$. Suppose that all operators T from H_n are bounded in $L^2(\mu)$. Then it is shown in [DS1] that E is uniformly rectifiable. See [DS2] for other related results.

Consider again the case of a general compact set $E \subset \mathbb{R}^d$ with $0 < \mathcal{H}^n(E) < \infty$, for some integer $0 < n < d$, and set $\mu = \mathcal{H}^n|_E$. If μ satisfies

$$\liminf_{r \to 0} \frac{\mu(B(x,r))}{r^n} > 0 \qquad \mu\text{-a.e. on } \mathbb{R}^d,$$

then the μ-a.e. existence of the principal value $\lim_{\varepsilon \to 0} R_{\mu,\varepsilon}^n 1(x)$ implies that E is n-rectifiable, by a theorem of Mattila and Preiss [MPr]. However, this does not help to solve the questions above because it is not known if the $L^2(\mu)$ boundedness of the Riesz transforms R_μ^n implies the existence of principal values. Notice the contrast with the case of the Cauchy transform (see Section 3), where the latter assertion is known to be true, because of curvature again.

I would like to thank Joan Verdera for his remarks on preliminary versions of this paper.

The Brunn–Minkowski theorem and related geometric and functional inequalities

Franck Barthe*

Abstract. The Brunn–Minkowski inequality gives a lower bound of the Lebesgue measure of a sum-set in terms of the measures of the individual sets. It has played a crucial role in the theory of convex bodies. This topic has many interactions with isoperimetry or functional analysis. Our aim here is to report some recent aspects of these interactions involving optimal mass transport or the Heat equation. Among other things, we will present Brunn–Minkowski inequalities for flat sets, or in Gauss space, as well as local versions of the theorem which apply to the study of entropy production in the central limit theorem.

Mathematics Subject Classification (2000). Primary 39B62; Secondary 52A40, 26D15, 94A17.

Keywords. Brunn–Minkowski, transport, Heat equation, entropy.

1. Introduction

The Brunn–Minkowski theory studies the relations between addition of vectors and the volume of convex sets. Let us start with some notation. For $\lambda \in \mathbb{R}$ and A a subset of $\mathbb{R}^d$, one sets $\lambda A = \{\lambda a;\ a \in A\}$. The Minkowski sum of two sets $A, B \subset \mathbb{R}^d$ is by definition

$$A + B := \{a + b;\ (a, b) \in A \times B\}.$$

The Brunn–Minkowski inequality gives a lower bound on the volume of a sum-set.

Theorem 1.1. *Let A, B be non-empty compact subsets of $\mathbb{R}^d$, then*

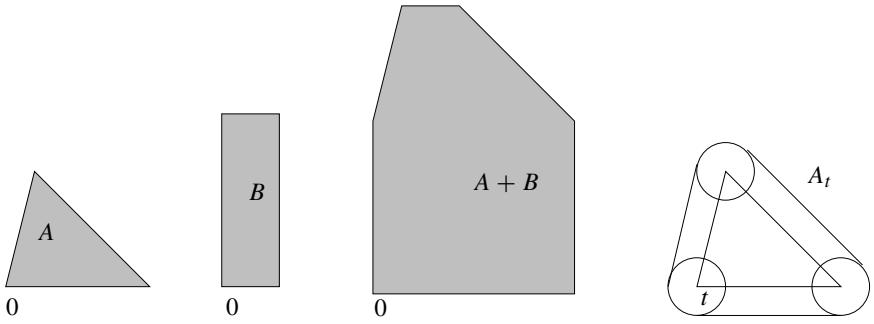
$$\mathrm{Vol}_d(A + B)^{\frac{1}{d}} \geq \mathrm{Vol}_d(A)^{\frac{1}{d}} + \mathrm{Vol}_d(B)^{\frac{1}{d}}. \tag{1}$$

If A, B are convex homothetic sets, there is equality. Brunn discovered this result in 1887 for A, B convex in dimension at most 3. Minkowski proved the inequality for convex sets in arbitrary dimension and realized the importance of the statement. Indeed, it could be combined with a former result by Steiner, which calculated the volume of the t-enlargement of a convex compact set $A \subset \mathbb{R}^3$ defined for $t > 0$ by

$$A_t = \{x \in \mathbb{R}^3;\ \text{there exists } y \in A \text{ such that } |x - y| \leq t\}.$$

*Research was supported in part by the European Network PHD, MCRN-511953.

Proceedings of the International Congress of Mathematicians, Madrid, Spain, 2006



Note that $A_t = A + tB^3$ where B^d denotes the Euclidean unit ball of $\mathbb{R}^d$. The Steiner formula asserts that for $t > 0$

$$\mathrm{Vol}_3(A + tB^3) = \mathrm{Vol}_3(K) + tS(A) + 2\pi t^2 W(A) + \frac{4}{3}\pi t^3,$$

where $S(A)$ is the surface area of A and $W(A)$ is its mean width (the average on unit vectors u of the width of the minimal slab orthogonal to u and containing A). The Brunn–Minkowski theorem provides relations between the above coefficients. Indeed, it implies that

$$\mathrm{Vol}_3(A + tB^3) \geq \left(\mathrm{Vol}_3(A)^{\frac{1}{3}} + t\mathrm{Vol}_3(B^3)^{\frac{1}{3}}\right)^3$$

with equality at $t = 0$. Comparing derivatives at zero gives

$$S(A) \geq 3\mathrm{Vol}_3(B^3)^{\frac{1}{3}}\mathrm{Vol}_3(A)^{\frac{2}{3}}.$$

This is the classical isoperimetric inequality; it means that among sets of given volume, balls have minimal surface area (the argument actually extends to non-convex sets). Another relation can be obtained by noting that the Brunn–Minkowski inequality shows that $\mathrm{Vol}_3(A + tB^3)^{\frac{1}{3}}$ is a concave function of $t \geq 0$ when A is convex.

Minkowski extended the Steiner formula as follows: for non-empty compact convex sets $K_1, \ldots, K_m \subset \mathbb{R}^d$ and $\lambda_1, \ldots, \lambda_m \geq 0$, the volume of $\lambda_1 K_1 + \cdots + \lambda_m K_m$ is a homogeneous polynomial of the form

$$\mathrm{Vol}_d(\lambda_1 K_1 + \cdots + \lambda_m K_m) = \sum_{i_1, \ldots, i_d = 1}^{m} \lambda_{i_1} \ldots \lambda_{i_d} V(K_{i_1}, \ldots, K_{i_d}).$$

Here and by definition $V(K_1, \ldots, K_d)$ is the mixed volume of d convex sets in $\mathbb{R}^d$. The theory of mixed volumes studies the properties of these quantities, their geometric interpretations and the inequalities among them. We refer to the book [53] for more on this topic. See also [52] where such volume estimates are used in the local theory of Banach spaces.

2. Functional extensions, functional tools

There exist several proofs of the Brunn–Minkowski theorem, see the surveys [34], [36] for details and precise references. However the most fruitful approach is probably the one based on the following functional version of the statement:

Theorem 2.1 (Prékopa–Leindler). *Let f, g, h be measurable non-negative functions on $\mathbb{R}^d$ and $\lambda \in [0,1]$. If for all x, y in $\mathbb{R}^d$,*

$$h(\lambda x + (1-\lambda)y) \geq f^\lambda(x) g^{1-\lambda}(y),$$

then $\int_{\mathbb{R}^d} h \geq \left(\int_{\mathbb{R}^d} f\right)^\lambda \left(\int_{\mathbb{R}^d} g\right)^{1-\lambda}$.

Remark 2.2. When applied to characteristic functions of sets, the above result provides a multiplicative version of the Brunn–Minkowski inequality, which is equivalent to the one we stated. The functional inequality can be written with an outer integral, as

$$\int_{\mathbb{R}^d}^* \sup_{\lambda x+(1-\lambda)y=z} f^\lambda(x) g^{1-\lambda}(y)\, dz \geq \left(\int_{\mathbb{R}^d} f\right)^\lambda \left(\int_{\mathbb{R}^d} g\right)^{1-\lambda}.$$

It appears as a reverse form of the classical inequality of Hölder which asserts that the right hand side in the latter inequality is at least $\int f^\lambda g^{1-\lambda}$.

An elementary proof of the above inequality appears in [52]. Here we sketch another proof. Its main idea is quite old and appears e.g. in [38]. It contains implicitly the idea of measure transportation which allowed recent developments.

Proof. We work in dimension 1, the general case follows by induction. By approximation arguments one may restrict to positive continuous f and g. One introduces functions $x, y\colon [0,1] \to \mathbb{R}$ satisfying for $t \in [0,1]$

$$\int_{-\infty}^{x(t)} f = t \int f; \quad \int_{-\infty}^{y(t)} g = t \int g. \tag{2}$$

Consequently for $t \in [0,1]$ it holds $x'(t) f(x(t)) = \int f$ and $y'(t) g(y(t)) = \int g$. One defines a third function z on $[0,1]$ by $z(t) = \lambda x(t) + (1-\lambda) y(t)$. Our three functions are strictly increasing. Comparing geometric mean and arithmetic mean yields $z'(t) \geq (x'(t))^\lambda (y'(t))^{1-\lambda}$. Finally we use z as a change of variables to evaluate the integral of h. Using the above relations

$$\begin{aligned}\int h &\geq \int_0^1 h(z(t)) z'(t)\, dt \\ &\geq \int_0^1 f^\lambda(x(t)) g^{1-\lambda}(y(t)) (x'(t))^\lambda (y'(t))^{1-\lambda}\, dt \\ &= \left(\int f\right)^\lambda \left(\int g\right)^{1-\lambda}.\end{aligned}$$

□

2.1. Measure transportation. If μ, ν are two probability measures on $\mathbb{R}^n$, one says that a map $T : \mathbb{R}^d \to \mathbb{R}^d$ transports μ to ν if $T\mu = \nu$, meaning $\nu(B) = \mu(T^{-1}(B))$ for every Borel set B.

In dimension 1, a canonical choice always exist when the first measure has no atoms: one can choose T non-decreasing. Note that the maps x, y of the previous proof are particular non-decreasing transporting maps. Indeed, if μ is the Lebesgue measure restricted to [0, 1] and $d\nu(t) = f(t)dt/\int f$ the first relation in (2) can be rewritten as follows

$$\mu((-\infty, t]) = \nu((-\infty, x(t)]).$$

Since x is increasing and onto, this is equivalent to $\nu(B) = \mu(T^{-1}(B))$ for $B = (-\infty, s]$, and this relation extends to the Borel σ-field.

In higher dimension a remarkable analogue is available due to the works of Brenier [22] and McCann [48].

Theorem 2.3. *Let μ, ν be probability measures on $\mathbb{R}^d$. Assume that whenever $B \subset \mathbb{R}^d$ is a Borel set with Hausdorff dimension $d-1$ one has $\mu(B) = 0$. Then there exists a convex function $\Phi : \mathbb{R}^d \to \mathbb{R}$ such that the map $T = \nabla\Phi$ (defined a.e.) satisfies $\nu = T\mu$. The map T is uniquely determined almost everywhere too.*

If μ and ν have second moments, then among all maps S with $S\mu = \nu$, T minimizes the quadratic transportation cost

$$\int_{\mathbb{R}^d} |x - S(x)|^2 d\mu(x).$$

As recalled in the second part of the theorem, this monotone transport T is related to the theory of optimal transportation, which looks for the best way to ship some amount of material from a configuration to another one. We refer to the book [59] for more on this fascinating topic.

If we consider measures with densities ρ_μ, ρ_ν with respect to Lebesgue's measure, then Φ is a generalized solution for the Monge–Ampère equation

$$\rho_\mu(x) = \rho_\nu(\nabla\Phi(x)) \det\big(\mathrm{Hess}\Phi(x)\big).$$

Weak and strong regularity theory for this equation were developed respectively by McCann [47] and Caffarelli [23]. McCann also introduced the following interpolation between the measures μ and ν: $((1-t)I + tT)\mu = \nabla(x \mapsto (1-t)|x|^2/2 + t\Phi(x))\mu$ for $t \in [0, 1]$. He found applications to equilibrium states (and also to a proof of the Brunn–Minkowski inequality). Optimal transport allows to interpolate between general densities. However it has more structure when Gaussian measures are involved, as Caffarelli proved:

Theorem 2.4 ([24]). *Let Q be a positive definite quadratic form on $\mathbb{R}^d$ let $d\mu(x) = e^{-Q(x)}dx/Z$ be the corresponding Gaussian probability measure. Let $d\nu = \rho\, d\mu$ be another probability measure with log-concave density ρ with respect to μ (i.e. $\rho(\lambda x + (1_\lambda)y) \geq \rho(x)^\lambda \rho(y)^{1-\lambda}$ for $x, y \in \mathbb{R}^d$ and $\lambda \in [0, 1]$). Then the monotone*

transportation map T such that $T\mu = \nu$ is a contraction for the canonical Euclidean distance.

2.2. Heat equation. Let $\Delta = \sum_{i=1}^{d} \frac{\partial^2}{\partial x_i^2}$ be the Laplace operator in $\mathbb{R}^d$. Following the probabilistic normalization we define the heat semigroup as $P_t = e^{t\Delta/2}$. More precisely, for a function f on $\mathbb{R}^d$ the function $u(t,x) = P_t f(x)$ solves the equation $\partial_t u = \frac{1}{2}\Delta u$ on $\mathbb{R}^+ \times \mathbb{R}^d$ with initial condition $u(0,\cdot) = f$. When f has three bounded derivatives, one has

$$P_t f(x) = \int_{\mathbb{R}^d} f(z) e^{-\frac{(z-x)^2}{2t}} \frac{dz}{(2\pi t)^{d/2}} \quad \text{for } t > 0.$$

C. Borell discovered that the heat flow preserves in some sense the hypothesis of the Prékopa–Leindler inequality. More precisely, given $\lambda \in (0,1)$ and three sufficiently regular non-negative functions $f, g, h\colon \mathbb{R}^d \to \mathbb{R}^+$ satisfying

$$h(\lambda x + (1-\lambda)y) \geq f(x)^\lambda g(y)^{1-\lambda},$$

he proved [18] that for all $t > 0$ and all x, y the following is true

$$P_t h(\lambda x + (1-\lambda)y) \geq P_t f(x)^\lambda P_t g(y)^{1-\lambda}.$$

The Prékopa–Leindler inequality is obtained in the limit $t \to +\infty$ since

$$P_t f(x) \sim_{t\to+\infty} (2\pi t)^{-d/2} \Big(\int f(y)dy \Big).$$

Borell's method was recently applied with success to derive other important Brunn–Minkowski type results. We will describe them in the next sections.

Remark 2.5. It has been known for many years that the heat equation is a powerful tool to prove functional inequalities of geometric flavor. In particular Bakry and Emery developed a general framework for deriving logarithmic Sobolev inequalities (which ensure Gaussian concentration of measure), or Sobolev type inequalities by semigroup techniques. More recently Bakry and Ledoux where able to prove Bobkov's functional form of the Gaussian isoperimetric inequality along these lines. It was also observed that the Brunn–Minkowski inequality implies various types of isoperimetric inequality. So morally, the use of the heat equation for Brunn–Minkowski type inequalities is not a complete surprise. The interested reader will find details in [3], [44], [43]. Recently the transportation method also allowed to derive concentration estimates and Sobolev type inequalities, see e.g. [59], [32].

2.3. Riemannian manifolds. McCann [49] has solved the optimal transport problem on a Riemannian manifold when the transportation cost is the square of the geodesic distance. This provides a natural generalization of the monotone map, and allowed remarkable extensions of the Prékopa–Leindler inequality by Cordero-Erausquin, McCann and Schmuckenschläger [31], [30]. The following statement is valid under a curvature assumption in the spirit of Bakry–Emery

Theorem 2.6 ([30]). *Let (M, g) be a Riemannian manifold, and let μ be a measure on M with density e^{-V} with respect to the volume measure. Assume that for $\rho \in \mathbb{R}$, the Ricci curvature and the Hessian of V satisfy*

$$\mathrm{Hess}_x V + \mathrm{Ric}_x \geq \rho g$$

for all $x \in M$. Let $\lambda \in [0,1]$ and $f, g, h : M \to \mathbb{R}^+$ such that for all $x, y \in M$ and all z such that $d(x,z) = (1-\lambda)d(x,y)$ and $d(z,y) = \lambda d(x,y)$ one has

$$h(z) \geq e^{-\rho d^2(x,y)/2} f^{\lambda}(x) g^{1-\lambda}(y),$$

then one gets: $\int_M h\, d\mu \geq \left(\int_M f\, d\mu\right)^{\lambda} \left(\int_M g\, d\mu\right)^{1-\lambda}$.

The condition on the intermediate point z (involving geodesic distances) simply means that z is a geodesic barycenter of x, y with weights λ, $1-\lambda$. Unlike in Euclidean spaces, there might be many of them.

3. Multilinear inequalities

The Brascamp–Lieb [21] inequalities are a powerful extension of Hölder's inequality. Their original motivation was the calculation of the best constant in Young's convolution inequality. Their most general form was established by Lieb. The setting of the theorem is the following. For $1 \leq i \leq m$, one considers linear surjective maps $B_i : \mathbb{R}^n \to \mathbb{R}^{n_i}$ and numbers $c_i \in [0,1]$.

Theorem 3.1 (Lieb [45]). *The best constant $K \in [0, +\infty]$ such that the inequality*

$$\int_{\mathbb{R}^n} \prod_{i=1}^m f_i(B_i x)^{c_i}\, dx \leq K \prod_{i=1}^m \left(\int_{\mathbb{R}} f_i\right)^{c_i}$$

holds for all integrable functions $f_i : \mathbb{R}^{n_i} \to \mathbb{R}^+$ can be computed by considering only centered Gaussian functions $f_i(x) = \exp(-\langle A_i x, x\rangle)$ where the A_i's are symmetric positive definite matrices of size n_i.

Homogeneity shows that the constant may be finite only when $\sum_{i=1}^m c_i n_i = n$. This condition is assumed in the following. Since Gaussian integral may be computed, one gets $K = D^{-1/2}$ where

$$D = \inf_{A_i > 0} \frac{\det\left(\sum_{i=1}^m c_i B_i^* A_i B_i\right)}{\prod_{i=1}^m \det(A_i)^{c_i}}. \tag{3}$$

Here B_i^* denotes the adjoint of B_i. The proofs of Brascamp–Lieb and Lieb relied partially on tensorization arguments in higher dimension. We gave another proof using the monotone transport when proving an extension of the Prékopa–Leindler

inequality conjectured by K. Ball. The inequality is a reverse form of the Brascamp–Lieb inequality. The argument of proof is sophistication of the one given in the previous section, and gives both inequalities at a time. It uses the fact that the Jacobian matrices of monotone transport are symmetric positive matrices. This matches exactly the quantity appearing in the calculation of the Gaussian constant (3). The statement is

Theorem 3.2 ([10]). *The best constant $L \geq 0$ such that for all integrable functions $f_i : \mathbb{R}^{n_i} \to \mathbb{R}^+$ one has*

$$\int_{\mathbb{R}^n} \sup_{\sum c_i B_i^* x_i = x;\ x_i \in \mathbb{R}^{n_i}} \prod_{i=1}^m f_i(x_i)^{c_i}\, dx \geq L \prod_{i=1}^m \left(\int_{\mathbb{R}^{n_i}} f_i \right)^{c_i},$$

can be computed on centered Gaussian functions, and $L = \sqrt{D}$.

Our motivation for studying these inequalities came from convex geometry. Ball first understood the relevance of the Brascamp–Lieb inequality for this topic. In the case $n_i = 1$, $B_i(x) = \langle x, u_i \rangle$ where u_i are unit vectors in $\mathbb{R}^n$ with the additional condition

$$\mathrm{Id}_{\mathbb{R}^n} = \sum_{i=1}^m c_i P_{u_i}$$

(P_u is the orthogonal projection onto the line spanned by u) he showed that $D = 1$. So for non-negative functions on $\mathbb{R}$ one has

$$\int_{\mathbb{R}^n} \prod_{i=1}^m f_i^{c_i}(\langle x, u_i \rangle) dx \leq \prod_{i=1}^m \left(\int_{\mathbb{R}} f_i \right)^{c_i}.$$

Applied to characteristic functions of intervals this inequality gives an upper bound on the volume of an intersection of slabs. This was one of the crucial ingredients in Ball's exact estimates on slices of the cubes or on the volume ratios of convex bodies, see [4] for details. The reverse Brascamp–Lieb inequality allows to estimate from below the volumes of convex hull and of sums of flat sets. For example, we obtain the following extension of the Brunn–Minkowski inequality

Theorem 3.3. *Let $(E_i)_{i=1}^m$ are vector-subspaces of $\mathbb{R}^n$ and $c_i \in (0, 1]$ be such that $\mathrm{Id}_{\mathbb{R}^n} = \sum_{i=1}^m c_i P_{E_i}$. Set $n_i = \dim(E_i)$. If $K_i \subset E_i$ then*

$$\mathrm{Vol}_n\Big(\sum_{i=1}^m c_i K_i \Big) \geq \prod_{i=1}^m \mathrm{Vol}_{n_i}(K_i)^{c_i}.$$

It was recently understood that the Brascamp–Lieb inequalities can be derived using the heat equation. This new approach is due to Carlen, Lieb and Loss [26] for functions of one variable and was developed to full generality by Bennett, Carbery,

Christ and Tao [15]. One advantage is that it allows a better description of equality cases. However, contrary to the mass transport approach, the heat equation method requires to know in advance which Gaussian functions are best, and to find a way around when there is no best Gaussian function. It was necessary to understand more precisely the Gaussian optimization problem summed up in Equation (3) and to understand when the constant D is positive (this corresponds to a non-trivial inequality) and when it is achieved (i.e. when a Gaussian maximizer exists). We present answer to the first question, which is of independent interest. The case of functions of one variable has a more explicit solution:

Theorem 3.4 ([10], [26]). *Let $(u_i)_{i\le m}$ be non-zero vectors in $\mathbb{R}^n$. There exists a finite constant K such that for all integrable functions $f_i : \mathbb{R} \to \mathbb{R}^+$,*

$$\int_{\mathbb{R}^n} \prod_{i=1}^m f_i(\langle x, u_i\rangle)^{c_i} dx \le K \prod_{i=1}^m \left(\int_{\mathbb{R}} f_i\right)^{c_i}$$

if and only if $c = (c_1, \dots, c_m)$ belongs to the set

$$\begin{aligned}\mathcal{C} &= \mathrm{conv}\{\mathbf{1}_I;\ I \subset \{1,\dots,m\} \text{ and } (u_i)_{i\in I} \text{ is a basis}\}\\ &= \Big\{c \in \mathbb{R}^m_+;\ \textstyle\sum_{i=1}^m c_i n_i = n \text{ and for all } S \subset \{1,\dots,m\},\\ &\qquad\qquad \textstyle\sum_{i\in S} c_i \le \dim(\mathrm{Span}(u_i, i \in S))\Big\}.\end{aligned}$$

Here $\mathbf{1}_I$ is a vector in $\mathbb{R}^m$ whose ith coordinate is 1 if $i \in I$ and 0 otherwise.

In the general case, only a description by facets of the set of exponents leading to a finite constant (*domain of finiteness*) is available

Theorem 3.5 ([16], [15]). *There exist $K < +\infty$ such that for all $f_i : \mathbb{R}^{n_i} \to \mathbb{R}^+$*

$$\int_{\mathbb{R}^n} \prod_{i=1}^m (f_i \circ B_i)^{c_i} \le K \prod_{i=1}^m \left(\int_{\mathbb{R}} f_i\right)^{c_i}$$

if and only if for all i, $c_i \ge 0$, $\sum_{i=1}^m c_i n_i = n$ and for all vector subspaces $V \subset \mathbb{R}^n$ it holds

$$\dim V \le \sum_{i=1}^m c_i \dim(B_i V).$$

Remark 3.6. In the interior of the domain of finiteness, Gaussian maximizers exist and the inequality is equivalent to the multidimensional version of Ball's form (also called the geometric form) of the Brascamp–Lieb inequality: if vector subspaces E_i and numbers $c_i \in (0, 1]$ are such that $\mathrm{Id}_{\mathbb{R}^n} = \sum_{i=1}^m c_i P_{E_i}$ then for non-negative functions $f_i : E_i \to \mathbb{R}^+$, one has

$$\int_{\mathbb{R}^n} \prod_{i=1}^m (f_i \circ P_{E_i})^{c_i} \le \prod_{i=1}^m \left(\int_{E_i} f_i\right)^{c_i}.$$

This is proved using the heat semigroup, showing that $t \mapsto \int \prod_{i=1}^m ((P_t f_i) \circ P_{E_i})^{c_i}$ is non-decreasing and interpolates between the two terms of the above inequality. On the boundary of the finiteness domain, a factorization argument allows to reduce the dimension and conclude by induction.

Remark 3.7. The reverse Brascamp–Lieb inequality can be proved by the heat flow too, along the lines of Borell's argument for the Prékopa–Leindler inequality. This is written in [12] for functions of one variables and the geometric form. However this easily extends as well as the others steps of the proof.

But the heat equation approach does not only provide us with new proofs. It allows remarkable extensions of the results together with new applications. We refer to [15] for inequalities restricted to special classes of functions. Carlen, Lieb and Loss where able to prove similar inequalities in other spaces as the sphere [26] and the symmetric group [25]. The spherical inequality was motivated by the study of a system of n particles in one dimension, preserving total kinetic energy. Hence their n speeds form a vector in the Euclidean sphere $S^{n-1} \subset \mathbb{R}^n$. In order to know how the information on an individual particle influences the one of the whole system, they established the following: for $f_i : [-1, 1] \to \mathbb{R}^+$,

$$\int_{S^{n-1}} \prod_{i=1}^m f_i(x_i)\, d\sigma(x) \leq \prod_{i=1}^m \left(\int_{S^{n-1}} f_i(x_i)^2 d\sigma(x) \right)^{\frac{1}{2}},$$

where σ is the uniform probability measure on the sphere. The surprise here is the 2-norm, which is best possible and in particular does not disappear when $n \to +\infty$. In [14] this is extended to general decompositions of the identity $\mathrm{Id}_{\mathbb{R}^n} = \sum_{i=1}^m c_i P_{E_i}$, where for functions $f_i : E_i \to \mathbb{R}^+$ it holds

$$\int_{S^{n-1}} \prod_{i=1}^m f_i(P_{E_i} x)^{c_i/2} d\sigma(x) \leq \prod_{i=1}^m \left(\int_{S^{n-1}} f_i(P_{E_i} x)\, d\sigma(x) \right)^{c_i/2}.$$

This allows to consider particle systems in d dimension, and also with fixed momentum for example. However the exponents $c_i/2$ may not be best possible in this generality. In the work [13] a general framework of commuting Markov generator is developed to deal with these inequalities in general settings. Also the geometric meaning of the best exponents is better understood in continuous settings, and several new examples are provided.

4. Geometry in Gauss space

Let us denote by γ_d the standard Gaussian probability measure on $\mathbb{R}^d$ with density with respect to Lebesgue's measure given by $\rho(x) = (2\pi)^{-d/2} \exp(-|x|^2/2)$, $x \in \mathbb{R}^d$. There is no need to emphasize its importance, and it is natural and useful to have

Brunn–Minkowski type inequalities for γ_d. Applying the Prékopa–Leindler theorem to $f = \rho \mathbf{1}_A$, $g = \rho \mathbf{1}_B$, where $A, B \subset \mathbb{R}^d$ and using the log-concavity of ρ yields

$$\gamma_d^*(\lambda A + (1-\lambda)B) \geq \gamma_d(A)^\lambda \gamma_d(B)^{1-\lambda}. \tag{4}$$

This inequality is not sharp. An optimal version was proved by Ehrhard [35] for convex sets, using a symmetrization procedure. Latała [40] showed next that one a the sets may be non-convex and recently Borell [19] completely removed the convexity assumption. His approach is functional and uses the Heat equation. The most general version of his result is given below.

Theorem 4.1 ([20]). *Let $\lambda, \mu \geq 0$ with $\lambda + \mu \geq 1$ and $|\lambda - \mu| \leq 1$. Then for all measurable sets $A, B \subset \mathbb{R}^d$ the following holds:*

$$\Phi^{-1}(\gamma_d^*(\lambda A + \mu B)) \geq \lambda \Phi^{-1}(\gamma_d(A)) + \mu \Phi^{-1}(\gamma_d(B)),$$

where Φ is the distribution function of γ_1, defined by $\Phi(t) = \int_{-\infty}^t e^{-u^2/2} du/\sqrt{2\pi}$ for $t \in \mathbb{R}$.

Here $\Phi^{-1}\colon [-1,1] \to [-\infty, +\infty]$ is the reciprocal of Φ and by convention $+\infty - \infty = -\infty$. The inequality becomes an equality when A and B are parallel half-spaces. It recovers and unifies classical results on dilates and enlargements of convex sets:

Corollary 4.2 ([56]). *Let A be a convex set in R^d, and let $H \subset \mathbb{R}^d$ be a half-space with $\gamma_d(A) = \gamma_d(H)$. Then for all $r \geq 1$,*

$$\gamma_d(rA) \geq \gamma_d(rH).$$

This is reversed when $r \in (0,1]$.

Corollary 4.3 ([56], [17]). *Let $A \subset R^d$ be measurable, and $H \subset \mathbb{R}^d$ be a half-space such that $\gamma_d(A) = \gamma_d(H)$. Then for all $r \geq 0$,*

$$\gamma_d(A + rB^d) \geq \gamma_d(H + rB^d).$$

The latter statement is the sharp Gaussian isoperimetric inequality. It implies among others the concentration phenomenon (see e.g. [44]). It asserts that every L-Lipschitz function $f\colon \mathbb{R}^d \to \mathbb{R}$ is close to its median M with high probability:

$$\gamma_d\left(|f - M| \geq t\right) \leq 2e^{-t^2/(2L^2)}.$$

This fact is of fundamental importance in particular in the geometry of Banach spaces [50], [52], where it is often applied to norms. This is one of the motivations for studying improvements of the above results for symmetric convex sets. Little is known in this direction. Latała–Oleszkiewicz [41]] established a sharp analogue of Corollary 4.2 for symmetric convex sets. Let us mention another result of similar flavor. Caffarelli's Theorem 2.4 on monotone transportation nicely enters its proof.

Theorem 4.4 (Cordero-Erausquin–Fradelizi–Maurey [29]). *Let $A \subset \mathbb{R}^d$ be an origin-symmetric convex set. Then the function $t \mapsto \log(\gamma_d(tA))$ is concave on $(0, +\infty)$.*

In other words for $\lambda \in (0,1)$ and $s, t > 0$, $\gamma_d(s^\lambda t^{1-\lambda} A) \geq \gamma_d(sA)^\lambda \gamma_d(tA)^{1-\lambda}$. As $s^\lambda t^{1-\lambda} A \subset (\lambda s + (1-\lambda)t)A$, this is an improvement on what could be obtained before from the Prékopa–Leindler inequality

$$\gamma_d((\lambda s + (1-\lambda)t)A) \geq \gamma_d(sA)^\lambda \gamma_d(tA)^{1-\lambda}.$$

This fact and the isoperimetric inequality were used to derive the following improvement of the Gaussian concentration of norm, as conjectured by Vershynin.

Theorem 4.5 (Latała–Oleszkiewicz [42]). *Let G be a standard Gaussian vector in $(\mathbb{R}^d, \|\cdot\|)$. Let M be a median of $\|G\|$ and $\sigma^2 = \sup_{\|f\|_* \leq 1} Ef^2(G)$. Then for all $t \in (0,1]$ one has*

$$P(\|G\| \leq tM) \leq \frac{1}{2}(2t)^{M^2/(4\sigma^2)}.$$

Remark 4.6. Finally let us point out that Caffarelli's contraction Theorem 2.4 also played a crucial role in the recent progress towards the Gaussian correlation conjecture which predicts that every two origin symmetric convex sets $A, B \subset \mathbb{R}^d$ satisfy $\gamma_d(A \cap B) \geq \gamma_d(A)\gamma_d(B)$. See [28], [37].

5. Shannon entropy

Let X be a random variable with density $f : \mathbb{R} \to [0, \infty)$ and, to fix ideas, such that $\mathbb{E}X = 0$ and $\mathbb{E}X^2 = 1$. Its Shannon entropy is by definition

$$\mathrm{Ent}(X) = -\int_{\mathbb{R}} f \log f.$$

This fundamental notion of information theory also plays a crucial role in the study of return to equilibrium of many random systems. In this section we are interested in entropic aspects of the Central Limit Theorem (CLT). A new approach to entropy estimates was developed, which was formally inspired by a local version of the Brunn–Minkowski theorem.

Among variables of given variance, Gaussian variables are known to maximize entropy. In other words, if G is a standard Gaussian variable with density given by $g(t) = (2\pi)^{-1} \exp(-|t|^2/2)$, $t \in \mathbb{R}$, it holds that

$$\mathrm{Ent}(X) \leq \mathrm{Ent}(G).$$

Moreover, the difference between these two entropies is a strong distance between the laws of X and G. Indeed, the Pinsker–Csiszar–Kullback inequality [51], [33], [39] asserts that it dominates the square of the total variation distance. If Y, Z are

independent random variables and $\lambda \in (0,1)$, the Shannon–Stam inequality [54], [55] asserts that

$$\lambda \mathrm{Ent}(Y) + (1-\lambda)\mathrm{Ent}(Z) \leq \mathrm{Ent}(\sqrt{\lambda}\, Y + \sqrt{1-\lambda}\, Z). \tag{5}$$

In particular if $(X_i)_{i\geq 1}$ are independent copies of X one gets that

$$\mathrm{Ent}(X_1) \leq \mathrm{Ent}\left(\frac{X_1+X_2}{\sqrt{2}}\right),$$

and by iteration that

$$\mathrm{Ent}\left(\frac{1}{\sqrt{2^k}}\sum_1^{2^k} X_i\right)$$

is non-decreasing k (and bounded from above by the entropy of the standard Gaussian variable). Linnik [46] was the first to prove the CLT using entropy. Next Barron [9] established the CLT with entropic convergence. Obtaining rates for the convergence of the entropy requires to improve on the Shannon–Stam inequality (5). Carlen and Soffer [27] obtained non-explicit results in this direction.

In [5] Ball, Naor and the author developed a new technique to estimate entropy production. It is based on a new representation of the Fisher information of a marginal. Recall that the Fisher information of a variable X with density f is defined as $I(X) = I(f) := \int (f')^2/f$. It corresponds to the derivative of entropy along the Ornstein–Uhlenbeck semigroup: let G be a standard Gaussian variable independent of X; set $X_t := \sqrt{e^{-t}}\, X + \sqrt{1-e^{-t}}\, G$ and let f_t denote its density. Then

$$\mathrm{Ent}(G) - \mathrm{Ent}(X) = \int_0^\infty (I(X_t) - I(G))\, dt.$$

This classical relation allows to integrate linear inequalities on I in order to derive entropic estimates. The Fisher information representation was inspired by the Brunn–Minkowski theorem, as explained in the following section.

Remark 5.1. There was already a nice connection with Brunn–Minkowski theory. Indeed an equivalent form of the Shannon–Stam inequality (5) known as the entropy power inequality asserts that for independent random variables Y, Z one has

$$e^{2\mathrm{Ent}(Y+Z)} \geq e^{2\mathrm{Ent}(Y)} + e^{2\mathrm{Ent}(Z)}.$$

The similarity with the Brunn–Minkowski theorem was noted early and it was supported by the interpretation of Shannon entropy in terms of volumes of typical sets of values of independent copies of a variable. This analogy as well as the occurrence of the number 2 was explained by Szarek and Voiculescu [57], [58], who derived the entropy power inequality from a *restricted* Brunn–Minkowski inequality. Mass transport allows to establish a functional version of the latter, see [11].

5.1. A local version of the Brunn–Minkowski theorem. Consider a probability density $w(x, y)$ on $\mathbb{R}^2$ together with the density of its first marginal.

$$h(x) = \int w(x, y)\, dy.$$

Under appropriate regularity and integrability assumptions, the Fisher information of the marginal is expressed in terms of $(\log h)''$:

$$I(h) = \int \frac{(h')^2}{h} = \int h'(\log h)' = -\int h(\log h)''.$$

A direct consequence of the Prékopa–Leindler theorem is that $\log h$ is concave when $\log w$ is (this fact is actually formally equivalent to Brunn–Minkowski for convex sets). In [5] this is explained in terms of second derivatives. The direct calculation is not conclusive and has to be rearranged as

$$h(x)(-\log h)''(x) = \int_{\mathbb{R}} w(x, y)\left[(\partial_y \rho)^2(x, y) + \mathrm{D}^2(-\log w)_{(x,y)} \cdot \begin{pmatrix} 1 \\ \rho(x, y) \end{pmatrix} \cdot \begin{pmatrix} 1 \\ \rho(x, y) \end{pmatrix}\right] dy$$

where ρ is defined by

$$\rho(x, y) = \frac{1}{w(x, y)} \left(\frac{h'(x)}{h(x)} \int_{-\infty}^{y} w(x, v)\, dv - \int_{-\infty}^{y} \partial_x w(x, v)\, dv \right).$$

One easily reads on the first formula that $\mathrm{D}^2(\log w) \leq 0$ implies $(\log h)'' \leq 0$. Actually the function $y \mapsto \rho(x, y)$ described above minimizes the term on the right. Hence we get the following representation

$$h(x)(-\log h)''(x) = \inf_{p:\, \mathbb{R} \to \mathbb{R}} \int_{\mathbb{R}} w(x, y)\left[(p'(y))^2 + \mathrm{D}^2(-\log w)_{(x,y)} \cdot \begin{pmatrix} 1 \\ p(y) \end{pmatrix} \cdot \begin{pmatrix} 1 \\ p(y) \end{pmatrix}\right] dy.$$

Integrating with respect to x yields an expression of the Fisher information of the marginal.

5.2. Variational expressions for the Fisher information. In subsequent papers with Artstein, Ball and Naor [2], [1], more intrinsic formulations are given: let $w: \mathbb{R}^n \to \mathbb{R}^+$ be a probability density and let $e \in S^{n-1}$ be a unit vector. One considers the marginal obtained by projection onto $\mathbb{R}e$:

$$h(t) = \int_{te+e^\perp} w.$$

Its Fisher information can be expressed as an infimum in the following ways:

$$\begin{aligned} I(h) &= \inf_k \int_{\mathbb{R}^n} wk^2 \\ &= \inf_q \int_{\mathbb{R}^n} w \left(\frac{\operatorname{div}(wq)}{w} \right)^2 \\ &= \inf_q \int_{\mathbb{R}^n} w \left[\operatorname{Tr}(Dq)^2 + D^2(-\log w).q.q \right] \end{aligned}$$

where the first infimum is over functions $k : \mathbb{R}^n \to \mathbb{R}$ such that for all $t \in \mathbb{R}$ it holds $\int_{te+e^\perp} \partial_e w = \int_{te+e^\perp} wk$. The last two infima range over applications $q : \mathbb{R}^n \to \mathbb{R}^n$ such that for all $x \in \mathbb{R}^n$ one has $\langle q(x), e \rangle = 1$ (we have omitted here a few regularity conditions).

These formulas are convenient tools to estimate the Fisher information of $(X_1 + \cdots + X_k)/\sqrt{k}$ which is a marginal of $(X_1, \ldots, X_k)$. Applications are presented next.

5.3. The monotonicity of entropy in the CLT. The paper [2] answers an old conjecture of Shannon by showing that if $(X_n)_{n \geq 1}$ are independent copies of square integrable a random variable X with finite entropy then the sequence

$$e_k := \operatorname{Ent}\left(\frac{X_1 + \cdots + X_k}{\sqrt{k}} \right)$$

is non-decreasing. The classical Shannon–Stam inequality gives $e_k \leq e_{2k}$, but $e_k \leq e_{k+1}$ is much harder. This is deduced from a similar fact for Fisher information, which is proved using the infimum representation: the best test function for k variables is used to build a suitable test functions for $k + 1$. A corresponding version of the entropy-power inequality is also proved

Theorem 5.2 ([2]). *Let $X_1, \ldots, X_{n+1}$ be independent square integrable random variables. Then*

$$\exp\Big[2\operatorname{Ent}\Big(\sum_{i=1}^{n+1} X_i\Big)\Big] \geq \frac{1}{n} \sum_{j=1}^{n+1} \exp\Big[2\operatorname{Ent}\Big(\sum_{i \neq j} X_i\Big)\Big].$$

5.4. Rate of convergence in the entropic CLT. In [5], [1] the rate of entropy production, when adding independent copies, is studied under a spectral gap hypothesis. Recall that a random variable X has a spectral gap (or satisfies a Poincaré inequality) if there exists $c > 0$ such that every smooth function $s : \mathbb{R} \to \mathbb{R}$ verifies

$$c(E(s(X)^2) - (Es(X))^2) \leq E(s'(X)^2). \tag{6}$$

The strategy of proof was to choose specific functions in the variational formula for the Fisher information. Barron and Johnson where able to recover this result by a different method [8].

Theorem 5.3 ([1]). *Let G be a standard Gaussian random variable and let X be a random variable with variance* 1. *Assume that X satisfies a spectral gap inequality with constant $c > 0$. If $X_1, \dots, X_n$ are independent copies of X, denote as usual $S_n = (X_1 + \cdots + X_n)/\sqrt{n}$. Then*

$$\mathrm{Ent}(G) - \mathrm{Ent}(S_n) \leq \frac{1}{1 + \frac{c}{2}(n-1)} (\mathrm{Ent}(G) - \mathrm{Ent}(X)).$$

The rate $1/n$ is best possible. The spectral gap assumption is easy to decide on the real line. It is however rather strong, as it imply in particular exponential integrability. It is natural to try and replace this assumption with weaker moment conditions. A first quantitative result in this direction was obtained by Ball and Cordero-Erausquin:

Theorem 5.4 ([6]). *Let X be a symmetric random variable with $E(X^2) = 1$. Assume that it has finite Fisher information $I(X)$ and third moment $\tau = (E|X|^3)^{1/3}$. Then for $n \geq 1$*

$$\mathrm{Ent}(G) - \mathrm{Ent}(S_n) \leq \frac{c\sqrt{\tau}\, I(X)^{3/2}}{n^{\alpha}},$$

where c, α are universal constants.

Remark 5.5. Entropy production in the case of Markov chains with spectral gap was recently understood [7].

Isomorphic and almost-isometric problems in high-dimensional convex geometry

Bo'az Klartag*

Abstract. The classical theorems of high-dimensional convex geometry exhibit a surprising level of regularity and order in arbitrary high-dimensional convex sets. These theorems are mainly concerned with the rough geometric features of general convex sets; the so-called "isomorphic" features. Recent results indicate that, perhaps, high-dimensional convex sets are also very regular on the almost-isometric scale. We review some related research directions in high-dimensional convex geometry, focusing in particular on the problem of geometric symmetrization.

Mathematics Subject Classification (2000). 52A20, 52A21, 46B07.

Keywords. Convex geometry, high dimension, concentration phenomenon, central limit theorem.

1. Introduction

We will begin by quoting a sample of two fundamental theorems from the asymptotic theory of finite-dimensional normed spaces. The first will be Dvoretzky's theorem (for proofs, credits and history see, e.g., [47], [58] and references therein). We work in $\mathbb{R}^n$, endowed with the standard Euclidean norm $|\cdot|$ and scalar product $\langle \cdot, \cdot \rangle$. A convex body in $\mathbb{R}^n$ is a compact, convex set with a non-empty interior.

Theorem 1.1 (Dvoretzky's theorem). *Let $K \subset \mathbb{R}^n$ be a convex body that is centrally-symmetric (i.e. $K = -K$) and let $0 < \varepsilon < 1$. Then there exist $r > 0$ and a subspace $F \subset \mathbb{R}^n$ with $\dim(F) > c\varepsilon^2 \log n$ such that*

$$(1-\varepsilon) r D_F \subset K \cap F \subset (1+\varepsilon) r D_F,$$

where $D_F = \{x \in F;\ |x| \leq 1\}$ is the Euclidean unit ball in the subspace F and $c > 0$ is a universal constant.

Theorem 1.1 reveals a basic property of centrally-symmetric convex sets in high dimension: They all contain almost-spherical sections of logarithmic dimension. The second theorem we quote is Milman's quotient of subspace theorem [53]. It presents an almost full-dimensional approximate ellipsoid that is "hidden" in a certain way within any convex body in high dimension.

*The author is a Clay Research Fellow. Partial support was also given by NSF grant #DMS-0456590.

Proceedings of the International Congress of Mathematicians, Madrid, Spain, 2006

Theorem 1.2 (Milman's quotient of subspace theorem). *Let $K \subset \mathbb{R}^n$ be a centrally-symmetric convex body, and let $0 < \delta < \frac{1}{2}$. Then there exist subspaces $E \subset F \subset \mathbb{R}^n$ with $\dim(E) > \lceil (1-\delta)n \rceil$ and an ellipsoid $\mathcal{E} \subset E$ such that*

$$\frac{1}{c(\delta)} \mathcal{E} \subset \mathrm{Proj}_E(K \cap F) \subset c(\delta) \mathcal{E}.$$

Here Proj_E stands for the orthogonal projection operator onto E in $\mathbb{R}^n$ and $c(\delta) < c\frac{1}{\delta} \log \frac{1}{\delta}$, where $c > 0$ is a universal constant.

Asymptotic convex geometry is a discipline that emerged in the 1970*s* and 1980*s* from the geometric study of Banach spaces. It is also known by other names, such as the theory of high-dimensional normed spaces, asymptotic geometric analysis, etc. Theorem 1.1 and Theorem 1.2 are typical representatives of the achievements of asymptotic convex geometry. We refer the reader to, e.g., [31] for a more complete picture of this theory. Theorem 1.1, Theorem 1.2 and other results impose stringent regularity on the geometry of a general high-dimensional convex set (the central symmetry requirement is, in many cases, not entirely essential). An important feature of these results is their broad scope; a not-so-obvious fact that we learn from the asymptotic theory of convex geometry, is that there exist non-trivial, structural geometric statements that apply to all high-dimensional convex bodies.

The precise convexity is rarely used in this theory, and corresponding principles also hold under much weaker assumptions, such as quasi convexity. The focus is on the high dimension; the theory makes sense only when the dimension n is a very large number, tending to infinity. A protagonist in many proofs of high-dimensional results is the concentration of measure phenomenon, that is, the strong concentration inequalities that typical high-dimensional measures satisfy. This phenomenon and its applications were largely put forward by Milman, starting from his proof of Dvoretzky's theorem [52]. The concentration phenomenon forces regularity and simplicity on some apriori complicated objects such as a Lipshitz function on the sphere, and is one reason for the success of the high-dimensional theory (see, e.g., the review [54]).

A key characteristic of the theory is its "isomorphic" nature. That is, the scale in which convex bodies are viewed is such that two centrally-symmetric convex bodies $K, T \subset \mathbb{R}^n$ are considered to be "close enough" when

$$c_1 K \subset T \subset c_2 K \tag{1}$$

for $c_1, c_2 > 0$ being universal constants, independent of the dimension. In other words, the norms that have K and T as their unit balls, are uniformly isomorphic. This approach is most natural to functional analysis, the origin of the subject, and has led to an interesting and elegant theory. On the other hand, even some of the most basic questions of an "almost-isometric" nature in high dimension (as opposed to "isomorphic" nature) still remain unanswered. Let us present two such "almost-isometric" problems. The first is due to Bourgain [15], and will be discussed in more detail in Section 3. One of its many formulations reads as follows:

Question 1.1 (*The slicing problem*). Does there exist $c > 0$, such that for any dimension n and every convex body $K \subset \mathbb{R}^n$ of volume one, there exists at least one hyperplane section of K whose $(n-1)$-dimensional volume is larger than c?

The second question we would like to present, is the almost-isometric version of Dvoretzky's theorem.

Question 1.2. Fix a positive integer k. Do there exist $c(k), c'(k) > 0$ such that for any $0 < \varepsilon < 1$, $N = \left\lfloor c'(k) \left(\frac{1}{\varepsilon}\right)^{c(k)} \right\rfloor$ and for any centrally-symmetric convex body $K \subset \mathbb{R}^N$, one may find $r > 0$ and a k-dimensional subspace $E \subset \mathbb{R}^N$ such that

$$(1-\varepsilon) r D_E \subset K \cap E \subset (1+\varepsilon) r D_E \ ?$$

In fact, it has been conjectured (see [55]) that the answer to Question 1.2 is affirmative, with $c(k) = \frac{k-1}{2}$. This was proven by Bourgain and Lindenstrauss [20], for $k \geq 4$ and up to a factor of $\log \frac{1}{\varepsilon}$, but only when the convex set K is assumed to have certain symmetries. Question 1.2 has not even been resolved for small values of k; in particular $k = 3$. An exception is the case $k = 2$, where a proof due to Gromov appears in [55].

Question 1.1, Question 1.2 and problems of the same spirit are sensitive to the fine geometry of the convex body K. In this sense, these questions are more related to classical convexity theory. Moreover, the answers to the above two questions are both negative, if we relax the exact convexity requirement to quasi convexity, or even to isomorphic convexity (i.e., if we only assume that the convex hull of K is contained in $2K$).

We expect that in order to better understand the almost-isometric nature of high-dimensional convex bodies, new techniques should be employed, beyond the traditional concentration of measure phenomenon. Those techniques should take into account the precise convexity of the bodies, unlike in the isomorphic theory. Next, we demonstrate the transition from isomorphic to almost-isometric behavior in a specific test problem, that of geometric symmetrization.

2. Symmetrization of convex bodies

Let $K \subset \mathbb{R}^n$ be a convex body. For any hyperplane H that passes through the origin in $\mathbb{R}^n$ we will consider two types of symmetrization procedures. Our first symmetrization technique was described by Steiner ([66], see also [13]) in his proof of the isoperimetric inequality in two and three dimensions. Let $h \in S^{n-1}$ be a unit vector such that $H = h^{\perp}$. The Steiner symmetral of K with respect to the hyperplane H is the unique set $\sigma_H(K)$ for which the following two conditions hold:

1. For any $y \in H$, the set $\sigma_H(K) \cap [y + \mathbb{R}h]$ is a translation of the (possibly empty) segment $K \cap [y + \mathbb{R}h]$.

2. For any $y \in H$, the segment $\sigma_H(K) \cap [y + \mathbb{R}h]$, whenever non-empty, is centered at H.

Here $y + \mathbb{R}h$ stands for the line through y that is orthogonal to H. The set $\sigma_H(K)$ is symmetric with respect to the hyperplane H, hence the term "symmetrization". In addition, $\sigma_H(K)$ is convex and has the same volume as that of K. We will examine processes of symmetrization, where one begins with a convex body $K \subset \mathbb{R}^n$, and consecutively applies Steiner symmetrizations with respect to varying hyperplanes. It is a classical fact (see [25]) that given an arbitrary convex body $K \subset \mathbb{R}^n$, one may select appropriate hyperplanes $H_1, H_2, \ldots$ in $\mathbb{R}^n$ so that the sequence of bodies

$$\sigma_{H_m} \ldots \left(\sigma_{H_2}\left(\sigma_{H_1}(K)\right)\right) \quad \text{for } m = 1, 2, \ldots$$

converges in the Hausdorff metric to a Euclidean ball. This Euclidean ball will clearly have the same volume as that of the body we started with. Moreover, suppose we symmetrize a given convex body $K \subset \mathbb{R}^n$ with respect to randomly chosen hyperplanes, that are selected independently and uniformly over the grassmannian. Then convergence to a Euclidean ball occurs with probability one [49].

The second symmetrization procedure we consider is Minkowski symmetrization (also known as Blaschke symmetrization [9]). As before, $K \subset \mathbb{R}^n$ is a convex body and $H \subset \mathbb{R}^n$ is a hyperplane through the origin. For $x \in \mathbb{R}^n$, let $\pi_H(x)$ stand for the reflection of x with respect to H. The Minkowski symmetral of K with respect to H is the set

$$\tau_H(K) = \frac{K + \pi_H(K)}{2},$$

where $\frac{K+\pi_H(K)}{2} = \left\{\frac{x+\pi_H(y)}{2};\, x, y \in K\right\}$ is half of the Minkowski sum of K and $\pi_H(K)$. The set $\tau_H(K)$ is convex, yet its volume is usually different from that of K. Minkowski symmetrization preserves a different characteristic of the body, namely the mean width. The mean width of K is the quantity

$$w(K) = 2 \int_{S^{n-1}} \left[\sup_{x \in K} \langle x, \theta \rangle \right] d\mu(\theta),$$

where $S^{n-1} = \{x \in \mathbb{R}^n;\, |x| = 1\}$ is the unit sphere in $\mathbb{R}^n$ and μ is the unique rotationally-invariant probability measure on S^{n-1}. Thus, $w(\tau_H(K)) = w(K)$. A simple relation between Steiner and Minkowski symmetrization is that

$$\sigma_H(K) \subset \tau_H(K). \tag{2}$$

As in the case of Steiner symmetrizations, by applying an appropriate series of consecutive Minkowski symmetrizations to a given convex body $K \subset \mathbb{R}^n$, we obtain a sequence of convex bodies that converges towards a Euclidean ball. This Euclidean ball has the same mean width as the original body K.

Many geometric inequalities in which the Euclidean ball is the extremal case, may be proven using symmetrization techniques. Once we know that a certain geometric

quantity is, say, decreasing under symmetrization, we deduce that this quantity is minimized for the Euclidean ball, among all convex bodies of a given volume or mean width. For instance, from (2) we conclude that the ratio $w(K)/\operatorname{Vol}_n(K)^{\frac{1}{n}}$ is minimal for the Euclidean ball, among all convex bodies in $\mathbb{R}^n$. A sample of geometric inequalities proven via symmetrization includes the Brunn–Minkowski inequality (see, e.g., [13]), Santaló's inequality [50], Sylvester's problem [10], best approximation by polytopes [48] and a rearrangement inequality for integrals [23].

For a convex body $K \subset \mathbb{R}^n$ and $\varepsilon > 0$, we define $S(K,\varepsilon)$ (or $M(K,\varepsilon)$) to be the minimal number ℓ for which there exist ℓ Steiner symmetrizations (or Minkowski symmetrizations) that transform K into $\tilde{K}$ such that

$$e^{-\varepsilon} r D \subset \tilde{K} \subset e^{\varepsilon} r D,$$

where $D = \{x \in \mathbb{R}^n; |x| \leq 1\}$ is the unit Euclidean ball and $r = \left(\frac{\operatorname{Vol}_n(K)}{\operatorname{Vol}_n(D)}\right)^{\frac{1}{n}}$ (or $r = \frac{w(K)}{2}$). An interpretation I learned from V. Milman (e.g., [57]), is that the functions $S(K,\varepsilon)$, $M(K,\varepsilon)$ measure the complexity of the body K in the following sense. We view the Euclidean ball as the simplest of all convex bodies. If few symmetrizations are sufficient in order to transform K to become only ε-far from a Euclidean ball, then we think of K as being geometrically "simple". Convex bodies that require a large number of symmetrizations to attain this goal are viewed as more "complex". Define

$$S(n,\varepsilon) = \sup_{K \subset \mathbb{R}^n} S(K,\varepsilon), \quad M(n,\varepsilon) = \sup_{K \subset \mathbb{R}^n} M(K,\varepsilon), \tag{3}$$

where the suprema run over all convex bodies in $\mathbb{R}^n$. Consider first the isomorphic problem, where we try to symmetrize a convex body to make it close to a Euclidean ball in the isomorphic sense, as in (1). That is, we take ε in (3) to be of the order of magnitude of 1.

Theorem 2.1 ([37], [44]). *There exists a universal constant $c > 0$ such that for any dimension $n \geq 1$,*

1. *$S(n,c) \leq 3n$, and*
2. *$M(n,c) \leq 5n$.*

In addition, the slightly better inequality $M\left(n, c\frac{\log\log(n+2)}{\sqrt{\log(n+1)}}\right) \leq 5n$ holds.

Previous estimates in the literature are $M(n,c) < c' n \log n$ [21] and $S(n,c) < \tilde{c} n \log n$ [22]. See also [33] and [67]. Here, and throughout this note, the letters c, C, c', $\tilde{c}$ etc. denote positive universal constants. These constants need not be the same from one occurrence to the next. According to Theorem 2.1, all convex sets in $\mathbb{R}^n$ are geometrically "simple" in the above sense, at least in the isomorphic scale. Indeed, the number of symmetrizations needed to transform an arbitrary convex body into an isomorphic Euclidean ball, the simplest body, is only linear in the dimension n.

The constants "3" and "5" in Theorem 2.1 are probably not optimal, and the best constants are yet to be found. Yet, the exact constant is essentially known for a variant of our problem: Suppose we apply consecutive Steiner symmetrizations to a given convex body, and we are already satisfied when we arrive at an isomorphic ellipsoid, rather than a Euclidean ball. It is not very difficult to see (e.g. [44]) that for some convex bodies, at least $(1 - o(1))n$ Steiner symmetrizations are required in order to arrive at an isomorphic ellipsoid. The following theorem expresses the fact that roughly n symmetrizations are also sufficient, for all n-dimensional convex sets.

Theorem 2.2 ([44]). *For any $\delta > 0$, there exists a number $c(\delta) > 0$ for which the following holds: For any dimension $n \geq 1$ and a convex body $K \subset \mathbb{R}^n$, there exist an ellipsoid $\mathcal{E} \subset \mathbb{R}^n$ and $\lfloor (1+\delta)n \rfloor$ Steiner symmetrizations that transform K into a convex body $\tilde{K}$ such that*

$$\frac{1}{c(\delta)} \mathcal{E} \subset \tilde{K} \subset c(\delta) \mathcal{E}.$$

Moreover, $c(\delta) < c' \frac{1}{\delta} \log \frac{1}{\delta}$, where c' is a universal constant.

The proofs of Theorem 2.1 and Theorem 2.2 utilize some of the cornerstones of the asymptotic theory of convex geometry, such as concentration of measure inequalities, Kashin's splitting ([35], and the precise estimates in [30]) and Milman's quotient of subspace theorem mentioned above. Let us discuss some details from the proof of Theorem 2.1. We will focus our attention on the case of Minkowski symmetrizations, which is easier to analyze.

Given a convex body $K \subset \mathbb{R}^n$, our task is to design a sequence of symmetrizations that transform K into an approximate Euclidean ball. A plausible solution is choosing the symmetrizations randomly, that is, the hyperplanes are selected independently and uniformly. This approach was manifested in [21], and leads to the bound $M(n, c) < c' n \log n$. In fact, the effect of random Minkowski symmetrizations may be described even more precisely: For any convex body $K \subset \mathbb{R}^n$, the minimal number of *random* Minkowski symmetrizations needed in order to transform K, with reasonable probability, into an isomorphic Euclidean ball, has the order of magnitude of

$$n \log \frac{\mathrm{diam}(K)}{w(K)}. \tag{4}$$

Here $\mathrm{diam}(K)$ is the diameter of K (See [36] for exact formulation of this statement, based on [21]. See also [36] for a related phase-transition of the diameter in the process). We would like to emphasize that (4) is not merely a bound; it is actually an asymptotic formula for the minimal number of random symmetrizations required, valid for each convex body in $\mathbb{R}^n$. Just two simple geometric parameters, the diameter and the mean width, suffice to completely characterize the performance of a complicated process such as random Minkowski symmetrizations. This is a typical situation in asymptotic convex geometry (compare with [56] and [59]). The ratio $\frac{\mathrm{diam}(K)}{w(K)}$ is never larger than $c\sqrt{n}$, when $K \subset \mathbb{R}^n$. There are convex bodies in $\mathbb{R}^n$ for which

$\frac{\mathrm{diam}(K)}{w(K)} > c'\sqrt{n}$; a segment in $\mathbb{R}^n$ is an example of such a body. We thus conclude from (4) that for some convex bodies $K \subset \mathbb{R}^n$, at least $cn \log n$ random Minkowski symmetrizations are necessary in order to transform, with reasonable probability, the body K into an isomorphic Euclidean ball.

Consequently, the proof of the estimate $M(n, c) \leq 5n$ must involve a different symmetrization process: It is not efficient to simply take random, independent, Minkowski symmetrizations. This is in contrast to some other results in the theory, where the random choice is essentially the best choice (see, e.g. [59]). The approach taken in [37] is to perform several iterations, each consisting of n symmetrizations, that are carried out with respect to n mutually orthogonal hyperplanes in $\mathbb{R}^n$. There is more than one way of selecting these n mutually orthogonal hyperplanes. For instance, one may choose them randomly; that is, the iterations are independent, and the choice of the hyperplanes corresponds to the uniform probability measure on the orthogonal group (this leads to a proof that $M(n, c) \leq 6n$). As in [21], the proof of Theorem 2.1 still involves randomness, but of a different type.

We have explained why high-dimensional convex bodies are "simple objects", in some sense, in the isomorphic scale. One might be tempted to believe that the true complexity of high-dimensional convex sets resides in the almost-isometric scale. Perhaps the simplicity of convex bodies, as manifested in Theorem 2.1 and in the prominent theorems of asymptotic convex geometry (e.g., Theorem 1.1 and Theorem 1.2 above), is relevant only in the isomorphic scale? For the case of symmetrization, a negative answer is provided by the next theorem.

Theorem 2.3 ([39]). *There exists a universal constant $c > 0$ such that for any dimension $n \geq 1$ and $0 < \varepsilon < \frac{1}{2}$,*

1. $M(n, \varepsilon) \leq cn \log \frac{1}{\varepsilon}$, *and*
2. $S(n, \varepsilon) \leq cn^4 \log^2 \frac{1}{\varepsilon}$.

The proof of Theorem 2.3 involves harmonic analysis on the sphere S^{n-1}. The dependence on n and the dependence on ε in the bound for $M(n, \varepsilon)$ are each optimal, up to the exact value of the constant c. The exponents "4" and "2" in the bound for $S(n, \varepsilon)$ are probably not optimal. Yet, the dependence on ε in Theorem 2.3 is surprisingly good. Very few results with a logarithmic dependence on the distance ε are known in high-dimensional convex geometry. Another example is described in [7] (see S. Szarek's contribution in these proceedings for an explanation). It would be interesting to also find such good dependencies in other problems in the theory.

3. Volume distribution in convex bodies

The next family of problems we consider is related to the distribution of mass in high-dimensional convex bodies. For a convex body $K \subset \mathbb{R}^n$, let $\mathcal{E} \subset \mathbb{R}^n$ be the

Legendre ellipsoid of inertia of K; that is, $\mathcal{E}$ is the unique ellipsoid that has the same barycenter as K and also

$$\int_K \langle x, \theta \rangle^2 dx = \int_{\mathcal{E}} \langle x, \theta \rangle^2 dx$$

for any $\theta \in \mathbb{R}^n$. A convex body $K \subset \mathbb{R}^n$ of volume one is called isotropic if its barycenter lies at the origin and its Legendre ellipsoid is a Euclidean ball. In that case,

$$\int_K \langle x, \theta \rangle^2 dx = L_K^2$$

independently of θ in the unit sphere S^{n-1}. The quantity L_K is the isotropic constant of the convex body K. For any convex body $K \subset \mathbb{R}^n$ there exists a unique, up to orthogonal transformations, isotropic body $\tilde{K}$ which is an affine image of K (see, e.g., [51]). The isotropic constant of a general convex body K is defined as $L_K := L_{\tilde{K}}$, where $\tilde{K}$ is an isotropic affine image of K.

The isotropic constant of K encompasses many of the volumetric properties of the convex body K. See [51] for a list. For instance, if K is isotropic, then for any hyperplane H through the origin,

$$\frac{c_1}{L_K} \leq \mathrm{Vol}_{n-1}(K \cap H) \leq \frac{c_2}{L_K} \tag{5}$$

where $c_1, c_2 > 0$ are universal constants (see [34], or the survey paper [51]). Note that the relation (5) is a non-trivial rigidity property of convex bodies, in the almost-isometric scale. It is well-known (e.g. [51]) that for any dimension n and a convex body $K \subset \mathbb{R}^n$, we have $L_K > c$ for some universal constant $c > 0$. Denote,

$$L_n = \sup_{K \subset \mathbb{R}^n} L_K$$

where the supremum runs over all convex bodies in $\mathbb{R}^n$. Question 1.1 is equivalent (see [51]) to the following question: Is it true that $\sup_{n \geq 1} L_n < \infty$? The best estimate for the isotropic constant known to date is

$$L_n < c n^{\frac{1}{4}} \tag{6}$$

for a universal constant $c > 0$. The estimate (6), proven in [41], is a slight improvement on a previous bound $L_n < c n^{1/4} \log n$, due to Bourgain (See [16], [17], [28]. See [60] or the last remark in [38] for the non-symmetric case of Bourgain's bound). Aside from the general bound (6), an affirmative answer to Question 1.1 was obtained for large classes of convex bodies, including unconditional convex sets, zonoids, duals to zonoids, convex bodies with a bounded outer volume ratio and unit balls of Schatten norms (see, e.g., references in [41]). A reduction of the slicing problem, from general convex bodies to the simpler class of finite-volume-ratio bodies, appears in [18], [19] (see [18], [19] for precise definitions and statements).

A possible relaxation of Question 1.1 is its isomorphic version. Rather than trying to bound the isotropic constant of a given convex body $K \subset \mathbb{R}^n$, the isomorphic version asks whether there exists another convex body K', isomorphic to K in the sense of (1), for which the isotropic constant is bounded. A positive answer is provided in the following theorem.

Theorem 3.1 ([41]). *Let $K \subset \mathbb{R}^n$ be a convex body, and let $0 < \varepsilon < 1$. Then there exists another convex body $K' \subset \mathbb{R}^n$ such that*

1. $L_{K'} < \frac{c}{\sqrt{\varepsilon}}$, *and*
2. *for some $x_0 \in \mathbb{R}^n$,*

$$(1-\varepsilon)K' \subset K + x_0 \subset (1+\varepsilon)K'.$$

Here, $c > 0$ is a universal constant.

Theorem 3.1 reduces the slicing problem to a question regarding the stability of the isotropic constant under isomorphic change of the body. Theorem 3.1, together with Ball's observation (see [4] or [51, page 78]), provides another derivation of the existence of a Milman ellipsoid with a universal constant, for any convex body $K \subset \mathbb{R}^n$. A Milman ellipsoid for K with constant c is an ellipsoid $\mathcal{E} \subset \mathbb{R}^n$ with $\mathrm{Vol}_n(K) = \mathrm{Vol}_n(\mathcal{E})$ such that K may be covered by e^{cn} translations of $\mathcal{E}$ (see, e.g., [56] for a detailed discussion).

Given a convex body $K \subset \mathbb{R}^n$, there are several ellipsoids or Euclidean structures associated with K, such as Milman ellipsoids, the maximal volume ellipsoid, the Legendre inertia ellipsoid, the minimal surface area ellipsoid, etc. It is customary to call these Euclidean structures various "positions" of K. The relations between different positions of a convex body are not clear in general. See [43] for a certain non-trivial relation, applicable only to 2-convex bodies. As is proven in [19], Question 1.1 is equivalent to the following question: Is it true that for any convex body $K \subset \mathbb{R}^n$, the Legendre ellipsoid of K is also a Milman ellipsoid for K, with a universal constant?

A very interesting development stems from the recent Paouris theorem. Suppose that $K \subset \mathbb{R}^n$ is an isotropic convex body. Let X be a random vector, that distributes uniformly over K. Then $\mathbb{E}X = 0$. What can be said about the distribution of $|X|$? Clearly $\sqrt{\mathbb{E}|X|^2} = \sqrt{n}L_K$. Moreover, a direct consequence of the Brunn–Minkowski inequality is that $\mathrm{Prob}(|X| > \sqrt{n}L_K t)$ decays exponentially in t, i.e., at least as fast as e^{-ct} for a universal constant $c > 0$ (see [1] for a subgaussian decay). A surprisingly strong improvement is contained in the following theorem [63], [64].

