Algorithmic randomness and computability

Rod Downey

Abstract. We examine some recent work which has made significant progress in out understanding of algorithmic randomness, relative algorithmic randomness and their relationship with algorithmic computability and relative algorithmic computability.

Mathematics Subject Classification (2000). Primary 68Q30, 68Q15, 03D15, 03D25, 03D28, 03D30.

Keywords. Kolmogorov complexity, computability, degrees of unsolvability, prefix-free complexity, lowness, incompressibility, martingales, computably enumerable.

1. Introduction

In the last few years we have seen some very exciting progress in our understanding of algorithmic randomness and its relationship with computability and complexity. These results have centered around a programme which attempts to answer questions of the following form: when is one real more random than another? How should this be measured? How would such measures of calibration relate to other measures of complexity of reals, such as the traditional measures of relative complexity like Turing degrees, which measure relative computability? These investigations have revealed deep and hitherto unexpected properties of randomness, anti-randomness and algorithmic complexity, as well as pointing at analogs in other areas, and answering questions from apparently completely unrelated areas.

In this paper I will attempt to give a brief (and biased) overview of some of the more recent highlights. I apologize for ignoring important work relating the collection of random strings with complexity theory such as [1], [2], and work on randomness for computably enumerable sets such as Kummer [48], [49], and Muchnik and Positelsky [71], purely for space reasons. This overview will be too short to give a complete account of the all of the progress. For a fuller picture, I refer the reader to the long surveys of Downey, Hirschfeldt, Nies and Terwijn [28], Downey [16], [15], [17], Terwijn [96] and the upcoming monographs Downey and Hirschfeldt [22][1], and Nies [77].

We will look at various methods of calibration by initial segment complexity such as those introduced by Solovay [89], Downey, Hirschfeldt, and Nies [26], Downey,

[1]Available in preliminary form at www.mcs.vuw.ac.nz/~downey.

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

Hirschfeldt, and LaForte [23], Downey [16], as well as other methods such as lowness notions of Kučera and Terwijn [47], Terwijn and Zambella [97], Nies [75], [76], Downey, Griffiths and Reid [21], and methods such as higher level randomness notions going back to the work of Kurtz [50], Kautz [38], and Solovay [89], and other calibrations of randomness based on changing definitions along the lines of Schnorr, computable, s-randomness, etc. Particularly fascinating is the recent work on lowness, which began with Downey, Hirschfeldt, Nies and Stephan, and developed in a series of deep papers by Nies [75], [76] and his co-authors.

2. Preliminaries

Since most of our results are concerned with effectiveness/computability, we assume that the reader is familiar with the basic facts concerning computability theory/recursion theory. Thus, we will regard countable sets as effectively coded in the natural numbers and consider effective processes on them as computable ones. For example, an effective prediction function would be classified according to it computability. We assume that the reader is also familiar with semi-computable (computably enumerable) processes such as the computably enumerable set coding the halting problem $\emptyset' = \{(e, x) : \text{the } e\text{-th program halts on input } x\}$. Such computable enumerable problems can be represented by sets W defined as $x \in W$ iff $\exists y R(x, y)$, where R is a computable relation. We will call a set in the form $\exists y R(x, y)$, Σ^0_1. If $\mathbb{N} - A$ is Σ^0_1, then we say that A is Π^0_1. If A is both Σ^0_1 and Π^0_1 we say that A is Δ^0_1 (and this is the same as being computable). This process can be extended to the *arithmetical hierarchy*. We will say that A is Σ^0_n iff there is a Π^0_{n-1} relation R such that $x \in A$ iff $\exists y R(x, y)$. (Equivalently, x is in A iff $\exists y \forall z \ldots$ (with n alternations)$Q(x, y, z, \ldots)$ and Q computable.) Analogously, we can define Π^0_n and Δ^0_n. We will also assume that the reader is familiar with the process of *relativization* which means that we put oracles (allowing for "read only memory") on our machines. These oracles allow for computations in which a finite number of effectively generated membership queries of the oracle set are allowed. Thus, for instance, $A' = \{(e, x) : \text{the } e\text{-th program halts on input } x \text{ when given oracle } A\}$. This is the halting problem *relativized to* A, usually pronounced "A-jump". If we classify sets under the preordering $\leq_T$ we will write $A \leq_T B$ to mean that membership of A can be computed by a program with access to B as an oracle. (Here we identify sets with their characteristic functions, and hence as reals: members of Cantor space 2^ω.) The equivalence classes of $\leq_T$, which calibrate countable sets into classes of "equi-computability" are called Turing degrees, after the famous Alan Turing. We remark that the simplest kind of Turing reduction is called an m-reduction (for many-one) and is defined as follows: $A \leq_m B$ means that there is a computable function f such that $x \in A$ iff $f(x) \in B$. Thus to figure out if x is in A from B, the algorithm simply says : compute $f(x)$ and ask B if $f(x)$ is in B. It is easy to show that for any computably enumerable set A, $A \leq_m \emptyset'$, so that the halting problem $\emptyset'$ if m-complete, in that it is the most complicated computably

enumerable set as measured by m-reducibility[2]. We remark that the relativization of the halting problem be algorithmically unsolvable is that $A' \not\leq_T A$ for any set A. The relativization of the halting problem is intrinsically tied with the halting problem. Namely, $\emptyset''$, which is defined as the halting problem gained with the halting problem as an oracle is a natural Σ^0_2 set and it can compute any Π^0_2 set and any Σ^0_2 set, and similarly for $\emptyset^{(n+1)}$.

Any other notions from computability needed are introduced in context. We also refer the reader to Soare [86] for further background material in computability, and to Li–Vitanyi [56] or Calude [6] for general background in algorithmic randomness.

In this paper "real" will be interpreted as a member of Cantor space 2^ω with sub-basic clopen sets $[\sigma] = \{\sigma\alpha : \alpha \in 2^\omega\}$, for $\sigma \in 2^{<\omega}$. This space is equipped with the standard Lebesgue measure, where, for $\sigma \in 2^{<\omega}$, $\mu([\sigma]) = 2^{-|\sigma|}$. There have been investigations on other measures than the uniform one, and on other spaces (the latter notably by Gács [34]), but space precludes a thorough discussion here. For Cantor space up to degree things, speaking loosely, it does not matter measure is used, so long as it is not atomic. Finally, the initial segment of a real α (or a string) of length n will be denoted by $\alpha \upharpoonright n$.

3. Three approaches to randomness

In terms of measure a any two reals occur with probability zero, yet we would argue that a real $\alpha = 01010101\ldots$ would not seem random. How should we understand this?

3.1. Martin-Löf randomness. The first author to attempt to grapple with trying to "define" randomness was von Mises [101]. Von Mises was a statistician and attempted to define randomness in terms of statistical laws. For instance, he argued that a random real should pass all statistical tests. Thus, he argued, if one "selected" from a real $\alpha = a_0a_1\ldots$ some subsequence $a_{i_0}, a_{i_1}, \ldots$, then $\lim_{n\to\infty} \frac{|\{j : a_{i_j} = 1 \wedge 1 \leq j \leq n\}|}{n}$ should be $\frac{1}{2}$. Naturally, von Mises lacked the language needed to suggest which selection rules should be considered. That awaited the development of computable function theory in the 1930s by Church and others, which then allowed us to argue that a random real should be "computably stochastic" in the sense of von Mises.

Unfortunately, Wald and others showed that there are some significant problems (see van Lambalgen [99] for a discussion) with this approach, known as computable stochasticity. Here I refer the reader to Ambos-Spies [3], Merkle [62], [63], and Uspensky, Semenov and Shen [98]. The first really acceptable version of von Mises idea was developed by Per Martin-Löf in [60]. He argued that any effective statistical

[2]Additionally, it might seem that there might be various versions of the halting problem depending of which programming language, or which encoding, is used. It can be shown that that are all of the same m-degree, and hence are basically all the same. More on this in the context of randomness later.

test was an effective null set and a random real should be one that simply avoids any effective null set.

The notion of an effective collection of reals is are called effective classes. As a direct analog of the arithmetical hierarchy. A Σ^0_1 class U is a "c.e. set of reals" in the sense that there is a computable relation R such that for each real α, $\alpha \in U$ iff $\exists x\, R^\alpha(x)$, where R^α denotes R with oracle α. An equivalent definition is that U is a Σ^0_1 class iff there is a c.e. set of intervals W such that $U = \cup\{[\sigma] : \sigma \in W\}$. Now we can make our intuition of avoiding all effective statistical tests more precise, as follows.

Definition 3.1 (Martin-Löf [60]). A set of reals $A \subseteq 2^\omega$ is Martin-Löf null (or Σ_1*-null*) if there is a uniformly c.e. sequence $\{U_i\}_{i\in\omega}$ of Σ^0_1-classes (called a *Martin-Löf test*) such that $\mu(U_i) \leq 2^{-i}$ and $A \subseteq \bigcap_i U_i$. $\alpha \in 2^\omega$ is Martin-Löf random, or 1-random, if $\{\alpha\}$ is not Σ_1-null.

This definition and variations form common bases for the theory of algorithmic randomness. There are also two other approaches aside from the measure-theoretical. These include the incompressibility paradigm and the unpredictability paradigm.

It is possible to calibrate randomness in a method similar to the arithmetical hierarchy, by defining n-randomness exactly as above, except that Σ^0_1 null sets are replaced by Σ^0_n null sets. It can be shown (Kurtz [50]) that $n+1$-randomness is 1-randomness relative to $\emptyset^{(n)}$, Stuart Kurtz [50] was the first meaning that if $\emptyset'$ is given as an oracle, what is the analog of Martin-Löf randomness. to systematically examine the relationship between n-randomness and the computability, although some unpublished work was to be found in Solovay [89], and 2-randomness was already to be found in Gaifman and Snir [35], in implicit form.

There has been quite some work clarifying the relationship between Turing reducibility and n-randomness. For example, it has long been known that if $\mathbf{a}$ is $n+1$-random then $\mathbf{a}$ is GL_n, meaning that $\mathbf{a} \cup \mathbf{0}^n = (\mathbf{a} \cup \mathbf{0})^n$, and that the "almost all" theory of degrees is decidable (Stillwell [93]). Recently some lovely new work has emerged. As an illustration, we mention the following unexpected result.

Theorem 3.2 (Miller and Yu [69]). *Suppose that $A \leq_T B$ and B is n-random and A is* 1*-random. Then A is n-random.*

3.2. Kolmogorov complexity. The key idea here is that a random string (as generated by a coin toss, say) should not be easily described by a short program. Thus, 10^{100} is easily described by a description much shorter than its length. This incompressibility idea was the famous approach pioneered by Kolmogorov [41] (also cf. Solomonoff [88]). For our programming language (which we take as Turing machines) we consider the lengths of strings σ producing a string τ. Think of σ as a description of τ under the action of the machine N. Then the N-complexity of the τ is the *length* of the shortest σ from which N produces τ. Since we can enumerate the machines $M_0, M_1, \ldots$, we can make a universal machine M which acts as

$M(1^{e+1}0\sigma) = M_e(\sigma)$.Thus, there is canonical choice for the choice of machine up to a constant, and we define the (plain) *Kolmogorov complexity* of τ as

$$C(\tau) = \min\{\infty, |\sigma| : M(\sigma) = \tau\}.$$

The we would say that τ is C-random iff $C(\tau) \geq |\tau|$. We will also need conditional versions of this (and other) measures. We will write $C(\sigma|\nu)$ as the conditional plain complexity of σ given ν as an oracle. (We will use analogous notation for K below.)

Plain Kolmogorov complexity produces a nice theory of randomness for strings, but as Martin-Löf argued, plain complexity fails to capture the intentional meaning of "the bits of σ producing the bits of τ". This is the length of σ itself can be used in the program, giving $\tau + |\tau|$ many bits of information. Thus, it is easily shown that if α is sufficiently long then there is some n such that $C(\alpha \upharpoonright n) < n$, meaning that there are *no* random reals if we take randomness to mean that all initial segments should be random[3].

This problem was overcome by Levin [51], [54], Schnorr [84], and Chaitin [10], using monotone, process and prefix-free complexities. Here we focus on the prefix-free complexity. Recall that A of intervals is called *prefix-free* iff for all σ, τ, if $\sigma \prec \tau$, then $[\sigma] \in A$ implies $[\tau] \notin A$. Note that for such a set A,

$$\mu(A) = \sum\{2^{-|\sigma|} : [\sigma] \in A\}.$$

Levin and then Chaitin defined prefix-free Kolmogorov complexity using machines whose domains were prefix free. Again there is a universal one U (same argument) and we define

$$K(\tau) = \min\{|\sigma| : U(\sigma) = \tau\}.$$

Finally we can define a real to be K-random iff for all n, $K(\alpha \upharpoonright n) \geq n - O(1)$. The concepts of Martin-Löf randomness and K-randomness are tied together as follows.

Theorem 3.3 (Schnorr, see Chaitin [10], [12]). *$A \in 2^\omega$ is Martin-Löf random if and only if it is K-random.*

Given Schnorr's Theorem, Solovay had asked if $\liminf_s K(\Omega \upharpoonright n) - n \to \infty$. This was solved affirmatively by Chaitin. However, there is a very attractive generalization of this due to Miller and Yu who show that the complexity of a random real must be above n eventually by "quite a bit."

Theorem 3.4 (Ample Excess Lemma, Miller and Yu [69]). *A real α is random iff*

$$\sum_{n\in\mathbb{N}} 2^{n-K(\alpha|n)} < \infty.$$

[3] Specifically, every string ν corresponds to some number (string) in the length/lexicographic ordering of $2^{<\omega}$. Given a long string α, take any initial segment $\alpha \upharpoonright n$. This corresponds to a number m in this way. Now consider the programme which, on input ρ interprets ρ's length as a string γ and outputs $\gamma\rho$. If this programme is enacted on $\alpha \upharpoonright_{n+1}^{n+m}$ the segment of α of length m beginning after α, it will output $\alpha \upharpoonright n + m$, allowing for compression of arbitrary segments.

Corollary 3.5 (Miller and Yu [70]). *Suppose that f is an arbitrary function with $\sum_{m\in\mathbb{N}} 2^{-f(m)} = \infty$. Suppose that α is 1-random. Then there are infinitely many m with $K(\alpha \upharpoonright m) > m + f(m)$.*

The reader might wonder whether plain complexity could be used to characterize 1-randomness. There had been some natural "C-conditions" which had been shown to guarantee randomness. Martin-Löf showed that if a real had infinitely often maximal C -complexity then it would be random. That is, Kolmogorov observed that the greatest plain complexity a string σ can have is $|\sigma|$. We will say that a real is *Kolmogorov random* iff $\exists^\infty n[C(\alpha \upharpoonright n) = n - O(1)$. If A is Kolmogorov random it is 1-random. But recently more has been shown. Chaitin showed that the highest prefix-free complexity a string can have is $|\sigma| + K(|\sigma|)$, and we define α to be strongly Chaitin random iff $\exists^\infty n[(K(\alpha \upharpoonright n) > n + K(n) - O(1)]$. Solovay [89] (see Yu, Ding, Downey [107]) showed that each 3-random is strongly Chaitin random, and every strongly Chaitin random real is Kolmogorov random and hence 1-random. It is not known if every Kolmogorov random real is strongly Chaitin random. The following remarkable result shows that Kolmogorov randomness can be characterized in terms of the randomness hierarchy.

Theorem 3.6 (Nies, Stephan and Terwijn [78]). *Suppose that α is Kolmogorov random. Then α is 2-random.*

Theorem 3.7 (Miller [66], Nies, Stephan and Terwijn [78]). *A real α is 2-random iff α is Kolmogorov random.*

We remark that there seems no *prima facie* reason for 2-randomness to be the same as Kolmogorov randomness! The question of whether there was a natural condition in terms of plain complexity which characterized 1-randomness was finally solved by Miller and Yu, having been open for 40 years.

Definition 3.8 (Miller and Yu [69]). Define a computable function $G : \omega \to \omega$ by

$$G(n) = \begin{cases} K_{s+1}(t), & \text{if } n = 2^{\langle s,t\rangle} \text{ and } K_{s+1}(t) \neq K_s(t), \\ n, & \text{otherwise.} \end{cases}$$

Theorem 3.9 (Miller and Yu [69]). *For $x \in 2^\omega$, the following are equivalent:*

(i) *x is 1-random.*

(ii) (One direction of this is in Gács [32]) $(\forall n)\ C(x \upharpoonright n) \geq n - K(n) \pm O(1)$.

(iii) $(\forall n)\ C(x \upharpoonright n) \geq n - g(n) \pm O(1)$, *for every computable $g : \omega \to \omega$ such that $\sum_{n\in\omega} 2^{-g(n)}$ is finite.*

(iv) $(\forall n)\ C(x \upharpoonright n) \geq n - G(n) \pm O(1)$.

While it is not hard to show that almost all reals are random (as one would hope), Schnorr's Theorem allows us to easily show that there are explicit random reals. The halting probabilities of prefix-free Turing machines occupy the same place in algorithmic randomness as computably enumerable sets (the domains of partial computable functions) do in classical computability theory. They are called *left-computably enumerable reals* (left-c.e.) and are defined as the limits of increasing computable sequences of rationals. A special left-c.e. real is $\Omega = \sum_{U(\sigma)\downarrow} 2^{-|\sigma|}$ where U is a universal prefix free machine.

Theorem 3.10 (Chaitin [10], [12]). *Ω is Martin-Löf random.*

Chaitin's Ω has had a lot of popular attention. It allows us to prove Gödel's incompleteness theorem and the like using Kolmogorov complexity. Solovay [89] was the first to look at basic computability-theoretical aspects of Ω. For instance, consider $D_n = \{x : |x| \leq n \wedge U(x)\downarrow\}$. Solovay proved that $K(D_n) = n + O(1)$, where $K(D_n)$ is the K-complexity for an index for D_n. Solovay also proved the following basic relationships between D_n and $\Omega \upharpoonright n$.

Theorem 3.11 (Solovay [89]).

(i) $K(D_n|\Omega \upharpoonright n) = O(1)$[4].

(ii) $K(\Omega \upharpoonright n|D_{n+K(n)}) = O(1)$.

The reader should note that in classical computability theory, we usually talk of *the* halting problem, whereas here the definition of Ω seems thoroughly machine dependent. To try to address this issue, Solovay [89] introduced the following definition, which is a kind of analytic version of m-reducibility.

Definition 3.12 (Solovay [89]). We say that a real α is *Solovay reducible* to β (or β *dominates* α), $\alpha \leq_S \beta$, iff there is a constant c and a partial computable function f, so that for all $q \in \mathbb{Q}$, with $q < \beta$,

$$c(\beta - q) > \alpha - f(q).$$

The intuition here is a sequence converging to β can generate one converging to α at the same rate, as clarified by Calude, Hertling, Khoussainov, Wang [9]. It is easy to see that $\leq_S$ implies $\leq_T$ for reals. Since there are only $O(2^{2d})$ many reals within a radius of 2^{-n+d} of a string representing a rational whose dyadic expansion has length n, it follows that $\leq_S$ has the *Solovay Property* of the lemma below.

Lemma 3.13 (Solovay [89]). *If $\alpha \leq_S \beta$ then there is a c such that, for all n,*

$$K(\alpha \upharpoonright n) \leq K(\beta \upharpoonright n) + c.$$

The same also holds for C in place of K.

[4]Indeed, $D_n \leq_{wtt} \Omega \upharpoonright n$ via a weak truth table reduction with identity use, where a Turing reduction is a weak truth table one if there is a computable bound on the size of the queries used.

This lemma shows that, if $\Omega \leq_S \beta$, then β is Martin-Löf random. The next result says the being Ω-like means that a left-c.e. real look like Ω.

Theorem 3.14 (Calude, Hertling, Khoussainov, Wang [9]). *Suppose that β is a left-c.e. real and that $\Omega \leq_S \beta$. Then β is a halting probability. That is, there is a universal machine $\widehat{U}$ such that $\mu(\mathrm{dom}(\widehat{U})) = \beta$.*

The final piece of the puzzle was provided by the following lovely result of Kučera and Slaman.

Theorem 3.15 (Kučera and Slaman [46]). *Suppose that α is random and a left-c.e. real. Then for all left-c.e. reals β, $\beta \leq_S \alpha$, and hence α is a halting probability.*

We know that all reals have complexity oscillations. The Kučera–Slaman Theorem says that for left-c.e. random reals, they all happen in the same places. Downey, Hirschfeldt and Nies [26], and Downey, Hirschfeldt and LaForte [24] were motivated to look at the structure of computably enumerable reals under Solovay reducibility. The structure remains largely unexplored.

Theorem 3.16 (Downey, Hirschfeldt and Nies [26]).

(i) *The Solovay degrees of left-c.e. reals forms a distributive upper semilattice, where the operation of join is induced by $+$, arithmetic addition* (*or multiplication*) (*namely* $[x] \vee [y] \equiv_S [x + y]$).

(ii) *This structure is dense.*[5] *In fact if* $\mathbf{a} < \mathbf{b} < [\Omega]$ *then there exist incomparable* $\mathbf{b_1}, \mathbf{b_2}$ *with* $\mathbf{a} < \mathbf{b_1} \vee \mathbf{b_2} = \mathbf{b}$.

(iii) *However, if* $[\Omega] = \mathbf{a} \vee \mathbf{b}$ *then either* $[\Omega] = \mathbf{a}$ *or* $[\Omega] = \mathbf{b}$.

Theorem 3.17 (Downey and Hirschfeldt [22]). *There exist left-c.e.* sets *A and B such that the Solovay degrees of A and B have no infimum in the* (*global*) *Solovay degrees.*

Theorem 3.18 (Downey, Hirschfeldt, and LaForte [24]). *The first order theory of the uppersemilattice of the Solovay degrees of left-c.e. reals is undecidable.*

We can view Ω as a fundamental operator on reals in the same way as we do for the jump operator. However, we need real care when dealing with relativizing Ω. We will take the notion of *universal machine* to mean that the machine U should be universal (and hence prefix-free) for all oracles, and if M_e is any machine, then M_e should be effectively coded in U, meaning that for some τ, $M_e(\sigma) = U(\tau\sigma)$. This definition avoids pathological machines.

The properties of omega operators acting on Cantor space and their relationship with, for instance, Turing reducibility was really initiated by Downey, Hirschfeldt, Miller and Nies [25]. It had been hoped, for instance, that these might be degree invariant operators on 2^ω. This hope failed about as badly as it could.

[5] In fact, Downey and Hirschfeldt [22] have sown the Density Theorem holds for the left-c.e. reals for any measure of relative randomness which has a Σ^0_3 definition, has a top degree of $[\Omega]$, + is a join, and where the computable sets are in the zero degree.

Theorem 3.19 (Downey, Hirschfeldt, Miller, Nies [25]). *For any omega operator* Ω*, there are reals* $A =^* B$ (*meaning that they differ only by a finite amount*) *such that* Ω^A *and* Ω^B *are relatively random* (*and hence* $\Omega^A|_T \Omega^B$).

One the other hand, omega operators do have some fascinating properties.

Theorem 3.20 (Downey, Hirschfeldt, Miller, Nies [25]). *Omega operators are lower semicontinuous but not continuous, and moreover, that they are continuous exactly at the* 1*-generic reals*[6].

In some sense Ω is kind of a red herring amongst random reals. It gives the impression that random reals have high computational power. Also results such as the famous Kučera–Gács Theorem below say that some random reals have high computational power.

Theorem 3.21 (Kučera [42], Gács [33]). *Every set is Turing* (wtt-)*reducible to a Martin-Löf random set.*

We remark that it is by no means clear this result should be true. After all, the very first result connecting measure and computability was the following:

Theorem 3.22 (de Leeuw, Moore, Shannon, and Shapiro [14]). *Define the* enumeration probability *of A as*

$$P(A) = \mu(\{X \in 2^\omega : U^X = A\}),$$

where U is some universal machine. Then if $P(A) > 0$*, A is a computably enumerable set.*

An immediate corollary is the result first stated by Sacks [81] that A is computable iff $\mu(\{Y : A \leq_T Y\}) > 0$.

The question is : "How do we reconcile the notions of high computational power and high randomness?". Frank Stephan gave a clarification to this dichotomy. We say that a function f is fixed point free iff for all partial computable functions φ_e, $f(e) \neq \varphi_e(e)$. We will say a set A has PA if it has the computational power to compute $\{0, 1\}$ valued fixed point free function[7]. Whilst Kučera [44], [45] had shown that random reals can always compute fixed point free functions[8], Stephan showed that the randoms above the degree of the halting problem are the only ones with sufficient computational power to be able to compute a $\{0, 1\}$-valued one[9].

Theorem 3.23 (Stephan [91]). *Suppose that* $\mathbf{a}$ *is PA and* 1*-random. Then* $\mathbf{0}' \leq_T \mathbf{a}$.

[6] Here recall that x is 1-generic means that it is Cohen generic for 1 quantifier arithmetic.

[7] They are called PA degrees since the coincide with the degrees bounding complete extensions of Peano Arithmetic. (Scott [85], Solovay.)

[8] Additionally, Kučera proved that if A is n-random, then A bounds an n-FPF function. We refer the reader to [45] or [22] for definitions and details.

[9] Also, Kjos-Hanssen, Merkle, and Stephan [39] give a variant of in terms of Kolmogorov complexity and is in some sense an explanation why it is true.

All of this might leads the reader to guess that Ω, and hence all halting probabilities, have little to do with algorithmic randomness in general. Again this is not the case.

Theorem 3.24 (Downey, Hirschfeldt, Miller, Nies [25]). *Suppose that A is 2-random. Then there is a universal machine U and set B such that $A = \Omega_U^B$.*

That is, almost all randoms are halting probabilities. Notice that $\overline{\Omega}$ is random, but cannot be a halting probability relative to any oracle.

By analyzing the "majority vote" proof of Sacks Theorem, it is easy to show that if A is 2-random and $B \leq_T A$, then A is *not* random relative to B. Thus Theorem 3.24 stands in contrast the classical theorem from Kurtz' regrettably unpublished Thesis. (Proofs of this result and others from Kurtz's Thesis, and from Solovay's notes can be found in Downey and Hirschfeldt [22].)

Theorem 3.25 (Kurtz [50]). *Suppose that A is 2-random. Then there is a set $B \leq_T A$ such that A is computably enumerable relative to B.*

3.3. Martingales and the prediction paradigm. The last major approach to the concept of algorithmic randomness uses the intuition that random reals should be *hard to predict*. This can be formalized by imagining you had some "*effective*" betting strategy which worked on the bits of a real α. At each stage you get to try to predict the next bit of α, knowing the previous n bits. This idea leads to the following concept.

Definition 3.26 (Levy [55]). A *martingale* (*supermartingale*) is a function $f : 2^{<\omega} \mapsto \mathbb{R}^+ \cup \{0\}$ such that for all σ,

$$f(\sigma) = \frac{f(\sigma 0) + f(\sigma 1)}{2} \quad (\text{resp.} f(\sigma) \geq \frac{f(\sigma 0) + f(\sigma 1)}{2}).$$

We say that the (super-)martingale *succeeds* on a real α, if $\limsup_n F(\alpha \upharpoonright n) \to \infty$.

Martingales were introduced by Levy [55], and Ville [102] proved that null sets correspond to success sets for martingales. They were used extensively by Doob in the study of stochastic processes. Schnorr [82], [83] effectivized the notion of a (super-)martingale.

Definition 3.27. We will define a (super-)martingale f as being *effective* or *computably enumerable* if $f(\sigma)$ is a c.e. real, and at every stage we have effective approximations to f in the sense that $f(\sigma) = \lim_s f_s(\sigma)$, with $f_s(\sigma)$ a computable increasing sequence of rationals.

We remark that the reader might have expected that an effective martingale would be one with f a computable function rather than one with computable *approximations*. This is an important point and we return to it later.

Theorem 3.28 (Schnorr [82]). *A real α is Martin-Löf random iff no effective (super-) martingale succeeds on α.*

Thus, we have nice evidence that we have captured a reasonable notion of algorithmic randomness in that the three approaches, measure-theoretical, compressional, and predictability, all give the same class.

3.4. Schnorr's critique. In [82], [83], Schnorr argued that Theorem 3.28 demonstrated a clear failure of the intuition behind the definition of algorithmic randomness in that it we had *computable enumerable* betting strategies corresponding to Martin-Löf randomness rather than *computable* ones. Schnorr proposed the two variations below, and these have had attracted considerable interest recently. The first is to replace computably enumerable martingales by computable martingales and obtain the concept of *computably random* meaning that no computable martingale can succeed on the real. The second is to take the definition of Martin-Löf randomness (Definition 3.1) and replace $\mu(U_i) \leq 2^{-i}$ by $\mu(U_i) = 2^{-i}$ so that we know exactly the measure of the test sets, and hence can decide if $[\sigma] \in U_i$ by waiting until we know the measure of U_i to within $2^{-|\sigma|}$. Some clarification of the relationships between these two concepts was obtained by Schnorr.

Definition 3.29. We say that a computable martingale *strongly* succeeds on a real x iff there is a computable unbounded nondecreasing function $h\colon \mathbb{N} \mapsto \mathbb{N}$ such that $F(x \upharpoonright n) \geq h(n)$ infinitely often.

Theorem 3.30 (Schnorr [82]). *A real x is Schnorr random iff no computable martingale strongly succeeds on x.*

Thus Martin-Löf randomness implies computable randomness which implies Schnorr randomness. None of the implications can be reversed (van Lambalgen [99]). These concepts were somewhat ignored for maybe 20 years after Schnorr defined them, possibly because Martin-Löf randomness sufficed for many tasks, and because they were rather more difficult to handle. There are no universal tests, for instance, for Schnorr randomness. Recently, Downey and Griffiths [19] gave a nice characterization of Schnorr randomness in terms of *computable* machines. Here prefix-free M is called computable iff the measure of its domain is a computable real.

Theorem 3.31 (Downey and Griffiths [19]). *A real α is Schnorr random iff for all computable machines M, there is a constant c such that, for all n, $K_M(\alpha \upharpoonright n) \geq n - c$.*

Related here is yet another notion of randomness called Kurtz or weak randomness. We define a *Kurtz test* (resp. Kurtz n-test) to be a Σ^0_1 (resp. Σ^0_n-) class of measure 1. Then a real A is called *weakly* (n-)*random* or *Kurtz n-random*[10] if it passes all Kurtz (n-)tests, meaning that $A \in U$ for all such U. There is a null test version.

[10] Now it could be argued that weak randomness is not really a randomness notion at all, but rather a genericity notion. However, for $n \geq 2$ it is certainly a randomness notion, and $n = 2$ corresponds to "Martin-Lóf tests with no effective rate of convergence."

Definition 3.32 (Wang [103]). A *Kurtz null test* is a collection $\{V_n : n \in \mathbb{N}\}$ of c.e. open sets, such that

(i) $\mu(V_n) \leq 2^{-n}$, and

(ii) there is a computable function $f : \mathbb{N} \to (\Sigma^*)^{<\omega}$ such that $f(n)$ is a canonical index for a finite set of σ's, say, $\sigma_1, \ldots, \sigma_n$ and $V_n = \{[\sigma_1], \ldots, [\sigma_n]\}$.

Theorem 3.33 (Wang [103], after Kurtz [50]). *A real α is Kurtz random iff it passes all Kurtz null tests.*

Wang also gave a martingale version of Kurtz randomness.

Theorem 3.34 (Wang [103]). *A real α is Kurtz random iff there is no computable martingale F and nondecreasing computable function h, such that for* almost all *n,*

$$F(\alpha \upharpoonright n) > h(n).$$

This should be directly compared with Schnorr's characterization of Schnorr randomness in terms of martingales and computable orders. Downey, Griffith and Reid [21] gave a machine characterization of Kurtz randomness, and showed that each computably enumerable non-zero degree contained a Kurtz random left-c.e. real. This contrasted with the theorem of Downey, Griffiths and LaForte [20] who showed that if a left-c.e. real was Kurtz random, then its Turing degree must resemble the halting problem in that it must be high (i.e. $A' \equiv_T \emptyset'$). The definitive (and rather difficult) result here is the following which builds on all of this work.

Theorem 3.35 (Nies, Stephan and Terwijn [78]). *For every set A, the following are equivalent.*

(I) *A is high (i.e. $A' \geq_T \emptyset''$).*

(II) *There exists $B \equiv_T A$, such that B is computably random but not Martin-Löf random.*

(III) *There exists $C \equiv_T A$, such that C is Schnorr random but not computably random.*

Moreover, the examples can be chosen as left-c.e. reals if the degrees are computably enumerable.

Remarkably, outside of the high degrees the notions coincide.

Theorem 3.36 (Nies, Stephan and Terwijn [78]). *Suppose that a set A is Schnorr random and does not have high degree. Then A is Martin-Löf random.*

An even more unexpected collapse occurs for the special class of degrees called hyperimmune-free degrees. Following Miller and Martin [73], we say that A is *hyperimmune-free* iff for all functions $f \leq_T A$, there is a computable function g such that for all x, $f(x) \leq g(x)$.

Theorem 3.37 (Nies, Stephan, Terwijn [78]). *Suppose that A is of hyperimmune-free degree. Then A is Kurtz random iff A is Martin-Löf random.*

Space precludes me for discussing a very attractive possible refutation of Schnorr's critique proposed by Muchnik, Semenov, and Uspensky [72] who looked at *nonmonotonic* betting strategies, where now we no longer pick the bits of the real in order. The open question is whether using computable nonmonotonic supermartingales, we might capture the notion of Martin-Löf randomness. We refer the reader to the paper of Merkle, Miller, Nies, Reimann and Stephan [65] and [72].

3.5. Hausdorff dimension. Whilst I do not really have enough space to do justice to the area, there has been a lot of very interesting work concerning effective Hausdorff dimension of even single reals and strings. For instance, we would expect that if $\Omega = w_0 w_1 \ldots$ then somehow $w_0 00 w_1 00 w_2 00 \ldots$ should be "$\frac{1}{3}$ random." We can address this issue using a refinement of the class of measure zero sets is given by the theory of Hausdorff Dimension. In 1919 Hausdorff [36] generalized earlier work of Carathéodory to define a notion of an s-dimensional measure to include non-integer values. The basic idea is that you replace measure by a kind of generalized measure, where $\mu([\sigma])$ is replaced by $2^{-s|\sigma|}$ where $0 < s \leq 1$. With $s = 1$ we get normal Lebesgue measure. For $s < 1$ we get a refinement of measure zero. We can translate this cover version into a s-gale (a version of martingales, namely $f(\sigma) = 2^{-s}(f(\sigma 0) + f(\sigma 1))$) definition in the same way that it is possible to frame Lebesgue measure in terms of martingales.

Here we are viewing betting strategies in a *hostile environment* (a model of Jack Lutz), where "inflation" is acting so *not winning* means that we automatically lose money. (For normal martingales, we are to choose not to bet on some bit saving our funds for later bits and this has no effect. Here failing to bet means that our capital shrinks. The most hostile environment where we can win will be the effective Hausdorff dimension.) That is, roughly speaking, it can be shown that there is some limsup where the s-measure is not zero, and this is called the Hausdorff dimension of the set.

The study of effective dimension was pioneered through the work of Jack Lutz though as with much of the area of randomness there is a lot of history. In any case, for the effective version through the work of Lutz, Mayordomo, Hitchcock, Staiger and others we find that the notion corresponds to $\liminf_n \frac{K(A\upharpoonright n)}{n}$, and can take that as a *working definition* of effective Hausdorff dimension. (Here I must refer the reader to Lutz [58], [59] for more details and history.)

With this definition, it can easily be shown that the "00" version of Ω above really has Hausdorff dimension $\frac{1}{3}$ and in fact is $\frac{1}{3}$ random as in Tadaki [94].

Terwijn [95], [96] and Reimann [80] have very nice results here relating Hausdorff dimension to degree structures. The latter as well and Lutz and Mayordomo have also looked at other dimensions, such as effective packing dimension, which can be characterized as $\limsup_n \frac{K(A\upharpoonright n)}{n}$. Again it is possible to examine these concepts for

stronger and weaker randomness notions such as Schnorr dimension. For instance, Downey, Merkle and Reimann [30] have shown that it is possible to have computably enumerable *sets* with nonzero Schnorr packing dimension, whereas their Schnorr Hausdorff dimension is 0. Much work remains to be done here with a plethora of open questions.

We finish this section by remarking that Lutz [58], [59] has even developed a notion of dimension for individual *strings*. The approach is to replace s-gales by "termgales" which are the analogues of s-gales for terminated strings. In essence he has characterized dimension for individual strings exactly in terms of prefix-free Kolmogorov complexity. Space does not allow for the development of this theory and we refer the reader to Lutz [58], [59] or Downey and Hirschfeldt [22] for further details.

4. Calibrating randomness

We have seen that we can classify randomness in terms of initial segment complexity. Thus it seems reasonable to think that we should also be able to classify *relative* randomness in terms of *relative* initial segment complexity. This motivates the following definition.

Definition 4.1 (Downey, Hirschfeldt, and LaForte [23]). We say a pre-ordering $\preceq$ is am *Q-initial segment measure of relative randomness* iff it obeys the Solovay property met earlier: $A \preceq B$ means that for all n, $Q(A \upharpoonright n) \leq Q(B \upharpoonright n) + O(1)$.

Here we are thinking of Q as C or K. We have already seen that Solovay reducibility is a measure of relative randomness and can be used to characterize the left-c.e. random reals. However, Solovay reducibility has a number of limitations such as being too fine and only really relating to left-c.e. reals.

There are a number of other interesting measures of relative randomness. They include segment ones $\leq_C$ and $\leq_K$ which are defined in the obvious way. Others include the following introduced by Downey, Hirschfeldt and LaForte [23]:

(i) $A \leq_{sw} B$ iff there is a c and a wtt procedure Γ with use $\gamma(n) = n + c$, and $\Gamma^B = A$. If $c = 0$, then this is called *ibT-reducibility* and is the one used by Soare and Csima in differential geometry, such as Soare [87].

(ii) $A \leq_{rK} B$ means that there is a c such that for all n,

$$K((A \upharpoonright n)|(B \upharpoonright n + c)) = O(1).$$

The reducibility (i) is also called effective Lipschitz reducibility and This reducibility has been analyzed by Yu and Ding [105], Barmpalias and Lewis (e.g. [4]), and Raichev and Stephan (e.g. [79]). While I do not really have space to discuss these reducibilities in detail, I would like to point out that they do give nice insight into relative computability. We briefly consider sw. The idea of this reducibility is that if

$A \leq_{sw} B$, then there is an *efficient* way to convert the *bits* of B into those of A. The Kučera–Slaman Theorem says that all versions of Ω are the same in terms of their S-degrees. But we may ask whether there is a "bit" version of this result? Yu and Ding [105] established the following.

Theorem 4.2 (Yu and Ding [105]).

(i) *There is no sw-complete c.e. real.*

(ii) *There are two c.e. reals β_0 and β_1 so that there is no c.e. real α with $\beta_0 \leq_{sw} \alpha$ and $\beta_1 \leq_{sw} \alpha$.*

There are other assorted results and reducibilities. However, things are still in their infancy here. We will simply refer the reader to Downey [17], or Downey and Hirschfeldt [22] for the current situation.

We return to looking at the basic measures $\leq_C$ and $\leq_K$. The reader should note that these are not really reducibilities but simply transitive pre-orderings. (Though following tradition we will continue to refer to them as reducibilities.)

Theorem 4.3 (Yu, Ding, Downey [107]). *For $Q \in \{K, C\}$, $\{X : X \leq_Q Y\}$ has size $2^{\aleph_0}$ and has members of each degree, whenever Y is random.*

The replacement for this theorem is a measure-theoretical one:

Theorem 4.4 (Yu, Ding, Downey [107]). *For any real A, $\mu(\{B : B \leq_K A\}) = 0$. Hence there are uncountably many K degrees.*

We had hoped that there might be nice hierarchies related to levels of randomness. We will denote by $\Omega^{(m+1)}$ to be Ω relative to $\emptyset^{(m)}$. We might have hoped that $\Omega^{(2)}$ was K-above Ω, but that hope turns out to be forlorn.

Theorem 4.5 (Yu, Ding, Downey [107]). *For all c and $n < m$,*

$$(\exists^\infty k)\,[\,K(\Omega^{(n)} \upharpoonright k) < K(\Omega^{(m)} \upharpoonright k) - c].$$

For $n = 0$, $m = 1$ Theorem 4.5 was proven by Solovay [89], using totally different methods.

Miller and Yu have made really significant progress in our understanding here by introducing yet more measures of relative randomness. They are based around van Lambalgen's Theorem which states that for all A, B, *B n-random and A is B-n-random iff $A \oplus B$ is n-random.*

Definition 4.6 (Miller and Yu [69]). We say that $\alpha \leq_{vL} \beta$, α is *van Lambalgen*[11] reducible to β if for all $x \in 2^\omega$, $\alpha \oplus x$ is random implies $\beta \oplus x$ is random.

Miller and Yu's basic result were as follows.

[11] This is closely related to a relation introduced by Nies: He defined $A \leq_{LR} B$ if for all Z, Z is 1-B-random implies Z is 1-A-random. If A and B are both random then $A \leq_{LR} B$ iff $B \leq_{LR} A$.

Theorem 4.7 (Miller and Yu [69]). *For all random α, β,*

(i) *α n-random and $\alpha \leq_{vL} \beta$ implies β is n-random.*

(ii) *If $\alpha \oplus \beta$ is random then α and β have no upper bound in the vL-degrees.*

(iii) *If $\alpha \leq_T \beta$ and α is 1-random, then $\beta \leq_{vL} \alpha$.*

(iv) *There are random $\alpha \equiv_{vL} \beta$ of different Turing degrees.*

(v) *There are no maximal or minimal random vL-degrees, and no join.*

(vi) *If $\alpha \oplus \beta$ is random then $\alpha \oplus \beta <_{vL} \alpha, \beta$.*

(vii) *The Σ^0_1 theory of the vL-degrees is decidable.*

Miller and Yu show that $\Omega^{(n)}$ and $\Omega^{(m)}$ have no upper bound in the vL degrees for $n \neq m$. This improves the Yu, Ding, Downey (Theorem 4.5) result above. All of this is filters through an interesting relationship between $\leq_{vL}$ and $\leq_C, \leq_K$.