Theorem 3.2 (Paouris theorem). *Let $K \subset \mathbb{R}^n$ be an isotropic convex body. Then, for any $t \geq 1$,*

$$\mathrm{Vol}_n\left(\{x \in K; |x| \geq ct\sqrt{n}L_K\}\right) \leq \exp(-t\sqrt{n}) \tag{7}$$

where $c > 0$ is a universal constant.

The proof of Theorem 3.2 involves, among other ingredients, a clever use of Dvoretzky's theorem. In the case where the convex body K is also assumed to be unconditional, the conclusion of Theorem 3.2 was proven in [11], [12], and for K being the normalized ℓ_1^n-ball, the result was proven in [65]. The inequality (7) is actually tight for the normalized ℓ_1^n-ball, up to the value of the constant c.

According to Theorem 3.2, all the mass of an isotropic convex body, except for a mere $e^{-\sqrt{n}}$-fraction, lies inside a ball of radius $c\sqrt{n}L_K$ around the origin. A conjecture put forward by Anttila, Ball and Perissinaki [2] suggests that there exists a sequence $\varepsilon_n \to 0$ with the following property: Whenever $K \subset \mathbb{R}^n$ is an isotropic convex body, then for some $\rho > 0$,

$$\mathrm{Vol}_n\left(\{x \in K;\, (1-\varepsilon_n)\rho \le |x| \le (1+\varepsilon_n)\rho\}\right) \ge 1 - \varepsilon_n. \tag{8}$$

This "thin shell" conjecture (8) was verified in [2] for unit balls of l_p^n-spaces, and for a large family of uniformly convex bodies. A positive answer to this conjecture would imply, in particular, that all high-dimensional isotropic convex bodies have many near-gaussian one-dimensional marginal distributions. See [2] for the exact formulation and proof of this implication, and see [24] for a discussion pertaining to the question of existence of near-gaussian marginals, for all high-dimensional convex bodies.

Our next topic is related to large deviation estimates for marginal distributions of general convex sets. Suppose $K \subset \mathbb{R}^n$ is a convex body of volume one, and let $\varphi\colon \mathbb{R}^n \to \mathbb{R}$ be a linear functional. Denote $\|\varphi\|_{L^1(K)} = \int_K |\varphi(x)|\,dx$. A well-known consequence of the Brunn–Minkowski inequality, observed by Borell [14], is that for all $t \ge 1$,

$$\mathrm{Vol}_n\left(\{x \in K;\, |\varphi(x)| \ge t\|\varphi\|_{L^1(K)}\}\right) \le \exp(-ct) \tag{9}$$

where $c > 0$ is a universal constant. Thus, a uniform sub-exponential estimate holds for the distribution of an arbitrary linear functional on an arbitrary convex set. A typical case in which (9) is sharp, is that of a cone over an $(n-1)$-dimensional base; the distribution of a linear functional that vanishes on the base of the cone, is very close to being an exact exponential.

When $K \subset \mathbb{R}^n$ is an ellipsoid of volume one, the sub-exponential bound (9) may be substantially improved. It is easy to see that in this case, any linear functional $\varphi\colon \mathbb{R}^n \to \mathbb{R}$ satisfies the sub-gaussian estimate

$$\mathrm{Vol}_n\left(\{x \in K;\, |\varphi(x)| \ge t\|\varphi\|_{L^1(K)}\}\right) \le \exp(-ct^2) \quad \text{for all } t \ge 1, \tag{10}$$

where $c > 0$ is a universal constant. Inequality (10) is rather sharp, since the distribution of a linear functional on an ellipsoid is very close to being gaussian. A question that is often attributed to Milman [6], [61], [62], asks whether for any convex body $K \subset \mathbb{R}^n$ of volume one, there exists a non-zero linear functional $\varphi\colon \mathbb{R}^n \to \mathbb{R}$, for which a sub-gaussian estimate holds as in (10). A positive answer to this question would have the interpretation that for any convex body $K \subset \mathbb{R}^n$, there exists a direction in which, in a sense, K does not look like an apex or a cone, but rather exhibits quite regular behavior, like that of an ellipsoid or a Euclidean ball.

An affirmative answer to Milman's question was obtained for unconditional convex bodies [11], for zonoids [61] and for some other classes of convex sets [61], [62]. A recent, general principle provides an affirmative answer to Milman's question, up to a logarithmic factor:

Theorem 3.3 ([42]). *Let $K \subset \mathbb{R}^n$ be a convex body of volume one. Then there exists a non-zero linear functional $\varphi\colon \mathbb{R}^n \to \mathbb{R}$, such that for any $t \geq 1$,*

$$\mathrm{Vol}_n\left(\{x \in K;\, |\varphi(x)| \geq t\|\varphi\|_{L^1(K)}\}\right) \leq \exp\left(-c\,\frac{t^2}{\log^5(t+1)}\right),$$

where $c > 0$ is a universal constant.

The proofs of Theorem 3.1 and Theorem 3.3 make use of several properties of the logarithmic Laplace transform of log-concave functions. We would like to conclude this section with the "random cotype-2" result of Gluskin and Milman. Suppose $K \subset \mathbb{R}^n$ is a centrally-symmetric convex body, and $X_1, \ldots, X_n$ are independent, random vectors, distributed uniformly in K. In [32] it is proven that with probability larger than $1 - e^{-cn}$,

$$\frac{1}{2^n}\sum_{\varepsilon\in\{-1,1\}^n}\left\|\sum_{i=1}^n \varepsilon_i\lambda_i X_i\right\|_K > c\sqrt{\sum_{i=1}^n \lambda_i^2} \quad \text{for all } (\lambda_1,\ldots,\lambda_n) \in \mathbb{R}^n, \tag{11}$$

where $\|\cdot\|_K$ is the norm whose unit ball is K and $c > 0$ is a universal constant. Consequently, any finite-dimensional norm satisfies a cotype-2 condition as in (11), with high probability, when the vectors $X_1, \ldots, X_n$ are random vectors that are selected independently and uniformly in the unit ball of that norm. See, e.g., [58, Section 9], for definitions and basic properties of type and cotype of normed spaces.

4. Beyond Brunn–Minkowski and Santaló inequalities

Some of the recent developments regarding volume distribution in high-dimensional convex sets are connected with a better understanding of log-concave functions, which are functions $f\colon \mathbb{R}^n \to [0,\infty)$ whose logarithm is concave. The relation between the slicing problem and log-concave functions goes back at least to [5]. Recall that the Legendre transform of a function $\varphi\colon \mathbb{R}^n \to \mathbb{R}$ is defined as

$$\mathcal{L}\varphi(x) = \sup_{y\in\mathbb{R}^n}\left[\langle x, y\rangle - \varphi(y)\right].$$

The following result follows from the Santaló and Bourgain–Milman inequalities [3], [45]: For any measurable function $\varphi\colon \mathbb{R}^n \to \mathbb{R}$, there exists $x_0 \in \mathbb{R}$ such that $\tilde{\varphi}(x) = \varphi(x - x_0)$ satisfies

$$c \leq \left(\int_{\mathbb{R}^n} e^{-\tilde{\varphi}} \int_{\mathbb{R}^n} e^{-\mathcal{L}\tilde{\varphi}}\right)^{\frac{1}{n}} \leq 2\pi, \tag{12}$$

where $c > 0$ is a universal constant (and we agree, for the purpose of (12), that $c \leq \infty \cdot 0 \leq 2\pi$). Equality on the right hand side of (12) holds if and only if φ is a.e. a positive definite quadratic form (see [3]). For the case where φ is an even function, we may select $x_0 = 0$ in (12). In that case, the right hand side of (12) was proven by K. Ball (see [4] and also [29], for related inequalities). When φ is an even function, the following generalization holds (see [40]):

$$\int_{\mathbb{R}^n} e^{-\varphi}\, d\mu \int_{\mathbb{R}^n} e^{-\mathcal{L}\varphi}\, d\mu \leq \left(\int_{\mathbb{R}^n} e^{-\frac{|x|^2}{2}}\, d\mu \right)^2 \tag{13}$$

where μ is any log-concave measure on $\mathbb{R}^n$ (for example, a measure on $\mathbb{R}^n$ whose density is a log-concave function). This is closely related to an interesting theorem of Cordero-Erausquin [26]: Suppose $K, T \subset \mathbb{R}^{2n}$ are convex bodies. We endow $\mathbb{R}^{2n}$ with a complex structure, and assume that K, T are unit balls of complex Banach norms, and $T = \overline{T}$ where $\overline{T}$ is the conjugate of T. Then

$$\mathrm{Vol}_{2n}(K \cap T)\, \mathrm{Vol}_{2n}(K^\circ \cap T) \leq \mathrm{Vol}_{2n}(D \cap T)^2, \tag{14}$$

where $K^\circ = \{x \in \mathbb{R}^{2n};\ \text{for all } y \in K,\ \langle x, y\rangle \leq 1\}$ is the dual body. The proof of (14) uses complex interpolation and a recent complex version of the Prékopa–Leindler inequality due to Berndtsson [8]. It is not clear at the moment whether (14) generalizes to arbitrary centrally-symmetric convex sets. Inequality (13) may be viewed as a functional version of this suspected generalization. See [40] for related inequalities.

Inequality (14) suggests that, perhaps, convex bodies obey some additional geometric inequalities, beyond the classical Santaló and Brunn–Minkowski inequalities. Further evidence for this stems from the result of Cordero-Erausquin, Fradelizi and Maurey in [27]. Solving a conjecture from [46], they show that for any centrally-symmetric convex body $K \subset \mathbb{R}^n$ and $s, t > 0$,

$$\gamma_n(\sqrt{st}K) \geq \sqrt{\gamma_n(sK)\gamma_n(tK)}, \tag{15}$$

where γ_n is the standard gaussian measure in $\mathbb{R}^n$, whose density is given by $d\gamma_n = (2\pi)^{-n/2} \exp(-|x|^2/2)dx$. The Brunn–Minkowski type arguments only yield (15) with $\sqrt{st}$ replaced by $\frac{s+t}{2}$ (see also F. Barthe's article in this volume). In the case where n is even, and K is the unit ball of a complex Banach norm, it is possible to replace the gaussian measure in (15) with any log-concave measure that respects the complex structure in a natural way (this follows from [26, Theorem 3.2]). It would be desirable to understand whether (14) and (15) actually hold in the context of arbitrary centrally-symmetric convex sets and arbitrary even log-concave measures, without an underlying complex structure.

Note added in proof. We would like to report on two very recent developments: First, Giannopoulos, Pajor and Paouris have simplified and slightly improved the proof of

Theorem 3.3, see http://arxiv.org/abs/math.FA/0604299. Second, the "thin shell" conjecture (8) has been proved by the author for all isotropic, convex sets. Consequently, typical one-dimensional marginal distributions of high-dimensional, isotropic, convex sets are approximately gaussian. Similar principles also hold for multi-dimensional marginal distributions. See http://arxiv.org/abs/math.MG/0605014.

Amenable actions and applications

Narutaka Ozawa

Abstract. We will give a brief account of (topological) amenable actions and exactness for countable discrete groups. The class of exact groups contains most of the familiar groups and yet is manageable enough to provide interesting applications in geometric topology, von Neumann algebras and ergodic theory.

Mathematics Subject Classification (2000). Primary 46L35; Secondary 20F65, 37A20, 43A07.

Keywords. Amenable actions, exact groups, group von Neumann algebras.

1. Introduction

The notion of amenable groups was introduced by J. von Neumann in 1929 in his investigation of the Banach–Tarski paradox. He observed that non-abelian free groups are not amenable and that this fact is the source of the Banach–Tarski paradox. Since then it has been shown that the amenability of a locally compact group is equivalent to many fundamental properties in harmonic analysis of the group: the Følner property, the fixed point property and the weak containment of the trivial representation in the regular representation, to name a few. For a discrete group, amenability of the group is also characterized by nuclearity of its group C^*-algebra, and by injectivity of its group von Neumann algebra. In this note, we are mainly interested in countable discrete groups. The class of amenable groups contains all solvable groups and is closed under subgroups, quotients, extensions and directed unions. As we mentioned before, a non-abelian free group, or any group which contains it, is not amenable. Amenable groups play a pivotal role in the theory of operator algebras. Many significant operator algebra-related problems on groups have been solved for amenable groups. We just cite two of them; the classification of group von Neumann algebras [14] and measure equivalences [16], [58] on the one hand, and the Baum–Connes conjecture [46] on the other hand. In recent years, there have been exciting breakthroughs in both subjects beyond the amenable cases. We refer to [68] and [84] for accounts of this progress. We will also treat the classification of group von Neumann algebras and measure equivalences in Section 4. Since many significant problems, if not all, are already solved for amenable groups, we would like to set out for the world of non-amenable groups. Still, as Gromov's principle goes, no statement about all groups is both non-trivial and true. So we want a *good* class of groups to play with. We consider a class

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

as good if it contains many of the familiar examples, is manageable enough so that it maintains non-trivial theorems, and can be characterized in various ways so that it is versatile. We believe that the class of exact groups, which will be introduced in the following section, stands these tests. The study of exactness originates in C^*-algebra theory [50], [51], [52] and was propagated to groups. The class of exact groups is fairly large and it contains all amenable groups, linear groups [39] and hyperbolic groups [2], to name a few. It is closed under subgroups, extensions, directed unions and amalgamated free products. (Since every free group is exact and there exists a non-exact group [37], a quotient of exact group needs not be exact unless the normal subgroup is amenable.) Moreover, there is a remarkable theorem that the injectivity part of the Baum–Connes conjecture holds for exact groups [45], [76], [83], [84]. Since this part of the Baum–Connes conjecture has a lot of applications in geometry and topology, including the strong Novikov conjecture, it is an interesting challenge to prove exactness of a given group. We will encounter some other applications in von Neumann algebra theory and ergodic theory in Section 4.

2. Amenable actions and exactness

We first review the definition of and basic facts on amenable actions. We refer to [65] for the theory of amenable groups and to [5], [11] for the theory of amenable actions. The notion of amenability for a group action was first introduced in the measure space setting in the seminal paper [85], which has had a great influence in both ergodic theory and von Neumann algebra theory. In this spirit the study of its topological counterpart was initiated in [3]. In this note, we restrict our attention to continuous actions of countable discrete groups on (not necessarily second countable) compact spaces. All topological spaces are assumed to be Hausdorff and all groups, written as $\Gamma, \Lambda, \dots$, are assumed to be countable and discrete. Let Γ be a group. A (topological) Γ-*space* is a topological space X together with a continuous action of Γ on it; $\Gamma \times X \ni (s, x) \mapsto s.x \in X$. For a group (or any countable set) Γ, we let

$$\mathrm{prob}(\Gamma) = \left\{\mu \in \ell_1(\Gamma) : \mu \geq 0,\ \textstyle\sum_{t\in\Gamma} \mu(t) = 1\right\} \subset \ell_1(\Gamma)$$

and equip $\mathrm{prob}(\Gamma)$ with the pointwise convergence topology. We note that this topology coincides with the norm topology. The space $\mathrm{prob}(\Gamma)$ is a Γ-space with the Γ-action given by the left translation: $(s.\mu)(t) = \mu(s^{-1}t)$.

Definition 2.1. We say that a compact Γ-space X is *amenable* (or Γ *acts amenably* on X) if there exists a sequence of continuous maps

$$\mu_n \colon X \ni x \mapsto \mu_n^x \in \mathrm{prob}(\Gamma)$$

such that for every $s \in \Gamma$ we have

$$\lim_{n\to\infty} \sup_{x\in X} \|s.\mu_n^x - \mu_n^{s.x}\| = 0.$$

When X is a point, the above definition degenerates to one of the equivalent definitions of amenability for the group Γ. Moreover, if Γ is amenable, then every Γ-space is amenable. Conversely, if there exists an amenable Γ-space which carries an invariant Radon probability measure, then Γ itself is amenable. If X is an amenable Γ-space, then X is amenable as a Λ-space for every subgroup Λ. It follows that all isotropy subgroups of an amenable Γ-space have to be amenable. We recall that the isotropy subgroup of x in a Γ-space X is $\{s \in \Gamma : s.x = x\}$. It is also easy to see that if there exists a Γ-equivariant continuous map from a Γ-space Y into another Γ-space X and if X is amenable, then so is Y. Finally, we only note that there are several equivalent characterizations of an amenable action which generalize those for an amenable group.

Many amenable actions naturally arise from the geometry of groups. The following are the most basic examples of amenable actions.

Example 2.2. Let $\mathbb{F}_r = \langle g_1, \ldots, g_r \rangle$ be the free group of rank $r < \infty$. Then its (Gromov) boundary $\partial\mathbb{F}_r$ is amenable. We note that the Cayley graph of $\mathbb{F}_r$ w.r.t. the standard set of generators is a simplicial tree and its boundary

$$\partial\mathbb{F}_r \subset \{g_1, g_1^{-1}, \ldots, g_r, g_r^{-1}\}^{\mathbb{N}}$$

is defined as the compact topological space of all infinite reduced words, equipped with the relative product topology (see Figure 1). Similarly, with an appropriate topology, $\mathbb{F}_r \cup \partial\mathbb{F}_r$ becomes a compactification of $\mathbb{F}_r$. The free group $\mathbb{F}_r$ acts continuously on $\partial\mathbb{F}_r$ by left multiplication (and rectifying possible redundancy). For $x \in \partial\mathbb{F}_r$ with its reduced form $x = a_1 a_2 \ldots$, we set $x_0 = e$ and $x_k = a_1 \ldots a_k$. For every $n \in \mathbb{N}$, we let

$$\mu_n \colon \partial\mathbb{F}_r \ni x \mapsto \mu_n^x = \frac{1}{n} \sum_{k=0}^{n-1} \delta_{x_k} \in \mathrm{prob}(\mathbb{F}_r).$$

Thus μ_n^x is the normalized characteristic function of the first n segments of the path in the Cayley graph of $\mathbb{F}_r$, connecting e to x (see Figure 1). It is not hard to see that μ_n is a continuous map such that

$$\sup_{x \in \partial\mathbb{F}_r} \|s.\mu_n^x - \mu_n^{s.x}\| \leq \frac{2|s|}{n}$$

for every $s \in \mathbb{F}_r$, where $|s|$ is the word length of s. Indeed, $s.\mu_n^x$ is the normalized characteristic function of the first n segments of the path connecting s to $s.x$, which has a large intersection with the path connecting e to $s.x$ (see Figure 2).

There are generalizations of this construction to groups acting on more general buildings [72] and on hyperbolic spaces [2].

Example 2.3. Let Γ be a discrete subgroup of the special linear group $\mathrm{SL}(n, \mathbb{R})$ (e.g., $\Gamma = \mathrm{SL}(n, \mathbb{Z})$) and $P \subset \mathrm{SL}(n, \mathbb{R})$ be the closed subgroup of upper triangular matrices.

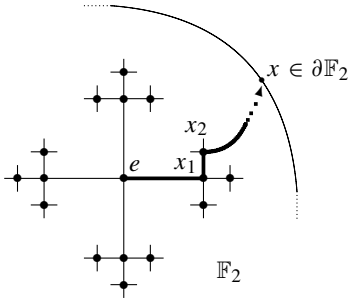

Figure 1. The Cayley graph of $\mathbb{F}_2$ and the boundary $\partial\mathbb{F}_2$.

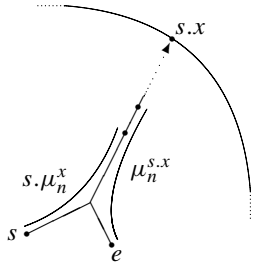

Figure 2. Amenability of $\partial\mathbb{F}_2$.

Then the left multiplication action of Γ on the Furstenberg boundary $\mathrm{SL}(n,\mathbb{R})/P$ is amenable. More generally, if G is a locally compact group with a closed amenable locally compact subgroup P (such that G/P compact), then every discrete subgroup Γ of G acts amenably on G/P.

A far-reaching generalization of this example is given in [39], where it is shown that any linear group admits an amenable action on some compact space. Thus many non-amenable groups admit amenable actions.

Definition 2.4. We say a group Γ is *exact* if there exists a compact Γ-space X which is amenable.

Exact groups are also said to be *boundary amenable*, *amenable at infinity* or to *have the property A*. By definition, all amenable groups are exact. Let X be a compact Γ-space. Then, by the universality of the Stone–Čech compactification $\beta\Gamma$, there exists a Γ-equivariant continuous map from $\beta\Gamma$ into X. It follows that Γ is exact iff $\beta\Gamma$ (or the boundary $\partial^\beta\Gamma = \beta\Gamma \setminus \Gamma$) is amenable. Moreover, whether Γ is exact or not, $\beta\Gamma$ is amenable as a Λ-space for every exact subgroup Λ of Γ since there exists a Λ-equivariant continuous map from $\beta\Gamma$ into $\beta\Lambda$. This observation implies that exactness is preserved under a directed union, i.e., a group Γ is exact iff all of its finitely generated subgroups are exact.

Amenability of the Stone–Čech compactification $\beta\Gamma$ leads to an intrinsic characterization of an exact group Γ. Before stating it, we introduce the notion of coarse metric spaces [36]. Let d be a left translation invariant metric on Γ which is proper in the sense that every subset of finite diameter is finite. Then $l(s) = d(s,e)$ is a length function on Γ, i.e., $l(s^{-1}) = l(s)$, $l(st) \leq l(s) + l(t)$ for every $s, t \in \Gamma$, and $l(s) = 0$ iff $s = e$. The length function l is proper in the sense that $l^{-1}([0, R])$ is finite for every $R > 0$. Conversely, every proper length function l gives rise to a proper left translation invariant metric d on Γ such that $d(s,t) = l(s^{-1}t)$. If $\mathcal{S}$ is a finite

generating subset of Γ, then the corresponding word metric is defined by

$$d_{\mathcal{S}}(s,t) = \min\{n : s^{-1}t = s_1 \dots s_n,\ s_i \in \mathcal{S} \cup \mathcal{S}^{-1}\}.$$

We note that even when Γ is not finitely generated, there exists a proper left translation invariant metric d on Γ (as we assume that Γ is countable). Two proper length functions l and l' are equivalent in the sense that $l(s_n) \to \infty$ iff $l'(s_n) \to \infty$. Thus we are lead to the notion of coarse equivalence, which is a very loose notion. Two metric spaces (X, d) and (X', d') are *coarsely isomorphic* if there exists a (not necessarily continuous) map $f\colon X \to X'$ such that $d(z, f(X)) < \infty$ for every $z \in X'$ and

$$\rho_-(d(x,y)) \le d'(f(x), f(y)) \le \rho_+(d(x,y))$$

for some fixed function $\rho_\pm$ on $[0,\infty)$ with $\lim_{r\to\infty} \rho_-(r) = \infty$. Such f is called a coarse isomorphism. We observe that any two proper left translation invariant metrics d and d' on Γ are *coarsely equivalent* in the sense that the formal identity map from (Γ, d) onto (Γ, d') is a coarse isomorphism. A *coarse metric space* is a space together with a coarse equivalence class of metrics. Hence, Γ is provided with a unique coarse metric space structure. Two groups Γ and Γ' are said to be *coarsely isomorphic* if they are coarsely isomorphic as coarse metric spaces. It follows from the following theorem that exactness is a coarse isomorphism invariant. In particular, a group is exact if it has a finite index subgroup which is exact.

Theorem 2.5 ([47], [83]). *For a group Γ, the following are equivalent.*

1. *The group Γ is exact.*
2. *The metric space (Γ, d) has the property A: For every $\varepsilon > 0$ and $R > 0$, there exist a map $\nu\colon \Gamma \to \mathrm{prob}(\Gamma)$ and $S > 0$ such that $\|\nu_s - \nu_t\| \le \varepsilon$ for every $s, t \in \Gamma$ with $d(s,t) < R$ and $\operatorname{supp} \nu_s \subset \{t : d(s,t) < S\}$ for every $s \in \Gamma$.*
3. *For every $\varepsilon > 0$ and $R > 0$, there exist a Hilbert space $\mathcal{H}$, a map $\xi : \Gamma \to \mathcal{H}$ and $S > 0$ such that $|1 - \langle \xi_t, \xi_s\rangle| < \varepsilon$ for every $s, t \in \Gamma$ with $d(s,t) < R$ and $\langle \xi_t, \xi_s\rangle = 0$ for every $s, t \in \Gamma$ with $d(s,t) \ge S$.*

Moreover, if Γ is exact, then Γ is coarsely isomorphic to a subset of a Hilbert space.

The main result of [83] is the injectivity part of the Baum–Connes conjecture for a group which is coarsely embeddable into a Hilbert space. (See also [45], [76], [84].) This justifies the study of exactness for groups. It is not known whether or not coarse embeddability into a Hilbert space implies exactness (even in the case of groups with the Haagerup property). We recall that a metric space (X, d) has *asymptotic dimension* $\le d$ [36] if for every $R > 0$, there exists a covering $\mathcal{U}$ of X such that $\sup_{U\in\mathcal{U}} \mathrm{diam}(U) < \infty$ and $|\{U \in \mathcal{U} : U \cap B \ne \emptyset\}| \le d + 1$ for any subset $B \subset X$ with $\mathrm{diam}(B) < R$. Asymptotic dimension is a coarse equivalence invariant and hence an invariant for a group. We note that the groups $\mathbb{Z}^d$ and $\mathbb{F}_r^d$ have asymptotic dimension d.

Corollary 2.6 ([47]). *A coarse metric space with finite asymptotic dimension has the property A. In particular, a group with finite asymptotic dimension is exact.*

It was shown in [22] that every Coxeter group has finite asymptotic dimension and hence is exact. We refer to [8] for more information on asymptotic dimension.

We describe a relative version of an amenable action, which is useful in proving various kinds of permanence properties of exactness. There are other approaches [6], [7], [20] which are as well useful. The following is in the spirit of [3].

Proposition 2.7 ([63]). *Let X be a compact Γ-space and K be a countable Γ-space. Assume that there exists a net of Borel maps*

$$\mu_n \colon X \to \mathrm{prob}(K)$$

(i.e., the function $X \ni x \mapsto \mu_n^x(a) \in \mathbb{R}$ is Borel for every $a \in K$) such that

$$\lim_n \int_X \|s.\mu_n^x - \mu_n^{s.x}\|\, dm(x) = 0$$

for every $s \in \Gamma$ and every Radon probability measure m on X. Then Γ is exact provided that all isotropy subgroups of K are exact. Indeed, if Y is a compact Γ-space which is amenable as a Λ-space for every isotropy subgroup Λ, then $X \times Y$ (with the diagonal Γ-action) is an amenable Γ-space.

Corollary 2.8 ([52]). *An extension of exact groups is again exact.*

Proof. If $\Lambda \lhd \Gamma$ is a normal subgroup such that Γ/Λ is exact, then Proposition 2.7 is applicable to an amenable compact (Γ/Λ)-space X and $K = \Gamma/\Lambda$ □

We turn our attention to a group acting on a countable simplicial tree T, which may not be locally finite. We will define a compactification $\overline{T} = T \cup \partial T$ of T, to which Proposition 2.7 is applicable. We recall that a *simplicial tree* is a connected graph without non-trivial circuits, and identify T with its vertex set. The boundary ∂T of T is defined as in Example 2.2. Thus ∂T is the set of all equivalence classes of (one-sided) infinite simple paths in T, where two infinite simple paths are equivalent if their intersection is infinite. For every $a \in T$ and $x \in \partial T$, there exists a unique infinite simple path γ in the equivalence class x which starts at a. We say that the path γ connects a to x. It follows that every two distinct points in $\overline{T} = T \cup \partial T$ are connected by a unique simple path (which is a biinfinite path, with the obvious definition, when both points are boundary points). Every edge separates $\overline{T}$ into two components, and every finite subset of edges separates X into finitely many components. Now we equip $\overline{T}$ with a topology by declaring that all such components are open. It turns out that $\overline{T}$ is compact with this topology. We note that T is dense but not open in $\overline{T}$ (unless T is locally finite) and that every automorphism s of T extends to a

homeomorphism on $\overline{T}$. Fixing a base point $e \in T$, we define $\mu_n \colon \partial T \to \mathrm{prob}(T)$ exactly as in Example 2.2. It is not hard to see that μ_n is a Borel map such that

$$\sup_{x \in \partial T} \|s.\mu_n^x - \mu_n^{s.x}\| \leq \frac{2d(s.e, e)}{n}$$

for every automorphism s of T (cf. Figure 2). We extend μ_n to $\overline{T}$ by simply letting $\mu_n^a = \delta_a \in \mathrm{prob}(T)$ for $a \in T$. Then the sequence of Borel maps $\mu_n \colon \overline{T} \to \mathrm{prob}(T)$ satisfies the assumption of Proposition 2.7 for $X = \overline{T}$, $K = T$ and any group Γ acting on T.

We recall that associated with the fundamental group of a graph of groups there exists a tree, called the *Bass–Serre tree*, on which the group acts. We describe it in the case of an amalgamated free product. Let $\Gamma = \Gamma_1 *_\Lambda \Gamma_2$ be the amalgamated free product of groups Γ_1 and Γ_2 with a common subgroup Λ. Then the associated Bass–Serre tree T is the disjoint union $\Gamma/\Gamma_1 \sqcup \Gamma/\Gamma_2$ of left cosets, where $s\Gamma_1$ and $t\Gamma_2$ are adjacent if $s\Gamma_1 \cap t\Gamma_2 \neq \emptyset$. Thus the edge set of T coincides with Γ/Λ, and an edge $s\Lambda$ connects $s\Gamma_1$ and $s\Gamma_2$. It turns out that T is a tree. The group Γ acts on T from the left in such a way that each vertex stabilizer is conjugate to either Γ_1 or Γ_2 and each edge stabilizer is conjugate to Λ. We note that the tree T is not locally finite unless Λ has finite index in both Γ_1 and Γ_2.

Corollary 2.9 ([25], [78]). *Let Γ be a group acting on a countable simplicial tree T. Then Γ is exact provided that all isotropy subgroups are exact. In particular, an amalgamated free product and an HNN-extension of exact groups are again exact.*

It follows that one-relator groups are exact [38] because they are made up by using HNN-extensions following the McCool–Schupp algorithm. A similar remark applies to a fundamental group of a Haken 3-manifold thanks to the Waldhausen decomposition.

Example 2.2 can be generalized to a hyperbolic space, too. The notion of hyperbolicity was introduced in the very influential paper [35] and has been extensively studied since. A metric space is said to be *hyperbolic* if it is "tree-like" in certain sense, and a finitely generated group Γ is said to be *hyperbolic* if its Cayley graph is hyperbolic. Hyperbolicity is a robust notion and there are many natural examples of hyperbolic groups including the free groups. Every hyperbolic group has a nice compactification, called the Gromov compactification, which is a generalization of that given in Example 2.2. It is shown in [2] that the action of a hyperbolic group on its Gromov compactification is amenable. (See also [9] and the appendix of [5].) The result is generalized in [48], [63] to a group acting on hyperbolic spaces, which are not necessarily locally finite. Compactification of a non-locally-finite hyperbolic graph was considered in [10], where its Bowditch compactification $\overline{K}$ is introduced for a *fine* hyperbolic graph K. A simplicial tree T and its compactification $\overline{T}$ are the simplest non-trivial examples of a uniformly fine hyperbolic graph and its Bowditch

compactification. See [10] for details. As in the case for a simplicial tree, the assumption of Proposition 2.7 is satisfied for a uniformly fine hyperbolic graph K, its Bowditch compactification $\overline{K}$ and any group acting on K [63]. By a characterization of a relatively hyperbolic group [10], we obtain the following corollary.

Corollary 2.10 ([20], [59], [63]). *A relatively hyperbolic group is exact provided that all peripheral subgroups are exact. In particular, every hyperbolic group is exact.*

Examples of relatively hyperbolic groups include the fundamental groups of complete non-compact finite-volume Riemannian manifolds with pinched negative sectional curvature (which are hyperbolic relative to nilpotent cusp subgroups) [26] and limit groups (which are hyperbolic relative to maximal non-cyclic abelian subgroups) [1], [21]. Exactness of limit groups also follows from their linearity.

Another interesting case of group actions which implies exactness is a proper and co-compact action on a finite dimensional CAT(0) cubical complex [12].

The mapping class group $\Gamma(S)$ of a compact orientable surface S is also a natural example of an exact group [42], [49]. Indeed, the action of $\Gamma(S)$ on the space of complete geodesic laminations is amenable [42]. In contrast, the more well-known action of $\Gamma(S)$ on the Thurston boundary $\mathcal{PMF}$ of Teichmüller space is not amenable because of non-amenable isotropy subgroups. However, if we denote by K the set of all non-trivial isotopy classes of non-peripheral simple closed curves on S (i.e., K is the vertex set of the curve complex of S), then the assumption of Proposition 2.7 is satisfied for $X = \mathcal{PMF}$ [49]. Since every isotropy subgroup of a point in K is a mapping class group of lower complexity, induction applies and the exactness of $\Gamma(S)$ follows.

So far we have enumerated examples of exact groups as many as we can (the author is sorry for any possible omission). Unfortunately, there does exist a (finitely presented) group which is neither exact nor coarsely embeddable into a Hilbert space [37]. Currently, it is not known whether the following groups are exact or not: Thompson's group F, $\mathrm{Out}(\mathbb{F}_r)$, automatic groups, 3-manifold groups, groups of homeomorphisms (resp. diffeomorphisms) on (say) the circle S^1, (free) Burnside groups and other monstrous groups.

The rest of this section is devoted to the relationship of exactness to operator algebras. Associated with a group, there are the reduced group C*-algebra $C^*_\lambda(\Gamma)$ and the group von Neumann algebra $\mathcal{L}(\Gamma)$. When Γ is abelian, $C^*_\lambda(\Gamma)$ is isomorphic to $C(\widehat{\Gamma})$, while $\mathcal{L}(\Gamma)$ is isomorphic to $L^\infty(\widehat{\Gamma})$, where $\widehat{\Gamma}$ is the Pontrjagin dual of Γ. Hence the study of $C^*_\lambda(\Gamma)$ corresponds to "noncommutative topology" and that of $\mathcal{L}(\Gamma)$ to "noncommutative measure theory" [15]. Amenability of Γ can be read from its operator algebras.

Theorem 2.11 ([41], [54], [74]). *For a group Γ, the following are equivalent.*

1. *The group Γ is amenable.*
2. *The reduced group C*-algebra $C^*_\lambda(\Gamma)$ is nuclear.*

3. *The group von Neumann algebra $\mathcal{L}(\Gamma)$ is injective.*

A generalization of this theorem to a group action goes as follows.

Theorem 2.12 ([3]). *For a (compact) Γ-space X, the following are equivalent.*

1. *The Γ-space X is amenable.*
2. *The reduced crossed product C*-algebra $C^*_\lambda(X \rtimes \Gamma)$ is nuclear.*
3. *The group-measure-space von Neumann algebra $\mathcal{L}(X \rtimes \Gamma, m)$ is injective for any Γ-quasi-invariant Radon probability measure m on X.*

The nuclear C*-algebras are accessible among the C*-algebras and the classification program of nuclear C*-algebras is a very active area of research in C*-algebra theory [73]. Many C*-algebras $C^*_\lambda(X \rtimes \Gamma)$ arising from various kinds of boundary actions are classifiable via their K-theory [4], [53], [77]. Unlike the group case, a C*-subalgebra of a nuclear C*-algebra needs not be nuclear. The notion of exactness was introduced to give an abstract characterization of subnuclearity and has met a great success [50], [51]. Exactness has a deep connection with operator space theory [51], [69]. A C*-algebra A is called *exact* if taking the minimal tensor product with A preserves short exact sequences of C^*-algebras. The following theorem explains the nomenclature of exact groups.

Theorem 2.13 ([11], [40], [51], [60]). *For a group Γ the following are equivalent.*

1. *The group Γ is exact.*
2. *The reduced group C*-algebra $C^*_\lambda(\Gamma)$ is exact.*
3. *The group von Neumann algebra $\mathcal{L}(\Gamma)$ is weakly exact.*

We note that a C*-subalgebra of an exact C*-algebra is always exact and that a von Neumann subalgebra of a weakly exact von Neumann algebra is weakly exact provided that there exists a normal conditional expectation. Since a von Neumann algebra with a weakly dense exact C*-algebra is weakly exact, we obtain the following corollary.

Corollary 2.14. *Exactness is closed under measure equivalence.*

We recall that two groups Γ and Λ are *measure equivalent* [36] if there exist commuting measure preserving free actions of Γ and Λ on some Lebesgue measure space (Ω, m) such that the action of each of the groups admits a finite measure fundamental domain. For example, lattices in the same (second countable) locally compact group G are measure equivalent. It is known that measure equivalence coincides with the stable orbit equivalence [29] and hence gives rise to a stable isomorphism of the corresponding group-measure-space von Neumann algebras.

3. Amenable compactifications which are small

We study the "size" of an amenable compactification with its application to von Neumann algebra theory in mind. A compactification of a group Γ is a compact space $\Delta\Gamma$ containing Γ as an open dense subset. We only consider those compactifications which are equivariant; the left multiplication action of Γ on Γ extends to a continuous action of Γ on $\Delta\Gamma$. A group Γ is amenable iff the one-point compactification is amenable, and a group Γ is exact iff the Stone–Čech compactification $\beta\Gamma$ is amenable. Thus we think that the "size" of an amenable compactification of a given group measures the "degree of amenability" of the group. We say that a compactification $\Delta\Gamma$ of Γ is *small at infinity* if for every net (s_n) in Γ with $s_n \to x \in \partial\Gamma$, we have $s_n t \to x$ for every $t \in \Gamma$ [13]. In other words, $\Delta\Gamma$ is small at infinity if every flow in Γ drives Γ to a single point. We note that $\Delta\Gamma$ is small at infinity iff the right multiplication action of Γ extends continuously on $\Delta\Gamma$ in such a way that it is trivial on $\Delta\Gamma \setminus \Gamma$. For instance, the Gromov compactification $\mathbb{F}_r \cup \partial\mathbb{F}_r$ of the free group $\mathbb{F}_r$ (cf. Example 2.2) is small at infinity since the first k segment of st is same as that of s as long as $|s| \geq k + |t|$. The same applies to general hyperbolic groups.

We say that a group Γ *belongs to the class* $\mathcal{S}$ if the compact $(\Gamma \times \Gamma)$-space $\partial^\beta\Gamma = \beta\Gamma \setminus \Gamma$ (with the bilateral action) is amenable. If Γ has an amenable compactification $\Delta\Gamma$ which is small at infinity, then we have $\Gamma \in \mathcal{S}$. It follows that the class $\mathcal{S}$ contains amenable groups and hyperbolic groups (or more generally, any group which is hyperbolic relative to a family of amenable subgroups). The class $\mathcal{S}$ is closed under subgroups and free products (with finite amalgamations). Moreover, the wreath product $\Lambda \wr \Gamma$ of an amenable group Λ by a group $\Gamma \in \mathcal{S}$ again belongs to $\mathcal{S}$ [62]. We observe that an inner amenable group in $\mathcal{S}$ has to be amenable because, by definition, a group Γ is *inner amenable* if $\partial^\beta\Gamma$ carries an invariant Radon probability measure for the conjugation action of Γ (cf. [44]). In general, for a given group Γ and a countable Γ-space K, it is an interesting problem to decide whether or not the compact Γ-space $\partial^\beta K = \beta K \setminus K$ is amenable (cf. [62]). We note the trivial case where the isotropy subgroups are all amenable.

The following is a relative version of smallness.

Definition 3.1. Let $\mathcal{G}$ be a non-empty family of subgroups of Γ. For a net (s_n) in Γ we say that $s_n \to \infty$ *relative to* $\mathcal{G}$ if $s_n \notin s\Lambda t$ for any $s, t \in \Gamma$ and $\Lambda \in \mathcal{G}$. We say that a compactification $\Delta\Gamma$ is *small relative to* $\mathcal{G}$ if for every net (s_n) in Γ with $s_n \to x \in \Delta\Gamma$ and with $s_n \to \infty$ relative to $\mathcal{G}$, we have $s_n t \to x$ for every $t \in \Gamma$.

Suppose that a group Γ acts on a simplicial tree T and let $\overline{T}$ be the compactification defined in the previous section. We recall that the open basis of the topology is given by cutting finitely many edges. We fix a base point $e \in T$ and consider the smallest compactification $\Delta^T\Gamma$ of Γ for which the map $\Gamma \ni s \mapsto s.e \in \overline{T}$ is continuous on $\Delta^T\Gamma$. Then $\Delta^T\Gamma$ is small relative to the family of edge stabilizers. Indeed, suppose that $s_n \to \infty$ relative to edge stabilizers and that $a, b \in T$ are given. Let γ be a path connecting a to b. Since the net $(s_n.\gamma)$ of paths leaves every edge, two end points

of $s_n.\gamma$ (i.e., $s_n.a$ and $s_n.b$) converge to the same point (if they converge). The same applies to general fine hyperbolic graphs.

For every non-empty family $\mathcal{G}$ of subgroups of Γ, there exists a compactification $\Delta^{\mathcal{G}}\Gamma$ which is small relative to $\mathcal{G}$ and is largest in the sense that the identity map on Γ extends to a continuous map from $\Delta^{\mathcal{G}}\Gamma$ onto any other compactification which is small relative to $\mathcal{G}$. In the case where $\mathcal{G}$ consists of the trivial subgroup $\{e\}$, a compactification $\Delta\Gamma$ is small relative to $\mathcal{G}$ iff it is small at infinity, and $\Delta^{\mathcal{G}}\Gamma$ is the Higson compactification of the coarse metric space Γ. On the contrary, if $\Gamma \in \mathcal{G}$ then $\Delta^{\mathcal{G}}\Gamma = \beta\Gamma$.

Definition 3.2. Let $\mathcal{G}$ be a non-empty family of subgroups of Γ. We say that $\mathcal{G}$ is *admissible* if there exists an amenable compactification of Γ which is small relative to $\mathcal{G}$, or equivalently if the Γ-space $\Delta^{\mathcal{G}}\Gamma$ is amenable.

From what we have seen, we obtain the following result.

Theorem 3.3. 1. *If Γ acts on a uniformly fine hyperbolic graph K with amenable isotropy subgroups, then the family of edge stabilizers is admissible. In particular, the trivial family of the trivial subgroup $\{e\}$ is admissible for a hyperbolic group.*

2. *Let $\Gamma = \Gamma_1 \times \Gamma_2$ be a direct product and suppose that $\mathcal{G}_i$ are admissible for Γ_i. Then $\mathcal{G} = \{\Gamma_1\} \times \mathcal{G}_2 \cup \mathcal{G}_1 \times \{\Gamma_2\}$ is admissible for Γ.*

3. *Let $\Gamma = \Gamma_1 * \Gamma_2$ be a free product and suppose that $\mathcal{G}_i$ are admissible for Γ_i. Then $\mathcal{G} = \mathcal{G}_1 \cup \mathcal{G}_2$ is admissible for Γ.*

4. Application to von Neumann algebra theory

Let Γ be a group and $\mathbb{C}\Gamma$ be its complex group algebra (with the convolution product). The left regular representation λ of $\mathbb{C}\Gamma$ on $\ell_2(\Gamma)$ is given by

$$(\lambda(f)\xi)(t) = (f * \xi)(t) = \sum_{s\in\Gamma} f(s)\xi(s^{-1}t)$$

for $f \in \mathbb{C}\Gamma$ and $\xi \in \ell_2(\Gamma)$. By taking completion w.r.t. an appropriate topology, we obtain the *group von Neumann algebra* [57]

$$\begin{aligned}\mathcal{L}(\Gamma) &= \text{the weak closure of } \{\lambda(f) : f \in \mathbb{C}\Gamma\} \text{ in } \mathbb{B}(\ell_2(\Gamma))\\ &= \{\lambda(f) : f \text{ a function on } \Gamma \text{ such that } \lambda(f) \text{ is bounded on } \ell_2(\Gamma)\},\end{aligned}$$

where $\mathbb{B}(\ell_2)$ is the algebra of all bounded linear operators on $\ell_2(\Gamma)$. We note that $\mathcal{L}$ is functorial w.r.t. inclusions, direct products and free products. The group von Neumann algebra $\mathcal{L}(\Gamma)$ is *finite* in the sense that it has a faithful finite trace

$$\tau : \mathcal{L}(\Gamma) \ni \lambda(f) \mapsto \langle \lambda(f)\delta_e, \delta_e\rangle = f(e) \in \mathbb{C}.$$

If Γ is an infinite abelian group, then we have $\mathcal{L}(\Gamma) = L^\infty(\widehat{\Gamma}) \cong L^\infty[0,1]$ by uniqueness of the Lebesgue measure space without atoms. (Note that we are still assuming that groups are countable.) Thus, group von Neumann algebras of infinite abelian groups are all isomorphic. The center $Z(\mathcal{L}(\Gamma))$ of $\mathcal{L}(\Gamma)$ is easy to describe;

$$Z(\mathcal{L}(\Gamma)) = \overline{Z(\mathbb{C}\Gamma)}^w = \{\lambda(f) : f \text{ is constant on every conjugacy class}\}.$$

A von Neumann algebra with a trivial center is called a *factor*. Since $f = \lambda(f)\delta_e$ belongs to $\ell_2(\Gamma)$ for every $\lambda(f) \in \mathcal{L}(\Gamma)$, the group von Neumann algebra $\mathcal{L}(\Gamma)$ is a factor iff all non-trivial conjugacy classes of Γ are infinite. Such a group Γ is said to be ICC (abbreviation of "Infinite Conjugacy Classes"). Examples of ICC groups include the free group $\mathbb{F}_r$ and the amenable group $S_\infty = \bigcup S_n$ of finite permutations on a countably infinite set. The classification problem of von Neumann factors was raised in [57], where it is shown that $\mathcal{L}(\mathbb{F}_r) \ncong \mathcal{L}(S_\infty)$. This result is clarified by Theorem 2.11 that Γ is amenable iff $\mathcal{L}(\Gamma)$ is injective. We note that a von Neumann subalgebra of an injective finite von Neumann algebra is again injective and hence injective finite von Neumann algebras are considered "small". Connes's celebrated theorem [14] asserts that $\mathcal{L}(\Gamma) \cong \mathcal{L}(S_\infty)$ for any amenable ICC group Γ. This can be regarded as uniqueness of the amenable noncommutative measure space. In contrast, it is the biggest open problem in the classification of group factors whether $\mathcal{L}(\mathbb{F}_r) \ncong \mathcal{L}(\mathbb{F}_s)$ for $r \neq s$ or not. Free probability theory was invented [80], [82] to tackle this problem and has revealed deep structures of the free group factors [34], [70], [81]. In particular, the free group factors $\mathcal{L}(\mathbb{F}_r)$ $(2 \leq r < \infty)$ are mutually *stably* isomorphic. Moreover, the following dichotomy is known [24], [71]; the free group factors are all isomorphic or all non-isomorphic.

We briefly review the notion of orbit equivalences, which is the ergodic theory counterpart of that of group von Neumann algebras. Let (X, μ) be a Lebesgue probability measure space with a measurable non-singular action of a group Γ. Then we have a group-measure-space von Neumann algebra $\mathcal{L}(X \rtimes \Gamma, \mu)$ which is generated by $L^\infty(X, \mu)$ and a copy of $\mathcal{L}(\Gamma)$ [57]. The von Neumann algebra $\mathcal{L}(X \rtimes \Gamma, \mu)$ is finite if the Γ-action is m.p. (measure preserving) and is a factor if the Γ-action is e.f. (ergodic and free). For two e.f.m.p. actions $\Gamma \curvearrowright (X, \mu)$ and $\Lambda \curvearrowright (Y, \nu)$, we have

$$(L^\infty(X, \mu) \subset \mathcal{L}(X \rtimes \Gamma, \mu)) \cong (L^\infty(Y, \nu) \subset \mathcal{L}(Y \rtimes \Lambda, \nu))$$

iff they are *orbit equivalent* [27], [57], i.e., there exists an isomorphism $F : X \to Y$ of measure spaces such that $F(\Gamma x) = \Lambda F(x)$ for a.e. $x \in X$. Thus the classification of von Neumann algebras and that of orbit equivalences are closely related. We note that it is possible that $\mathcal{L}(X \rtimes \Gamma, \mu) \cong \mathcal{L}(Y \rtimes \Lambda, \nu)$ without being orbit equivalent [17]. We say that two e.f.m.p. actions are *stably orbit equivalent* (or *weakly orbit equivalent*) if they are orbit equivalent "after stabilization", and that two groups Γ and Λ are (resp. *stably*) *orbit equivalent* if they have e.f.m.p. actions which are (resp. stably) orbit equivalent. As we mentioned at the end of Section 2, two groups are stably orbit equivalent iff they are measure equivalent. Connes's aforementioned theorem has the

following counterpart [58]; e.f.m.p. actions of amenable groups are all orbit equivalent to each other. Beyond the amenable case, there has been remarkable progress [86] and exciting new developments [28], [29], [30], [31], [33], [43], [56], [67] in this subject. In particular, it is shown that free groups of different ranks are mutually non-orbit equivalent [30]. We do not further elaborate on ergodic theory, but refer to [32], [68], [75] for details. Before leaving this subject, we mention that as far as we know, the following bold conjecture (communicated to us by D. Shlyakhtenko) stands; ICC groups are (stably) orbit equivalent iff they have (stably) isomorphic group von Neumann algebras.

We now focus on von Neumann algebras. Generally speaking, distinguishing group von Neumann algebras is a difficult task. Indeed, most of known invariants for group von Neumann algebras are binary; injectivity, the property (Γ), the property (T), Haagerup's property, etc. A notable exception is the Cowling–Haagerup constant [19]. Free entropy (dimension) [80], [82] and L^2-homology [18], [55] are candidates for invariants. Recently, a breakthrough was obtained in [66], where a longstanding problem from [57] is solved. It is shown that under certain circumstances, one can specify the position of a prescribed von Neumann subalgebra in the ambient von Neumann algebra. This versatile method found several applications [33], [43], [67], [68]. The following result is obtained by combining this device with theory of exact C*-algebras. In the last few pages, we allow ourselves to be more technical.

Theorem 4.1. *Let Γ be a group and $\mathcal{G}$ be an admissible family of its subgroups. Suppose that $\mathcal{N} \subset \mathcal{L}(\Gamma)$ is an injective von Neumann subalgebra whose relative commutant $\mathcal{N}' \cap \mathcal{L}(\Gamma)$ is non-injective. Then there exist $\Lambda \in \mathcal{G}$ and a non-zero projection $p \in \mathcal{N}$ such that $p\mathcal{N}p$ is conjugated into $\mathcal{L}(\Lambda)$ by a partial isometry in $\mathcal{L}(\Gamma)$.*

We recall that $\mathcal{N}' \cap \mathcal{M} = \{a \in \mathcal{M} : [a, \mathcal{N}] = \{0\}\}$. Sometimes we can patch the pieces $p\mathcal{N}p$ together and find a unitary element $u \in \mathcal{L}(\Gamma)$ such that $u\mathcal{N}u^* \subset \mathcal{L}(\Lambda)$. By Theorems 3.3 and 4.1 and a bit more effort, we obtain the following corollaries.

Recall that a von Neumann algebra $\mathcal{M}$ is *prime* if it does not decompose into a tensor product of two infinite dimensional (diffuse) von Neumann algebras. The free group factor $\mathcal{L}(\mathbb{F}_r)$ is the first example of a separable prime factor [34].

Corollary 4.2 ([61]). *Suppose that Γ belongs to the class $\mathcal{S}$. Then $\mathcal{L}(\Gamma)$ is solid, i.e., for any diffuse subalgebra $\mathcal{N} \subset \mathcal{L}(\Gamma)$, the relative commutant $\mathcal{N}' \cap \mathcal{L}(\Gamma)$ is injective. In particular, $\mathcal{L}(\Gamma)$ is prime unless Γ is amenable.*

Indeed, replacing $\mathcal{N}$ with its maximal abelian subalgebra, we may assume that $\mathcal{N}$ is injective. Then $p\mathcal{N}p$ is conjugated into $\mathcal{L}(\{e\}) = \mathbb{C}$ iff the projection p is atomic in $\mathcal{N}$. Thus, if $\mathcal{N}' \cap \mathcal{L}(\Gamma)$ is non-injective, then $\mathcal{N}$ is not diffuse. We note that if a solid group von Neumann algebra $\mathcal{L}(\Gamma) \cong \mathcal{N}_1 \otimes \mathcal{N}_2$ is not prime, then both $\mathcal{N}_i$ have to be injective and hence $\mathcal{L}(\Gamma)$ itself is injective. Similarly, one can prove that a group-measure-space von Neumann algebra $\mathcal{L}(X \rtimes \Gamma, \mu)$ for $\Gamma \in \mathcal{S}$ is prime [62]. This generalizes a result in [2] that an orbit equivalence relation of a hyperbolic group

is indecomposable. In passing, we mention that an analogous result is obtained for discrete quantum groups and their von Neumann algebras [79]. The following is a von Neumann algebra analogue of the result in [56].

Corollary 4.3 ([64]). *Let $\Gamma_1, \dots, \Gamma_n \in \mathcal{S}$ and assume that they are all non-amenable and ICC. If $\mathcal{M}_1, \dots, \mathcal{M}_m$ are non-injective factors such that*

$$\bigotimes_{j=1}^{m} \mathcal{M}_j \subset \bigotimes_{i=1}^{n} \mathcal{L}(\Gamma_i),$$

then we have $m \leq n$. If in addition $m = n$, then we have "$\mathcal{M}_i \subset \mathcal{L}(\Gamma_i)$" modulo permutation of indices, rescaling, and unitary conjugacy.

We have a Kurosh type theorem for non-prime von Neumann factors. Another version of Kurosh type theorem in presence of rigidity is found in [43], [68].

Corollary 4.4 ([62]). *Let $\Gamma_1, \dots, \Gamma_n$ and $\Lambda_1, \dots, \Lambda_m$ be ICC exact non-amenable groups all of which decompose into non-trivial direct products. Suppose that*

$$\mathcal{L}(\mathbb{F}_\infty * \Lambda_1 * \cdots * \Lambda_m) \cong \mathcal{L}(\mathbb{F}_\infty * \Gamma_1 * \cdots * \Gamma_n).$$

Then $n = m$ and, modulo permutation of indices, $\mathcal{L}(\Lambda_i)$ is unitarily conjugated onto $\mathcal{L}(\Gamma_i)$ for every $i \geq 1$.

It follows that iterated free product factors $\mathcal{L}(\mathbb{F}_\infty * (\mathbb{F}_\infty \times S_\infty)^{*n})$ are mutually non-isomorphic. In contrast, $\mathcal{L}(\mathbb{F}_\infty * (\mathbb{F}_\infty \times \mathbb{Z})^{*n})$ are all isomorphic [23].

We describe one more application of amenable actions in von Neumann algebra theory and ergodic theory. Let Γ be a group acting on a group Λ by automorphisms. Then the semi-direct product $(\Lambda \times \Lambda) \rtimes \Gamma$ naturally acts on Λ, where $\Lambda \times \Lambda$ acts on Λ bilaterally. This action extends to a continuous action on the Stone–Čech compactification $\beta\Lambda$ and then restricts to $\partial^\beta \Lambda = \beta\Lambda \setminus \Lambda$.

Proposition 4.5. *Let Γ and Λ be as above with Λ amenable and assume that the compact $(\Lambda \times \Lambda) \rtimes \Gamma$-space $\partial^\beta \Lambda$ is amenable. Then, for any diffuse von Neumann subalgebra $\mathcal{N} \subset \mathcal{L}(\Lambda) \subset \mathcal{L}(\Lambda \rtimes \Gamma)$, the relative commutant $\mathcal{N}' \cap \mathcal{L}(\Lambda \rtimes \Gamma)$ is injective.*

This proposition applies to the wreath product $\Lambda \wr \Gamma = \left(\bigoplus_\Gamma \Lambda\right) \rtimes \Gamma$ for every amenable group Λ and for every exact group Γ. In the case where Λ is an infinite abelian group, the group factor $\mathcal{L}(\Lambda \wr \Gamma)$ is isomorphic to the group-measure-space factor $\mathcal{L}([0,1]^\Gamma \rtimes \Gamma)$ of the Bernoulli shift action over the base space ([0, 1], Lebesgue). Hence, we obtain the following corollary. We note that the same holds for a noncommutative Bernoulli shift by setting $\Lambda = S_\infty$.

Corollary 4.6 ([62]). *Let Γ be an exact group and $\mathcal{M} = \mathcal{L}([0,1]^\Gamma \rtimes \Gamma)$ be the group-measure-space factor of the Bernoulli shift action. Then, for any diffuse von Neumann subalgebra $\mathcal{A} \subset L^\infty([0,1]^\Gamma)$, the relative commutant $\mathcal{A}' \cap \mathcal{M}$ is injective. In particular, the orbit equivalence relation of a Bernoulli shift action by an exact non-amenable group is indecomposable.*

Structure and classification of C^*-algebras

Mikael Rørdam

Abstract. We give an overview of the development over the last 15 years of the theory of simple C^*-algebras, in particular in regards to their classification and structure. We discuss dimension theory for (simple) C^*-algebras, in particular the so-called stable and real ranks, and we explain how properties of C^*-algebras of low dimension (stable rank one and real rank zero) was used by the author and P. Friis to give a new and simple proof of a theorem of H. Lin that almost commuting self-adjoint matrices are close to exactly commuting self-adjoint matrices. Elliott's classification program is explained and is contrasted with recent examples of C^*-algebras of "high dimension", including an example of a simple C^*-algebra with a finite and an infinite projection.

Mathematics Subject Classification (2000). Primary 46L35; Secondary 46L80.

Keywords. Simple C^*-algebras, classification, K-theory, dimension, almost commuting matrices.

1. Introduction

A (represented) C^*-algebra is a norm closed self-adjoint sub-algebra of the bounded operators on a Hilbert space. One can alternatively describe C^*-algebras axiomatically as complex Banach algebras with an involution that satisfies $\|a^*a\| = \|a\|^2$, thanks to a theorem of Gelfand, Naimark and Segal. Each commutative C^*-algebra is isomorphic to $C_0(X)$ for some locally compact Hausdorff space X, and $C_0(X)$ is isomorphic to $C_0(Y)$ if and only if X and Y are homeomorphic. This justifies the jargon that the study of C^*-algebras is *non-commutative topology*.

One can associate a C^*-algebra to each (locally compact) group, and the representation theory of the group C^*-algebra coincides with the representation theory of the group. Much of the early interest in C^*-algebras lay in their representation theory, and in their connection with other objects (such as groups).

Nearly 50 years ago, Glimm constructed a class of C^*-algebras, now called UHF- or Glimm algebras, that are the C^*-algebra analog of the hyperfinite II_1-factor. Unlike the situation for von Neumann algebras, there is not one UHF-algebra but in fact uncountably many. Glimm classified UHF-algebras by an invariant that we today can identify as the K_0-group of the algebra. Glimm's work was extended by Bratteli and Elliott who classified the larger class of AF-algebras (approximately finite dimensional C^*-algebras) that arise as inductive limits of finite dimensional C^*-algebras (the latter

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

are just direct sums of matrix algebras). All UHF-algebras are *simple*, ie. have no non-trivial closed two-sided ideals. AF-algebras may or may not be simple, and far from all simple AF-algebras are UHF-algebras. Simple AF-algebras need not have unique trace, actually any metrizable Choquet simplex can arise as the trace simplex of a simple unital AF-algebra.

Many other interesting examples of (simple) C^*-algebras saw the light in the 1970s and 1980s. Cuntz invented his algebras $\mathcal{O}_n$. These are, for $2 \leq n < \infty$, generated by n isometries $s_1, s_2, \ldots, s_n$ satisfying the relation $1 = s_1 s_1^* + s_2 s_2^* + \cdots + s_n s_n^*$. (For $n = \infty$ this relation is replaced with the relation that the support projections $s_j s_j^*$ are mutually orthogonal.) Cuntz proved that his algebras are simple and purely infinite (see Definition 2.3) and independent on the choice of generators. These were the first explicit examples of simple infinite separable C^*-algebras. Cuntz and Krieger later associated a C^*-algebra to each finite Markov chain. This construction has today been generalized considerably in parts by Pimsner, who associated a Pimsner algebra to each Hilbert bi-module over a C^*-algebra, and with the constructions of C^*-algebras associated with infinite graphs. Many of these C^*-algebras are simple and purely infinite.

One can also obtain simple C^*-algebras from groups. The reduced groups C^*-algebra $C^*_{\mathrm{red}}(G)$ associated with a (discrete) group is simple for many interesting cases of non-amenable groups G, for example when G is a free group (other than $\mathbb{Z}$). These C^*-algebras are often exact, but never nuclear. Non-amenable groups can act amenably on spaces and can in this way give rise to simple, purely infinite, and nuclear C^*-algebra. Dynamical systems in general, also with amenable groups and in particular with $\mathbb{Z}$, give rise to many interesting examples of C^*-algebras, many of which are simple.

The irrational rotation C^*-algebra, A_θ, associated with an irrational number θ, is the universal C^*-algebra generated by two unitaries u and v satisfying the commutation relation $uv = e^{2\pi i\theta} vu$. They were first studied by Rieffel and shown to be simple with a unique trace and being independent of the generators u and v. The irrational rotation C^*-algebra A_θ contains the Harper operator $u + u^* + \lambda(v + v^*)$, where λ is a non-zero real parameter, whose spectrum recently has been shown to be a Cantor set.

These examples, and many more like them, have spurred the interest in understanding, and perhaps classifying, C^*-algebras, in particular the simple ones. This study was first suggested by Dixmier in the 1960s, and later taken up by Cuntz and Blackadar to mention just a few. It was investigated when finite simple C^*-algebras have a trace, and Cuntz studied the purely infinite C^*-algebras (that resemble the type III_1 von Neumann factors). The question, if all simple C^*-algebras are either (stably) finite or purely infinite was left open until a few years ago where the author found a counterexample inspired by ideas of Villadsen.

The most significant progress in our understanding of C^*-algebras comes from the program initiated by Elliott, and known as Elliott's classification program. Elliott predicts that (simple) separable nuclear C^*-algebras can be classified by natural invariants including K-theory as the most prominent ingredient. This conjecture

has now been verified for a surprisingly wide class of C^*-algebras, for example for all simple separable nuclear purely infinite K-amenable C^*-algebras (the Kirchberg–Phillips theorem). We also know that we must make modifications to the classification conjecture if we want to turn it into a theorem.

We give here an overview of the theory of simple C^*-algebras including some of the recent examples of exotic "high-dimensional" simple C^*-algebras. We also include a solution to a classical problem, if almost commuting matrices must be close to commuting matrices, as the methods to solve this problem grew out of the methods used to study (simple) C^*-algebras.

2. The structure of simple C^*-algebras

Von Neumann algebra factors were by their inventors, von Neumann and Murray, divided into types: I_n, I_∞, II_1, II_∞, and III. The types are distinguished by the *dimension range* of the projections in the factor, which for the 5 types above are $\{0, 1, 2, \ldots, n\}$, $\{0, 1, 2, \ldots, \infty\}$, $[0, 1]$, $[0, \infty]$, and $\{0, \infty\}$, respectively. A type I_n-factor, with n finite, is isomorphic to the algebra of $n \times n$ matrices, and, more generally a type I_n factor is the algebra of all bounded operators on an n-dimensional Hilbert space. Type II_1-factors admit a unique tracial state, and type III-factors are traceless. A separable von Neumann algebra is simple (has no non-trivial closed two-sided ideals) if and only if it is a factor of type I_n, with n finite, type II_1, or of type III.

Can one similarly divide the (infinite dimensional) simple C^*-algebras into two types; a *finite type* resembling the type II_1-factors and an *infinite type* resembling the type III-factors? Existence of traces and of finite and infinite projections should be natural dividing criterions:

Definition 2.1. Two projections p and q in a C^*-algebra A are said to be (Murray–von Neumann) *equivalent*, written $p \sim q$, if $p = v^*v$ and $q = vv^*$ for some (partial isometry) v in A; and p is *subequivalent* to q, written $p \precsim q$, if p is equivalent to a subprojection of q.

A projection in a C^*-algebra A is said to be *infinite* if it is equivalent to a proper subprojection of itself; and it is said to be *finite* otherwise.

A simple C^*-algebra A is called *stably infinite* if its stabilization $A \otimes \mathcal{K}$ contains an infinite projection, and it is called *stably finite* otherwise.

The notion of finiteness relate, as we would expect, to the existence of traces. As C^*-algebras need not be unital, we allow our traces to be unbounded and densely (not necessarily everywhere) defined.

The usual construction of a trace on an abstract C^*-algebra goes via a so-called *dimension function* (a "measure" rather than the "integral"), which by "integration" gives rise to a functional, which is slightly short of being a trace: additivity is known to hold only on abelian subalgebras. Such functionals are called *quasitraces*. Uffe

Haagerup proved in [16] that quasitraces are in fact traces on *exact* C^*-algebras (Haagerup proved this for unital C^*-algebras, and Kirchberg extended the result to the non-unital case).

We have the following fundamental theorem on the existence of traces on simple C^*-algebra:

Theorem 2.2 (Blackadar-Cuntz–Haagerup). *A simple C^*-algebra A admits a quasitrace* (*and hence a trace, if A is exact*) *if and only if A is stably finite.*

Outline of proof: Blackadar and Cuntz proved in [2] that the following three conditions are equivalent for a simple *stable* C^*-algebra A: 1) A contains an infinite projection, 2) A has no dimension function, and 3) A is algebraically simple. Any dimension function lifts to a quasitrace by [3], so the equivalence of 1) and 2) together with Haagerup's result, that quasitraces on exact C^*-algebras are traces, yields the theorem.

How finite are stably finite simple C^*-algebras? and how infinite are the stably infinite ones? The definition below, due to Cuntz, is relevant for the discussion of the latter.

Definition 2.3. A simple C^*-algebra A is said to be *purely infinite* if every non-zero hereditary subalgebra of A contains an infinite projection.

Any subalgebra of the form $\overline{xAx^*}$ is hereditary, and the converse holds in the separable case. In other words, a simple C^*-algebra is purely infinite if one can find infinite projections in all "arbitrarily small corners" of A. A purely infinite C^*-algebra is clearly stably infinite. The opposite does not hold as we shall see in Section 5.

2.1. Dimensions of C^*-algebras. A commutative C^*-algebra is isomorphic to $C_0(X)$ for some locally compact Hausdorff space X, and the space X is determined up to homeomorphism by the isomorphism class of the C^*-algebra. In the commutative case we can therefore define the dimension of the C^*-algebra to be the classical dimension of the space X. What about the non-commutative case? It turns out that there are several, and unfortunately mutually disagreeing, ways of extending dimension to the non-commutative setting. The low dimension cases are of most interest in particular in the study of simple C^*-algebras (many nicely behaving simple C^*-algebras are of very low dimension). Two notions of "low dimension" are particularly important:

Definition 2.4. Let A be a C^*-algebra. If the set of invertible elements in A (or in the unitization of A, if A is non-unital) is dense in A, then A is said to be of *stable rank one*, written $\mathrm{sr}(A) = 1$.

If the set of *self-adjoint* invertible elements in A (or in the unitization of A, if A is non-unital) is dense in the set of self-adjoint elements in A, then A is said to be of *real rank zero*, written $\mathrm{RR}(A) = 0$.

Rieffel introduced stable rank in his paper [24], and Brown and Pedersen introduced real rank in [5]. A commutative C^*-algebra $C_0(X)$ is of stable rank one if $\dim(X) \leq 1$, and of real rank zero if $\dim(X) = 0$.

Brown and Pedersen show that a C^*-algebra is of real rank zero if and only if the set of self-adjoint elements with finite spectrum is dense in the set of all self-adjoint elements. All purely infinite simple C^*-algebras are of real rank zero:

Proposition 2.5 (Cuntz [6], Zhang [35]). *The following three conditions are equivalent for any simple C^*-algebra (other than $\mathbb{C}$):*

(i) *A is purely infinite,*

(ii) *for all non-zero positive elements a, b in A there exists $x \in A$ such that $b = x^*ax$,*

(iii) $\mathrm{RR}(A) = 0$ *and all non-zero projections in A are infinite.*

Stably infinite C^*-algebras are never of stable rank one (in fact they have stable rank $+\infty$). It was a surprise when Villadsen in [33] showed that stably finite simple C^*-algebras need not be of stable rank one. Stably finite C^*-algebras can have very few projections and hence have real rank greater than zero.