Lemma 4.8 (Miller and Yu [69]). *For random α, β,*

(i) *Suppose that $\alpha \leq_K \beta$. Then $\alpha \leq_{vL} \beta$.*

(ii) *Suppose that $\alpha \leq_C \beta$. Then $\alpha \leq_{vL} \beta$.*

We state the following for $\leq_K$ but they hold equally for $\leq_C$, as has been shown by Miller and Yu.

Corollary 4.9 (Miller and Yu [69]).

(i) *Suppose that $\alpha \leq_K \beta$, and α is n-random and β is random. Then β is n-random.*

(ii) *If $\alpha \oplus \beta$ is 1-random, then $\alpha|_K \beta$ and have no upper bound in the K-degrees.*

(iii) *For all $n \neq m$, the K-degrees of $\Omega^{(n)}$ and $\Omega^{(m)}$ have no upper bound.*

Miller and Yu have many other very interesting results on the K degrees of c.e. reals. For instance, they show that if $\alpha \oplus \beta$ is 1-random, then $\alpha|_K \alpha \oplus \beta$. Miller has proven the following.

Theorem 4.10 (Miller [67]).

(i) *If α, β are random, and $\alpha \equiv_K \beta$, then $\alpha' \equiv_{tt} \beta'$. As a consequence, every K-degree of a random real is countable.*

(ii) *If $\alpha \leq_K \beta$, and α is 3-random, then $\beta \leq_T \alpha \oplus \emptyset'$.*

Notice that (ii) implies that the cone of K-degrees above a 3-random is countable. On the other hand, Miller and Yu have constructed a 1-random whose K-upper cone is uncountable. The construction of an uncountable random K-degree uses their method of constructing K-comparable reals. Its proof uses the following clever lemma. The current proof of Theorem 4.11 is quite difficult.

Theorem 4.11 (Miller and Yu [70]). *Suppose that* $\sum_n 2^{-f(n)} < \infty$, *then there is a* 1*-random* Y *with*

$$K(Y \upharpoonright n) < n + f(n),$$

for almost all n.

To finish this section, we mention further evidence that randomness is a "lowness" notion. Miller has shown that if α is 3-random then its often useless as an oracle. We will call α *weakly-low for* K if $(\exists^\infty n)[K(n) \leq K^\alpha(n) + O(1)]$. Thus in a weakly-low real, the information in α is so useless that it cannot help to compress n. The following result echoes the theme articulated by Stephan that most random reals have little *usable* information in them.

Theorem 4.12 (Miller [67]).

(i) *If* α *is* 3*-random it is weakly-low for* K.

(ii) *If* α *is weakly-low for* K, *and random, then* α *is strongly Chaitin random in that*

$$(\exists^\infty n)\left[K(\alpha \upharpoonright n) \geq n + K(n) - O(1)\right].$$

5. Lowness and triviality

There have been some truly dramatic results in what has now become known as lowness and triviality. If Q is a measure of relative randomness then we can say that A is Q*-trivial* iff $A \leq_Q 1^\omega$. Thus using Q we cannot distinguish A from a computable set. We will say that A is Q*-low* if $Q^A(\sigma) = Q(\sigma) + O(1)$, for all σ. Thus, for instance A is K-low would mean that $K^A(\sigma) = K(\sigma) + O(1)$ for all σ.

We say that a set A is low for a randomness notion V iff the V-randoms relative to A remain the same. (One would usually expect that fewer sets would be random.) An apparently weaker notion is that of being low for V tests. That is, every if $\{U_i : i \in \mathbb{N}\}$ is a V^A test, then there is a V-test $\{\hat{U}_i : i \in \mathbb{N}\}$ such that $\cap_i U_i \subseteq \cap_i \hat{U}_i$. We remark that since there are universal Martin-Löf tests the test set notion and the lowness notion are the same.

5.1. The remarkable Martin-Löf case. There have been a series of amazing results in the case of 1-randomness. Historically, these results began with triviality. An old result of Loveland [57] shows that $Q(\alpha \upharpoonright n|n) = O(1)$ for all n, $(Q \in \{C, K\})$ iff α is computable. This result was generalized by Chaitin [11], who proved the following.

Theorem 5.1 (Chaitin [11]). α *is computable iff* $\alpha \leq_C 1^\omega$. (*That is, iff* α *is* C*-trivial.*)

I think this squares with our intuition that should α be indistinguishable from a computable string in terms of its initial segment complexity it should itself be

computable. Chaitin also noted that essentially the same proof shows that if α is K-trivial, the α is Δ^0_2 and hence computable from the halting problem. The breakthrough was again by Solovay.

Theorem 5.2 (Solovay [89]). *There are noncomputable α which are K-trivial.*

Solovay's argument was complex and mysterious. It turned out that the example α could even be chosen as a computably enumerable *set* (Calude and Coles [7], Downey, Hirschfeldt, Nies and Stephan [27], Kummer (unpubl.), An. A. Muchnik (unpubl.)). The paper [27] gave a very simple construction of a computably enumerable K-trivial set along the lines of the Dekker deficiency set. What is remarkable is that such K-trivial sets solve Post's problem.

Theorem 5.3 (Downey, Hirschfeldt, Nies and Stephan [27]). *Suppose that α is K-trivial. Then $\alpha <_T \emptyset'$.*

The method of proof of Theorem 5.3 uses what has become known as the "decanter method"(terminology of Nies) and is unfortunately very complicated, though it does *not* use the priority method. No easy proof of Theorem 5.3 is known.

It was noted that the short [27] proof constructing a K-trivial set strongly resembled and earlier construction of a computably enumerable set A which was low for Martin-Löf randomness by Kučera and Terwijn [47]. It was conjectured that perhaps these classes might have something to do with each other. In a ground breaking series of papers, Nies (and Hirschfeldt) proved some completely unexpected facts.

Theorem 5.4 (Nies (and Hirschfeldt for some), [75], [76]).

(a) *The following classes of reals coincide.*

  (i) *K-low.*
  (ii) *K-trivial.*
  (iii) *Low for Martin-Löf randomness.*

(b) *All the members A of this class $\mathcal{C}$ are* superlow *in that $A' \equiv_{wtt} \emptyset'$.*

(c) *The class $\mathcal{C}$ forms a natural Σ^0_3 ideal in the Turing degrees. There is a low$_2$ computably enumerable degree $\mathbf{a}$ such that if $\mathbf{c} \in \mathcal{C}$, the $\mathbf{c} < \mathbf{a}$.*

(d) *If A is a K-trivial real, then there is a computably enumerable set $\hat{A}$ with $A \leq_T \hat{A}$.*

The K-trivials form the only known natural nontrivial Σ^0_3 ideal in the (computably enumerable) Turing degrees. Item (c) in the above is a special case of a general unpublished Theorem of Nies that every Σ^0_3 ideal in the computably enumerable degrees is bounded by a low$_2$ computably enumerable degree. (A proof can be found in Downey and Hirschfeldt [22].) It is possible that there is a low (non-computably enumerable) degree $\mathbf{a}$ which bounds $\mathcal{C}$, and even possible that such a degree could be random. This problem seems hard.

Subsequently, other quite deep results have been proven. For instance, we have seen that if A is noncomputable then $\mu(\{X : A \leq_T X\}) = 0$, but since there are K-low reals, there must be reals A and randoms X such that X is A-random and $A \leq_T X$. In that case, we say that A is a *base of Martin-Löf randomness*.

Theorem 5.5 (Hirschfeldt, Nies, Stephan [37]). *A is K-trivial iff it is a base of Martin-Löf randomness.*

We remark that Slaman has used the class of K-trivials to solve a longstanding problem in computable model theory. As a final result in this area we mention some interesting results of Csima and Montalbán. These results are related to the enumeration of the K-trivials.

Theorem 5.6 (Chaitin [11], Zambella [108]). *There are only $O(2^d)$ members of $KT(d)$. They are all Δ^0_2.*

The reader might wonder with the nice computable bound how many K-trivial reals there are. Let $G(d) = |\{X : X \in KT(d)\}$. Then there is a crude estimate that $G(d) \leq_T \emptyset''$. This is the best upper bound known. In unpublished work, Downey, Miller and Yu have shown that $G(d) \not\leq_T \emptyset'$, using the fact that $\sum_d \frac{G(d)}{2^d}$ is convergent. This is all related to the Csima–Montalbán functions. We say that f is a *Csima–Montalbán function* if f is nondecreasing and

$$K(A \upharpoonright n) \leq K(n) + f(n) + O(1)$$

implies that $A \upharpoonright n$ is K-trivial. Such functions can be constructed from $\emptyset'' \oplus G$. We define f to be *weakly* Csima–Montalbán, if we weaken the hypothesis to be that $\liminf_n f(n) \to \infty$. Little is known here. It is not known if the arithmetical complexity of f depends upon the universal machine chosen. We remark that the original use of Csima–Montalbán functions was to construct a minimal pair of K-degrees: K-degrees $\mathbf{a}, \mathbf{b}$ such that $\mathbf{a} \wedge \mathbf{b} = \mathbf{0}$.

In other more recent work, Downey, Nies, Weber and Yu [29] have also looked at lowness for weak 2-randomness. Here it has been shown that such degrees do exist, and are all K-trivial. It is not known if the converse holds.

5.2. Other lowness and triviality. One thing which this work has brought (back) to the fore is the use of domination properties in classical computability. This was first recognized in the study of lowness for Schnorr randomness. Terwijn and Zambella [97] defined a degree $\mathbf{a}$ to be computably traceable iff there is a single computable function f such that for all functions $g \leq_T \mathbf{a}$, there is a computable collection of canonical finite sets $\{D_{p(x)} : x \in \mathbb{N}\}$, such that

(i) $|D_{p(x)}| < f(x)$, and

(ii) $g(x) \in D_{p(x)}$ for almost all x.

Being computably traceable is a strong form of being hyperimmune-free. Terwijn and Zambella showed that there are $2^{\aleph_0}$ many degrees that are hyperimmune-free yet not computably traceable. There are also $2^{\aleph_0}$ degrees that are computably traceable. The following theorem completely classifies the low for Schnorr random reals. Its proof is far from easy.

Theorem 5.7 (Terwijn and Zambella [97]). *A is low for Schnorr random null sets iff A is computably traceable.*

It is clear that if A is low for tests then A is low for Schnorr randoms. But the converse is not at all clear and had been an open question of Ambos-Spies and Kučera [3]. The question was finally solved by Kjos-Hanssen, Stephan, and Nies [40], using Bedregal and Nies [5]. Summarizing the results proven there, we have:

Theorem 5.8 (Kjos-Hanssen, Stephan, and Nies [40]). **a** *is low for Schnorr null sets iff* **a** *is low for Schnorr randomness.*

I remark in passing that I am not aware of any lowness notion that differs for null sets and for the randomness notion. In other work, Nies has examined lowness for polynomial time randomness, and lowness for computable randomness. For computable randomness, the answer is rather surprising.

Theorem 5.9 (Nies [76]). *Suppose that A is low for computable randomness. Then A is computable.*

Finally there has been a little work on triviality notions here. Recall that Downey and Griffiths [19] proved that A is Schnorr trivial iff for all *computable* machines M, $K_M(A \upharpoonright n) \geq n - O(1)$. This definition naturally allows us to define a reducibility notion.

Definition 5.10 (Downey and Griffiths [19]). We say that α is Schnorr reducible to β, $\alpha \leq_{Sch} \beta$, iff for all computable machines M, there is a computable machine $\widehat{M}$ such that $K_M(\beta \upharpoonright n) - O(1) > K_{\widehat{M}}(\alpha \upharpoonright n)$, for all n.

This definition allows us to say that a real α is *Schnorr trivial* iff $\alpha \leq_{Sch} 1^\omega$. Schnorr trivial reals behave quite differently than do Schnorr low reals and the K-trivials. Downey and Griffiths constructed a Schnorr trivial real and Downey, Griffiths and LaForte [20] showed that they can even be Turing complete, though they do not occur in every computably enumerable Turing degree. Subsequently, they have been investigated by Johanna Franklin [31]. Her results are summarized below.

Theorem 5.11 (Franklin [31]).

(i) *There is a perfect set of Schnorr trivials* (*and thus some are not* Δ^0_2).

(ii) *Every degree above* $\mathbf{0}'$ *contains a Schnorr trivial.*

(iii) *Every Schnorr low is Schnorr trivial.*

(iv) *The Schnorr lows are not closed under join.*

Finally, we mention that other lowness notions both in randomness and in other contexts have been analyzed. Yu [104] (also Miller and Greenberg (unpublished)) proved that there are no sets low for 1-genericity. Sets low for Kurtz randomness were first constructed by Downey, Griffiths and Reid [21]. They were shown there to be all hyperimmune-free and were implied by Schnorr lowness. Stephan and Yu [92] have shown that lowness for Kurtz randomness differs from lowness for Schnorr randomness and lowness for weak genericity. To wit, they have shown the following.

Theorem 5.12 (Stephan and Yu [92]).

(i) *Low for weakly generic is the same hyperimmune-free plus not of diagonally noncomputable degree.*

(ii) *There is a set of hyperimmune-free degree which is neither computably traceable nor diagonally noncomputable.*

(iii) *Low for weakly generic implies low for Kurtz random.*

(iv) *In particular, low for weakly generic and hence low for Kurtz randomness is not the same as Schnorr low.*

The topic of lowness for such concepts remains in its infancy, and promises fascinating results.

Determinacy and large cardinals

Itay Neeman*

Abstract. The principle of determinacy has been crucial to the study of definable sets of real numbers. This paper surveys some of the uses of determinacy, concentrating specifically on the connection between determinacy and large cardinals, and takes this connection further, to the level of games of length ω_1.

Mathematics Subject Classification (2000). 03E55; 03E60; 03E45; 03E15.

Keywords. Determinacy, iteration trees, large cardinals, long games, Woodin cardinals.

1. Determinacy

Let ω^ω denote the set of infinite sequences of natural numbers. For $A \subset \omega^\omega$ let $G_\omega(A)$ denote the length ω game with payoff A. The format of $G_\omega(A)$ is displayed in Diagram 1. Two players, denoted I and II, alternate playing natural numbers forming together a sequence $x = \langle x(n) \mid n < \omega \rangle$ in ω^ω called a *run* of the game. The run is won by player I if $x \in A$, and otherwise the run is won by player II.

I	$x(0)$		$x(2)$		.....	
II		$x(1)$		$x(3)$		.....

Diagram 1. The game $G_\omega(A)$.

A game is *determined* if one of the players has a winning strategy. The set A is determined if $G_\omega(A)$ is determined. For $\Gamma \subset \mathcal{P}(\omega^\omega)$, $\det(\Gamma)$ denotes the statement that all sets in Γ are determined.

Using the axiom of choice, or more specifically using a wellordering of the reals, it is easy to construct a non-determined set A. $\det(\mathcal{P}(\omega^\omega))$ is therefore false. On the other hand it has become clear through research over the years that $\det(\Gamma)$ is true if all the sets in Γ are definable by some concrete means. Moreover $\det(\Gamma)$, taken as an axiom, gives rise to a rich structure theory that establishes a hierarchy of complexity on the sets in Γ, and completely answers all natural questions about the sets in each level of the hierarchy. Determinacy is therefore accepted as the natural hypothesis in the study of definable subsets of ω^ω.

*This material is based upon work supported by the National Science Foundation under Grant No. DMS-0094174.

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

Definability takes increasingly liberal meanings as one progresses higher in the hierarchy of complexity. At the lower levels it is very concrete. Let $\omega^{<\omega}$ denote the set of finite sequences of natural numbers. For $s \in \omega^{<\omega}$ let $N_s = \{x \in \omega^\omega \mid x \text{ extends } s\}$. The sets N_s ($s \in \omega^{<\omega}$) are the *basic open* neighborhoods in ω^ω. $A \subset \omega^\omega$ is *open* if it is a union of basic open neighborhoods.

ω^ω with the topology defined above is isomorphic to the irrational numbers. Following standard abuse of notation in descriptive set theory we use $\mathbb{R}$ to denote ω^ω, and refer to its elements as *reals*.

A set is *Borel* if it can be obtained from open sets using repeated applications of complementations and countable unions. The *projection* of a set $B \subset \mathbb{R} \times \mathbb{R}$ is the set $\{x \in \mathbb{R} \mid (\exists y)\langle x, y\rangle \in B\}$. A set is *analytic* if it is the projection of the complement of an open set. A set is *projective* if it can be obtained from open sets using repeated applications of complementations and projections. Analyzing the logical complexity of these definitions and using diagonal arguments one can establish that {Borel sets} $\subsetneq$ {analytic sets} $\subsetneq$ {projective sets}, so that these classes form a proper hierarchy.

Theorem 1.1 (Gale–Stewart [4], 1953). *All open sets are determined.*

Theorem 1.2 (Martin [20], 1975). *All Borel sets are determined.*

Theorem 1.3 (Martin [19], 1970). *All analytic sets are determined.*

Theorem 1.4 (Martin–Steel [22], 1985). *All projective sets are determined.*

Theorems 1.1 and 1.2 are theorems of ZFC, the basic system of axioms for set theory and mathematics. Theorems 1.3, 1.4, and 1.5 (below) have additional stronger assumptions known as large cardinal axioms, which are not listed here but will be discussed in Section 2.[1]

Recall that $\mathrm{L}(\mathbb{R})$ is the smallest model of set theory which contains all the reals and all the ordinals. It is obtained as the union $\bigcup_{\alpha\in\mathrm{ON}} \mathrm{L}_\alpha(\mathbb{R})$ of the hierarchy defined by the conditions: $\mathrm{L}_0(\mathbb{R}) = \mathbb{R}$; for limit ordinals λ, $\mathrm{L}_\lambda(\mathbb{R}) = \bigcup_{\alpha<\lambda} \mathrm{L}_\alpha(\mathbb{R})$; and for each ordinal α, $\mathrm{L}_{\alpha+1}(\mathbb{R})$ consists of the sets in $\mathrm{L}_\alpha(\mathbb{R})$, and of all subsets of $\mathrm{L}_\alpha(\mathbb{R})$ which are definable over $\mathrm{L}_\alpha(\mathbb{R})$ by first order formulae with parameters. The third condition is the crucial one, placing a definability requirement on the sets that make it into $\mathrm{L}(\mathbb{R})$. $\mathrm{L}(\mathbb{R})$ is constructed through a transfinite sequence of applications of this condition. Notice that the projective sets are subsumed already into $\mathrm{L}_1(\mathbb{R})$, the first stage of this transfinite sequence.

Theorem 1.5 (Woodin [40], 1985). *All sets of reals in* $\mathrm{L}(\mathbb{R})$ *are determined.*

Theorems 1.1 through 1.5 establish determinacy for sets of varying levels of definability, starting from open sets which are very directly definable from real numbers,

[1] The determinacy of Borel sets of course follows from the determinacy of analytic sets. The new element in Theorem 1.2 is a proof of Borel determinacy from the axioms of ZFC, without using large cardinals.

continuing with the projective sets, which are definable from open sets using existential quantifications and negations, and ending with all sets in $\mathrm{L}(\mathbb{R})$. More is possible, as we shall see in Section 3. The remainder of this section is devoted to consequences of determinacy.

Let Γ be an adequate pointclass (that is a collection of subsets of ω^ω, closed under some basic operations, see Moschovakis [27]). The first results derived from determinacy concerned regularity properties, such as Lebesgue measurability, the Baire property, and the perfect set property. All these properties fail outside the realm of determinacy; counterexamples to each of them can be constructed easily using a wellordering of the reals. Determinacy serves as an intermediary in establishing these properties for definable sets.

Theorem 1.6 (Banach, Oxtoby [37], 1957). *Assume* $\det(\Gamma)$. *Let* $A \in \Gamma$. *Then* A *has the property of Baire* (*meaning that* A *is either meager, or comeager on a basic open neighborhood*).

Theorem 1.7 (Mycielski–Swierczkowski [29], 1964). *Assume* $\det(\Gamma)$. *Then all sets in* Γ *are Lebesgue measurable.*

Theorem 1.8 (Davis [3], 1964). *Assume* $\det(\Gamma)$. *Let* $A \in \Gamma$. *Then either* A *is countable, or else* A *contains a perfect set.*

More importantly, determinacy was seen to imply various structural properties of classes of sets within its realm. For a pointclass Γ let $\neg\Gamma$ denote the pointclass consisting of complements of sets in Γ, and let $\exists\Gamma$ denote the pointclass consisting of projections of sets in Γ. Recall that $\mathbf{\Sigma}^1_1$ is the pointclass of analytic sets, $\mathbf{\Pi}^1_n = \neg\mathbf{\Sigma}^1_n$, and $\mathbf{\Sigma}^1_{n+1} = \exists\mathbf{\Pi}^1_n$. $\mathbf{\Delta}^1_n$ is the pointclass consisting of sets which are both $\mathbf{\Sigma}^1_n$ and $\mathbf{\Pi}^1_n$. Each $\mathbf{\Sigma}^1_n$ set A (similarly $\mathbf{\Pi}^1_n$) is definable through a string of quantifiers from an open set. The open set itself, call it D, is definable from a real number, coding the set $\{s \in \omega^{<\omega} \mid N_s \subset D\}$. A is *lightface* Σ^1_n (similarly Π^1_n) if the underlying real that defines it is recursive, that is computable by a Turing machine.