2.2. Comparison theory for C^*-algebras. Comparison theory for projections in von Neumann algebras is a crucial ingredient in the classification of von Neumann factors into types and to proving existence of traces on finite von Neumann algebras. Comparison of projections in a von Neumann factor is total: for any two projections p, q one has either $p \precsim q$ or $q \precsim p$ (see Definition 2.1). The comparison theory for C^*-algebras is far more delicate as is in parts reflected by looking at the ordered K_0-group. Any simple dimension group arises as the ordered K_0-group of a simple AF-algebra, and such ordered groups easily fail to be totally ordered. The second best thing after total comparison of projection is weak (or almost) unperforation, described below.

The comparison properties for a C^*-algebra A are contained in the ordered monoids $V(A)$ and $W(A)$ consisting of equivalence classes of projections and positive elements, respectively, in the (non-unital) *-algebra $M_\infty(A) = \bigcup_{n=1}^{\infty} M_n(A)$. Equivalence of projections is the usual Murray–von Neumann equivalence (see Definition 2.1). Following Cuntz, comparison of positive elements $a, b \in M_\infty(A)$ is defined as follows: $a \precsim b$ if there is a sequence $\{x_n\}$ in $M_\infty(A)$ such that $x_n^* b x_n \to a$; and by $a \approx b$ iff $a \precsim b$ and $b \precsim a$ one defines an equivalence relation on the positive elements, which by the way does not quite agree with Murray–von Neumann equivalence when restricted to projections.

The sets $V(A)$ and $W(A)$ become ordered abelian semigroups by defining addition to be "orthogonal addition":

$$[a] + [b] = \left[\begin{pmatrix} a & 0 \\ 0 & b \end{pmatrix} \right],$$

and ordering to be induced by $\precsim$. The ordering on $V(A)$ coincides with the algebraic ordering: $x \leq y$ iff there is z such that $y = x + z$. The ordering on $W(A)$ is not

algebraic. Both semigroups are *positive* in the sense that they have a zero element which at the same time is the smallest element of the semigroup; hence $x \leq x + y$ for all x, y. The semigroup $V(A)$ is called the Murray–von Neumann semigroup of A, and $W(A)$ is called the Cuntz semigroup of A.

If A is generated as an ideal by its projections (which is the case for all simple C^*-algebras with a non-trivial projection), then $K_0(A)$ is the Grothendieck group of $V(A)$, and the positive cone, $K_0(A)^+$, is the image of $V(A)$ in $K_0(A)$.

It was shown in [3] that there is a one-to-one correspondence between (lower semi-continuous) states on $W(A)$ and quasitraces on A, and by Haagerup's theorem in [16], quasitraces are traces on exact C^*-algebras. States on $V(A)$ extends (possibly non-uniquely) to (lower semi-continuous) states on $W(A)$ as shown in [4]. It follows in particular that each state on $V(A)$ lifts to a trace on A if A is exact. A new proof of this fact was recently given by Haagerup and Thorbjørnsen, [17], using random matrix methods.

An ordered abelian positive semigroup $(W, +, \leq)$ is said to be *almost unperforated* if

$$\forall n, m \in \mathbb{N}\ \forall x, y \in W : nx \leq my \text{ and } n > m \implies x \leq y.$$

(The negation of almost unperforation is *strong perforation*.) One can use a Hahn–Banach type argument (see [15] and [29]) to show that $(W, +, \leq)$ is almost unperforated if and only if the order on W is determined by states on W. It follows in particular, that if A is simple and exact, if $V(A)$ is almost unperforated, and if p, q are two projections in $M_\infty(A)$, then $p \precsim q$ if $\tau(p) < \tau(q)$ for all traces τ on A. A similar statement, with dimension functions in the place of traces, holds for $W(A)$ (see [29]).

A simple C^*-algebra A is purely infinite if and only if $W(A)$ has only one non-zero element; and if $W(A)$ is almost unperforated, then A is either purely infinite or stably finite. It is known that $W(A)$ and $V(A)$ are almost unperforated for many C^*-algebras of interest including, besides all purely infinite C^*-algebras, also all C^*-algebras that tensorially absorb the Jiang-Su algebra $\mathcal{Z}$ (see [29]).

It is quite often the case that the semigroups $V(A)$ and $W(A)$ are almost unperforated, but it is not true in general for simple C^*-algebras as shown in the pioneering work of Villadsen (see Section 5). Almost unperforation can fail spectacularly. For example there is a simple nuclear C^*-algebra A in which one has elements $x, y_1, y_2, y_3, \ldots \in V(A)$ satisfying $2x = 2y_1 = 2y_2 = \cdots$ and $x \not\leq y_1 + y_2 + \cdots + y_n$ for all natural numbers n, see [26].

It is not known if such exotic phenomenons can occur for C^*-algebras of real rank zero:

Question 2.6. Suppose that A is a simple C^*-algebra of real rank zero.

(i) Does it follow that A is either stably finite or purely infinite?

(ii) Does it follow that $V(A)$ and $W(A)$ are almost unperforated?

2.3. Tensor products and free products. Takesaki proved that the minimal (= spatial) tensor product of two simple C^*-algebras is again simple. This is at first thought perhaps not surprising, but one should bear in mind that the minimal tensor product of two (non-simple and non-exact) C^*-algebras can have unexpected and exotic ideals.

Following the similar notion from von Neumann factors we say that a simple C^*-algebra is *tensorially prime* if it is not isomorphic to a tensor product $A \otimes B$, where both A and B are (simple and) non-type I (i.e., are not isomorphic to the compact operators on a finite or infinite dimensional Hilbert space). We consider here only the minimal tensor product, which we denote by $\otimes$.

Proposition 2.7 (Kirchberg, see [27]). *Let A and B be simple non-type I C^*-algebras. If A or B is stably infinite, then $A \otimes B$ is purely infinite. If A and B are both stably finite* and exact*, then $A \otimes B$ is stably finite.*

In particular, if D is a simple, exact, and non-tensorially prime C^*-algebra, then D is either stably finite and admits a trace or D is purely infinite.

Note that we do not know if the tensor product of two (non-exact) stably finite simple C^*-algebras is stably finite. This would be the case if we knew that quasitraces on arbitrary (non-exact) C^*-algebras are traces.

Several simple C^*-algebras are non-tensorially prime without obviously being so. Jiang and Su constructed in [18] a simple separable unital stably finite non-type I C^*-algebra $\mathcal{Z}$, called the Jiang–Su algebra, that has the same K-theory (and the same Elliott invariant, see Section 3) as the complex numbers. It has been shown that many C^*-algebras are $\mathcal{Z}$-absorbing, i.e., they satisfy $A \cong A \otimes \mathcal{Z}$; $\mathcal{Z}$-absorbing C^*-algebras are obviously non-tensorially prime.

The most non-commutative product of two C^*-algebras is the free product (= the "largest" C^*-algebra generated by copies of the two C^*-algebras). We also have the unital free product $A *_{\mathbb{C}} B$ of two unital C^*-algebras A and B, which is defined to be the "largest" unital C^*-algebras generated by a unital copy of A and a unital copy of B.

Consider the C^*-algebra $A = M_2 *_{\mathbb{C}} \mathcal{O}_2$, and let $e \in M_2 \subseteq A$ be a 1-dimensional projection in M_2. Then $e \oplus e$ is equivalent to 1_A, which is a (properly) infinite projection in A. The projection e is finite in A, intuitively because it is in free position from $\mathcal{O}_2$ (a rigorous proof of this fact is non-trivial). The free product C^*-algebra A however is very far away from being simple.

Voiculescu introduced the notion of *reduced free products* of C^*-algebras, or rather of non-commutative probability spaces (A, ρ_A) and (B, ρ_B), where A and B are unital C^*-algebras, and ρ_A and ρ_B are states on A and B, respectively. The reduced free product is again a non-commutative probability space, denoted $(A *_{\mathrm{red}} B, \rho_A * \rho_B)$. The associated C^*-algebra $A *_{\mathrm{red}} B$ is very often simple (see [1]), and it is exact if both A and B are exact (see [8] and [11]), but it is almost never nuclear.

At a first glance one might expect that the (simple) reduced free product C^*-algebra $M_2 *_{\mathrm{red}} \mathcal{O}_2$ (with respect to suitable states on M_2 and $\mathcal{O}_2$) would be an example of an infinite C^*-algebra with a finite projection $e \in M_2$ (as above). However, it

turns out that most reduced free product C^*-algebras, including $M_2 *_{\mathrm{red}} \mathcal{O}_2$, have excellent comparison theory (eg., their Murray–von Neumann semigroup is almost unperforated), and one can show that the projection e from above is infinite in the reduced free product, and, moreover, that $M_2 *_{\mathrm{red}} \mathcal{O}_2$ (and other C^*-algebras like it) is purely infinite. Results along these lines were obtained by Dykema and the author in [9] and [10].

3. Elliott's classification conjecture

The possibility that C^*-algebras can be classified – up to *-isomorphism – by K-theory was perhaps first suggested by Glimm's classification of UHF-algebras (also called Glimm algebras) by supernatural numbers, or, equivalently, by a subgroup of the rational numbers, their K_0-group. This classification was later extended to AF-algebras by Bratteli and Elliott to yield a one-to-one correspondence between dimension groups and AF-algebras. The former were axiomatically described by Effros, Handelman, and Shen as being the unperforated ordered abelian groups with the Riesz Interpolation Property. In the late 1980s in [12] Elliott extended the classification of AF-algebras to include a class of C^*-algebras, now called A$\mathbb{T}$-algebras, that arise as inductive limits of direct sums of matrix algebras over $C(\mathbb{T})$, with the added assumption that the inductive limit C^*-algebra is of real rank zero. These algebras can have non-trivial K_1-group. Elliott raised in the same paper the possibility that his classification might encompass much more than this apparently rather special class of C^*-algebras: many naturally occurring C^*-algebras might be A$\mathbb{T}$-algebras of real rank zero. Moreover, the same invariant, or possibly an expanded version of it, might classify an even wider class of C^*-algebras. These ideas, expressed in more detail below, are known as the *Elliott classification conjecture*.

Elliott's prediction, that A$\mathbb{T}$-algebras of real rank zero are rather frequently occurring C^*-algebras, was shortly after confirmed by himself and Evans as they discovered that the irrational rotation C^*-algebras mentioned in the introduction are A$\mathbb{T}$-algebras. Putnam showed around the same time that C^*-algebras associated with a minimal action on the Cantor set likewise are A$\mathbb{T}$-algebras.

Turning to the precise formulation of the classification conjecture, we only expect to be able to deal with separable and nuclear C^*-algebras (nuclearity is for C^*-algebras what injectivity, or equivalently, hyperfiniteness, is for von Neumann algebras). The K-theory of a C^*-algebra A consists of two abelian groups $K_0(A)$ and $K_1(A)$. The K_0-group has a distinguished subset, $K_0(A)^+$, (the image of $V(A)$ in $K_0(A)$, cf. Section 2), which gives $K_0(A)$ the structure of an ordered abelian group when A has an approximate unit consisting of projections and when A is stably finite.

To simplify its statement, and to state the conjecture in a situation, where no counterexamples (yet) exist, we state formally the Elliott conjecture only in the real rank zero case:

Conjecture 3.1 (Elliott – the real rank zero case). Let A and B be simple separable nuclear unital C^*-algebras of real rank zero. Then

$$A \cong B \iff (K_0(A), K_0(A)^+, [1_A], K_1(A)) \cong (K_0(B), K_0(B)^+, [1_B], K_1(B)).$$

The isomorphism on the right-hand side asserts that there exist isomorphisms $\alpha_0 \colon K_0(A) \to K_0(B)$ and $\alpha_1 \colon K_1(A) \to K_1(B)$ such that $\alpha_0(K_0(A)^+) = K_0(B)^+$ and $\alpha_0([1_A]) = [1_B]$. The invariant can detect whether A is stably finite or stably infinite: $K_0(A)^+ = K_0(A)$ in the latter case, and $K_0(A) \neq 0$ and $K_0(A) \cap -K_0(A)^+ = 0$ in the former case.

The conjecture can – with due care – be extended to non-simple C^*-algebras. We have already mentioned that Elliott's results in [12] confirms his conjecture for A$\mathbb{T}$-algebras of real rank zero. Dadarlat and Gong, [7], later verified the conjecture for the much wider class of so-called AH-algebras (of slow dimension growth) of real rank zero. These classification results also hold in the non-simple case, but the invariant becomes more complicated. It is an open problem if all simple separable nuclear stably finite C^*-algebras of real rank zero are AH-algebras of slow dimension growth and hence classifiable. The range of the invariant has been completely described by Elliott and Gong (see [27, Proposition 3.3]).

K-theory alone will not classify stably finite C^*-algebras not of real rank zero. Intuitively, if a C^*-algebra has very few – or no – projections, then its K_0-group probably say less about the algebra, so we need more information in our invariant. Goodearl produced a class of C^*-algebras (now known as Goodearl algebras) where the trace simplex of the C^*-algebra cannot be detected from its K-theory. This suggests that the trace simplex must be included in the invariant, and – as pointed out by Thomsen – also the pairing between traces and K_0. The resulting invariant (see eg. [27, Chapter 3]) is known as the *Elliott invariant*. The literature contains strong classification results in terms this invariant also for non-real rank zero C^*-algebras, eg. the classification of all simple AH-algebras of bounded dimension by Elliott, Gong and Li, [13], and there is a good description of the range of the invariant for this class due to Villadsen (see [27, Proposition 3.3.7]). A more ultimate result on the range of the invariant within the still not classified class of so-called ASH-algebras due to Elliott and Thomsen can be looked up in [27, Theorem 3.4.4].

The best classification results exist in the stably infinite case. There are no traces on simple stably infinite C^*-algebras, and the order structure on K_0 degenerates: $K_0^+ = K_0$. The Elliott invariant therefore collapses to the two groups $K_0(A)$ and $K_1(A)$ with no other structure except the position of the unit in $K_0(A)$ in the unital case.

The classification result below, that confirms the Elliott conjecture for a sweeping class of stably infinite C^*-algebras, was obtained independently by Kirchberg and Phillips, [19] and [23]:

Theorem 3.2 (Kirchberg–Phillips). *Let A and B be separable, nuclear, simple, purely infinite, K-amenable, unital C^*-algebras. Then*

$$A \cong B \iff (K_0(A), [1_A], K_1(A)) \cong (K_0(B), [1_B], K_1(B)).$$

A C^*-algebra A is *K-amenable* if it is KK-equivalent to an abelian C^*-algebra; and the class of K-amenable C^*-algebras forms a bootstrap class, see [30]. Two K-amenable C^*-algebras are KK-equivalent if and only if they have isomorphic K-groups. One can remove the condition that A and B are K-amenable by replacing the assumption that the K-groups are isomorphic with the assumption that A and B are KK-equivalent. It is an important open problem if all nuclear C^*-algebras are K-amenable.

The Kirchberg–Philips theorem verifies the Elliott conjecture in the stably infinite, real rank zero case modulo two open problems: Are all separable simple nuclear stably infinite C^*-algebras of real rank zero purely infinite (cf. Question 2.6 (i))? And the problem above if all (separable, simple, purely infinite) nuclear C^*-algebras are K-amenable.

The range of the invariant in the stably infinite case is easy to describe: all pairs of countable abelian groups can arise as K_0 and K_1, and there are no restriction on the position of the unit, see [27, Propositions 4.3.3 and 4.3.4]. The Elliott conjecture would predict that all separable nuclear simple stably infinite C^*-algebras are actually purely infinite. As already mentioned, and as will be shown in Section 5, this is not the case. It may still be that separable nuclear simple stably infinite C^*-algebras of *real rank zero* are purely infinite, cf. Question 2.6 and that the Elliott conjecture holds for these C^*-algebras.

The status for the Elliott conjecture is nonetheless open. It may be that the invariant will be refined, so that it can distinguish also the "high-dimensional" examples that we shall discuss in Section 5, but it may also be that the class of C^*-algebras to be classified must be restricted, for example to the class of $\mathcal{Z}$-absorbing C^*-algebras (that briefly were discussed at the end of Section 2). There are some positive results in this direction, eg. by W. Winter, [34], who verified Elliott's conjecture for $\mathcal{Z}$-stable C^*-algebras of real rank zero and with finite decomposition rank.

4. Almost commuting self-adjoint matrices: an application of real rank zero and stable rank one

The classical problem, if two almost commuting self-adjoint matrices are close to two exactly commuting self-adjoint matrices, was solved in the early 1990s by Huaxin Lin, [20], using techniques from C^*-algebras. His long and technical proof was shortened significantly by Friis and the author, [14], where the analysis was reduced to using known properties of C^*-algebras of real rank zero and stable rank one. We outline the ideas of this argument here, and begin by stating the exact formulation of Lin's theorem:

Theorem 4.1. *For each $\varepsilon > 0$ there is a $\delta > 0$ such that for every natural number n and for every pair of self-adjoint $n \times n$ matrices A and B satisfying*

$$\|AB - BA\| < \delta, \quad \|A\| \leq 1, \ \|B\| \leq 1,$$

there exists a pair of commuting self-adjoint $n \times n$ matrices A' and B' such that $\|A - A'\| \leq \varepsilon$ and $\|B - B'\| \leq \varepsilon$.

As an instructive example of almost commuting self-adjoint matrices that not obviously are close to commuting self-adjoint matrices, consider the following $n \times n$ matrices:

$$A_n = \begin{pmatrix} 1/n & 0 & 0 & \cdots & 0 \\ 0 & 2/n & 0 & \cdots & 0 \\ 0 & 0 & 3/n & \cdots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & 0 & \cdots & 1 \end{pmatrix}, \quad B_n = \begin{pmatrix} 0 & 1/2 & 0 & \cdots & 0 \\ 1/2 & 0 & 1/2 & \cdots & 0 \\ 0 & 1/2 & 0 & \cdots & 0 \\ \vdots & \ddots & \ddots & \ddots & \vdots \\ 0 & 0 & 0 & \cdots & 0 \end{pmatrix}.$$

Note that $\|A_n B_n - B_n A_n\| \leq 1/n \to 0$ as $n \to \infty$. It follows from Theorem 4.1 that there are commuting $n \times n$ matrices A'_n and B'_n such that $\|A_n - A'_n\| \to 0$ and $\|B_n - B'_n\| \to 0$. Curiously, there are – to the knowledge of the author – no known *explicit* choices for such sequences of matrices $\{A'_n\}$ and $\{B'_n\}$.

The theorem is proved indirectly. If it were wrong, then there would exist a counterexample: $\varepsilon > 0$ and sequences $\{A_n\}$ and $\{B_n\}$ of self-adjoint $k_n \times k_n$ matrices all of norm at most one such that $\|A_n B_n - B_n A_n\| \to 0$ and such that the distance from (A_n, B_n) to a commuting pair of self-adjoint matrices is at least ε for all n. We show that the existence of such a counterexample leads to a contradiction.

Set $T_n = A_n + i B_n$, and note that $\|T_n\| \leq 2$ and that $\|T_n T_n^* - T_n^* T_n\| \to 0$. Let $\mathfrak{A} = \prod_{n=1}^{\infty} M_{k_n}$ be the ℓ^∞-direct product of the matrix algebras and let $\mathfrak{I} = \sum_{n=1}^{\infty} M_{k_n}$ be the c_0-direct sum of matrix algebras. Then $\mathfrak{I}$ is a closed two-sided ideal in $\mathfrak{A}$, and so we can consider the quotient $\mathfrak{B} = \mathfrak{A}/\mathfrak{I}$ and the quotient mapping $\pi : \mathfrak{A} \to \mathfrak{B}$. Put $T = \{T_n\} \in \mathfrak{A}$. Then $TT^* - T^*T$ belongs to $\mathfrak{I}$, and so $\pi(T)$ is a normal operator in the C^*-algebra $\mathfrak{B}$.

If we could lift $\pi(T)$ to a normal operator $S = \{S_n\}$ in $\mathfrak{A}$, then we would have our contradiction: Write $S_n = A'_n + i B'_n$, with A'_n and B'_n self-adjoint – and necessarily commuting, because S_n is normal – and note that $\|A_n - A'_n\| \to 0$ and $\|B_n - B'_n\| \to 0$ because $\{A_n - A'_n\}$ and $\{B_n - B'_n\}$ both belong to $\mathfrak{I}$. However, we do not know if such a normal lift S exits.

To obtain the contradiction we need less: It suffices to find a normal operator T' in $\mathfrak{B}$ within distance $\varepsilon/2$ to $\pi(T)$ such that T' lifts to a normal operator in $\mathfrak{A}$. This is shown in the three propositions below, as we remark that $\mathfrak{B}$ is of real rank zero, stable rank one, and has connected unitary group (these facts are easily seen to hold for matrix algebras, and hence also for $\mathfrak{B}$).

For each $\varepsilon > 0$ let Γ_ε be the one-dimensional grid in the complex plane consisting of those points $x + iy$ where either x or y belongs to $\varepsilon\mathbb{R}$.

Proposition 4.2. *Let T be a normal operator in a unital C^*-algebra $\mathfrak{B}$ of stable rank one. Then for each $\varepsilon > 0$ there is a normal operator $T' \in \mathfrak{B}$ such that* $\mathrm{sp}(T') \subseteq \Gamma_\varepsilon$ *and $\|T - T'\| < \varepsilon$.*

Outline of proof: By the definition of stable rank one, every element in $\mathfrak{B}$ can be approximated by invertible elements in $\mathfrak{B}$. It was shown in [25] that this implies that any *normal* operator can be approximated by *normal* invertible operators. By translation, one obtains that any normal operator can be approximated by normal operators that do not have a given complex number in its spectrum; and hence – by iteration – by normal operators whose spectrum do not intersect any given finite set. Choosing a suitable finite set of points in the holes of the grid Γ_ε one obtains a normal operator S close to T for which there is a continuous function $f\colon \mathrm{sp}(S) \to \Gamma_\varepsilon$ (in fact, a retract), such that $|f(t) - t|$ is small for all t; and we can then take T' to be $f(S)$.

The proposition below was first proved by Lin in [21]; a more direct proof is given in [14].

Proposition 4.3. *Let $\mathfrak{B}$ be a unital C^*-algebra of real rank zero and with connected unitary group. Let $\varepsilon > 0$ be given and let T be a normal operator in $\mathfrak{B}$ with $\mathrm{sp}(T) \subseteq \Gamma_\varepsilon$. Then there is a normal operator T' in $\mathfrak{B}$ with $\mathrm{sp}(T')$ finite such that $\|T - T'\| < \varepsilon$.*

By definition, a C^*-algebra is of real rank zero if any normal element with spectrum contained in the real line (a self-adjoint operator) can be approximated by a normal element with finite spectrum. Passing from the spectrum being a subset of the real line (a self-adjoint operator) to a more general one-dimensional spectrum permitting loops (in our case: a closed subset of Γ_ε), introduces extra complications that, besides making the proof harder, also force us to require that the unitary group be connected.

Proposition 4.4. *Let $\mathfrak{A}$ and $\mathfrak{B}$ be C^*-algebras and let $\pi\colon \mathfrak{A} \to \mathfrak{B}$ be a surjective *-homomorphism. Each normal operator in $\mathfrak{B}$ of finite spectrum lifts to a normal operator in $\mathfrak{A}$.*

Proof. Let T be a normal operator in $\mathfrak{B}$ with finite spectrum, and find continuous functions $f\colon \mathrm{sp}(T) \to \mathbb{R}$ and $g\colon \mathbb{R} \to \mathbb{C}$ such that $(g \circ f)(t) = t$ for all $t \in \mathrm{sp}(T)$. Lift the self-adjoint operator $f(T)$ to a self-adjoint operator A in $\mathfrak{A}$; then $g(A)$ is a normal operator in $\mathfrak{A}$ that lifts T. (Note that $g(A)$ not necessarily has finite spectrum.) □

5. High dimensional simple C^*-algebras

In Section 2 we discussed properties of a simple C^*-algebra A, including the somewhat technical notions of almost unperforation of the semigroup of equivalence classes of projections, $V(A)$, and of the Cuntz semigroup, $W(A)$. Until the mid 1990s it was believed that all simple C^*-algebras might enjoy these properties; then Jesper Villadsen constructed a counterexample, [32], by taking an inductive limit of algebras of the form $M_{k(n)}(X^{d(n)})$ for a suitable space X (eg. $X = S^2$) and for suitable increasing sequences $k(n)$ and $d(n)$ of natural numbers. It is a crucial point in the construction

that the connecting mappings $M_{k(n)}(X^{d(n)}) \to M_{k(n+1)}(X^{d(n+1)})$ be chosen in such a way that the inductive limit C^*-algebra becomes simple and – at the same time – that certain high-dimensional properties of the spaces $X^{d(n)}$ are preserved. These techniques of Villadsen have since then been used by several people, including Villadsen himself, to construct many other simple C^*-algebras with various exotic properties, including the example by the author of a simple C^*-algebra with a finite and an infinite projection (and hence a simple stably infinite C^*-algebra which is not purely infinite) as well as various counterexamples to Elliott's classification conjecture (as formulated in Section 3).

5.1. The C^*-algebra associated with a multiplier endomorphism. The construction presented here is a special case of Pimsner's construction of a class of C^*-algebras, called the Pimsner algebras, associated with Hilbert bimodules over C^*-algebras. The construction is implicitly contained in our paper [28], where the reader can find more details. Recall that the multiplier algebra, $\mathcal{M}(A)$, of a C^*-algebra A is the largest unital C^*-algebra that contains A as an essential closed two-sided ideal.

To each pair (A, ρ), where A is a (stable) C^*-algebra and $\rho\colon A \to \mathcal{M}(A)$ is a non-degenerate[1] injective *-homomorphism, we associate a C^*-algebra $C^*(A, \rho)$, which in spirit is the crossed product of A by ρ. (We also use the term *multiplier endomorphism* to denote a *-homomorphism from a C^*-algebra into its multiplier algebra.)

The C^*-algebra $C^*(A, \rho)$ is formally constructed as follows. Since ρ is non-degenerate it extends (uniquely) to a strictly continuous unital *-homomorphism $\rho\colon \mathcal{M}(A) \to \mathcal{M}(A)$. Put

$$B = C^*(A, \rho(A), \rho^2(A), \rho^3(A), \dots) \subseteq \mathcal{M}(A),$$

note that ρ restricts to an endomorphism on B; form the inductive limit

$$B \xrightarrow{\rho} B \xrightarrow{\rho} B \xrightarrow{\rho} \cdots \longrightarrow \overline{B},$$

and extend ρ to an automorphism $\bar{\rho}$ on $\overline{B}$. More explicitly, if $\mu_n\colon B \to \overline{B}$ is the inductive limit map from the nth copy of B, $n \geq 0$, then $\bar{\rho}(\mu_n(b)) = \mu_n(\rho(b)) = \mu_{n-1}(b)$, for $b \in B$. The inverse of $\bar{\rho}$ is given by $(\bar{\rho})^{-1}(\mu_n(b)) = \mu_{n+1}(b)$ for $b \in B$. Put $A_{k-\ell} = \mu_\ell(\rho^k(A))$. Then $A_0 = A$, $\bar{\rho}(A_n) = A_{n+1}$ for all $n \in \mathbb{Z}$, and

$$\overline{B} = C^*(\dots, A_{-2}, A_{-1}, A_0, A_1, A_2, \dots).$$

Let $C^*(A, \rho)$ be the crossed product $\overline{B} \rtimes_{\bar{\rho}} \mathbb{Z}$.

Let u be the canonical unitary in the multiplier algebra of $C^*(A, \rho)$ that implements $\bar{\rho}$. Then $C^*(A, \rho)$ is the closure of the span of elements of the form $a_k u^k$, where

[1] By non-degenerate we mean that ρ maps an approximate unit for A into a sequence that converges strictly to 1 in $\mathcal{M}(A)$.

$k \in \mathbb{Z}$ and $a_k \in C^*(A_n \mid n \in \mathbb{Z})$. $C^*(A_n, A_{n+1}, \ldots, A_m)$ is a closed two-sided ideal in $C^*(A_n, A_{n+1}, \ldots, A_k)$ whenever $n \leq m \leq k$. In particular, $A_0 = A$ is a closed two-sided ideal in $C^*(A_0, A_1)$. If we view $C^*(A_0, A_1)$ as being a sub-C^*-algebra of $\mathcal{M}(A)$, then $\rho(a) = uau^*$ holds for all a in A.

Proposition 5.1. *If A is nuclear, then so is $C^*(A, \rho)$.*

Proof. This follows from the construction of $C^*(A, \rho)$ and the fact that the class of nuclear C^*-algebras is closed under extensions, inductive limits, and crossed products by $\mathbb{Z}$. □

Proposition 5.2. *$C^*(A, \rho)$ is simple if ρ is minimal[2] and if ρ^n is properly outer[3] for every natural number n.*

Proof. If ρ is minimal, then so is the automorphism $\bar{\rho}$ on $\bar{B}$; and if all powers of ρ are properly outer, then the same holds for all powers of $\bar{\rho}$. The proposition therefore follows from [22, Theorem 7.2]. □

If ρ is minimal, and if $\rho(A) \subsetneq A$, as will be the case in the situation we consider in the next subsection, then ρ^n is automatically properly outer for all $n \neq 0$.

We give below conditions that will ensure that a projection p in A is finite, respectively, infinite in $C^*(A, \rho)$.

Proposition 5.3. *Let p be a projection in A.*

(i) *If there exists a projection q in A which is equivalent to p (relatively to A) and is a proper subprojection of $\rho(p)$, then p is infinite in $C^*(A, \rho)$.*

(ii) *If $C^*(A, \rho)$ is simple, and if there is a projection e in A such that $e \not\lesssim p \oplus \rho(p) \oplus \rho^2(p) \oplus \cdots \oplus \rho^n(p)$ (inside $\mathcal{M}(A)$) for all natural numbers n, then p is finite in $C^*(A, \rho)$.*

Recall that we have a canonical unitary u in the multiplier algebra of $C^*(A, \rho)$ that implements ρ, ie., $\rho(a) = uau^*$ for $a \in A$. In particular, $\rho(p) \sim p$ in $C^*(A, \rho)$, so the assumption in (i) implies that p is equivalent to a proper subprojection of itself, and hence that p is infinite. Part (ii) is a more technical and is verified (in a slightly different setting) in [28, Lemma 6.4].

5.2. A simple C^*-algebra with a finite and an infinite projection. We apply the crossed product construction from the previous section to the stable C^*-algebra $A = C(Z) \otimes \mathcal{K} = C(Z, \mathcal{K})$ where Z is the infinite Cartesian product of 2-spheres, $Z = \prod_{n=1}^{\infty} S^2$, and where $\mathcal{K}$ denotes the compact operators on a separable Hilbert space. The multiplier algebra $\mathcal{M}(A)$ coincides in this case with the set of all bounded

[2] ρ is minimal if there are no non-trivial ρ-invariant closed two-sided ideals in A; and an ideal I in A is said to be ρ-invariant if $A\rho(I)A \subseteq I$.

[3] An endomorphism $\rho\colon A \to \mathcal{M}(A)$ is properly outer if its restriction to each non-zero ρ-invariant ideal has norm distance 2 to a multiplier inner endomorphism.

*-strongly continuous functions from Z into $B(H)$, the bounded operators on the Hilbert space on which the compact operators $\mathcal{K}$ acts.

The multiplier endomorphism $\rho\colon A \to \mathcal{M}(A)$ of our construction is of the form $\sum_{j=-\infty}^{\infty} \rho_j$, where each ρ_j is an endomorphism on A, and where the sum $\sum_{j=-\infty}^{\infty} \rho_j(a)$ is strictly convergent for each $a \in A$. (We ensure non-degeneracy of ρ by replacing it with $V^*\rho(\cdot)V$ for some isometry V in $\mathcal{M}(A)$ if necessary.) Each endomorphism ρ_j is induced by a continuous function $Z \to Z$ of the form $(z_1, z_2, \dots) \mapsto (c_1, \dots, c_k, z_{\nu(k+1)}, z_{\nu(k+2)}, \dots)$ (or of the form $(z_1, z_2, \dots) \mapsto (z_{\nu(1)}, z_{\nu(2)}, \dots)$) for suitable $k \in \mathbb{N}$, points $c_i \in S^2$, and for a suitable "shuffle-map" $\nu\colon \mathbb{N} \to \mathbb{N}$ (that all depend on j). The points c_i are chosen such that ρ becomes minimal. As $\rho^n(A) \subsetneq A$ for all n, it follows from Proposition 5.2 that $C^*(A, \rho)$ is simple. The shuffle maps ν (one for each j) are chosen in such a way that certain projections (defined below) have non-trivial Euler class.

If e is a constant 1-dimensional projection in A, then $\rho(e)$ is infinite dimensional and constant, so e is equivalent to a proper subprojection of $\rho(e)$ thus making e infinite in $C^*(A, \rho)$, cf. Proposition 5.3 (i).

It requires more effort to get a finite projection in $C^*(A, \rho)$. For every non-zero projection p in A the projection $\rho(p)$ is a pointwise infinite dimensional in $\mathcal{M}(A)$ (when viewed as a *-strongly continuous function $Z \to B(H)$). We want this projection to be finite in $C^*(A, \rho)$; even more, p must satisfy the condition in Proposition 5.3 (ii) wrt. some projection e.

To this end we take a one-dimensional projection p in $C(S^2, M_2)$ with non-trivial Euler class (p could be the "Bott projection" over S^2). For each $j \in \mathbb{N}$, define $p_j \in C(Z, M_2) \subset A$ by $p_j(z) = p(z_j)$, where $z = (z_1, z_2, \dots) \in Z$; so that p_j is the Bott projection over the jth copy of S^2. For each finite set $I = \{j_1, j_2, \dots, j_k\} \subseteq \mathbb{N}$, let $p_I \in C(Z, M_2 \otimes M_2 \otimes \cdots \otimes M_2) \subseteq A$ be the projection given by

$$p_I(z) = p_{j_1}(z) \otimes p_{j_2}(z) \otimes \cdots \otimes p_{j_k}(z), \quad z \in Z.$$

It is shown in [28] that p_1, the Bott projection over the first copy of S^2 in Z, is a finite projection in $C^*(A, \rho)$. The proof uses the precise definition of the multiplier endomorphism $\rho\colon A \to \mathcal{M}(A)$, Proposition 5.3 (ii) applied to p_1 and with e being a constant one-dimensional projection, and the proposition below (cf. [28, Proposition 3.2]). (Note that if q is a projection in $C(Z, \mathcal{K})$ with non-trivial Euler class then $e \not\precsim q$ by a fundamental property of the Euler class.)

Proposition 5.4. *Let $I_1, I_2, \dots, I_m$ be non-empty finite subsets of $\mathbb{N}$. Then the following conditions are equivalent:*

(i) *The Euler class of $p_{I_1} \oplus p_{I_2} \oplus \cdots \oplus p_{I_m}$ is non-trivial.*

(ii) *For all subsets F of $\{1, 2, \dots, m\}$ we have $\left|\bigcup_{j\in F} I_j\right| \geq |F|$.*

(iii) *There is a matching $t_1 \in I_1, t_2 \in I_2, \dots, t_m \in I_m$.*

Putting these results together we obtain the following main result from [28]:

Theorem 5.5. *The C^*-algebra $C^*(A, \rho)$, with $A = C(Z, \mathcal{K})$, with $Z = \prod_{n=1}^{\infty} S^2$, and with $\rho\colon A \to \mathcal{M}(A)$ being the multiplier endomorphism described above, is simple, separable, nuclear, and it contains an infinite projection and a non-zero finite projection.*

Corollary 5.6. *There is a simple, separable, nuclear C^*-algebra that is stably infinite but not purely infinite; and there is a simple, separable, nuclear, unital, finite C^*-algebra that is not stably finite.*

Proof. The C^*-algebra $B = C^*(A, \rho)$ from Theorem 5.5 is stably infinite (containing an infinite projection) and not purely infinite (because it contains a non-zero finite projection). If p is a non-zero finite projection in B, then pBp is finite but not stably finite. □

5.3. Applications and other examples. The example of a simple C^*-algebra with a finite and an infinite projection as well as other examples constructed later by A. Toms give counterexamples to Elliott's conjecture, or at least they show that the Elliott invariant as defined in Section 3 does not suffice to classify separable nuclear simple (unital) C^*-algebras.

Recall from Section 3 that if A is a stably infinite, simple, unital C^*-algebra, then its Elliott invariant reduces to the triple $(K_0(A), [1_A], K_1(A))$.

Theorem 5.7. *There are simple, separable, nuclear, stably infinite unital C^*-algebras A and B such that*

$$(K_0(A), [1_A], K_1(A)) \cong (K_0(B), [1_B], K_1(B)) \quad \textit{and} \quad A \ncong B.$$

Proof. Let A be as in the first part of Corollary 5.6. There is a purely infinite simple nuclear unital C^*-algebra B such that $(K_0(A), [1_A], K_1(A))$ is isomorphic to $(K_0(B), [1_B], K_1(B))$ (see [27, Proposition 4.3.3 and 4.3.4]). As B is purely infinite and A is not, the two C^*-algebras are not isomorphic. □

Note also that it follows from Proposition 2.7 that the C^*-algebra $C^*(A, \rho)$ from Theorem 5.5 is tensorially prime (see Subsection 2.3).

Toms used Villadsen's techniques to construct simple stably finite (AH- and ASH-algebras) with explicit strong perforation in K_0 (eg. with (K_0, K_0^+) isomorphic to $(\mathbb{Z}, S)$ where S can be almost any subsemigroup of $\mathbb{Z}^+$ with $S - S = \mathbb{Z}$). Recently, Toms also constructed ingenious counterexamples to Elliott's conjecture in the stably finite case, ie. pairs of non-isomorphic simple, separable, nuclear, stably finite C^*-algebras with the same Elliott invariant (and for this matter also other invariants, not normally included in the Elliott invariant) (see [31]).

Convexity, complexity, and high dimensions

Stanislaw J. Szarek*

Abstract. We discuss metric, algorithmic and geometric issues related to broadly understood complexity of high dimensional convex sets. The specific topics we bring up include metric entropy and its duality, derandomization of constructions of normed spaces or of convex bodies, and different fundamental questions related to geometric diversity of such bodies, as measured by various isomorphic (as opposed to isometric) invariants.

Mathematics Subject Classification (2000). Primary 46B20; Secondary 46B09, 47B06, 52A21, 52C17, 15A52, 90C25, 94B75.

Keywords. Convex body, high dimension, complexity, metric entropy, asymptotic geometric analysis.

1. Introduction

When modeling complex (real-life or abstract) systems with many degrees of freedom, we are frequently led to mathematical objects whose dimension can be related to the number of free parameters in the underlying system and, as a consequence, is very large. Since many naturally appearing relationships between, or constraints on the parameters are linear or at least convex, we are thus led to high dimensional convex sets. Two areas of traditional mathematics that come to mind when faced with the problem of analyzing such sets are *classical geometry* and *functional analysis*. However, geometry is usually focused on obtaining very precise information for a fixed, not-too-large dimension. Functional analysis, on the other hand, is typically concerned with the infinite-dimensional setting (which frequently is an idealization of a very large dimension), but often provides only qualitative information. Fortunately, there is a middle ground between these two approaches and it has turned out to be quite fertile. The last few decades witnessed the development of a quite powerful quantitative methodology in geometric functional analysis that, together with similar advances in areas such as combinatorics or theoretical computer science, has been lately referred to as *asymptotic geometric analysis*. In a nutshell, the prescription for success of the asymptotic theory depends on identifying and exploiting *approximate* symmetries of various problems that escaped the earlier "too qualitative" or "too rigid" methods of classical functional analysis and classical geometry. More specifically,

*Supported in part by a grant from the National Science Foundation (U.S.A.).

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

an important feature of the area is the predominantly *isomorphic* (as opposed to *isometric*) character of the questions: one is usually after the rough (i.e., "up to a universal constant") asymptotic order of the quantities studied and not their more precise behavior. This sometimes makes the problem solvable. [See the article [48] by B. Klartag in this collection for a discussion of developments in the so-called "almost isometric" theory.] However, universal estimates are required, independent of the particular instance of the problem, most notably of the dimension. As is very well known to specialists, but perhaps not fully appreciated by non-experts, this last feature is absolutely crucial because it allows for applications to infinite dimensional functional analysis and to quantitative questions in applied fields. This framework led to discoveries of many surprising phenomena, which may be subsumed in the following "experimental" observation: low-dimensional intuitions are often *very* wrong in high dimensions. However, as opposed to other fields such as topology, high-dimensional curiosities generally do not appear via a quantum jump; say, when passing from dimension 3 to 4, or from 7 to 8. Instead, small changes accumulate as the dimension increases, leading ultimately to a qualitatively new picture.

In the present article we shall focus on those aspects of the theory that are relevant to broadly defined *complexity* of convex sets. To exemplify what we mean by complexity, we will now hint at three alternative viewpoints on the notion. Below K will stand for a generic *convex body* in $\mathbb{R}^n$ (i.e., compact convex set with nonempty interior).

(i) *The algorithmic complexity.* How difficult is it to describe K? A prime example (which we mention mainly for demonstration purposes) is here the algorithmic complexity of the *membership oracle*: How difficult is it to decide whether a point belongs to K? Another class of questions is: Suppose that the existence of K with certain properties is given by a non-constructive proof, or by probabilistic considerations; is it possible to give an explicit example, or an efficient derandomized algorithm?

(ii) *The geometric complexity, or diversity.* How complicated (in an appropriate geometric sense) is K? To what extent do convex bodies of the same dimension exhibit common features? In particular, to what extent do they resemble the arguably most regular body, the Euclidean ball?

(iii) *The metric entropy.* Here we need an underlying metric structure, typically given by a norm. Given $\varepsilon > 0$, how many balls of radius ε do we need to cover K? The logarithm (to base 2) of the minimal cardinality of such cover is called the *metric entropy function* of K and can be interpreted as the complexity of K, measured in bits, at the level of resolution ε with respect to the metric in question.

In what follows we will provide some background information concerning these three aspects of complexity, describe recent developments in each area, and list related open problems. Each of the viewpoints (i)–(iii) will correspond to one section in the exposition; however, we will reverse the order. On the other hand, we emphasize that the three points of view are intimately interconnected. For example, one aspect of geometric diversity involves approximating convex bodies by simple ones, a problem which has obvious algorithmic ramifications. A sample such question, approximating by polytopes, has been extensively studied and reported on in [14], see also [92].

Notation will be introduced as we proceed, but we list below a few general rules and conventions that will be used throughout the paper. We will sometimes use unexplained (but standard in the field) notation in side remarks. For this and for more background on the issues discussed here we refer the reader to the monographs [75], [108], [84] and, for more up-to-date expositions, to surveys contained in [41], especially the chapters [42], [18], [24], [30], [43], [50], [56], [59], [63], [64], and – particularly for the motivational aspects – to the 1996 ECM and the 1998 ICM talks by V. Milman [72], [73].

If X is a normed space, we will write B_X for its unit ball (centered at the origin). In the other direction, if K is a convex body in $\mathbb{R}^n$ containing the origin in its interior, $\|\cdot\|_K$ will stand for the gauge of K (i.e., $\|x\|_K := \inf\{t > 0 : x \in tK\}$); if K is symmetric with respect to the origin, the gauge of K is just the norm for which K is the unit ball. Thus, in a way, the body K (symmetric with respect to the origin) is identified with the normed space $(\mathbb{R}^n, \|\cdot\|_K)$; this is the main reason for the interplay of geometric and functional analytic ideas.

The letters $C, c_0, C', \ldots$ will stand for absolute positive constants, independent of the particular instance of the problem considered, most notably of the dimension. However, the numerical values corresponding to the same symbol may vary between occurrences. Similarly, $C(\alpha)$ will denote a constant depending only on the parameter α, and so on. For two functions f, g (depending on the same or on different parameters), $f \sim g$ will mean that f and g are of the same order, i.e., $cf \le g \le Cf$ (with $C, c > 0$ independent of the parameters involved, as required by the previous convention).

2. Metric entropy and its duality

While in many applications *calculating* the metric entropy of *specific* sets is the primary objective, here we will mention applications only in passing and concentrate instead on the more fundamental properties of the notion, particularly those connected to duality considerations.

2.1. Notation and historical background, the duality conjecture. If K, B are subsets of a vector space, the *covering number* of K by B, denoted $N(K, B)$, is the minimal number of translates of B needed to cover K. Similarly, the *packing* number $M(K, B)$ is the maximal number of disjoint translates of B by elements of K. [Note that geometers usually require only that the *interiors* of the translates be disjoint.] The two concepts are closely related, particularly if B is centrally symmetric; we have then $N(K, 2B) \le M(K, B) \le N(K, B)$. If B is a ball in a normed space and K a subset of that space (the setting and the point of view we will usually employ), these notions reduce to considerations involving the smallest ε-nets or the largest ε-separated (or 2ε-separated) subsets of K.

Besides the immediate geometric framework, packing and covering numbers appear naturally in numerous subfields of mathematics, ranging from classical and functional analysis through operator theory and probability theory (particularly when studying stochastic processes, see [26], [95], [61], [53]) to information theory and computer science (where, for example, a code is typically a packing). As with other notions touching on convexity, an important role is played by considerations involving duality. The central problem in this area is the 1972 *duality conjecture for covering numbers* due to Pietsch [79], which has been originally formulated in the operator-theoretic context (see below), but which in the present setting can be stated as

Conjecture 2.1 (*The Duality Conjecture*). There exist numerical constants $a, b \geq 1$ such that for any dimension n and for any two symmetric convex bodies K, B in $\mathbb{R}^n$ one has

$$b^{-1} \log N(B^\circ, aK^\circ) \leq \log N(K, B) \leq b \log N(B^\circ, a^{-1}K^\circ). \tag{1}$$

Above and in what follows $A^\circ := \{u \in \mathbb{R}^n : \sup_{x\in A} \langle x, u\rangle \leq 1\}$ is the polar body of A; "symmetric" is a shorthand for "symmetric with respect to the origin" and, for definiteness, all logarithms are to the base 2. For simplicity, we will generally restrict our attention to symmetric sets; however, most statements can be formulated without the symmetry assumption. Of course, due to the bipolar theorem, K and B are exchangeable in (1) and so it is enough to prove only one of the two inequalities. We emphasize that the "equivalence" of the quantities in (1), and overall in this section, is more involved than the relation $\sim$ defined in the introduction.

In our preferred setting of a normed space X, the proper generality is achieved by considering $\log N(K, t\,B_X)$, where $t > 0$ and K is a general (convex, symmetric) subset of X. The polars should then be thought of as subsets of X^*, with $(B_X)^\circ$ coinciding with B_{X^*}, the unit ball of that space, and (1) becomes

$$b^{-1} \log N(B_{X^*}, atK^\circ) \leq \log N(K, tB_X) \leq b \log N(B_{X^*}, a^{-1}tK^\circ). \tag{2}$$

With minimal care, infinite-dimensional spaces and sets may be likewise considered. To avoid stating boundedness/compactness hypotheses, which are peripheral to the phenomena in question, it is convenient to allow $N(\cdot,\cdot)$, $M(\cdot,\cdot)$ etc. to take the value $+\infty$. Finally, the original operator-theoretic formulation of the conjecture is as follows. Given (linear bounded, or compact) operator $u\colon Y \to X$ between two normed spaces we define *entropy numbers* of u as $e_k(u) := \inf\{\varepsilon > 0 : N(uB_Y, \varepsilon B_X) \leq 2^{k-1}\}$. Do we have then

$$a^{-1} e_{bk}(u) \leq e_k(u^*) \leq a e_{k/b}(u^*) \tag{3}$$

(where $u^*\colon X^* \to Y^*$ is the adjoint of u) uniformly over spaces X, Y, operators u and $k \geq 1$?

2.2. The Hilbert space case. To indicate where the difficulty of the problem lies, we shall comment on the enlightening special cases when, in the language of (3), X and/or Y is a Hilbert space. If *both* X and Y are Hilbert spaces, the situation is nearly trivial. Indeed, entropy numbers of a Hilbert space operator depend only on its singular numbers, and the singular numbers of an operator and its adjoint are identical. In the setting of (1), this corresponds to the bodies K, B (and hence K°, B°) being ellipsoids with the pair (K, B) affinely equivalent to the pair (B°, K°) (in that order!). As a consequence, (1), (3), and the appropriate version of (2), hold with $a = b = 1$. At the other extreme, in the general case, the four bodies K, B, K°, B° appearing in (1) may be *all* very different and so the reasons for the duality result (if it indeed does hold) must be much deeper. Finally, if one of the spaces (say, X) is a Hilbert space, looking at the equivalence (2) we see that it expresses what seems to be a rather fundamental property of *all* convex subsets of the Hilbert space.

Let us also point out that if $\dim X = \dim K := k < \infty$ (and K is bounded), then standard considerations show that, as $t \to 0^+$, both metric entropy functionals $\log N(K, t\, B_X)$ and $\log N(B_{X^*}, t\, K^\circ)$ are equivalent to $k \log(1/t)$. In fact, it is even true that the differences between the functionals and $k \log(1/t)$ are bounded. However, the bounds for the two differences depend in an intricate way on K, not allowing for any meaningful quantitative inferences, nor for deriving any conclusions about reasonably general infinite dimensional sets. [Comments in this paragraph are not dependent on X being a Hilbert (i.e., Euclidean) space.]

2.3. Duality results. The three decades following the statement of the conjecture brought many useful partial and/or related results, see [91], [51], [107], [19], [78], [33], [85] and their references. However, only in the last few years substantial progress was achieved with respect to the original problem. We have (see [8], [9])

Theorem 2.2. *There exist universal constants $a, b \geq 1$ such that* (2) *holds if X is a Hilbert space, uniformly over all symmetric convex sets $K \subset X$ and over $t > 0$. Moreover, the same is true if X is K-convex, with a, b depending on the K-convexity constant of X.*

The notion of *K-convexity* (the notation which, by the way, has nothing to do with our convex set K) goes back to [65] and is well known to specialists; we refer to [84], [64] for a precise definition, background and properties. Requiring K-convexity imposes a rather mild geometric restriction on the underlying space. For example, the class of K-convex spaces includes all L_p-spaces for $1 < p < \infty$ (classical or non-commutative), and similarly all uniformly convex and all uniformly smooth spaces. While many interesting descriptions of this class are possible (see [56], [64]), here we just mention that K-convexity is equivalent (see [82]) to the absence of large subspaces resembling (in the sense of the next section) finite-dimensional ℓ_1-spaces, and that it can be nicely quantified: there is a parameter called the *K-convexity constant*, which can be defined both for finite and infinite dimensional normed spaces, and which has good permanence properties with respect to standard functors of functional analysis.

Translating Theorem 2.2 to the other formulations is straightforward. For example, we get that (3) holds if one of the spaces X, Y is a Hilbert space or, more generally, is K-convex. Similarly, if (say) B is an ellipsoid, then (1) holds uniformly over $n \in \mathbb{N}$ and over (symmetric convex bodies) $K \subset \mathbb{R}^n$ etc. Regarding constants, we know how to prove (2) for the Hilbert space with any $a > 2$, with $b = b(a)$; improvements (to "any $a > 1$") would follow if a certain geometric statement conjectured in [76] was true.

2.4. The convexified packing. An interesting feature of [9] is the formal introduction and an initial study of a modified notion of packing that has already been implicit in [19]. We will provide now some details since this will allow us to present a sketch of the proof of Theorem 2.2 and to pinpoint the ingredients that are missing in the general case of Conjecture 2.1; at the same time, the new notion appears to be interesting by itself. A sequence $x_1, \ldots, x_m$ is called a *convexified B-packing* iff

$$(x_j + B) \cap \operatorname{conv} \bigcup_{i<j} (x_i + B) = \emptyset$$

for $j = 2, \ldots, m$. [We emphasize that, as opposed to the usual notions of packing and covering, the *order* of the points *is* important here.] Next, the *convexified packing number* $\hat{M}(K, B)$ is the maximal length of a sequence in K which is a convexified B-packing. It turns out that for this modified notion the duality in the sense analogous to (1)–(3) does hold, and that it is (essentially) a consequence of a Hahn–Banach type separation theorem. For example, we have (see [9])

If $K, B \subset \mathbb{R}^n$ are convex symmetric bodies, then $\hat{M}(K, B) \le \hat{M}(B^\circ, K^\circ/2)^2$.

Accordingly, if we knew that the numbers $M(\cdot, \cdot)$ and $\hat{M}(\cdot, \cdot)$ were in the appropriate sense equivalent, the original duality conjecture would follow immediately. While clearly $\hat{M}(K, B) \le M(K, B)$, any general inequality going in the opposite direction appears at the first sight unlikely. However, the following reduction (shown in [8]) simplifies the matter substantially.

For a given space X, if (2) *holds for $t = 1$ and all $K \subset X$ verifying $B_X/4 \subset K \subset 4B_X$, then it holds* (*perhaps with different $a, b > 0$*) *for all K and all $t > 0$.*

In other words, it is enough to prove (1) (or even the first inequality in (1)) for K, B such that $B/4 \subset K \subset 4B$. This reduction allows us to close the loop, at least under some additional mild geometric assumptions about the ambient normed space.

For bounded sets in a K-convex space X, $M(\cdot, B_X)$ and $\hat{M}(\cdot, B_X)$ are comparable.

More precisely, we have $\log M(T, B_X) \le \beta \log \hat{M}(T, B_X/4)$ where β depends only on the diameter of the convex set T and (the upper bound on) the K-convexity constant of X. Moreover, the roles of B and T can be reversed if T is symmetric and $T \supset rB$

for some $r > 0$ (with β depending on r). Proofs of both these facts (contained in [9]) are based on the so-called Maurey's lemma (see [81]) and on the ideas from [19].

Theorem 2.2 follows now by combining (more or less) formally the three statements above. The argument suggests several natural questions.

Problem 2.3. Are the quantities $M(\cdot, B_X)$ and $\hat{M}(\cdot, B_X)$ always (in the appropriate sense) comparable? Comparable uniformly over well-bounded subsets of (an arbitrary) normed space X? Comparable uniformly over subsets of a Hilbert space X (without restriction on the diameter)?

An affirmative answer to the second question would imply an affirmative answer to Conjecture 2.1 in full generality. Similarly, an affirmative answer for a specific non-K-convex space X would imply the form (2) of the conjecture for that space (and the form (3), with the second space Y arbitrary). An interesting test case is $X = \ell_1$.

While equivalence of $M(\cdot, B_X)$ and $\hat{M}(\cdot, B_X)$ over all convex subsets of X (i.e., in absence of a uniform upper bound on the diameter, the first and the third part of Problem 2.3) is not required for the corresponding case of the Duality Conjecture 2.1, good understanding of the relationship between the two quantities may have implications for complexity theory. Indeed, a standard device in constructing geometric algorithms is a *separation oracle* (cf. [35]): if T is a convex set then, for a given x, the oracle either attests that $x \in T$ or returns a functional efficiently separating x from T. It is arguable that quantities of the type $\hat{M}(T, \cdot)$ correctly describe complexities of the set T with respect to many such algorithms.

3. Geometric complexity of convex bodies and their diversity

When comparing shapes of convex bodies, it is most natural in our context to not distinguish K from its images via invertible affine maps. This may be thought of as choosing for each body the coordinate system that is most appropriate for the particular property that is being studied, and leads to the concept of the *Banach–Mazur distance*. For (symmetric) convex bodies $U, V \subset \mathbb{R}^n$ one sets

$$d(U, V) := \inf\{\lambda > 0 : \text{there exists } w \in \mathrm{GL}(n) \text{ such that } U \subset wV \subset \lambda U\}.$$

This definition is usually formulated in the language of normed spaces: $d(X, Y) := \inf\{\|w\| \cdot \|w^{-1}\| : w\colon X \to Y \text{ an isomorphism}\}$. We refer to the monograph [108] for an exhaustive study of issues related to this notion.

3.1. The structure of the Banach–Mazur compactum. The set of (classes of affinely equivalent) symmetric convex bodies in $\mathbb{R}^n$ (or, equivalently, of classes of isometric n-dimensional normed spaces), endowed with the Banach–Mazur distance, is usually called the (nth) *Banach–Mazur compactum* or the *Minkowski compactum*. [See [1] for most recent results about the *topological* structure of this set.] It is actually

$\log d(\cdot,\cdot)$ which has the usual properties of a distance function, but it is customary to abuse the notation and talk about $d(\cdot,\cdot)$ as if it was a metric. It is a fundamental result due to F. John [40]) that for any n-dimensional symmetric convex body K its distance $d(K, B_2^n)$ to the Euclidean ball B_2^n may be at most $\sqrt{n}$, and it is easy to see that this bound can not be in general improved. It follows right away that the *diameter* of the compactum is at most n, and the remarkable result of Gluskin [31] shows that this bound can not be substantially improved: we do have pairs K, B of n-dimensional symmetric convex bodies for which $d(K, B) \geq cn$ (where $c > 0$ is, according to our convention, a universal constant independent of n). We take this opportunity to point out several unsolved problems in this general direction. First, it would be interesting to determine the *exact* diameter of the Banach–Mazur compactum for specific low dimensions; in fact, the only case when the diameter of the compactum is precisely known is $n = 2$ (see [11]), and the complex analogue is unknown even in dimension 2. A more serious problem is the question of finding (the order of) the maximal distance of specific important convex bodies to general ones of the same dimension. For the *n-dimensional cube* B_∞^n (the unit ball of ℓ_∞^n), the easy lower and upper bounds of $\sqrt{n}$ and n were improved only around 1990 in, respectively, [98] and [20]. The lower bound $cn \log n$ from [98] remains the best known, while the upper one has been tightened in [101] and in a series of papers by Giannopoulos culminating in $Cn^{5/6}$ in [29]. Clearly, a wide gap still persists. Another wide open question is that about the diameter of the compactum of the *not-necessarily-symmetric* n-dimensional convex bodies, with the definition of the distance involving additionally a minimum over translations. The analogue of John's result (also contained in [40]) yields the value n for the radius with center at B_2^n. The resulting estimate n^2 on the diameter has been improved in [86] (see also [13]) to $n^{4/3}$ (times a logarithmic factor). For a more general discussion of the isomorphic theory of non-symmetric convex bodies we refer to the recent articles [54], [74], [34] and their references.

3.2. Quotient of a subspace theorem and its aftermath. It follows from the results quoted in Section 3.1 that convex bodies/normed spaces can be quite distant in the Banach–Mazur sense. Accordingly, it was a major surprise when Milman ([69]) discovered in the mid 1980s that, in some sense, every convex body hides somewhere inside its structure an ellipsoid of nearly full dimension. More precisely, we have (in the language of normed spaces)

Theorem 3.1 (Quotient of a subspace theorem). *Given $\theta \in (0, 1)$ and an n-dimensional normed space X there exists a* subspace of a quotient *of X whose dimension is $\geq \theta n$ and whose Banach–Mazur distance to the Euclidean space does not exceed $C(\theta)$. Moreover, $C(\theta)$ can be chosen to verify* $\lim_{\theta\to 0^+} = 1$.

In other words, every n-dimensional symmetric convex body admits a central section and an affine image (not necessarily bijective) of that section which is of dimension $\geq \theta n$ and which is $C(\theta)$-equivalent (in the sense of the Banach–Mazur distance) to a Euclidean ball. Theorem 3.1 should be compared with the much earlier

celebrated Dvoretzky theorem (see [27], and [68] for the improved version quoted here) which, in the same context, asserts existence of almost Euclidean *sections*, or subspaces, whose dimension is just of order $\log n$. It is easy to see that, in general, if we only use the operation of passing to a subspace (or, dually, only the operation of passing to a quotient), then this logarithmic order can not be improved. [We discuss some remarkable special cases when it can be dramatically improved in the next section.] Still, it is conceivable that *some* considerable regularity can be achieved by a single operation of passing to a "proportional" subspace (or to a "proportional" quotient). In the wake of his quotient of a subspace theorem Milman stated in his 1986 ICM lecture ([70]) several specific problems going in that direction. All these problems were recently answered in the negative due to the discovery of a new phenomenon which we will next describe.

3.3. The saturation phenomenon. The following result from [103] is a sample illustration of the phenomenon.

Theorem 3.2 (The saturation phenomenon). *Let n and m_0 be positive integers with $\sqrt{n}\,\log n \le m_0 \le n$. Then, for every finite dimensional normed space W with*

$$\dim W \le c_1 m_0/\sqrt{n} \tag{4}$$

there exists an n-dimensional normed space X such that every subspace Y of X with $\dim Y \ge m_0$ contains a contractively complemented subspace isometric to W.

Loosely speaking, Theorem 3.2 says that the space X is so "saturated" with subspaces isometric to W (copies of W), that such subspaces persist in every "sufficiently large" subspace of X. Furthermore, due to the complementability clause in the assertion of Theorem 3.2, the statement can be dualized, i.e., "every subspace Y of X" can be replaced by "every quotient Y of X." Thus, in general, passing to large subspaces *or* large quotients can not erase k-dimensional features of a space if k is below certain threshold value. This is in stark contrast to the operation of passing to a large quotient of a subspace, which – by Theorem 3.1 – may lead, in a sense, to losing *all* information about the original space, no matter how complicated that space was.

Let us point out that, under the hypotheses of the Theorem, the dimension $k := \dim W$ is always nontrivial (i.e., large, if n is large), and in the most interesting case when $m_0 \sim n$ (say, $m_0 \approx n/2$) we can have $k \sim \sqrt{n}$. It follows that Theorem 3.2 imposes strict limits on properties that may be achieved (or improved) by passing to a large subspace (resp., quotient). Indeed, no property of normed spaces whose violation can be witnessed inside subspaces of dimension $\ll \sqrt{\dim X}$ (and which is inherited by complemented subspaces of a space) can be in general achieved by passing to a subspace (resp., quotient) of X whose dimension is comparable to that of X. To demonstrate that, we choose any space W with $\dim W \ll \sqrt{n}$ which does not have the property in question and use Theorem 3.2 to construct an n-dimensional space; then every sufficiently large subspace (resp., quotient) of X contains a contractively

complemented subspace isometric to W and consequently can not have our property. Examples of properties which can be so "prevented" include being of nontrivial type or cotype, which immediately settles in the negative (and in a very strong sense) Problem 1 from [70]: *Does every n-dimensional normed space admit a quotient of dimension $\geq n/2$ whose cotype 2 constant is bounded by a universal numerical constant?*

Statements similar to Theorem 3.2 hold if it is additionally required that X has certain regularity properties. For example, if we insist that the cotype q constant of X (for some $q \in (2, \infty)$) be controlled, it is possible to construct X which is saturated with copies of any given space W whose cotype q constant is not too large, provided $\dim W$ verifies a condition resembling (4). These topics were developed in [103], [104] and led to negative answers to Problems 2 and 3 from [70].

All the above notwithstanding, some *global* regularity of bodies/spaces may be achievable by passing to proportional quotient or subspaces. For example, already in [69], as a step in the proof of Theorem 3.1, it was established that every finite dimensional normed space admits a "proportional" quotient of well-bounded *volume ratio*, a volumetric characteristic of a convex body closely related to cotype 2 property of the corresponding normed space. It would be important to find more examples of, and/or limitations on such results. As a sample problem we mention the following

Problem 3.3. Given a finite dimensional normed space X, does there exist a subspace $Y \subset X$ with $m := \dim Y \geq \dim X/2$ and a basis $y_1, \ldots, y_m$ of Y such that, denoting by $y_1^*, \ldots, y_m^*$ the dual basis of Y^* we have

$$\mathrm{Ave}_{\varepsilon_i=\pm 1} \left\| \sum_{i=1}^{m} \varepsilon_i y_i \right\| \cdot \mathrm{Ave}_{\eta_j=\pm 1} \left\| \sum_{j=1}^{m} \eta_j y_j^* \right\| \leq Cm \,?$$

It is in fact an open problem whether a similar property holds for every normed space *without* passing to a subspace. [For example, a slightly weaker form of this last question was stated as Problem 6 in [70].]

3.4. Products of convex bodies and the nontrivial projection problem. A measure of geometric complexity of a high dimensional convex body K is whether it can be "reduced," in some meaningful sense, to bodies of substantially lower dimension. One such natural reduction would be approximating K, in the sense of Banach–Mazur distance, by Cartesian products of (two or more) convex bodies, each of which has a reasonably large dimension. The so phrased problem makes sense also for non-symmetric bodies, but in the symmetric case it reduces to the well-known *nontrivial projection problem*.

Problem 3.4. Do there exist $C > 0$ and a sequence $k_n \to +\infty$ such that for every n-dimensional normed space X there is a projection P on X with $\|P\| \leq C$ and $\min\{\mathrm{rank}\, P, \mathrm{rank}(I - P)\} \geq k_n$?

A question about somewhat stronger property, the *finite-dimensional basis problem* was resolved in early 1980s (after having been open for about 50 years) in [32] and [97] (see also [60]), where it was shown that the statement from Problem 3.4 can not hold with k_n substantially larger than $\sqrt{n}$ (more precisely, with $k_n \gg \sqrt{n \log n}$) and that, in general, we can not find projections on X whose rank and corank are of the same order as $\dim X$ and whose norm is $o(\sqrt{\dim X})$. [Note that every k-dimensional subspace of a normed space is complemented via a projection of norm $\leq \sqrt{k}$, see [44], or even slightly smaller, see [52], [50].] Various versions of Problem 3.4 were stated in the ICM talks by Milman (1986, [70]) and, most notably, by Pisier (1983, [83]), with the latter reporting also on the definitive treatment of the case when $\dim X = \infty$: it may then happen that, for any finite rank projection P on X one has $\|P\| \geq c\sqrt{\operatorname{rank} P}$. [The purely infinite dimensional counterexample to splitting into a nontrivial Cartesian product, or even to a weaker property, is provided by the Gowers–Maurey *hereditarily indecomposable* spaces, see [63].]

In spite of all these negative results it is still conceivable that the answer to Problem 3.4 is affirmative, even with $k_n \sim \sqrt{n}$; this threshold is precise (on the power scale) in the case of "the usual suspects," Gluskin-type random spaces, (see [60]) and – perhaps for a reason – parallels some thresholds related to the saturation phenomenon from Section 3.2. In fact, improvements on the extremal order $\sqrt{\operatorname{rank} P}$ for norms of projections have been known for quite a while, see [80], [83]. The following bound ([105]) can be obtained by combining known techniques (in a not-so-straightforward manner, though).

Theorem 3.5. *There exist $C, c > 0$ and a sequence $k_n \geq \exp(c\sqrt{\log n})$ such that, for every n-dimensional normed space X, there is a projection P on X with* $\min\{\operatorname{rank} P, \operatorname{rank}(I - P)\} \geq k_n$ *and* $\|P\| \leq C(\log k_n)^2$.

Going even further, we do not see easy counterexamples to the following (sample) statement stronger than the one in Problem 3.4: *Given an n-dimensional normed space X and an integer m with $\sqrt{n} < m \leq n$, the space X can be split into a direct sum of m subspaces $E_1, \ldots, E_m$ of approximately equal dimensions, and such that if P_j is the projection onto E_j that annihilates all E_i with $i \neq j$, then* $\max_{1 \leq j \leq m} \|P_j\| \leq C$. This would be a generalization of the classical Auerbach lemma which asserts that the answer is yes, with $C = 1$, if $m = n$. However, it is possible that, at least for some range of m, an argument in the spirit of [98] may yield a counterexample.