The boldface pointclasses were studied by analysts in the early 20th century. Recall for example the following theorem of Kuratowski [16]: the intersection of any two $\mathbf{\Sigma}^1_1$ (analytic) sets $A, B \subset \mathbb{R}$ can be presented as the intersection of two $\mathbf{\Sigma}^1_1$ sets $A' \supset A$ and $B' \supset B$, such that $A' \cup B' = \mathbb{R}$. This is today recast as a theorem about the pointclass $\mathbf{\Pi}^1_1$. A pointclass Γ is said to have the *reduction property* if for any two sets $A, B \subset \mathbb{R}$ in Γ there are sets $A' \subset A$ and $B' \subset B$, both in Γ, so that $A' \cup B' = A \cup B$ and $A' \cap B' = \emptyset$. Kuratowski's theorem establishes that $\mathbf{\Pi}^1_1$ has the reduction property. Kuratowski also showed that $\mathbf{\Sigma}^1_2$ has the reduction property. This was as far up along the projective hierarchy as one could get in those days. The basic axioms of set theory, without the addition of determinacy or large cardinals, do not decide questions such as the reduction property for projective pointclasses above $\mathbf{\Sigma}^1_2$.

In 1967 Blackwell [2] used the determinacy of open games, Theorem 1.1, to give a new proof of Kuratowski's reduction theorem. Inspired by his proof, Martin [18]

and Addison–Moschovakis [1] proved that $\mathbf{\Pi}^1_3$ has the reduction property, assuming $\det(\mathbf{\Delta}^1_2)$.

The reduction property is a consequence of a stronger property known as the prewellordering property. Martin and Addison–Moschovakis obtained this stronger property, and in fact propagated it along the odd levels of the projective hierarchy, using determinacy.

A *prewellorder* on $A \subset \mathbb{R}$ is a relation $\preceq$ on A which is transitive, reflexive, and wellfounded. The prewellorder $\preceq$ induces an equivalence relation $\sim$ on A ($x \sim y$ iff $x \preceq y \wedge y \preceq x$), and gives rise to a wellorder of $A/\sim$. $\preceq$ is said to belongs to a pointclass Γ if there are two relations Y and N, in Γ and $\neg\Gamma$ respectively, so that for every $y \in A$, $\{x \mid x \preceq y\} = \{x \mid \langle x, y\rangle \in Y\} = \{x \mid \langle x, y\rangle \in N\}$. Γ has the *prewellordering property* just in case that every set $A \in \Gamma$ admits a prewellorder in Γ.

Theorem 1.9 (Martin [18], Addison–Moschovakis [1], 1968). *Assume projective determinacy. Then the projective pointclasses with the prewellordering* (*similarly reduction*) *property are* $\mathbf{\Pi}^1_1$, $\mathbf{\Sigma}^1_2$, $\mathbf{\Pi}^1_3$, $\mathbf{\Sigma}^1_4$, $\mathbf{\Pi}^1_5$, ...

Remark 1.10. For $B \subset \mathbb{R} \times \mathbb{R}$ and $x \in \mathbb{R}$ let B_x denote $\{y \mid \langle x, y\rangle \in B\}$. Recall that $\circlearrowright B$ is the set $\{x \in \mathbb{R} \mid$ player I has a winning strategy in $G_\omega(B_x)\}$. It is common to write $(\circlearrowright y)B(x, y)$, or $(\circlearrowright y)\langle x, y\rangle \in B$, for the statement $x \in \circlearrowright B$. This notation is similar to the notation used for the quantifiers $(\forall y)$ and $(\exists y)$, and $(\circlearrowright y)$ too is viewed as a quantifier, giving precise meaning to the chain $(\exists y(0))(\forall y(1))(\exists(y(2)) \cdots\cdots$ of quantifiers over ω. For a pointclass Γ let $\circlearrowright\Gamma = \{\circlearrowright B \mid B \in \Gamma\}$. It is easy to check that $\circlearrowright\mathbf{\Pi}^1_n = \mathbf{\Sigma}^1_{n+1}$ and (using determinacy) $\circlearrowright\mathbf{\Sigma}^1_n = \mathbf{\Pi}^1_{n+1}$. Theorem 1.9 therefore states that the pointclasses $\circlearrowright^{(n)}\mathbf{\Pi}^1_1$, $n < \omega$, all have the reduction and prewellordering properties.

Theorem 1.9 helped establish the use of determinacy as a hypothesis in the study of definable sets of reals. In particular it became standard to study $\mathrm{L}(\mathbb{R})$ using the relativization to $\mathrm{L}(\mathbb{R})$ of the assumption that *all* sets of reals are determined, known as the axiom of determinacy (AD) and initially advanced by Mycielski–Steinhaus [28]. The use of this assumption in $\mathrm{L}(\mathbb{R})$ is justified in retrospect by Theorem 1.5.

There has been a wealth of results on sets of reals, on structural properties of pointclasses, and on $\mathrm{L}(\mathbb{R})$, assuming determinacy. Only a couple of results, the ones which are directly relevant to this paper, are listed below. A more complete account can be found in Moschovakis [27] and in the Cabal volumes [13], [10], [11], [12].

Recall that the symbol $\boldsymbol{\delta}$ is used to denote the supremum of the ordertypes of $\mathbf{\Delta}$ prewellorders on $\mathbf{\Delta}$ sets.

Theorem 1.11. *Assume* AD. *Then* $\boldsymbol{\delta}^1_1$ *is equal to* ω_1, $\boldsymbol{\delta}^1_2$ *is equal to* ω_2 (*Martin*), *and* $\boldsymbol{\delta}^1_3$ *is equal to* $\omega_{\omega+1}$ (*Martin*). *Much more is known, see Kechris* [9] *and Jackson* [7].

The values of the ordinals $\boldsymbol{\delta}^1_1$, $\boldsymbol{\delta}^1_2$, etc. are absolute between $\mathrm{L}(\mathbb{R})$ and the true universe V. Theorem 1.11 therefore implies that $\boldsymbol{\delta}^1_1 = (\omega_1)^{\mathrm{L}(\mathbb{R})}$, $\boldsymbol{\delta}^1_2 = (\omega_2)^{\mathrm{L}(\mathbb{R})}$, and $\boldsymbol{\delta}^1_3 = (\omega_{\omega+1})^{\mathrm{L}(\mathbb{R})}$. ω_1 is absolute between $\mathrm{L}(\mathbb{R})$ and V, so $\boldsymbol{\delta}^1_1 = \omega_1$. But other

cardinals need not be absolute. Theorem 1.11 by itself therefore does not provide information on the cardinalities of $\boldsymbol{\delta}^1_2$ and $\boldsymbol{\delta}^1_3$.

Theorem 1.12 (Steel–Van Wesep [38], Woodin [39]). *Assume* $\mathsf{AD}^{\mathrm{L}(\mathbb{R})}$. *Then it is consistent* (*with* $\mathsf{AD}^{\mathrm{L}(\mathbb{R})}$ *and the axiom of choice*) *that* $(\omega_2)^{\mathrm{L}(\mathbb{R})} = \omega_2$, *and hence that* $\boldsymbol{\delta}^1_2 = \omega_2$.

Note that the statement that $\boldsymbol{\delta}^1_2 = \omega_2$ implies a strong failure of the continuum hypothesis: not only must the continuum have size at least ω_2, but this must be witnessed by $\boldsymbol{\Delta}^1_2$ prewellorders.

2. Large cardinals

An embedding $\pi : P \to M$ is *elementary* just in case that it preserves truth, meaning that $\varphi[x_1, \ldots, x_k]$ holds in P iff $\varphi[\pi(x_1), \ldots, \pi(x_k)]$ holds in M, for all formulae φ and all $x_1, \ldots, x_k \in P$. Large cardinal axioms state the existence of elementary embeddings of the universe. For example, a cardinal κ is *measurable* if it is the critical point of an elementary embedding $\pi : \mathrm{V} \to M \subset \mathrm{V}$. The axiom "there exists a measurable cardinal" thus asserts the existence of a non-trivial elementary embedding acting on the entire universe.

An elementary embedding $\pi : \mathrm{V} \to M$ is λ-*strong* if M and V agree to λ, that is if M and V have the same bounded subsets of λ, and *superstrong* if M and V agree to $\pi(\mathrm{crit}(\pi))$. $\pi : \mathrm{V} \to M$ is λ-*strong with respect to* H if it is λ-strong and $\pi(H) \cap \lambda = H \cap \lambda$. κ is λ-strong if it is the critical point of a λ-strong embedding, and similarly for superstrength and strength with respect to H. κ is $<\delta$-strong with respect to H if it is λ-strong with respect to H for each $\lambda < \delta$. Finally, and most importantly, δ is a *Woodin cardinal* if for every $H \subset \delta$ there is $\kappa < \delta$ which is $<\delta$-strong with respect to H. In the hierarchy of large cardinal axioms, the existence of Woodin cardinals lies above the existence of measurable cardinals, but well below the existence of superstrong cardinals.

Let $\pi : \mathrm{V} \to M$ be elementary. Let $\kappa = \mathrm{crit}(\pi)$ and let $\lambda < \pi(\kappa)$. The (κ, λ)-*extender* induced by π is the function $E : \mathcal{P}([\kappa]^{<\omega}) \to \mathcal{P}([\lambda]^{<\omega})$ defined by $E(A) = \pi(A) \cap [\lambda]^{<\omega}$. The extender E codes enough of the embedding π to reconstruct an embedding $\sigma : \mathrm{V} \to N$ with the property that $\sigma(A) \cap [\lambda]^{<\omega} = \pi(A) \cap [\lambda]^{<\omega}$ for all $A \subset [\kappa]^{<\omega}$. For sufficiently closed λ this is enough that the λ-strength of π implies the λ-strength of σ, and similarly for strength with respect to H. Thus, the existence of strong embeddings is equivalent to the existence of strong extenders, and the property of being a Woodin cardinal can be recast as a statement about the existence of certain extenders. (The point here is that extenders are sets, while embeddings are classes.)

The embedding $\sigma : \mathrm{V} \to N$ is obtained from the extender E using an ultrapower construction. Very briefly, N is the model $(H/\!\sim; R)$ where $H = \{\langle f, a\rangle \mid a \in [\lambda]^{<\omega}$ and $f : [\kappa]^{\mathrm{lh}(a)} \to \mathrm{V}\}$, $\langle f, a\rangle \sim \langle g, b\rangle$ iff $a^\frown b \in E(\{x^\frown y \mid f(x) = g(y)\})$, and $[f, a]\ R\ [g, b]$ iff $a^\frown b \in E(\{x^\frown y \mid f(x) \in g(y)\})$. The embedding σ is defined

by the conditions $\sigma(x) = [c_x, \emptyset]$ where $c_x : [\kappa]^0 \to \mathrm{V}$ is the function taking constant value x. The model N is called the *ultrapower* of V by E, denoted $\mathrm{Ult}(\mathrm{V}, E)$, and σ is the *ultrapower embedding*.

An extender E can also be derived from an embedding $\pi : Q \to M$ for $Q \neq \mathrm{V}$. The result is an *extender over* Q. In the other direction, the ultrapower of a model Q by an extender E with critical point κ can be defined so long as $(\mathcal{P}([\kappa]^{<\omega}))^Q = \mathrm{dom}(E)$, simply by adding the restriction $f \in Q$ to the definition of H above. The resulting ultrapower is denoted $\mathrm{Ult}(Q, E)$.

The process of taking ultrapowers can be iterated, and such iterations are crucial to the study of large cardinals. Their first use appeared in Kunen [15]. Kunen worked with measurable cardinals. The associated extenders can only give rise to linear iteration, and this has become the norm until the work of Martin–Steel [23], who introduced the general format of an iteration tree. This general format, which allows non-linearity, is both necessary to the study of Woodin cardinals, and non-trivial in their presence.

A *tree order* on an ordinal α is an order T so that: T is a suborder of $< \restriction \alpha$; for each $\eta < \alpha$, the set $\{\xi \mid \xi \ T \ \eta\}$ is linearly ordered by T; for each ξ so that $\xi + 1 < \alpha$, the ordinal $\xi + 1$ is a successor in T; and for each limit ordinal $\gamma < \alpha$, the set $\{\xi \mid \xi \ T \ \gamma\}$ is cofinal in γ. An *iteration tree* $\mathcal{T}$ of length α on a model M consists of a tree order T on α, and sequences $\langle M_\xi, j_{\zeta,\xi} \mid \zeta \ T \ \xi < \alpha\rangle$ and $\langle E_\xi \mid \xi + 1 < \alpha\rangle$ satisfying the following conditions:

1. $M_0 = M$.
2. For each ξ so that $\xi + 1 < \alpha$, E_ξ is an extender of M_ξ.
3. $M_{\xi+1} = \mathrm{Ult}(M_\zeta, E_\xi)$ and $j_{\zeta,\xi+1} : M_\zeta \to M_{\xi+1}$ is the ultrapower embedding, where ζ is the T-predecessor of $\xi + 1$. It is implicit in this condition that $\mathcal{P}([\mathrm{crit}(E_\xi)]^{<\omega})$ must be the same in M_ζ and M_ξ, so that the ultrapower makes sense.
4. For limit $\lambda < \alpha$, M_λ is the direct limit of the system $\langle M_\zeta, j_{\zeta,\xi} \mid \zeta \ T \ \xi \ T \ \lambda\rangle$, and $j_{\zeta,\lambda} : M_\zeta \to M_\lambda$ for $\zeta \ T \ \lambda$ are the direct limit embeddings.
5. The remaining embeddings $j_{\zeta,\xi}$ for $\zeta \ T \ \xi < \alpha$ are obtained through composition.

An iteration tree is *linear* if for every ξ, the T-predecessor of $\xi + 1$ is ξ.

A *branch* through an iteration tree $\mathcal{T}$ is a set b which is linearly ordered by T. The branch is *cofinal* if $\sup(b) = \mathrm{lh}(\mathcal{T})$. The branch is maximal if either $\sup(b) = \mathrm{lh}(\mathcal{T})$ or else $b \neq \{\xi \mid \xi \ T \ \sup(b)\}$. The *direct limit* along b, denoted $M_b^{\mathcal{T}}$ or simply M_b, is the direct limit of the system $\langle M_\xi, j_{\zeta,\xi} \mid \zeta \ T \ \xi \in b\rangle$. $i_b^{\mathcal{T}} : M \to M_b$ is the direct limit embedding of this system. The branch b is called *wellfounded* just in case that the model M_b is wellfounded.

Theorem 2.1 (Martin–Steel [23]). *Let M be a countable elementary substructure of a rank initial segment of* V*, and let $\pi : M \to \mathrm{V}_\nu$ be elementary. Let $\mathcal{T}$ be a countable*

iteration tree on M. Then there is a maximal branch b through $\mathcal{T}$, and an embedding $\sigma : M_b \to \mathrm{V}_\nu$, so that $\pi = \sigma \circ i^{\mathcal{T}}_b$. (*A branch b whose direct limit can be embedded into V_ν in this way is called* realizable.)

Let M be a model of ZFC. In the (full, length $\omega_1 + 1$) *iteration game* on M players "good" and "bad" collaborate to construct an iteration tree $\mathcal{T}$ of length $\omega_1^{\mathrm{V}} + 1$ on M. "bad" plays all the extenders, and determines the T-predecessor of $\xi + 1$ for each ξ. "good" plays the branches $\{\zeta \mid \zeta \ T \ \lambda\}$ for limit λ, thereby determining the direct limit model M_λ. Note that "good" is also responsible for the final move, which determines $M_{\omega_1^{\mathrm{V}}}$.

If ever a model along the tree is reached which is illfounded then "bad" wins. Otherwise "good" wins. M is (fully) *iterable* if "good" has a winning strategy in this game. An *iteration strategy* for M is a winning strategy for the good player in the iteration game on M.

Notice that if Theorem 2.1 could be strengthened to state that the realizable branch is unique, then repeated applications of the theorem (including a final application over $\mathrm{V}^{\mathrm{col}(\omega,\omega_1)}$ to obtain a branch through a tree of length ω_1^{V}) would demonstrate that countable elementary substructures of rank initial segments of V are iterable. This observation is the key to many of the known iterability proofs, but unfortunately uniqueness fails beyond certain large cardinals. A general proof of iterability would be a great step forward in the study of large cardinals.

A (fine structural) *inner model* is a model of the form $M = \mathrm{L}_\alpha(\vec{E})$, that is the smallest model of set theory containing the ordinals below α and closed under comprehension relative to $\vec{E}$, where $\vec{E}$ is a sequence of extenders, over M or over initial segments of M, satisfying certain coherence requirements. (There are various ways to structure the sequences. For precise definitions see Mitchell–Steel [26] or Zeman [42].) $M = \mathrm{L}_\alpha(\vec{E})$ is an *initial segment* of $N = \mathrm{L}_\beta(\vec{F})$ just in case that $\alpha \leq \beta$ and $\vec{E}$ is an initial segment of $\vec{F}$. Since the extenders in $\vec{E}$ may be extenders not over M but over strict initial segments of M, an iteration tree on M may involve *dropping* to initial segments, that is applying an extender in M_ξ to an initial segment of M_ζ. In such cases the embedding $j_{\zeta,\xi+1}$ acts on an initial segment of M_ζ.

The following fact is the key to the use of iteration trees in the study of inner models:

Fact 2.2 (Comparison). Let M and N be countable inner models. Suppose that M and N are both iterable. Then there are iteration trees $\mathcal{T}$ and $\mathcal{U}$ of countable lengths on M and N respectively, leading to final models M^* and N^*, so that at least one of the following conditions holds:

1. M^* is an initial segment of N^* and there are no drops on the branch of $\mathcal{T}$ leading from M to M^*.

2. N^* is an initial segment of M^* and there are no drops on the branch of $\mathcal{U}$ leading from N to N^*.

The iteration trees $\mathcal{T}$ and $\mathcal{U}$ witnessing Fact 2.2 are constructed inductively. Suppose the construction reached models M_ξ on $\mathcal{T}$ and N_ξ on $\mathcal{U}$. If the extender sequences of M_ξ and N_ξ agree, meaning that they are equal or that one is a strict initial segment of the other, then the construction is over and one of conditions (1) and (2) in Fact 2.2 holds. If the sequences do not agree, let ρ be least so that the extender sequences of M_ξ and N_ξ disagree on the ρth extender. Set E_ξ to be the ρth extender on the sequence of M_ξ, and use this assignment to continue the construction of $\mathcal{T}$, applying E_ξ to M_ζ for the smallest possible ζ, to give rise to $M_{\xi+1}$. Continue $\mathcal{U}$ similarly using the ρth extender on the sequence of N_ξ. These assignments determine the parts of $\mathcal{T}$ and $\mathcal{U}$ corresponding to the bad player's moves in the iteration game. Using the assumption that M and N are iterable, fix iteration strategies Σ and Λ for the two models, and let these strategies determine the remaining elements of $\mathcal{T}$ and $\mathcal{U}$, namely the branches to be used at limit stages.

It is one of the great discoveries of inner model theory that the process described above, of repeatedly forming ultrapowers by disagreeing extenders, terminates, leading therefore to models which are lined-up with their extender sequences in complete agreement. The discovery was first made by Kunen [15] in the context of a single measurable cardinal, where linear iterations suffice. Mitchell [24], [25] developed the framework for models with many measurable cardinals, still using linear iterations. Martin–Steel [22], [23] discovered that in the context of Woodin cardinals the more general (non-linear) iteration trees are both needed and sufficient. Mitchell–Steel [26] used iteration trees, fine structure (see Jensen [8]), and several additional ideas to develop inner models for Woodin cardinals, and reach Fact 2.2 as stated above.

The following folklore claim illustrates a simple application of the comparison process. An inner model M is called a *minimal* model for a sentence θ if M satisfies θ and no strict initial segment of M satisfies θ.

Claim 2.3. *Let M and N be minimal countable inner models for the same sentence θ. Suppose that both M and N are iterable. Then M and N have the same theory.*

Proof sketch. Compare M and N, that is form $\mathcal{T}$ and $\mathcal{U}$ leading to models M^* and N^* which are in complete agreement, using Fact 2.2. Neither one of M^* and N^* can be a strict initial segment of the other, since otherwise the longer of the two will have a strict initial segment satisfying θ. M^* and N^* must therefore be equal. Similar reasoning shows that there can be drops on either side of the comparison. Using the elementarity of the iteration embeddings (from M to M^* along $\mathcal{T}$, and from N to N^* along $\mathcal{U}$) it follows that M has the same theory as M^* and N has the same theory as N^*. Since $M^* = N^*$, M and N have the same theory. □

An inner model M is a *sharp* if its extender sequence has a final element, E^M_{top}, and E^M_{top} is an extender over M. For a sharp M let M^* be the result of iterating E^M_{top} through the countable ordinals, that is set M' equal to the final model of the iteration tree $\mathcal{T}$ defined by the condition $E_\xi = j_{0,\xi}(E^M_{\text{top}})$ and the T-predecessor of $\xi+1$ is ξ for all $\xi < \omega_1$, and let $M^* = M'\|\omega_1$. The set $I = \{j_{0,\xi}(\text{crit}(E^M_{\text{top}})) \mid \xi < \omega_1\}$

is club in ω_1. The ordinals in I are indiscernibles for M^*, in the sense that for any formula φ, and any increasing sequences $\{\alpha_1, \ldots, \alpha_k\}$ and $\{\beta_1, \ldots, \beta_k\}$ in $[I]^k$, $M^* \models \varphi[\alpha_1, \ldots, \alpha_k]$ iff $M^* \models \varphi[\beta_1, \ldots, \beta_k]$. The *theory of k indiscernibles for M*, denoted $\mathrm{Th}_k(M)$, is the set of formulae φ so that $M^* \models \varphi[\alpha_1, \ldots, \alpha_k]$ for some (equivalently all) $\{\alpha_1, \ldots, \alpha_k\} \in [I]^k$.