4. Algorithmic complexity and derandomization, pseudorandom matrices

Many results in asymptotic geometric analysis, including virtually all cited in the preceding section, have been obtained by *probabilistic* considerations. For example, when the objective is to prove the existence of a convex body (or a normed space) with certain property, the strategy is to come up with an appropriate random variable

whose values are convex bodies, and then to show that with nonzero (and typically close to 1) probability the property in question is satisfied. [The arguments usually involve precise metric entropy estimates for various subsets of $\mathbb{R}^n$, or for sets of operators on $\mathbb{R}^n$, combined with large deviation and, particularly, small ball estimates for vector-valued random variables; the latter two are aspects of the celebrated *measure concentration phenomenon*, the standard form of which is more adapted to almost isometric questions than to isomorphic ones.] For many more examples of similar arguments in other contexts see [5].

In all such cases, a natural question is: *Is it possible to give an explicit example, or a derandomized algorithm?* An explicit example must have an explicit reason, and this should presumably be reflected by the presence of some additional structure and a more natural, "nicer" end-product. Even more importantly, if a question is motivated by applications, it is usually imperative that the solution be explicit, or at least easily verifiable. In this section we will sketch several sample contexts when a derandomized proof would be desirable, and describe a few attempts at derandomization (or partial derandomization) of constructions that were originally obtained using probabilistic methods.

Very often the object one constructs (a convex body, a normed space, or a subspace or a quotient) can be fully described by a matrix, which in a probabilistic construction will be random. [This link is even more explicit when the objective is to find an operator.] Since we aim at producing explicit matrices that behave like random ones, one may say that this section is mostly about *pseudorandom matrices*.

4.1. Kashin decompositions and linear vs. quadratic programming. We begin by recalling the following spectacular result motivated by questions in approximation theory and usually referred to as *Kashin decomposition* (see [45], [96], [102], [84])

Theorem 4.1 (Kashin decomposition). *Given $m = 2n \in 2\mathbb{N}$, there exist two orthogonal m-dimensional subspaces $E_1, E_2 \subset \mathbb{R}^m$ such that*

$$\frac{1}{8}\|x\|_2 \le \frac{1}{\sqrt{m}}\|x\|_1 \le \|x\|_2 \quad \textit{for all } x \in E_i,\ i = 1, 2. \tag{5}$$

In other words, the space ℓ_1^{2n} is an orthogonal (in the ℓ_2^{2n} sense) sum of two *nearly Euclidean* subspaces. The existence of such a decomposition was surprising because, as is easily seen, on the *entire* space $\mathbb{R}^m$, the ratio between the ℓ_1 and ℓ_2 norms varies between 1 and $\sqrt{m}$ (in fact, the Banach–Mazur distance between ℓ_1^m and ℓ_2^m equals $\sqrt{m}$). [See [84], p. 95, for an exposition of the equally striking infinite-dimensional analogue due to Krivine and independently to Kashin.] A slightly different form of the theorem (the original one) asserts the existence of a matrix $V \in O(n)$ such that

$$\max\{\|x\|_1, \|Vx\|_1\} \ge c\sqrt{n}\|x\|_2 \quad \text{for all } x \in \mathbb{R}^n$$

the graphs of V and $-V$ yield then a desired decomposition of $\mathbb{R}^m$ (with $\frac{1}{8}$ in (5) replaced by $\frac{c}{2}$). In both formulations the standard arguments yield that, for large n,

the assertion holds for nearly all decompositions $E_1 \oplus E_2$ or, resp., for nearly all $V \in O(n)$ (with respect to the corresponding Haar measure); see [7], [90], [55] and their references for an in-depth discussion of other random models. However, no explicit families of E_1, E_2 or V with $n \to \infty$ are known. This leads naturally to

Problem 4.2. Given $n \in \mathbb{N}$, exhibit an explicit Kashin decomposition of ℓ_1^{2n}.

A formally easier, and perhaps more to the point, as it corresponds to *constructive Dvoretzky theorem* for ℓ_1^m (cf. Section 3.2), is the question (also stated as Problem 7 in [70]) about exhibiting explicit proportional nearly Euclidean subspaces of ℓ_1^m, i.e., subspaces $E \subset \ell_1^m$ with $k := \dim E \geq cm$ and $d(E, \ell_2^k) \leq C$. The best to date result of this nature is due to Rudin [88] and yields merely $k = O(\sqrt{m})$. The construction in [88] was based on finite fields and difference sets (or the so called *finite geometries*), and the topic directly considered was that of exact Λ_p-sets for even integers $p \geq 4$. This leads to another question: finding explicit exact Λ_p-sets for other values of p; for definitions and probabilistic results see [17], [106], [18].

A very interesting result (whose relevance is not completely clear yet) in the direction of Problem 4.2 was obtained in [15], which – in our language – contains a constructive version of the quotient of a subspace Theorem 3.1 for the simplex. [See also [77], where this and many more related issues are discussed.]

Theorem 4.3. *Given $n \in \mathbb{N}$, there exists a set $S \subset \mathbb{R}^n$ which is an explicit affine image of an explicit section of the $5n$-dimensional simplex and which verifies*

$$B_2^n \subset S \subset C B_2^n.$$

Moreover, C can be replaced by $1+\varepsilon$, for $\varepsilon \in (0, 1)$, if we use a simplex of dimension $\geq C_1 n \log(2/\varepsilon)$.

One thus finds an explicit approximate of the n-dimensional Euclidean ball B_2^n "hidden" in the $5n$-dimensional simplex. The original motivation for Theorem 4.3 was approximating *quadratic programming* problems by *linear programming* problems while increasing the size of a problem only moderately. Here n is the size of the original quadratic problem related to the Euclidean ball, or to an ellipsoid. The dimension of the simplex corresponds to the size of the linear problem (its faces represent constraints), with the increase in size related to the number of auxiliary variables. Representing auxiliary variables in terms of the original variables corresponds to a section of the simplex, and the affine image, or projection, corresponds to verifying whether there is a point with certain coordinates pre-assigned which verifies the constraints. Finally, ε is the precision of the approximation. We emphasize the very weak dependence of the increase in dimension on ε; it is more standard in similar statements in geometric functional analysis to have in place of $\log(2/\varepsilon)$ a factor which is a power of ε (we again refer to the article [48] in this collection for a more detailed discussion of the almost isometric theory, where this particular issue more properly belongs). This is another indication of possible advantages of explicit objects over random ones.

It is not clear whether the approach of [15] can be developed to handle the symmetric case corresponding to a constructive Dvoretzky theorem for ℓ_1^m (closely related to Problem 4.2), or even to a constructive version of Theorem 3.1 for that space. In any case, it seems that the more directly relevant point of view is here the dual form of the Dvoretzky theorem, or of the Kashin decomposition: find an explicit projection, or an affine image, of the m-dimensional cube (the unit ball of ℓ_∞^m) which approximates a Euclidean ball of dimension $\approx cm$.

A vaguely similar topic in that it connects algorithmic issues (approximating, this time in the *isomorphic* sense, problems in combinatorial optimization by their *semi-definite relaxations*) with functional analytic phenomena (*Grothendieck-type inequalities* and the geometry of various high dimensional convex sets) has been studied, among others, in [4], [67], [3], [47]; see the first three of these articles and [77], and their references, for the background. The same circle of ideas, related to inhomogeneity of high dimensional cubes and linked to some of the issues discussed in Section 3, led to the solution – in the negative, for large dimensions – of the following (central case of the) well-known problem of Knaster stated in 1946 in the *New Scottish Book* and published in 1947 in [49]: *Given a continuous function on the sphere in $\mathbb{R}^n$ and a configuration of n points on that sphere, is there a rotation of the configuration on which the function is constant?* See [46] for details and for the background. We refer to [39] for improvements yielding (negative) solutions also for moderate dimensions (at this point the answer is unknown for n between 4 and about 60; the answer is affirmative for $n < 4$) and to [71] for a link between Knaster-like statements and precise versions of Dvoretzky theorem. [Some such statements may still be true, see [46].]

4.2. Decreasing randomness and expander graphs. A significant step in the direction of the problems stated or hinted in the preceding subsection was made in [10]. The approach of that paper uses the paradigm introduced earlier in combinatorics and computer science: if we do not know how to completely dispense with randomness in certain construction, let us at least reduce the number of random bits needed to implement the construction; see [2] for an early article in that direction, usually referred to as the *combinatorial derandomization*. As in [2], pseudorandomness is brought in by *pseudorandom expander graphs* based on Kazhdan property T for groups (see [62], [57]). Rather than flipping the coin $2n^2$ times to obtain a $n \times 2n$ matrix of ± 1's, which represents a linear map from $\mathbb{R}^{2n}$ to $\mathbb{R}^n$ whose kernel is typically an n-dimensional subspace of $\mathbb{R}^{2n}$, one identifies the 2^{2n} possible rows of such matrix (i.e., vectors of length $2n$ with ± 1 coordinates) with vertices of an appropriate explicit expander graph, and then decides which vertices/rows to use by performing a random walk on that graph. Obtaining n rows requires n (or $n-1$) steps, for which we need approximately $n \log_2 d$ random bits (where d is the degree of the graph), to which we need to add $2n$ bits for a random choice of the starting point. Specifics depend on a particular problem considered (the technical details are no longer primarily combinatorial, but field specific), for example to obtain a nearly Euclidean n-dimensional subspace of

ℓ_1^{2n} (or a partially derandomized Dvoretzky theorem for that space), d can be chosen to be polynomial in n and so the cost in random bits is of order $n \log n$.

This is an extremely interesting and promising approach. In addition to Dvoretzky theorem for ℓ_1^n, the authors of [10] partially derandomize, among others, the quotient of a subspace Theorem 3.1. Full derandomization does not seem to be possible there since the initial space X is not concrete; alternatively, the hypothesis would need to include conditions on the presentation of X. This example, while pointing to the "more correct" questions that should be asked in certain contexts, also reveals the limitations of the approach. However, progress beyond those limitations may conceivably be possible if one uses the more sophisticated pseudorandom techniques from, say, [58], [89], the contributions whose full implications have not been completely "digested" yet.

It is interesting to note that, in addition to the *classical* theoretical computer science, the same paradigm (from randomizing to partial derandomizing) and the same underlying techniques have been exploited in the *quantum information theory*, see [36], [6]; this circle of ideas also vaguely relates to random codes from Subsection 4.4 below. Thus one may hope that the interaction of asymptotic geometric analysis and the quantum theory expands beyond the initial encounters such as [12], [100].

4.3. Reducibility of matrices and the property τ. An $n \times n$ matrix M is said to be reducible if, in some orthonormal basis, it can be written as a block matrix

$$M = \begin{bmatrix} M_1 & 0 \\ 0 & M_2 \end{bmatrix},$$

where M_1 and M_2 are square matrices of sizes which are (necessarily) between 1 and $n-1$. This is equivalent to M commuting with a nontrivial orthogonal projection. Based on an analysis of a large class of natural examples it was suggested around 1980 that, as n increases to ∞, the reducible matrices may become more and more dense in the space of all $n \times n$ matrices. A confirmation of this fact from "experimental mathematics" would have had interesting consequences in the theory of quasidiagonal operators, and (likely) some useful implications for numerical linear algebra. However, this hope was soon laid to rest by the following result [37]

Theorem 4.4. *There is a computable constant $c > 0$ such that for every $n \geq 2$ there is an $n \times n$ (real or complex) matrix of norm one which cannot be approximated within c by a reducible matrix.*

The argument given in [37] was non-constructive, the "poorly" reducible matrices being random (albeit of a somewhat special form), and the value of c obtained there was of order 10^{-7}. A construction yielding explicit pseudorandom matrices which are poorly approximable by reducible matrices was given recently in [16] (cf. [99], [109]). The construction in [16] is based on property τ from representation theory.

[A preprint containing a simpler, but weaker, version using Kazhdan's property T was circulated among some specialists in 2002.] The construction depends on noting that a unitary representation $g \to \pi(g)$ on $\mathbb{C}^n$ is irreducible iff the adjoint representation $g \to \mathrm{Ad}_\pi(g)$, defined by $\mathrm{Ad}_\pi(g)(X) := \pi(g)X\pi(g)^*$, does not have non-trivial fixed points when restricted to (the invariant subspace of) trace zero $n \times n$ matrices. On the other hand, the property T (or τ) of a group G says, roughly, that every failure of a unitary representation ρ of G to have non-trivial fixed points can be witnessed in a uniform way on the finite set $S = \{\rho(g_1), \ldots, \rho(g_k)\}$, where $g_1, \ldots, g_k$ are generators of G (independent of ρ). Careful but elementary calculations involving various matrix ideal norms show then that irreducibility of ρ can be likewise (uniformly) witnessed on S, and the argument is concluded, as in [37], by producing an appropriate block matrix some of whose entries are elements of S. The key point in the argument is that k and the estimates quantifying irreducibility and lack of non-trivial fixed points are independent of the dimension of the representation (of course, to begin with, we need to choose a group which – in addition to possessing property τ – has many finite dimensional representations; e.g., $\mathrm{SL}_2(\mathbb{Z})$ fulfills this role well). Again, as a bonus, we get a constant c which is better than that in [37] by several orders of magnitude.

While this argument appears to be tightly connected to the Hilbert space structure and, accordingly, not immediately applicable to our more general setting of normed spaces, it is conceivable that (for example) by considering specific instances of the principle that is behind the construction, and by appealing in a deeper way to their structure, one may obtain pseudorandom matrices that are of relevance to some of the questions suggested elsewhere in this article. [The fact that Hilbert spaces are *the* setting for property T or τ is not disqualifying *per se*; in fact, constructions of, say, random bodies typically appeal to Euclidean structures of the underlying spaces by working, e.g., with Gaussian measures.]

4.4. Random linear codes and other topics. Other situations calling for pseudorandom models that have been mentioned in this article are Gluskin-type random Banach spaces [31], [32], [97], [98], [59], some of which are implicit in Section 3.1, or the spaces exemplifying the saturation phenomenon from Section 3.3. We point out that while the latter spaces depend on the initial, *a priori* arbitrary lower dimensional space W with which we saturate them, the dependence is very canonical. Indeed, what really counts is the arrangement of a finite family of lower dimensional subspaces in the larger space, just as Gluskin-type spaces exploited, in a sense, arrangements of finite sets of points. A construction that comes to mind here is [52], which, in particular, contains a successful derandomization of the example of a space with several extremal parameters, including the so called unconditional basis constant, given previously in [28] as an application of non-constructive Kashin decomposition (Theorem 4.1). However, the approach of [52] is based on spherical codes constructed via finite geometries and so its applicability seems somewhat limited, cf. our discussion of [88] in the paragraph following Theorem 4.1.

Another, quite different question is related to modeling free random variables in

free probability (see [110], [112], [111], [38]) with independent random matrices of increasing size. Due to the apparent central role of the idea of *freeness* in the subject of random matrices it would be very interesting to have also sufficiently canonical pseudorandom models (we note that there exist here constructions based on Clifford matrices [110], [94] which are, however, not fully satisfactory).

We conclude by describing briefly one more development that occurred recently on the border of high-dimensional convexity and computer science and which concerns self-correcting linear codes. The context is roughly as follows. We want to transmit a signal which is a vector $x \in \mathbb{R}^n$. Since some coordinates may get corrupted in the transmission, we introduce some *redundancy* by transmitting instead the vector $y = Ax \in \mathbb{R}^N$, where A is an $N \times n$ matrix independent of x and N is larger, but *not much larger* than n. We then hope that if not too many of the coordinates of y get corrupted in the transmission, then we will be able to recover, in a robust way, the original signal x. In this context, some specific efficient strategies (based on linear programming) for recovery of the original signal along this line were proposed by Donoho and his collaborators (see, e.g., [25] and references in [22]), and existence of very efficient codes, with redundancy close to the theoretical minimum (which depends, of course, on the reliability of the transmission channel) was shown in [23], [87], [22]. However, in a twist which is reminiscent of the classical random *Shannon codes* [93], in the most efficient encoding schemes the matrix A is not explicit! This is not the worst possible scenario since once an appropriate A (of given size) is found in the pre-processing stage, it subsequently can be repeatedly used to encode *all possible* signals $x \in \mathbb{R}^n$. However, in spite of some promising leads, fully satisfactory constructive and algorithmically efficient methods for producing large encoding matrices are still missing here.

We refer the reader to [21] for more background on the topic mentioned above and for other information/communication theory problems that have a similar flavor, and to [66] for a study of linear encoding for random models more general than that of [23], [87], [22] (but still employing the same setup involving vectors from $\mathbb{R}^n$ and $\mathbb{R}^N$).

Higher index theory of elliptic operators and geometry of groups

Guoliang Yu*

Abstract. The Atiyah–Singer index theorem has been vastly generalized to higher index theory for elliptic operators in the context of noncommutative geometry. Higher index theory has important applications to problems in differential topology and differential geometry such as the Novikov Conjecture on homotopy invariance of higher signatures and the existence problem of Riemannian metrics with positive scalar curvature. In this article, I will give a survey on recent development of higher index theory, its applications, and its fascinating connection to the geometry of groups and metric spaces.

Mathematics Subject Classification (2000). Primary 46L87, 58J20; Secondary 46L80, 20F65.

Keywords. Noncommutative geometry, index theory, elliptic operator, K-theory, operator algebras, metric geometry, geometric group theory.

1. Introduction

An elliptic differential operator D on a compact manifold M is Fredholm in the sense that the kernel and cokernel of D are finite dimensional and the image of D is closed. The Fredholm index of D is defined to be

$$\operatorname{index}(D) = \dim(\ker D) - \dim(\operatorname{coker} D).$$

Roughly speaking, $\operatorname{index}(D)$ measures the size of the solution space of a certain system of differential equations associated to D. The Fredholm index has the following fundamental properties: (1) it is an obstruction to invertibility of D; (2) it is invariant under homotopy equivalence. These are essential properties for the purpose of applications. The celebrated Atiyah–Singer index theorem computes the Fredholm index of elliptic differential operators on compact manifolds and has important applications [4].

Elliptic differential operators on noncompact manifolds are in general not Fredholm in the usual sense but Fredholm in a generalized sense. The generalized Fredholm index for such operators is called the higher index. Higher index theories for elliptic operators in various noncompact situations have been successfully developed

by Kasparov [51], [52], Mishchenko–Fomenko [60], Baum–Connes [6], Connes–Skandalis [23], Connes–Moscovici [22], and Roe [67]. In this survey, we will focus on higher index theory in the following two cases: (1) noncompact manifolds with proper and free cocompact actions of discrete groups, (2) noncompact complete Riemannian manifolds.

In the case of a manifold $\tilde{M}$ with a proper and free cocompact action of a discrete group Γ, let M be the compact quotient $\tilde{M}/\Gamma$, let D be an elliptic differential operator on M and let $\tilde{D}$ be the lifting of D to $\tilde{M}$. $\tilde{D}$ is a generalized Fredholm operator and its generalized Fredholm index is an element in the K-theory of the reduced group C^*-algebra $C^*_r(\Gamma)$ [51], [52], [60], [6]. The Fredholm index of D is essentially the 0-dimensional information of the generalized Fredholm index of $\tilde{D}$. For this reason, the generalized Fredholm index of $\tilde{D}$ is called the higher index of $\tilde{D}$. The higher index of $\tilde{D}$, denoted by H-index$(\tilde{D})$, has properties similar to that of the classical Fredholm index: (1) H-index$(\tilde{D})$ is an obstruction to invertibility of $\tilde{D}$; (2) H-index$(\tilde{D})$ is invariant under homotopy equivalence. These properties are crucial for purpose of applications. For example, property (1) implies that if H-index$(\tilde{D})$ is non-zero for the Dirac operator, then the manifold M can not carry a Riemannian metric of positive scalar curvature (as a consequence of the Lichnerowicz formula, positive scalar curvature implies that the Dirac operator $\tilde{D}$ is invertible) [69]. The Baum–Connes Conjecture provides an algorithm to compute the higher index of $\tilde{D}$. The Baum–Connes Conjecture was proved by Higson–Kasparov when Γ has the Haagerup property (e.g. all amenable groups) [43] and by Lafforgue for a large class of groups with Property T [56]. I should also mention important work by Puschnigg [66] and Chabert–Echterhoff–Nest [14]. The general problem of computing the higher index of $\tilde{D}$ is still wide open. However, for the purpose of applications to geometry and topology, it is often enough to determine when the higher index is non-zero. The Strong Novikov Conjecture is an algorithm of determining non-vanishing of the higher index. Currently much more is known about this conjecture than the Baum–Connes Conjecture. In this article, we will focus on the recent development of the Strong Novikov Conjecture.

In the case of a general noncompact complete Riemannian manifold M, Roe has introduced a higher index theory for elliptic differential operators on M [67]. The Coarse Baum–Connes Conjecture is an algorithm to compute the higher index of elliptic differential operators on noncompact complete Riemannian manifolds. This conjecture has been proved for a large class of interesting spaces. In general, there are counter-examples to the Coarse Baum–Connes Conjecture [80], [44]. The Coarse Strong Novikov Conjecture is an algorithm of determining non-vanishing of the higher index. There is an unbounded geometry counter-example to this conjecture [80]. This conjecture is still open for spaces with bounded geometry. In this article, we will also report recent progress on the Coarse Baum–Connes Conjecture and the Coarse Strong Novikov Conjecture.

There is a beautiful link between higher index theory and a certain aspect of metric geometry. At this stage, this part of metric geometry is mostly uncharted territory.

One purpose of this survey is to advertise this aspect of metric geometry.

We remark that all manifolds in this article are smooth.

2. Higher index theory of elliptic operators

In this section we briefly review the higher index theory of elliptic operators. The first part of this section is devoted to higher index theory for noncompact manifolds with a proper and free cocompact action of a discrete group [51], [52], [60], [6]. In the second part of this section, we discuss higher index theory for noncompact complete Riemannian manifolds [67].

2.1. Higher index theory and discrete groups. Let Γ be a discrete group acting properly and freely on a manifold $\tilde{M}$ with compact quotient $M = \tilde{M}/\Gamma$.

We first recall the concept of the reduced group C^*-algebra for any countable discrete group Γ.

Let $l^2(\Gamma)$ be the Hilbert space defined by

$$l^2(\Gamma) = \{\xi : \Gamma \to \mathbb{C} \mid \textstyle\sum_{\gamma\in\Gamma} |\xi(\gamma)|^2 < \infty\}.$$

For each $g \in \Gamma$ we define a unitary operator U_g acting on $l^2(\Gamma)$ by

$$(U_g\xi)(\gamma) = \xi(g^{-1}\gamma)$$

for all $\xi \in l^2(\Gamma)$ and $\gamma \in \Gamma$.

We define the group algebra $\mathbb{C}\Gamma$ by

$$\mathbb{C}\Gamma = \{ \textstyle\sum_{g\in\Gamma} c_g U_g : c_g \in \mathbb{C}\},$$

where $\sum_{g\in\Gamma} c_g U_g$ is a finite sum. Observe that $\mathbb{C}\Gamma$ is an algebra over $\mathbb{C}$.

Definition 2.1. The *reduced* group C^*-algebra $C_r^*(\Gamma)$ is the closure of $\mathbb{C}\Gamma$ under operator norm.

In general, $C_r^*(\Gamma)$ is a highly noncommutative C^*-algebra and is a typical example of a "noncommutative space" in Connes' noncommutative geometry [16].

Let D be an elliptic differential operator on the compact manifold M. Let $\tilde{D}$ be the lifting of D to $\tilde{M}$. Recall that a classical theorem in functional analysis says that an operator is Fredholm if and only if it is invertible modulo K, the algebra of all compact operators. $\tilde{D}$ is in general not Fredholm. However, $\tilde{D}$ is a generalized Fredholm operator in the sense that $\tilde{D}$ is invertible modulo $C_r^*(\Gamma) \otimes K$. By a standard procedure in K-theory, one can define the higher index of $\tilde{D}$, denoted by H-index$(\tilde{D})$, as an element of the K-group $K_0(C_r^*(\Gamma))$. When D is a self-adjoint elliptic differential operator, we can define the higher index of $\tilde{D}$, denoted by H-index$(\tilde{D})$, as an element of the K-group $K_1(C_r^*(\Gamma))$. The higher index of $\tilde{D}$ has the following important

properties: (1) it is an obstruction to invertibility of $\tilde{D}$, (2) it is invariant under homotopy equivalence of $\tilde{D}$.

Let $\mathrm{tr}\colon C_r^*(\Gamma) \to \mathbb{C}$ be the canonical trace defined by

$$\mathrm{tr}(T) = \langle T\delta_e, \delta_e \rangle$$

for every $T \in C_r^*(\Gamma)$, where $\delta_e \in l^2(\Gamma)$ is the Dirac function at the identity element e of the group Γ. This trace induces a homomorphism

$$\mathrm{tr}_*\colon K_0(C_r^*(\Gamma)) \to \mathbb{C}.$$

Atiyah's L^2-index theorem in [3] implies the following identity:

$$\mathrm{tr}_*(H\text{-index}(\tilde{D})) = \mathrm{index}(D).$$

It follows that the Fredholm index of D is the 0-dimensional information of the higher index of $\tilde{D}$.

Let Z be a locally compact space with a proper cocompact Γ-action. The Γ-equivariant K-homology group $K_0^\Gamma(Z)$ is generated by all Γ-invariant "abstract elliptic operators" on Z [51], [52]. Similarly, the Γ-equivariant K-homology group $K_1^\Gamma(Z)$ is generated by all Γ-invariant self-adjoint "abstract elliptic operators" on Z.

Let $\mathcal{E}\Gamma$ be the universal space for proper Γ-actions [7]. The Γ-equivariant K-homology group $K_*^\Gamma(\mathcal{E}\Gamma)$ is defined to be the inductive limit

$$\lim_{Z \subseteq \mathcal{E}\Gamma} K_*^\Gamma(Z),$$

where the inductive limit is taken over all Γ-invariant and Γ-cocompact subsets of $\mathcal{E}\Gamma$.

The Baum–Connes map μ associates each Γ-invariant "abstract elliptic operator" to its higher index:

$$\mu\colon K_*^\Gamma(\mathcal{E}\Gamma) \to K_*(C_r^*(\Gamma)).$$

Conjecture 2.2 (*The Baum–Connes Conjecture* [6], [7]). Let Γ be a countable discrete group. The Baum–Connes map $\mu\colon K_*^\Gamma(\mathcal{E}\Gamma) \to K_*(C_r^*(\Gamma))$ is an isomorphism for Γ.

Let Γ be a discrete group acting properly and freely on a manifold $\tilde{M}$ with compact quotient $M = \tilde{M}/\Gamma$. Let D be an elliptic differential operator on M and $\tilde{D}$ be its lifting to $\tilde{M}$. Denote by $[\tilde{D}]$ the K-homology class of $\tilde{D}$ in $K_*^\Gamma(\tilde{M})$. By the universality of $\mathcal{E}\Gamma$, there exists a Γ-invariant classifying map $f\colon \tilde{M} \to \mathcal{E}\Gamma$.

We have

$$H\text{-index}(\tilde{D}) = \mu(f_*[\tilde{D}]).$$

It follows that the Baum–Connes Conjecture would reduce the computation of the higher index H-index$(\tilde{D})$ to that of $f_*[\tilde{D}]$ in $K_*^\Gamma(\mathcal{E}\Gamma)$, which is in principle computable.

Conjecture 2.3 (*The Strong Novikov Conjecture*). Let Γ be a countable discrete group. The Baum–Connes map $\mu\colon K_*^\Gamma(\mathcal{E}\Gamma) \to K_*(C_r^*(\Gamma))$ is injective for Γ.

The Strong Novikov Conjecture would reduce the non-vanishing problem of the higher index H-index$(\tilde{D})$ to that of $f_*[\tilde{D}]$ in $K_*^\Gamma(\mathcal{E}\Gamma)$, which is in principle decidable.

If M is an aspherical compact manifold (i.e. its universal cover is contractible), the Strong Novikov Conjecture implies the Gromov–Lawson Conjecture which claims that an aspherical compact manifold can not carry a Riemannian metric with positive scalar curvature [67]. Let Γ be the fundamental group of M and $\tilde{M}$ be the universal cover of M. In this case f_* is an isomorphism and the Strong Novikov Conjecture implies that the higher index of the Dirac operator is non-zero [67]. However, by the Lichnerowicz formula, positive scalar curvature would imply invertibility of the Dirac operator. In general, the Strong Novikov Conjecture implies a stable version of the Gromov–Lawson–Rosenberg Conjecture [73]. This stable version of the Gromov–Lawson–Rosenberg Conjecture provides a complete answer to the question when a compact manifold can stably carry a Riemannian metric with positive scalar curvature.

Another very important corollary of the Strong Novikov Conjecture is the Novikov Conjecture on homotopy invariance of higher signatures. The Novikov Conjecture is a central problem in the classification of higher dimensional compact manifolds (see [32] for a historic account of the Novikov Conjecture). In the case of aspherical compact manifolds, the Novikov Conjecture states that rational Pontryagin classes are homotopy invariants. In this case the Novikov Conjecture can be considered as an infinitesimal version of the Borel Conjecture, which claims that any aspherical compact manifold M is rigid in the sense that if another compact manifold M' is homotopy equivalent to M, then M' is homeomorphic to M. The Strong Novikov Conjecture implies an integral version of the Novikov Conjecture in L-theory after inverting 2 [70]. This integral version of the Novikov Conjecture implies the stable Borel Conjecture which states that if a compact manifold M is aspherical and another compact manifold M' is homotopy equivalent to M, then $M' \times \mathbb{R}^n$ is homeomorphic to $M \times \mathbb{R}^n$ for some large n [31].

2.2. Higher index theory for noncompact complete Riemannian manifolds. We shall briefly review Roe's higher index theory for noncompact complete Riemannian manifolds [67].

We first recall the concept of Roe algebra. Let Γ be a locally finite discrete metric space (recall that a discrete metric space is said to be locally finite if every ball has finitely many elements). Let H be a separable and infinite dimensional Hilbert space. We decompose

$$l^2(\Gamma) \otimes H = \oplus_{\gamma \in \Gamma}(\delta_\gamma \otimes H),$$

where $\delta_\gamma \in l^2(\Gamma)$ is the Dirac function at γ. For each bounded linear operator $T : l^2(\Gamma) \otimes H \to l^2(\Gamma) \otimes H$, we have a corresponding decomposition:

$$T = (T_{x,y})_{x,y \in \Gamma},$$

where $T_{x,y}$ is a bounded linear operator from $\delta_y \otimes H$ to $\delta_x \otimes H$.

Definition 2.4 (Roe [67]). Let Γ be a locally finite discrete metric space.

(1) A bounded linear operator $T: l^2(\Gamma) \otimes H \to l^2(\Gamma) \otimes H$ is said to be *locally compact* if $T_{x,y}$ is compact for all $x, y \in \Gamma$;

(2) A bounded linear operator $T: l^2(\Gamma) \otimes H \to l^2(\Gamma) \otimes H$ is said to have *finite propagation* if there exists $R \geq 0$ such that $T_{x,y} = 0$ for all $x, y \in \Gamma$ satisfying $d(x, y) > R$.

(3) The *Roe algebra* $C^*(\Gamma)$ is defined to be the operator norm closure of all locally compact operators acting on $l^2(\Gamma) \otimes H$ with finite propagation.

An important feature of the Roe algebra is that, up to $*$-isomorphism, it depends only on the quasi-isometry type (or more generally the coarse type) of the locally finite discrete metric space.

If Z is a locally compact metric space, we choose a net Γ in Z and define the Roe algebra $C^*(Z)$ by $C^*(\Gamma)$. Recall that a locally finite discrete subspace $\Gamma \subseteq Z$ is said to be a net if there exists $c \geq 0$ satisfying $d(z, \Gamma) \leq c$ for every $z \in Z$. We observe that the definition of $C^*(Z)$ is independent of the choice of Γ up to $*$-isomorphism.

If M is a noncompact complete Riemannian manifold and D is a geometric elliptic operator on M, then D is a generalized Fredholm operator in the sense that it is invertible modulo $C^*(M)$. One can define a higher index, denoted by H-index(D), as an element of the K-group $K_0(C^*(M))$ [67]. Similarly when D is a self-adjoint geometric elliptic operator on M, one can define a higher index, denoted by H-index(D), as an element of the K-group $K_1(C^*(M))$. This higher index is an obstruction to invertibility and is invariant under homotopy equivalence.

Definition 2.5. Let Γ be a locally finite metric space. For each $d \geq 0$, the *Rips complex* $P_d(\Gamma)$ is the simplicial polyhedron where the set of all vertices is Γ, and a finite subset $\{\gamma_0, \ldots, \gamma_n\} \subseteq \Gamma$ spans a simplex iff $d(\gamma_i, \gamma_j) \leq d$ for all $0 \leq i, j \leq n$.

Let Z be a locally compact space. Recall that the K-homology group $K_0(Z)$ is generated by all "abstract elliptic operators" on Z [51], [52]. Similarly, the K-homology group $K_1(Z)$ is generated by all self-adjoint "abstract elliptic operators" on Z.

Let Γ be a locally finite discrete metric space. The coarse Baum–Connes map μ associates every "abstract elliptic operator" to its higher index:

$$\mu: \lim_{d \to \infty} K_*(P_d(\Gamma)) \to K_*(C^*(\Gamma)).$$

Conjecture 2.6 (*The Coarse Baum–Connes Conjecture* [45], [78]). If Γ is a locally finite discrete metric space, then the coarse Baum–Connes map μ is an isomorphism.

If Γ is a countable discrete group with a length metric and its classifying space $B\Gamma$ has the homotopy type of a finite CW-complex, then the descent principle says that the Coarse Baum–Connes Conjecture for Γ as a metric space implies the Strong Novikov Conjecture for Γ as a group [68].

Recall that a function $l: \Gamma \to [0, \infty)$ is said to be a length function if

(1) $l(g) = 0$ for some $g \in \Gamma$ if and only if g is the identity element;

(2) $l(g) = l(g^{-1})$ for all $g \in \Gamma$ and $l(g_1 g_2) \leq l(g_1) + l(g_2)$ for all g_1 and g_2 in Γ;

(3) l is proper in the sense that $l^{-1}(K)$ is a finite subset of Γ for every compact subset K of $[0, \infty)$.

We remark that such a length function always exists for any countable discrete group. If Γ is a finitely generated group, we can construct a word length for any finite generating set. For any length function l on a countable group Γ, we can associate a length metric d on Γ by: $d(g_1, g_2) = l(g_1^{-1} g_2)$ for all g_1 and g_2 in Γ. We remark that a countable discrete group with a length metric has bounded geometry (recall that a discrete metric space Γ is said to have bounded geometry if for all $r > 0$ there exists $N(r) > 0$ such that the number of elements in every ball with radius r is at most $N(r)$).

A counterexample to the injectivity of the coarse Baum–Connes map is found in [81]. However, this example does not have bounded geometry. A bounded geometry counterexample to surjectivity is found in [44].

The following conjecture is still wide open.

Conjecture 2.7 (*The Coarse Strong Novikov Conjecture*). If Γ is a discrete metric space with bounded geometry, then the coarse Baum–Connes map μ is injective.

If M is a noncompact complete Riemannian manifold with bounded geometry (i.e. M has bounded curvature and positive injectivity radius), then there exists a net Γ in M such that Γ has bounded geometry. Let $\{U_\gamma\}_{\gamma \in \Gamma}$ be an open cover of M such that $\gamma \in U_\gamma$ for each $\gamma \in \Gamma$ and $\{\text{diameter}(U_\gamma)\}_{\gamma \in \Gamma}$ is uniformly bounded. Let $\{\phi_\gamma\}_{\gamma \in \Gamma}$ be a partition of unity subordinate to $\{U_\gamma\}_{\gamma \in \Gamma}$. We define a continuous map $\phi \colon M \to P_d(\Gamma)$ for some large d by

$$\phi(x) = \sum_{\gamma \in \Gamma} \phi_\gamma(x)\gamma$$

for all $x \in M$.

Let D be a geometric elliptic operator on M and $[D]$ be its K-homology class in $K_*(M)$.

We have

$$H\text{-index}(D) = \mu(\phi_*[D]).$$

It follows that the Coarse Strong Novikov Conjecture would reduce the non-vanishing problem of H-index(D) to that of $\phi_*([D])$ in $\lim_{d \to \infty} K_*(P_d(\Gamma))$, which is in principle decidable.

Recall that a Riemannian manifold M is said to be uniformly contractible if for every $r > 0$, there exists $R \geq r$ such that for each $x \in M$, the ball with radius r and center x can be contracted to a point within the ball with radius R and center x. If M is a uniformly contractible Riemannian manifold with bounded geometry, then the Coarse

Strong Novikov Conjecture implies a conjecture of Gromov which states that M can not have uniform positive scalar curvature [36]. In this case ϕ_* is an isomorphism and therefore the Coarse Strong Novikov Conjecture implies that the higher index of the Dirac operator is non-zero. However, by the Lichnerowicz formula, uniform positive scalar curvature would imply invertibility of the Dirac operator.

3. Geometry of groups and metric spaces

In this section we briefly discuss several useful concepts from metric geometry. These concepts play important roles in higher index theory.

The following concept plays an important role in the study of Novikov type conjectures.

Definition 3.1 (Gromov [35]). Let Γ be a metric space; let X be a Banach space. A map $f\colon \Gamma \to X$ is said to be a (*coarse*) *uniform embedding* if there exist non-decreasing functions ρ_1 and ρ_2 from $\mathbb{R}_+ = [0, \infty)$ to $\mathbb{R}$ such that

(1) $\rho_1(d(x, y)) \leq \|f(x) - f(y)\| \leq \rho_2(d(x, y))$ for all $x, y \in \Gamma$;

(2) $\lim_{r\to+\infty} \rho_i(r) = +\infty$ for $i = 1, 2$.

Intuitively (coarse) uniform embeddability of a metric space Γ into a Banach space X means that we can draw a "nice" picture of Γ in X which reflects the large scale geometry of Γ. If Γ is a countable discrete group with a length metric, the concept of (coarse) uniform embeddability of Γ into a Banach space X does not depend on the choice of the length metric.

The following construction implies that every discrete metric space admits a (coarse) uniform embedding into some Banach space, and we need to consider reasonably nice Banach spaces to do anything interesting.

Let Γ be a discrete metric space, let $X = l^\infty(\Gamma)$. Fix $x_0 \in \Gamma$. We define an isometric embedding of Γ into X by

$$(f(x))(\gamma) = d(\gamma, x) - d(\gamma, x_0)$$

for every $x, \gamma \in \Gamma$.

The Hilbert space case is particularly important. Examples of groups which admit (coarse) uniform embedding into Hilbert space include

(1) amenable groups (Bekka–Cherix–Valette [8]);

(2) groups with finite asymptotic dimension (e.g. a certain mapping class groups [9]), more generally groups with polynomial asymptotic dimension growth [26];

(3) hyperbolic groups [71], more generally a class of relatively hyperbolic groups [62], [65], [25];

(4) countable subgroups of any almost connected Lie groups (Guentner–Higson–Weinberger [39]);

(5) Coxeter groups [29], more generally certain diagram groups (including R. Thompson's group F) [30], [12], [1];

(6) semi-direct products of groups of the above types.

In [34], Gong–Yu proved that a noncompact Riemannian manifold with subexponential volume growth admits a (coarse) uniform embedding into Hilbert space.

The following concept provides the most effective method to construct (coarse) uniform embedding into Hilbert space.

Definition 3.2 ([81]). A locally finite discrete metric space Γ is said to have *Property A* if for any $r > 0$, $\varepsilon > 0$, there exist a family of finite subsets $\{A_\gamma\}_{\gamma\in\Gamma}$ of $\Gamma \times \mathbb{N}$ ($\mathbb{N}$ is the set of all natural numbers) such that

(1) $(\gamma, 1) \in A_\gamma$ for all $\gamma \in \Gamma$;

(2) if γ and γ' are two points in Γ satisfying $d(\gamma, \gamma') \leq r$, then

$$\frac{\#(A_\gamma - A_{\gamma'}) + \#(A_{\gamma'} - A_\gamma)}{\#(A_\gamma \cap A_{\gamma'})} < \varepsilon,$$

where $\#S$ is the number of elements in S for any finite set S;

(3) there exists $R > 0$ such that if $(x, m) \in A_\gamma$, $(y, n) \in A_\gamma$ for some $\gamma \in \Gamma$, then $d(x, y) \leq R$.

The set of natural numbers $\mathbb{N}$ in the above definition allows one to count points in Γ with multiplicity. We remark that the concept of Property A is invariant under quasi-isometry (more generally it is invariant under coarse equivalence). If Z is a locally compact metric space, we say that Z has Property A if a net Γ of Z has Property A.

Proposition 3.3 (Yu [81]). *If a locally compact metric space Z has Property A, then Z admits a (coarse) uniform embedding into Hilbert space.*

In the case of a countable discrete group Γ with a length metric, Higson–Roe proved that Γ has Property A if and only if Γ acts amenably on some compact space [46]. Guentner–Kaminker proved that a certain exactness of the reduced group C^*-algebra $C^*_r(\Gamma)$ implies that Γ admits a (coarse) uniform embedding into Hilbert space [40]. Ozawa further proved that exactness of the reduced group C^*-algebra $C^*_r(\Gamma)$ is equivalent to Property A of Γ [63]. In [15], Chen–Wang established a very nice connection between Property A and the ideal structure of the Roe algebra.

Many of the known examples of locally finite discrete metric spaces (coarsely) uniformly embeddable into Hilbert space have Property A. In a recent paper [61], Nowak constructed the first example of a locally finite discrete metric spaces which does not have Property A, but admits a (coarse) uniform embedding into Hilbert space.

Based on ideas of Enflo, Dranishnikov–Gong–Lafforgue–Yu found the first example of a locally finite discrete metric space which does not admit a (coarse) uniform

embedding into Hilbert space [28]. But this example does not have bounded geometry. In [37], Gromov used expanding graphs to construct examples of discrete metric spaces with bounded geometry and also finitely generated groups which do not admit a (coarse) uniform embedding into Hilbert space.

For purpose of the Novikov Conjecture, we need to introduce the following convexity conditions for Banach spaces.

Definition 3.4. Let X be a Banach space.

(1) X is said to be *strictly convex* if

$$\left\| \frac{x+y}{2} \right\| < 1$$

whenever $x,\ y \in S(X)$ and $x \neq y$, where $S(X) = \{x \in X,\ \|x\| = 1\}$;

(2) X is called *uniformly convex* if for all $\varepsilon > 0$ there exists $\delta > 0$ such that if $x,\ y \in S(X)$ and $\|x - y\| \geq \varepsilon$, then

$$\left\| \frac{x+y}{2} \right\| < 1 - \delta.$$

Examples of uniformly convex Banach spaces include l^p, L^p, and C_p for all $1 < p < \infty$, where C_p is the Banach space of all Schatten-p class operators on a Hilbert space, i.e. $C_p = \{T : H \to H \mid \mathrm{tr}(T^*T)^{\frac{p}{2}} < \infty\}$ (H is a Hilbert space).

N. Brown and E. Guentner proved that every countable discrete metric space admits a (coarse) uniform embedding into a strictly convex and reflexive Banach space [11]. W. B. Johnson and N. L. Randrianarivony showed that l^p $(p > 2)$ does not admit a (coarse) uniform embedding into a Hilbert space [50]. More recently, M. Mendel and A. Naor proved that l^p does not admit a (coarse) uniform embedding into l^q if $p > q \geq 2$ [57].

Problem 3.5. Let $p > q \geq 2$. Construct a discrete metric space with bounded geometry which admits a (coarse) uniform embedding into l^p but not into l^q;

Problem 3.6. Let $p > q \geq 2$. Construct a countable discrete group which admits a (coarse) uniform embedding into l^p but not into l^q.

Such a group would be fascinating in the world of group theory since it is neither among Gromov's random groups [37] nor among the familiar class of groups constructed algebraically using amenable groups, hyperbolic groups and linear groups.

Question 3.7. Does every discrete metric space with bounded geometry admit (coarse) uniform embedding into a uniformly convex Banach space?

A negative answer to this question might reveal a geometric phenomenon leading to counter-examples of the Novikov Conjecture. Of course, a positive answer to the

question would imply the Novikov Conjecture for every countable discrete group [55]. We should mention that Ozawa proved that if X is a uniformly convex Banach space with an unconditional basis, then a sequence of expanding graphs does not admit a (coarse) uniform embedding into X [64].

The following concept plays a very useful role in my work with Kasparov on the Baum–Connes Conjecture (in preparation).

Definition 3.8. Let X be a Banach space and Γ be a countable discrete group. An affine and isometric action α of Γ on X is said to be *proper* if

$$\lim_{l(g)\to\infty} \|\alpha(g)\xi\| = \infty$$

for every $\xi \in X$, where l is a length metric on Γ.

Roughly speaking, if a group Γ admits a proper and affine isometric action on X, it means that Γ can be effectively realized as symmetries of the Banach space X. If α is a proper affine isometric action of Γ on a Banach space X, then the map $\gamma \to \alpha(\gamma)0$ is a (coarse) uniform embedding of Γ into X, where 0 is the zero vector in X.

We remark that the concept of proper affine isometric action does not depend on the choice of the length function. If Γ admits a proper isometric affine action on Hilbert space, then Γ is said to satisfy the Haagerup property [41] or to be a-T-menable [35].

The following example shows that every countable discrete group admits a proper affine isometric action on some Banach space.

Let $X = l^\infty(\Gamma)$. Let π be the regular action of Γ on X defined by

$$((\pi(g))\xi)(\gamma) = \xi(g^{-1}\gamma)$$

for every $\xi \in X$, all g and γ in Γ. We define an affine and isometric action α on X by:

$$\alpha(g)\xi = \pi(g)\xi + \pi(g)l - l$$

for every $\xi \in X$ and $g \in \Gamma$, where l is a length function on Γ. It is not difficult to verify that α is a proper action.

It is well known that an infinite Property T group does not admit a proper affine isometric action on Hilbert space. A theorem of Zuk says that most (infinite) hyperbolic groups have Property T and therefore do not admit a proper affine isometric action on Hilbert space [83]. The following result shows the usefulness of considering more general uniformly convex Banach spaces.

Proposition 3.9 ([82]). *If Γ is a hyperbolic group, then there exists $2 \le p < \infty$ such that Γ admits a proper affine isometric action on an l^p-space.*

A very recent result of Bader–Furman–Gelander–Monod says that $\mathrm{SL}(n, \mathbb{Z})$ does not admit a proper affine isometric action on l^p-spaces if $n \ge 3$ [5]. A natural question is the following.

Question 3.10. Does $\mathrm{SL}(n, \mathbb{Z})$ admit a proper affine isometric action on some uniformly convex Banach space for $n \geq 3$?

A positive answer to this question would have interesting applications to the Baum–Connes Conjecture.

4. Main results

In this section, we briefly discuss several recent results in higher index theory and their applications.

Theorem 4.1 ([81]). *Let Γ be a discrete metric space with bounded geometry. If Γ admits a (coarse) uniform embedding into Hilbert space, then the Coarse Baum–Connes Conjecture is true for Γ.*

The special case of finite asymptotic dimension was first proved in [80] by a controlled operator K-theory method.

Corollary 4.2. *Let M be a uniformly contractible Riemannian manifold with bounded geometry. If M admits a (coarse) uniform embedding into Hilbert space, then M can not have uniform positive scalar curvature.*

Theorem 4.3 ([81], [74]). *Let Γ be a countable discrete group. If Γ admits a (coarse) uniform embedding into Hilbert space, then the Strong Novikov Conjecture holds for Γ.*

By the descent principle, Theorem 4.3 follows from Theorem 4.1 under an additional finiteness assumption on the homotopy type of the classifying space $B\Gamma$ [81]. This finiteness assumption was removed in [74] with the help of a technique introduced by Higson [42] and a theorem of Tu [75].

Corollary 4.4. *The Novikov Higher Signature Conjecture is true if the fundamental group admits a (coarse) uniform embedding into Hilbert space.*

By discussions in Section 2, the Novikov Conjecture is essentially a topological "recognition" problem for compact manifolds. Roughly speaking, Corollary 4.4 says if we can draw a "nice" picture of the fundamental group of a compact manifold in Hilbert space, then we can "recognize" the manifold topologically.

The following result is a generalization of the injectivity part of Theorem 4.1.

Theorem 4.5 ([54]). *Let Γ be a discrete metric space with bounded geometry. If Γ admits a (coarse) uniform embedding into a uniformly convex Banach space, then the Coarse Strong Novikov Conjecture is true for Γ.*

Corollary 4.6. *If a uniformly contractible Riemannian manifold M with bounded geometry admits a (coarse) uniform embedding into a uniformly convex Banach space, then M can not have uniform positive scalar curvature.*

The following result is a generalization of Theorem 4.3.

Theorem 4.7 ([55]). *Let Γ be a countable discrete group. If Γ admits a (coarse) uniform embedding into a uniformly convex Banach space, then the Strong Novikov Conjecture is true for Γ.*

A key ingredient in the proofs of Theorems 4.5 and 4.7 is the construction of an infinite dimensional Bott bundle over the Banach space. Uniform convexity is used to show that this Bott bundle is almost flat in a certain Banach sense.

Corollary 4.8. *The Novikov Higher Signature Conjecture is true if the fundamental group admits a (coarse) uniform embedding into a uniformly convex Banach space.*

We end this survey with the following folklore conjecture.

Conjecture 4.9. Let M be a compact manifold and $\mathrm{Diff}(M)$ be the group of all diffeomorphisms of M. If Γ is a countable subgroup of $\mathrm{Diff}(M)$, then Γ admits a uniform embedding into C_p for some $1 < p < \infty$, where p depends on the dimension of M and C_p is the Banach space of all Schatten-p class operators on Hilbert space.

It is an open question whether every countable subgroup of $\mathrm{Diff}(M)$ for a compact manifold M admits a proper affine isometric action on C_p for some $1 < p < \infty$. This question and Conjecture 4.9 are open even for the case of the circle. If Conjecture 4.9 is true, then Theorem 4.7 implies the Strong Novikov Conjecture for every countable subgroup of $\mathrm{Diff}(M)$ for a compact manifold M.

Note added in proof. Y. Kida has proved that a mapping class group admits a (coarse) uniform embedding into Hilbert space in his recent preprint "The mapping class group from the viewpoint of measure equivalence theory". U. Hamenstädt has independently obtained the same result in her recent preprint "Geometry of the mapping class groups I: Boundary amenability".

On spectral invariants in modern ergodic theory

Oleg N. Ageev *

Abstract. This is a short survey of recent developments in one of the oldest areas of ergodic theory, sometimes called the spectral theory of dynamical systems. We mainly discuss the spectral realization problem in the rich class of all invertible measure preserving dynamical systems, a "behavior" of different spectral invariants in natural subclasses of dynamical systems, and a complete solution of Rokhlin's problem on homogeneous spectrum in ergodic theory.

Mathematics Subject Classification (2000). Primary 37A, 28D; Secondary 47A05, 47A35, 47D03.

Keywords. Ergodic theory, spectral invariants, homogeneous spectrum problem.

1. Introduction

Ergodic theory, also called *measurable dynamics*, studies iterations of a map (a collection of maps forming an image of some (semi) group G with respect to a homomorphism) equipped with at least one (quasi) invariant measure. The maps are called *transformations, automorphisms*, or *dynamical systems* (the collection of maps is called a *G-action*, or a *dynamical system*, where G plays a role of "time").

One of the main classes of dynamical systems is the group of all invertible measure-preserving maps (automorphisms of a σ-algebra of measurable sets) defined on a non-atomic Lebesgue space (X, μ), $\mu(X) = 1$, where the Lebesgue space (X, μ) can be viewed as an interval $[0, 1]$ with the Lebesgue measure. This group is a Polish (complete metrizable separable) topological group, denoted by $\mathrm{Aut}(\mu)$, with respect to the weak (coarse) topology defined by

$$T_n \to T \Leftrightarrow \mu(T_n^{-1} A \Delta T^{-1} A) \to 0 \text{ for each measurable } A$$

(we identify transformations if they are coincide up to a measure zero set). We say that a property holds for a *typical* element from a topological space D if the set of elements with this property contains a dense G_δ-subset of D; in particular, for Polish spaces D a property holds for a *typical* element if the set of such elements is a comeager set. Iterations of $T \in \mathrm{Aut}(\mu)$ define a $\mathbb{Z}$-action denoted by the same

of Mathematicians, Madrid, Spain, 2006

symbol T. More generally, given a discrete countable group G, the set of all G-actions, i.e. homomorphisms $T\colon G \to \mathrm{Aut}(\mu)$, equipped with the weak topology defined by

$$T(n) \to T \Leftrightarrow (\forall g \in G)\ T_g(n) \to T_g,$$

forms a Polish space denoted by Ω_G.

We are interested in *metrical* properties (equivalently, *metrical invariants*) of dynamical systems, i.e. in properties which are invariant with respect to measurable isomorphisms. Since every Polish space equipped with a Borel probability measure is measurably isomorphic to a Lebesgue space (X, μ) (not necessarily non-atomic, but usually we have a very easy dynamic on an atomic part), a "large" class of dynamical systems can be viewed as elements of $\mathrm{Aut}(\mu)$ or Ω_G.

If we wish to consider non-discrete groups G (the most famous example here is the case of $\mathbb{R}$, called a *flow*), then by G-action we mean only continuous homomorphisms (and their images) into $\mathrm{Aut}(\mu)$. As a rule it is no problem to find an invariant measure for a more or less natural map preserving some space. So dynamical systems are sufficiently common in different areas of mathematics. We are not able to discuss every result on this very rich theory. So we restrict ourselves to the main 'classical' subclass of one-to-one dynamical systems, i.e. to $\mathrm{Aut}(\mu)$ or Ω_G including, for example, shifts and automorphisms of commutative compact groups, interval exchanges, and billiards.

There exist many natural (or not so natural) ways to associate operators with dynamical systems. We will discuss the historically first classical operator introduced by Koopman [26]. A unitary operator $\hat{T}f(x) = f(Tx)$ induced on $L_2(X, \mu)$ by a transformation $T \in \mathrm{Aut}(\mu)$ is called *Koopman operator*. Unitary isomorphisms of Hilbert spaces define a spectral equivalence relation on the set of Koopman operators and, consequently, on $\mathrm{Aut}(\mu)$ or Ω_G.

Spectral invariants of dynamical systems, i.e. properties depending only on classes of the spectral equivalence relation, have become classical in the theory of dynamical systems after the celebrated work of John von Neumann [29] on classical mechanics.

Let us recall the properties

1. *to be ergodic* $\Leftrightarrow [\forall$ measurable $A[(\forall\, g \in G)[T_g A = A] \Rightarrow \mu(A)\mu(X\backslash A) = 0]]$,
2. *to be weakly mixing* $\Leftrightarrow [\exists g_n \to \infty[\hat{T}_{g_n} \to \int]]$,
3. *to be mixing* $\Leftrightarrow [\forall g_n \to \infty[\hat{T}_{g_n} \to \int]]$,

where we consider the weak operator topology and $\int$ is an operator of the orthogonal projection onto the space of constants. These are natural examples of (non-complete) spectral invariants, because each of them divides $\mathrm{Aut}(\mu)$ (resp. Ω_G) into only two subsets consisting of full classes of the spectral equivalence relation.

Consider a pair (ν, M), where ν is a Borel measure on $\mathbb{T}$ and M is a ν measurable function $M\colon \mathbb{T} \to \mathbb{N} \cup \{\infty\}$. Let $H^{\nu,M}$ be the subspace of the ν measurable square integrable functions $\varphi\colon \mathbb{T} \to l_2$ such that at a point $\lambda \in \mathbb{T}$ all but the first $M(\lambda)$

coordinates of $\varphi(\lambda)$ vanish. The space $H^{\nu,M}$ is a separable Hilbert space with respect to the inner product

$$\langle \varphi, \psi \rangle = \int_{\mathbb{T}} (\varphi(\lambda), \psi(\lambda))_{l_2} \, d\nu,$$

and the group $\mathbb{Z}$ acts unitarily on $H^{\nu,M}$ by the natural scalar multiplications:

$$U_n^{\nu,M} \varphi(\lambda) = \lambda^n \varphi(\lambda).$$

Due the spectral theorem for any unitary representation of $\mathbb{Z}$, say U, in a separable Hilbert space, there exists a pair (ν, M) such that $U^{\nu,M}$ is unitarily equivalent to U. This pair (ν, M) is unique in the sense that representations U^{ν_1,M_1} and U^{ν_2,M_2} are unitarily equivalent if and only if the measures ν_1 and ν_2 are equivalent and $M_1 = M_2$ almost everywhere with respect to ν_1 (or ν_2). Therefore a pair $([\nu], M(\hat{T}))$ is an example of a complete spectral invariant, where the *maximal spectral type* $[\nu]$ of $\hat{T}$ (or T) is a class of mutually equivalent Borel measures on $\mathbb{T}$ and $M(\hat{T})$ modulo ν-zero sets is the *spectral multiplicity function*. More concerning definitions of different spectral properties common in dynamics can be found in [13].

The setting of "*freeness*", where one says that a G-action is *free* if $\mu\{x \in X : (\exists g \neq 1)\ T_g x = x\} = 0$, can be viewed as the first trivial example of a non-spectral metrical invariant. However, usually in ergodic theory one considers only ergodic dynamical systems, because the "typical" problem in this area can be naturally reduced to the "ergodic" one. Since every ergodic transformation is obviously free, this setting is trivial in the class of ergodic $T \in \mathrm{Aut}(\mu)$. However there are many theorems going back to Anzai who showed that the spectral invariant is not a complete metrical invariant even in sufficiently "small" subclasses of $\mathrm{Aut}(\mu)$, and there are a few non-spectral metrical invariants. Let us especially remind here that the notion of *entropy* introduced by Kolmogorov [25] is one of those. In spite of these facts, in modern ergodic theory spectral invariants form a very rich class, and their study sometimes has essential influence on different branches of modern mathematics.

2. General classical problems of the spectral ergodic theory

1. *Spectral realization problem:* to determine precise conditions on the spectrum, i.e. spectral invariants, of a unitary operator under which it can be realized by a dynamical system.

2. *Spectral computation problem:* to calculate spectral invariants for every transformation of the Lebesgue space.

3. *Spectral isomorphism problem:* to describe the "gap" between spectral and metrical properties, i.e., to realize what kind of extra information should be added to spectral invariants for the purpose of having a complete metrical invariant.

There are numerous theorems, examples and counterexamples to different conjectures, which provides evidence of the extreme difficulty of handling these problems, because $\mathrm{Aut}(\mu)$ is a very rich class from the spectral point of view. This implies the importance of studying of general spectral problems in natural subclasses of dynamical systems, where such problems have not been solved yet.

3. Weak operator convergence

From time to time in the spectral ergodic theory was a pulsing activity stimulated by coming of new ideas. In the 60s and 70s some very importants problems were solved by approximations. We will concentrate our attention on $M(T)$ (i.e. $M(\hat{T})$). All known constructions of transformations T with calculations of nontrivial $M(T)$ are quite complicated. Oseledec [31] constructed a first example of an ergodic transformation T with $2 \le m(T) < 30$ where

$$m(T) = \sup\{n : n \in M(T)\}.$$

For a given number n, Robinson [33] used approximations for calculations and found an ergodic (even weakly mixing) transformation T with $m(T) = n$. More information about the history of the spectral multiplicity in ergodic theory can be found in [33], [27].

The main problem of the realization of possible values of the spectral multiplicity function was the homogeneous spectrum problem:

For any $n > 1$, does there exist an ergodic transformation T with $M(T) = \{n\}$ in the orthogonal complement of the space of constants?

This is a so-called Rokhlin problem on homogeneous spectrum. There is no written confirmation signed by V. Rokhlin of the fact that he suggested this problem. However in the memory of many (former) Russian mathematicians this long standing problem is associated with V. Rokhlin who posed this question in many discussions. Moreover, he even asked for less, namely

whether an ergodic transformation can have homogeneous spectrum with multiplicity different from 1 *or infinity in the orthogonal complement of the space of constants*.

The main goal of this section is to advertise a new sufficiently recent approach which uses weak operator convergence. This approach recently allowed the possibility to solve (Ageev, Ryzhikov) Rokhlin's old problem and to answer some other well-known questions, for example, Katok's question.

3.1. The case $1 \in M(T)$

Theorem 3.1. *For any $M \subseteq \mathbb{N} \cup \{\infty\}$ $(1 \in M)$ there exists an ergodic automorphism T with $M(T) = M$.*

Theorem 3.1 was proved in [27] for natural factors of transformations constructed in [19]. However the proof of the main result in [19] used, in fact, limit points (with respect to the weak operator convergence) of iterations of $\hat{T}$ in $\hat{T}$-invariant subspaces of $L_2(X, \mu)$. We remark here that Theorem 3.1 was also proved independently in [3] in the framework of a new direct construction.

Theorem 3.1 can be viewed as the complete solution of the realization problem of $M(T)$ in $L_2(X, \mu)$ for ergodic transformations T, because an easy corollary of the fact that the space of invariant functions is one dimensional is that $1 \in M(T)$.

3.2. Cartesian powers. For a typical T, Katok (see [21] and a renewed version [22]) showed using some approximation methods that

$$M(T \times T) \in \{\{2\}, \{2, 4\}\}$$

and conjectured that

$$M(\underbrace{T \times \cdots \times T}_{n \text{ times}}) = \{n, n(n-1), \ldots, n!\}.$$

It was the unique known construction, where a solution of Rokhlin's problem (only for $n = 2$) was expected.

This conjecture was confirmed completely by Ageev [2] (see also [6]) and, independently, by Ryzhikov [35] for $n = 2$, thereby giving a positive answer to Rokhlin's problem for $n = 2$. The solution of this version of Rokhlin's problem was a sufficiently simple application of the very unexpected fact that, for a typical transformation $T \in \mathrm{Aut}(\mu)$, all polynomials $P_n(\hat{T})$ forming a convex combination of some $\hat{T}^k$'s are limit points (with respect to the weak operator convergence) of iterations of $\hat{T}$.

This approach via so-called limit polynomials gave a lot of new additional information about $M(T)$. However, it did not give a possibility to solve the homogeneous spectrum problem for arbitrary n.

4. The homogeneous spectrum problem of arbitrary multiplicity

The homogeneous spectrum problem was solved completely in [7].

Theorem 4.1. *For any n there exists an ergodic transformation with homogeneous spectrum of multiplicity n in the orthogonal complement of the constant functions.*

One of the new guesses to prove this theorem was to apply the inner group symmetry coming from appropriate identities to symmetry in the spectrum of elements of corresponding group actions. Consider the following (quite exceptional for our purposes) group:

$$G_n = \mathrm{gr}\langle t, s; t_i t_j t_i^{-1} t_j^{-1} = 1 = t_0 \ldots t_{n-1} \text{ for all } i, j\rangle,$$

where $t_i = s^i t s^{-i}$, $t_0 = t$.

Theorem 4.1 is a natural corollary of the following main theorem:

Theorem 4.2 ([7]). *For a typical G_n-action T, T_{s^n} is a weakly mixing transformation with homogeneous spectrum of multiplicity n in the orthogonal complement of the constant functions.*

4.1. Sketch of Proof. By our choice G_n contains a normal subgroup G of finite index so that G is a free commutative group in generators $t_0, \dots, t_{n-2}, s^n$. The spectral theorem applied for G-subaction of a G_n-action T implies that the Hilbert space $L_2(X, \mu)$ can be decomposed into the direct sum of mutually orthogonal T_{s^n}-invariant subspaces $H_i, i = 1, \dots, n$, and a remaining part L, so that both restrictions of T_{s^n} to H_i are mutually unitarily equivalent and L is a subspace of $L_2(X, \mu)$ spanned by all eigenfunctions of T_g, $g \in G$. Therefore if L is trivial, i.e. it consists of constant functions, then the values of the spectral multiplicity function of T_{s^n} are multiples of n in the orthogonal complement of the constant functions.

By our choice G_n is sufficiently "close" to the class of commutative groups. This implies the guess that, given $g \in G_n$, the topological status in Ω_{G_n} of different spectral invariants of T_g is "almost" the same as in $\mathrm{Aut}(\mu)$. More precisely, we found counterparts in Ω_{G_n} of well-known classical results that, for a typical T in $\mathrm{Aut}(\mu)$, the transformations T^k ($k \neq 0$) are weakly mixing and have a simple spectrum. Namely, for a typical G_n-action we prove two statements: (I) Transformations T_s have a simple spectrum. (II) T_g ($g \neq 1$)[1] are weakly mixing (or, equivalently, have no eigenfunctions in the orthogonal complement of the constant functions).

To show (II) we follow a classical method to prove that some property A is typical in the space of all actions of some group. Namely, we find a free action having the property A. Rokhlin's lemma usually implies that the set of conjugations of any fixed free action is dense. Since we only consider properties which are invariant with respect to any metrical isomorphism (in particular, any conjugation), the set of actions having the property A is dense. Finally, we use convenient approximations by elements of this dense set to show that A is valid for a typical action. This method explains the importance to construct examples of dynamical systems having different metrical properties in ergodic theory.

A priori, we have no example of a free G_n-action T ($n \geq 3$) such that T_s has a simple spectrum. Therefore to show (I) we applied another (more delicate) method that used cyclic approximations [24][2]. Namely, we proved that a typical G_n-action T can be approximated by appropriate finite G_n-actions $T(k)$ so that T_s is approximated sufficiently fast by a cyclic $T_s(k)$.

[1] Formally, (II) was proved in [7] only for a certain subset of elements of G. This was sufficient to establish Theorem 4.2. However, following the same method of the proof, we can then deduce almost automatically that (II) holds.

[2] A very interesting recent preprint of Danilenko contains a few technical improvements. Using our method, he proved Theorem 4.2 for a simplified version G^* of G, and, in particular, he replaced arguments of cyclic approximations by algebraic ones. He also constructed explicit examples of ergodic transformations with homogeneous spectrum of multiplicity n on L_2^0 using (not directly) the well-known fact that transformations admitting a sufficiently fast approximation can be constructed explicitly. Proofs for G^* are simpler, but my choice of G_n in [7] was made due to different reasons, for example, to show that even in the well-studied class of transformations conjugated to their inverses (i.e. $T_t, t \in G_2$) we have a few new interesting results.

Finally, to have a homogeneous spectrum of multiplicity n, we note that L is trivial, because there is no non-constant eigenfunction for any T_g ($g \neq 1$) if the G_n-action T is typical, and the upper bound n of $M(T_{s^n})$ follows from simplicity of the spectrum of T_s.

I would like to stress that an analogy between Ω_{G_n} and $\mathrm{Aut}(\mu)$ is not always certain, because, for example, for a typical G_n-action T, T_s^n does not have a simple spectrum.

4.2. Some spectral properties of typical G_n-actions. Using a technique from [7], we can say somewhat more concerning elements of a typical G_n-action. More precisely, the first simple observation in the proof of the main theorem in [7] is the remark that for a typical T from Ω_{G_n}, T_s (equivalently, T_s^n) is a *rigid* (non-mixing) transformation, i.e. $T_t^{k_i} \to E$ for some $k_i \to \infty$ (E the identity map). In particular, this means that a σ_{T_s} (or $\sigma_{T_{s^n}}$) is singular, where σ_T is the measure of the maximal spectral type of T.

It is easy to check that for the transformations in Theorem 4.2, $\sigma'_{T_s} \sim \varphi\sigma'_{T_s}$, where $\varphi\colon \mathbb{T} \to \mathbb{T}$ is a map defined by $\varphi(\lambda) = \exp(2\pi i/n)\lambda$, and σ'_S is the measure of the maximal spectral type of $\hat{S}$ on $\{\mathrm{const}\}^\perp$. Therefore we have the following corollary:

Corollary 4.3 ([7]). *For a typical G_n-action T, if $k|n$ then T_s^k is a weakly mixing transformation with homogeneous spectrum of multiplicity k in the orthogonal complement of the constant functions.*

Analogous results for an element T_t are somewhat surprising.

Theorem 4.4 ([7]). *For a typical T from Ω_{G_n}, the following properties hold:*

1. *T_t is weakly mixing.*
2. *T_t is rigid.*
3. *If $n = 2$, then T_t has a homogeneous spectrum of multiplicity 2 on $\{const\}^\perp$.*
4. *If $n > 2$, then T_t has a simple spectrum.*

5. Spectral rigidity of group actions

Our discussion in this section focuses on values of the spectral multiplicity function of elements of typical dynamical systems.

It is easy to see that $M(T_g) = \{\infty\}$ if g has a finite order.

Remark 5.1. Let G be a countable abelian group. Then, for a typical G-action T, $M(T_g) = \{1\}$ if g has infinite order.

The proof is more or less a standard application of approximation arguments.

All discussion above suggests us to conclude that, as a rule, groups fulfill some (new) effect which I call spectral rigidity.

Definition 5.2. Following [7] we say that an element h of a group H has *spectral rigidity* if for a typical H-action T the set of essential values $M(\hat{T}_h)$ of the spectral multiplicity function of T_h is constant. If every element of H has this property we say that the group H has *spectral rigidity*.

It is easy to see that the notion of spectral rigidity can be considered as an invariant with respect to group or metrical isomorphisms.

In fact, the main theorem on the homogeneous spectrum could be proved because certain elements of G_n have spectral rigidity. Let us mention a partial result valid for every countable group.

Proposition 5.3. *Suppose g is an element of a countable group G; then $m(T_g)$ is independent of our choice of T from Ω_G except for a meager set of actions.*[3]

This proposition is an easy corollary of Proposition 3 in [7] and the fact that every countable group G has the *weak Rokhlin property*, i.e. $\{T \in \Omega_G : T \cong T'\}$ is dense for some $T' \in \Omega_G$, where $\cong$ is a metrical isomorphism established by Glasner, Thouvenot, and Weiss in [16].

Let us also mention that an easy application of the technique to study spectral rigidity [7] to solvable Baumslag–Solitar groups is the following theorem (cf. [9]).

Theorem 5.4. *For a typical G-action T, T_t is a weakly mixing rank one transformation, where $G = \mathrm{gr}\langle t, s;\ ts = st^2\rangle$.*

This theorem gives a positive answer to a well-known question (see, for example, [18]).

6. Spectral invariants in natural subclasses of dynamical systems

6.1. Finite rank case. Let us recall one of the metrical invariants introduced by Ornstein and Chacon and intensively studied over the last three decades.

Definition 6.1. The transformation T has *rank n* if n is the smallest number such that, for any k, there exist towers (columns)

$$A_{k,i}, TA_{k,i}, \ldots, T^{h_{k,i}}A_{k,i}, \quad i = 1, \ldots, n$$

such that all levels $T^j A_{k,i}$ and the remaining set form a measurable partition ξ_k of X and $\xi_k \to \varepsilon$, i.e., for any measurable set A there are ξ_k-measurable sets A_k such

[3] Recently, this proposition was extended in [10] to the case $M(T_g)$, i.e. every countable group has spectral rigidity. However, the calculation of values of $M(T_g)$ for a typical group action T remains an interesting unsolved problem even in the class of countable groups.

that $\mu(A\Delta A_k) \to 0$ as $k \to \infty$. A transformation has *infinite* rank if there is no such number. Finally, a transformation has *uniform* rank n if the towers above can be chosen in such a way that $h_{k,i}$ is independent of i.

Let us mention a few results on spectral invariants in the case of finite rank transformations. Chacon [14] proved that this class does not contain transformations with an unbounded spectral multiplicity function since always

$$m(T) \leq \text{rank } T.$$

Ornstein [30] proved that there exist rank one mixing transformations (see also another staircase construction of mixing rank one transformations [1]). Bourgain [12] showed that Ornstein's transformations have a singular spectrum. In [4] it was proved that there exist finite rank mildly mixing transformations with a Lebesgue component of any even multiplicity in the spectrum (see also [32],[28]). Every finite subset of $\mathbb{N}$ (with 1) can be a spectral multiplicity function of finite rank transformations (see [3]).

Observe that the setting to be of finite rank can be viewed as the easiest geometrical version of an appropriate approximation. Therefore the solution of the homogeneous spectrum problem in the class of finite rank transformations was a natural addition to the main result of [7]. More precisely, we have the following result.

Theorem 6.2 ([7]). *For a typical G_n-action T, T_{s^n} is a weakly mixing transformation with homogeneous spectrum of the multiplicity n in the orthogonal complement of the constant functions. Moreover, T_{s^n} has uniform rank n.*

Remark 6.3. All transformations of the form $T \times T$ have infinite rank (Ryzhikov [36]). Therefore the transformations in Theorem 4.2 (and 4.4) are from a new class with homogeneous spectra.

6.2. Mixing case In spite of the fact that in the set of all ergodic transformations we have almost full information concerning possible values of the spectral multiplicity function, the case of mixing transformations is still weakly studied, because many useful methods working for typical transformations are not applicable to the subset of mixing transformations.

The complete calculation of values of the spectral multiplicity function of natural factors of the Cartesian power of a transformation (under certain conditions on a transformation) was given in [5]. This construction can be considered as a source of mixing transformations having new (highly nonhomogeneous) spectral multiplicity functions, and covers all currently known non-trivial (i.e. $M(\hat{T}) \neq \{1\}, \{\infty\}$) examples of $M(\hat{T})$ for mixing transformations.

Let G be any subgroup of the *symmetric* group $\mathfrak{S}_n$ acting on $\{1, \ldots, n\}$ by permutations. For any $1 \leq k \leq n$ denote by the same symbol G the *diagonal* action of G on $I_k = \{1, \ldots, n\}^k$. Consider a restriction of the G-action to a G-invariant subset

$$I_k' = \{i_k = (i_k(1), \ldots, i_k(k)) \in I_k : i_k(l) = i_k(m) \text{ iff } l = m\}.$$

Suppose $\sim$ is an orbital equivalence relation naturally defined by G on I'_k. Define

$$D_k = \sharp I'_k/\sim\ (1 \le k \le n) \quad \text{and} \quad M_G(n) = \{D_1, \dots, D_n\}.$$

Theorem 6.4 ([5]). *For any subgroup G of $\mathfrak{S}_n$ there exists a mixing (of all orders) transformation T satisfying*

$$M(\hat{T}|_{L_2^0}) = M_G(n),$$

where $L_2^0 = \{f \in L_2 : \int f\,d\mu = 0\}$.

Corollary 6.5. *For any n there exists a mixing (of all orders) transformation T satisfying*

$$M(\hat{T}) = \{2, 3, \dots, n\} \quad \text{on } L_2^0.$$

This gives

$$M(\hat{T}) = \{1, 2, 3, \dots, n\} \quad \text{on } L_2.$$

Let us remark that for the case $n = 2$ this was proved earlier by Ryzhikov (see [37]), and that Corollary 6.5 also gives an answer to a question of Robinson (see [34] and [17], 5.3) about the set of possible values of $m(T) = \max M(\hat{T})$ for mixing transformations.

6.3. Interval exchanges Let us remind the definition of interval exchange (transformation). Let $n > 1$ and let π be an irreducible permutation of $\{1, \dots, n\}$, where a permutation π is called *irreducible* if $\pi\{1, \dots, m\} \ne \{1, \dots, m\}$, $1 \le m < n$. Let Δ be the simplex in $\mathbb{R}^n$,

$$\lambda = (\lambda_1, \dots, \lambda_n), \quad \lambda_i \ge 0,\ \sum_i \lambda_i = 1.$$

The unit interval $I = [0, 1)$ is divided into semi-open intervals

$$I_m = \Big[\sum_{i<m} \lambda_i, \sum_{i\le m} \lambda_i\Big), \quad 1 \le m \le n.$$

Definition 6.6. The *interval exchange transformation* $T_{\pi,\lambda}$ is uniquely defined on every I_m as a *shift*, i.e. a map $T_m\colon x \to x + \alpha_m$ such that that the intervals I_m are rearranged according to the permutation π, where α_m is

$$\sum_{i:\pi\{i\}\le\pi\{m\}} \lambda_i - \sum_{i\le m} \lambda_i.$$

If π is a *rotation*, i.e. $\pi(i+1) \equiv \pi(i) + 1 \pmod n$, then $T_{\pi,\lambda}$ has a very easy dynamical behavior, because it is a shift on $I \equiv \mathbb{R}/\mathbb{Z}$. Given an irreducible permutation π which is not a rotation, we restrict ourselves to the study of the topological status of subsets of transformations with fixed spectral invariants. Then the class of all interval

exchanges $T_{\pi,\lambda}$, say Ω_π, looks like a small model of $\mathrm{Aut}(\mu)$. However, due a natural parametrization of Ω_π by elements of Δ, it is more natural to consider the setting "to be typical" from the measure theoretical point view, i.e. to say that a property A is "typical" in Ω_π if the set of $\lambda \in \Delta$ such that $T_{\pi,\lambda}$ satisfies A forms a set of full Lebesgue measure. Indeed, analogs of the very well-known results that a typical transformation $\mathrm{Aut}(\mu)$ is not mixing, weakly mixing, and has a simple spectrum are the following. Katok [23] showed that there do not exist mixing interval exchanges. Veech [38] proved that a "typical" interval exchange has a simple spectrum. And only recently Avila and Forni [11] solved the long-standing problem that a "typical" interval exchange is weakly mixing.

As an analog to Theorem 3.1 it was proved in [8] that for any bounded M, $1 \in M \subseteq \mathbb{N}$, there exists an ergodic interval exchange T with $M(T) = M$ in the class of all interval exchanges. Using Oseledec's [31] result that the upper bound of the spectral multiplicity of an ergodic interval exchange of n intervals is at most n, we see that this is a complete solution of the problem of possible values of the spectral multiplicity function ($1 \in M(T)$) in the subclass of ergodic interval exchanges.

No ergodic interval exchange T is known with $1 \notin M(T)$.

7. Some more problems

Spectral invariants were studied in ergodic theory for more than seven decades and a lot of unsolved problems have been accumulated. Let me formulate some of them.

7.1. (One of the oldest problems in ergodic theory associated with Banach.) Does there exist a (mixing) transformation with simple Lebesgue spectrum in the orthogonal complement of constant functions?

7.2. (A well-known problem.) Is it true that every rank one transformation has a singular spectrum?

7.3. Is the property to be mixing of all orders spectral (i.e. a spectral invariant)?

7.4. (Another well-known problem.) Is the property to have a fixed rank spectral?

7.5. Given $n > 1$, find the set of pairs (g, G), where G is a countable group and $g \in G$ such that, for a typical G-action T, a transformation T_g has a homogeneous spectrum of multiplicity n in the orthogonal complement of the constant functions.

Ergodic Ramsey theory: a dynamical approach to static theorems

Vitaly Bergelson*

Abstract. We discuss classical results of Ramsey theory together with their dynamical counterparts, survey recent developments and formulate some natural open questions and conjectures.

Mathematics Subject Classification (2000). Primary 28D15, 05D10; Secondary 37A45, 37B10.

Keywords. Amenable group, ergodic theory, Furstenberg's correspondence principle, nilmanifold, Ramsey theory, recurrence, Stone–Čech compactification.

Introduction

Since its inception, ergodic theory was successfully employing combinatorial ideas and methods – from the use of the ubiquitous pigeonhole principle in the proof of the Poincaré recurrence theorem to combinatorial proofs of maximal inequalities, to the utilization of the marriage lemma in Ornstein's isomorphism theory. This debt to combinatorics is amply repaid by the accomplishments of the ergodic Ramsey theory.

Ergodic Ramsey theory was initiated in 1977 when H. Furstenberg [F3] proved a far reaching extension of the classical Poincaré recurrence theorem and derived from it the celebrated Szemerédi's theorem [Sz], which states that every set $E \subset \mathbb{N}$ with $\bar{d}(E) := \limsup_{N\to\infty} \frac{|E\cap\{1,2,\dots,N\}|}{N} > 0$ contains arbitrarily long arithmetic progressions. Furstenberg's ergodic approach to Szemerédi's theorem has not only revealed the dynamical underpinnings of this seemingly static result, but has also opened new vistas for mutually perpetuating research in ergodic theory, combinatorics, and number theory.

This survey is organized as follows. In Section 1 we formulate some of the classical theorems of Ramsey theory and discuss their dynamical counterparts. The subsequent sections are devoted to more recent developments and contain formulations of some natural open questions and conjectures. Unfortunately, due to space constraints, some of the topics will not get the attention they deserve. The readers will find more material together with much more elaborated discussion in the recent survey [B4]. (See also [F4], [B1] and [B3].)

of Mathematicians, Madrid, Spain, 2006

1. A brief survey

In *partition Ramsey theory* the focus is on patterns which can always be found in one cell of any finite partition of a highly organized structure such as $\mathbb{Z}^d$, a complete graph, a vector space, etc.[1] Here are some examples.

Theorem 1.1 (Gallai–Grünwald[2]). *For all $r, d \in \mathbb{N}$, if $\mathbb{Z}^d = \bigcup_{i=1}^r C_i$, then one of C_i has the property that for every finite set $B \subset \mathbb{Z}^d$, there exist $n \in \mathbb{N}$ and $v \in \mathbb{Z}^d$ such that $v + nB = \{v + nu : u \in B\} \subset C_i$. In other words, C_i contains a homothetic image of every finite set.*

Theorem 1.2 (cf. [GraRS], p. 40). *Let V be an infinite vector space over a finite field. For all $r \in \mathbb{N}$, if $V = \bigcup_{i=1}^r C_i$, then one of C_i contains affine vector spaces of arbitrary finite dimension.*

Theorem 1.3 (Hindman's Theorem, [Hi]). *Given an infinite set $E = \{x_1, x_2, \dots\}$ of natural numbers let $FS(E) = \{x_{i_1} + x_{i_2} + \cdots + x_{i_k} : i_1 < i_2 < \cdots < i_k,\ k \in \mathbb{N}\}$. For all $r \in \mathbb{N}$, if $\mathbb{N} = \bigcup_{i=1}^r C_i$, then one of C_i contains a set of the form $FS(E)$ for some infinite set $E \subset \mathbb{N}$.*

The *density Ramsey theory* attempts to explain (and enhance) the results of the partition Ramsey theory by studying the patterns which ought to appear in any "large" set. The notion of largeness may vary but it is always assumed to be partition regular in the sense that for any finite partition of a large set at least one of the cells is large. One also assumes (of course) that the family of large subsets of the ambient structure S includes S itself. We will formulate now density results which correspond to (and refine) the partition results contained in Theorems 1.1, 1.2, and 1.3.

Theorem 1.4 (Furstenberg–Katznelson's multidimensional Szemerédi theorem, [FK1]). *Let $d \in \mathbb{N}$ and assume that $E \subset \mathbb{Z}^d$ is a set of positive upper density, that is*

$$\bar{d}(E) = \limsup_{N\to\infty} \frac{|E \cap [-N, N]^d|}{(2N+1)^d} > 0.$$

For every finite set $B \subset \mathbb{Z}^d$ there exist $n \in \mathbb{N}$ and $v \in \mathbb{Z}^d$ such that $v + nB \subset E$.

Let F be a finite field and let V_F be a countably infinite vector space over F. To define a notion of largeness which will allow us to formulate a density version of Theorem 1.2, observe that, as an abelian group, V_F is isomorphic to the direct sum F_∞ of countably many copies of F:

$$F_\infty = \{(a_1, a_2, \dots) : a_i \in F \text{ and all but finitely many } a_i = 0\} = \bigcup_{n=1}^{\infty} F_n,$$

[1] More precisely, one either deals with arbitrary finite partitions of an infinite structure or with partitions into a fixed number of cells of sufficiently large finite structures.

[2] Gruńwald (who later changed his name to Gallai) apparently never published his proof. See [R], p. 123 and [GraRS], p. 38.

where $F_n = \{(a_1, a_2, \dots) : a_i = 0 \text{ for } i > n\} \cong F \oplus \cdots \oplus F (n \text{ times})$. For a set $E \subset V_F$ (where V_F is identified with F_∞), define the upper density $\bar{d}(E)$ as[3]

$$\bar{d}(E) = \limsup_{n\to\infty} \frac{|E \cap F_n|}{|F_n|}.$$

Theorem 1.5. *Every set of positive upper density in the vector space V_F contains affine subspaces of every finite dimension.*

Before introducing a family of notions of largeness which is pertinent to Hindman's theorem (Theorem 1.3 above), let us remark that the naive attempt to use the notion of upper density (which works well for the Szemerédi-type theorems) immediately fails. Indeed, while the set of odd integers has density $\frac{1}{2}$, it clearly does not contain the sum of any two of its elements. One can actually construct, for any $\varepsilon > 0$, a set $S \subset \mathbb{N}$ with $d(S) = \lim_{N\to\infty} \frac{|S\cap\{1,2,\dots,N\}|}{N} > 1 - \varepsilon$, which does not contain $FS(E)$ for any infinite set $E \subset \mathbb{N}$.

It turns out that a natural notion of largeness appropriate for Hindman's theorem can be introduced with the help of $\beta\mathbb{N}$, the Stone–Čech compactification of $\mathbb{N}$. In view of the increasingly important role which Stone–Čech compactifications play in ergodic Ramsey theory, we will briefly discuss some of the relevant definitions and facts. For missing details see ([B1], Section 3) and [B3]. (See also [HiS] for a comprehensive treatment of topological algebra in Stone–Čech compactifications.)

A convenient way of dealing with $\beta\mathbb{N}$ is to view it as an appropriately topologized set of ultrafilters on $\mathbb{N}$. Recall that an *ultrafilter* p on $\mathbb{N}$ is a maximal filter, namely a family of subsets of $\mathbb{N}$ satisfying the following conditions (the first three of which constitute, for a nonempty family of sets, the definition of a *filter*).

(i) $\emptyset \notin p$;

(ii) $A \in p$ and $A \subset B$ imply $B \in p$;

(iii) $A \in p$ and $B \in p$ imply $A \cap B \in p$;

(iv) (maximality) if $r \in \mathbb{N}$ and $\mathbb{N} = \bigcup_{i=1}^{r} C_i$ then for some $i \in \{1, 2, \dots, r\}$, $C_i \in p$.

One can naturally identify each ultrafilter p with a finitely additive $\{0, 1\}$-valued probability measure μ_p on the power set $\mathcal{P}(\mathbb{N})$. This measure μ_p is defined by the requirement $\mu_p(C) = 1$ iff $C \in P$. Without saying so explicitly, we will always think of ultrafilters as such measures, but will prefer to write $C \in p$ instead of $\mu_p(C) = 1$.

Any $n \in \mathbb{N}$ defines the so-called *principal* ultrafilter $\{C \subset \mathbb{N} : n \in C\}$. Principal ultrafilters can be viewed as point measures corresponding to elements of $\mathbb{N}$, and are the only ones which can be constructed without the use of Zorn's lemma (see [CN], pp. 161–162). Since ultrafilters are maximal filters, any family of subsets of $\mathbb{N}$ which

[3]This definition depends, of course, on the way V_F is represented as an infinite direct sum. Each such representation leads to a notion of upper density in V_F.

has the finite intersection property can be "extended" to an ultrafilter. Given $C \subset \mathbb{N}$, let $\overline{C} = \{p \in \beta\mathbb{N} : C \in p\}$. The family $\mathcal{G} = \{\overline{C} : C \in \mathbb{N}\}$ forms a basis for the open sets of a topology on $\beta\mathbb{N}$ (as well as a basis for the closed sets), and, with this topology, $\beta\mathbb{N}$ is a compact Hausdorff space. Clearly, $\overline{\mathbb{N}} = \beta\mathbb{N}$, which hints that the operation of addition (and that of multiplication, as well) can be extended from $\mathbb{N}$ to $\beta\mathbb{N}$. In the following definition, $C - n$ (where $C \subset \mathbb{N}$ and $n \in \mathbb{N}$) is the set of all m such that $m + n \in C$. For $p, q \in \beta\mathbb{N}$, define

$$p + q = \{A \subset \mathbb{N} : \{n \in \mathbb{N} : (A - n) \in p\} \in q\} \tag{1}$$

It is not hard to check that for principal ultrafilters the operation $+$ corresponds to addition in $\mathbb{N}$. One can show that $p + q$ is an ultrafilter, that the operation $+$ is associative and that, for any fixed $p \in \beta\mathbb{N}$, the function $\lambda_p(q) = p + q$ is a continuous self-map of $\beta\mathbb{N}$. It follows that with the operation $+$, $\beta\mathbb{N}$ becomes a compact *left topological* semigroup. By a theorem due to R. Ellis, [E], any such semigroup has an idempotent. It turns out the idempotent ultrafilters in $(\beta\mathbb{N}, +)$ (viewed as measures) have a natural shift-invariant property which is responsible for a variety of applications including the following result which may be regarded as a density version of Hindman's theorem.

Theorem 1.6. *Let p be an idempotent ultrafilter in $(\beta\mathbb{N}, +)$. If $C \in p$, then there is an infinite set $E \subset \mathbb{N}$ such that $FS(E) \subset C$.*

While Theorems 1.1 through 1.6 obviously have a common Ramsey-theoretical thread, their formulations do not reveal much about their dynamical content. Our next goal is to convince the reader that all of these results can be interpreted as recurrence theorems in either topological or measure-preserving dynamics. (Topological dynamics forms the natural framework for partition results; measure preserving dynamics corresponds to density statements).

We start with formulating the dynamical version of the Gallai–Grünwald theorem. The idea to apply the methods of topological dynamics to partition results is due to H. Furstenberg and B. Weiss (See [FW]).

Theorem 1.7 (cf. [FW], Theorem 1.4). *Let $d \in \mathbb{N}, \varepsilon > 0$, and let X be a compact metric space. For any finite set of commuting homeomorphisms $T_i : X \to X, i = 1, 2, \ldots, k$, there exist $x \in X$ and $n \in \mathbb{N}$ such that* $\operatorname{diam}\{x, T_1^n x, T_2^n x, \ldots, T_k^n x\} < \varepsilon$.

To derive Theorem 1.1 from Theorem 1.7, one utilizes the fact that, for fixed $r, d \in \mathbb{N}$, the r-colorings of $\mathbb{Z}^d$ (viewed as mappings from $\mathbb{Z}^d$ to $\{1, 2, \ldots, r\}$) are naturally identified with the points of the compact product space $\Omega = \{1, 2, \ldots, r\}^{\mathbb{Z}^d}$. For $m = (m_1, m_2, \ldots, m_d) \in \mathbb{Z}^d$, let $|m| = \max_{1 \le i \le d} |m_i|$. Introduce a metric on Ω by defining, for any pair $x, y \in \Omega$, $\rho(x, y) = \inf_{n \in \mathbb{N}} \left\{\frac{1}{n} : x(m) = y(m) \text{ for } |m| < n\right\}$. Note that $\rho(x, y) < 1 \iff x(0) = y(0)$. Let $B = \{b_1, \ldots, b_k\} \subset \mathbb{Z}^d$. Define the homeomorphisms $T_i : \Omega \to \Omega$, $i = 1, 2, \ldots, k$ by $(T_i x)(m) = x(m + a_i)$, and set, for $l = (l_1, l_2, \ldots, l_k) \in \mathbb{Z}^k$, $T^l = T_1^{l_1} T_2^{l_2} \cdots T_k^{l_k}$. Let $y(m)$, $m \in \mathbb{Z}^d$, be the element

of Ω which corresponds to the given coloring $\mathbb{Z}^d = \bigcup_{i=1}^r C_i$. let $X = \overline{\{T^l y\}}_{l\in\mathbb{Z}^k}$ be the orbital closure of x in Ω. It follows from Theorem 1.7 that for some $x \in X$ which can without loss of generality be chosen to be of the form $T^u y$ for some $u \in \mathbb{Z}^k$, one has $\operatorname{diam}\{x, T_1^n x, T_2^n x, \dots, T_k^n x\} = \operatorname{diam}\{T^u y, T^u T_1^n y, T^u T_2^n y, \dots, T^u T_k^n y\} < 1$. This implies that, for $v = u_1 b_1 + u_2 b_2 + \cdots + u_k b_k$, $y(v) = y(v + nb_1) = \cdots = y(v + nb_k)$, which means that the set $v + nB$ is monochromatic.

In a similar fashion one can derive Theorem 1.2 from the following dynamical result. (Cf. [B4], p. 766).

Theorem 1.8. *Let F be a finite field and let F_∞ be the direct sum of countably many copies of F. Assume that $(T_g)_{g\in F_\infty}$ is an action of F_∞ by homeomorphisms on a compact metric space X. Then for all $\varepsilon > 0$, there exist $x \in X$ and $g \in F_\infty$, $g \neq (0, 0, \dots)$ such that* $\operatorname{diam}\{T_{cg}x, c \in F\} < \varepsilon$.

We move now to dynamical formulations of Theorems 1.4 and 1.5. We start with the discussion of Szemerédi's theorem (corresponding to $d = 1$ in Theorem 1.4). Let $E \subset \mathbb{N}$ with $\bar{d}(E) > 0$. Observe that E contains a progression of the form $\{a, a+n, \dots, a+kn\}$ if and only if $E\cap(E-n)\cap\cdots\cap(E-kn) \neq \emptyset$. It is not too hard to see that Szemerédi's theorem is actually equivalent to an ostensibly stronger statement: for all $k \in \mathbb{N}$ there exists $n \in \mathbb{N}$ such that $\bar{d}(E \cap (E - n) \cap \cdots \cap (E - kn)) > 0$. This version of Szemerédi's theorem has already a detectible dynamical content (arithmetic progressions are "produced" as the result of shifting E by $n, 2n, \dots, kn$ and getting the intersection of positive upper density). This dynamical essence of Szemerédi's theorem is embodied in Furstenberg's multiple recurrence theorem (which implies Szemerédi's result):

Theorem 1.9 ([F3]). *Let T be a measure preserving transformation of a probability measure space $(X, \mathcal{B}, \mu)$. For all $k \in \mathbb{N}$ and all $A \in \mathcal{B}$ with $\mu(A) > 0$, there exists $n \in \mathbb{N}$ such that*

$$\mu(A \cap T^{-n}A \cap T^{-2n}A \cap \cdots \cap T^{-kn}A) > 0.$$

To derive Szemerédi's theorem from Theorem 1.9 one uses *the Furstenberg's correspondence principle* which allows one to connect the dynamics in the "pseudo-dynamical" system $(\mathbb{Z}, \mathcal{P}(\mathbb{Z}), \bar{d}, \tau)$ (where τ is the shift map: $\tau(n) = n + 1, n \in \mathbb{Z}$) with a genuine measure preserving symbolic system which can be naturally constructed given a set $E \subset \mathbb{Z}$ with $\bar{d}(E) > 0$.

Let E be a set of integers with $\bar{d}(E) > 0$ and let X be the orbital closure of $1_E \in \{0, 1\}^{\mathbb{Z}}$ under the transformation $T\colon \omega(l) \to \omega(l + 1)$, $\omega \in \{0, 1\}^{\mathbb{Z}}$. Let $C = \{\omega \in X : \omega(0) = 1\}$. One can show (see, for example, [F4], Lemma 3.17) that there exists a T-invariant Borel measure μ on X which satisfies $\mu(C) \geq \bar{d}(E)$. By Theorem 1.9 there exists $n \in \mathbb{N}$ such that $\mu(C \cap T^{-n}C \cap T^{-2n}C \cap \cdots \cap T^{-kn}C) > 0$. If $\omega \in C \cap T^{-n}C \cap T^{-2n}C \cap \cdots \cap T^{-kn}C$ then $\{\omega, T^n\omega, T^{2n}\omega, \dots, T^{kn}\omega\} \in C$, which implies $\omega(0) = \omega(n) = \omega(2n) = \cdots = \omega(kn)$. Since ω belongs to the orbital closure of 1_E, there is an $m \in \mathbb{Z}$ such that the sequences $\omega(l)$ and $T^m 1_E(l)$ coincide for

$0 \le l \le kn$. This implies $1_E(m) = 1_E(m+n) = 1_E(m+2n) = \cdots = 1_E(m+kn)$ and gives a progression $\{m, m+n, \dots, m+kn\} \subset E$.

Similar considerations (involving Furstenberg's correspondence principle for $\mathbb{Z}^d$- and F_∞-actions) allow one to derive Theorems 1.4 and 1.5 from the following dynamical theorems.

Theorem 1.10 ([FK1]). *Let $(X, \mathcal{B}, \mu)$ be a probability measure space. For any finite set $\{T_1, T_2, \dots, T_k\}$ of commuting measure-preserving transformations of X and for all $A \in \mathcal{B}$ with $\mu(A) > 0$, there exists $n \in \mathbb{N}$ such that*

$$\mu(A \cap T_1^{-n} A \cap T_2^{-n} A \cap \cdots \cap T_k^{-n} A) > 0.$$

Theorem 1.11. *Let $(T_g)_{g \in F_\infty}$ be a measure preserving action of $V_F = F_\infty$ on a probability measure space $(X, \mathcal{B}, \mu)$. Let $A \in \mathcal{B}$, $\mu(A) > 0$. Then for some $g \in F_\infty$, $g \neq (0, 0, \dots)$, one has $\mu\big(\bigcap_{c \in F} T_{cg} A\big) > 0$.*[4]

Remark. It is not hard to derive from Theorem 1.11 (by simple iterating procedure) the following fact: for all $k \in \mathbb{N}$ there exist $g_1, \dots, g_k \in F_\infty$ such that $\dim(\mathrm{span}\{g_1, g_2, \dots, g_k\}) = k$ and $\mu\big(\bigcap_{i=1}^k \bigcap_{c \in F} T_{cg_i} A\big) > 0$. It is this result, which, via the appropriate version of Furstenberg's correspondence principle, implies Theorem 1.5.

We will briefly discuss now the dynamical content of Hindman's theorem. Let $p \in \beta\mathbb{N}$ be an idempotent ultrafilter. The relation $p = p + p$ implies (via (1)) that a set $C \subset \mathbb{N}$ is p-large (i.e. belongs to p) if and only if $\{n \in \mathbb{N} : (C - n) \in p\} \in p$. In other words, if $p \in \beta\mathbb{N}$ is an idempotent, then every p-large set has the property that, for p-many $n \in \mathbb{N}$, the shifted set $C - n$ is also p-large. This, in turn, means that, if C is p-large then for p-many n, the set $C \cap (C - n)$ is p-large. This can be interpreted as a version of the Poincaré recurrence theorem for idempotent ultrafilter measures. The fact that the "shifting" n can itself be chosen to belong to the p-large set C comes as a bonus which, as we will presently see, immediately leads to a short and streamlined proof of Hindman's theorem.[5] Fix an idempotent ultrafilter p and let $\mathbb{N} = \bigcup_{i=1}^r C_i$ be an arbitrary finite partition of $\mathbb{N}$. Since p is a finitely additive probability measure, one (and only one) of C_i, call it C, will be p-large. As we have seen above, we can choose $n_1 \in C$ so that the set $C_1 = C \cap (C - n_1)$ is in p. We can now choose $n_2 \in C_1$ so that $n_2 > n_1$ and $C_2 = C_1 \cap (C_1 - n_2) = C \cap (C - n_1) \cap (C - n_2) \cap (C - (n_1 + n_2))$ is in p. Continuing in this fashion we will obtain an infinite set $E = \{n_1, n_2, \dots\}$ such that $FS(E) \subset C$, which concludes the proof of Hindman's theorem.

The sets of finite subsets which appear in Hindman's theorem are called in ergodic Ramsey theory *IP sets* (for infinite-dimensional parallelepiped, a term coined by H. Furstenberg and B. Weiss[6]). The notion of IP set makes sense in any commutative

[4] Theorem 1.11 follows, for example, from Theorems 1.13 and 2.9 below.

[5] The original proof of Hindman's theorem in [Hi] was very complicated. See [HiS], pp. 102–103 for references to other proofs and interesting historical comments.

[6] As we have seen, IP also naturally connects to IdemPotent.

semigroup and it is often convenient to think of IP sets as generalized semigroups. Many recurrence and convergence theorems which deal with semigroup actions can be extended to actions "along" IP sets, which leads to significant strengthening (and unification) of known results. As an illustration, we will formulate now IP versions of Theorems 1.7 and 1.10.

An $\mathcal{F}$*-sequence* in an arbitrary space Y is a sequence $(y_\alpha)_{\alpha\in\mathcal{F}}$ indexed by the set $\mathcal{F}$ of the finite nonempty subsets of $\mathbb{N}$. If Y is a commutative and multiplicative semigroup, one says that an $\mathcal{F}$-sequence defines an *IP-system* if for any $\alpha = \{i_1, i_2, \dots, i_m\} \in \mathcal{F}$ one has $y_\alpha = y_{i_1} y_{i_2} \dots y_{i_m}$. Note that if $\alpha \cap \beta = \emptyset$, then $y_{\alpha\cup\beta} = y_\alpha y_\beta$. This "partial" semigroup property turns out to be sufficient to guarantee the validity of the following multiple recurrence result which simultaneously extends Theorems 1.7 and 1.8. (It was proved first in [FW]. For a shorter proof based on the idea from [BPT], see [B2] and [B4], Cor. 2.3.)

Theorem 1.12. *If X is a compact metric space and G a commutative group of its homeomorphisms, then for any k IP-systems $(T_\alpha^{(1)})_{\alpha\in\mathcal{F}}, \dots, (T_\alpha^{(k)})_{\alpha\in\mathcal{F}}$ in G, and all $\varepsilon > 0$, there exists $\alpha \in \mathcal{F}$ and $x \in X$ such that* $\operatorname{diam}\{x, T_\alpha^{(1)}x, T_\alpha^{(2)}x, \dots, T_\alpha^{(k)}x\} < \varepsilon$.

It is clear that Theorem 1.12 implies Theorem 1.7 (any $\mathbb{Z}$ action can be viewed as a special case of an IP-system). But it is also not hard to see that Theorem 1.12 implies Theorem 1.8. See [B4], pp. 765–766 for details.

IP sets can be conveniently utilized to measure the abundance of configurations which are studied in Ramsey theory. Call a set E in a commutative semigroup G an IP* set if E has nonempty intersection with every IP set in G. It is not hard to show that every IP* set is *syndetic*.[7] To see this, one has to observe that the complement of a non-syndetic set has to contain arbitrarily long intervals, and it is not hard to show that any such set contains an IP set.

The advantage of IP* sets over syndetic sets is that the family of IP* sets has the finite intersection property (this can be shown with the help of Hindman's theorem). It follows that Theorem 1.12 not only gives a simultaneous extension of Theorems 1.7 and 1.8, but also refines each of them. For example, it follows from Theorem 1.12 that for any finite partition $\mathbb{N} = \bigcup_{i=1}^r C_i$, one of C_i has the property that, for any $k \in \mathbb{N}$, the set

$$R_k = \{d \in \mathbb{N} : \text{ for some } m \in \mathbb{N}, \{m, m+d, m+2d, \dots, m+kd\} \subset C_i\}$$

is IP*. We will see in the next section that this set R_k has much stronger intersectivity properties. (For example, R_k has nontrivial intersection with the set of values of any integer-valued polynomial $p(n)$ satisfying $p(0) = 0$).

The following powerful ergodic IP Szemerédi theorem obtained by H. Furstenberg and Y. Katznelson in [FK2] is a natural measure preserving analogue of Theorem 1.12.

[7] A subset S in a discrete semigroup G is called syndetic if finitely many translates of S cover G. If G is not commutative one has to distinguish between the notions of left and right syndetic. A left translate of S is defined as $x^{-1}S = \{g \in G : xg \in S\}$ and a right translate is defined as $Sx^{-1} = \{g \in G : gx \in S\}$.

Theorem 1.13 (See [FK2], Theorem A). *Let $(X, \mathcal{B}, \mu)$ be a probability space and G an abelian group of measure-preserving transformations of X. For all $k \in \mathbb{N}$, any IP-systems $(T_\alpha^{(1)})_{\alpha\in\mathcal{F}}, (T_\alpha^{(2)})_{\alpha\in\mathcal{F}}, \ldots, (T_\alpha^{(k)})_{\alpha\in\mathcal{F}}$ in G and all $A \in \mathcal{B}$ with $\mu(A) > 0$ there exists $\alpha \in \mathcal{F}$ such that*

$$\mu(A \cap T_\alpha^{(1)}A \cap T_\alpha^{(2)}A \cap \cdots \cap T_\alpha^{(k)}A) > 0.$$

Since the notion of an IP-system of commuting invertible measure preserving transformations generalizes the notion of a measure preserving action of a countable abelian group, Theorems 1.10 and 1.11 are immediate corollaries of Theorem 1.13. It also follows that, on a combinatorial level, Theorem 1.13 implies Theorems 1.4 and 1.5. However, Theorem 1.13 gives more! For example, it follows from it that the sets of configurations always to be found in "large" sets in $\mathbb{Z}^d$ or F_∞ are abundant in the sense that their parameters form IP* sets. These IP* versions of combinatorial results can be derived, with the help of an appropriate version of Furstenberg's correspondence principle, from the following corollary of Theorem 1.13.

Theorem 1.14. *Let $(X, \mathcal{B}, \mu)$ be a probability space, and let G be a countable Abelian group. For all $k \in \mathbb{N}$ and any measure preserving actions $(T_g^{(1)})_{g\in G}$, $(T_g^{(2)})_{g\in G}, \ldots, (T_g^{(k)})_{g\in G}$ of G on $(X, \mathcal{B}, \mu)$ and any $A \in \mathcal{B}$ with $\mu(A) > 0$, the set*

$$\{g \in G : \mu(A \cap T_g^{(1)}A \cap T_g^{(2)}A \cap \cdots \cap T_g^{(k)}A) > 0\}$$

is an IP set in G (and in particular, is syndetic).*

We will conclude this section by discussing two more classical results of Ramsey theory – the Hales–Jewett partition theorem and its density version proved in [FK3].

Consider the following generalization of tic-tac-toe: r players are taking turns in placing the symbols $s_1, \ldots, s_r$ in the $k \times k \times \cdots \times k$ (n times) array which one views as the n^{th} cartesian power A^n of a k-element set $A = \{a_1, a_2, \ldots, a_k\}$. (In the classical tic-tac-toe, we have $r = 2, k = 3, n = 2$). We are going to define now the notion of a *combinatorial line* in A^n. Identify the elements of A^n with the set $W_n(A)$ of words of length n over the alphabet A. Let $\tilde{A} = A \cup \{t\}$ be an extension of the alphabet A obtained by adding a new symbol t, and let $W_n(t)$ be the set of words of length n over $\tilde{A}$ in which the symbol t occurs. Given a word $w(t) \in W_n(t)$ let us define a combinatorial line as a set $\{w(a_1), w(a)2, \ldots, w(a_k)\}$ obtained by substituting for t the elements of A. For example, the word $43t241t2$ over the alphabet $\{1, 2, 3, 4, 5\} \cup \{t\}$ gives rise to the combinatorial line

$$\{43124112,\ 43224122,\ 43324132,\ 43424142,\ 43524152\}.$$

It is convenient to think of symbols $s_1, \ldots, s_r$ as colors; the goal of the players (in our slightly modified tic-tac-toe) is to obtain a monochromatic combinatorial line. The following theorem of Hales and Jewett [HaJ] implies that for fixed r, k and large enough n, the first player can always win.

Theorem 1.15. *Let $k, r \in \mathbb{N}$. There exists $c = c(k, r)$ such that if $n \geq c$, then for any r-coloring of the set $W_n(A)$ of words of length n over the k-letter alphabet $A = \{a_1, a_2, \ldots, a_k\}$, there is a monochromatic combinatorial line.*

One of the signs of the fundamental nature of the Hales–Jewett theorem is that one can easily derive from it its multidimensional version. For $m \in \mathbb{N}$, let $t_1, t_2, \ldots, t_m$ be m distinct variables, and let $w(t_1, t_2, \ldots, t_m)$ be a word of length n over the alphabet $A \cup \{t_1, t_2, \ldots, t_m\}$. (We assume that the letters t_i do not belong to A). If $w(t_1, t_2, \ldots, t_m)$ is a word of length n over $A \cup \{t_1, t_2, \ldots, t_m\}$ in which all of the variables $t_1, t_2, \ldots, t_m$ occur, the result of the substitution

$$\{w(t_1, t_2, \ldots, t_m)\}_{(t_1,t_2,\ldots,t_m)\in A^m} = \{w(a_{i_1}, a_{i_2}, \ldots, a_{i_m}) : a_{i_j} \in A,\ j = 1, 2, \ldots, m\}$$

is called a combinatorial m-space. Observe now that if we replace the original alphabet A by A^m, then a combinatorial line in $W_n(A^m)$ can be interpreted as a combinatorial m-space in $W_{nm}(A)$. Thus we have the following ostensibly stronger theorem as a corollary of Theorem 1.15.

Theorem 1.16. *Let $r, k, m \in \mathbb{N}$. There exists $c = c(r, k, m)$ such that if $n \geq c$, then for any r-coloring of the set $W_n(A)$ of words of length n over the k-letter alphabet A, there exists a monochromatic combinatorial m-space.*

The Hales–Jewett theorem is truly one of the cornerstones of Ramsey theory. Not only many familiar partition results such as Theorems 1.1 and 1.2 are immediate corollaries of the Hales–Jewett theorem,[8] but this result is the natural basis of many further generalizations, some of which we will encounter in the next sections. Also, the Hales–Jewett theorem and its various generalizations are utilized in proofs of various multiple recurrence results in measure preserving dynamics. For example, the Hales–Jewett theorem is used in [FK2] in the proof of Theorem 1.13. While the Hales–Jewett theorem was originally proved in a purely combinatorial way, it can also be proved with the help of Stone–Čech compactifications and by using the tools of topological dynamics. Each of these additional proofs leads in its turn to further useful results and ramifications. See [BL2], [BL3], [BBHi], [C].

In anticipation of the discussion in the next section, we are going to formulate two more versions of the Hales–Jewett theorem. Let $\mathcal{F}_0$ denote the set of finite (potentially empty) subsets of $\mathbb{N}$.

Given $k \in \mathbb{N}$, write $\mathcal{F}_0^k$ for the set of k-tuples of sets form $\mathcal{F}_0$. Let us call any $(k + 1)$ element subset of $\mathcal{F}_0^k$ of the form

$$\{(\alpha_1, \alpha_2, \ldots, \alpha_k), (\alpha_1 \cup \gamma, \alpha_2, \ldots, \alpha_k),$$
$$(\alpha_1, \alpha_2 \cup \gamma, \ldots, \alpha_k), \ldots, (\alpha_1, \alpha_2, \ldots, \alpha_k \cup \gamma)\}$$

a *simplex*.

[8] To see, for example, that Theorem 1.1 follows from the Hales–Jewett theorem, take A to be a finite field F. Then $W_n(F) = F^n$ has the natural structure of an n-dimensional vector space over F. It is easy to see that, in this case, a combinatorial m-space is an affine m-dimensional subspace of F^n.

Theorem 1.17. *For any $k \in \mathbb{N}$ and any finite coloring (= partition) of $\mathcal{F}_0^k$, there exists a monochromatic simplex.*

Here is a dynamical counterpart of Theorem 1.17.

Theorem 1.18. *Let (X, ρ) be a compact metric space. For $k \in \mathbb{N}$, let $T_{(\alpha_1,\alpha_2,\ldots,\alpha_k)}$, $(\alpha_1, \alpha_2, \ldots, \alpha_k) \in \mathcal{F}_0^k$ be a family of continuous self-maps of X such that for any $(\alpha_1, \alpha_2, \ldots, \alpha_k)$, $(\beta_1, \beta_2, \ldots, \beta_k) \in \mathcal{F}_0^k$ satisfying $\alpha_i \cap \beta_i = \emptyset$, $i = 1, 2, \ldots, k$, one has*

$$T_{(\alpha_1\cup\beta_1,\alpha_2\cup\beta_2,\ldots,\alpha_k\cup\beta_k)} = T_{(\alpha_1,\alpha_2,\ldots,\alpha_k)} T_{(\beta_1,\beta_2,\ldots,\beta_k)}.$$

Then for all $\varepsilon > 0$ and for all $x \in X$ there exist a nonempty finite set γ and a k-tuple $(\alpha_1, \alpha_2, \ldots, \alpha_k) \in \mathcal{F}_0^k$ such that $\alpha_i \cap \gamma = \emptyset$, $i = 1, 2, \ldots, k$ and

$$\operatorname{diam}\{T_{(\alpha_1,\alpha_2,\ldots,\alpha_k)}x, T_{(\alpha_1\cup\gamma,\alpha_2,\ldots,\alpha_k)}x, T_{(\alpha_1,\alpha_2\cup\gamma,\ldots,\alpha_k)}x, \ldots, T_{(\alpha_1,\alpha_2,\ldots,\alpha_k\cup\gamma)}x\} < \varepsilon.$$

See [B1] for more discussion of various equivalent forms of the Hales–Jewett theorem and ([BL2], Proposition L) for a proof via topological dynamics.

2. Ramsey theory and multiple recurrence along polynomials

We start this section with the formulation of the Furstenberg–Sárközy theorem which has interesting links with spectral theory, Diophantine approximations, combinatorics, and dynamical systems.

Theorem 2.1 ([F4], [Sa]). *Let $E \subset \mathbb{N}$ be a set of positive upper density, and let $p(n) \in \mathbb{Z}[n]$ be a polynomial with $p(0) = 0$. Then there exist $x, y \in E$ and $n \in \mathbb{N}$ such that $x - y = p(n)$.*

This result is quite surprising. While it is not hard to show that the set of differences $E - E = \{x - y : x, y \in E\}$ of a set E with $\bar{d}(E) > 0$ is syndetic, there is, a priori, no obvious reason for the set $E - E$ to be so "well spread" as to nontrivially intersect the set of values of every polynomial $p(n) \in \mathbb{Z}[n]$ which vanishes at zero.[9] The following dynamical counterpart of Theorem 2.1, from which Theorem 2.1 follows with the help of Furstenberg's correspondence principle, is just as striking.

Theorem 2.2. *For any invertible measure preserving system $(X, \mathcal{B}, \mu, T)$, any $A \in \mathcal{B}$ with $\mu(A) > 0$, and any polynomial $p(n) \in \mathbb{Z}[n]$ with $p(0) = 0$, there exists $n \in \mathbb{N}$ such that $\mu(A \cap T^{p(n)}A) > 0$.*

The following result obtained in [BL1] gives a simultaneous generalization of Theorem 2.1 and of the Furstenberg–Katznelson multidimensional Szemerédi theorem, Theorem 1.4.

[9] T. Kamae and M. Mendès-France have shown in [KM] that a polynomial $p(n) \in \mathbb{Z}[n]$ has this "intersectivity" property if and only if $\{p(n) : n \in \mathbb{Z}\} \cap a\mathbb{Z} \neq \emptyset$ for all $a \in \mathbb{N}$. For example, the polynomial $p(n) = (n^2 - 13)(n^2 - 17)(n^2 - 221)$ is such.

Theorem 2.3 (cf. [BL1], Theorem B′). *Let $r, l \in \mathbb{N}$ and let $P\colon \mathbb{Z}^r \to \mathbb{Z}^l$ be a polynomial mapping satisfying $P(0) = 0$. For all $S \subset \mathbb{Z}^l$ with $\bar{d}(S) > 0$ and for all finite sets $F \subset \mathbb{Z}^r$, there exists elements $n \in \mathbb{N}$ and $n \in \mathbb{Z}^l$ such that $u + P(nF) = \{u + P(nx_1, nx_2, \ldots, nx_r) : (x_1, x_2, \ldots, x_r) \in F\} \subset S$.*

The ergodic theoretic result from which Theorem 2.3 is derived in [BL1] involves products of commuting measure preserving transformations evaluated at "polynomial times":

Theorem 2.4 ([BL1], Theorem A). *Let, for some $t, k \in \mathbb{N}$, $p_{1,1}(n), \ldots, p_{1,t}(n)$, $p_{2,1}(n), \ldots, p_{2,t}(n), \ldots, p_{k,1}(n), \ldots, p_{k,t}(n)$ be polynomials with rational coefficients taking integer values on the integers and satisfying $p_{i,j}(0) = 0$, $i = 1, 2, \ldots, k$, $j = 1, 2, \ldots, t$. Then for all probability space $(X, \mathcal{B}, \mu)$, all commuting invertible measure preserving transformations $T_1, T_2, \ldots, T_t$ of X and all $A \in \mathcal{B}$ with $\mu(A) > 0$, one has*

$$\liminf_{N\to\infty} \frac{1}{N} \sum_{n=0}^{n-1} \mu(A \cap \prod_{j=1}^{t} T_j^{-p_{1,j}(n)} A \cap \prod_{j=1}^{t} T_j^{-p_{2,j}(n)} A \cap \cdots \cap \prod_{j=1}^{t} T_j^{-p_{k,j}(n)} A) > 0.$$

As we have seen in the previous section, the "linear" multiple recurrence results admit far reaching IP refinements. This leads to the question whether similar IP extensions may be obtained for polynomial results as well. For example, one would like to know whether, for every invertible measure preserving system $(X, \mathcal{B}, \mu, T)$, every polynomial $p(n) \in \mathbb{Z}[n]$ with $p(0) = 0$, and every $A \in \mathcal{B}$ with $\mu(A) > 0$, the set $\{n \in \mathbb{Z} : \mu(A \cap T^{p(n)} A) > 0\}$ is an IP* set. In other words, one would like to know whether for every infinite set $\{n_1, n_2, \ldots\} \subset \mathbb{N}$ there exists $\alpha \in \mathcal{F}$ such that $\mu(A \cap T^{p(n_\alpha)} A) > 0$, where, as in Section 1, the IP set $(n_\alpha)_{\alpha\in\mathcal{F}}$ is defined by $n_\alpha = \sum_{i\in\alpha}, \alpha \in \mathcal{F}$. The answer turns out to be yes and can be obtained by considering, instead of the conventional ergodic averages $\frac{1}{N}\sum_{n=1}^{N} \mu(A \cap T^{p(n)} A)$, the limits along IP sets (or, alternatively, limits along idempotent ultrafilters). However, a much more important novelty which is encountered when one deals with IP analogues of polynomial recurrence theorems is that one has now a bigger family of functions, namely the IP polynomials, for which the IP versions of familiar theorems make sense.

Let $q(t_1, \ldots, t_k) \in \mathbb{Z}[t_1, \ldots, t_k]$ and let $(n_\alpha^{(i)})_{\alpha\in\mathcal{F}}$, $i = 1, 2 \ldots, k$, be IP sets in $\mathbb{Z}$. Then $q(\alpha) = q(n_\alpha^{(1)}, n_\alpha^{(2)}, \ldots, n_\alpha^{(k)})$ is an example of an IP polynomial. For example, if $\deg q(t_1 \ldots, t_k) = 2$, the $q(\alpha)$ will typically look like

$$q(\alpha) = \sum_{i=1}^{s} n_\alpha^{(i)} m_\alpha^{(i)} + \sum_{i=1}^{r} k_\alpha^{(i)}.$$

The following result obtained in [BFM] gives an IP extension of Theorem 2.2 for the case of several commuting transformations.

Theorem 2.5 (cf. [BFM], Corollary 2.1). *Suppose that $(X, \mathcal{B}, \mu)$ is a probability space and that $\{T_1, T_2, \dots, T_t\}$ is a collection of commuting invertible measure preserving transformations of X. Suppose that $(n_\alpha^{(i)})_{\alpha\in\mathcal{F}} \subset \mathbb{N}$ are IP sets, $i = 1, 2, \dots, k$, and that $p_j(x_1, \dots, x_k) \in \mathbb{Z}[x_1, \dots, x_k]$ satisfy $p_j(0, 0, \dots, 0) = 0$ for $j = 1, 2, \dots, t$. Then for all $A \in \mathcal{B}$, and all $\varepsilon > 0$, there exist $\alpha \in \mathcal{F}$ such that*

$$\mu\Big(A \cap \prod_{i=1}^{t} T_i^{p_i(n_\alpha^{(1)}, n_\alpha^{(2)}, \dots, n_\alpha^{(k)})} A\Big) \geq (\mu(A))^2 - \varepsilon.$$

The next natural step is to try to extend Theorem 2.3 to a multiple recurrence result. The following IP polynomial Szemerédi theorem, obtained in [BM2] is an IP extension of Theorem 2.3.

Theorem 2.6 ([BM2], Theorem 0.9). *Suppose we are given t commuting invertible measure preserving transformations $T_1, \dots, T_t$ of a probability space $(X, \mathcal{B}, \mu)$. Let $k, r \in \mathbb{N}$ and suppose that $p_{i,j}(n_1, \dots, n_k) \in \mathbb{Q}[n_1, \dots, n_k]$ satisfy $p_{i,j}(\mathbb{Z}^k) \subset \mathbb{Z}$ and $p_{i,j}(0, 0, \dots, 0) = 0$ for $1 \leq i \leq t$, $1 \leq j \leq r$. Then for every $A \in \mathcal{B}$ with $\mu(A) > 0$, the set*

$$\big\{(n_1, \dots, n_k) \in \mathbb{Z}^k : \mu\big(\textstyle\bigcap_{j=1}^{r} \big(\prod_{i=1}^{t} T_i^{p_{i,j}(n_1,\dots,n_k)} A\big)\big) > 0\big\}$$

is an IP set in $\mathbb{Z}^k$.*

The following corollary of Theorem 2.6 can be viewed as an IP refinement of Theorem 2.5.

Theorem 2.7. *Assume that $P\colon \mathbb{Z}^r \to \mathbb{Z}^l$, $r, l \in \mathbb{N}$ is a polynomial mapping satisfying $P(0) = 0$ and let $F \subset \mathbb{Z}^r$ be a finite set. Then for all $E \subset \mathbb{Z}^l$ with $\bar{d}(E) > 0$ and all IP sets $(n_\alpha^{(i)})_{\alpha\in\mathcal{F}}$, $i = 1, \dots, r$, there exist $u \in \mathbb{Z}^l$ and $\alpha \in \mathcal{F}$ such that*

$$\{u + P(n_\alpha^{(1)} x_1, n_\alpha^{(2)} x_2, \dots, n_\alpha^{(r)} x_r) : (x_1, \dots, x_r) \in F\} \subset S.$$

We would like to mention the two combinatorial facts which play a decisive role in the proof of Theorem 2.6. The first is the Milliken–Taylor theorem ([M], [T]) which was also utilized in the proof of Theorem 2.5. The second is the polynomial Hales–Jewett theorem obtained via topological dynamics in [BL2]. The following formulation of the polynomial Hales–Jewett theorem should be juxtaposed with the formulation of its "linear" case given in Theorem 1.17.

Theorem 2.8. *For $k, d \in \mathbb{N}$, let $\mathcal{F}_0^k(\mathbb{N}^d)$ denote the set of k-tuples of finite (possibly empty) subsets of $\mathbb{N}^d = \mathbb{N} \times \cdots \times \mathbb{N}$ (d times). For every finite coloring of $\mathcal{F}_0^k(\mathbb{N}^d)$ there exists a monochromatic simplex of the form*

$$\{(\alpha_1, \alpha_2, \dots, \alpha_k), (\alpha_1 \cup \gamma^d, \alpha_2, \dots, \alpha_k),$$
$$(\alpha_1, \alpha_2 \cup \gamma^d, \dots, \alpha_k), \dots, (\alpha_1, \alpha_2, \dots, \alpha_k \cup \gamma^d)\},$$

where γ is a finite nonempty subset of $\mathbb{N}$ and $\alpha_i \cap \gamma^d = \emptyset$ for all $i = 1, 2, \dots, k$.

The polynomial Hales–Jewett theorem plays also a crucial role in the proof of the following recent result of a polynomial nature obtained in [BLM].

Theorem 2.9. *Let V, W be finite dimensional vector spaces over a countable field, let T be a measure preserving action of W on a probability measure space $(X, \mathcal{B}, \mu)$ and let $p_1, \ldots, p_k$ be polynomial mappings $V \to W$ with zero constant term. Then for all $A \in \mathcal{B}$ with $\mu(A) > 0$ there exists $c > 0$ such that the set*

$$\{v \in V : \mu(\textstyle\bigcap_{i=1}^{k} T_{(p_i(v))} A) > c\}$$

is syndetic in V.

Corollary 2.10. *Let $p_1, \ldots, p_k$ be polynomials with integer coefficients and zero constant term. For all $\varepsilon > 0$, there exists $N \in \mathbb{N}$ such that whenever F is a field with $|F| \geq N$ and $E \subset F$ with $\frac{|E|}{|F|} \geq \varepsilon$, there exist $v \in F$, $v \neq 0$, and $w \in E$ such that $p_i(v) \neq 0$, $i = 1, \ldots, k$, and $\{w, w + p_1(v), \ldots, w + p_k(v)\} \subset E$ for all $i = 1, \ldots, k$.*

A dynamical counterpart of Theorem 2.8 can be formulated in direct analogy to Theorem 1.8 which corresponds to the "linear" case. (See [B1], Section 4 and [BL2] for more discussion on various equivalent forms of the polynomial Hales–Jewett theorem). Rather than dealing here with the full-fledged dynamical version, we are going to formulate a rather general corollary of the polynomial Hales–Jewett theorem which is suggestive of a further, nilpotent, generalization to be discussed in the next section.

A mapping $\mathcal{P}$ from $\mathcal{F}_0$ into a commutative (semi)group G is an *IP polynomial* of degree 0 if $\mathcal{P}$ is constant, and, inductively, is an *IP polynomial of degree $\leq d$* if for all $\beta \in \mathcal{F}_0$ there exists an IP polynomial $\mathcal{D}_\beta \mathcal{P} \colon \mathcal{F}_0(\mathbb{N} \setminus \beta) \to G$ of degree $\leq d-1$ (where $\mathcal{F}_0(\mathbb{N} \setminus \beta)$ is the set of finite subsets of $\mathbb{N} \setminus \beta$) such that $\mathcal{P}(\alpha \cup \beta) = \mathcal{P}(\alpha) + (\mathcal{D}_\beta \mathcal{P})(\alpha)$ for every $\alpha \in \mathcal{F}_0$ with $\alpha \cap \beta = \emptyset$. (One can easily check that the IP-systems introduced in Section 1 correspond to IP polynomials of degree 1 satisfying $\mathcal{P}(\emptyset) = 1_G$.)

Theorem 2.11 ([BL2]). *Let G be an abelian group of self-homeomorphisms of a compact metric space (X, ρ), let $k \in \mathbb{N}$ and let $\mathcal{P}_1, \ldots, \mathcal{P}_k$ be IP-polynomials mapping $\mathcal{F}_0$ into G and satisfying $\mathcal{P}_1(\emptyset) = \cdots = \mathcal{P}_k(\emptyset) = 1_G$. For all $\varepsilon > 0$ there exist $x \in X$ and a nonempty $\alpha \in \mathcal{F}_0$ such that $\rho(\mathcal{P}_i(\alpha)x, x) < \varepsilon$ for $i = 1, \ldots, k$.*

We conclude this section by formulating a conjecture about a density version of the polynomial Hales–Jewett theorem which would extend the partition results from [BL2], the Furstenberg–Katznelson density version of the "linear" Hales–Jewett theorem, as well as Theorems 2.4 and 2.9. For $q, d, N \in \mathbb{N}$, let $M_{q,d,N}$ be the set of q-tuples of subsets of $\{1, 2, \ldots, N\}^d$:

$$M_{q,d,N} = \{(\alpha_1, \ldots, \alpha_q) : \alpha_i \subset \{1, 2, \ldots, N\}^d, i = 1, 2, \ldots, q\}.$$

Conjecture 2.12. For all $q, d \in \mathbb{N}$ and $\varepsilon > 0$ there exists $c = c(q, d, \varepsilon)$ such that if $N > c$ and a set $S \subset M_{q,d,N}$ satisfies $\frac{|S|}{|M_{q,d,N}|} > \varepsilon$, then S contains a "simplex" of the form

$$\{(\alpha_1, \alpha_2, \dots, \alpha_q), (\alpha_1 \cup \gamma^d, \alpha_2, \dots, \alpha_q), \\ (\alpha_1, \alpha_2 \cup \gamma^d, \dots, \alpha_q), \dots, (\alpha_1, \alpha_2, \dots, \alpha_q \cup \gamma^d),$$

where $\gamma \subset \mathbb{N}$ is a nonempty set and $\alpha_i \cap \gamma^d = \emptyset$ for all $i = 1, \dots, q$.

3. Ergodic Ramsey theory in a noncommutative setting

The Ramsey theoretical results surveyed in the previous sections deal with commutative (semi)groups. One may wonder whether these results extend to noncommutative structures. A similar question suggests itself with respect to dynamics: is it true that multiple recurrence results such as, say, Theorems 1.10 and 2.4 hold true if the involved transformations do not necessarily commute? It turns out that many of the partition and density theorems (as well as their dynamical counterparts) that we encountered above do hold for nilpotent groups. On the other hand, the analogous results fail quite dramatically for solvable groups of exponential growth. (See Theorem 3.7 below).

We now formulate a nilpotent version of the polynomial Hales–Jewett theorem (see Theorems 2.8 and 2.11), from which one can derive nilpotent extensions of various abelian theorems. In order to do so we have to extend first the notion of a polynomial mapping $\mathcal{P}\colon \mathcal{F}_0 \to G$ (discussed at the end of the previous section) to a nilpotent setup.

If G is an abelian group, one can show (see [BL2], Theorem 8.3) that a mapping $\mathcal{P}\colon \mathcal{F}_0 \to G$ is an IP polynomial of degree $\leq d$ with $P(\emptyset) = 1_G$ if and only if there exists a family $\{g_{j_1,\dots,j_d}\}_{(j_1,\dots,j_d)\in\mathbb{N}^d}$ of elements of G such that for all $\alpha \in \mathcal{F}_0$ one has $\mathcal{P}(\alpha) = \prod_{(j_1,\dots,j_d)\in\alpha^d} g_{j_1,\dots,j_d}$. This characterization of IP polynomials makes sense in the nilpotent setup as well. Given a nilpotent group G, let us call a mapping $\mathcal{P}\colon \mathcal{F}_0 \to G$ an IP polynomial if for some $d \in \mathbb{N}$ there exists a family $\{g_{j_1,\dots,j_d}\}_{(j_1,\dots,j_d)\in\mathbb{N}^d}$ of elements of G and a linear order $<$ on $\mathbb{N}^d$ such that, for any $\alpha \in \mathcal{F}_0$, one has $\mathcal{F}\,P(\alpha) = \prod^{<}_{(j_1,\dots,j_d)\in\alpha^d} g_{j_1,\dots,j_d}$ (the entries in the product $\prod^{<}$ are multiplied in accordance with the order $<$). The following nilpotent version of the polynomial Hales–Jewett theorem which was obtained in [BL3] contains many of the above partition results as special cases.

Theorem 3.1 ([BL3], Theorem 0.24). *Let G be a nilpotent group of homeomorphisms of a compact metric space (X, ρ) and let $\mathcal{P}_1, \dots, \mathcal{P}_k\colon \mathcal{F}_0 \to G$ be IP polynomials satisfying $\mathcal{P}_1(\emptyset) = \cdots = \mathcal{P}_k(\emptyset) = 1_G$. Then, for all $\varepsilon > 0$, there exist $x \in X$ and a nonempty $\alpha \in \mathcal{F}_0$ such that $\rho(\mathcal{P}_i(\alpha)x, x) < \varepsilon$ for all $i = 1, 2, \dots, k$.*

One of the corollaries of Theorem 3.1 is the following nilpotent version of Theorem 1.12.

Theorem 3.2 ([BL3], Theorem 0.13). *Let G be a nilpotent group of homeomorphisms of a compact metric space (X, ρ), let $k \in \mathbb{N}$ and let $g_j^{(i)} \in G$, $i = 1, \dots, k$, $j \in \mathbb{N}$. For all $\varepsilon > 0$, there exist an element x in X and a nonempty finite subset α of $\mathbb{N}$ such that $\rho\big(\prod_{j\in\alpha} g_j^{(i)} x, x\big) < \varepsilon$ for all $i = 1, \dots, k$.*

Theorem 3.1 implies also the following results, both of which can be viewed as nilpotent extensions of Theorem 1.2.

Theorem 3.3 (cf. [BL3], Theorem 0.16). *Let $q \in \mathbb{N}$ and let G be the multiplicative group of $q \times q$ upper triangular matrices with unit diagonal over an infinite field of finite characteristic. For any finite coloring of G and any $c \in \mathbb{N}$ there exists a subgroup H of G of nilpotency class q and of cardinality $\geq c$, such that for some $h \in G$ the coset hH is monochromatic.*

Theorem 3.4 ([BL3], Theorem 0.17). *Let $q \in \mathbb{N}$ and p be a prime, with $p > q$. Let G be an infinite free q-step nilpotent group with torsion p. For any finite coloring of G and any $c \in \mathbb{N}$ there exists a free q-step nilpotent subgroup $H \subset G$ of cardinality $|H| \geq c$, such that, for some $h \in G$, the coset hH is monochromatic.*

The following theorem obtained by A. Leibman in [L1] is a nilpotent extension of Theorem 2.4, from which one can also derive a nilpotent generalization of Theorem 2.3.

Theorem 3.5 (cf. [L1], Theorem NM). *Let $k, t, r \in \mathbb{N}$. Assume G is a nilpotent group of measure preserving transformations of a probability measure space $(X, \mathcal{B}, \mu)$. Let $p_{ij}(n_1, \dots, n_k) \in \mathbb{Z}[n_1, \dots, n_k]$ with $p_{ij}(\mathbb{Z}^k) \subset \mathbb{Z}$ and $p_{ij}(0, 0, \dots, 0) = 0$, $1 \leq i \leq t$, $1 \leq j \leq r$. Then for every $A \in \mathcal{B}$ with $\mu(A) > 0$ and any $T_1, T_2, \dots, T_t \in G$, the set*

$$\Big\{(n_1, \dots, n_k) \in \mathbb{Z}^k : \mu\Big(\bigcap_{j=1}^{r} \Big(\prod_{i=1}^{t} T_i^{p_{ij}(n_1,\dots,n_k)} A\Big)\Big) > 0\Big\}$$

is syndetic.

There is every reason to believe that nilpotent versions of Theorems 2.6 and 2.9 also hold. The following conjecture, if true, will contain these and many other nilpotent results as special cases.

Conjecture 3.6. Let G be a nilpotent group of measure preserving transformations of a probability measure space $(X, \mathcal{B}, \mu)$, and let $\mathcal{P}_1, \dots, \mathcal{P}_k \colon \mathcal{F}_0 \to G$ be IP polynomials. Then for all $A \in \mathcal{B}$ with $\mu(A) > 0$ there exists a nonempty $\alpha \subset \mathbb{N}$ such that $\mu(A \cap \mathcal{P}_1(\alpha)A \cap \cdots \cap \mathcal{P}_k(\alpha)A) > 0$.

Theorem 3.5 raises question whether the assumptions can be further relaxed and whether, in particular, an analogue of Theorem 3.5 holds true if the measure preserving transformations $T_1, T_2, \dots, T_k$ generate a solvable group. Note that every finitely

generated solvable group is either of exponential growth or is virtually nilpotent, i.e. it contains a nilpotent group of finite index. (See, for example, [Ro]). Since Theorem 3.5 easily extends to virtually nilpotent groups, the question boils down to solvable groups of exponential growth. The following result answers this question in the negative, in a strong way.

Theorem 3.7 ([BL4], Theorem 1.1 (A)). *Assume that G is a finitely generated solvable group of exponential growth. There exists a measure preserving action $(T_g)_{g\in G}$ of G on a probability measure space $(X, \mathcal{B}, \mu)$, elements $g, h \in G$, and a set $A \in \mathcal{B}$ with $\mu(A) > 0$) such that $T_{g^n} A \cap T_{h^n} A = \emptyset$ for all $n \neq 0$.*

It is of interest to know to which extent the property of growth of the acting group alone is responsible for the validity of the positive and negative results formulated above. It was R. Grigorchuk who constructed in [Gri] a large family of groups of *intermediate growth*, which occupy an intermediate place between the groups of polynomial and exponential growth.

Question 3.8. Which of the above results extend to Grigorchuck's groups?