An argument similar to that of Claim 2.3 shows that if M and N are both minimal iterable sharps for the same sentence θ, then $\mathrm{Th}_k(M) = \mathrm{Th}_k(N)$. The join $\bigoplus_{k<\omega} \mathrm{Th}_k(M)$ is called *the* sharp for θ. The sharp for the sentence "there are n Woodin cardinals" is called the sharp for n Woodin cardinals. The sharp for a tautology is denoted $0^\sharp$. It codes a club of indiscernibles for L.

The existence of $0^\sharp$ follows from the existence of a measurable cardinal. But in general the existence of the sharp for θ does not follow directly from the existence of large cardinals in V. The sharp also requires *iterability*, which is used in an essential way through the appeal to the comparison process in the proof of Claim 2.3. At the level of finitely many Woodin cardinals iterability can be obtained using Theorem 2.1 and additional arguments on the uniqueness of realizable branches, so that the existence of the sharp for n Woodin cardinals follows from the existence in V of n Woodin cardinals and a measurable cardinal above them.

It was noted in Section 1 that proofs of determinacy for pointclasses from $\mathbf{\Pi}^1_1$ onward require large cardinal axioms. To be specific, a proof of determinacy for the pointclass $\mathbf{\Pi}^1_1$ (Theorem 1.3) requires roughly the existence of a measurable cardinal, a proof of determinacy for the pointclass $\mathbf{\Pi}^1_{n+1}$ (Theorem 1.4) requires roughly the existence of n Woodin cardinals and a measurable cardinal above them, and a proof of determinacy for the pointclass of all sets in $\mathrm{L}(\mathbb{R})$ (Theorem 1.5) requires roughly the existence of ω Woodin cardinals and a measurable cardinal above them. But this is only the beginning of the connection between these pointclasses and Woodin cardinals.

Recall that a set A is α-$\mathbf{\Pi}^1_1$ if there is a sequence $\langle A_\xi \mid \xi < \alpha\rangle$ of $\mathbf{\Pi}^1_1$ sets so that $x \in A$ iff the least ξ so that $x \notin A_\xi \vee \xi = \alpha$ is odd. (The hierarchy generated by this definition is the *difference hierarchy* on $\mathbf{\Pi}^1_1$ sets. Note for example that for $\alpha = 2$ the condition states simply that $A = A_0 - A_1$.) The set A is (lightface) α-Π^1_1 if the underlying code for the sequence $\langle A_\xi \mid \xi < \alpha\rangle$ is recursive. A is $<\omega^2$-Π^1_1 if it is α-Π^1_1 for some $\alpha < \omega^2$.

Theorem 2.4 (Martin [21]). *Let B_i $(i < \omega)$ be a recursive enumeration of the $<\omega^2$-Π^1_1 sets. Then each of $0^\sharp$ and $\{i \mid$ player* I *has a winning strategy in $G_\omega(B_i)\}$ is recursive in the other.*

Theorem 2.4 provides a very tight connection between a large cardinal object, $0^\sharp$, and infinite games. For every formula φ there is a $<\omega^2$-Π^1_1 set B so that φ belongs to $0^\sharp$ iff I wins $G_\omega(B)$, and conversely (for every B there is φ).

Theorem 2.5. *Let B_i $(i < \omega)$ be a recursive enumeration of the $\supset^{(n)}(<\omega^2$-$\Pi^1_1)$ sets. Then the sharp for n Woodin cardinals and $\{i \mid$ player* I *has a winning strategy in $G_\omega(B_i)\}$ are each recursive in the other.*

Theorem 2.5 generalizes Theorem 2.4 to $n > 0$. It has two directions. The first states that membership in the sharp for n Woodin cardinals is equivalent to winning a $\Game^{(n)}(<\omega^2\text{-}\Pi^1_1)$ game. This follows from the results of Martin–Steel [23]. Essentially they show that iterability (or more precisely the ability to survive through the comparison process) for minimal sharps for n Woodin cardinals, can be expressed as a $\Game^{(n)}(<\omega^2\text{-}\Pi^1_1)$ statement. The other direction of Theorem 2.5 states that sharps for n Woodin cardinals can discern which player wins a $\Game^{(n)}(<\omega^2\text{-}\Pi^1_1)$ game. This direction follows from the determinacy proof in Neeman [30], [32]. The proof reduces the quantifiers involved in the $\Game^{(n)}(<\omega^2\text{-}\Pi^1_1)$ set to an iteration game on any model which has a sharp for n Woodin cardinals. The reduction takes place inside the model, and the model can tell which player in the $\Game^{(n)}(<\omega^2\text{-}\Pi^1_1)$ game is matched to the good player in the iteration game. Since the sharp is iterable, this player wins the $\Game^{(n)}(<\omega^2\text{-}\Pi^1_1)$ game.

Theorem 2.5 is an indication of the close connections between the study of inner models for Woodin cardinals and the study of projective pointclasses. The connections are tight enough that inner models can be used directly in the study of projective pointclasses, and further up in the study of $\mathrm{L}(\mathbb{R})$ under determinacy.

Theorem 2.6 (Neeman–Woodin, see [30]). *Determinacy for all $\mathbf{\Pi}^1_{n+1}$ sets implies determinacy for all sets in the larger pointclass $\Game^{(n)}(<\omega^2\text{-}\mathbf{\Pi}^1_1)$.*

Theorem 2.7 (Hjorth [6]). *Work in $\mathrm{L}(\mathbb{R})$ assuming AD. Let $\preceq$ be a $\Game(\alpha\text{-}\mathbf{\Pi}^1_1)$ prewellorder with $\alpha < \omega \cdot k$. Then the ordertype of $\preceq$ is smaller than ω_{k+1}.*

Theorem 2.8 (Neeman, Woodin, see [36]). *Assume $\mathsf{AD}^{\mathrm{L}(\mathbb{R})}$. Then it is consistent (with $\mathsf{AD}^{\mathrm{L}(\mathbb{R})}$ and the axiom of choice) that $\boldsymbol{\delta}^1_3 = \omega_2$.*

Theorem 2.6 for $n = 0$ is a combination of the work of Harrington [5], who obtained $0^\sharp$ and its relativized versions for all reals from $\mathbf{\Pi}^1_1$ determinacy, and Martin, who obtained $<\omega^2\text{-}\mathbf{\Pi}^1_1$ determinacy from the sharps. At higher levels Woodin obtained sharps for n Woodin cardinals from $\mathbf{\Pi}^1_{n+1}$ determinacy and Neeman [30] obtained $\Game^{(n)}(<\omega^2\text{-}\mathbf{\Pi}^1_1)$ determinacy from these sharps. Theorem 2.6 had already been proved for odd n by Kechris–Woodin [14], using methods which are purely descriptive set theoretic. For even n the only known proofs involve large cardinals.

Hjorth [6] proved Theorem 2.7 by embedding a given $\Game(<\omega \cdot k\text{-}\mathbf{\Pi}^1_1)$ prewellorder into a directed system of iterates of a sharp for one Woodin cardinal, and proving that the rank of the directed system is smaller than ω_{k+1}. Again, the proof is closely tied up with large cardinals and iteration trees, even though the result is purely descriptive set theoretic.

Theorem 2.8 is proved by collapsing ω_ω to ω_1 over $\mathrm{L}(\mathbb{R})$, so that $(\omega_{\omega+1})^{\mathrm{L}(\mathbb{R})}$, which is equal to $\boldsymbol{\delta}^1_3$ by Theorem 1.11, becomes ω_2 of the generic extension. The forcing to collapse ω_ω involves an ultrafilter on $[\mathcal{P}_{\omega_1}(\omega_\omega)]^{<\omega_1}$, and the construction of this ultrafilter uses a directed system of iterates of fine structural inner models with Woodin cardinals.

3. Larger cardinals, longer games

For $\alpha < \omega_1$ and $B \subset \mathbb{R}^\alpha$ let $G_{\omega\cdot\alpha}(B)$ denote the length $\omega \cdot \alpha$ game with payoff B. Players I and II alternate playing natural numbers in the format of Diagram 2, taking $\omega \cdot \alpha$ moves to produce together a sequence $r = \langle r(\xi) \mid \xi < \omega \cdot \alpha\rangle$ in $\omega^{\omega\cdot\alpha}$. The sequence r may be viewed as an element of $(\omega^\omega)^\alpha = \mathbb{R}^\alpha$. If r belongs to B then player I wins, and otherwise player II wins.

I	$r(0)$		$r(2)$		$\ldots$	$r(2\xi)$		$\ldots\ldots$	
II		$r(1)$		$\ldots$			$r(2\xi+1)$		$\ldots\ldots$

Diagram 2. General format of a transfinite game.

Determinacy for all length ω games with payoff in $\mathcal{D}^{(n)}(<\omega^2\text{-}\Pi^1_1)$ is easily seen to be the same as determinacy for all games of length $\omega \cdot (n+1)$ with payoff in $<\omega^2\text{-}\Pi^1_1$. Theorem 2.5 and the part of Theorem 2.6 dealing with a proof of determinacy from sharps can therefore be rephrased as follows:

Theorem 3.1. *Let B_i $(i < \omega)$ be a recursive enumeration of all the $<\omega^2\text{-}\Pi^1_1$ sets. Suppose that there is an iterable sharp for n Woodin cardinals. Then all length $\omega \cdot (n+1)$ games with payoff in $<\omega^2\text{-}\Pi^1_1$ are determined. Moreover, the sharp for n Woodin cardinals and $\{i \mid$ player* I *wins $G_{\omega\cdot(n+1)}(B_i)\}$ are each recursive in the other.*

The same precise connection between large cardinals and determinacy can be obtained higher up. Theorems 3.2, 3.3, and 3.4 below give several markers along the hierarchies of large cardinals and determinacy, progressively moving upward on both.

Theorem 3.2 (Neeman, Woodin, see [33, Chapter 2]). *Let α be a countable ordinal. Let B_i $(i < \omega)$ be a recursive[2] enumeration of all the $<\omega^2\text{-}\Pi^1_1$ subsets of $\mathbb{R}^{1+\alpha}$. Suppose that there is an iterable sharp for α Woodin cardinals. Then all length $\omega \cdot (1+\alpha)$ games with payoff in $<\omega^2\text{-}\Pi^1_1$ are determined. Moreover, the sharp for α Woodin cardinals and $\{i \mid$ player* I *wins $G_{\omega\cdot(1+\alpha)}(B_i)\}$ are each recursive in the other.*

For $B \subset \omega^{<\omega_1}$ let $G_{\mathrm{adm}}(B)$ be the following game: Players I and II alternate natural numbers as in Diagram 2, continuing until they reach the first ordinal α so that $\mathrm{L}_\alpha[r(\xi) \mid \xi < \alpha]$ is admissible. At that point the game ends. Player I wins if $\langle r(\xi) \mid \xi < \alpha\rangle \in B$, and otherwise player II wins.

The run $\langle r(\xi) \mid \xi < \alpha\rangle$ has the property that for every $\beta < \alpha$, $\mathrm{L}_\beta[r(\xi) \mid \xi < \beta]$ is not admissible. Using this property the run can be coded by a real in a canonical, uniform manner. The payoff set B is said to be Γ *in the codes* just in case that the set of real codes for sequences in B belongs to Γ.

$G_{\mathrm{adm}}(B)$ is a game of *variable countable length*. Its runs are countable, but the length of a particular run depends on the moves made during the run. Each of the

[2] Recursiveness here is relative to a code for α.

players can force the length of the run to be greater than any fixed countable ordinal α, and the determinacy of $G_{\text{adm}}(B)$ for all B in $<\omega^2\text{-}\Pi^1_1$ implies the determinacy of $G_\alpha(B)$ for all B in $<\omega^2\text{-}\Pi^1_1$, for each countable α.

The *Mitchell order* on extenders is the order $E \lhd F$ iff $E \in \text{Ult}(\text{V}, F)$. The Mitchell order of a cardinal κ is the ordertype of the restriction of $\lhd$ to extenders with critical point κ.

Theorem 3.3 (Neeman [34]). *Let B_i $(i < \omega)$ be a recursive enumeration of the subsets of $\omega^{<\omega_1}$ which are $<\omega^2\text{-}\Pi^1_1$ in the codes. Suppose that there is an iterable sharp for the statement "there is a cardinal κ which is a limit of Woodin cardinals and has Mitchell order κ^{++}". Then the games $G_{\text{adm}}(B)$ are determined for all B which are $<\omega^2\text{-}\Pi^1_1$ in the codes. Moreover the sharp and the real $\{i \mid$ player* I *wins $G_{\text{adm}}(B_i)\}$ are each recursive in the other.*

For $B \subset \omega^{<\omega_1}$ let $G_{\text{local}}(\text{L}, B)$ be the following game: Players I and II alternate natural numbers as in Diagram 2, continuing until they reach the first $\alpha > \omega$ so that α is a cardinal in $\text{L}[r(\xi) \mid \xi < \alpha]$. At that point the game ends. Player I wins if $\langle r(\xi) \mid \xi < \alpha\rangle \in B$. Otherwise player II wins. $G_{\text{local}}(\text{L}, B)$ is a *game ending at ω_1 in* L *of the play*. It too is a game of variable countable length.

A code for a run $\langle r(\xi) \mid \xi < \alpha\rangle$ of $G_{\text{local}}(\text{L}, B)$ is simply a pair $\langle w, x\rangle$ where w is a wellorder of ω of ordertype α, $x \in \omega^\omega$, and for each n, $x(n)$ is equal to $r(\xi)$ where ξ is the ordertype of n in w. These codes belong to $\mathcal{P}(\omega \times \omega) \times \omega^\omega$, which is isomorphic to ω^ω. As before, B is said to be Γ *in the codes* just in case that the set of codes for sequences in B belongs to Γ.

Theorem 3.4 (Neeman [33, Chapter 7]). *Let B_i $(i < \omega)$ be a recursive enumeration of the subsets of $\omega^{<\omega_1}$ which are $\partial(<\omega^2\text{-}\Pi^1_1)$ in the codes. Suppose that there is an iterable sharp for the statement "there is a Woodin cardinal which is also a limit of Woodin cardinals". Then the games $G_{\text{local}}(\text{L}, B)$ are determined for all B which are $\partial(<\omega^2\text{-}\Pi^1_1)$ in the codes. Moreover the sharp and the real $\{i \mid$ player* I *wins $G_{\text{local}}(\text{L}, B_i)\}$ are each recursive in the other.*

Remark 3.5. Theorem 3.4 has an interesting corollary, due to Woodin: Suppose that there is an iterable sharp for a Woodin limit of Woodin cardinals. Then it is consistent that all ordinal definable games of length ω_1 are determined. The model witnessing this is of the form $M = \text{L}[x(\xi) \mid \xi < \gamma]$ where $\gamma = \omega_1^M$, and the strategies witnessing determinacy in this model are obtained through uses of Theorem 3.4 on games ending at ω_1 in L of the play. For a complete proof of the corollary see Neeman [33, 7F.13–15].

Remark 3.6. There is another interesting game that comes up in the proof of Theorem 3.4. For a partial function $f : \mathbb{R} \to \omega$ and a set $B \subset \omega^{<\omega_1}$ let $G_{\text{cont}}(f, B)$ be the following game: Players I and II alternate natural numbers as in Diagram 2. In addition, after each block of ω moves they write a natural numbers on a "side board". Let $x_\alpha = \langle r(\omega \cdot \alpha + i) \mid i < \omega\rangle$ be the αth block of moves. The natural number

they write following this block is $n_\alpha = f(x_\alpha)$. They continue playing until reaching the first α so that $x_\alpha \notin \mathrm{dom}(f)$ or $n_\alpha \in \{n_\beta \mid \beta < \alpha\}$ (meaning that the natural number written after block α is a repetition of a number written previously). At that point the game ends, player I wins if $\langle r(\xi) \mid \xi < \omega \cdot \alpha + \omega\rangle \in B$, and player II wins otherwise. The large cardinal strength of determinacy for these games is roughly a cardinal κ which is $\delta + 1$-strong for some Woodin cardinal $\delta > \kappa$ (see Neeman [33, Chapter 3]), and the determinacy proof for these games is a precursor to the use of extenders overlapping Woodin cardinals in the proof of Theorem 3.4.

Determinacy in Theorems 3.2, 3.3, and 3.4 is proved by reducing the long game to an iteration game on the given model. The reduction, which uses the large cardinals of the model, matches one of the players in the long game to the good player in the iteration game. In effect it converts the iteration strategy for the model into a winning strategy for this player in the long game. Determinacy therefore rests on the existence of *iterable* models; the existence of large cardinals by itself is not directly sufficient.

In the case of Theorems 3.2 and 3.3, the long game is reduced to an iteration game of a specific format, involving only linear compositions of iteration trees of length ω. The fact that the good player can win games of this format, on countable models which embed into rank initial segments of V, follows directly from Theorem 2.1. The determinacy proved in Theorems 3.2 and 3.3 therefore follows from just the assumptions of large cardinals in V: α Woodin cardinals and a measurable cardinal above them in the case of Theorem 3.2, and a measurable cardinal above a cardinal κ so that $o(\kappa) = \kappa^{++}$ and κ is a limit of Woodin cardinals in the case of Theorem 3.3.

The iteration game generated by the proof of Theorem 3.4 is as complicated as the full iteration game, and Theorem 2.1 by itself is not enough to produce a winning strategy for the good player in this game. Still, by Neeman [31], the existence of an iterable model satisfying the large cardinal assumptions of Theorem 3.4 follows from the existence of the large cardinals, a Woodin limit of Woodin cardinals and a measurable cardinal above it, in V.

Theorems 3.2, 3.3, and 3.4 extend the precise connection between determinacy and inner models to levels of games of variable countable lengths, and Woodin limits of Woodin cardinals. It is generally believed that the large cardinal hierarchy is rich enough to calibrate the strength of all natural statements. Could determinacy provide a rich enough hierarchy to match the full extent of the large cardinal hierarchy? If not, how far does determinacy reach? How far does the hierarchy of long games reach? We are very far from answers to these questions.

Let θ be a large cardinal assumption at or below the existence of a superstrong cardinal. (Beyond the level of superstrong cardinals there are problems with the comparison process and Claim 2.3.) The comparison process provides the best clues in the search for long games strong enough to match θ in the sense of Theorems 3.2, 3.3, and 3.4: If a particular format of long games subsumes the iteration games appearing in the comparison of minimal models of θ, then the associated game quantifier is strong enough to define the sharp for θ.

The following format is strong enough to subsume the full iteration game, and therefore all iteration games appearing in all comparisons of all inner models up to superstrong cardinals. Let $\mathcal{L}^+$ denote the language of set theory with an added unary relation symbol $\dot{r}$, and let $\varphi(\alpha, \beta)$ be a formula in $\mathcal{L}^+$. Define $G_{\text{club},2}(\varphi)$ to be the following game: Players I and II alternate playing ω_1 natural numbers in the manner of Diagram 2, producing together a sequence $\langle r(\xi) \mid \xi < \omega_1 \rangle$ in ω^{ω_1}. If there is a club $C \subset \omega_1$ so that $\langle \mathrm{L}_{\omega_1}[r], r \rangle \models \varphi[\alpha, \beta]$ for all $\alpha < \beta$ both in C then player I wins, and otherwise player II wins. (A quick word on notation: r formally is a set of pairs in $\omega_1 \times \omega$. $\langle \mathrm{L}_{\omega_1}[r], r \rangle \models \varphi$ iff φ holds in $\mathrm{L}_{\omega_1}[r]$ with appearances of the predicate $\dot{r}$ in φ interpreted by r.)

The number 2 in $G_{\text{club},2}(\varphi)$ refers to the number of free variables in φ. Games $G_{\text{club},k}(\varphi)$, for $k \neq 2$ in ω and φ a formula with k free variables, can defined similarly. All the definitions can be relativized to a real x by replacing $\mathrm{L}_{\omega_1}[r]$ with $\mathrm{L}_{\omega_1}[r, x]$ and letting φ take x as a parameter. They can be relativized to a set of reals A by replacing L with L^A and allowing φ to take an additional predicate interpreted by $A \cap \mathrm{L}^A_{\omega_1}[r]$.

The full iteration game on a countable model M can be recast as a game of the form $G_{\text{club},2}(\varphi)$ relativized to a real coding M. Woodin [41] connects the determinacy of the games $G_{\text{club},k}(\varphi)$ and their relativizations to Σ^2_2 absoluteness under the combinatorial principle generic diamond ($\diamondsuit_G$). Determinacy for the games $G_{\text{club},2}(\varphi)$ is not provable from large cardinals, by Larson [17], but it may be provable from large cardinals and $\diamondsuit_G$. Unfortunately the games are too strong to be handled by current methods in proofs of determinacy, precisely because they are strong enough to subsume the full iteration game. If there were a match for $G_{\text{club},2}$ similar to the matches in Theorems 2.4, 2.5, 3.2, 3.3, and 3.4, then the large cardinal involved would have to be stronger than a superstrong, far beyond the level of Woodin cardinals.