4. Generalized polynomials and dynamical systems on nilmanifolds

As we have seen in the previous section, the nilpotent framework is a natural (and often, ultimate) setup for multiple recurrence and combinatorial applications thereof. It also turns out that dynamical systems on nilmanifolds[10] are indispensable in solving problems which, on the face of it, have purely abelian character. For example, it is shown in the work of Host and Kra ([HK1]) and Ziegler ([Z]) that one can reduce the problem of establishing the existence of the L^2 limit

$$\lim_{N\to\infty} \frac{1}{N} \sum_{n=0}^{N-1} f_1(T^n x) f_2(T^{2n} x) \dots f_k(T^{kn} x),$$

where T is an invertible measure preserving transformation of a probability space $(X, \mathcal{B}, \mu)$ and $f_i \in L^\infty(X)$, to the study of the special case where (X, T) is a nilsystem. It also turns out that polynomial sequences of nilrotations (see [L2], [L3], [L5]) form an adequate setup for extending Host–Kra's and Ziegler's results to polynomial situations, that is to establishing the existence of the L^2-limit

$$\lim_{N\to\infty} \frac{1}{N} \sum_{n=0}^{N-1} f_1(T^{p_1(n)} x) \dots f_k(T^{p_k(n)} x),$$

[10] A nilmanifold is a compact homogeneous space X of a nilpotent Lie group G; a *nilrotation* is a translation of X by an element $g \in G$, $x \mapsto gx$; a *nilsystem* is a pair (X, T) where X is a nilmanifold and T is a nilrotation on X.

where the p_i are integer-valued polynomials. See [HK2] and [L4].

Another example, pertaining to recurrence, is given by the following result from [BHKR], the proof of which crucially uses the facts about nilsystems.

Theorem 4.1 ([BHKR]). *For every invertible ergodic probability measure preserving system $(X, \mathcal{B}, \mu, T)$, all $A \in \mathcal{B}$ and all $\varepsilon > 0$, the sets*

$$\{n : \mu(A \cap T^n A \cap T^{2n} A) \geq \mu(A)^3 - \varepsilon\}$$

and

$$\{n : \mu(A \cap T^n A \cap T^{2n} A \cap T^{3n} A) \geq \mu(A)^4 - \varepsilon\}$$

are syndetic.

On the other hand, there exists an ergodic system $(X, \mathcal{B}, \mu, T)$ such that for every integer $l > 1$ there exists a set $A = A(l) \in \mathcal{B}$ with $\mu(A) > 0$ and $\mu(A \cap T^n A \cap T^{2n} A \cap T^{3n} A \cap T^{4n} A) \leq \frac{1}{2}\mu(A)^l$.

We will describe now one more "nilpotent connection" recently established in [BL5]. The main object of study in [BL5] is the class of *generalized polynomials*, that is, functions obtained from conventional polynomials of one or several variables by applying the operations of addition, multiplication, and that of taking the integer part. Various classes of generalized polynomials naturally appear in diverse mathematical contexts, ranging from symbolic dynamics and mathematical games to Weyl's theorem on equidistribution[11] and recent work of Green and Tao [GreT] on arithmetic progressions in primes.[12]

Before formulating a general result from [BL5] which links generalized polynomials with nilsystems, let us briefly review a dynamical approach, due to Furstenberg, to the proof of Weyl's equidistribution theorem (see [F4], [F2]). Let $p(x) = a_0 + a_1 x + a_2 x^2 + \cdots + a_k x^k = b_0 + b_1 x + b_2 \binom{x}{2} + \cdots + b_k \binom{x}{k} \in \mathbb{R}[x]$. Consider the following affine transformation, called a *skew product*, of the k-dimensional torus $\mathbb{T}^k = \mathbb{R}^k/\mathbb{Z}^k$:

$$\tau(y_1, t_2, \ldots, y_k) = (y_1 + b_k, y_2 + y_1 + b_{k-1}, \ldots, y_k + y_{k-1} + b_1).$$

Let $y = (0, \ldots, 0, b_0) \in \mathbb{T}^k$. One can check by induction that $(\tau^n y)_k = \{p(n)\}$. If a_k is irrational, the system $(\mathbb{T}^k, \tau)$ is *uniquely ergodic* (with the unique τ-invariant measure being the Lebesgue measure on $\mathbb{T}^k$) which implies (the one-dimensional version of) Weyl's theorem. (For details, see [F4], Chapter 3, Section 3.)

One can also view the skew product transformation τ as a nilrotaion. Indeed, let G be the group of upper triangular matrices $\begin{pmatrix} 1 & \alpha_{1,2} & \alpha_{1,3} & \ldots & \alpha_{1,k} \\ 0 & 1 & \alpha_{2,3} & \ldots & \alpha_{2,k} \\ \vdots & \ddots & \ddots & \vdots & \vdots \\ 0 & \cdots & 0 & 1 & a_{k,k+1} \\ 0 & 0 & \cdots & 0 & 1 \end{pmatrix}$, where $a_{i,j} \in \mathbb{Z}$ for

[11] Weyl's theorem (or rather the most quotable special case of it) says that if p is a real polynomial with at least one coefficient other than the constant term irrational then the sequence $\{p(n)\} = p(n) - [p(n)], n \in \mathbb{N}$ is uniformly distributed in the unit interval

[12] See, for example, [Gre], p. 13

$1 \le i < j \le k, a_{i,k+1} \in \mathbb{R}$ for $1 \le i < k\}$, and let Γ be the subgroup of G consisting of the matrices with integer entries. Then G is a nilpotent (non-connected) Lie group with $X = G/\Gamma \cong \mathbb{T}^k$, and the system defined on X by the nilrotation by the element $g = \begin{pmatrix} 1 & 0 & 0 & \dots & b_k \\ 0 & 1 & 0 & \dots & b_{k-1} \\ \vdots & \ddots & \ddots & \vdots & \vdots \\ 0 & \dots & 0 & 1 & b_1 \\ 0 & 0 & \dots & 0 & 1 \end{pmatrix} \in G$ is isomorphic to the dynamical system on $\mathbb{T}^k$ defined by the skew product τ.

The following result obtained in [BL5] says, roughly, that not only generalized polynomials of the special form $\{p(n)\} = p(n) - [p(n)]$, but *any* bounded generalized polynomial can be "read off" of a nilmanifold.

Theorem 4.2. *For all $d \in \mathbb{N}$ and all bounded generalized polynomials $p\colon \mathbb{Z}^d \to \mathbb{R}$ there exists a compact nilmanifold X, an ergodic $\mathbb{Z}^d$ action $(T_n)_{n\in\mathbb{Z}^d}$ by nilrotations on X, a Riemann integrable function f on X and a point $x \in X$ such that for all $n \in \mathbb{Z}^d$ one has $p(n) = f(T_n x)$.*

Here is one of the numerous corollaries of Theorem 4.2:

Theorem 4.3. *Let $k \in \mathbb{N}$, let $U_1, \dots, U_k$ be commuting unitary operators on a Hilbert space and let $p_1, \dots, p_k$ be generalized polynomials $\mathbb{Z}^d \to \mathbb{Z}$. For any Følner sequence*[13] *$(\Phi_N)_{N=1}^{\infty}$ in $\mathbb{Z}^d$ the sequence*

$$\frac{1}{|\Phi_N|} \sum_{n\in\Phi_N} U_1^{p_1(n)} \dots U_k^{p_k(n)}$$

is convergent in the strong operator topology.

Theorem 4.3 leads to the following conjecture.

Conjecture 4.4. Theorem 4.3 remains true if the operators $U_1, \dots, U_k$ appearing in its formulation generate a nilpotent group.

Assume now that the unitary operators $U_1, \dots, U_k$ are induced by commuting measure preserving transformations $T_1, \dots, T_k$ acting on a probability space $(X, \mathcal{B}, \mu)$. In this case it is natural to inquire under which conditions on the generalized integer-valued polynomials p_i one has

$$\lim_{N-M\to\infty} \frac{1}{N-M} \sum_{n=M}^{N-1} \mu(A \cap T_1^{p_1(n)} T_2^{p_2(n)} \dots T_k^{p_k(n)} A) > 0$$

for all $A \in \mathcal{B}$ with $\mu(A) > 0$. In the case of conventional integer-valued polynomials a satisfactory sufficient condition for positivity of the above limit is that $p_i(0) = 0$,

[13] A sequence $(\Phi_N)_{N=1}^{\infty}$ of finite subsets of a (countable) group G is called (left) *Følner* if for all $g \in G$, $|g\Phi_N \cap \Phi_N|/|\Phi_N| \to 1$ as $N \to \infty$. In $\mathbb{Z}^d$ a common choice of Følner sequence is a sequence of parallelepipeds $\Phi_N = \prod_{i=1}^d [a_{N,i}, b_{N,i}]$ with $b_{N,i} - a_{N,i} \to \infty$ as $N \to \infty$ for all $i = 1, \dots, d$.

$i = 1, \ldots, k$; the following conjecture extends this fact to generalized polynomials. Let us denote by $\mathcal{P}_0$ the set of generalized polynomials which can be constructed (with the help of addition, multiplication, and taking of integer part) from conventional polynomials with *zero constant term*.

Conjecture 4.5. Let $k \in \mathbb{N}$ and $p_1, \ldots, p_k \in \mathcal{P}_0$. Then for any commuting invertible measure preserving transformations $T_1, \ldots, T_k$ of a probability measure space $(X, \mathcal{B}, \mu)$ and all $A \in \mathcal{B}$ with $\mu(A) > 0$ one has

$$\lim_{N-M\to\infty} \frac{1}{N-M} \sum_{n=M}^{N-1} \mu(A \cap T_1^{p_1(n)} T_2^{p_2(n)} \ldots T_k^{p_k(n)} A) > 0.$$

Note that Conjecture 4.5 implies that $\{n : \mu(A \cap T_1^{p_1(n)} T_2^{p_2(n)} \ldots T_k^{p_k(n)} A) > 0\}$ is a syndetic set. This, in turn, is a special case of the following conjecture, which extends the polynomial Szemerédi theorem (cf. Theorem 2.4 above) to generalized polynomials belonging to $\mathcal{P}_0$.

Conjecture 4.6. Let $(X, \mathcal{B}, \mu)$ be a probability measure space, let $k, r \in \mathbb{N}$, let $T_1, \ldots, T_k$ be commuting invertible measure preserving transformations of X and let $p_{i,j} \in \mathcal{P}_0$, $i = 1, \ldots, k$, $j = 1, \ldots, r$. Then for all $A \in \mathcal{B}$ with $\mu(A) > 0$, the set

$$\{n \in \mathbb{Z} : \mu(A \cap T_1^{p_{1,1}(n)} \ldots T_k^{p_{k,1}(n)} A \cap \cdots \cap T_1^{p_{1,r}(n)} \ldots T_k^{p_{k,r}(n)} A) > 0\}$$

is syndetic in $\mathbb{Z}$.

5. Amenable groups and ergodic Ramsey theory

It was John von Neumann who, in his study of the Hausdorff–Banach–Tarski paradox, introduced a class of group which nowadays are called *amenable* and which are widely recognized as providing the natural context for ergodic theory. In particular, many classical notions and results pertaining to 1-parameter group actions extend naturally to amenable groups. (See for example [OW] and [Li]). As we will see in this section, countable amenable groups also form a natural framework for Furstenberg's correspondence principle and hence for ergodic Ramsey theory.

Definition 5.1. A semigroup G is amenable if there exists an *invariant mean* on the space $B(G)$ of real-valued bounded functions on G, that is, a positive linear function $L\colon B(G) \to \mathbb{R}$ satisfying

(i) $L(\mathbf{1}_G) = 1$.

(ii) $L(f_g) = L({}_g f) = L(f)$ for all $f \in B(G)$ and $g \in G$, where $f_g(t) := f(tg)$ and ${}_g f(t) := f(gt)$.

The existence of an invariant mean is only one item from a long list of equivalent properties , such as the characterization of amenability given in the next theorem, some of which are far from being obvious and, moreover, are valid for groups (or special classes of semigroups) only. (See, for example, [W], Theorem 10.11.) The following theorem was established by Følner in [Fø]. (See also [N] for a simplified proof.)

Theorem 5.2. *A countable group G is amenable if and only if it has a left Følner sequence, namely a sequence of finite sets $\Phi_n \subset G$, $n \in \mathbb{N}$, with $|\Phi_n| \to \infty$ and such that for all $g \in G$, $\frac{|g\Phi_n \cap \Phi_n|}{|\Phi_n|} \to 1$ as $n \to \infty$.*

While there seems to be no general method of constructing a Følner sequence in an amenable group defined, say, by generators and relations, in many concrete, especially abelian situations, one has no problem finding a Følner sequence. For example, the parallelepipeds mentioned in footnote 13 and the sets $F_n \subset F_\infty$ defined in section 1 form natural Følner sequences in $\mathbb{Z}^d$ and in F_∞, respectively.

Before moving to discuss the Ramsey-theoretical aspects of amenable groups we want to mention that while the class of amenable groups is quite rich (in particular it contains all solvable and locally finite groups), it does not contain such classical groups as $\mathrm{SL}(n, \mathbb{Z})$ for $n \geq 2$.

Given a countable amenable group G and a left Følner sequence $(\Phi_n)_{n\in\mathbb{N}}$, one can define the upper density of a set $E \subset G$ with respect to $(\Phi_n)_{n\in\mathbb{N}}$ by $\bar{d}_{(\Phi_n)}(E) = \limsup_{n\to\infty} \frac{|E\cap\Phi_n|}{|\Phi_n|}$. Note that it immediately follows from the definition of a left Følner sequence that for all $g \in G$ and $E \subset G$ one has $\bar{d}_{(\Phi_n)}(gE) = \bar{d}_{(\Phi_n)}(E)$. By analogy with some known results about sets of positive density in abelian or nilpotent groups, one can expect that large sets in G, i.e. sets having positive upper density with respect to some Følner sequence, will contain some nontrivial configurations. The known results support this point of view and lead to a natural conjecture which will be formulated at the end of this section.

We formulate now a version of Furstenberg's correspondence principle for countable amenable groups.

Theorem 5.3 (See [B2] , Theorem 6.4.17). *Let G be a countable amenable group and assume that $E \subset G$ has positive upper density with respect to some left Følner sequence $(\Phi_n)_{n\in\mathbb{N}}$: $\bar{d}_{(\Phi_n)}(E) > 0$. Then there exists a probability measure preserving system $(X, \mathcal{B}, \mu, (T_g)_{g\in G})$ and a set $A \in \mathcal{B}$ with $\mu(A) = \bar{d}_{(\Phi_n)}(E)$ such that for all $k \in \mathbb{N}$ and $g_1, \ldots, g_k \in G$ one has*

$$\bar{d}_{(\Phi_n)}(E \cap g_1 E \cap \cdots \cap g_k E) \geq \mu(A \cap T_{g_1} A \cap \cdots \cap T_{g_k} A).$$

Remark. One can extend Theorem 5.3 to general countable amenable semigroups if instead of using Følner sequences (which cannot always be found in amenable semigroups) one defines a set $E \subset G$ to be large if for some left-invariant mean L on $B(G)$ one has $L(1_E) > 0$. (See [BM1], Theorem 2.1.)

As an illustration of the usefulness of amenable considerations, let us consider the (abelian and cancellative) semigroup $(\mathbb{N}, \cdot)$. Let

$$S_n = \{p_1^{i_1} p_2^{i_2} \cdots p_n^{i_n}, 0 \le i_j \le n, 1 \le j \le n\},$$

where p_i, $i = 1, 2, \ldots$, are primes in arbitrary order. It is not hard to show that for any sequence of positive integers $(a_n)_{n\in\mathbb{N}}$, the sets $a_n S_n$, $n \in \mathbb{N}$ form a Følner sequence in $(\mathbb{N}, \cdot)$.

Definition 5.4. A set $E \subset \mathbb{N}$ is called *multiplicatively large* if for some Følner sequence $(\Phi_n)_{n\in\mathbb{N}}$ in $(\mathbb{N}, \cdot)$ one has $\overline{d}_{(\Phi_n)}(E) > 0$.

Notice that the notions of additive and multiplicative largeness which are defined via Følner sets in, respectively, $(\mathbb{N}, +)$ and $(\mathbb{N}, \cdot)$ are different. For example the set O of odd natural numbers has additive density $\frac{1}{2}$ with respect to every Følner sequence in $(\mathbb{N}, +)$, while O has zero density with respect to every Følner sequence in $(\mathbb{N}, \cdot)$. In the other direction, consider for example a Følner sequence $(a_n S_n)_{n\in\mathbb{N}}$ in $(\mathbb{N}, \cdot)$, where the S_n are defined above and the a_n satisfy $a_n > |S_n|$. Then the set $E = \bigcup_{n=1}^{\infty} a_n S_n$ has zero additive density with respect to every Følner sequence in $(\mathbb{N}, +)$, while E has multiplicative density 1 with respect to the Følner sequence $(a_n S_n)_{n\in\mathbb{N}}$.

As may be expected by mere analogy with additively large sets, multiplicatively large sets always contain (many) geometric progressions. (This can be derived, for example, with the help of the IP Szemerédi theorem, Theorem 1.13 above). It turns out, however, that multiplicatively large sets also contain some other, somewhat unexpected *geoarithmetic* configurations.

Theorem 5.5 (See [B5], Theorems 3.11 and 3.15). *Let $E \subset \mathbb{N}$ be a multiplicatively large set. For all $k \in \mathbb{N}$, there exist $a, b, c, d, e, q \in \mathbb{N}$ such that $\{q^i(a + id) : 0 \le i, j \le k\} \subset E$ and $\{b(c + ie)^j : 0 \le i, j \le k\} \subset E$.*

We conclude this section (and this survey) by addressing the question about possible amenable extensions of the multiple recurrence results. While it is not clear how even to formulate an amenable generalization of the one-dimensional Szemerédi theorem, it is not too hard to guess what should be an amenable version of the multidimensional Szemerédi theorem!

Let G be a group and $k \in \mathbb{N}$. Let us call a $(k + 1)$-element set in the cartesian product G^k a *simplex* if it is of the form

$$\{(a_1, a_2, \ldots, a_k), (ga_1, a_2, \ldots, a_k), (ga_1, ga_2, \ldots, a_k), \ldots, (ga_1, ga_2, \ldots, ga_k)\}$$

for some $a_1, \ldots, a_k, g \in G$, and denote it by $S(a_1, \ldots, a_k; g)$. The following conjecture is known for $k = 2$. (See [BMZ], Theorem 6.1.)

Conjecture 5.6. Let $k \in \mathbb{N}$ and suppose that G is a countable amenable group. Assume that a set $E \subset G^k$ has positive upper density with respect to some Følner

sequence in G^k. Then the set

$$\{g \in G : \text{there exist } (a_1, \dots, a_k) \in G^k \text{ such that } S(a_1, \dots, a_k; g) \subset E\}$$

is syndetic in G.

Hyperbolic billiards and statistical physics

Nikolai Chernov and Dmitry Dolgopyat[1]

Abstract. Mathematical theory of billiards is a fascinating subject providing a fertile source of new problems as well as conjecture testing in dynamics, geometry, mathematical physics and spectral theory. This survey is devoted to planar hyperbolic billiards with emphasis on their applications in statistical physics, where they provide many physically interesting and mathematically tractable models.

Mathematics Subject Classification (2000). Primary 37D50; Secondary 34C29, 60F.

Keywords. Hyperbolic billiards, mixing, limit theorems.

1. Introduction

Let $\mathcal{D}$ be a bounded domain on a plane or a 2D torus with piecewise smooth boundary. A billiard system in $\mathcal{D}$ is generated by a single particle moving freely inside $\mathcal{D}$ with specular reflections off the boundary $\partial\mathcal{D}$. The phase space of a billiard is a 3D manifold Ω; the corresponding flow $\Phi^t : \Omega \to \Omega$ preserves the Liouville measure μ (which is uniform on Ω). The space of all collision points makes a 2D cross-section $\mathcal{M} \subset \Omega$, and the corresponding return map $\mathcal{F} : \mathcal{M} \to \mathcal{M}$ (called billiard map) preserves a natural smooth probability measure m.

The billiard is hyperbolic if the flow Φ^t and the map $\mathcal{F}$ have non-zero Lyapunov exponents. The first class of hyperbolic billiards was introduced [86] by Sinai in 1970; he proved that if the boundary of $\mathcal{D}$ is convex inward, then the billiard is hyperbolic, ergodic, mixing and K-mixing. He called such models dispersing billiards, now they are called Sinai billiards. They are also proven to be Bernoulli [43]. A few years later Bunimovich discovered [9], [10] that billiards in some domains $\mathcal{D}$ whose boundary is convex outward are also hyperbolic, due to a special 'defocusing mechanism'; the most celebrated example of his billiards is a stadium. More general classes of planar hyperbolic billiards are described in [94], [95], [63], [41]; we refer to [48], [26] for extensive surveys on hyperbolic billiards.

Billiards differ from classical smooth hyperbolic systems (Anosov and Axiom A flows and maps) in several respects. First of all, many hyperbolic billiards have

[1]We thank our adviser Ya. G. Sinai for introducing us to this subject and constant encouragement during our work. We thank our numerous collaborators, especially P. Balint, L. A. Bunimovich, R. de la Llave, G. Eyink, J. Jebowitz, R. Markarian, D. Szasz, T. Varju, L.-S. Young, and H.-K. Zhang, for many useful discussions on the subject of this survey. Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

non-uniform expansion and contraction rates (for example, if the moving particle is almost tangent to a convex outward arc of the boundary, then it will 'slide', and many reflections will occur in rapid succession during a short interval of time; a similar phenomenon occurs in a cusp on the boundary). Only dispersing billiards without cusps have uniform expansion and contraction rates.

Second, and most importantly, the billiard dynamics have singularities – phase points where both map $\mathcal{F}$ and flow Φ^t become discontinuous and have unbounded derivatives. Singularities come from two sources:

(a) Grazing collisions. In this case nearby trajectories can land on boundary components that lie far apart.

(b) Corners. In this case two nearby trajectories can hit different boundary pieces converging to a corner and get reflected at substantially different angles.

Moreover, billiards without horizon (where the length of the free path between collisions is unbounded) have infinitely many singularity curves in phase space.

Singularities in billiards lead to an unpleasant fragmentation of phase space. More precisely, any curve in unstable cones gets expanded (locally), but the singularities may cut its image into many pieces, some of them shorter than the original curve, which then will have to spend time on recovering. This makes billiards similar to non-uniformly hyperbolic systems such as quadratic maps or Henon attractors.

In [96], [97] Young has proposed two general methods for studying non-uniformly hyperbolic systems: tower method and coupling method.

The first one generalizes well-known Markov partitions ([85]). The latter divide phase space into rectangles ('building blocks') that have a direct product structure and being moved under the dynamics intersect one another in a proper (Markov) way. In the tower method only one rectangle is used and its images only need to intersect itself in the Markov way for some (not all) iterations. The tower construction is thus more flexible than that of Markov partitions, but the symbolic dynamics it provides is just as good as the one furnished by a Markov partition.

The coupling method is designed to directly control the dependence between the past and the future. Since points with the same past history form unstable manifolds, one wants to show that the images of any two curves in unstable cones have asymptotically the same distribution ([84]). To this end one partitions those curves into small subsets and pairs subsets of the first curve with those of the second one so that the images of the paired (coupled) points remain close to each other at all times (i.e. lie on the same stable manifold).

Both methods proved to be very efficient and produced many sharp results, as we describe below. We observe here that the tower method allows us to use functional analytic tools, in particular the theory of transfer operators [3], [71], which provide very precise asymptotic expansions. However the transfer operator approach requires a suitably defined space of functions (observables), which is sometimes too restrictive and dependent on the model at hand. For this reason the results obtained by the tower approach are often less explicit and the dependence on parameters of the model is less transparent. The coupling approach, being more elementary if less sophisticated,

gives more explicit bounds and makes it easier to work with several systems at a time.

Our survey is organized as follows. Section 2 describes statistical properties of dispersing billiards. Section 3 is devoted to systems with slow mixing rates. Section 4 deals with billiards in the presence of external forces and discusses transport coefficients and their dependence on parameters. Section 5 is devoted to interacting billiard particles, and Section 6 deals with infinite volume billiards.

We will denote by $\mathcal{N}(0, \sigma^2)$ a normal random variable (vector) with zero mean and variance (covariance matrix) σ^2, and by ρ_{σ^2} its density function.

2. Dispersing billiards

Dispersing billiards make the oldest and most extensively studied class of all chaotic billiards. They, arguably, have the strongest statistical properties among all billiards. We need to suppose that all corners have positively measured angles (no cusps) to guarantee uniform expansion and contraction rates.

The main difficulty in the studies of billiards is to cope with the destructive effect of fragmentation caused by singularities (we note that fragmentation may badly affect even relatively simple expanding maps so that they would fail to have good statistical properties [92]). In billiards, to cope with pathological fragmentation one imposes the following 'non-degeneracy' condition: there exist $m \in \mathbb{N}$, $\delta > 0$, and $\theta_0 < 1$ such that for any smooth unstable curve W of length less than δ

$$\sum_i \lambda_{i,m} \le \theta_0, \tag{1}$$

where the sum runs over all smooth components $W_{i,m} \subset \mathcal{F}^m(W)$ and $\lambda_{i,m}$ is the factor of contraction of $W_{i,m}$ under $\mathcal{F}^{-m}$. Roughly speaking (1) says that there no too-degenerate singularities such as multiple passages through the corners. (1) always holds if there are no corners, i.e. if $\partial\mathcal{D}$ is smooth, because for grazing collisions the expansion factor approaches infinity on one side of each singularity line, but in it is unknown if the condition (1) always holds in dispersing billiards with corners, nor if it is really necessary for the results presented below.

Let $\mathbb{B}^d_\alpha$ be the space of bounded $\mathbb{R}^d$-valued functions which are uniformly α-Hölder continuous on each component of $\mathcal{M}$ where the map $\mathcal{F}$ is smooth. We write $\mathbb{B}_\alpha$ for $\mathbb{B}^1_\alpha$. Let $\overline{\mathbb{B}}^d_\alpha = \{A \in \mathbb{B}^d_\alpha : m(A) = 0\}$. For any function $A \in \overline{\mathbb{B}}^d_\alpha$ we denote by $\sigma^2(A)$ the $d \times d$ (diffusion) matrix with components

$$\sigma^2_{ij}(A) = \sum_{n=-\infty}^{\infty} m\big(A_i\,(A_j \circ \mathcal{F}^n)\big) \tag{2}$$

(if this series converges). Denote $S_n(x) = \sum_{k=0}^{n-1} A(\mathcal{F}^k x)$.

Theorem 1. *The following four results hold under the condition* (1):

(a) (Exponential mixing [96], [18], [20]) *There is a constant* $\theta < 1$ *such that for every* $A, B \in \overline{\mathbb{B}}_\alpha$, *for all* $n \in \mathbb{Z}$

$$\left|m\big(A\,(B \circ \mathcal{F}^n)\big)\right| \le \text{const}\,\theta^{|n|},$$

which, in particular, implies the convergence of the series (2).

(b) (Functional Central Limit Theorem [11], [12], [20]) *For* $A \in \overline{\mathbb{B}}_\alpha^d$ *define a continuous function* $W_n(t)$ *by letting* $W_n(k/n) = S_k/\sqrt{n}$ *and interpolating linearly in between. Then* $W_n(t)$ *weakly converges, as* $n \to \infty$, *to a Brownian motion* (*Wiener process*) *with covariance matrix* $\sigma^2(A)$.

(c) (Almost sure invariance principle [66], [20]) *There exist* $\lambda > 0$ *such that for any* $A \in \overline{\mathbb{B}}_\alpha$ *we can find* (*after possibly enlarging the phase space*) *a Brownian motion* (*Wiener process*) $w(t)$ *with variance* $\sigma^2(A)$ *such that for almost all* x *there is* n_0 *such that for* $n \ge n_0$,

$$|S_n - w(n)| < n^{\frac{1}{2}-\lambda}.$$

(d) (Local Limit Theorem [90]) *Suppose* $A \in \overline{\mathbb{B}}_\alpha^d$ *takes values in a closed subgroup* $V \subset \mathbb{R}^d$ *of rank* r *and that there is no* $B \in L^2_m(\mathcal{M})$ *such that* $A + B - B \circ \mathcal{F}$ *belongs to a proper closed subgroup of* V. *Then for any continuous function* G *with compact support and for any sequence* $\{k_n\}$ *such that* $k_n/\sqrt{n} \to z \in \mathbb{R}^d$,

$$n^{r/2} m\big(G(S_n - k_n)\big) \to \rho_{\sigma^2(A)}(z) \int F\,dl$$

where l *is the Haar measure on* V.

Parts (a)–(c) of Theorem 1 can be proved by both tower method and coupling method ([96], [18], [20], [66]). The only known proof of part (d) uses the tower construction. It would be useful to derive the last part also by the coupling approach, since then it would be applicable to systems depending on parameters.

If $\mathcal{A}$ is a function on Ω, then standard reduction methods [73], [67] allow us to extend parts (b) and (c) to $S_t(X) = \int_0^t \mathcal{A}(\Phi^s X)\,ds$. The corresponding covariance matrix $\tilde{\sigma}^2(\mathcal{A})$ can be computed as follows. Consider the function $A(x) = \int_0^{\tau(x)} \mathcal{A}(\Phi^s x)\,ds$ on $\mathcal{M}$, where $\tau(x)$ is the length of the free path. Then

$$\tilde{\sigma}^2(\mathcal{A}) = \sigma^2(A)/\bar{\tau}, \tag{3}$$

where $\bar{\tau} = \pi\,\text{Area}(\mathcal{D})/\text{length}(\partial\mathcal{D})$ is the mean free path in the billiard system [16].

It would be also nice to extend the part (c) to multidimensional observables, as the almost sure invariance principle readily implies other limit laws – the law of iterated logarithm, integral tests, etc. [20].

Problem 1. Prove the almost sure invariance principle for $\mathbb{R}^d$ valued observables.

The above results can be applied to the Lorentz gas in $\mathbb{R}^2$. Consider a particle moving on the plane between a periodic array of fixed convex disjoint obstacles (scatterers). The natural phase space of this system is the unit tangent bundle to the plane minus the scatterers, and the natural invariant measure is infinite (σ-finite). But since the dynamics commute with the $\mathbb{Z}^2$ action we can factor the latter out and reduce the system to a dispersing billiard on the unit torus.

Let S_n be the center of the scatterer the particle hits at the nth collision. Then $S_n - S_{n-1}$ factors to a function $H(\mathcal{F}^{n-1}x)$ on the collision space $\mathcal{M}$ of the toral billiard. To apply Theorem 1 we need to assume that this billiard has finite horizon (a uniformly bounded free path), since otherwise $H(x)$ is unbounded and has infinite second moment. (This is *not* a technical restriction, the following result actually fails without the horizon assumption, see Section 3.) Let $q(t)$ be the position of the moving particle at time t.

Theorem 2. *The following five results hold for finite horizon Lorentz gases:*

(a) ([11], [12]) $S_n/\sqrt{n}$ *converges weakly to* $\mathcal{N}(0, \sigma^2)$ *where*

$$\sigma_{ij}^2 = \sum_{n=-\infty}^{\infty} m\big(H_i\,(H_j \circ \mathcal{F}^n)\big). \tag{4}$$

(b) ([11], [12]) $q(t)/\sqrt{t}$ *converges to* $\mathcal{N}(0, \sigma^2/\bar{\tau})$.

(c) ([90]) $m(S_n = 0) \sim 1/(2\pi \det(\sigma)n)$.

(d) ([30], [78]) S_n *is recurrent.*

(e) *The Lorentz gas is ergodic with respect to its* σ*-finite invariant measure.*

Parts (c) and (d) are recent. Part (e) follows from part (d) and [79].

Parts (c) and (d) indicate that S_n behaves like a random walk.

Problem 2. Extend the analogy between S_n and random walks (for instance, investigate the statistics of returns).

Some results in this direction are obtained in [40]. Results for geodesic flows on negatively curved surfaces can be found in [1].

3. Slow mixing and non-standard limit theorems

Here we describe some hyperbolic billiards with non-uniform expansion and contraction rates. Such are billiards with convex outward boundary components, semidispersing billiards (where the boundary is convex inward, but at some points its curvature vanishes, i.e. the boundary 'flattens'), as well as dispersing billiards with cusps. All these billiards have one feature in common - there are arbitrarily long series of reflections without expansion or contraction, which compromise the hyperbolicity.

Such series of 'idle' reflections occur in certain well defined regions in phase space. If $\hat{\mathcal{M}} \subset \mathcal{M}$ is their complement, then the return map $\hat{\mathcal{F}} : \hat{\mathcal{M}} \to \hat{\mathcal{M}}$ will have uniform expansion and contraction rates, so Young's methods will apply. The distribution of return times to $\hat{\mathcal{M}}$ then determines the rates of mixing:

Theorem 3. (a) ([28]) *If $\mathcal{D}$ is a Bunimovich stadium (a table with C^1 boundary consisting of two semicircles and two parallel line segments) and $A, B \in \overline{\mathbb{B}}_\alpha$, then*

$$\left|m\big(A\,(B \circ \mathcal{F}^n)\big)\right| \le \text{const} \cdot (\ln |n|)^2/|n|. \tag{5}$$

The same bound holds for modified stadia bounded by two circular arcs and two non-parallel line segments.

(b) ([28]) *If $\mathcal{D}$ is a Bunimovich billiard table bounded by several circular arcs that do not exceed semicircles an $A, B \in \overline{\mathbb{B}}_\alpha$, then*

$$\left|m\big(A\,(B \circ \mathcal{F}^n)\big)\right| \le \text{const} \cdot (\ln |n|)^3/|n|^2.$$

(c) ([29]) *Let $\mathcal{D}$ be a dispersing billiard table except the curvature of $\partial\mathcal{D}$ vanishes at two points $P, Q \in \partial\mathcal{D}$ such that the segment PQ is a periodic orbit of period two. More precisely let the boundary $\partial\mathcal{D}$ contain two curves $y = \pm(|x|^\beta + 1)$, where $\beta > 2$, so that $P = (0, 1)$ and $Q = (0, -1)$. Then for $A, B \in \overline{\mathbb{B}}_\alpha$,*

$$\left|m\big(A\,(B \circ \mathcal{F}^n)\big)\right| \le \text{const} \cdot (\ln |n|)^{a+1}/|n|^a \text{ where } a = \frac{\beta+2}{\beta-2}.$$

The logarithmic factors here are an artifact of the method used; they can presumably be removed [22] by approximating the map $\mathcal{F}$ on $\mathcal{M} \setminus \hat{\mathcal{M}}$ with a Markov chain (the region $\mathcal{M} \setminus \hat{\mathcal{M}}$ consists of countably many 'cells' that make almost a Markov partition). The bound (5) is expected for dispersing billiards with cusps [61], but this case turns out to be much harder; it is currently under investigation [27].

If correlations decay like $\mathcal{O}(1/n)$, as in Bunimovich stadia, the series (2) is likely to diverge, so the central limit theorem is likely to fail. This happens because the main contribution to the sum S_n comes from long series of (highly correlated) reflections without expansion or contraction. Again, we can employ the return map $\hat{\mathcal{F}} : \hat{\mathcal{M}} \to \hat{\mathcal{M}}$ and replace the given observable A with its 'cumulative' version

$$\bar{A}(x) = \sum_{n=0}^{R(x)-1} A(\mathcal{F}^n x), \tag{6}$$

where $\hat{\mathcal{F}}(x) = \mathcal{F}^{R(x)}(x)$, i.e. $R(x)$ is the first return time (to $\hat{\mathcal{M}}$), but such $\bar{A}$ will usually be unbounded and have heavy tails.

First studies of limit laws for observables with heavy tails were undertaken by Aaronson and Denker [2] for systems with Markov partitions. Their results were extended to non-uniformly hyperbolic maps with Young towers by Balint and Gouezel [4]; they gave an abstract criterion for convergence to a Gaussian law under a non-classical normalization (the case which is most relevant for billiards).

Balint and Gouezel [4] redefined $R(x)$ in (6) to be the first return time to the only rectangle in Young's tower and proved a limit theorem under the assumption that $\bar{A}$ has a distribution in a non-standard domain of attraction of Gaussian law. They applied this criterion to a Bunimovich stadium bounded by two semicircles of radius 1 and two line segments Γ_1 and Γ_2 of length $L > 0$ each: given a Hölder continuous observable $A \in C^\alpha(\mathcal{M})$, denote by

$$I(A) = \frac{1}{2L} \int_{\Gamma_1 \cup \Gamma_2} A(s, \boldsymbol{n})\, ds$$

its average value on the set of normal vectors $\boldsymbol{n}$ attached to Γ_1 and Γ_2. (A slower decay of correlations for the stadium, compared to other Bunimovich billiards, is caused by trajectories bouncing between two flat sides of $\mathcal{D}$ and $I(A)$ represents the contribution of such trajectories.)

Theorem 4. *The following results hold for Bunimovich stadia:*

(a) *If* $I(A) \neq 0$ *then* $S_n/\sqrt{n \ln n} \to \mathcal{N}(0, \sigma^2(A))$, *where*

$$\sigma^2(A) = \frac{4 + 3\ln 3}{4 - 3\ln 3} \times \frac{[I(A)]^2 L^2}{4(\pi + L)}. \tag{7}$$

(b) *If* $I(A) = 0$, *then there is* $\sigma_0^2 > 0$ *such that* $S_n/\sqrt{n} \to \mathcal{N}(0, \sigma_0^2)$.

As before, the approach of [67] allows us to extend this result to flows.

The abstract criterion of [4] should be applicable to a large number of systems. One of them is a periodic Lorentz gas without horizon [91]. In this case orbits which never collide with the scatterers lie in a finite number of families of corridors $\Pi_i \subset \mathbb{R}^2$. The projection of each corridor onto the torus is a strip bounded by two periodic orbits (which in general case correspond to fixed points of the collision map $\mathcal{F}$). Let w_i denote the vector joining the successive collisions along the bounding orbits for the corridor Π_i. Let also f_i denote a vector parallel to w_i but whose length equals the width of Π_i. Consider a nonnegative quadratic form

$$Q(v) = \frac{1}{\text{length}(\partial\mathcal{D})} \sum_i |w_i|\, \langle f_i, v\rangle^2.$$

This form corresponds to a 2×2 symmetric positive semidefinite matrix σ^2.

Theorem 5 ([91]). *Suppose there are at least two non-parallel corridors in a Lorentz gas without horizon. Then* $\sigma^2 > 0$ *and*

(a) $S_n/\sqrt{n \ln n} \to \mathcal{N}(0, \sigma^2)$;

(b) *If* $k_n/\sqrt{n \ln n} \to z$ *then* $n \ln n \cdot m(S_n = k_n) \to \rho_{\sigma^2}(z)$;

(c) S_n *is recurrent*;

(d) *the Lorentz gas is ergodic with respect to its* σ*-finite invariant measure.*

Problem 3. Prove a functional central limit theorem in the setting of [4].

Solving this problem would lead to a complete asymptotic description of the flight process in Lorentz gases without horizon.

4. Transport coefficients

Here we begin the discussion of billiard-related models of mathematical physics. The simplest one is a billiard $\mathcal{D}$ where the particle moves under an external force

$$\dot{v} = F(q, v). \tag{8}$$

Such systems were investigated in [19] under the assumptions that $\mathcal{D}$ is the torus with a finite number of disjoint convex scatterers and finite horizon. To prevent unlimited acceleration or deceleration of the particle, it was assumed that there was an integral of motion ("energy") $\mathcal{E}(q, v)$ such that each ray $(q, \alpha v)$, $\alpha \in \mathbb{R}_+$ intersects each level surface $\{\mathcal{E} = c\}$ in exactly one point. To preserve hyperbolicity, it was assumed that $\|F\|_{C^1}$ is small.

Such forces include potential forces ($F = -\nabla U$), magnetic forces ($F = B(q) \times v$) and electrical forces with the so-called Gaussian thermostat:

$$F = E(q) - \frac{\langle E(q), v\rangle}{\|v\|^2} v. \tag{9}$$

Fix an energy surface $\{\mathcal{E}(q, v) = \text{const}\}$ containing a point with unit speed. Under our assumptions on $\mathcal{E}$ this level surface is diffeomorphic to the unit tangent bundle Ω over $\mathcal{D}$ and the collision space $\mathcal{M}_F$ is diffeomorphic to $\mathcal{M}$. Denote by $\mathcal{F}_F \colon \mathcal{M}_F \to \mathcal{M}_F$ the corresponding return map.

Theorem 6 ([19]). *$\mathcal{F}_F$ has a unique SRB (Sinai–Ruelle–Bowen) measure m_F, i.e. for Lebesgue almost every $x \in \mathcal{M}_F$ and all $A \in C(\mathcal{M}_F)$*

$$\frac{1}{n} \sum_{i=0}^{n-1} A(\mathcal{F}_F^i x) \to \int_{\mathcal{M}_F} A \, dm_F.$$

The map $\mathcal{F}_F$ is exponentially mixing and satisfies the Central Limit Theorem (cf. Theorem 1).

As usual one can derive from this the existence (and uniqueness) of the SRB measure μ_F for the continuous time system.

Another interesting modification of billiard dynamics results from replacing the "hard core" collisions with the boundary by interaction with a"soft" potential near the boundary. We do not describe such systems here for the lack of space referring the reader to [60].

Theorem 6 implies the existence of various transport coefficients for planar Lorentz gas with finite horizon. For example, consider a thermostated electrical force (9) with a constant field $E(q) = E = \text{const}$, and let m_E denote the SRB measure on the $\{\mathcal{E} = 1/2\}$ energy surface.

Theorem 7 ([24]). *There is a bilinear form ω such that for $A \in C^\alpha(\mathcal{M})$*

$$m_E(A) = m(A) + \omega(A, E) + o(\|E\|).$$

To illustrate these results, let q_n denote the location of the particle on the plane at its nth collision, then Theorem 6 implies for almost all x the average displacement $(q_n - q_0)/n$ converges to a limit, $J(E)$, i.e. the system exhibits an electrical current. Theorem 7 implies

$$J(E) = ME + o(\|E\|) \quad \text{(Ohm's Law)},$$

where M is a 2×2 matrix, see below.

One interesting open problem is to study the dependence of the measure m_F of the force F, for example the smoothness of m_E as a function of the electrical field E. For hyperbolic maps without singularities SRB measure depends smoothly on parameters [51], [76], [77]. For systems with singularities the results and methods of [24] demonstrate that the SRB measure is differentiable at points where it has smooth densities (e.g. $E = 0$ in the previous example).

In fact there is an explicit expression for the derivative (Kawasaki formula). To state it let $\mathcal{F}_\varepsilon$ be a one-parameter family of maps such that $\mathcal{F}_0 = \mathcal{F}$ has a smooth SRB measure and for small ε the map $\mathcal{F}_\varepsilon$ has an SRB measure m_ε, too, and the convergence to the steady state m_ε, in the sense that if ν is a smooth probability measure on $\mathcal{M}$ and $A \in C^\alpha(\mathcal{M})$ then $\nu(A \circ \mathcal{F}_\varepsilon^n) \to m_\varepsilon(A)$, is exponential in n and uniform in ε. Let $X = \frac{d}{d\varepsilon}\big|_{\varepsilon=0}(\mathcal{F}_\varepsilon \circ \mathcal{F}^{-1})$. Then

$$\frac{d}{d\varepsilon}\Big|_{\varepsilon=0} m_\varepsilon(A) = -\sum_{n=0}^{\infty} \int_{\mathcal{M}} \operatorname{div}_m(X)\, A(\mathcal{F}^n x)\, dm(x). \tag{10}$$

For the constant electrical field E the Kawasaki formula reads $DJ|_{E=0} = \frac{1}{2}\sigma^2$, where σ^2 is defined by (4). Hence

$$J = \frac{1}{2}\sigma^2 E + o(\|E\|), \tag{11}$$

which is known in physics as Einstein relation.

On the other hand numerical experiments [8] seem to indicate that $J(E)$ is *not* smooth for $E \neq 0$. Similar lack of smoothness is observed in ([44], [45], [47]) for expanding interval maps, but the billiard case seems to be more complicated. Indeed the smoothness of SRB measures (or the lack thereof) seems to be intimately related to the dynamics of the singularity set. For 1D maps the singularity set is finite whereas for 2D maps the singularity set is one-dimensional, and so one can expect some statistics for the evolution of that set.

Problem 4. Prove that the SRB measure, as a function of parameters, is not smooth (generically). Derive relations between its Hölder exponent near a given parameter value and other dynamical invariants, such as Lyapunov exponents, entropy, etc.

A related issue is the dependence of infinite correlation sums, such as the one in (10), on the geometry of the billiard table. This issue was addressed in [23]. Given

a domain $\mathcal{D} \subset \mathbb{T}^2$, an additional round scatterer is placed in $\mathcal{D}$ with a fixed radius $R > 0$ and a (variable) center Q; then one gets a family of billiard maps $\mathcal{F}_Q$ acting on the same collision space $\mathcal{M}$ and having a common smooth invariant measure m. For any smooth functions A, B on $\mathcal{M}$ with zero mean let

$$\sigma^2_{A,B}(Q) = \sum_{n=-\infty}^{\infty} m\big(A\,(B \circ \mathcal{F}_Q^n)\big). \tag{12}$$

It is proven in [23] that $\sigma^2_{A,B}(Q)$ is a log-Lipschitz continuous function of Q:

$$\big|\sigma^2_{A,B}(Q_1) - \sigma^2_{A,B}(Q_2)\big| \le \text{const}\,\Delta \ln(1/\Delta), \quad \text{where } \Delta = \|Q_1 - Q_2\|. \tag{13}$$

Problem 5. Is (13) an optimal bound?

Problem 6. Extend the analysis of [23] to dissipative systems studied in [19].

In particular is it true that the dependence on parameters is typically more regular for conservative systems?

Problem 7. Consider the class $\mathbb{S}$ of all Sinai billiard tables on $\mathbb{T}^2$ and deform a given table $\mathcal{D}$ continuously in C^4 so that it approaches the natural boundary of $\mathbb{S}$. Investigate the limit behavior of the diffusion matrix $\sigma^2(\mathcal{D})$.

If we only consider generic boundary points of $\mathbb{S}$, then this problem splits into three subproblems:

(a) What happens when two scatterers nearly touch each other?

(b) What happens when the boundary flattens so that a periodic trajectory with nearly zero curvature appears?

(c) What happens when one of the scatterers shrinks to a point?

Analogues of Problem 7 were investigated for expanding maps [38] and for geodesic flows on negatively curved surfaces [13]. For Sinai billiards, only problem (c) has been tackled in [23], see Theorem 9 (a) below. The first step towards problem (a) is to establish mixing bounds for billiards with cusps (for problem (b) this task has been accomplished in [29], see Theorem 3 (c)).

One can also study the behavior of other dynamical invariants, such as entropy and Lyapunov exponents, see [16], [32], [48], [14].

5. Interacting particles

One may hope that after so many results have been obtained for one particle dynamics in dispersing billiards, a comparable analysis could be done for multi-particle systems, including models of statistical mechanics where the number of particles grows to infinity. However not much has been achieved up to now. Recently there has been a significant progress in the study of stochastically interacting particles [52], [93], but

the problems involving deterministic systems appear to be much more difficult. One notable result is [70] where Euler equation is derived for Hamiltonian systems with a weak noise, however that particular noise is of a very special form, and its choice remains to be justified by microscopic considerations.

Regarding models with finitely many particles, the most celebrated one is a gas of hard balls in a box with periodic boundary conditions (i.e. on a torus $\mathbb{T}^d$). The ergodicity of this system is a classical hypothesis in statistical mechanics attributed to L. Boltzmann and first mathematically studied by Sinai [83], [86], see [48]. The hyperbolicity and ergodicity for this system have been proven in fairly general cases only recently [80], [81], but a proof in full generality is not yet available.

Problem 8. Prove the ergodicity of N hard balls on a torus $\mathbb{T}^d$ for every $N \geq 3$ and $d \geq 2$ and for arbitrary masses $m_1, \ldots, m_N$ of the balls.

The existing proofs [80], [81] cover 'generic' mass vectors $\{m_1, \ldots, m_N\}$ (apart from unspecified submanifolds of codimension one in $\mathbb{R}^N$). Besides, the existing proofs heavily rely on abstract algebraic-geometric considerations, and it is important to find more explicit and dynamical arguments.

A system of N hard balls on $\mathbb{T}^d$ can be reduced to semi-dispersing billiards in a Nd-dimensional torus with a number of multidimensional cylinders removed. Now the considerations of Section 3 suggest that the rate of mixing for gases of hard balls is quite slow. Physicists estimated that correlation functions for the flow decay as $\mathcal{O}(t^{-d/2})$, see [42], [72].

Problem 9. Investigate mixing rate for gases of N hard balls in $\mathbb{T}^d$ or N hard disks on a Sinai billiard table.

An important feature of systems considered in statistical mechanics is that there are several different scales in space and time. This can complicate the study since the problem of interest tend to involve several 'levels' of parameters, but on the other hand one can expect certain simplifications; for example, Hamiltonian systems of N particles which are not ergodic (and this is, generically, the case due to the KAM theory) may behave as ergodic in the thermodynamical limit $N \to \infty$ (see e.g. [31], Chapter 9). Another example is that some pathologies slowing the mixing rates can be suppressed on large time-space scales, thus the system may behave as strongly chaotic.

A significant progress in the study of multi-scale systems with chaotic fast motion has been achieved recently, see [39] and references wherein. In this section we describe the first rigorous result on multi-scale billiard systems [23].

Consider a system of two particles moving on a 2D torus with a finite number of fixed convex scatterers (we assume that the resulting region $\mathcal{D} \subset \mathbb{T}^2$ has finite horizon). Particles collide with the scatterers and with each other elastically. The first particle called **P** is a heavy disk of mass $M \gg 1$ and radius $R \sim 1$. The second particle called **p** is a dimensionless point of unit mass.

In equilibrium, the kinetic energies of **P** and **p** are comparable, and then **P** will move practically with constant velocity, without noticing **p**. A more interesting development occurs if the initial velocity of **P** is zero. Assume that the initial speed of **p** is 1 and that its initial state is chosen randomly from the unit tangent bundle over $\mathcal{D}$. Then the position Q of **P** at time t becomes a random process $Q_M(t)$. We want to describe the motion of **P** in the interior of $\mathcal{D}$ (before it has chance to reach $\partial\mathcal{D}$), so we fix a small $\delta > 0$ and stop **P** once it comes within distance δ from $\partial\mathcal{D}$. Under a non-degeneracy condition on $\mathcal{D}$, see below, the following is proved:

Theorem 8 ([23]). *As $M \to \infty$, the process $Q_M(\tau M^{2/3})$ converges weakly to the solution of the following stochastic differential equation*

$$\ddot{Q} = \tilde{\sigma}(Q)\,\dot{w} \tag{14}$$

where $\dot{w}$ is the white noise and the 2×2 matrix $\tilde{\sigma}(Q)$ is the positive square root of

$$\tilde{\sigma}^2(Q) = \sigma^2(Q)/\bar{\tau},$$

compare this to (3); *here $\bar{\tau} = \pi(\mathrm{Area}(\mathcal{D}) - \mathrm{Area}(\mathbf{P}))/(\mathrm{length}(\partial\mathcal{D}) + \mathrm{length}(\partial\mathbf{P}))$ is the mean free path for the fast particle* **p** *and*

$$\sigma^2(Q) = \sum_{n=-\infty}^{\infty} m\big(A\,(A \circ \mathcal{F}_Q^n)^T\big)$$

where $\mathcal{F}_Q$ is defined before Eq. (12) *and $A \in \mathbb{B}^2$ is defined by* (18) *below.*

The non-degeneracy condition mentioned above is $\sigma^2(Q) > 0$ for all Q. This condition allows us to 'promote' the log-Lipschitz continuity of σ^2 given by (13) to the log-Lipschitz continuity of $\tilde{\sigma}$ and then show that the equation (14) is well posed. This illustrates the importance of Problems 5 and 6 for homogenization theory. The fact that $\sigma^2(Q)$ is non-degenerate, apart from a codimension infinity subset of $\mathbb{S}$, follows from [12].

To understand (14) observe that when **P** collides with **p** the tangential component of its velocity remains unchanged while the normal component changes as follows

$$V_{\mathrm{new}}^{\perp} = \frac{M-1}{M+1}\,V_{\mathrm{old}}^{\perp} + \frac{2}{M+1}\,v_{\mathrm{old}}^{\perp} = V_{\mathrm{old}}^{\perp} + \frac{2}{M}\,v_{\mathrm{old}}^{\perp} + \mathcal{O}\Big(\frac{1}{M^{3/2}}\Big) \tag{15}$$

where $v_{\mathrm{old}}^{\perp}$ is the normal component of the velocity of **p** (the estimate on the remainder term uses the fact that due to the energy conservation $M\|V\|^2 + \|v\|^2 = 1$ the speed of **P** never exceeds $1/\sqrt{M}$). Hence velocity of **P** after n collisions equals

$$V_n = \frac{2}{M}\sum_{i=1}^{n} v_i^{\perp} + \mathcal{O}\Big(\frac{n}{M^{3/2}}\Big) \tag{16}$$

where $v_i^\perp$ is the normal component of the velocity of **p** before the i-th collision of **P** with **p**. As we need to count all the collisions of **p**, both with **P** and $\partial\mathcal{D}$, then (16) takes form

$$V_n = \frac{2}{M}\sum_{i=1}^{n} A\circ\mathcal{F}^i + \mathcal{O}\Big(\frac{n}{M^{3/2}}\Big) \tag{17}$$

where $\mathcal{F}$ is the collision map in our system of two particles and

$$A = 2v^\perp \text{ if } \mathbf{p} \text{ collides with } \mathbf{P} \text{ and } 0 \text{ otherwise.} \tag{18}$$

As $M\to\infty$, our system approaches the limit where **P** does not move ($Q\equiv$ const) and **p** bounces off $\partial\mathcal{D}\cup\mathbf{P}$ elastically, thus its collision map is $\mathcal{F}_Q$. For this limiting system, Theorem 1 (c) says that if $n = M^\alpha d\tau$, then

$$\sum_{i=1}^{n} A\circ\mathcal{F}_Q^i \sim M^{\alpha/2}\,\sigma(Q)\,dw(\tau) \tag{19}$$

where $w(\tau)$ is the standard Brownian motion. Since $Q = \int V dt$ and the integral of the Brownian motion grows as $t^{3/2}$, it is natural to take $\alpha = 2/3$ in (19), so that $M^{3\alpha/2}/M \sim 1$, cf. (16), and expect the limiting process to satisfy (14).

In the proof of Theorem 8 we had to show that the two-particle collision map $\mathcal{F}$ in (17) could be well approximated by the limiting billiard map $\mathcal{F}_Q$ in (19). While the trajectories of individual points under these two maps tend to diverge exponentially fast, the images of curves in unstable cones tend to stay close together, and we proved this by a probabilistic version of the shadowing lemma developed in [37]. Then we decomposed the initial smooth measure into one-dimensional measures on unstable curves (each curve W with a smooth measure ν on it was called a standard pair) and adapted Young's coupling method to relate the image of each standard pair (W,ν) under the map $\mathcal{F}^n$ and that under $\mathcal{F}_Q^n$, as n grows.

The system described above is a very simplified version of the classical Brownian motion where a macroscopic particle is submerged into a liquid consisting of many small molecules. In our model the liquid is represented by a single particle, but its chaotic scattering off the walls effectively replaced the chaotic motion of the molecules coming presumably from inter-particle interactions.

One feature of Theorem 8 which may be surprising at first glance is that the diffusion matrix σ^2 is position dependent – the feature one does not expect for the classical Brownian particle. The reason is that the size of **P** is comparable to the size of the container $\mathcal{D}$, so that typical time between successive collisions of **p** with **P** is of order one, hence **p** has memory of the previous collisions with **P** giving rise to a location dependent diffusion matrix. This dependence disappears if **P** is macroscopically small (but microscopically large!):

Theorem 9 ([23]). *As $R\to 0$ we have*

$$\tilde\sigma^2(Q) = \frac{8R}{3\mathrm{Area}(\mathcal{D})}\,I + \mathcal{P}(Q)\,R^2 + o(R^2), \tag{20}$$

where $\mathcal{P}(Q)$ is a weighted Poincaré series. Furthermore, there is a function $M_0(R)$ such that if $M \to \infty$ and $R \to 0$ with $M > M_0(R)$, then $Q(\tau R^{-1/3} M^{2/3})$ converges weakly to the process

$$\sqrt{\frac{8}{3\text{Area}(\mathcal{D})}} \int_0^\tau w(s)\, ds$$

where $w(s)$ is the standard Brownian Motion.

Observe that the formula (20) would easily follow if the collisions between **p** and **P** made a random Poisson process with intensity proportional to $2R/\text{Area}(\mathcal{D})$ (the inverse of the mean intercollision time).

We remark that since we have a single fast particle **p**, its collisions with the boundary $\partial\mathcal{D}$ are the only source of chaos. If $\mathcal{D}$ is a convex smooth table, for example, then due to the presence of caustics [53] there is a positive probability that **p** and **P** will never meet, so Theorem 8 fails in that case.

Problem 10. Prove Theorems 8 and 9 for two particles in a square box.

In a square box, the fast particle may bounce off between two parallel sides for a long time without running into the disk, so the dynamics has slow mixing rates, cf. Section 3. According to the results of [4], see Theorem 4, one expects a non-standard normalization for most observables. However the observable given by (18) vanishes on $\partial\mathcal{D}$ (since the velocity of **P** does not change during the collisions of **p** with the walls), so we are actually in the context of Theorem 4 (b), hence Central Limit Theorem may hold despite the overall slow mixing rates.

The extension of Theorem 9 to a square box leads (by using a standard reflection of the box across its boundary) to a new model – a fast particle moving on a plane with a periodic configuration of identical circular scatterers of radius $R \to 0$. This system is interesting in its own rights, but not much is known about its asymptotic properties as $R \to 0$. A lot of work has been done on the case where scatters are placed at random (see [7], [82] and references wherein) but the periodic case is much more complicated, see [46]. Even the distribution of the free path is a non-trivial task accomplished only recently [6].

The results of [23] extend, without much changes, to systems with several heavy disks and one fast particle, as long as the disks do not collide with each other or with the boundary of the table (of course this restricts the analysis to a fairly short interval of time). Let us, for example, formulate an analogue of Theorem 8 in this situation. Let k be the number of heavy disks which are initially at rest. Then, after rescaling time by $\tau = M^{-2/3}t$, the velocity of the limiting process satisfies

$$\frac{d}{d\tau}\begin{pmatrix} V_1 \\ \vdots \\ V_k \end{pmatrix} = \sigma_{Q_1 \dots Q_k}\, \dot{w}(\tau),$$

where $\dot{w}$ is a standard k-dimensional white noise. Note that even though the heavy disks are not allowed to interact with each other directly, each one "feels" the presence of the others through the diffusion matrix $\sigma_{Q_1 \dots Q_k}$, which depends on the positions of all the disks.

A much more difficult problem arises if there are several fast particles.

Problem 11. Extend Theorems 8 and 9 to systems with several fast particles.

In this case the limiting ($M \to \infty$) system consists of several non-interacting particles moving on the same dispersing billiard table (the heavy disk(s) will be "frozen" as $M = \infty$). Such a system can be reduced to a semidispersing billiard in a higher dimensional container, however that billiard will have very poor statistical properties. In fact, it will not be even fully hyperbolic – several of its Lyapunov exponents corresponding to the flow directions of the particles will vanish.

A more promising strategy for this case is to deal directly with the continuous time dynamics. Then the limiting system of several non-interacting fast particles is a direct product of one-particle billiard flows. To extend the results of [23] to this model we need to generalize their methods to the continuous time setting, and we also need good estimates for mixing rates of dispersing billiard flows.

Problem 12. Estimate the decay of correlations for dispersing billiard flows.

The studies of flow correlations are notoriously difficult (the main reason is that there is no expansion or contraction in the flow direction). Even for classical Anosov flows no estimates on correlations were available until the late 1990s. Only recently various estimates were obtained on the decay of correlations for smooth uniformly hyperbolic flows [17], [35], [59]. Some of them were just extended to nonuniformly hyperbolic flows [65], including Sinai billiards: it was shown [65] that for a 'prevalent' set of Sinai billiards with finite horizon, flow correlations decay faster than any polynomial function.

We expect that the flow correlations for Sinai billiards with finite horizon actually decay exponentially fast. Moreover, it appears that a sub-optimal ('stretched exponential') bound developed in [17] can be extended to billiard flows, and this is our work in progress. With some of these estimates, albeit less than optimal, we might be able to handle the above system of several fast particles.

Interestingly, the mixing rates of the billiard flow may not match those of the billiard map. For instance, in Sinai billiards without horizon the billiard map has fast (exponential) decay of correlations [18], but the flow is apparently very slowly mixing due to long flights without collisions [5]. On the contrary, in Sinai tables with cusps, the billiard map appears to have polynomial mixing rates, see Section 3, but the flow may very well be exponentially mixing, as the particle can only spend a limited time in a cusp. The same happens in Bunimovich billiards bounded only by circular arcs that do not exceed semicircles – the billiard map has slow mixing rates (Theorem 3), but the flow is possibly fast mixing, as sliding along arcs (which slows down the collision map) does not take much flow time.

The next step toward a more realistic model of Brownian motion would be to study several light particles of a positive radius $r > 0$. (If there is only one light particle, such an extension is immediate since 'fattening' the light particle is equivalent to 'fattening' the disk **P** and the scatterers by the same width r.) It is however reasonable to assume that the light particles are much smaller than the heavy one, i.e. $r \ll R$. In this case one can presumably treat consecutive collisions as independent, so that in the limit $r \to 0$ the collision process becomes Markovian. An intermediate step in this project would be

Problem 13. Consider a system of k identical particles of radius $r \ll 1$ moving on a dispersing billiard table $\mathcal{D}$. Let $E_i(t)$ denote the energy of the ith particle at time t. Prove that the vector

$$\{E_1(\tau/r), E_2(\tau/r), \dots, E_k(\tau/r)\}$$

converges, as $r \to 0$, to a Markov process with transition probability density given by the Boltzmann collision kernel [15]. This means that if particles i and j collide so that the angles between their velocities and the normal are in the intervals $[\phi_i, \phi_i + d\phi_i]$ and $[\phi_j, \phi_j + d\phi_j]$, respectively, with intensity

$$\frac{\left|\sqrt{2E_i}\cos\phi_i - \sqrt{2E_j}\cos\phi_j\right| d\phi_i\, d\phi_j}{4\pi^2 \text{Area}(\mathcal{D})},$$

and then the particle i transfers energy $E_i\cos^2\phi_i - E_j\cos^2\phi_j$ to the particle j.

The proof should proceed as follows. As long as the particles do not interact, the evolution of the system is a direct product of dynamics of individual particles. This holds true whenever the particle centers $q_1, \dots, q_k$ are $> 2r$ units of length apart. Hence we need to investigate the statistics of visits of phase orbits to $\Delta_r = \{\min_{i\neq j} \|q_i - q_j\| \le 2r\}$, which is a set of small measure. Visits of orbits of (weakly) hyperbolic systems to small measure sets have been studied in many papers, see [36], [50] and the references wherein We observe that Theorem 9 (a) is the first step in the direction of Problem 13.

Next, recall that in Theorem 8 we did not allow the disk **P** to come too close to the boundary $\partial\mathcal{D}$; this restricted our analysis to intervals of time $t = \mathcal{O}(M^{2/3})$. During these times the speed of **P** remains small, $\|V\| = \mathcal{O}(M^{-2/3})$, thus the system is still far from equilibrium, as $M\|V\|^2 = \mathcal{O}(M^{-1/3}) \ll 1$.

Problem 14. Investigate the system of two particles **P** and **p** beyond the time of the first collision of **P** with $\partial\mathcal{D}$. In particular, how long does it take this system to approach equilibrium (where the energies of the particles become equal)?

There are two difficulties here. First, when **P** comes too close to the wall $\partial\mathcal{D}$, the mixing properties of the limiting ($M \to \infty$) billiard system deteriorate, because a narrow channel forms between **P** and the wall. Once the fast particle **p** is trapped in

that channel, it will bounce between **P** and the wall for quite a while before getting out; thus many highly correlated collisions between our particles occur, all pushing **P** in the same direction (off the wall). Thus we expect $\|\sigma(Q)\| \to \infty$ as the channel narrows. The precise rate of growth of $\|\sigma(Q)\|$ is important for the boundary conditions for equation (14), hence Problem 7 is relevant here.

The second difficulty is related to the accuracy of our approximations. The two particle system in Theorem 8 can be put in a fairly standard slow-fast format. Namely let (q, v) denote the position and velocity of **p** and (Q, V) those of **P**. Put $\varepsilon = 1/\sqrt{M}$ and denote $x = (q, v/\|v\|)$ and $y = (Q, V)$ (note that $\|v\|$ can be recovered from x and y due to the energy conservation). Then x and y transform at the nth collision by

$$\begin{aligned} x_{n+1} &= T_{y_n}(x_n) + \mathcal{O}(\varepsilon), \\ y_{n+1} &= y_n + B(x_n, y_n) + \mathcal{O}(\varepsilon^2). \end{aligned} \tag{21}$$

If $T_y(x)$ is a smooth hyperbolic map, the following averaging theorem holds [39]. Let $W \ni (x_0, y_0)$ be a submanifold in the unstable cone, almost parallel to the x-coordinate space (i.e. $y \approx y_0$ on W), and such that $\dim W$ equals the dimension unstable subspace. Then for $|\ln \varepsilon| \ll n \ll 1/\varepsilon$ and any smooth observable A we have

$$\int_W A(x_n, y_n)\, dx_0 = \int A(x, y)\, dm^{y_0}(x) + \varepsilon\, \omega(A, y_0) + o(\varepsilon), \tag{22}$$

where m^{y_0} denotes the SRB measure of the map $T_{y_0}(x)$. This result is a local version of Theorem 7 (consider the case $y_n \equiv y_0$!). In the presence of singularities, however, only a weaker estimate is obtained in [23]:

$$\int_W A(x_n, y_n)\, dx_0 - \int A(x, y)\, dm^{y_0}(x) = \mathcal{O}(\varepsilon\, |\ln \varepsilon|). \tag{23}$$

The extra factor $|\ln \varepsilon|$ appears because we have to wait $\mathcal{O}(|\ln \varepsilon|)$ iterates before the image of W under the unperturbed (billiard) map becomes sufficiently uniformly distributed in the collision space, and at each iteration we have to throw away a subset of measure $\mathcal{O}(\varepsilon)$ in the vicinity of singularities where the shadowing is impossible. The weak estimate (23) was sufficient for time intervals $\mathcal{O}(M^{2/3})$ considered in [23] since the corresponding error term in the expression for V_n, see (17), is

$$\mathcal{O}\left(\frac{n}{M} \times \frac{\ln M}{\sqrt{M}}\right) = \mathcal{O}\left(\frac{\ln M}{M^{5/6}}\right)$$

because $n = \mathcal{O}(M^{2/3})$. This error term is much smaller than the typical value of the velocity, $V_n \sim M^{-2/3}$.

However for $n \sim M$ the above estimate is not good as the error term would far exceeds the velocity itself. To improve the estimate (23) we have to incorporate the vicinity of singularities into our analysis. As the singularities are one-dimensional curves, we expect points falling into their vicinities to have a limit distribution, as

$\varepsilon \to 0$, whose density is smooth on each singularity curve. Finding this distribution requires an accurate counting of billiard orbits passing near singularities. Such counting techniques have been applied to negatively curved manifolds [62], and we hope to extend them to billiards.

Another interesting model involving large mass ratio is so-called piston problem. In that model a container is divided into two compartments by a heavy insulating piston, and these compartments contain particles at different temperatures. If the piston were infinitely heavy, it would not move and the temperature in each compartment would remain constant. However, if the mass of the piston M is finite the temperatures would change slowly due to the energy and momenta exchanges between the particles and the piston. There are several results about infinite particle case (see [21] and references wherein) but the case when the number of particles is finite but grows with M is much more complicated (see [54]). On the other hand if the number of particles is fixed and M tends to infinity then it was shown in [88], [69] under the assumption of ergodicity of billiard in each half of the container that after rescaling time by $1/\sqrt{M}$ the motion of the piston converges to the Hamiltonian system

$$\ddot{Q} = \Delta P := \frac{K^- \ell}{2\pi \operatorname{Area}(\mathcal{D}^-)} - \frac{K^+ \ell}{2\pi \operatorname{Area}(\mathcal{D}^+)}$$

where $\mathcal{D}^-(\mathcal{D}^+)$ is the part of the container to the left(right) of the piston $K^-(K^+)$ is the energy of the particles in $\mathcal{D}^-(\mathcal{D}^+)$ and ℓ is the length of the piston so that ΔP is the pressure difference. In particular if $\Delta P = 0$ and piston is initially at rest then the system does not move significantly during the time $\sqrt{M}$ and the question is what happens on a longer time scale. For the infinite system it was shown in [21] that the motion converges to a diffusion process with the drift in the direction of the hotter gas. In the finite system (for example in a stadium container) this process will be accompanied by simultaneous heating of the piston so that the system may develop rapid ($\dot{Q} \sim \frac{1}{\sqrt{M}}$) oscillations. A similar phenomenon was observed numerically in [25] for a system of $M^{2/3}$ particles in a 3D container. Those oscillations may be responsible for the fact that the system of [25] approaches its thermal equilibrium in $t \sim M^a$ units of time with some $1 < a < 2$ (computer experiments showed that $a \approx 1.7$).

If there is only one particle on either side of the piston the formula (17) suggests that the time of relaxation to equilibrium is of order M, as in $n \sim M$ collisions the heavy disk will reach its maximum velocity $\|V_n\| \sim \sqrt{n}/M = 1/\sqrt{M}$; to prove this we need to improve our approximations along the above lines.

6. Infinite measure systems

Here we discuss several systems with infinite invariant measure, which can serve as tractable models of some non-equilibrium phenomena.

In ergodic theory, systems with infinite (σ-finite) invariant measure are often regarded as exotic and attract little attention. However, hyperbolic and expanding maps with infinite invariant measure appear, more and more often, in various applications. Recently Lenci [55], [56] extended Pesin theory and Sinai's (fundamental) ergodic theorem to unbounded dispersing billiard tables (regions under the graph of a positive monotonically decreasing function $y = f(x)$ for $0 \le x < \infty$), where the collision map, and often the flow as well, have infinite invariant measures.

Another example that we already mentioned is the periodic Lorentz gas with a diffusive particle, but this one can be reduced, because of its symmetries, to a finite measure system by factoring out the $\mathbb{Z}^2$ action (Section 2). The simplest way to destroy the symmetry is to modify the location (or shape) of finitely many scatterers in $\mathbb{R}^2$. We call these finite modifications of periodic Lorentz gases.

Theorem 10. *Consider a periodic Lorentz gas with finite horizon. Then*

(a) ([57]) *its finite modifications are ergodic;*

(b) ([40]) *its finite modifications satisfy Central Limit Theorem with the same covariance matrix as the original periodic gas does.*

The proof of part (a) is surprisingly short. Every finite modification is recurrent, because if it was not, then the particle would not come back to the modified scatterers after some time, so it would move as if in a periodic domain, but every periodic Lorentz gas is recurrent (Theorem 2). Ergodicity then follows by [79].

The proof of (b) uses an analogy with a simple random walk (already observed in Section 2). Recall the proof of Central Limit Theorem for finite modifications of simple random walks [89]. Let ξ_n be a simple random walk on $\mathbb{Z}^2$ whose transition probabilities are modified at one site (the origin). Define $\tilde{\xi}_n$ as follows: initially we set $\tilde{\xi}_0 = \xi_0 = 0$, for every $n \ge 0$ we put

$$\tilde{\xi}_{n+1} - \tilde{\xi}_n = \begin{cases} \xi_{n+1} - \xi_n & \text{if } \xi_n \neq 0, \\ X_n & \text{if } \xi_n = 0, \end{cases}$$

where $X_n = \pm e_i$, $i = 1, 2$, is a random unit step independent of everything else. Then $\tilde{\xi}_n$ is a simple random walk and

$$|\xi_n - \tilde{\xi}_n| \le \mathrm{Card}\{k \le n : \xi_k = 0\}. \tag{24}$$

Since the number of visit to the origin depends only on the behavior of the walk *outside* of the origin the RHS of (24) is $\mathcal{O}(\ln n)$ (see e.g. [33]) so Central Limit Theorem for $\tilde{\xi}_n$ implies Central Limit Theorem for ξ_n.

The analogue of (24) for Lorentz gas if the following. Let $\tilde{\mathbb{B}}_\alpha$ denote the space of α Hölder continuous functions on the collision space of our periodic Lorentz gas with a finite modification, such that every $A \in \tilde{\mathbb{B}}_\alpha$ differs from a periodic function only on a compact set and the periodic part has zero mean. Then if $x_n = (q_n, v_n)$

denotes the position and velocity of the particle after the nth collision and x_0 has a smooth distribution ν with compact support, then for $A \in \tilde{\mathbb{B}}_\alpha$

$$\left|\mathbb{E}(A(x_n))\right| \le c\,\nu\big(\exists k \in [n - c\ln n, n]\colon q_k \text{ is on a modified scatterer}\big) + \mathcal{O}(n^{-100}),$$

where $c > 0$ is a constant. The proof of Theorem 1 (d) given in [90] allows us to estimate the first term here by $\mathcal{O}(\ln^\beta n/n)$ for some $\beta > 0$. The $\ln n$ factor is perhaps an artifact of the proof; on the other hand even for the much simpler case of a modified random walk one has $\mathbb{E}\big(A(\xi_n)\big) \sim c(A)/n$. This implies $\mathbb{E}\big(A(\xi_0)A(\xi_n)\big) \sim \bar{c}(A)/n$. Also there is a quadratic form $q(A)$ such that

$$\mathbb{E}\big(A(\xi_m)A(\xi_{m+n})\big) \sim \bar{q}(A)/(nm), \quad m, n \to \infty. \tag{25}$$

Here we see a new feature of non-stationary systems which does not happen in finite ergodic theory. The correlation series $\sum_{n=1}^{\infty} \mathbb{E}(A(\xi_m)A(\xi_{m+n}))$ diverges for all m but Central Limit Theorem still holds, since the contribution of the off-diagonal terms to $\mathbb{E}(\xi_n^2)$ is much smaller than the contribution of near diagonal terms.

Finite modifications of periodic Lorentz gases are among the simplest billiards with infinite invariant measures, so we hope to move further in their analysis:

Problem 15. Extend (25) to finite modifications of periodic Lorentz gases (with finite horizon).

The reason for this simplicity is that finite modifications are restricted to a 'codimension two' subset of $\mathbb{R}^2$. The particle runs into modified scatterer very rarely, so that its limit distribution is the same as for the unperturbed periodic gas. The situation appears to be different for 'codimension one' modifications.

For example, consider a periodic Lorentz gas and make the particle move in the $N \times N$ box bouncing off its sides and off the scatterers in the box. Denote by $q_N(t)$ the position of the particle at time t.

Problem 16. Prove that $q_N(\tau N^2)/N$ converges, as $N \to \infty$, to the Brownian motion on the unit square with mirror reflections at its boundary.

If the box boundaries are symmetry axis of the Lorentz gas then the result follows easily from Theorem 1 (b) but the general case appears more difficult. In fact if the boundaries of the box are not straight lines (so-called rough boundaries) then one can expect the limit to be different due to trapping and it is an interesting problem to construct such counterexample.

As a more sophisticated example, consider a 'one-dimensional' Lorentz gas – a particle moving in an infinite strip $I = \{(x, y)\colon 0 \le y \le 1\}$ (with identification $(x, 0) = (x, 1)$) and a periodic (in x) configuration of scatterers in I. Suppose a small external force F acts by (8) in a compact domain $x_{\min} \le x \le x_{\max}$. Denote by $q_F(t)$ the position of the moving particle at time t.

Problem 17. Find the limit distribution of $q_F(\tau N)/\sqrt{N}$ as $N \to \infty$.

The analogy with the random walk [89] suggests that $q_F(\tau N)/\sqrt{N}$ should converge to $|\zeta|\eta$ where ζ and η are independent, ζ is a one-dimensional normal distribution $\mathcal{N}(0, \sigma^2)$ where σ^2 is the same as for the system without the field, and η takes values ± 1, so that $\mathbb{P}(\eta = 1) \sim \mathbb{P}(q_n > 0)$ depends on the evolution in the region $x_{\min} \le x \le x_{\max}$. One can further conjecture a functional limit theorem, namely that $q_F(\tau N)/\sqrt{N}$ converges to the so-called skew Brownian motion [49].

While the problems described above could be attacked along the lines of [40], the situation becomes much more difficult if modifications are less regular. In particular very little is known if the location of all scatterers is purely random (if there are infinitely many independent particles in a random Lorentz gas, ergodicity was proven by Sinai [87]).

Problem 18. Do the results of Theorem 10 hold for random Lorentz gas?

The key question is the recurrence of the random Lorentz gas (this issue is irrelevant for infinite particle systems since if one particle wonders to infinity then another one comes to replace it, cf. [31], Chapter 9).

Lenci [58] uses Theorem 10 to show that recurrence holds for an 'open dense set' of Lorentz gases, but this remains to be shown for 'almost every' gas in a measure-theoretic sense.

Problem 17 brings us back to billiards with external forces, see Section 4. We assumed that (8) had an integral of motion. Without this assumption, the system would typically heat up (the particle accelerates indefinitely) or cool down (the particle slows down and stalls). It is interesting to determine which scenario occurs. Denote by $K(t) = \|v(t)\|^2/2$ the particle's kinetic energy at time t.

Problem 19. Consider a Sinai billiards with a velocity-independent external force $\dot{v} = F(q)$. Is $\liminf_{t\to\infty} K(t)$ finite or infinite for most initial conditions?

The particular case of a constant force $F = \text{const}$ is long discussed in physics literature, see [74] and the references therein, but it is yet to be solved mathematically. This model is known in physics as Galton board – a titled plane with a periodic array of pins (scatterers) and a ball rolling on it under a constant (gravitational) force and bouncing off the pins. Due to the conservation of the total energy, the particle accelerates as it goes down the board. Physicists are interested in finding the limit distribution of its position (in a proper time-space scale).

To address this problem observe that if we have a fast particle, i.e. $K(0) = \frac{1}{2\varepsilon}$, then by rescaling the time variable by $s = t/\sqrt{\varepsilon}$ and denoting the rescaled velocity by $u = dx/ds$ we obtain a new equation of motion

$$\frac{du}{ds} = \varepsilon F(q). \tag{26}$$

This system is of type (21) with fast variables $(q, u/\|u\|)$ and a slow variable $T = \|u\|^2/2$. For random Lorentz gases heuristic arguments [74] suggests that in a new

time variable $\tau = \text{const} \cdot \varepsilon^{-2} s$ the limit evolution of T will be given by

$$\dot{T} = \frac{1}{2\sqrt{2T}} + (2T)^{1/4} \dot{w} \tag{27}$$

where $\dot{w}$ is a white noise. The same conclusion is reached in [34] for the geodesic flow on a negatively curved surface in the presence of a weak external force.

As a side remark, observe that the fast motion is obtained here by projecting the right hand side of (26) onto the energy surface, which gives us a thermostated force. In particular (11) plays an important role in the derivation of (27). This shows that the Gaussian thermostat (9), even though regarded as 'artificial' by some physicists, appears naturally in the analysis of weakly forced systems.

We return to the conjecture (27). In terms of our original variables, equation (27) says that $[K(t)]^{3/2}$ is the so-called Bessel square process of index $4/3$, see [75, Chapter XI]. This indicates that $\|v(t)\| \sim t^{1/3}$ so the energy conservation implies $\|q(t) - q(0)\| \sim t^{2/3}$ (cf. [68]). Since the Bessel square process of index $4/3$ is recurrent, it is natural to further conjecture that there is a threshold $K_0 > 0$ such that for almost all initial conditions $\liminf_{t\to\infty} K(t) \le K_0$. This conclusion apparently contradicts a common belief that the particle on the Galton board, see above, generally goes down and accelerates. Rather paradoxically, it will come back up (and hence slow down) infinitely many times! It appears that rigorous mathematics may disagree here with physical intuition, in a spectacular way. The first step in solving this startling paradox would be to extend the averaging theorem (22) to billiards.

Some recent progress in geometric methods in the instability problem in Hamiltonian mechanics

Rafael de la Llave

Abstract. We discuss some geometric structures that lead to instability in Hamiltonian systems arbitrarily close to integrable.

The structures covered in this report are joint work with A. Delshams, T. M. Seara and M. Gidea.

Mathematics Subject Classification (2000). Primary 37J40, 37C29, 34C37; Secondary 70H08, 37C50, 34C29.

Keywords. Arnol'd diffusion, normally hyperbolic manifolds, whiskered tori, homoclinic intersections.

1. Introduction

Suppose that we have a system (without friction) and that we perturb it periodically. Will the effect of the forces accumulate or, on the contrary, will the forces average out?

Versions of this question have appeared since ancient times. One of the more ancients versions is the solar system. The Kepler model results from ignoring the interactions between the planets. This model can be solved explicitly and the system persists forever. We can think of the real solar system as a small modification of the Kepler model and wonder if the constant push and pull between the planets will eventually accumulate or whether they would average out and the orbits will remain bounded. See [LP66], [Arn63b] for surveys of the problem at different times. Similar problems appear in many areas of applications. For example, in the study of plasma confinement, or accelerator physics, one can rather easily exhibit confinement for idealized models which ignore mutual interactions, imperfections, etc. One can wonder whether including back the approximations of the model will spoil the confinement.

In other areas of applications, the instabilities are features that have to be sought out and exploited. (Indeed, one of the main goals of human kind has been to get as far as possible with as little effort as possible.) For example, in spacecraft dynamics, there is a great interest in finding ways of moving satellites using the (free!) gravitational forces rather than the (rather expensive!) forces generated by the engines [Bel04]. In theoretical chemistry an important problem is to understand whether the vibrations

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

of one part of a molecule will affect other parts or whether small perturbations will lead to dissociation [JVMU96].

Given the importance and difficulty of the problem, it is no surprise that it has received substantial attention from mathematicians and more applied scientists and that it has been studied by a variety of methods, both rigorous and heuristic.

In this lecture we cannot hope to do justice to this extremely rich history or to survey the recent developments in this very active area. Among several others, we mention the papers [Ber04], [BB02], [BBB03], [Bes96], [BCV01], [BT99], [BK04], [CY04b], [CY04a], [CG94], [CG98], [CP02], [CG03], [Cre03], [Dou88], [DLC83], [FM01], [FM03], [Itu96], [Kal03, LM05], [MS02], [MS04], [Moe96], [Moe02], [Tre02], [Tre04] and the announcements [Xia98], [Mat95], [Mat02]. This list is clearly incomplete!

The only goal of this lecture is to present a concrete point of view, namely, to explain the results in the papers [DdlLS00], [DdlLS03a], [DdlLS03b], [dlL02], [DdlLS05], [GdlL06b] as well as some work in progress (as of Dec. 05) based on the same circle of ideas. We cannot attempt here the much needed systematic survey of the area. We will not even attempt to cover the area of geometric methods and will omit topics such as the *separatrix map*, the study of phenomena that happen in adiabatic phenomena at resonances [Nei86], [NSV03], [IdlLNV02] or the generation of unbounded orbits in Newtonian systems taking advantage of the singularities [Ger91], [Xia92].

Our only goal of this lecture is to present the milestones in a particular approach to the problem. The passage from one milestone to the next is accomplished using a toolkit of standard techniques in the geometric theory of dynamical systems (normal hyperbolicity, averaging methods, KAM theory, Melnikov theory, obstruction theory, and correctly aligned windows). A less standard tool is the scattering map for a normally hyperbolic manifold, which we describe in Section 4.1). Many of the steps could be achieved in different ways. We certainly expect that more techniques will be incorporated in the near future to make the proofs sharper or shorter.

Since we are mainly covering material which is already published or available in much more detailed form, we have omitted important details and assumptions, hence we have not stated theorems. For precise statements and detailed proofs we refer to the references quoted.

2. A mathematical formulation of the instability problem

We will consider a mechanical system. That is a Hamiltonian system defined on a exact symplectic manifold. In some of the models we will discuss, it will be in fact, the product of a torus times and an Euclidean space.[1]

[1] If one considers Hamiltonian systems defined in more general symplectic manifolds, the problems of stability may be very different [Her91].

We will be concerned with situations where our system is close to "integrable." That is, our system can be written as

$$H = H_0(I, \varphi) + \varepsilon H_1(I, \varphi, t) \tag{1}$$

where H_0 is supposed to be integrable and H_1 is periodic (or quasi-periodic) in t.

"Integrable" is often an ill-defined term. In this lecture, we will consider two notions of integrable:

$$H_0 = \sum_{i=1}^{d} h_i(I_i), \tag{2}$$

$$H_0 = \sum_{i=1}^{d} \tilde{h}_i(I_i, \varphi_i). \tag{3}$$

Typical examples are $h_i(I_i) = \frac{1}{2} m_i I_i^2$, $\tilde{h}_i(I_i) = \pm\big(\frac{1}{2m_i} I_i^2 + V_i(\varphi_i)\big)$ with V_i functions with non-degenerate critical points (we will assume $V_i'(0) = 0$, $V_i''(0) > 0$). It is common usage to refer to (2) as "a-priori stable" and (3) as "a-priori unstable", at least when there are hyperbolic fixed points in (3). In the classical terminology used in [AKN88], they are called, respectively, "completely integrable" and "integrable with separable variables". Note that for the systems H_0, the quantities $h_i, \tilde{h}_i$ are conserved quantities. Nevertheless, in (3) the quantities $\tilde{h}_i$ have critical points and indeed, it is impossible to transform them into action-angle variables across the separatrices.

The problem we will consider is to give conditions on H_0 and on the ε-jet of H_1 which guarantee that for $0 < \varepsilon \ll 1$, there are orbits for which some of the variables I experience changes of order 1. This is not the only problem formulated in the literature (see e.g. [Arn68], [Arn04]) but it is the one we will considerer here. The author remembers a round table in S'Agaro [Sim99] in which the organizers asked a distinguished and broad panel to make standard a precise definition of Arnol'd instability. The unanimous consensus was that it was better to let each author make a precise definition of the problems considered in the paper. We note that many papers starting with [HM82] give the name Arnol'd diffusion to the existence of intersections between whiskered tori in (3). This is weaker than the problem we consider here since it ignores the *large gap problem*. See Section 5.

We would also like to describe quantitatively and qualitatively the orbits found. In particular, we would like to describe them in geometric terms and provide geometric features such as estimates on the time they take to move, Hausdorff measure of the orbits described and statistical properties.

Remark. We point out that the distinction between a-priori stable and a-priori unstable models makes sense only for models with one parameter. The model (6) is close to a-priori stable systems, but if $\varepsilon \ll \mu$ we can treat it by methods associated with a-priori unstable systems.

Another important set of models that will be described in Section 4 are systems described by the Hamiltonian

$$\begin{aligned} &H : T^*M \times \mathbb{T}^d \to \mathbb{R}, \\ &H = H_0(p,q) + V(q, \omega t) \end{aligned} \tag{4}$$

where (p, q) denotes a point in T^*M and ω is an external perturbation. We will assume that $H_0(\lambda p, q) = \lambda^2 H_0(p, q)$. Note that the potential term is homogeneous of degree zero.

In the models (4), we would like to find conditions on for which H_0 – which is conserved when $\varepsilon = 0$ – changes by amounts of order 1 whenever $\varepsilon > 0$.

The models (4) were introduced in [Mat95] with H_0 a Riemannian metric and $M = \mathbb{T}^2$, the method presented in [Mat95] is variational. The discussion presented here in section 4 will be based on [DdlLS00], [DdlLS05], [dlL02], [GdlL06b]. Related results are in [BT99]. We note that the geometric methods do not require that the metric is positive definite, so that they apply to Lorenz metrics too. A more detailed comparison between the related results is in [DdlLS05].

Closely related to the models (4) are models the form

$$H(p, q, t) = \frac{1}{2} p^2 + V_n(q) + V_m(q, t) \tag{5}$$

where $p, q \in \mathbb{R}^d$, $d \geq 2$, V_n, V_m are homogeneous of degree n, m respectively, $n > m$, $n > 2$,$V_n > 0$, V_m periodic or quasi-periodic in t. The fact that different terms have different homogeneities makes the geometric analysis similar to that of the models (4). Nevertheless, there are some differences, since the energy surface of (5) has less topology.

The models (5) are extensions to higher dimensions of the models introduced in [Lit66a], [Lit66b] for $d = 1$. A detailed survey of the results on $d = 1$ and important simplifications and corrections to the proofs in the literature is [Lev92] (the original paper [Lit66a], contains a serious error). For $d = 1$, if the terms are sufficiently close to polynomial, [LZ95] show that the orbits remain bounded.

Remark. The main reason to consider periodic or quasi-periodic perturbations is that this is the case that appears in many applications and also as intermediate models after averaging. (Some excellent references for averaging theory are [AKN88], [LM88].)

If one considers more general dependence on time, there is no reason to expect that all orbits average out and indeed, in many cases, it has recently been shown that one should expect instability [Ort04].

2.1. Some early mathematical results on stability. In spite of extremely insightful pioneering works [Poi99], [Lya92] it is not unfair to say that the first definitive and systematic mathematical results to deal with the stability problem arrived in the late 1950s.

The KAM theorem [Kol79], [Arn63a], [Mos66b], [Mos66a] – see also [dlL01] for a modern review – showed that, for a set of initial conditions of large measure, the oscillations of actions remain $O(\varepsilon^{1/2})$ for all time. The applications to celestial mechanics are particularly subtle. (see [Arn63b], [Féj04]) because the system – as many systems of physical interest – fails to satisfy the "generic" assumptions made in many results.

The result [Neh77], [Loc92], [DG96] showed that under "steepness" properties on H_0, one gets stability of $O(\varepsilon^a)$ for very long times $O(\exp(-1/\varepsilon^b))$ for some positive a, b. Hence, in many systems, one can only expect oscillations of the actions of size $\varepsilon^{1/2}$ for all conditions for exponentially long times or for all times in sets of large measure.

It is important to realize that in the a-priori unstable models, the hypotheses of KAM and Nekhoroshev theorem fail in neighborhoods of the separatrices where action-angle coordinates cannot be introduced.

2.2. Some early mathematical results on instability. The first real progress in the mathematical treatment of the problem of instability is the paper [Arn64]. This paper introduces the remarkable example

$$H = \frac{1}{2}p^2 + \frac{1}{2}I^2 + \mu(\cos q - 1) + \varepsilon(\cos q - 1)(\sin\varphi + \cos t), \tag{6}$$

and shows that for $0 < \varepsilon \ll \mu \ll 1$ there are orbits for which the action changes order 1. The mechanism introduced there has served as the basis of much progress. I guess that it will be hard to find a 4 page paper that has generated so much.

The striking example (6) lead to the problems of instability being termed "Arnol'd diffusion". The use of "diffusion" should not imply that it has anything to do with the heat equation.

Some other early results on instability which we will not be able to discuss are [Pus95], [Dou89], [Sit60], [Ale71]. The last two papers consider problems in celestial mechanics and use methods of normally hyperbolic manifolds, so are somewhat related to the methods described here.

2.3. Heuristic studies. Starting in the late 1960s there were extensive numerical studies on the instability problem by many authors. Notably, among many others, we will just mention the surveys [Chi79], [ZZN$^+$89], [TLL80], [Ten82].

Even if these studies were not rigorous, they identified several possible geometric mechanisms for instability and gave empirical mechanisms for their existence. Perhaps the most important fact uncovered by the numerical experiments was that the diffusion is caused by resonances. That is, the trajectories move along the regions where $k \cdot \nabla H_0 = 0$ for $k \in \mathbb{Z}^d$. These curves form the so-called "Arnold web" [Chi79], [ZZN$^+$89], [LR02]. It also became clear that there are different mechanisms at play. A very lucid – albeit non-rigorous – explanation of different mechanisms at play in instability is [Ten82].

3. The example of [Arn64] and the large gap problem

The analysis of [Arn64] is based on a few easy geometric observations, which we will review briefly now in language that we will use later.

We observe that for $0 < \mu$ the manifold $\Lambda = \{A_2 = 0\}$ is invariant. Moreover, Λ is foliated by invariant tori. The stable and unstable manifolds of these tori coincide.

The crucial point of the example is that the ε-dependent term vanishes together with its gradient in Λ. Therefore Λ and the dynamics on it remain unaltered when we make ε positive (but sufficiently small).

Even if the ε term does not have any effect on the manifold Λ it does have an effect on the stable and unstable manifolds. As it turns out, this effect can be computed perturbatively. The idea of the calculation is that the stable and unstable manifolds depend smoothly on parameters. Therefore, the first order term can be computed simply by integrating the variational equations. Some of these calculations in particular cases appear already in [Poi99]. Nowadays these calculations are referred to in the literature as *Melinkov method*.

The last step of the argument of [Arn64] is to show that given any sequence of tori τ_i such that the motion on them is minimal, and such that $W^u_{\tau_i} \pitchfork W^s_{\tau_{i+1}}$ then there is an orbit that follows them.

We note that, because of the exponential convergence, any point which converges to the torus converges to a concrete orbit: $W^{s,u}_{\tau_i} = \bigcup_{x_i \in \tau_i} W^{s,u}_{x_i}$. Therefore, given a sequence of tori, whose manifolds have intersections, there is a sequence of points $x_i \in \tau_i$ such that $W^u_{\tilde{x}_i} \pitchfork W^s_{\tilde{x}_{i+1}}$.

If we start in τ_i, we can wait long enough to move δ-close to $\tilde{x}_i$. Then, we can just move to $W^u_{\tilde{x}_i}$, and then arrive ε-close to τ_{i+1}. Then, a jump allows us to get into τ_{i+1} so that we can get to the next transition point.

If we follow the procedure sketched above, the orbits for each δ are different, so that one needs a separate argument to conclude that there is a true orbit. In the original paper, this is accomplished by a method, which is essentially topological – the obstruction method – but which uses some mild differentiability properties (some version of the λ lemma).

In the words of J. Moser's review in Mathscinet on the 4 page gem is: "The details of the proof must be formidable, although the idea of the proof is clearly outlined". By now, all the details are clearly in print. A modern exposition of the method, including some generalizations is [FM00]. A rather different approach to the analysis of the example in [Arn64] is in [Bes96], which uses variational methods rather than geometric to obtain orbits that shadow the connections between the tori. Unfortunately, we cannot describe the deep and numerous developments generated by [Arn64]. We refer to the comments in [Arn04]. The reader should be warned that many of these papers differ in technical – but crucial! – details. For example, many of the implementations of the obstruction argument on the literature differ on whether or not the method applies to infinitely long orbits. Several important papers assume that one of the terms of the normal form around the torus is zero or that the

stable and unstable bundles are trivial. A sharp version of the argument of [AA67] with references to several other variants is in [DdlLS05]. Other arguments will be described in Sections 7, 9.

3.1. The large gap problem. If rather than taking a perturbation which vanishes on Λ, we had taken a generic perturbation, the tori in Λ that have a rational frequency (resonances) would break, [Poi99], [Tre91], [dlLW04]. These destroyed tori will leave a gap of size $\varepsilon^{1/2}a_i + O(\varepsilon)$ where a_i is a coefficient that depends on the resonance. The fact that outside of these gaps one can find whiskered tori is proved in [Val00].

Since the first order calculations can only predict connections $O(\varepsilon)$ – with a coefficient that is exponentially small in μ – we see that the argument in [Arn64] does not conclude that there are orbits that transverse the gaps generated by a resonance. This is what has been called the "large gap problem". A very lucid discussion of this problem can be found in [Moe96].

This is somewhat unfortunate because the heuristic and numerical explorations suggest that diffusion is more intense near resonance.

Remark. The above discussion has been restricted to second order resonances for flows. That is, $\{k \in \mathbb{Z}^d \mid \frac{\partial H_0}{\partial A} \cdot k = 0\}$ is a 2-dimensional module. One can also wonder about what happens near higher order resonances.

For higher order resonances, the gaps between whiskered tori are larger and the normal forms are not "integrable", so that the discussion of Section 5 does not apply.

Nevertheless, we note that these resonances happen in sets of higher codimension so that using the methods of Section 5, it is possible to construct trajectories that detour around them [DdlLS06a]. A heuristic description of the role of higher order resonances can be found in [Chi79].

4. The role of normally hyperbolic manifolds

One of the main observations of [DdlLS00] (which was crucial for [DdlLS05], [DdlLS03a], [DdlLS03b], [GdlL06b], [CY04b], [CY04a], [Kal03], [BK04] is that the main geometric structure organizing the instability is the presence of a normally hyperbolic invariant manifold Λ whose stable and unstable manifolds intersect transversely.

This invariant manifold Λ acts like a distribution center or a hub. Orbits come to it and get rearranged to exit in a different direction. By returning to Λ again and again, the orbits can change the action systematically. As we will see, in some mechanisms, the orbits gain energy while staying close to Λ and in others, the main gain of energy during the homoclinic excursions.

4.1. The scattering map. A particularly useful tool to keep track of homoclinic excursions to a normally hyperbolic manifold is the scattering map introduced in

[DdlLS00]. Essentially the same idea in a slightly more restrictive context appeared in [Gar00].

Given a family of homoclinic excursions, the scattering map – very similar to the scattering matrix in quantum mechanics – gives the behavior in the distant future as a function of the behavior in the distant past.

The main idea of the scattering map is that the theory of normally hyperbolic invariant manifolds provides a very efficient geometric description of the orbits with a certain asymptotic behavior. By reducing the description of the excursions to the theory of normally hyperbolic manifolds, we obtain a theory which is analytically well behaved. Moreover, the scattering map has very nice geometric properties. By taking the geometry in consideration, it is possible to develop very efficient perturbative calculations [DdlLS06b].

4.1.1. The theory of normally hyperbolic invariant manifolds. We recall some of the results of [Fen72], [Fen74], [HPS77], [Pes04] on normally hyperbolic manifolds. Given a normally hyperbolic manifold Λ, the papers above give an efficient description of the orbits that converge (with a good exponential rate) to Λ, either in the future or in the past. These papers show that these orbits lie on manifolds, which we will denote as W^s_Λ, W^u_Λ, W^s_x, W^u_x. Moreover, these manifolds depend smoothly on parameters. Therefore, by expressing as much as possible the excursions in terms of intersections of invariant manifolds, we obtain remarkable geometric properties and smooth dependence on parameters that will be used to obtain rather explicit perturbative calculations.

Denoting by $W^{s,u}_x$ the set of points whose iterates converge exponentially fast – with an appropriate exponential rate – to the iterates of x,

$$W^s_\Lambda = \bigcup_{x\in\Lambda} W^s_x\,, \quad W^u_\Lambda = \bigcup_{x\in\Lambda} W^s_x \tag{7}$$

and that the decompositions in (7) are a foliation. That is, if $W^s_x \cap W^s_{\tilde x} \neq \emptyset$ then $x = \tilde x$.

The leaves $W^{s,u}_x$ are as smooth as the flow (or map). The map $x \to W^{s,u}_x$ may be significantly less differentiable than the flow (or map) depending on ratios of rates of contraction and expansions. In the applications here, we will have regularities as high as desired since the manifolds have motions close to integrable.

4.1.2. Definition of the scattering map. Let $y \in W^s_\Lambda \cap W^u_\Lambda$ satisfy

$$T_y W^s_\Lambda + T_y W^u_\Lambda = T_y M. \tag{8}$$

By the implicit function theorem, we can find a locally unique manifold $\Gamma \subset W^s_\Lambda \cap W^u_\Lambda$ such that all its points satisfy also (8). Then $T_y(W^s_\Lambda \cap W^u_\Lambda) = T_y\Gamma$.

Given $y \in W^s_\Lambda$, we can associate to it $\Omega_+(y) \in \Lambda$ determined uniquely by $y \in W^s_{\Omega_+(y)}$. Analogously, given $y \in W^u_\Lambda$ we associate to it $\Omega_-(y) \in \Lambda$ determined uniquely by $y \in W^u_{\Omega_-(y)}$.

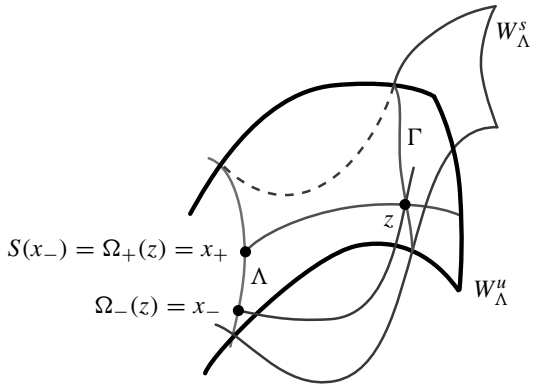

Figure 1. Illustration of the scattering map associated to an intersection Γ.

It is easy to see counting dimensions that, then, the stable and unstable manifolds have a clean intersection along Γ. That is,

$$T_y W^s_{\Omega_+(y)} \oplus T_y\Gamma = T_y W^s_\Lambda; \quad T_y W^u_{\Omega_-(y)} \oplus T_y\Gamma = T_y W^u_\Lambda.$$

Moreover, by taking Γ sufficiently small if necessary, the implicit function theorem ensures that $\Omega_\pm$ are local diffeomorphisms from Γ to their images.

When Ω_- is a local diffeomorphism from Γ to its image we define the mapping S^Γ by

$$S^\Gamma(x_-) = \Omega_+ \circ (\Omega_-)^{-1}. \tag{9}$$

The domain of S^Γ is $H^\Gamma_- \equiv \Omega_-(\Gamma)$. We denote the range of S^Γ as H^Γ_+. We will assume that S^Γ is a diffeomorphism from H^Γ_- to H^Γ_+. By the implicit function theorem, this is true if we have (8) and we take Γ small enough.

Note that, under the assumption that Γ is small enough, that we use to obtain the local uniqueness, it could happen that H^Γ_- is a strict subset of Λ. Nevertheless, for the applications in [DdlLS03b], it is important to observe that the domain of the scattering map can be chosen uniformly for $|\varepsilon|$ small enough.

4.1.3. Geometric properties of the scattering map. Many properties of the scattering map studied in [DdlLS00], [Gar00], [DdlLS03b] are systematized in [DdlLS06b].

Among the properties of the scattering map established in [DdlLS00], [Gar00], [DdlLS03a], [DdlLS03b], [DdlLS05] we mention somewhat informally, ignoring regularity requirements and some subtle points about domains of definition etc. A detailed discussion appears in [DdlLS06b].

- The map S^Γ is (exact) symplectic when f,Γ,Λ are (exact) symplectic diffeomorphisms and manifolds.

- The map S^Γ depends smoothly on parameters when f depends smoothly on parameters.

- There are rather explicit formulas for the derivative of the scattering map with respect to a parameter. These formulas are particularly explicit in the case of symplectic mappings.

- The scattering map associated to an intersection is locally unique. It may happen that when we propagate around a loop, the scattering map has a monodromy.

The scattering map provides a generalization and a more geometric interpretation of the more customary Melinkov theory, which generally assumes that the limiting behavior is of a specific type (e.g., quasi-periodic).

This generality is crucial for the applications in [DdlLS03a], [DdlLS03b] in which transitions to orbits of different topological types are considered. Much more so in [GdlL06a], [GdlL06b] which consider global phenomena.

We also note that the explicit perturbative formulas for the scattering map developed in [DdlLS06b] are always bona fide convergent integrals.

Remark 4.1. The corresponding discussion of the convergence for the Melinkov integrals is rather subtle [Rob96]. Unfortunately, the literature on Melnikov functions is often wrong because it omits a geometric term and the indefinite integrals have a quasi-periodic integrand. The usual explanation that one can take the limit along a subsequence (which one?) is meaningless and, of course, the real reason for this problem is that the argument presented is incorrect. This affects quite a number of papers in the literature. Of course, some of the conclusions may still be true, but they need separate arguments. The reader is alerted to check for this point in the literature.

5. Overcoming the large gap problem by the method of [DdlLS03b]

The work [DdlLS03b] is concerned with one parameter families of the form (2). To simplify the geometric intuition, we will consider f, the time-1 map of the flow.

The first observation is that by appealing to the theory of normally hyperbolic manifolds, in the models (1), there is a normally hyperbolic manifold Λ and that the time-1 map is exact symplectic. This *"inner"* map can be computed to high enough orders in perturbation theory.

A second observation is that, inside Λ, we can perform averaging procedures to high enough order outside of the resonances, so that, outside the resonances, the system can be considered, in an appropriate system of coordinates, as integrable up to order ε^m and m as large as we want. Therefore, outside the resonances, applying the KAM theorem to the averaged system, we can find KAM tori $\varepsilon^{m/2}$ close with m large.

Remark. For the sake of simplicity, the paper [DdlLS03b] includes the hypothesis that the perturbation is a trigonometric polynomial. This allowed to consider uniform several constants appearing in the analysis of the resonances and, therefore, simplified the detailed calculations.

This assumption can be removed by performing a more delicate analysis of the resonances that takes into account that, if the system is differentiable enough, the size of the resonances decreases rapidly and that, for a fixed ε, only a finite number of resonances have width bigger than ε and need to use secondary tori. This is accomplished in [DH06] which contains very detailed analysis of the geometry around resonances. The hypothesis of polynomial perturbations in [DdlLS03b] to conclude topological instability can also be eliminated using topological methods as in [GdlL06a]. See the discussion in Section 7.

As we will see later, the only resonances that play a role in the argument are the resonances that appear during the first averaging procedure and those that appear during the second averaging procedure. These resonances have size $O(\varepsilon^{1/2})$ and $O(\varepsilon)$ respectively.

One key observation for the method of [DdlLS03b] is that, within the resonances, we can find secondary tori – i.e. contractible tori which were not present in the unperturbed system – which dovetail very precisely in the gaps of the foliation of KAM tori. So that, up to precision $O(\varepsilon^{3/2})$ the dynamics on the invariant manifold Λ can be understood as in Figure 2. We emphasize that the invariant sets are, very approximately, the level sets of an averaged energy.

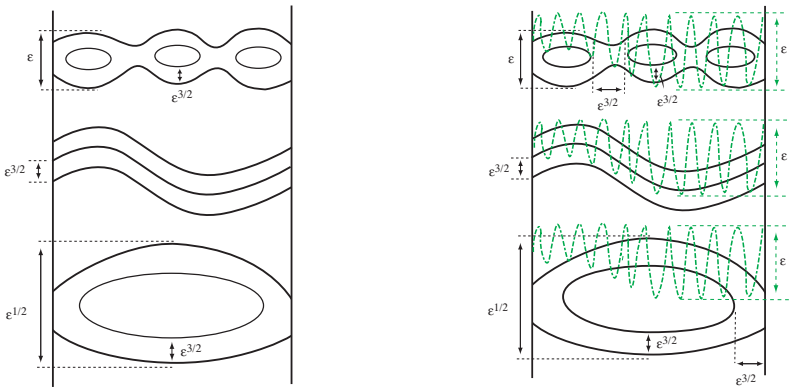

Figure 2. Illustration of the primary and secondary tori in Λ and their images under the scattering map.

If the image under the scattering map of an invariant circle $\tau_1 \subset \Lambda$ crosses transversally another invariant circle $\tau_2 \subset \Lambda$ then $W^u_{\tau_1}$ crosses transversally $W^s_{\tau_2}$.

Lets fix a section in the set of tori (both primary and secondary), say $\theta = \theta_0$ contained in the domain of the scattering map. In [DdlLS03b] there are perturbative calculations of $\frac{d}{d\theta}\bar{H} \circ S|_{\theta=\theta_0}$, where $\bar{H}$ is the averaged energy. If the first order term

happens to be different from zero in an open set (notice it can be chosen independent of ε) then, one can show that given τ_1, it intersects transversally all the tori in a neighborhood of size $O(\varepsilon)$. Using that bounded sets are compact and all the quantities involved are continuous, the order of magnitude estimates have coefficients uniform across a set of size independent of ε. In such a way, one obtains increases of the action in sets of order 1. See a pictorial illustration in Figure 2.

The calculation of the expressions of the angles of intersections is different depending on the types of the tori (primary or secondary) that are involved in the intersections. The hypothesis H5 of [DdlLS03b] is precisely imposing that all the leading terms in the expansion of these angles are different from zero. The geometric meaning of the hypothesis is a transversality condition between the scattering map and the inner dynamics. Since both of them are affected in different ways by the perturbations, it is intuitively clear that the hypothesis should hold for many systems. Given a concrete systems, the conditions can be verified by a finite computation.

Remark. Inside the resonances, one can also find (weakly) hyperbolic periodic orbits for the inner map. Their (weak) stable and unstable manifolds can play the same role as the secondary tori in the construction of transition chains. We refer to [DdlLS03b].

6. Perturbations of geodesic flows and of superlinear oscillators

Variations of the method described in Section 5 can be applied to establish the existence of orbits of unbounded energy in (4) and (5).

In the Mather models (4) we will refer to H_0 as the main term and in the Littlewood models (5) we refer to $\frac{1}{2}p^2 + V_n(q)$ as the main term. The other terms are referred to as perturbative terms.

The reason is that, for high energies, if we scale the time, and the coordinates p, q appropriately, we can map one energy surface of the main term into another. When we perform these scalings, the perturbative terms become small and slow. So that the perturbative parameter ε is just a negative power of the energy. Note that the main term is autonomous and, therefore, the energy is conserved.

The main assumptions (we omit several assumptions on regularity etc. but we refer to the detailed papers) are:

H1 Considering the system generated by the main part restricted to its unit energy surface, there exists a hyperbolic periodic orbit. Its stable and unstable manifolds cross transversally in the unit energy surface.

H2 There are some integrals of the perturbation along the unperturbed orbit that do not vanish identically

H3 The frequency of the external perturbation, ω is Diophantine.

Under these assumptions, the papers [DdlLS00], [DdlLS05] establish the existence of orbits of unbounded energy in (4). The adaptation of these methods to (5) is work in progress. As we will see, there are other methods that allow the elimination of H3, at the price of changing slightly H2.

The idea of the proof is very simple. We observe that, given a hyperbolic orbit in the unit energy, by the scaling properties of the geodesic flow, there are corresponding hyperbolic orbits in any energy surface. The union of all these orbits is a normally hyperbolic manifold for the whole system. If we take the product with the manifold of the phases of the external perturbation, we obtain a normally hyperbolic manifold in the extended system.

In the scaled variables, the external perturbation is slow and small. The fact that the perturbation is slow allows us to conclude that the normally hyperbolic invariant manifold persists, and the fact that the perturbation is slow allows us to average an arbitrarily large number of times. Hence, we can conclude that the invariant manifold contains invariant circles very densely spaced, so that these models do not present the large gap problem and we are in a situation very similar to that of [Arn64].

The calculation of the intersections of the tori can be done rather comfortably using the scattering map. The assumption H2 alluded above is just that the scattering map is non-trivial.

It is quite remarkable that the leading term of the scattering map as the energy grows to infinity is the same expression that was found in [Mat95]. The work [Kal03] uses the geometric approach described above but at some stages of the argument uses variational methods.

It is quite clear that once we choose an orbit and a homoclinic intersection in the main term, the set of lower order terms which verify H2 is a submanifold of infinite codimension.

The assumption of existence of periodic orbits with transversal homoclinic intersections has been studied in great detail for Riemannian manifolds. It holds in great generality. For example, it holds for *all* $C^{2+\alpha}$ Riemannian metrics in a surface of genus greater or equal than 2 and it is known to be generic in many other cases. The paper [Lev97] shows that the hypothesis H1 is verified in the classical Hedlund example.

The paper [BT99] uses instead of periodic orbits the existence of whiskered tori with one dimensional stable and unstable manifolds and with homoclinic intersections. In the case of geodesic flows on surfaces, this coincides with periodic orbits, but in more general cases, both hypothesis are very different.

In the Littlewood models, the hypothesis of the method presented here can be verified when $V_n(q)$ is a small perturbation of $|q_1|^4 + |q_2|^4$, a model for which the conclusions are false.

Remark. Another model that can also be treated by similar methods is billiards with periodically moving boundaries. These models were considered in [KMKPdC96]. In these models, the scaling with the energy is rather different from that in the previous

cases. The motion of the boundary becomes slow but not small, so that, to apply the methods discussed here, one has to add the smallness of the motion as an extra assumption.

Under the hypothesis that the unperturbed billiard has a homoclinic intersection, that the perturbation is small and satisfies a non-degeneracy assumption, using the methods described here, it is possible to show that there are orbits of unbounded energy. Similar results using variational methods have been announced in [Lev05]. It will be quite interesting to develop detailed comparisons between these methods.

7. The method of correctly aligned windows

The method of correctly aligned windows originated in [Eas75], [Eas78], [EM79] and was extended in [ZG04], [GZ04], [GR03], [GR04]. The main tool of the windowing method is the result that shows that if there is a sequence of *well aligned windows*, there is an orbit that follows all of them. As we will see, the construction of such a sequence of well aligned windows follows from an analysis of the geometric structures discussed before. This leads to alternative methods for several steps of the models described in Section 5 which, eliminate some of the hypothesis and provide explicit estimates on the time. They also allow to analyze some other models.

In some ways, the method of well aligned windows can be considered as a topological version of hyperbolicity since it allows shadowing. Nevertheless, an important difference is that the construction of well aligned windows only uses information for a finite number of iterates. As it is well known, hyperbolicity is very delicate to verify since hyperbolicity built up over arbitrarily long times can be destroyed at longer times. Also, one can use windows that are quite extended in some directions. These two advantages are crucial for the applications to diffusion considered in [GdlL06b], [GdlL06a]. Another important advantage is that the fact that well aligned windows are stable under C^0 perturbations. This allows us to use quite comfortably approximately invariant objects.

The following version of the method is taken from [GdlL06b], which in turn relied on [GR03], [GR04].

Definition 7.1. An (n_1,n_2)-window in an n-dimensional manifold M is a compact subset W of M together with a parametrization given by a homeomorphism $\chi^W : [0,1]^{n_1} \times [0,1]^{n_2} \to W$, where $n_1 + n_2 = n$. The set $W^- = \chi^W\left(\partial[0,1]^n_1 \times [0,1]^{n_2}\right)$ is called the 'exit set' and the set $W^+ = \chi^W([0,1]^{n_1} \times \partial[0,1]^{n_2})$ is called the 'entry set' of W. Here ∂ denotes the topological boundary of a set.

Two windows are correctly aligned under some map, provided that the image of the first window under the map can be stretched out and flattened down to a disk crossing the second window all the way through its exist set, so that the induced map on that disk has non-zero degree.

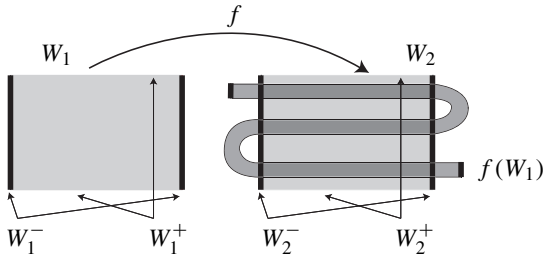

Figure 3. A pair of correctly aligned windows in the plane.

Definition 7.2. Let W_1, W_2 be two (n_1, n_2)-windows in M, and f be a continuous map on M with $f(\mathrm{im}(\chi^{W_1})) \subseteq \mathrm{im}(h^{W_2})$. Denote $f_\chi = (\chi^{W_2})^{-1} \circ f \circ \chi^{W_1}$. We say that W_1 is correctly aligned with W_2 under f provided that the following conditions are satisfied:

(i) $f_\chi((W_1^-)_\chi) \cap (W_2)_\chi = \emptyset, \quad f_\chi((W_1)_\chi) \cap ((W_2)^+_\chi = \emptyset.$

(ii) there exists a point $y_0 \in [0,1]^{n_2}$ such that

(ii.a) $f_\chi([0,1]^{n_1} \times \{y_0\}) \subseteq \mathrm{int}\,([0,1]^{n_1} \times [0,1]^{n_2} \cup (\mathbb{R}^{n_1} \setminus (0,1)^{n_1}) \times \mathbb{R}^{n_2})$,

(ii.b) If $n_1 = 0$, then $f_\chi((W_1)_\chi) \subseteq \mathrm{int}((W_2)_\chi)$. If $n_1 > 0$, then the map $A_{y_0} : \mathbb{R}^{n_1} \to \mathbb{R}^{n_1}$ defined by $A_{y_0}(x) = \pi_{n_1}\left(f_\chi(x, y_0)\right)$ satisfies

$$A_{y_0}\left(\partial[0,1]^{n_1}\right) \subseteq \mathbb{R}^{n_1} \setminus [0,1]^{n_1}, \quad \deg(A_{y_0}, 0) \neq 0.$$

Here π_x denotes the projection $(x, y) \in \mathbb{R}^{n_1} \times \mathbb{R}^{n_2} \to x \in \mathbb{R}^{n_1}$.

The main tool of the method is that *"one can see through a sequence of correctly aligned windows"*. Namely, that if we have a sequence of windows $\{W_i\}_{i\in\mathbb{Z}}$, each one of them correctly aligned with the next under the map f, then, there is a point x such that $f^i(x) \in W_i$ for all $i \in \mathbb{Z}$.

In the applications to the models in Sections 5 and 6 considered in [GdlL06b], the windows are constructed as products of intervals in the hyperbolic variables and intervals in the angles and the averaged energy. The windows are laid out around a pseudo-orbit which stays around a constant energy surface but performs jumps at appropriate times.

If we take a window which is an interval slightly offset in the unstable variables and along a homoclinic connection, it will perform a homoclinic excursion and come back as an rectangle very similar to the image under the scattering map of the circle corresponding to a level set of the averaged energy. The transversality between the scattering map and the surfaces of constant averaged energy imply that these windows are well aligned. To construct well aligned windows around the orbits that stay around an invariant circle, the paper [GdlL06b] uses the fact that the inner map has the twist property. We refer to [GdlL06b] for some possible choices of the widths and the choices of exit sets that make the sequence of windows correctly aligned. Compared

with the methods in [DdlLS03b], the method of correctly aligned windows uses the same transversality assumptions but does not need to appeal to the KAM theorem – it suffices to use approximately invariant objects – and it also provides explicit estimates of the time it takes the orbits considered to move order 1 in the action variables.

The paper [GdlL06a] provides with a different choice of windows for the large gap problem (and, quite possibly, different orbits) than those in [GdlL06b]. The main idea is to choose windows which are very wide in the action variables. Indeed, they are wider than the resonances in Λ. As a consequence, the resonances in Λ do not cause any problem in the construction and the paper does not need the transversality hypothesis between the scattering map and the constant average energy foliation. It also can eliminate the hypothesis of the perturbation being a trigonometric polynomial and it suffices just that the problem is differentiable enough. As a further advantage, the orbits constructed move rather fast. The amount it takes them to gain $O(1)$ of energy is $\varepsilon|\log\varepsilon|$, which agrees – up to a multiplicative constant – with lower bounds obtained in [BBB03] for certain models (models without large gaps).

One can hope that the method can be developed much more. Indeed, given the robustness of the windows, it is not necessary to appeal to the theory of normally hyperbolic invariant manifolds. It would suffice to have approximately invariant manifolds which may not be hyperbolic in the strict sense but that expand and contract some directions enough for some finite time. This could be useful in applications since numerical calculations (or fits of dynamical systems obtained from measurements of physical systems) can easily give good information on expansiveness for finite time. Nevertheless, assessing true hyperbolicity is only possible under much more restrictive circumstances.

8. The method of normally hyperbolic laminations

This method is developed in [dlL02]. Some antecedents are the *modulational diffusion* of [Chi79], [Ten82]. On the mathematical side, topological versions in dimension two appear in [Moe02], [EMR01]. For simplicity, we will discuss here only the models (4), but as we will see, they apply to all the models discussed in Section 6.

The main assumptions (again ignoring differentiability assumptions, etc.) are:

H1 There exists a transitive hyperbolic set (e.g. a horseshoe) containing $N \geq 2$ hyperbolic periodic orbits γ_i.

H2 For each of the orbits γ_i above, define $G_i(t) = \frac{1}{|\gamma_i|}\int_0^{|\gamma_i|} \partial_2 V(\gamma_i(s), t)\, ds$. Assume that there exist $0 = a_0 < a_1 < \cdots < a_N = 1$ such that

$$\mathscr{A} \equiv \int_{a_0}^{a_1} G_1(t)\, dt + \int_{a_1}^{a_2} G_2(t)\, dt + \cdots + \int_{a_{N-1}}^{a_N} G_N(t)\, dt \neq 0.$$

Using that $\int_0^1 G_i(t)\, dt = 0$, we will assume without loss of generality that $\mathscr{A} > 0$.

Then, we can find a set of orbits with positive Hausdorff dimension such that for an orbit $x(t)$ in this set,

$$H_0(x(t)) \geq \mathcal{A}t - C.$$

We note that the hypotheses are very abundant. For example, H1 is true for *all* $C^{2+\delta}$ Riemannian metrics in a surface of genus bigger than 1. If we consider a metric of negative curvature (with some pinching conditions in dimensions greater than 2), using results of [GK80] we conclude that H2 is verified for all the potentials which are not of the form $V(q,t) = V_1(q) + V_2(t)$. For potentials of the form above, the conservation of energy shows that there are no orbits of unbounded H_0. For negative curvature metrics, these trivial potentials are the only potentials which fail to have a set of positive Hausdorff dimension of orbits whose energy grows linearly.

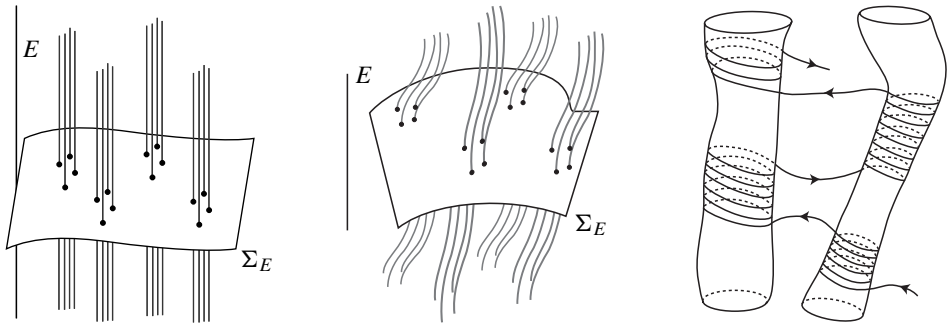

Figure 4. Illustration of the persistence of the invariant laminations and the orbit gaining energy by staying close to periodic orbits.

The idea of the proof is very simple: We observe that, by the scaling properties, for each energy surface there is a transitive hyperbolic set of the geodesic flow. This hyperbolic set satisfies specification and there is a symbolic dynamics that allows us to prescribe times spent in a neighborhood of each of the periodic orbits and connect them by jumps which happen in a scaled time which is uniformly bounded.

If we consider the union of all the hyperbolic sets for all sufficiently large energy, we obtain a normally hyperbolic lamination in the sense of [HPS77].

For high enough energy, the normally hyperbolic lamination persists (one needs to take care of some technicalities such as that the leaves of the foliation have boundary). Indeed, it is possible to find a Hölder map between the new invariant manifold and the old one.

Using the symbolic dynamics given by the normally hyperbolic manifold, we conclude that there are transitions between the periodic orbits happening at times very similar to the a_i in the assumption 2. As can be seen using averaging theory, the meaning of G_i is approximately the gain of energy of orbits that remain close to γ_i but move at high energy. Hence, we can construct orbits which sail along the periodic orbits so that the gains are, on the average $\mathcal{A}$.

Even if the assumptions in Section 6 imply the assumptions in this method, the orbits are very different. Note that the orbits constructed here gain energy near the periodic orbits while the orbits in Section 6 gain energy in the homoclinic excursions.

The method can be adapted to the models (5) and to the billiards with moving boundary. The only differences are that the rate of growths of energy are polynomial and exponential respectively. The adaptation to the time-dependent billiards models requires also the assumption that the motion of the boundary is small. (For these models related results are obtained by variational methods [Lev05].)

9. The scattering map and the obstruction mechanism

By using at the same time arguments similar to the obstruction mechanism of [Arn64], [AA67] it is possible to obtain a mechanism that includes only assumptions on scattering maps. This is work in progress based on preliminary discussions with A. Delshams, M. Gidea and V. Kaloshin. We will only report the simplest case.

We will assume that the manifold Λ is invariant and that it has some homoclinic connections. We will assume without loss of generality that Poincaré's recurrence theorem applies.

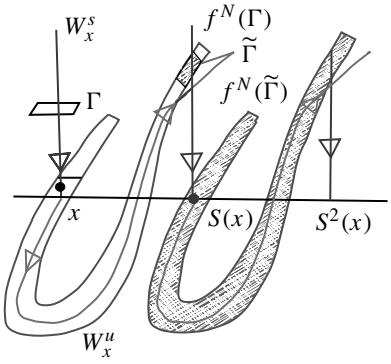

Figure 5. Illustration of the argument in Section 9.

The main inductive lemma starts by considering that Γ is an invariant manifold transverse to W^s_x. It is clear that for all N, we have that $f^N(\Gamma) = \widetilde{\Gamma}$ is transversal to $W^s_{f^N(x)}$. Using the Poincaré recurrence we can assume without loss of generality that $f^N(x)$ comes close to x. On the other hand, by the λ-lemma, the iterates of Γ will be getting aligned with W^u_x. Hence, we can conclude that Γ will intersect transversally the stable manifold of $S(x)$ where S is any of the scattering maps that can be obtained.

In particular, we obtain that if there is a scattering map such that its iterates move order 1, then there is instability in our sense. In the models of the form (1), (3), it suffices that some of the Melnikov integrals do not vanish. Similar results can be obtained for models of the form (4).

10. Conclusions

We have described several different geometric structures that lead to instability in near integrable dynamical systems. These methods rely on normally hyperbolic manifolds acting as a hub for homoclinic excursions. There are other methods, geometric or variational, which we have not covered.

The orbits generated by these different methods have different quantitative properties. It therefore seems that Arnol'd diffusion is not just one phenomenon, but rather a variety of phenomena. It seems that several of the mechanisms are intermingled. When one can find one, one can also find several others.

It seems that the broad array of methods currently under development by a large group of people can lead to answers in different areas. One can hope that even more methods will be brought to bear in a near future.

One can hope that some parts of the very rich heuristic studies – often without a clear statement of conditions of validity – can be clarified by theorems with precise conditions. In particular, it would be quite interesting to develop a rigorous statistical theory of instability.

Relatedly, one can hope that some of the mechanisms can be verified in concrete systems of practical interest or used to design systems with useful properties. From the mathematical point of view, it would also interesting to discuss properties of generic systems.

Diagonalizable flows on locally homogeneous spaces and number theory

Manfred Einsiedler and Elon Lindenstrauss*

Abstract. We discuss dynamical properties of actions of diagonalizable groups on locally homogeneous spaces, particularly their invariant measures, and present some number theoretic and spectral applications. Entropy plays a key role in the study of theses invariant measures and in the applications.

Mathematics Subject Classification (2000). 37D40, 37A45, 11J13, 81Q50.

Keywords. Invariant measures, locally homogeneous spaces, Littlewood's conjecture, quantum unique ergodicity, distribution of periodic orbits, ideal classes, entropy.

1. Introduction

Flows on locally homogeneous spaces are a special kind of dynamical systems. The ergodic theory and dynamics of these flows are very rich and interesting, and their study has a long and distinguished history. What is more, this study has found numerous applications throughout mathematics.

The spaces we consider are of the form $\Gamma\backslash G$ where G is a locally compact group and Γ a discrete subgroup of G. Typically one takes G to be either a Lie group, a linear algebraic group over a local field, or a product of such. Any subgroup $H < G$ acts on $\Gamma\backslash G$ and this action is precisely the type of action we will consider here. One of the most important examples which features in numerous number theoretical applications is the space $\mathrm{PGL}(n,\mathbb{Z})\backslash \mathrm{PGL}(n,\mathbb{R})$ which can be identified with the space of lattices in $\mathbb{R}^n$ up to homothety.

Part of the beauty of the subject is that the study of very concrete actions can have meaningful implications. For example, in the late 1980s G. A. Margulis proved the long-standing Oppenheim conjecture by classifying the closed orbits of the group of matrices preserving an indefinite quadratic form in three variables in $\mathrm{PGL}(3,\mathbb{Z})\backslash \mathrm{PGL}(3,\mathbb{R})$ – a concrete action of a three-dimensional group on an eight-dimensional space.

An element h of a linear group G (considered as a group of $n \times n$ matrices over

*The research presented was partially supported by the authors' NSF grants, in particular DMS-0509350 and DMS-0500205. Generous support of the Clay Mathematics Institute of both E. L. and M. E. facilitated much of this research.

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

some field K) is said to be *unipotent* if $h - e$ is a nilpotent matrix, e being the identity. Using the adjoint representation one can similarly define unipotent elements for Lie groups. Thanks to the work of M. Ratner, actions of groups H generated by unipotent elements are well understood, and this has numerous applications to many subjects. We refer to [37, Chapter 3], [51] and [59] for more information on this important topic.

In this paper, we focus on the action of diagonalizable groups which of course contain no nontrivial unipotent elements. A prototypical example is the action of the group A of diagonal matrices on $\mathrm{PGL}(n, \mathbb{Z})\backslash \mathrm{PGL}(n, \mathbb{R})$. There is a stark difference between the properties of such actions when $\dim A = 1$ and when $\dim A \geq 2$. In the first case the dynamics is very flexible, and there is a wealth of irregular invariant probability measures and irregular closed invariant sets (though we present some results for one-dimensional actions in § 2.2 under an additional recurrence condition). If $\dim A \geq 2$, the dynamics changes drastically. In particular, it is believed that in this case the invariant probability measures (and similarly the closed invariant sets) are much less abundant and lend themselves to a meaningful classification. Another dynamical property which is less often considered in this context but which we believe is important is the distribution of periodic orbits, i.e. closed orbits of the acting group with finite volume. The purpose of this paper is to present some results in these directions, particularly with regards to the classification of invariant measures, and their applications.

A basic invariant in ergodic theory is the ergodic theoretic entropy introduced by A. Kolmogorov and Ya. Sinai. This invariant plays a surprisingly big role in the study of actions of diagonalizable groups on locally homogeneous spaces as well as in the applications. We discuss entropy and how it naturally arises in several applications in some detail.

In an attempt to whet the reader's appetite, we list below three questions on which the ergodic theoretic properties of diagonalizable flows give at least a partial answer:

- Let $F(x_1, \ldots, x_n)$ be a product of n linear forms in n variables over $\mathbb{R}$. Assume that F is not proportional to such a form with integral coefficients. What can be said about the values F attains on $\mathbb{Z}^n$? In particular, is $\inf_{0 \neq x \in \mathbb{Z}^n} |F(x)| = 0$?
- Let ϕ_i be a sequence of Hecke–Maass cusp forms[1] on $\mathrm{SL}(2, \mathbb{Z})\backslash\mathbb{H}$. What can be said about weak* limits of the measure $|\phi_i|^2\, dm$ (m being the uniform measure on $\mathrm{SL}(2, \mathbb{Z})\backslash\mathbb{H}$)?
- Suppose $n \geq 3$ is fixed. Is it true that any ideal class in a totally real[2] number field K of degree n has a representative of norm $o(\sqrt{\mathrm{disc}(K)})$?

E. L. is scheduled to give a presentation based on this work in the ordinary differential equations and dynamical systems section of the 2006 International Congress of

[1] See §5 for a definition.

[2] A number field K is said to be totally real if any embedding of K to $\mathbb{C}$ is in fact an embedding to $\mathbb{R}$.

Mathematicians. Since much of this is based on our joint work, we have decided to write this paper jointly. Some of the results we present here are joint with P. Michel and A. Venkatesh and will also be discussed in their contribution to these proceedings [50]. We thank H. Oh, M. Ratner, P. Sarnak for comments on our paper. Both M. E. and E. L. have benefited tremendously by collaborations and many helpful discussions related to the topics covered in this survey, and are very thankful to these friends, mentors, colleagues and collaborators.

2. Entropy and classification of invariant measures

2.1. Measures invariant under actions of big diagonalizable groups

2.1.1. We begin by considering a special case where it is widely expected that there should be a complete measure classification theorem for the action of a multidimensional diagonal group. The space we shall consider is $X_n = \mathrm{PGL}(n, \mathbb{Z})\backslash \mathrm{PGL}(n, \mathbb{R})$, which can be identified with the space of lattices in $\mathbb{R}^n$ up to homothety.

Conjecture 2.1. Let A be the group of diagonal matrices in $\mathrm{PGL}(n, \mathbb{R})$, $n \geq 3$. Then any A-invariant and ergodic probability measure μ on the space X_n is homogeneous[3], i.e. is the L-invariant measure on a closed orbit of some group $L \geq A$.

While at present this conjecture remains open, the following partial result is known:

Theorem 2.2 (Einsiedler, Katok, Lindenstrauss [14]). *Let A be the group of diagonal matrices as above and $n \geq 3$. Let μ be an A-invariant and ergodic probability measure on $\mathrm{PGL}(n, \mathbb{Z})\backslash \mathrm{PGL}(n, \mathbb{R})$. If for some $a \in A$ the entropy $h_\mu(a) > 0$ then μ is homogeneous.*

It is possible to explicitly classify the homogeneous measures in this case (see e.g. [42]), and except for measures supported on a single A-orbit none of them is compactly supported. It follows that:

Corollary 2.3. *Let $n \geq 3$. Any compactly supported A-invariant and ergodic probability measure on $\mathrm{PGL}(n, \mathbb{Z})\backslash \mathrm{PGL}(n, \mathbb{R})$ has $h_\mu(a) = 0$ for all $a \in A$.*

For an application of this corollary to simultaneous Diophantine approximation and values of products of linear forms see §4.

2.1.2. We now give a general conjecture, which is an adaptation of conjectures of A. Katok and R. Spatzier [33, Main conjecture] and G. A. Margulis [49, Conjecture 2]. Similar conjectures were made by H. Furstenberg (unpublished).

Let S be a finite set of places for $\mathbb{Q}$ (i.e. a subset of the set of finite primes and ∞). By an S-algebraic group we mean a product $G_S = \prod_{v \in S} G_v$ with each G_v an algebraic

[3]The adjective "algebraic" is also commonly used for this purpose. We follow in this the terminology of [51].

group over $\mathbb{Q}_v$. A $\mathbb{Q}_v$-algebraic group G_v is *reductive* if its unipotent radical is trivial. An S-algebraic group G_S is reductive (semisimple) if each of the G_v is reductive (respectively, semisimple). For any group G and $\Gamma \subset G$ a discrete subgroup, we will denote the image of $g \in G$ under the projection $G \to \Gamma\backslash G$ by $(\!(g)\!)_\Gamma$ or simply $(\!(g)\!)$ if Γ is understood. We shall say that two elements a_1, a_2 of an Abelian topological group A are *independent* if they generate a discrete free Abelian subgroup.

Conjecture 2.4. Let S be a finite set of places for $\mathbb{Q}$, let $G_S = \prod_{v\in S} G_v$ be an S-algebraic group, $G \le G_S$ closed, and $\Gamma < G$ discrete. For each $v \in S$ let $A_v < G_v$ be a maximal $\mathbb{Q}_v$-split torus, and let $A_S = \prod_{v\in S} A_v$. Let A be a closed subgroup of $A_S \cap G$ with at least two independent elements. Let μ be an A-invariant and ergodic probability measure on $\Gamma\backslash G$. Then at least one of the following two possibilities holds:

1. μ is homogeneous, i.e. is the L-invariant measure on a single, finite volume, L-orbit for some closed subgroup $A \le L \le G$.
2. There is some S-algebraic subgroup L_S with $A \le L_S \le G_S$, an element $g \in G$, an algebraic homeomorphism $\phi\colon L_S \to \tilde{L}_S$ onto some S-algebraic group $\tilde{L}_S$, and a closed subgroup $H < \tilde{L}_S$ satisfying $H \ge \phi(\Gamma)$ so that (i) $\mu((L_S \cap G).(\!(g)\!)_\Gamma) = 1$, (ii) $\phi(A)$ does not contain two independent elements, and (iii) the image of μ to $H\backslash\tilde{L}_S$ is not supported on a single point.