The following format produces a weaker game. Let $k < \omega$. Let $\vec{S} = \langle S_a \mid a \in [\omega_1]^{<k} \rangle$ be a collection of mutually disjoint stationary subsets of ω_1, with a stationary set S_a associated to each tuple $a \in [\omega_1]^{<k}$. Let $[\vec{S}]$ denote the set $\{\langle \alpha_0, \dots, \alpha_{k-1} \rangle \in [\omega_1]^k \mid (\forall i < k)\ \alpha_i \in S_{\langle \alpha_0, \dots, \alpha_{i-1} \rangle}\}$. Let $\varphi(x_0, \dots, x_{k-1})$ be a formula in $\mathcal{L}^+$. Define $G_{\omega_1,k}(\vec{S}, \varphi)$ to be the following game: Players I and II alternate playing ω_1 natural numbers in the manner of Diagram 2, producing together a sequence $r \in \omega^{\omega_1}$. If there is a club $C \subset \omega_1$ so that $\langle \mathrm{L}_{\omega_1}[r], r \rangle \models \varphi[\alpha_0, \dots, \alpha_{k-1}]$ for all $\langle \alpha_0, \dots, \alpha_{k-1} \rangle \in [\vec{S}] \cap [C]^k$ then player I wins the run r. If there is a club $C \subset \omega_1$ so that $\langle \mathrm{L}_{\omega_1}[r], r \rangle \models \neg\varphi[\alpha_0, \dots, \alpha_{k-1}]$ for all $\langle \alpha_0, \dots, \alpha_{k-1} \rangle \in [\vec{S}] \cap [C]^k$ then player II wins r. If neither condition holds then both players lose.

Note that the two winning conditions in the definition of $G_{\omega_1,k}(\vec{S}, \varphi)$ cannot both hold. This uses the fact that each of the sets S_a is stationary in ω_1, and the demand in the conditions that C must be club in ω_1. Thus at most one player wins each run of $G_{\omega_1,k}(\vec{S}, \varphi)$. For $k > 0$ it may well be that neither one of the winning conditions holds. So there may well be runs of $G_{\omega_1,k}(\vec{S}, \varphi)$ which are won by neither player. Determinacy for $G_{\omega_1,k}(\vec{S}, \varphi)$ is defined in the stronger of the two possible senses. The game is determined if one of the players has a winning strategy; a strategy which

merely avoids losing is not enough.

Recall that a sharp for θ is an inner model M with a final extender E^M_{top}, so that E^M_{top} is an extender over M and $M \models \theta$. Let θ be the sentence "crit(E^M_{top}) is a Woodin cardinal". The minimal iterable sharp for θ, if it exists, is denoted 0^W. Recall that iterating out the top extender of a sharp M produces a model M^* and a club $I \subset \omega_1$ of indiscernibles for M^*, consisting of the images of crit(E^M_{top}) under the iteration embeddings. In the case of $M = 0^W$, the ordinals in I are Woodin cardinals of M^*. The existence of 0^W thus implies the existence of an iterable model with a club of indiscernible Woodin cardinals, and in fact the two are equivalent.

Remark 3.7. Iterability for countable elementary substructures of V is not known at the level of 0^W – the strongest results in this direction are the ones of Neeman [31], reaching to the level of Woodin limits of Woodin cardinals – and the existence of 0^W is not known to follow from large cardinals in V.

Theorem 3.8 (Neeman [35]). *Suppose that 0^W exists. Then the games $G_{\omega_1,k}(\vec{S}, \varphi)$ are determined, for all $\vec{S}$, k, and φ.*

There are two parameters determining the payoff of the game $G_{\omega_1,k}(\vec{S}, \varphi)$. One is the formula φ and the number k of its free variables. The other is the sequence $\vec{S}$. The formula φ, or the formula φ and the real x in the case of games relativized to a real, is the definable part of the payoff condition, analogous to the $<\omega^2$-Π^1_1 set, or more precisely to its recursive definition, in Theorems 3.2, 3.3, and 3.4. The sequence $\vec{S}$ consists of disjoint stationary sets, and this makes it highly non-definable. It has no parallel in Theorems 3.2, 3.3, and 3.4. It is necessary in Theorem 3.8, and the winning strategy in $G_{\omega_1,k}(\vec{S}, \varphi)$ depends on $\vec{S}$. But which of the players has a winning strategy is determined independently of $\vec{S}$:

Theorem 3.9 (Neeman [35]). *Suppose that 0^W exists. Let $\vec{S} = \langle S_a \mid a \in [\omega_1]^{<k} \rangle$ and $\vec{S}^* = \langle S^*_a \mid a \in [\omega_1]^{<k} \rangle$ be two sequences of mutually disjoint stationary subsets of ω_1. Then player* I (*respectively* II) *has a winning strategy in $G_{\omega_1,k}(\vec{S}, \varphi)$ iff she has a winning strategy in $G_{\omega_1,k}(\vec{S}^*, \varphi)$.*

Define $\beth_{\omega_1}(k, \varphi)$ to be 1 if player I has a winning strategy in $G_{\omega_1,k}(\vec{S}, \varphi)$ for some, and using Theorem 3.9 equivalently for all, $\vec{S}$. Define $\beth_{\omega_1}(k, \varphi)$ to be equal to 0 otherwise.

Theorem 3.10 (Neeman [35]). *Suppose that 0^W exists. Then $\{\langle k, \varphi \rangle \mid \beth_{\omega_1}(k, \varphi) = 1\}$ and 0^W are each recursive in the other.*

Theorems 3.8 and 3.10 establish the same precise connection between 0^W and games of length ω_1 that exists between $0^\sharp$ and $<\omega^2$-Π^1_1 games of length ω. They provide another step, the first to reach games of length ω_1, in the project of matching the hierarchy of large cardinals with the hierarchy of long games.

The art of ordinal analysis

Michael Rathjen

Abstract. Ordinal analysis of theories is a core area of proof theory whose origins can be traced back to Hilbert's programme – the aim of which was to lay to rest all worries about the foundations of mathematics once and for all by securing mathematics via an absolute proof of consistency. Ordinal-theoretic proof theory came into existence in 1936, springing forth from Gentzen's head in the course of his consistency proof of arithmetic. The central theme of ordinal analysis is the classification of theories by means of transfinite ordinals that measure their 'consistency strength' and 'computational power'. The so-called *proof-theoretic ordinal* of a theory also serves to characterize its provably recursive functions and can yield both conservation and combinatorial independence results.

This paper intends to survey the development of "ordinally informative" proof theory from the work of Gentzen up to more recent advances in determining the proof-theoretic ordinals of strong subsystems of second order arithmetic.

Mathematics Subject Classification (2000). Primary 03F15, 03F05, 03F35; Secondary 03F03, 03-03.

Keywords. Proof theory, ordinal analysis, ordinal representation systems, proof-theoretic strength.

1. Introduction

Ordinal analysis of theories is a core area of proof theory. The origins of proof theory can be traced back to the second problem on Hilbert's famous list of problems (presented at the Second International Congress in Paris on August 8, 1900), which called for a proof of consistency of the arithmetical axioms of the reals. Hilbert's work on axiomatic geometry marked the beginning of his live-long interest in the axiomatic method. For geometry, he solved the problem of consistency by furnishing arithmetical-analytical interpretations of the axioms, thereby reducing the question of consistency to the consistency of the axioms for real numbers. The consistency of the latter system of axioms is therefore the ultimate problem for the foundations of mathematics.

Which axioms for real numbers Hilbert had in mind in his problem was made precise only when he took up logic full scale in the 1920s and proposed a research programme with the aim of providing mathematics with a secure foundation. This was to be accomplished by first formalizing logic and mathematics in their entirety, and then showing that these formalizations are consistent, that is to say free of contra-

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

dictions. Strong restrictions were placed on the methods to be applied in consistency proofs of axiom systems for mathematics: namely, these methods were to be completely *finitistic* in character. The proposal to obtain finitistic consistency proofs of axiom systems for mathematics came to be called *Hilbert's Programme*.

Hilbert's Programme is a reductive enterprise with the aim of showing that whenever a 'real' proposition can be proved by 'ideal' means, it can also be proved by 'real', finitistic means. However, Hilbert's so-called formalism was not intended to eliminate nonconstructive existence proofs in the practice of mathematics, but to vindicate them.

In the 1920s, Ackermann and von Neumann, in pursuit of Hilbert's Programme, were working on consistency proofs for arithmetical systems. Ackermann's 1924 dissertation gives a consistency proof for a second-order version of primitive recursive arithmetic which explicitly uses a finitistic version of transfinite induction up to the ordinal ω^{ω^ω}. The employment of transfinite induction on ordinals in consistency proofs came explicitly to the fore in Gentzen's 1936 consistency proof for Peano arithmetic, **PA**. This proof led to the assignment of a *proof-theoretic ordinal* to a theory. This so-called *ordinal analysis* of theories allows one to classify theories by means of transfinite ordinals that measure their 'consistency strength' and 'computational power'.

The subject of this paper is the development of ordinal analysis from the work of Gentzen up to very recent advances in determining the proof-theoretic ordinals of strong subsystems of second order arithmetic.

1.1. Gentzen's result. The most important structure in mathematics is arguably the structure of the natural numbers $\mathfrak{N} = \big(\mathbb{N}; 0^{\mathfrak{N}}, 1^{\mathfrak{N}}, +^{\mathfrak{N}}, \times^{\mathfrak{N}}, E^{\mathfrak{N}}, <^{\mathfrak{N}}\big)$, where $0^{\mathfrak{N}}$ denotes zero, $1^{\mathfrak{N}}$ denotes the number one, $+^{\mathfrak{N}}$, $\times^{\mathfrak{N}}$, $E^{\mathfrak{N}}$ denote the successor, addition, multiplication, and exponentiation function, respectively, and $<^{\mathfrak{N}}$ stands for the less-than relation on the natural numbers. In particular, $E^{\mathfrak{N}}(n, m) = n^m$.

Many of the famous theorems and problems of mathematics such as Fermat's and Goldbach's conjecture, the Twin Prime conjecture, and Riemann's hypothesis can be formalized as sentences of the language of $\mathfrak{N}$ and thus concern questions about the structure $\mathfrak{N}$.

Definition 1.1. A theory designed with the intent of axiomatizing the structure $\mathfrak{N}$ is *Peano arithmetic*, **PA**. The language of **PA** has the predicate symbols $=$, $<$, the function symbols $+$, $\times$, E (for addition, multiplication, exponentiation) and the constant symbols 0 and 1. The *Axioms of* **PA** comprise the usual equations and laws for addition, multiplication, exponentiation, and the less-than relation. In addition, **PA** has the *Induction Scheme*

$$(\mathbf{IND}) \qquad \varphi(0) \wedge \forall x[\varphi(x) \to \varphi(x+1)] \to \forall x \varphi(x)$$

for all formulae φ of the language of **PA**.

Gentzen showed that transfinite induction up to the ordinal

$$\varepsilon_0 = \sup\{\omega, \omega^\omega, \omega^{\omega^\omega}, \dots\} = \text{least } \alpha.\ \omega^\alpha = \alpha$$

suffices to prove the consistency of **PA**. To appreciate Gentzen's result it is pivotal to note that he applied transfinite induction up to ε_0 solely to elementary computable predicates and besides that his proof used only finitistically justified means. Hence, a more precise rendering of Gentzen's result is

$$\mathbf{F} + \text{EC-TI}(\varepsilon_0) \vdash \mathsf{Con}(\mathbf{PA}); \tag{1}$$

here **F** signifies a theory that embodies only finitistically acceptable means, EC-TI(ε_0) stands for transfinite induction up to ε_0 for elementary computable predicates, and $\mathsf{Con}(\mathbf{PA})$ expresses the consistency of **PA**. Gentzen also showed that his result was the best possible in that **PA** proves transfinite induction up to α for arithmetic predicates for any $\alpha < \varepsilon_0$. The compelling picture conjured up by the above is that the non-finitist part of **PA** is encapsulated in EC-TI(ε_0) and therefore "measured" by ε_0, thereby tempting one to adopt the following definition of *proof-theoretic ordinal* of a theory T:

$$|T|_{\mathsf{Con}} = \text{least } \alpha.\ \mathbf{F} + \text{EC-TI}(\alpha) \vdash \mathsf{Con}(T). \tag{2}$$

In the above, many notions were left unexplained. We will now consider them one by one. The *elementary computable functions* are exactly the Kalmar *elementary functions,* i.e. the class of functions which contains the successor, projection, zero, addition, multiplication, and modified subtraction functions and is closed under composition and bounded sums and products. A predicate is elementary computable if its characteristic function is elementary computable.

According to an influential analysis of finitism due to W.W. Tait, finististic reasoning coincides with a system known as *primitive recursive arithmetic*. For the purposes of ordinal analysis, however, it suffices to identify **F** with an even more restricted theory known as *Elementary Recursive Arithmetic*, **ERA**. **ERA** is a weak subsystem of **PA** having the same defining axioms for $+, \times, E, <$ but with induction restricted to elementary computable predicates.

In order to formalize EC-TI(α) in the language of arithmetic we should first discuss ordinals and the representation of particular ordinals α as relations on $\mathbb{N}$.

Definition 1.2. A set A equipped with a total ordering $\prec$ (i.e. $\prec$ is transitive, irreflexive, and $\forall x, y \in A\,[x \prec y \vee x = y \vee y \prec x]$) is a *wellordering* if every non-empty subset X of A contains a $\prec$-least element, i.e. $(\exists u \in X)(\forall y \in X)[u \prec y \vee u = y]$.

An *ordinal* is a transitive set wellordered by the elementhood relation $\in$.

Fact 1.3. Every wellordering $(A, \prec)$ is order isomorphic to an ordinal $(\alpha, \in)$.

Ordinals are traditionally denoted by lower case Greek letters $\alpha, \beta, \gamma, \delta, \dots$ and the relation $\in$ on ordinals is notated simply by $<$. The operations of addition, multiplication, and exponentiation can be defined on all ordinals, however, addition and multiplication are in general not commutative.

We are interested in representing specific ordinals α as relations on $\mathbb{N}$. In essence Cantor [10] defined the first ordinal representation system in 1897. Natural ordinal representation systems are frequently derived from structures of the form

$$\mathfrak{A} = \langle \alpha, f_1, \ldots, f_n, <_\alpha \rangle \tag{3}$$

where α is an ordinal, $<_\alpha$ is the ordering of ordinals restricted to elements of α and the f_i are functions

$$f_i : \underbrace{\alpha \times \cdots \times \alpha}_{k_i \text{ times}} \longrightarrow \alpha$$

for some natural number k_i.

$$\mathbb{A} = \langle A, g_1, \ldots, g_n, \prec \rangle \tag{4}$$

is a *computable* (or *recursive*) *representation* of $\mathfrak{A}$ if the following conditions hold:

1. $A \subseteq \mathbb{N}$ and A is a computable set.
2. $\prec$ is a computable total ordering on A and the functions g_i are computable.
3. $\mathfrak{A} \cong \mathbb{A}$, i.e. the two structures are isomorphic.

Theorem 1.4 (Cantor, 1897). *For every ordinal $\beta > 0$ there exist unique ordinals $\beta_0 \geq \beta_1 \geq \cdots \geq \beta_n$ such that*

$$\beta = \omega^{\beta_0} + \cdots + \omega^{\beta_n}. \tag{5}$$

The representation of β in (5) is called the *Cantor normal form*. We shall write $\beta =_{CNF} \omega^{\beta_1} + \cdots + \omega^{\beta_n}$ to convey that $\beta_0 \geq \beta_1 \geq \cdots \geq \beta_k$.

ε_0 denotes the least ordinal $\alpha > 0$ such that $(\forall \beta < \alpha)\, \omega^\beta < \alpha$. ε_0 can also be described as the least ordinal α such that $\omega^\alpha = \alpha$.

Ordinals $\beta < \varepsilon_0$ have a Cantor normal form with exponents $\beta_i < \beta$ and these exponents have Cantor normal forms with yet again smaller exponents. As this process must terminate, ordinals $< \varepsilon_0$ can be coded by natural numbers. For instance a coding function

$$\ulcorner \, . \, \urcorner : \varepsilon_0 \longrightarrow \mathbb{N}$$

could be defined as follows:

$$\ulcorner \alpha \urcorner = \begin{cases} 0 & \text{if } \alpha = 0, \\ \langle \ulcorner \alpha_1 \urcorner, \ldots, \ulcorner \alpha_n \urcorner \rangle & \text{if } \alpha =_{CNF} \omega^{\alpha_1} + \cdots + \omega^{\alpha_n} \end{cases}$$

where $\langle k_1, \ldots, k_n \rangle := 2^{k_1+1} \ldots p_n^{k_n+1}$ with p_i being the ith prime number (or any other coding of tuples). Further define:

$$A_0 := \text{range of } \ulcorner . \urcorner, \quad \ulcorner \alpha \urcorner \prec \ulcorner \beta \urcorner :\Leftrightarrow \alpha < \beta$$
$$\ulcorner \alpha \urcorner \hat{+} \ulcorner \beta \urcorner := \ulcorner \alpha + \beta \urcorner, \quad \ulcorner \alpha \urcorner \hat{:} \ulcorner \beta \urcorner := \ulcorner \alpha \cdot \beta \urcorner, \quad \hat{\omega}^{\ulcorner \alpha \urcorner} := \ulcorner \omega^\alpha \urcorner.$$

Then

$$\langle \varepsilon_0, +, \cdot, \delta \mapsto \omega^\delta, < \rangle \cong \langle A_0, \hat{+}, \hat{\cdot}, x \mapsto \hat{\omega}^x, \prec \rangle.$$

$A_0, \hat{+}, \hat{\cdot}, x \mapsto \hat{\omega}^x, \prec$ are computable (recursive), in point of fact, they are all elementary computable.

Finally, we can spell out the scheme EC-TI(ε_0) in the language of **PA**:

$$\forall x\ [\forall y\ (y \prec x \to P(y)) \to P(x)] \to \forall x\, P(x)$$

for all elementary computable predicates P.

1.2. Cut Elimination: Gentzen's Hauptsatz. In the consistency proof, Gentzen used his sequent calculus and employed the technique of *cut elimination*. As this is a tool of utmost importance in proof theory and ordinal analysis, a rough outline of the underlying ideas will be discussed next.

The most common logical calculi are *Hilbert-style* systems. They are specified by delineating a collection of schematic logical axioms and some inference rules. The choice of axioms and rules is more or less arbitrary, only subject to the desire to obtain a *complete* system (in the sense of Gödel's completeness theorem). In model theory it is usually enough to know that there is a complete calculus for first order logic as this already entails the compactness theorem.

There are, however, proof calculi without this arbitrariness of axioms and rules. The *natural deduction calculus* and the *sequent calculus* were both invented by *Gentzen*. Both calculi are pretty illustrations of the symmetries of logic. The sequent calculus since is a central tool in ordinal analysis and allows for generalizations to so-called infinitary logics. Gentzen's main theorem about the sequent calculus is the *Hauptsatz*, i.e. *the cut elimination theorem*.

A *sequent* is an expression $\Gamma \Rightarrow \Delta$ where Γ and Δ are finite sequences of formulae $A_1, \ldots, A_n$ and $B_1, \ldots, B_m$, respectively. We also allow for the possibility that Γ or Δ (or both) are empty. The empty sequence will be denoted by $\emptyset$. $\Gamma \Rightarrow \Delta$ is read, informally, as Γ yields Δ or, rather, the *conjunction* of the A_i yields the *disjunction* of the B_j. In particular, we have:

- If Γ is empty, the sequent asserts the disjunction of the B_j.
- If Δ is empty, it asserts the negation of the conjunction of the A_i.
- if Γ and Δ are both empty, it asserts the *impossible*, i.e. a *contradiction*.

We use upper case Greek letters $\Gamma, \Delta, \Lambda, \Theta, \Xi \ldots$ to range over finite sequences of formulae. $\Gamma \subseteq \Delta$ means that every formula of Γ is also a formula of Δ.

Next we list the axioms and rules of the sequent calculus.

- *Identity Axiom:*

  $$A \Rightarrow A$$

  where A is any formula. In point of fact, one could limit this axiom to the case of atomic formulae A.

- *Cut Rule:*

$$\frac{\Gamma \Rightarrow \Delta, A \qquad A, \Lambda \Rightarrow \Theta}{\Gamma, \Lambda \Rightarrow \Delta, \Theta}\ \mathrm{Cut}$$

The formula A is called the *cut formula* of the inference.

- *Structural Rules:*

$$\frac{\Gamma \Rightarrow \Delta}{\Gamma' \Rightarrow \Delta'} \qquad \text{if } \Gamma \subseteq \Gamma',\ \Delta \subseteq \Delta'.$$

A special case of the structural rule, known as *contraction*, occurs when the lower sequent has fewer occurrences of a formula than the upper sequent. For instance, $A, \Gamma \Rightarrow \Delta, B$ follows structurally from $A, A, \Gamma \Rightarrow \Delta, B, B$.