Examples due to M. Rees [60] show that μ need not be algebraic, even if $G = \mathrm{SL}(3,\mathbb{R})$ and Γ a uniform lattice; see [12, Section 9] for more details. Such μ arise from algebraic rank one factors of locally homogeneous subspaces as in case 2 of Conjecture 2.4.

2.1.3. We note that the following conjecture is a special case of Conjecture 2.4:

Conjecture 2.5 (Furstenberg). Let μ be a probability measure on $\mathbb{R}/\mathbb{Z}$ invariant and ergodic under the natural action of the multiplicative semigroup $\{p^n q^l\}_{k,l\in\mathbb{Z}^+}$ with p, q multiplicatively independent integers[4]. Then either μ is Lebesgue or it is supported on finitely many rational points.

For simplicity, assume p and q are distinct prime numbers. Then Conjecture 2.5 is equivalent to Conjecture 2.4 applied to the special case of

$$\begin{aligned} A_S &= \{(t_\infty, t_p, t_q) : t_v \in \mathbb{Q}_v^* \text{ for } v \in S\}, \quad S = \{\infty, p, q\},\\ A &= \{(t_\infty, t_p, t_q) \in A_S : |t_\infty| \cdot |t_p|_p \cdot |t_q|_q = 1\},\\ G &= A \ltimes (\mathbb{R} \times \mathbb{Q}_p \times \mathbb{Q}_q),\\ \Gamma &= \Lambda \ltimes \mathbb{Z}[1/pq], \end{aligned}$$

with Λ the group $\{p^k q^l\}_{k,l\in\mathbb{Z}}$ embedded diagonally in A, and $\mathbb{Z}[1/pq]$ embedded diagonally in $\mathbb{R} \times \mathbb{Q}_p \times \mathbb{Q}_q$.

[4] I.e. integers which are not both powers of the same integer.

2.1.4. Following is a theorem towards Conjecture 2.4 generalizing Theorem 2.2. We note that the proof of this more general theorem is substantially more involved.

Theorem 2.6 (Einsiedler, Lindenstrauss [19]). *Let S be a finite set of places for $\mathbb{Q}$ as above, $G_S = \prod_{v\in S} G_v$ a reductive S-algebraic group, and $\Gamma < G_S$ discrete. Let $S' \subset S$ and for any $v \in S'$, let A_v be a maximal $\mathbb{Q}_v$-split torus in G_v. Set $A_{S'} = \prod_{v\in S'} A_v$, and assume $A_{S'}$ has at least two independent elements*[5]*. Let μ be an $A_{S'}$-invariant and the ergodic probability measure on $\Gamma\backslash G_S$. Then at least one of the following two possibilities holds:*

1. *There is some nontrivial semisimple $H < G_S$ normalized by $A_{S'}$ so that* (i) *μ is H invariant,* (ii) *there is some $g \in G_S$ so that $\mu(N_{G_S}(H).(\!(g)\!)_\Gamma) = 1$, and* (iii) *for any $a \in C_{A_{S'}}(H)$, the entropy $h_\mu(a) = 0$.*
2. *There is some $v \in S$ and a reductive $L_v \subset G_v$ of $\mathbb{Q}_v$-rank one satisfying the following: setting $N = C_{G_S}(L_v)$ and $L = NL_v$ (so that $N \lhd L$), there is some $g \in G_S$ so that $\mu(L.(\!(g)\!)_\Gamma) = 1$ and the image of $g^{-1}\Gamma g \cap L$ under the projection $L \to L/N$ is closed.*

Note that option 2 above precisely corresponds to the existence of an algebraic rank one factor of the action as in Conjecture 2.4.

2.2. Recurrence as a substitute for bigger invariance. It is well known that invariance under a one-parameter diagonalizable group is not sufficient to obtain a useful measure classification theorem. On the other hand, it seems that in many situations one can replace additional invariance with a weaker requirement: that of recurrence under some further action.

2.2.1. Let X be a measurable space, equipped with a measure μ, and L a locally compact second countable group acting on X. We first give a definition of recurrence.

Definition 2.7. We say that μ is *recurrent* under L (or L-recurrent) if for every set $B \subset X$ with $\mu(B) > 0$ for a.e. $x \in B$ the set $\{\ell \in L : \ell.x\}$ is unbounded, i.e. has non-compact closure.

This condition is also called conservativity of μ; we find recurrence a more natural term when dealing with the action of general group actions. It can be defined alternatively in terms of *cross-sections*: a set $Y \subset X$ is said to be a cross-section for L if $\mu(L.Y) > 0$ and for every $y \in Y$ there is a neighborhood U of the identity in L so that $\ell.y \notin Y$ for every $\ell \in U \setminus \{e\}$. A cross-section is said to be *complete* if $\mu(X \setminus L.Y) = 0$. We can define recurrence using cross-sections as follows: a measure μ is recurrent under L if there is no cross-section intersecting each L-orbit in at most a single point. This definition is equivalent to the one given in Definition 2.7. An advantage of this viewpoint is that it allows us to consider more refined properties of the action:

[5] Equivalently, that $\operatorname{rank}(A_{S'}) \geq 2$.

Definition 2.8. We say that the L-recurrence of a measure μ is *dominated* by H if there is a complete cross-section $Y \subset X$ for L so that for every $y \in Y$

$$\{\ell \in L : \ell.y \in Y\} \subset H.$$

We say that the L-recurrence of a measure μ is *weakly dominated* by H if there is a (not necessarily complete) cross-section $Y \subset X$ satisfying the same.

2.2.2. We now give a specific rigidity theorem employing recurrence as a substitute for invariance under a multidimensional group. For an application of this theorem to arithmetic quantum unique ergodicity, see §5.

Theorem 2.9 (Einsiedler, Lindenstrauss [20]). *Let v be either ∞ or a finite prime, and let G_v be a semisimple algebraic group over $\mathbb{Q}_v$ with $\mathbb{Q}_v$-rank one. Let A_v be a $\mathbb{Q}_v$-split torus in G_v and let L be an S-algebraic group (S a finite set of places for $\mathbb{Q}$ as above). Let $\Gamma < G_v \times L$ be a discrete subgroup so that $|\Gamma \cap \{e\} \times L| < \infty$. Suppose μ is an A_v-invariant, L-recurrent probability measure on $\Gamma\backslash G_v \times L$, and that for a.e. A_v-ergodic component μ_ξ the entropy $h_{\mu_\xi}(A_v) > 0$. Then a.e. A_v-ergodic component is homogeneous.*

The case $G_v = \mathrm{SL}(2, \mathbb{R})$ was proved in [39] and was used to prove arithmetic quantum unique ergodicity (see §5).

It would be interesting to prove a version of Theorem 2.9 where G_v is replaced by a higher rank algebraic group, e.g. $\mathrm{SL}(3, \mathbb{Q}_v)$, and A_v any algebraic embedding of $\mathbb{Q}_v^* \to G_v$. This seems like a feasible undertaking, but would require new ideas.

2.2.3. It seems desirable to have a general conjecture similar to Conjecture 2.4 where additional invariance is replaced by recurrence. The following seems not completely implausible:

Conjecture 2.10. Let S be a finite set of places for $\mathbb{Q}$, and $G_S = \prod_{v \in S} G_v$ an S-algebraic group and $\Gamma < G_S$ discrete as above. Fix $v \in S$ and let A_v be a rank one $\mathbb{Q}_v$-split torus. Let $L < G_S$ be a closed subgroup commuting with A_v such that $|A_v \cap L| < \infty$. Suppose μ is an A_v-invariant, L-recurrent probability measure. Then there is a $A_v L$-invariant Borel set X' of positive μ-measure so that at least one of the following holds:

1. There are closed subgroups $\tilde{A} \geq A_v$ and $\tilde{L}$ so that (i) $\tilde{A}$ and $\tilde{L}$ commute and have compact intersection[6], (ii) for every $x \in X'$ both $\tilde{L}.x$ and $\tilde{A}.x$ are closed and furthermore $\tilde{A}.x$ has finite $\tilde{A}$-invariant measure, (iii) $\mu|_{X'}$ is $\tilde{A}$-invariant, (iv) the L-recurrence of $\mu|_{X'}$ is dominated by $\tilde{A} \cdot \tilde{L}$.
2. There is a closed subgroup $\tilde{L} < G_S$ commuting with A_v such that for a set of positive μ-measure of $x \in X'$ we have that $\tilde{L}.x$ is closed, and the L-recurrence of $\mu|_{X'}$ is dominated by $\tilde{L}$.

[6]Note that $\tilde{L}$ may be trivial.

If true, this conjecture implies many (if not all) cases of Conjecture 2.4, in particular Conjecture 2.1.

2.2.4. In the notations of the above conjecture, let a be an element in A_v which does not generate a bounded subgroup[7] of A_v. Let

$$G_a^+ = \{g \in G_v : a^{-n} g a^n \to e \quad \text{as } n \to \infty\}$$
$$G_a^- = \{g \in G_v : a^n g a^{-n} \to e \quad \text{as } n \to \infty\}$$
$$G_a^0 = C_{G_v}(a).$$

In the paper [20] we give some nontrivial information on an A_v-invariant, L-recurrent probability measure μ for A_v, L as in the conjecture, under the additional conditions that μ is U_v-recurrent for some $\mathbb{Q}_v$-algebraic subgroup $U_v \leq G_v^-$ such that

1. U_v commutes with L,
2. the U_v recurrence of μ is not weakly dominated by any proper A_v-normalized algebraic subgroup of U_v ,
3. for any $g \in G_v^+$, there is a $u \in U_v$ so that $ugu^{-1} \notin G_v^0 G_v^+$.

The exact conclusions we derive about μ in this case is somewhat technical but in particular they imply Theorem 2.9. Note that one consequence of these conditions is that $h_\mu(A_v) > 0$ (see §3).

2.3. Joinings

2.3.1. Let (X, μ) and (Y, ν) be two measure spaces, and suppose that A is some locally compact group that acts on both (X, μ) and (Y, ν) in a measure preserving way. A *joining* between (X, μ) and (Y, ν) is a measure ρ on $X \times Y$ whose push forward under the obvious projection to X and Y are μ and ν respectively, and which is invariant under the diagonal action of A on $X \times Y$.

One example of a joining which always exists is taking $\rho = \mu \times \nu$ (the *trivial joining*). If $\phi\colon X \to Y$ is a measure preserving map which is A equivariant (i.e. $a.\phi(x) = \phi(a.x)$ for all $a \in A$ and a.e. $x \in X$) then $\rho = (\mathrm{Id} \times \phi)_* \mu$ is a nontrivial joining between (X, μ) and (Y, ν). Note that this joining is supported on the graph of ϕ. Let (Z, η) be another measure space on which A acts preserving the measure. (Z, η) is a *factor*[8] of (X, μ) if there is an A equivariant measurable map $\psi : X \to Z$ so that $\eta = \psi_* \mu$. Any common factor of (X, μ) and (Y, ν) can also be used to give a nontrivial joining called the *relatively independent joining*.

Typically the most interesting case is studying the joinings of a space (X, μ) with itself (called *self joinings*).

[7] I.e. a subgroup with noncompact closure.

[8] It may be more consistent with standard mathematical terminology to call (Z, η) a quotient, but factor is the standard term in ergodic theory.

2.3.2. We now consider joinings between locally homogeneous spaces $\Gamma\backslash G_S$ on which we have an action of a higher rank diagonalizable group. Even though we currently do not have a complete understanding of invariant measures in this context, we are able to give a complete classification of joining between two such actions in many cases.

Theorem 2.11 (Einsiedler, Lindenstrauss [18], [17]). *Let S be a finite set of places for $\mathbb{Q}$, and $G_i = \prod_{v\in S} G_{i,v}$ for $i = 1, 2$ two S-algebraic semisimple groups, $\Gamma_i < G_i$ be lattices*[9]*, and m_i Haar measure on $\Gamma_i\backslash G_i$ normalized to have total mass one. Let $A = \prod_{v\in S'} A_v$ with each A_v a $\mathbb{Q}_v$-split torus and $S' \subseteq S$ satisfying* $\operatorname{rank} A \geq 2$. *Let τ_i $(i = 1, 2)$ be embeddings of A into G_i with the property that*

1. *$\tau_i(A)$ is generated by the subgroups $\tau_i(A) \cap H$ where H runs through the $\mathbb{Q}_v$ simple normal subgroups of $G_{i,v}$ $(v \in S)$.*
2. *For both $i = 1, 2$, there is no S-algebraic group L and an S-algebraic homomorphism $\phi\colon G_i \to L$ so that $\phi(\Gamma_i)$ is discrete and* $\operatorname{rank}(\phi \circ \tau_i(A)) \leq 1$.

Then any ergodic joining between $(\Gamma_1\backslash G_1, m_1)$ and $(\Gamma_2\backslash G_2, m_2)$ is homogeneous[10].

The assumptions of the theorem imply that the action of A on $(\Gamma_i\backslash G_i, m_i)$ $(i = 1, 2)$ is ergodic, and so any joining can be written as the integral of ergodic joinings. The second assumption in Theorem 2.11 regarding the non-existence of rank one factors is clearly necessary. There is no reason to believe the same is true regarding the first assumption.

A special case of the theorem is when G_i are simple algebraic groups over $\mathbb{Q}_v$, v either a finite prime or ∞, and τ_i any algebraic embeddings of $(\mathbb{Q}_v^*)^k$ to G_i, $k \geq 2$. In this case the two assumptions regarding τ_i are automatically satisfied. This case has been treated in [17] using the methods developed by M. E. and A. Katok in [13] (to be precise, only $v = \infty$ is considered in [17] , but there are no difficulties in extending that treatment to $\mathbb{Q}_v$ for any v). The proof of the more general Theorem 2.11 requires also the results in [20].

2.3.3. A different approach to studying joinings was carried out by B. Kalinin and R. Spatzier in [32] using the methods developed by A. Katok and R. Spatzier in [33], [34]. A basic limitation of this technique is that e.g. for actions of split algebraic tori on semisimple or reductive algebraic groups they are able to analyze joinings only if the joining is ergodic not only under the action of the full acting group A but also under the action of certain one parameter subgroups of A. Typically, this is a fairly restrictive assumption, but for joinings which arise from isomorphisms as discussed

[9] I.e. discrete subgroups of finite covolume.

[10] A joining is in particular a measure on $\Gamma_1\backslash G_1 \times \Gamma_2\backslash G_2$ invariant under the diagonal action of the group A. Properties of invariant measures such as ergodicity, homogeneity etc. are in particular equally applicable to joinings.

in § 2.3.1 this assumption is indeed satisfied[11]. This has been used by B. Kalinin and R. Spatzier to classify all measurable isomorphisms between actions of $\mathbb{R}^k$ on $\Gamma_i \backslash G_i$ $(i = 1, 2)$ with G_i a Lie group, $\Gamma_i < G_i$ a lattice and the action of $t \in \mathbb{R}^k$ on $\Gamma_i \backslash G_i$ is given by right translation by $\rho_i(t)$, ρ_i a proper embedding[12] of the group $\mathbb{R}^k$ in G_i whose image is Ad-diagonalizable over $\mathbb{C}$ under some mild conditions on the action of $\rho_i(\mathbb{R}^k)$ on $\Gamma_i \backslash G_i$.

2.3.4. We end our discussion of joinings by noting that extending these joining results to the general context considered in Conjecture 2.4 is likely to be difficult; at the very least it would directly imply Conjecture 2.5.

To see this, let p, q be two multiplicative independent integers, m Lebesgue measure on $\mathbb{R}/\mathbb{Z}$ and μ any other continuous probability measure on $\mathbb{R}/\mathbb{Z}$ invariant and ergodic under the action of the multiplicative semigroup S generated by p and q. Let ρ denote the map $(x, y) \to (x, x + y)$ from $\mathbb{R}/\mathbb{Z} \times \mathbb{R}/\mathbb{Z}$ to itself. Then since m is weakly mixing for S, the measure $m \times \mu$ is ergodic for S and so $\rho_*(m \times \mu)$ is an ergodic self joining of the action of S on $(\mathbb{R}/\mathbb{Z}, m)$. What we have seen is that a counterexample to Furstenberg's Conjecture 2.5 would give a nonhomogeneous ergodic self joining of $(\mathbb{R}/\mathbb{Z}, m)$, which can be translated to a nonhomogeneous ergodic self joining of the group action considered in § 2.1.3.

One can, however, classify joinings of the actions of commuting endomorphisms of tori with no algebraic projections on which the action degenerates to the action of a virtually cyclic group up to this problem of zero entropy factors. This has been carried out for actions by a group of commuting toral automorphisms satisfying a condition called total nonsymplecticity by B. Kalinin and A. Katok [31] using an adaptation of the methods of A. Katok and R. Spatzier. In [16] the authors deal with general actions of commuting toral automorphisms (without the total nonsymplecticity condition).

2.4. Historical discussion

2.4.1. In 1967 Furstenberg proved that any orbit of the multiplicative semigroup $\{p^k q^l\}_{k,l \in \mathbb{Z}^+}$ on $\mathbb{R}/\mathbb{Z}$ for p, q multiplicatively independent integers is either finite or dense and conjectured Conjecture 2.5 apparently at around the same time. This conjecture seems to have appeared in print only much later (and by other authors quoting Furstenberg). Furstenberg's work was extended to the case of automorphisms of tori and other compact abelian groups by D. Berend (see e.g. [5]).

The first substantial result towards Conjecture 2.5 was published in 1988 by R. Lyons [46], who proved it under the assumption that μ has completely positive entropy for the action generated by the single element p (in particular, μ is ergodic for the single transformation $x \mapsto px \bmod 1$). D. Rudolph [62] showed for p, q relatively prime that it is sufficient to assume that $h_\mu(p) > 0$; this is still the best

[11] The same observation in the context of toral automorphisms was used by A. Katok, S. Katok and K. Schmidt in [36].

[12] I.e. the preimage of compact sets is compact.

result known in this case. The restriction that p, q were relatively prime was lifted by A. Johnson [29]. As Rudolph explicitly pointed out in his paper his proof significantly simplifies if one assumes that μ is ergodic under $x \mapsto px \bmod 1$. Other proofs of this result were given by J. Feldman [24] and B. Host [26] (B. Host actually proves a stronger result that implies Rudolph's). We also note that Host's proof employed recurrence for a certain action which does not preserve the measure, and was one of the motivations for Theorem 2.9.

2.4.2. The first results towards measure classification for actions of diagonalizable groups on quotients of Lie groups and automorphisms of tori were given by A. Katok and R. Spatzier [33], [34]; certain aspects of their work were clarified in [30]. Their proof replaces Rudolph's symbolic description by more geometric concepts, and in particular highlighted the role of conditional measures on invariant foliations on which a subaction acts isometrically. In most cases Katok and Spatzier needed to assume both a condition about entropy and an assumption regarding ergodicity of these subactions. Removing the extra ergodicity assumptions proved to be critical for arithmetic and other applications. M. E. and Katok [12], [13] and E. L. [39] developed two completely different and complementary approaches to proving measure rigidity results in the locally homogeneous context without additional ergodicity assumptions. Both of these techniques were used in [14]. We note that in [39] essential use was made of techniques introduced by M. Ratner to study unipotent flows, particularly her work on rigidity of horocycle flows [56], [54], [55]. Ratner's measure classification theorem [57] and its extensions, such as [58], [48], are also used in these three approaches.

In the context of action by automorphisms on tori no ergodicity assumption was needed by Katok and Spatzier under an assumption they term total nonsymplecticity. A uniform treatment for the general case, using entropy inequalities which should be of independent interest, was given by the authors in [16]. Host [27] has a treatment of some special cases (and even some non commutative actions) by other methods.

2.4.3. We have restricted our attention in this section solely to the measure classification question, but it is interesting to note that already in 1957, J. W. S. Cassels and H. P. F. Swinnerton-Dyer [8] stated a conjecture regarding values of products of three linear forms in three variables (case $n = 3$ of Conjecture 4.1) which is equivalent to Conjecture 4.4 regarding behavior of orbits of the full diagonal group on $\mathrm{SL}(3, \mathbb{Z})\backslash \mathrm{SL}(3, \mathbb{R})$, and which can be derived from Conjecture 2.1. It seems that the first to observe the connection between Furstenberg's work and that of Cassels and Swinnerton-Dyer was G. A. Margulis [47].

3. Brief review of some elements of entropy theory

In this section we give several equivalent definitions of entropy in the context of actions of diagonalizable elements on locally homogeneous spaces, and explain the relations between them.

3.1. General definition of entropy

3.1.1. Let (X, μ) be a probability space. The entropy $H_\mu(\mathcal{P})$ of a finite or countable partition of X into measurable sets measures the average information of $\mathcal{P}$ in the following sense. The partition can be thought of as an experiment or observation whose outcome is the partition element $P \in \mathcal{P}$ the point $x \in X$ belongs to. The information obtained about x from this experiment is naturally measured on a logarithmic scale, i.e. equals $-\log \mu(P)$ for $x \in P \in \mathcal{P}$. Therefore, the average information or *entropy* of $\mathcal{P}$ (with respect to μ) is

$$H_\mu(\mathcal{P}) = -\sum_{P\in\mathcal{P}} \mu(P)\log\mu(P).$$

One basic property of entropy is sub-additivity; the entropy of the refinement $\mathcal{P}\vee\mathcal{Q} = \{P\cap Q : P\in\mathcal{P}, Q\in\mathcal{Q}\}$ satisfies

$$H_\mu(\mathcal{P}\vee\mathcal{Q}) \le H_\mu(\mathcal{P}) + H_\mu(\mathcal{Q}). \tag{3.1}$$

However, this is just a starting point for many more natural identities and properties of entropy, e.g. equality holds in (3.1) if and only if $\mathcal{P}$ and $\mathcal{Q}$ are independent.

The ergodic theoretic entropy $h_\mu(a)$ associated to a measure preserving map $a\colon X \to X$ measures the average amount of information one needs to keep track of iterates of a. To be more precise we need to start with a fixed partition $\mathcal{P}$ (either finite or countable with $H_\mu(\mathcal{P}) < \infty$) and then take the limit

$$h_\mu(a,\mathcal{P}) = \lim_{N\to\infty} \frac{1}{N} H_\mu\Big(\bigvee_{n=0}^{N-1} a^{-n}\mathcal{P}\Big).$$

To get independence of the choice of $\mathcal{P}$ the ergodic theoretic entropy is defined by

$$h_\mu(a) = \sup_{\mathcal{P}:H_\mu(\mathcal{P})<\infty} h_\mu(a,\mathcal{P}).$$

The ergodic theoretic entropy was introduced by A. Kolmogorov and Ya. Sinai and is often called the Kolmogorov–Sinai entropy; it is also somewhat confusingly called the metric entropy even though X often has the additional structure of a metric space and in that case there is a *different* (though related) notion of entropy, the topological entropy (see §4.2.2), which is defined using the metric on X.

3.1.2. Entropy has many nice properties and is manifest in many different ways. We mention a few which will be relevant in the sequel.

A partition $\mathcal{P}$ is said to be a *generating partition* for a and μ if the σ-algebra $\bigvee_{n=-\infty}^{\infty} a^{-n}\mathcal{P}$ (i.e. the σ-algebra generated by the sets $\{a^n.P : n\in\mathbb{Z}, P\in\mathcal{P}\}$) separates points, that is for μ-almost every x, its atom with respect to this σ-algebra is $\{x\}$.[13]

[13] Recall that the atom of x with respect to a countably generated σ-algebra $\mathcal{A}$ is the intersection of all $B\in\mathcal{A}$ containing x and is denoted by $[x]_{\mathcal{A}}$.

The Kolmogorov–Sinai theorem asserts the nonobvious fact that $h_\mu(a) = h_\mu(a, \mathcal{P})$ whenever $\mathcal{P}$ is a generating partition.

Entropy is most meaningful when μ is ergodic. In this case, positive entropy $h_\mu(a) > 0$ means that the entropy of the repeated experiment grows linearly, i.e. every new iteration of it reveals some new information of the point. In fact, one can go to the limit here and say that the experiment reveals new information even when one already knows the outcome of the experiment in the infinite past. Similarly, zero entropy means that the observations in the past completely determine the present one. If μ is an a-invariant but not necessarily ergodic measure, with an ergodic decomposition $\mu = \int \mu_x^{\mathcal{E}}\, d\mu(x)$,[14] then

$$h_\mu(a) = \int h_{\mu_x^{\mathcal{E}}}(a)\, d\mu(x), \tag{3.2}$$

i.e. the entropy of a measure is the average of the entropy of its ergodic components.

3.2. Entropy on locally homogeneous spaces

3.2.1. Let $G = \prod_{v\in S} G_v$ be an S-algebraic group, $\Gamma < G$ discrete, and set $X = \Gamma\backslash G$. The Lie algebra of G_S can be defined as the product of the Lie algebra of the G_v, and the group G acts on its Lie algebra of G by conjugation; this action is called the adjoint representation and for every $a \in G$ the corresponding Lie algebra endomorphisms is denoted by $\operatorname{Ad} a$. Fix an $a \in G$ for which $\operatorname{Ad} a$ restricted to the Lie algebra of each G_v is diagonalizable over $\mathbb{Q}_v$. We implicitly identify between $a \in G$ and the corresponding map $x \mapsto a.x$ from X to itself.

The purpose of this subsection is to explain how the entropy $h_\mu(a)$ of an a-invariant measure μ relates to more geometric properties of X. A good reference for more advanced results along this direction is [48, Section 9] which contains an adaptation of results of Y. Pesin, F. Ledrappier, L. S. Young and others to the locally homogeneous context.

3.2.2. Fundamental to the dynamics of a are the stable and unstable horospherical subgroups G_a^- and G_a^+ introduced in § 2.2.4. Both G_a^- and G_a^+ are unipotent algebraic groups and the Lie algebras of G_a^- (resp. G_a^+) are precisely the sums of the eigenspaces of the adjoint Ad_a of eigenvalue with absolute value less than (resp. bigger than) one. For any $x \in X$ the orbits $G_a^-.x$ and $G_a^+.x$ are precisely the stable and unstable manifolds of x. We will also need the group

$$G_a^0 = \{g \in G : \text{the set } \{a^n g a^{-n}, n \in \mathbb{Z}\} \text{ is bounded}\}.$$

Under our assumptions G_a^0 can be shown to be an algebraic subgroup of G, and if 1 is the only eigenvalue of $\operatorname{Ad} a$ of absolute value one, $G_a^0 = C_G(a)$. This subgroup G_a^0 together with G_a^- and G_a^+ give a local coordinate system of G, i.e. there are

[14] This decomposition has the property that $\mu_x^{\mathcal{E}}$ is ergodic and for a.e. x, the ergodic averages of a function f along the orbit of x converge to $\int f\, d\mu_x^{\mathcal{E}}$.

neighborhoods $V^- \subset G_a^-$, $V^+ \subset G_a^+$, and $V^0 \subset G_a^0$ of e for which $V^+V^-V^0$ is a neighborhood of e in G and the map from $V^+ \times V^- \times V^0$ to $V^+V^-V^0$ is a bijection.

3.2.3. Suppose X is compact. If $\mathcal{P}$ is a finite partition with elements of small enough diameter, then the atoms of x with respect to $\mathcal{A} = \bigvee_{n=1}^{\infty} a^{-n}\mathcal{P}$ is a subset of $V^-V^0.x$ for all $x \in X$ as x and y are in the same $\mathcal{A}$-atom if and only if $a^n.x$ and $a^n.y$ are in the same partition element of $\mathcal{P}$ for $n = 1, 2, \ldots$. In particular, they must be close-by throughout their future, which can only be if the V^+-component of their relative displacement is trivial. Similarly, the atom of x with respect to $\bigvee_{-\infty}^{\infty} a^{-n}\mathcal{P}$ is a subset of $V^0.x$ for all $x \in X$.

Thus even though $\mathcal{P}$ might not be a generator, the atoms of the σ-algebra generated by $a^{-n}\mathcal{P}$ for $n \in \mathbb{Z}$ are small, with each atom contained in a uniformly bounded subset of a single G_a^0-orbit. G_a^0 possesses a metric invariant under conjugation by a, and this implies that a acts isometrically on these pieces of G_a^0-orbits. Such isometric extensions cannot produce additional entropy, and indeed a modification of the proof of the Kolmogorov–Sinai theorem gives that

$$h_\mu(a, \mathcal{P}) = h_\mu(a) \quad \text{for } \textit{all } a\text{-invariant measures } \mu. \tag{3.3}$$

In the non-compact case there is a somewhat weaker statement of this general form that is still sufficient for most applications.

3.2.4. Positive entropy can be characterized via geometric tubes as follows. Let B be a fixed open neighborhood of $e \in G$, and define $B_n = \bigcap_{k=-n}^{n} a^k B$. A tube around $x \in X = \Gamma\backslash G$ is a set of the form $B_n.x$ for some n. Then for a as in § 3.2.1, it can be shown using the Shannon–McMillan–Breiman theorem that if B is sufficiently small, for any measure μ with ergodic decomposition $\int \mu_x^{\mathcal{E}}\, d\mu(x)$

$$h_{\mu_x^{\mathcal{E}}}(a) = \lim_{n\to\infty} \frac{-\log \mu(B_n.x)}{2n} \qquad \text{for } \mu\text{-a.e. } x. \tag{3.4}$$

In particular, positive entropy of μ is equivalent to the exponential decay of the measure of tubes around a set of points which has positive μ-measure, and positive entropy of all ergodic components of μ is equivalent to the same holding for a conull subset of X. We note that (3.4) is a variant of a more general result of Y. Brin and A. Katok [7].

3.2.5. Positive entropy can also be characterized via recurrence. For μ, a as above the following are equivalent: (i) $h_{\mu_x^{\mathcal{E}}}(a) > 0$ for a.e. a-ergodic component $\mu_x^{\mathcal{E}}$, (ii) μ is G_a^--recurrent, and (iii) μ is G_a^+-recurrent (see e.g. [39, Theorem 7.6]).

3.2.6. A quite general phenomenon is upper semi-continuity of entropy $h_\mu(a)$ as a function of μ in the weak* topology[15]. Deep results of Yomdin, Newhouse and Buzzi

[15] A sequence of measures μ_i converges in the weak* topology to μ if for every compactly supported continuous function f one has that $\int f\, d\mu_i \to \int f\, d\mu$.

establish this for general C^∞ diffeomorphisms of compact manifolds, but in our context establishing such semi-continuity is elementary, particularly in the compact case. For non-compact quotients $X = \Gamma\backslash G$ and a sequence of a-invariant probability measures we might have escape of mass in the sense that a weak* limit might not be a probability measure. In that case entropy might get lost (even if some mass remains). However, if we assume that the weak* limit is again a probability measure then upper semi-continuity still holds in this context. The case where the whole sequence is supported on a compact set is discussed in [14, Cor. 9.3]. The general case follows along similar lines, the key step is showing that there is a finite partition capturing almost all of the ergodic theoretic entropy uniformly for the sequence, cf. §3.2.3.

4. Entropy and the set of values obtained by products of linear forms

4.1. Statements of conjectures and results regarding products of linear forms

4.1.1. In this section we consider the following conjecture:

Conjecture 4.1. Let $F(x_1, x_2, \dots, x_n)$ be a product of n linear forms in n variables over the real numbers with $n \geq 3$, and assume that F is not proportional to a homogeneous polynomial with integer coefficients. Then

$$\inf_{0\neq x\in\mathbb{Z}^d} |F(x)| = 0. \tag{4.1}$$

We are not sure what is the proper attribution of this conjecture, but the case $n = 3$ was stated by J. W. S. Cassels and H. P. F. Swinnerton-Dyer in 1955 [8]. In that same paper, Cassels and Swinnerton-Dyer show that Conjecture 4.1 implies the following conjecture of Littlewood:

Conjecture 4.2 (Littlewood (c. 1930)). For any $\alpha, \beta \in \mathbb{R}$,

$$\liminf_{n\to\infty} n \, \|n\alpha\| \, \|n\beta\| = 0,$$

where for any $x \in \mathbb{R}$ we denote $\|x\| = \min_{n\in\mathbb{Z}} |x - n|$.

We let $\mathcal{F}_n$ denote the set of products of n linear forms in n-variables, considered as a subvariety of the space of degree n homogeneous polynomials in n-variables, and $P\mathcal{F}_n$ the corresponding projective variety with proportional forms identified. For any $F \in \mathcal{F}_n$ we let $[F]$ denote the corresponding point in $P\mathcal{F}_n$.

4.1.2. The purpose of this section is to explain how measure classification results (specifically, Corollary 2.3) can be used to prove the following towards the above two conjectures:

Theorem 4.3 (Einsiedler, Katok, Lindenstrauss [14]). 1. *The set of products* $[F] \in P\mathcal{F}_n$ *for which* $\inf_{0\neq x\in\mathbb{Z}^n} |F(x)| > 0$ *has Hausdorff dimension zero.*

2. *The set of* $(\alpha, \beta) \in \mathbb{R}^2$ *for which* $\liminf_{n\to\infty} n \, \|n\alpha\| \, \|n\beta\| > 0$ *has Hausdorff dimension zero.*

Even though Conjecture 4.1 implies Conjecture 4.2, part 2 of Theorem 4.3 does not seem to be a formal consequence of part 1 of that theorem. The proofs, however, are very similar. Related results by M. E. and D. Kleinbock in the S-arithmetic context can be found in [15].

4.1.3. As noted by G. A. Margulis [47], Conjecture 4.1 is equivalent to the following conjecture regarding the orbits of the diagonal group on $X_n = \mathrm{PGL}(n, \mathbb{Z})\backslash \mathrm{PGL}(n, \mathbb{R})$ (cf. Conjecture 2.1 above):

Conjecture 4.4. Let A be the group of diagonal matrices in $\mathrm{PGL}(n, \mathbb{R})$, and X_n as above. Then for any $x \in X_n$ its orbit under A is either periodic (closed of finite volume) or unbounded[16].

The equivalence between Conjecture 4.1 and Conjecture 4.4 is a consequence of the following simple proposition (the proof is omitted):

Proposition 4.5. *The product of n linear forms*

$$F(x_1, \ldots, x_n) = \prod_{i=1}^{n} (\ell_{i1}x_1 + \cdots + \ell_{in}x_n)$$

satisfies $\inf_{0\neq x\in\mathbb{Z}^n} |F(x)| \geq \delta$ *if and only if there is no* $(\!(g)\!) \in A.(\!(\ell)\!)$ *where* $\ell = (\ell_{ij})_{i,j=1}^n$ *and a nonzero* $x \in \mathbb{Z}^n$ *so that*

$$\|xg\|_\infty^n < \det(g)\delta.$$

In particular, by Mahler's compactness criterion, (4.1) holds if and only if $A.(\!(\ell)\!)$ is unbounded.

The map $F \mapsto N_G(A).(\!(\ell)\!)$, $N_G(A)$ being the normalizer of A in $G = \mathrm{PGL}(n, \mathbb{R})$ gives a bijection between $\mathrm{PGL}(n, \mathbb{Z})$ orbits in $P\mathcal{F}_n$ and orbits of $N_G(A)$ in X_n. Note that $N_G(A)$ is equal to the semidirect product of A with the group of $n \times n$ permutation matrices.

4.1.4. In a somewhat different direction, G. Tomanov [71] proved that if F is a product of n linear forms in n variables, $n \geq 3$, and if the set of values $F(\mathbb{Z}^n)$ is discrete, then F is proportional to a polynomial with integer coefficients. Translated to dynamics, this statement reduces to a classification of all *closed* A-orbits (bounded or unbounded) which was carried out by Tomanov and B. Weiss in [72].

[16] I.e. does not have compact closure.

4.2. Topological entropy and A-invariant closed subsets of X_n

4.2.1. Corollary 2.3 regarding A-invariant measures on X_n which have positive ergodic theoretic entropy with respect to some $a \in A$ implies the following purely topological result towards Conjecture 4.4 (this theorem is essentially [14, Theorem 11.2]):

Theorem 4.6. *Let Y be a compact A-invariant subset of X_n. Then for every $a \in A$ the topological entropy $h_{\mathrm{top}}(Y, a) = 0$.*

Theorem 4.3 can be derived from Theorem 4.6 by a relatively straightforward argument that in particular uses Proposition 4.5 to translate between the orbits of A and Diophantine properties of products of linear forms (and a similar variant to relate orbits of a semigroup of A with the behavior of $\liminf_{k\to\infty} k \|k\alpha\| \|k\beta\|$).

4.2.2. We recall the definition of topological entropy, which is the topological dynamical analog of the ergodic theoretic entropy discussed in §3.1: Let (Y, d) be a compact metric space and $a\colon Y \to Y$ a continuous map[17]. Two points $y, y' \in Y$ are said to be k, ε-*separated* if for some $0 \le \ell < k$ we have that $d(a^\ell.y, a^\ell.y') \ge \varepsilon$. Set $N(Y, a, k, \varepsilon)$ to be the maximal cardinality of a k, ε-separated subset of Y. Then the topological entropy of (Y, a) is defined by

$$H(Y, a, \varepsilon) = \liminf_{k\to\infty} \frac{\log N(Y, a, k, \varepsilon)}{k},$$
$$h_{\mathrm{top}}(Y, a) = \lim_{\varepsilon\to 0} H(Y, a, \varepsilon).$$

We note that in analogy to §3.2.3, for the systems we are considering, i.e. $a \in A$ acting on a compact $Y \subset X_n$ there is some $\varepsilon(Y)$ so that

$$h_{\mathrm{top}}(Y, a) = H(Y, a, \varepsilon) \quad \text{for } \varepsilon < \varepsilon(Y).$$

4.2.3. Topological entropy and the ergodic theoretic entropy are related by the *variational principle* (see e.g. [25, Theorem 17.6] or [35, Theorem 4.5.3])

Proposition 4.7. *Let Y be a compact metric space and $a\colon Y \to Y$ continuous. Then*

$$h_{\mathrm{top}}(Y, a) = \sup_{\mu} h_\mu(a)$$

where the sup *runs over all a-invariant probability measures supported on Y.*

Note that when $\mu \mapsto h_\mu(a)$ is upper semicontinuous (see §3.2.6), in particular if $a \in A$ (identified with the corresponding translation on X_n) and $Y \subset X_n$ compact, this supremum is actually attained by some a-invariant measure on Y.

[17] For Y which is only locally compact, one can extend a to a map $\tilde{a}$ on its one-point compactification $\tilde{Y}$ fixing ∞ and define $h_{\mathrm{top}}(Y, a) = h_{\mathrm{top}}(\tilde{Y}, \tilde{a})$.

4.2.4. We can now explain how Theorem 4.6 can be deduced from the measure classification results quoted in §2

Proof of Theorem 4.6 *assuming Corollary* 2.3. Let $Y \subset X_n$ be compact, and $a \in A$ be such that $h_{\text{top}}(Y, a) > 0$. Then by Proposition 4.7 there is an a-invariant probability measure μ supported on Y with $h_\mu(a) > 0$. Let

$$S_r = \{a \in A : \|a\|,\ \|a^{-1}\| < e^r\}.$$

Since A is a commutative group

$$\mu_r = \int_{S_r} (a'.\mu)\, dm_A(a')$$

(where m_A is Haar measure on A) is also a-invariant, and in addition it follows directly from the definition of entropy that $h_{a'.\mu}(a) = h_\mu(a)$ for any $a' \in A$. Using (3.2) it follows that $h_{\mu_r}(a) = h_\mu(a)$.

Let ν be any weak* limit point of μ_r. Then by semicontinuity of entropy,

$$h_\nu(a) \geq \liminf_{r\to\infty} h_{\mu_r}(a) > 0$$

and since S_r is a Folner sequence in A we have that ν is A-invariant. Finally, since Y is A-invariant, and μ is supported on Y, so is ν. But by Corollary 2.3, ν cannot be compactly supported – a contradiction. □

5. Entropy and arithmetic quantum unique ergodicity

Entropy plays a crucial role also in a completely different problem: arithmetic quantum unique ergodicity. Arithmetic quantum unique ergodicity is an equidistribution question, but unlike most equidistribution questions it is not about equidistribution of points but about equidistribution of eigenfunction of the Laplacian. A more detailed discussion of this topic can be found in [40] and the surveys [63], [65] as well as the original research papers, e.g. [61], [39].

5.1. The quantum unique ergodicity conjecture

5.1.1. Let M be a complete Riemannian manifold with finite volume which we initially assume to be compact. Then since M is compact, $L^2(M)$ is spanned by the eigenfunctions of the Laplacian Δ on M. Let ϕ_n be a complete orthonormal sequence of eigenfunctions of Δ ordered by eigenvalue. These can be interpreted for example as the steady states for Schrödinger's equation

$$-i\frac{\partial \psi}{\partial t} = \Delta\psi$$

describing the quantum mechanical motion of a free (spinless) particle of unit mass on M (with the units chosen so that $\hbar = 1$). According to Bohr's interpretation

of quantum mechanics $\tilde{\mu}_n(A) := \int_A |\phi_n(x)|^2 \, dm_M(x)$ is the probability of finding a particle in the state ϕ_n inside the set A at any given time, m_M denoting the Riemannian measure on M, normalized so that $m_M(M) = 1$. A. I. Šnirel′man, Y. Colin de Verdière and S. Zelditch [69], [9], [75] have shown that whenever the geodesic flow on M is ergodic, for example if M has negative curvature, there is a subsequence n_k of density one on which $\tilde{\mu}_{n_k}$ converge in the weak* topology to m, i.e. $\tilde{\mu}_n$ become equidistributed *on average*. Z. Rudnick and P. Sarnak conjectured that in fact if M has negative sectional curvature, $\tilde{\mu}_n$ become equidistributed *individually*, i.e. that $\tilde{\mu}_n$ converge in the weak* topology to the uniform measure m_M.

5.1.2. As shown in [69], [9], [75] any weak* limit $\tilde{\mu}$ of a subsequence of the $\tilde{\mu}_i$ is the projection of a measure μ on the unit tangent bundle SM of M invariant under the geodesic flow. This measure μ can be explicitly constructed directly from the ϕ_i. We shall call μ the *microlocal lift* of $\tilde{\mu}$. We shall call any measure μ on SM arising in this way a *quantum limit*. A stronger form of Rudnick and Sarnak's conjecture regarding $\tilde{\mu}_n$ is the following (also due to Rudnick and Sarnak).

Conjecture 5.1 (Quantum unique ergodicity conjecture [61]). Let M be a compact Riemannian manifold with negative sectional curvature. Then the uniform measure m_{SM} on SM is the only quantum limit.

There is numerical evidence towards this conjecture in the analogous case of 2D concave billiards by A. Barnett [3], and some theoretical evidence is given in the next two subsections, but whether this conjecture should hold for general negatively curved manifolds remains unclear.

5.2. Arithmetic quantum unique ergodicity

5.2.1. Consider now the special case of $M = \Gamma\backslash\mathbb{H}$, for Γ one of the following:

1. Γ is a congruence sublattice of $\mathrm{PGL}(2, \mathbb{Z})$.
2. D is a quaternion division algebra over $\mathbb{Q}$, split over $\mathbb{R}$ (i.e. $D(\mathbb{R}) := D \otimes \mathbb{R} \cong M(2, \mathbb{R})$). Let $\mathcal{O}$ be an Eichler order in D.[18] Then the norm one elements in $\mathcal{O}$ are a co-compact lattice in $D(\mathbb{R})^*/\mathbb{R}^*$. Let Γ be the image of this lattice under the isomorphism $D(\mathbb{R})^*/\mathbb{R}^* \cong \mathrm{PGL}(2, \mathbb{R})$.

We shall call such lattices *lattices of congruence type* over $\mathbb{Q}$.

5.2.2. If Γ is as in case 1 of §5.2.1, then $M = \Gamma\backslash\mathbb{H}$ has finite volume, but is not compact. A generic hyperbolic surface of finite volume is expected to have only finitely many eigenfunctions of Laplacian in L^2; consequently Conjecture 5.1 needs some modification to remain meaningful in this case. However, a special property

[18] A subring $\mathcal{O} < D$ is said to be an order in D if $1 \in \mathcal{O}$ and every for $\beta \in \mathcal{O}$ its trace and its norm are in $\mathbb{Z}$. An order $\mathcal{O}$ is an Eichler order if it is the intersection of two maximal orders.

of congruence sublattices of $\mathrm{PGL}(2,\mathbb{Z})$ congruence is the abundance of cuspidal eigenfunctions of the Laplacian (in particular, the existence of many eigenfunctions in L^2) on the corresponding surface, and so Conjecture 5.1 as stated is both meaningful and interesting for these surfaces. The abundance of cuspidal eigenfunctions follows from Selberg's trace formula [66]; see [41] for an elementary treatment.

We remark that for congruence sublattices of $\mathrm{PGL}(2,\mathbb{Z})$ the continuous spectrum of the Laplacian is given by Eisenstein series; equidistribution (appropriately interpreted) of these Eisenstein series has been established by W. Luo and P. Sarnak [44] and by D. Jakobson [28].

5.2.3. The lattices given in §5.2.1 have the property that for all but finitely many primes p, there is a lattice Λ_p in $\mathrm{PGL}(2,\mathbb{R}) \times \mathrm{PGL}(2,\mathbb{Q}_p)$ so that

$$\Gamma \backslash \mathrm{PGL}(2,\mathbb{R}) \cong \Lambda_p \backslash \mathrm{PGL}(2,\mathbb{R}) \times \mathrm{PGL}(2,\mathbb{Q}_p)/K_p \tag{5.1}$$

with $K_p = \mathrm{PGL}(2,\mathbb{Z}_p) < \mathrm{PGL}(2,\mathbb{Q}_p)$. For example, for $\Gamma = \mathrm{PGL}(2,\mathbb{Z})$ one can take $\Lambda_p = \mathrm{PGL}(2,\mathbb{Z}[1/p])$ (embedded diagonally in $\mathrm{PGL}(2,\mathbb{R}) \times \mathrm{PGL}(2,\mathbb{Q}_p)$).

5.2.4. The isomorphism (5.1) gives us a map $\pi_p \colon \Lambda_p\backslash\mathbb{H} \times \mathrm{PGL}(2,\mathbb{Q}_p) \to \Gamma\backslash\mathbb{H}$. The group $\mathrm{PGL}(2,\mathbb{Q}_p)$ acts on $\Lambda_p\backslash\mathbb{H} \times \mathrm{PGL}(2,\mathbb{Q}_p)$ by right translation, and using this action we set for every $x \in \Gamma\backslash\mathbb{H}$

$$T_p(x) = \pi_p\left(\begin{pmatrix} p & 0 \\ 0 & 1 \end{pmatrix}.\pi_p^{-1}(x)\right);$$

this is a set of $p+1$ points called the *p-Hecke correspondence*. Using this correspondence we define the *p-Hecke operator* (also denoted T_p) on functions on $\Gamma\backslash\mathbb{H}$ by

$$[T_p(f)](x) = p^{-1/2} \sum_{y \in T_p(x)} f(y).$$

The Hecke operators (considered as operators on $L^2(M)$) are self adjoint operators that commute with each other and with the Laplacian, so one can always find an orthonormal basis of the subspace of $L^2(M)$ which corresponds to the discrete part of the spectrum consisting of such joint eigenfunctions. Furthermore, if the spectrum is simple (as is conjectured e.g. for $\mathrm{PGL}(2,\mathbb{Z})$), eigenfunctions of the Laplacian are automatically eigenfunctions of all Hecke operators. These joint eigenfunctions of the Laplacian and all Hecke operators are called *Hecke–Maass cusp forms*.

5.2.5. We define an *arithmetic quantum limit* to be a measure μ on SM which is a quantum limit constructed from a sequence of Hecke–Maass cusp forms (see §5.1.2). The *arithmetic quantum unique ergodicity* question, also raised by Rudnick and Sarnak in [61] is whether the uniform measure on SM is the only arithmetic quantum limit. Some partial results towards answering this question were given

in [61], [38], [74], [64]. Assuming the Riemann hypothesis for suitable automorphic L-functions, T. Watson [73] has shown that the only arithmetic quantum limit for both types of lattices considered in §5.2.1 is the normalized volume measure. In fact, to obtain this conclusion one does not need the full force of the Riemann hypothesis but only subconvexity estimates on the value of these L-functions at $1/2$, which are known for some families of L-functions but not for the ones appearing in Watson's work. Assuming the full force of the Riemann hypothesis gives a rate of convergence of the $\tilde{\mu}_k$ to the uniform measure that is known to be best possible [45].

Using measure classification techniques one can unconditionally prove the following:

Theorem 5.2 (Lindenstrauss, [39]). *Let M be $\Gamma\backslash\mathbb{H}$ for Γ one of the lattice as listed in §5.2.1. Then if M is compact the arithmetic quantum limit is the uniform measure m_{SM} on SM (normalized to be a probability measure). In the noncompact case, any arithmetic quantum limit is of the form cm_{SM} some $c \in [0, 1]$.*

It is desirable to prove unconditionally that even in the non-compact case m_{SM} is the only arithmetic quantum limit. A weaker version would be to prove unconditionally that for any sequence of Hecke–Maass cusp forms ϕ_i and $f, g \in C_c(M)$ with $g \geq 0$

$$\frac{\int f(x)\,|\phi_i(x)|^2\,dm(x)}{\int g(x)\,|\phi_i(x)|^2\,dm(x)} \to \frac{\int f\,dm(x)}{\int g\,dm(x)}.$$

5.2.6. We briefly explain how measure rigidity results are used to prove Theorem 5.2. Let ϕ_i be a sequence of Hecke–Maass cusp forms on $\Gamma\backslash\mathbb{H}$, and let μ be the associated arithmetic quantum limit, which we recall is a measure on SM which is essentially $\Gamma\backslash\mathrm{PGL}(2,\mathbb{R})$. Using the isomorphism (5.1) and in the notations of §5.2.3, one can identify μ with a right K_p-invariant measure, say μ', on $\Lambda_p\backslash\mathrm{PGL}(2,\mathbb{R}) \times \mathrm{PGL}(2,\mathbb{Q}_p)$. Using the fact that ϕ_i is an eigenfunction of the Hecke operators and some elementary fact regarding the regular representations of $\mathrm{PGL}(2,\mathbb{Q}_p)$ one can show that μ' is recurrent under $\mathrm{PGL}(2,\mathbb{Q}_p)$ (see Definition 2.7).

Building upon an idea of Rudnick and Sarnak from [61], J. Bourgain and E. L. [6] have shown that any ergodic component $\mu_x^{\mathcal{E}}$ of μ with respect to the action of the group $a(t) = \left(\begin{smallmatrix} e^t & 0 \\ 0 & e^{-t} \end{smallmatrix}\right)$ (equivalently, any ergodic component of μ' with respect to the action of the group $a'(t) = (a(t), e)$) has positive entropy (in fact, $h_{\mu_x^{\mathcal{E}}}(a) \geq 2/9$). One can now use Theorem 2.9 for $\mathrm{PGL}(2,\mathbb{R})$ to deduce that μ' and hence the arithmetic quantum limit μ is proportional to the Haar measure.

The entropy bound of [6] is proved by giving a uniform bound for every x in a compact $K \subset \Gamma\backslash\mathrm{PGL}(2,\mathbb{R})$ on the measure of geometric tubes around x of the form $\mu(B_k.x) < c_{B,K}\exp(-4k/9)$, with B_k as in §3.2.4. This bound holds already for appropriate lifts of the measures $\tilde{\mu}_n$, and depends only on ϕ_n being eigenfunctions of all Hecke operators (but does not use that they are also eigenfunctions of the Laplacian).

5.2.7. Using the same general strategy, L. Silberman and A. Venkatesh have been able to prove arithmetic quantum unique ergodicity for other $\Gamma\backslash G/K$, specifically for $G = \mathrm{PGL}(p, \mathbb{R})$ ($p > 2$ prime) and Γ a lattice arising from an order in a division algebra of degree p over $\mathbb{Q}$ (for $p = 2$ this gives precisely the lattices considered in part 2 of §5.2.1). While the strategy remains the same, several new ideas are needed for this extension, in particular a new micro-local lift for higher rank groups [68], [67]. Silberman has informed us that these methods can be used to establish analogs of Theorem 5.2 in some three-dimensional hyperbolic (arithmetic) manifolds; to the best of our knowledge such extensions are not known for any higher dimensional hyperbolic manifolds.

5.3. A result of N. Anantharaman. We conclude this section by discussing some very recent results of N. Anantharaman which shed some light on quantum limits in full generality (and not just in the arithmetic context). It can be deduced from her paper [1] that if M is a compact manifold with negative sectional curvature then every quantum limit has positive ergodic theoretic entropy. In the case of surfaces of constant curvature -1 Anantharaman actually proves that for any $\delta > 0$ any quantum limit has a positive measure of ergodic components with ergodic theoretic entropy $\geq (d-1)/2 - \delta$; in this normalization the ergodic theoretic entropy of the uniform measure m_{SM} is $d - 1$.

An exposition of some of her ideas as well as a different but closely related approach, both applied to a simpler toy model, can be found in [2] by N. Anantharaman and S. Nonnenmacher.

Note that in contrast to [6], this method inherently can only prove that some ergodic components have positive entropy. In the nonarithmetic situation it seems very hard to show that all ergodic components have positive entropy; indeed, this is false in the toy model considered in [2] as well as for an appropriately quantized hyperbolic toral automorphism [23].

6. Entropy and distribution of periodic orbits

Let G be a semisimple $\mathbb{R}$-split algebraic group, $\Gamma < G$ a lattice, and A an $\mathbb{R}$-split Cartan subgroup of G [53]. Then there are always infinitely many periodic A orbits in $\Gamma\backslash G$. Uniform measure on these orbits give examples of A-invariant measures with zero entropy. It is surprising therefore that entropy plays a key role in our understanding of distribution properties of such compact orbits. The results described in this section are joint work of the authors with P. Michel and A. Venkatesh [21] and are also described from a somewhat different viewpoint in [50] in these proceedings. Unless otherwise stated, proofs of all the statements below can be found in [21]. Periodic orbits of $\mathbb{R}$-split Cartan subgroups have also been studied elsewhere. We mention in particular the papers [52] by H. Oh where finiteness theorems regarding these orbits are proved and [4] where Y. Benoist and H. Oh prove equidistribution of Hecke orbits of a fixed A-periodic orbit.

6.1. Discriminant and regulators of periodic orbits. For concreteness, we restrict to the case $G = \mathrm{PGL}(n, \mathbb{R})$, $\Gamma = \mathrm{PGL}(n, \mathbb{Z})$ and $A < G$ the group of diagonal matrices. Later, we will also allow Γ to be a lattice associated to an order in a division algebra D over $\mathbb{Q}$ of degree n with $D \otimes \mathbb{R} \cong M(n, \mathbb{R})$ (e.g. for $n = 2$ a lattice as in part 2 in §5.2.1).

6.1.1. We wish to attach to every periodic A orbit in $X_n = \Gamma\backslash G$ two invariants: discriminant and regulator. Before doing this, we recall the following classical construction of such orbits:

Let K be a totally real extension of $\mathbb{Q}$ with $[K : \mathbb{Q}] = n$. Let $\mathcal{O}_K$ be the integers of K, and let $I \lhd \mathcal{O}_K$ be an ideal. Chose an ordering $\tau_1, \dots, \tau_n$ of the n embeddings of K in $\mathbb{R}$, and let $\tau = (\tau_1, \dots, \tau_n) \colon K \to \mathbb{R}^n$. Then $\tau(I)$ is a lattice in $\mathbb{R}^n$, hence corresponds to a point $(\!(g_I)\!) \in X_n$. If $\alpha_1, \dots, \alpha_n$ generate I as an additive group we can take $g_I = (\tau_j(\alpha_i))_{i,j=1}^n$. For any $v \in \mathbb{R}^n$ we let $\mathrm{diag}(v)$ be the diagonal matrix with entries $v_1, v_2, \dots, v_n$. If $\alpha \in \mathcal{O}_K^*$ then $I = \alpha I$ and

$$(\!(g_I)\!) = \mathrm{diag}(\tau(\alpha)).(\!(g_I)\!).$$

$\mathrm{diag}(\tau(\cdot))$ embeds $\mathcal{O}_K^*$ discretely in A, and Dirichlet's unit theorem gives us that $\mathcal{O}_K^*/\{\pm 1\}$ is a free Abelian group with $n-1$ generators. It follows that $(\!(g_I)\!)$ has periodic orbit under A. Two ideals $I, J \lhd \mathcal{O}_K$ are equivalent if $I = \alpha J$ for some $\alpha \in K$; in this case $\mathrm{diag}(\tau(\alpha)).(\!(g_I)\!) = (\!(g_J)\!)$ hence $A.(\!(g_I)\!) = A.(\!(g_J)\!)$ iff $I \sim J$. The number of equivalence classes of ideals is denoted by C_K and is called the *class number* of K; given τ we see that there are C_K distinct periodic A-orbits associated with $\mathcal{O}_K$.

A small variation of this construction allowing a general order $\mathcal{O} < \mathcal{O}_K$ and I a proper ideal of $\mathcal{O}$ gives all periodic A-orbits.

6.1.2. Let D be the algebra of all $n \times n$ (not necessarily invertible) diagonal matrices over $\mathbb{R}$. Let $x = (\!(g)\!)$ be a point with periodic A-orbit. Define $\Gamma_{A,g} := \Gamma \cap gAg^{-1}$. Then since x is periodic, $g^{-1}\Gamma_{A,g}g$ is a lattice in A. To $\Gamma_{A,g}$ we can also attach a subring $\mathbb{Q}[\Gamma_{A,g}]$ in $M(n, \mathbb{R})$ in an obvious way. Let $\Delta_{A,g} = g^{-1}(\mathbb{Q}[\Gamma_{A,g}] \cap M(n, \mathbb{Z}))g$; this ring can be shown to be a lattice in D (considered as an additive group).

We define the *regulator* $\mathrm{reg}(x)$ of a periodic $x \in X_n$ for $x = (\!(g)\!)$ to be the volume of $A/(g^{-1}\Gamma_{A,g}g)$ and the *discriminant* $\mathrm{disc}(x)$ by

$$\mathrm{disc}(x) = m_D(D/\Delta_{A,g})^2.$$

Note that $\mathrm{reg}(x)$ is simply the volume of the periodic orbit $A.x$. This defines both of these notions up to a global multiplicative constant corresponding to fixing a Haar measure on A and D respectively. This normalization can be chosen in such a way that $\mathrm{disc}(x)$ is an integer for every A-periodic x and so that for $(\!(g_I)\!)$, g_I as in §6.1.1 for $I \lhd \mathcal{O}_K$, the discriminant and regulator of $(\!(g_I)\!)$ coincide with the discriminant

and regulator of the number field K. The regulator and discriminant of a periodic orbit are related, but in a rather weak way: in general for any periodic orbit $A.x$,

$$\log \operatorname{disc}(x) \ll \operatorname{reg}(x) \ll_\varepsilon \operatorname{disc}(x)^{1/2+\varepsilon}.$$

If e.g. K has no subfields other than $\mathbb{Q}$ the lower bound on $\operatorname{reg}(x)$ can be improved to $c'_n[\log \operatorname{disc}(x)]^{n-1}$, which is tight. However, if K, I and $x = (\!(g_I)\!)$ are as in §6.1.1, $C_K \operatorname{reg}(x)$, i.e. the total volume of all periodic A orbits coming from ideals in $\mathcal{O}_K$, is closely related to the discriminant:

$$\operatorname{disc}(x)^{1/2-o(1)} \leq C_K \operatorname{reg}(x) \leq \operatorname{disc}(x)^{1/2+o(1)}.$$

Properly formulated (the easiest formulation is Adelic) a similar relation holds also for periodic A orbits coming from non-maximal orders $\mathcal{O} < \mathcal{O}_K$.

6.2. Some distribution properties of periodic orbits. We would like to prove statements regarding how sequences of periodic orbits are distributed. Care must be taken however as even for the simplest cases such as X_3 it is not true that for any sequence of A-periodic points $x_i \in X_3$ with $\operatorname{disc}(x_i) \to \infty$ the orbits $A.x_i$ become equidistributed. Let $\mu_{A.x_i}$ be the unique A-invariant probability measure on $A.x_i$. One problem, for $n = 3$ or more generally, is that it is possible to construct sequences x_i such that $\mu_{A.x_i}$ converge weak* to a measure μ with $\mu(X_n) < 1$. However, as remarked by Margulis the following is a consequence of Conjecture 4.4:

Conjecture 6.1. For any fixed compact $K \subset X_n$, $n \geq 3$, there are only finitely many periodic A-orbits contained in K.

Using Corollary 2.3 and what we call the Linnik principle (see §6.3) we prove the following towards this conjecture:

Theorem 6.2 ([21]). *For any fixed compact $K \subset X_n$, $n \geq 3$, for any $\varepsilon > 0$, the total volume of all periodic A-orbits contained in K of discriminant $\leq D$ is at most $O_\varepsilon(D^\varepsilon)$.*

In contrast, for $n = 2$, for any ε one can find a compact $K_\varepsilon \subset X_2$ so that the total volume of all periodic A-orbits contained in K of discriminant $\leq D$ is $\gg D^{1-\varepsilon}$.

Theorem 6.2 directly implies that for any $\varepsilon > 0$ and $n \geq 3$ the number of totally real numbers fields K of degree $[K : \mathbb{Q}] = n$ and discriminant $\operatorname{disc}(K) \leq D$ for which for some ideal class there is no representative of norm $\leq \varepsilon \operatorname{disc}(K)^{1/2}$ is $\ll D^\varepsilon$, giving a partial answer to the third question posed in the introduction.

The same method gives the following in the compact case:

Theorem 6.3 ([21]). *Let Γ be a lattice in $\mathrm{PGL}(n, \mathbb{R})$ associated with a division algebra over degree n over $\mathbb{Q}$ and $\eta > 0$ arbitrary. For any i let $(x_{i,j})_{j=1,\dots,N_i}$ be a finite collection of A-periodic points with distinct A-orbits such that*

$$\sum_{j=1}^{N_i} \operatorname{reg}(x_{i,j}) \geq \max_j (\operatorname{disc}(x_{i,j}))^\eta.$$

Suppose that there is no locally homogeneous proper subset of $\Gamma\backslash G$ *containing infinitely many* $x_{i,j}$. *Then* $\overline{\bigcup_{i,j} A.x_{i,j}} = \Gamma\backslash G$.

6.3. The Linnik principle. In the proofs of Theorems 6.2 and 6.3 a crucial point is establishing that a limiting measure has positive entropy under some $a \in A$, which allows one to apply the measure classification results described in §2. Positivity of the entropy is established using the following proposition, which links entropy with the size (regulator) of a periodic orbit (or a collection of periodic orbits) compared to its discriminant(s). We give it below for some lattices Γ in $G = \mathrm{PGL}(n, \mathbb{R})$, but this phenomenon is much more general. We call this relation between orbit size and entropy the *Linnik principle* in honor of Yu. Linnik in whose book [43] a special case of this relation is implicit.

Proposition 6.4 ([21]). *For every* ℓ, *let* $A.x_{\ell,j}$ $(j = 1 \dots N_\ell)$ *be a finite collection of* (*distinct*) *periodic* A*-orbits in* $\Gamma\backslash \mathrm{PGL}(n, \mathbb{R})$ *with* Γ *either* $\mathrm{PGL}(n, \mathbb{Z})$ *or a lattice corresponding to an order in a division algebra of degree* n *over* $\mathbb{Q}$. *Let* $\mu_{(\ell)}$ *be the average of the measures* $\mu_{A.x_{\ell,1}}, \dots, \mu_{A.x_{\ell,N_\ell}}$ *weighted by regulator. Suppose that*

$$\sum_{j=1}^{N_\ell} \mathrm{reg}(x_{\ell,j}) \geq \max_j (\mathrm{disc}(x_{\ell,j}))^\eta.$$

and that the $\mu_{(\ell)}$ *converge weak* to a* probability *measure* μ. *Then for any regular*[19] $a \in A$, *there is an* $c_{a,n} > 0$ (*which can be easily made explicit*) *so that*

$$h_\mu(a) \geq c_{a,n}\eta. \tag{6.1}$$

If $\mathrm{disc}(x_{\ell,j}) = \mathrm{disc}(x_{\ell,j'})$ *for all* ℓ, j, j' *then* (6.1) *can be improved to* $h_\mu(a) \geq 2c_{a,n}\eta$.

The key observation lies in the fact that for any compact $K \subset \Gamma\backslash G$ if x and $x' \in K$ are periodic with discriminant $\leq D$ then either $x = a.x'$ for some small $a \in A$ or $d(x, x') > CD^{-2}$ where $C = C(K)$ depends on K (if $\mathrm{disc}(x) = \mathrm{disc}(x')$ then $d(x, x') > CD^{-1}$ hence the improved estimate in this case). This fact is used together with the subadditivity of $H_{\mu_{(\ell)}}(\cdot)$ (see §3.1.1) to show that $h_\mu(a) \geq c_{a,n}\eta$.

6.4. Packets of periodic orbits and Duke's theorem. Another completely different way to establish positive entropy for limiting measures is given by subconvex estimates on L-functions.

Theorem 6.5 ([21]). *Let* $K_{(\ell)}$ *be a sequence of totally real degree three extensions of* $\mathbb{Q}$, $C_{(\ell)}$ *the class number of* $K_{(\ell)}$, *and* $\tau_{(\ell)} : K_{(\ell)} \to \mathbb{R}^3$ *a* 3*-tuple of embeddings. Let* $A.x_{1,\ell}, \dots, A.x_{C_{(\ell)},\ell}$ *be the periodic* A *orbits corresponding to the ideal classes of* $K_{(\ell)}$ *as in* §6.1.1. *Let* $\mu_{(\ell)} = \frac{1}{C_{(\ell)}} \sum_i \mu_{A.x_{i,\ell}}$. *Then* $\mu_{(\ell)}$ *converge in the weak* topology to the* $\mathrm{PGL}(3, \mathbb{R})$ *invariant probability measure* m_{X_3} *on* X_3.

[19] I.e. with no multiple eigenvalues.

Subconvexity estimates of W. Duke, J. Friedlander and H. Iwaniec [11] imply that for certain test functions f, the integrals $\int_{X_3} f d\mu_{(\ell)}$ converge to the right value (i.e. $\int_{X_3} f dm_{X_3}$). The space of test functions on which this convergence can be established from the subconvex estimates of Duke, Friedlander and Iwaniec is far from dense, but is sufficiently rich to show that any limiting measure of $\mu_{(\ell)}$ is a probability measure (i.e. there is no escape of mass to the cusp) and that the entropy of *every* ergodic component in such a limiting measure is greater than an explicit lower bound. Once these two facts have been established, Theorem 2.2 can be used to bootstrap entropy to equidistribution.

Theorem 6.5 is a generalization to the case $n = 3$ of the following theorem of Duke, proved using earlier and related subconvexity estimates of Duke and Iwaniec:

Theorem 6.6 (Duke [10]). *Let $K_{(\ell)} = \mathbb{Q}(\sqrt{D_\ell})$ be a sequence of real quadratic fields and $\mu_{(\ell)}$ an average of the corresponding measures on A-periodic orbits in X_2 as above. Then $\mu_{(\ell)}$ converge weak* to m_{X_2}.*

We note that Duke also gives an explicit rate of equidistribution of the $\mu_{(\ell)}$.

There is an alternative, ergodic theoretic, approach to this theorem that dates back to Yu. Linnik and B. F. Skubenko. Skubenko [70], building on work of Linnik [43], used this approach, which is closely related to techniques discussed in §6.3, to prove Theorem 6.6 under a congruence condition on the sequence D_ℓ (see [43, Chapter VI]). In [22] we show that a variation of this method can actually be used to give a complete proof of Theorem 6.6 using only ergodic theory and some properties of quadratic forms.