- *Rules for Logical Operations:*

Left	Right
$\dfrac{\Gamma \Rightarrow \Delta, A}{\neg A, \Gamma \Rightarrow \Delta}$	$\dfrac{B, \Gamma \Rightarrow \Delta}{\Gamma \Rightarrow \Delta, \neg B}$
$\dfrac{\Gamma \Rightarrow \Delta, A \qquad B, \Lambda \Rightarrow \Theta}{A \to B, \Gamma, \Lambda \Rightarrow \Delta, \Theta}$	$\dfrac{A, \Gamma \Rightarrow \Delta, B}{\Gamma \Rightarrow \Delta, A \to B}$
$\dfrac{A, \Gamma \Rightarrow \Delta}{A \wedge B, \Gamma \Rightarrow \Delta} \quad \dfrac{B, \Gamma \Rightarrow \Delta}{A \wedge B, \Gamma \Rightarrow \Delta}$	$\dfrac{\Gamma \Rightarrow \Delta, A \qquad \Gamma \Rightarrow \Delta, B}{\Gamma \Rightarrow \Delta, A \wedge B}$
$\dfrac{A, \Gamma \Rightarrow \Delta \qquad B, \Gamma \Rightarrow \Delta}{A \vee B, \Gamma \Rightarrow \Delta}$	$\dfrac{\Gamma \Rightarrow \Delta, A}{\Gamma \Rightarrow \Delta, A \vee B} \quad \dfrac{\Gamma \Rightarrow \Delta, B}{\Gamma \Rightarrow \Delta, A \vee B}$
$\dfrac{F(t), \Gamma \Rightarrow \Delta}{\forall x\, F(x), \Gamma \Rightarrow \Delta}\ \forall \mathrm{L}$	$\dfrac{\Gamma \Rightarrow \Delta, F(a)}{\Gamma \Rightarrow \Delta, \forall x\, F(x)}\ \forall \mathrm{R}$
$\dfrac{F(a), \Gamma \Rightarrow \Delta}{\exists x\, F(x), \Gamma \Rightarrow \Delta}\ \exists \mathrm{L}$	$\dfrac{\Gamma \Rightarrow \Delta, F(t)}{\Gamma \Rightarrow \Delta, \exists x\, F(x)}\ \exists \mathrm{R}$

In $\forall$L and $\exists$R, t is an arbitrary term. The variable a in $\forall$R and $\exists$L is an *eigenvariable* of the respective inference, i.e. a is not to occur in the *lower sequent*.

In the rules for logical operations, the formulae highlighted in the premisses are called the *minor formulae* of that inference, while the formula highlighted in the conclusion is the *principal formula* of that inference. The other formulae of an inference are called *side formulae*.

A *proof* (also known as *deduction* or *derivation*) $\mathcal{D}$ is a tree of sequents satisfying the following conditions:

- The topmost sequents of $\mathcal{D}$ are identity axioms.

- Every sequent in $\mathcal{D}$ except the lowest one is an upper sequent of an inference whose lower sequent is also in $\mathcal{D}$.

A sequent $\Gamma \Rightarrow \Delta$ is *deducible* if there is a proof having $\Gamma \Rightarrow \Delta$ as its the bottom sequent.

The Cut rule differs from the other rules in an important respect. With the rules for introduction of a connective on the left or the right, one sees that every formula that occurs above the line occurs below the line either directly, or as a subformula of a formula below the line, and that is also true for the structural rules. (Here $A(t)$ is counted as a subformula, in a slightly extended sense, of both $\exists x A(x)$ and $\forall x A(x)$.) But in the case of the Cut rule, the cut formula A vanishes. Gentzen showed that such "vanishing rules" can be eliminated.

Theorem 1.5 (Gentzen's Hauptsatz). If a sequent $\Gamma \Rightarrow \Delta$ is provable, then it is provable without use of the Cut Rule (called a *cut-free proof*).

The secret to Gentzen's Hauptsatz is the symmetry of left and right rules for the logical connectives. The proof of the cut elimination theorem is rather intricate as the process of removing cuts interferes with the structural rules. The possibility of contraction accounts for the high cost of eliminating cuts. Let $|\mathcal{D}|$ be the *height* of the deduction $\mathcal{D}$. Also, let $\mathrm{rank}(\mathcal{D})$ be *supremum* of the *lengths of cut formulae* occurring in $\mathcal{D}$. Turning $\mathcal{D}$ into a cut-free deduction of the same end sequent results, in the worst case, in a deduction of height $\mathcal{H}(\mathrm{rank}(\mathcal{D}), |\mathcal{D}|)$ where $\mathcal{H}(0, n) = n$ and $\mathcal{H}(k+1, n) = 4^{\mathcal{H}(k,n)}$, yielding hyper-exponential growth.

The *Hauptsatz* has an important corollary which explains its crucial role in obtaining consistency proofs.

Corollary 1.6 (The Subformula Property). *If a sequent $\Gamma \Rightarrow \Delta$ is provable, then it has a deduction all of whose formulae are subformulae of the formulae of Γ and Δ.*

Corollary 1.7. *A contradiction, i.e. the empty sequent $\emptyset \Rightarrow \emptyset$, is not deducible.*

Proof. According to the Hauptsatz, if the empty sequent were deducible it would have a deduction without cuts. In a cut-free deduction of the empty sequent only empty sequents can occur. But such a deduction does not exist. □

While mathematics is based on logic, it cannot be developed solely on the basis of *pure logic*. What is needed in addition are *axioms* that assert the *existence* of *mathematical objects* and their properties. Logic plus axioms gives rise to (formal) *theories* such as *Peano arithmetic* or the axioms of *Zermelo–Fraenkel set theory*. What happens when we try to apply the procedure of cut elimination to theories? Well, axioms are poisonous to this procedure. It breaks down because the symmetry of the sequent calculus is lost. In general, we cannot remove cuts from deductions in a theory T when the cut formula is an axiom of T. However, sometimes the axioms of a theory are of *bounded syntactic complexity*. Then the procedure applies

partially in that one can remove all cuts that exceed the complexity of the axioms of T. This gives rise to *partial cut elimination*. It is a very important tool in proof theory. For example, it works very well if the axioms of a theory can be presented as *atomic intuitionistic sequents* (also called *Horn clauses*), yielding the completeness of *Robinsons resolution method*. Partial cut elimination also pays off in the case of *fragments* of **PA** and set theory with *restricted induction schemes*, be it induction on natural numbers or sets. This method can be used to extract bounds from proofs of Π^0_2 statements in such fragments.

Full arithmetic (i.e. **PA**), though, does not even allow for partial cut elimination since the induction axioms have unbounded complexity. However, one can remove the obstacle to cut elimination in a drastic way by going *infinite*. The so-called *ω-rule* consists of the two types of *infinitary inferences*:

$$\frac{\Gamma \Rightarrow \Delta, F(0);\ \Gamma \Rightarrow \Delta, F(1);\ \ldots\ ; \Gamma \Rightarrow \Delta, F(n);\ \ldots}{\Gamma \Rightarrow \Delta, \forall x\, F(x)}\ \omega\mathrm{R}$$

$$\frac{F(0), \Gamma \Rightarrow \Delta;\ F(1), \Gamma \Rightarrow \Delta;\ \ldots\ ; F(n), \Gamma \Rightarrow \Delta;\ \ldots}{\exists x\, F(x), \Gamma \Rightarrow \Delta}\ \omega\mathrm{L}$$

The price to pay will be that deductions become infinite objects, i.e. *infinite well-founded trees*.

The sequent-style version of Peano arithmetic with the *ω-rule* will be termed $\mathbf{PA}_\omega$. $\mathbf{PA}_\omega$ has no use for free variables. Thus free variables are discarded and all *terms* will be closed. All formulae of this system are therefore closed, too. The *numerals* are the terms $\bar{n}$, where $\bar{0} = 0$ and $\overline{n+1} = S\bar{n}$. We shall identify $\bar{n}$ with the natural number n. All terms t of $\mathbf{PA}_\omega$ evaluate to a numeral $\bar{n}$.

$\mathbf{PA}_\omega$ has all the inference rules of the sequent calculus except for $\forall R$ and $\exists L$. In their stead, $\mathbf{PA}_\omega$ has the ωR and ωL inferences. The *Axioms* of $\mathbf{PA}_\omega$ are the following: (i) $\emptyset \Rightarrow A$ if A is a *true* atomic sentence; (ii) $B \Rightarrow \emptyset$ if B is a *false* atomic sentence; (iii) $F(s_1, \ldots, s_n) \Rightarrow F(t_1, \ldots, t_n)$ if $F(s_1, \ldots, s_n)$ is an atomic sentence and s_i and t_i evaluate to the same numeral.

With the aid of the ω-rule, each instance of the induction scheme becomes logically deducible, albeit the price to pay will be that the proof tree becomes infinite. To describe the cost of cut elimination for $\mathbf{PA}_\omega$, we introduce the measures of *height* and *cut rank* of a $\mathbf{PA}_\omega$ deduction $\mathcal{D}$. We will notate this by

$$\mathcal{D} \ \vert\!\vert^{\alpha}_{k}\ \Gamma \Rightarrow \Delta\,.$$

The above relation is defined inductively following the buildup of the deduction $\mathcal{D}$. For the *cut rank* we need the definition of the *length*, $|A|$ of a formula: $|A| = 0$ if A is atomic; $|\neg A_0| = |A_0| + 1$; $|A_0 \Box A_1| = \max(|A_0, A_1|) + 1$ where $\Box = \wedge, \vee, \rightarrow$; $|\exists x\, F(x)| = |\forall x\, F(x)| = |F(0)| + 1$.

Now suppose the last inference of $\mathcal{D}$ is of the form

$$\frac{\begin{array}{cccc}\mathcal{D}_0 & & \mathcal{D}_n & \\ \Gamma_0 \Rightarrow \Delta_0 & \cdots & \Gamma_n \Rightarrow \Delta_n & \ldots\quad n < \tau\end{array}}{\Gamma \Rightarrow \Delta}\ I$$

where $\tau = 1, 2, \omega$ and the $\mathcal{D}_n$ are the immediate subdeductions of $\mathcal{D}$. If

$$\mathcal{D}_n \vdash_k^{\alpha_n} \Gamma_n \Rightarrow \Delta_n$$

and $\alpha_n < \alpha$ for all $n < \tau$ then

$$\mathcal{D} \vdash_k^{\alpha} \Gamma \Rightarrow \Delta$$

providing that in the case of I being a *cut* with cut formula A we also have $|A| < k$. We will write $\mathbf{PA}_\omega \vdash_k^{\alpha} \Gamma \Rightarrow \Delta$ to convey that there exists a $\mathbf{PA}_\omega$-deduction $\mathcal{D} \vdash_k^{\alpha} \Gamma \Rightarrow \Delta$. The ordinal analysis of **PA** proceeds by first unfolding any **PA**-deduction into a $\mathbf{PA}_\omega$-deduction:

$$\text{If } \mathbf{PA} \vdash \Gamma \Rightarrow \Delta, \text{ then } \mathbf{PA}_\omega \vdash_k^{\omega+m} \Gamma \Rightarrow \Delta \tag{6}$$

for some $m, k < \omega$. The next step is to get rid of the cuts. It turns out that the cost of lowering the cut rank from $k+1$ to k is an exponential with base ω.

Theorem 1.8 (Cut Elimination for $\mathbf{PA}_\omega$).

$$\textit{If } \mathbf{PA}_\omega \vdash_{k+1}^{\alpha} \Gamma \Rightarrow \Delta, \textit{ then } \mathbf{PA}_\omega \vdash_k^{\omega^\alpha} \Gamma \Rightarrow \Delta.$$

As a result, if $\mathbf{PA}_\omega \vdash_n^{\alpha} \Gamma \Rightarrow \Delta$, we may apply the previous theorem n times to arrive at a cut-free deduction $\mathbf{PA}_\omega \vdash_0^{\rho} \Gamma \Rightarrow \Delta$ with $\rho = \omega^{\omega^{\cdot^{\cdot^{\omega^\alpha}}}}$, where the stack has height n. Combining this with the result from (6), it follows that every sequent $\Gamma \Rightarrow \Delta$ deducible in **PA** has a cut-free deduction in $\mathbf{PA}_\omega$ of length $< \varepsilon_0$. Ruminating on the details of how this result was achieved yields a consistency proof for **PA** from transfinite induction up to ε_0 for elementary decidable predicates on the basis of finitistic reasoning (as described in (1)).

Deductions in $\mathbf{PA}_\omega$ being well-founded infinite trees, they have a natural associated ordinal length, namely: the height of the tree as an ordinal. Thus the passage from finite deductions in **PA** to infinite cut-free deductions in $\mathbf{PA}_\omega$ provides an explanation of how the ordinal ε_0 is connected with **PA**.

Gentzen, however, did not consider infinite proof trees. The infinitary version of **PA** with the ω-rule was introduced by Schütte in [35]. Incidentally, the ω-rule had already been proposed by Hilbert [18]. Gentzen worked with finite deductions in the sequent calculus version of **PA**, devising an ingenious method of assigning ordinals to purported derivations of the empty sequent (inconsistency). It turns out in recent work by Buchholz [9] that in fact there is a much closer intrinsic connection between the way Gentzen assigned ordinals to deductions in **PA** and the way that ordinals are assigned to infinite deductions in $\mathbf{PA}_\omega$.

In the 1950s infinitary proof theory flourished in the hands of Schütte. He extended his approach to **PA** to systems of ramified analysis and brought this technique to perfection in his monograph "Beweistheorie" [36]. The ordinal representation systems necessary for Schütte's work will be reviewed in the next subsection.

1.3. A brief history of ordinal representation systems: 1904–1950. Ordinals assigned as lengths to deductions to keep track of the cost of operations such as cut elimination render ordinal analyses of theories particularly transparent. In the case of **PA**, Gentzen could rely on Cantor's normal form for a supply of ordinal representations. For stronger theories, though, segments larger than ε_0 have to be employed. Ordinal representation systems utilized by proof theorists in the 1960s arose in a purely set-theoretic context. This subsection will present some of the underlying ideas as progress in ordinal-theoretic proof theory also hinges on the development of sufficiently strong and transparent ordinal representation systems.

In 1904, Hardy [17] wanted to "construct" a subset of $\mathbb{R}$ of size $\aleph_1$. His method was to represent countable ordinals via increasing sequence of natural numbers and then to correlate a decimal expansion with each such sequence. Hardy used two processes on sequences: (i) Removing the first element to represent the successor; (ii) Diagonalizing at limits. E.g., if the sequence $1, 2, 3, \ldots$ represents the ordinal 1, then $2, 3, 4, \ldots$ represents the ordinal 2 and $3, 4, 5, \ldots$ represents the ordinal 3 etc., while the 'diagonal' $1, 3, 5, \ldots$ provides a representation of ω. In general, if $\lambda = \lim_{n\in\mathbb{N}} \lambda_n$ is a limit ordinal with $b_{n1}, b_{n2}, b_{n3}, \ldots$ representing $\lambda_n < \lambda$, then $b_{11}, b_{22}, b_{33}, \ldots$ represents λ. This representation, however, depends on the sequence chosen with limit λ. A sequence $(\lambda_n)_{n\in\mathbb{N}}$ with $\lambda_n < \lambda$ and $\lim_{n\in\mathbb{N}} \lambda_n = \lambda$ is called a *fundamental sequence* for λ. Hardy's two operations give explicit representations for all ordinals $< \omega^2$.

Veblen [44] extended the initial segment of the countable for which fundamental sequences can be given effectively. The new tools he devised were the operations of *derivation* and *transfinite iteration* applied to *continuous increasing functions* on ordinals.

Definition 1.9. Let ON be the class of ordinals. A (class) function $f : ON \to ON$ is said to be *increasing* if $\alpha < \beta$ implies $f(\alpha) < f(\beta)$ and *continuous* (in the order topology on ON) if

$$f(\lim_{\xi<\lambda} \alpha_\xi) = \lim_{\xi<\lambda} f(\alpha_\xi)$$

holds for every limit ordinal λ and increasing sequence $(\alpha_\xi)_{\xi<\lambda}$. f is called *normal* if it is increasing and continuous.

The function $\beta \mapsto \omega + \beta$ is normal while $\beta \mapsto \beta + \omega$ is not continuous at ω since $\lim_{\xi<\omega}(\xi + \omega) = \omega$ but $(\lim_{\xi<\omega} \xi) + \omega = \omega + \omega$.

Definition 1.10. The *derivative* f' of a function $f : ON \to ON$ is the function which enumerates in increasing order the solutions of the equation $f(\alpha) = \alpha$, also called the *fixed points* of f.

If f is a normal function, $\{\alpha : f(\alpha) = \alpha\}$ is a proper class and f' will be a normal function, too.

Definition 1.11. Now, given a normal function $f : ON \to ON$, define a hierarchy of normal functions as follows:

$$f_0 = f, \quad f_{\alpha+1} = f'_\alpha,$$
$$f_\lambda(\xi) = \xi^{th} \text{ element of } \bigcap_{\alpha<\lambda} (\text{Range of } f_\alpha) \text{ for } \lambda \text{ a limit ordinal.}$$

In this way, from the normal function f we get a two-place function, $\varphi_f(\alpha, \beta) := f_\alpha(\beta)$. Veblen then discusses the hierarchy when $f = \ell$, where $\ell(\alpha) = 1 + \alpha$.

The least ordinal $\gamma > 0$ closed under φ_ℓ, i.e. the least ordinal > 0 satisfying $(\forall \alpha, \beta < \gamma)\ \varphi_\ell(\alpha, \beta) < \gamma$ is the famous ordinal Γ_0 which Feferman [13] and Schütte [37], [38] determined to be the least ordinal 'unreachable' by *predicative means*.

Veblen extended this idea first to arbitrary finite numbers of arguments, but then also to transfinite numbers of arguments, with the proviso that in, for example $\Phi_f(\alpha_0, \alpha_1, \ldots, \alpha_\eta)$, only a finite number of the arguments α_ν may be non-zero. Finally, Veblen singled out the ordinal $E(0)$, where $E(0)$ is the least ordinal $\delta > 0$ which cannot be named in terms of functions $\Phi_\ell(\alpha_0, \alpha_1, \ldots, \alpha_\eta)$ with $\eta < \delta$, and each $\alpha_\gamma < \delta$.

Though the "great Veblen number" (as $E(0)$ is sometimes called) is quite an impressive ordinal it does not furnish an ordinal representation sufficient for the task of analyzing a theory as strong as Π^1_1 comprehension. Of course, it is possible to go beyond $E(0)$ and initiate a new hierarchy based on the function $\xi \mapsto E(\xi)$ or even consider hierarchies utilizing finite type functionals over the ordinals. Still all these further steps amount to rather mundane progress over Veblen's methods. In 1950 Bachmann [3] presented a new kind of operation on ordinals which dwarfs all hierarchies obtained by iterating Veblen's methods. Bachmann builds on Veblen's work but his novel idea was the systematic use of *uncountable ordinals* to keep track of the functions defined by diagonalization. Let Ω be the first uncountable ordinal. Bachmann defines a set of ordinals $\mathfrak{B}$ closed under successor such that with each limit $\lambda \in \mathfrak{B}$ is associated an increasing sequence $\langle \lambda[\xi] : \xi < \tau_\lambda \rangle$ of ordinals $\lambda[\xi] \in \mathfrak{B}$ of length $\tau_\lambda \in \mathfrak{B}$ and $\lim_{\xi<\tau_\lambda} \lambda[\xi] = \lambda$. A hierarchy of functions $(\varphi^{\mathfrak{B}}_\alpha)_{\alpha\in\mathfrak{B}}$ is then obtained as follows:

$$\begin{aligned}
&\varphi^{\mathfrak{B}}_0(\beta) = 1 + \beta, \qquad \varphi^{\mathfrak{B}}_{\alpha+1} = \left(\varphi^{\mathfrak{B}}_\alpha\right)', \\
&\varphi^{\mathfrak{B}}_\lambda \text{ enumerates } \bigcap_{\xi<\tau_\lambda} (\text{Range of } \varphi^{\mathfrak{B}}_{\lambda[\xi]}) \qquad \text{if } \lambda \text{ is a limit with } \tau_\lambda < \Omega, \\
&\varphi^{\mathfrak{B}}_\lambda \text{ enumerates } \{\beta < \Omega : \varphi^{\mathfrak{B}}_{\lambda[\beta]}(0) = \beta\} \qquad \text{if } \lambda \text{ is a limit with } \tau_\lambda = \Omega.
\end{aligned} \tag{7}$$

After the work of Bachmann, the story of ordinal representations becomes very complicated. Significant papers (by Isles, Bridge, Pfeiffer, Schütte, Gerber to mention a few) involve quite horrendous computations to keep track of the fundamental sequences. Also Bachmann's approach was combined with uses of higher type functionals by Aczel and Weyhrauch. Feferman proposed an entirely different method for

generating a Bachmann-type hierarchy of normal functions which does not involve fundamental sequences. Buchholz further simplified the systems and proved their recursivity. For details we recommend the preface to [7].

2. Ordinal analyses of systems of second order arithmetic and set theory

Ordinal analysis is concerned with theories serving as frameworks for formalising significant parts of mathematics. It is known that virtually all of ordinary mathematics can be formalized in Zermelo–Fraenkel set theory with the axiom of choice, **ZFC**. Hilbert and Bernays [19] showed that large chunks of mathematics can already be formalized in second order arithmetic. Owing to these observations, proof theory has been focusing on set theories and subsystems of second order arithmetic. Further scrutiny revealed that a small fragment is sufficient. Under the rubric of *Reverse Mathematics* a research programme has been initiated by Harvey Friedman some thirty years ago. The idea is to ask whether, given a theorem, one can prove its equivalence to some axiomatic system, with the aim of determining what proof-theoretical resources are necessary for the theorems of mathematics. More precisely, the objective of reverse mathematics is to investigate the role of set existence axioms in ordinary mathematics. The main question can be stated as follows:

> *Given a specific theorem τ of ordinary mathematics, which set existence axioms are needed in order to prove τ?*

Central to the above is the reference to what is called 'ordinary mathematics'. This concept, of course, doesn't have a precise definition. Roughly speaking, by ordinary mathematics we mean main-stream, non-set-theoretic mathematics, i.e. the core areas of mathematics which make no essential use of the concepts and methods of set theory and do not essentially depend on the theory of uncountable cardinal numbers.

2.1. Subsystems of second order arithmetic. The framework chosen for studying set existence in reverse mathematics, though, is second order arithmetic rather than set theory. Second order arithmetic, $\mathbf{Z_2}$, is a two-sorted formal system with one sort of variables $x, y, z, \ldots$ ranging over natural numbers and the other sort $X, Y, Z, \ldots$ ranging over sets of natural numbers. The language $\mathcal{L}_2$ of second-order arithmetic also contains the symbols of **PA**, and in addition has a binary relation symbol $\in$ for elementhood. Formulae are built from the prime formulae $s = t$, $s < t$, and $s \in X$ (where s, t are numerical terms, i.e. terms of **PA**) by closing off under the connectives $\wedge, \vee, \rightarrow, \neg$, numerical quantifiers $\forall x, \exists x$, and set quantifiers $\forall X, \exists X$.

The basic arithmetical axioms in all theories of second-order arithmetic are the defining axioms for $0, 1, +, \times, E, <$ (as for **PA**) and the *induction axiom*

$$\forall X(0 \in X \wedge \forall x(x \in X \rightarrow x + 1 \in X) \rightarrow \forall x(x \in X)).$$

We consider the axiom schema of $\mathcal{C}$-*comprehension* for formula classes $\mathcal{C}$ which is given by

$$\mathcal{C}\text{-}\mathbf{CA} \quad \exists X \forall u (u \in X \leftrightarrow F(u))$$

for all formulae $F \in \mathcal{C}$ in which X does not occur. Natural formula classes are the *arithmetical formulae*, consisting of all formulae without second order quantifiers $\forall X$ and $\exists X$, and the Π^1_n-*formulae*, where a Π^1_n-formula is a formula of the form $\forall X_1 \dots Q X_n \, A(X_1, \dots, X_n)$ with $\forall X_1 \dots Q X_n$ being a string of n alternating set quantifiers, commencing with a universal one, followed by an arithmetical formula $A(X_1, \dots, X_n)$.

For each axiom scheme $\mathbf{Ax}$ we denote by $(\mathbf{Ax})_0$ the theory consisting of the basic arithmetical axioms plus the scheme $\mathbf{Ax}$. By contrast, $(\mathbf{Ax})$ stands for the theory $(\mathbf{Ax})_0$ augmented by the scheme of induction for all $\mathcal{L}_2$-formulae.

An example for these notations is the theory $(\Pi^1_1\text{-}\mathbf{CA})_0$ which has the comprehension schema for Π^1_1-formulae.

In **PA** one can define an elementary injective pairing function on numbers, e.g $(n, m) := 2^n \times 3^m$. With the help of this function an infinite sequence of sets of natural numbers can be coded as a single set of natural numbers. The n^{th} section of set of natural numbers U is defined by $U_n := \{m : (n, m) \in U\}$. Using this coding, we can formulate the axiom of choice for formulae F in $\mathcal{C}$ by

$$\mathcal{C}\text{-}\mathbf{AC} \quad \forall x \exists Y \, F(x, Y) \to \exists Y \forall x \, F(x, Y_x).$$

For many mathematical theorems τ, there is a weakest natural subsystem $S(\tau)$ of $\mathbf{Z_2}$ such that $S(\tau)$ proves τ. Very often, if a theorem of ordinary mathematics is proved from the weakest possible set existence axioms, the statement of that theorem will turn out to be provably equivalent to those axioms over a still weaker base theory. This theme is referred to as *Reverse Mathematics*. Moreover, it has turned out that $S(\tau)$ often belongs to a small list of specific subsystems of $\mathbf{Z_2}$ dubbed $\mathbf{RCA}_0$, $\mathbf{WKL_0}$, $\mathbf{ACA}_0$, $\mathbf{ATR}_0$ and $(\Pi^1_1\text{-}\mathbf{CA})_0$, respectively. The systems are enumerated in increasing strength. The main set existence axioms of $\mathbf{RCA}_0$, $\mathbf{WKL_0}$, $\mathbf{ACA}_0$, $\mathbf{ATR}_0$, and $(\Pi^1_1\text{-}\mathbf{CA})_0$ are recursive comprehension, weak König's lemma, arithmetical comprehension, arithmetical transfinite recursion, and Π^1_1-comprehension, respectively. For exact definitions of all these systems and their role in reverse mathematics see [40]. The proof-theoretic strength of $\mathbf{RCA}_0$ is weaker than that of **PA** while $\mathbf{ACA}_0$ has the same strength as **PA**. Let $|T| = |T|_{\mathsf{Con}}$. To get a sense of scale, the strengths of the first four theories are best expressed via their proof-theoretic ordinals: $|\mathbf{RCA}_0| = |\mathbf{WKL_0}| = \omega^\omega$, $|\mathbf{ACA}_0| = \varepsilon_0$, $|\mathbf{ATR}_0| = \Gamma_0$. $|(\Pi^1_1\text{-}\mathbf{CA})_0|$, however, eludes expression in the ordinal representations introduced so far. $\Pi^1_1\text{-}\mathbf{CA}$ involves a so-called *impredicative definition*. An impredicative definition of an object refers to a presumed totality of which the object being defined is itself to be a member. For example, to define a set of natural numbers X as $X = \{n \in \mathbb{N} : \forall Y \subseteq \mathbb{N} \, F(n, Y)\}$ is impredicative since it involves the quantified variable 'Y' ranging over arbitrary subsets of the natural numbers $\mathbb{N}$, of which the set X being defined is one member.

Determining whether $\forall Y \subseteq \mathbb{N}\ F(n, Y)$ holds involves an apparent circle since we shall have to know in particular whether $F(n, X)$ holds – but that cannot be settled until X itself is determined. Impredicative set definitions permeate the fabric of Zermelo–Fraenkel set theory in the guise of the separation and replacement axioms as well as the powerset axiom.

A major breakthrough was made by Takeuti in 1967, who for the first time obtained an ordinal analysis of an impredicative theory. In [41] he gave an ordinal analysis of (Π^1_1-**CA**), extended in 1973 to (Π^1_1-**AC**) in [43] jointly with Yasugi. For this Takeuti returned to Gentzen's method of assigning ordinals (ordinal diagrams, to be precise) to purported derivations of the empty sequent (inconsistency).

The next wave of results, which concerned theories of iterated inductive definitions, were obtained by Buchholz, Pohlers, and Sieg in the late 1970s (see [7]). Takeuti's methods of reducing derivations of the empty sequent ("the inconsistency") were extremely difficult to follow, and therefore a more perspicuous treatment was to be hoped for. Since the use of the infinitary ω-rule had greatly facilitated the ordinal analysis of number theory, new infinitary rules were sought. In 1977 (see [5]) Buchholz introduced such rules, dubbed Ω-rules to stress the analogy. They led to a proof-theoretic treatment of a wide variety of systems, as exemplified in the monograph [8] by Buchholz and Schütte. Yet simpler infinitary rules were put forward a few years later by Pohlers, leading to the *method of local predicativity*, which proved to be a very versatile tool (see [23]).

2.2. Set theories. With the work of Jäger and Pohlers (see [20], [21]) the forum of ordinal analysis then switched from the realm of second-order arithmetic to set theory, shaping what is now called *admissible proof theory*, after the models of *Kripke–Platek set theory*, **KP**. Their work culminated in the analysis of the system Π^1_1-**AC** plus an induction principle called *Bar Induction* **BI** which is a scheme asserting that transfinite induction along well-founded relations holds for arbitrary formulae (see [21]).

By and large, ordinal analyses for set theories are more uniform and transparent than for subsystems of $\mathbf{Z_2}$. The axiom systems for set theories considered in this paper are formulated in the usual language of set theory (called $\mathcal{L}_\in$ hereafter) containing $\in$ as the only non-logical symbol besides $=$. Formulae are built from prime formulae $a \in b$ and $a = b$ by use of propositional connectives and quantifiers $\forall x, \exists x$. Quantifiers of the forms $\forall x \in a$, $\exists x \in a$ are called *bounded*. *Bounded* or Δ_0*-formulae* are the formulae wherein all quantifiers are bounded; Σ_1-formulae are those of the form $\exists x \varphi(x)$ where $\varphi(a)$ is a Δ_0-formula. For $n > 0$, Π_n-formulae (Σ_n-formulae) are the formulae with a prefix of n alternating unbounded quantifiers starting with a universal (existential) one followed by a Δ_0-formula. The class of Σ-formulae is the smallest class of formulae containing the Δ_0-formulae which is closed under $\wedge$, $\vee$, bounded quantification and unbounded existential quantification.

One of the set theories which is amenable to ordinal analysis is Kripke–Platek set theory, **KP**. Its standard models are called *admissible sets*. One of the reasons that this is an important theory is that a great deal of set theory requires only the

axioms of **KP**. An even more important reason is that admissible sets have been a major source of interaction between model theory, recursion theory and set theory (cf. [4]). **KP** arises from **ZF** by completely omitting the power set axiom and restricting separation and collection to bounded formulae. These alterations are suggested by the informal notion of 'predicative'. To be more precise, the axioms of **KP** consist of *Extensionality, Pair, Union, Infinity, Bounded Separation*

$$\exists x\, \forall u\, [u \in x \leftrightarrow (u \in a \ \wedge\ F(u))]$$

for all bounded formulae $F(u)$, *Bounded Collection*

$$\forall x \in a\, \exists y\, G(x, y) \ \rightarrow\ \exists z\, \forall x \in a\, \exists y \in z\, G(x, y)$$

for all bounded formulae $G(x, y)$, and *Set Induction*

$$\forall x\ [(\forall y \in x\ H(y)) \rightarrow H(x)] \ \rightarrow\ \forall x\, H(x)$$

for all formulae $H(x)$.

A transitive set A such that $(A, \in)$ is a model of **KP** is called an *admissible set*. Of particular interest are the models of **KP** formed by segments of Gödel's *constructible hierarchy* **L**. The constructible hierarchy is obtained by iterating the definable powerset operation through the ordinals

$$\begin{aligned}
\mathbf{L}_0 &= \emptyset,\\
\mathbf{L}_\lambda &= \bigcup\{\mathbf{L}_\beta : \beta < \lambda\}\ \lambda \text{ limit}\\
\mathbf{L}_{\beta+1} &= \big\{X :\ X \subseteq \mathbf{L}_\beta;\ X \text{ definable over } \langle \mathbf{L}_\beta, \in\rangle\big\}.
\end{aligned}$$

So any element of **L** of level α is definable from elements of **L** with levels $< \alpha$ and the parameter $\mathbf{L}_\alpha$. An ordinal α is *admissible* if the structure $(\mathbf{L}_\alpha, \in)$ is a model of **KP**.

Formulae of $\mathcal{L}_2$ can be easily translated into the language of set theory. Some of the subtheories of $\mathbf{Z_2}$ considered above have set-theoretic counterparts, characterized by extensions of **KP**. **KPi** is an extension of **KP** via the axiom

$$(Lim) \quad \forall x \exists y [x \in y \ \wedge\ y \textit{ is an admissible set}].$$

KPl denotes the system **KPi** without Bounded Collection. It turns out that $(\Pi^1_1\text{-}\mathbf{AC})+\mathbf{BI}$ proves the same $\mathcal{L}_2$-formulae as **KPi**, while $(\Pi^1_1\text{-}\mathbf{CA})$ proves the same $\mathcal{L}_2$-formulae as **KPl**.

2.3. Sketches of an ordinal analysis of KP. Serving as a miniature example of an ordinal analysis of an impredicative system, the ordinal analysis of **KP** (see [20], [6]) we will sketched in broad strokes. Bachmann's system can be recast without fundamental sequences as follows: Let Ω be a "big" ordinal, e.g. $\Omega = \aleph_1$. By

recursion on α we define sets $C^{\Omega}(\alpha, \beta)$ and the ordinal $\psi_{\Omega}(\alpha)$ as follows:

$$C^{\Omega}(\alpha, \beta) = \begin{cases} \text{closure of } \beta \cup \{0, \Omega\} \text{ under:} \\ +, (\xi \mapsto \omega^{\xi}) \\ (\xi \longmapsto \psi_{\Omega}(\xi))_{\xi < \alpha} \end{cases} \tag{8}$$

$$\psi_{\Omega}(\alpha) \simeq \min\{\rho < \Omega : \ C^{\Omega}(\alpha, \rho) \cap \Omega = \rho \}. \tag{9}$$

It can be shown that $\psi_{\Omega}(\alpha)$ is always defined and that $\psi_{\Omega}(\alpha) < \Omega$. Moreover, $[\psi_{\Omega}(\alpha), \Omega) \ \cap \ C^{\Omega}(\alpha, \psi_{\Omega}(\alpha)) = \emptyset$; thus the order-type of the ordinals below Ω which belong to the set $C^{\Omega}(\alpha, \psi_{\Omega}(\alpha))$ is $\psi_{\Omega}(\alpha)$. $\psi_{\Omega}(\alpha)$ is also a countable ordinal. In more pictorial terms, $\psi_{\Omega}(\alpha)$ is the α^{th} *collapse* of Ω.

Let $\varepsilon_{\Omega+1}$ be the least ordinal $\alpha > \Omega$ such that $\omega^{\alpha} = \alpha$. The set of ordinals $C^{\Omega}(\varepsilon_{\Omega+1}, 0)$ gives rise to an elementary computable ordinal representation system. In what follows, $C^{\Omega}(\varepsilon_{\Omega+1}, 0)$ will be abbreviated to $\mathcal{T}(\Omega)$.

In the case of **PA** the addition of an infinitary rule restored the possibility of cut elimination. In order to obtain a similar result for set theories like **KP**, one has to work a bit harder. A peculiarity of **PA** is that every object n of the intended model has a canonical name in the language, namely, the n^{th} numeral. It is not clear, though, how to bestow a canonical name to each element of the set-theoretic universe. This is where *Gödel's constructible universe* **L** comes in handy. As **L** is "made" from the ordinals it is pretty obvious how to "name" sets in **L** once one has names for ordinals. These will be taken from $\mathcal{T}(\Omega)$. Henceforth, we shall restrict ourselves to ordinals from $\mathcal{T}(\Omega)$. The set terms and their ordinal levels are defined inductively. First, for each $\alpha \in \mathcal{T}(\Omega) \cap \Omega$, there will be a set term $\mathbb{L}_{\alpha}$. Its ordinal level is declared to be α. If $F(a, \vec{b})$ is a set-theoretic formula (whose free variables are among the indicated) and $\vec{s} \equiv s_1, \ldots, s_n$ are set terms with levels $< \alpha$, then the formal expression $\{x \in \mathbb{L}_{\alpha} : F(x, \vec{s})^{\mathbb{L}_{\alpha}}\}$ is a set term of level α. Here $F(x, \vec{s})^{\mathbb{L}_{\alpha}}$ results from $F(x, \vec{s})$ by restricting all unbounded quantifiers to $\mathbb{L}_{\alpha}$.

The collection of set terms will serve as a formal universe for a theory $\mathbf{KP}_{\infty}$ with infinitary rules. The infinitary rule for the universal quantifier on the right takes the form: From $\Gamma \Rightarrow \Delta, F(t)$ for all RS_{Ω}-terms t conclude $\Gamma \Rightarrow \Delta, \forall x \ F(x)$. There are also rules for bounded universal quantifiers: From $\Gamma \Rightarrow \Delta, F(t)$ for all RS_{Ω}-terms t with levels $< \alpha$ conclude $\Gamma \Rightarrow \Delta, (\forall x \in \mathbb{L}_{\alpha}) \ F(x)$. The corresponding rule for introducing a universal quantifier bounded by a term of the form $\{x \in \mathbb{L}_{\alpha} : F(x, \vec{s})^{\mathbb{L}_{\alpha}}\}$ is slightly more complicated. With the help of these infinitary rules it now possible to give logical deductions of all axioms of **KP** with the exception of Bounded Collection. The latter can be deduced from the rule of Σ-Reflection: From $\Gamma \Rightarrow \Delta, C$ conclude $\Gamma \Rightarrow \Delta, \exists z \, C^z$ for every Σ-formula C. The class of Σ-formulae is the smallest class of formulae containing the bounded formulae which is closed under $\wedge$, $\vee$, bounded quantification and unbounded existential quantification. C^z is obtained from C by replacing all unbounded quantifiers $\exists x$ in C by $\exists x \in z$.

The length and cut ranks of $\mathbf{KP}_\infty$-deductions will be measured by ordinals from $\mathcal{T}(\Omega)$. If

$$\mathbf{KP} \vdash F(u_1, \ldots, u_r)$$

then $\mathbf{KP}_\infty \vdash^{\Omega\cdot m}_{\Omega+n} B(s_1, \ldots, s_r)$ holds for some m, n and all set terms $s_1, \ldots, s_r$; m and n depend only on the **KP**-derivation of $B(\vec{u})$.

The usual cut elimination procedure works unless the cut formulae have been introduced by Σ-reflection rules. The obstacle to pushing cut elimination further is exemplified by the following scenario:

$$\dfrac{\dfrac{\vdash^{\delta}_{\Omega} \Gamma \Rightarrow \Delta, C}{\vdash^{\xi}_{\Omega} \Gamma \Rightarrow \Delta, \exists z\, C^z}(\Sigma\text{-Ref}) \qquad \dfrac{\cdots \vdash^{\xi_s}_{\Omega} \Xi, C^s \Rightarrow \Lambda \cdots (|s| < \Omega)}{\vdash^{\xi}_{\Omega} \Xi, \exists z\, C^z \Rightarrow \Lambda}(\exists L)}{\vdash^{\alpha}_{\Omega+1} \Gamma, \Xi \Rightarrow \Delta, \Lambda}(\text{Cut})$$

In general, it won't be possible to remove such an instance of the Cut Rule. However, if the complexity of the side formulae is just right, the cut can be removed by a technique called *collapsing of deductions*. This method applies when the formulae in Γ and Ξ are Π-formulae and the formulae in Δ and Λ are Σ-formulae. The class of Π-formulae is the smallest class of formulae containing the bounded formulae which is closed under $\wedge$, $\vee$, bounded quantification and unbounded universal quantification.

For the technique of collapsing one needs the function $\alpha \mapsto \psi_\Omega(\alpha)$ and, moreover, it is necessary to ensure that the infinite deductions are of a very uniform character. The details are rather finicky and took several years to work out. The upshot is that every Σ sentence C deducible in **KP** has a cut-free deduction in $\mathbf{KP}_\infty$ of length $\psi_\Omega(\varepsilon_{\Omega+1})$, which entails that $L_{\psi_\Omega(\varepsilon_{\Omega+1})} \models C$. Moreover, the proof-theoretic ordinal of **KP** is $\psi_\Omega(\varepsilon_{\Omega+1})$, also known as the *Bachmann–Howard ordinal*.

2.4. Admissible proof theory. **KP** is the weakest in a line of theories that were analyzed by proof theorists of the Munich school in the late 1970s and 1980s. In many respects, **KP** is a very special case. Several fascinating aspects of ordinal analysis do not yet exhibit themselves at the level of **KP**.

Recall that **KPl** is the set-theoretic version of $(\Pi^1_1\text{-}\mathbf{AC}) + \mathbf{BI}$, while **KPi** is the set-theoretic counterpart to $(\Pi^1_1\text{-}\mathbf{AC}) + \mathbf{BI}$. The main axiom of **KPl** says that every set is contained in an admissible set (one also says that the admissible sets are cofinal in the universe) without requiring that the universe is also admissible, too. To get a sense of scale for comparing **KP**, **KPl**, and **KPi** it is perhaps best to relate the large cardinal assumptions that give rise to the pertaining ordinal representation systems. In the case of **KPl** the assumptions is that there are infinitely many large ordinals Ω_1, Ω_2, Ω_3, ... (where Ω_n can be taken to be $\aleph_n$) each equipped with their own 'collapsing' function $\alpha \mapsto \psi_{\Omega_n}(\alpha)$. The ordinal system sufficient for **KPi** is built using the much bolder assumption that there is an inaccessible cardinal I.

As the above set theories are based on the notion of admissible set it is suitable to call the proof theory concerned with them 'admissible proof theory'. The salient

feature of admissible sets is that they are models of Bounded Collection and that that principle is equivalent to Σ Reflection on the basis of the other axioms of **KP** (see [4]). Furthermore, admissible sets of the form $\mathbf{L}_\kappa$ also satisfy Π_2 reflection, i.e., if $\mathbf{L}_\kappa \models \forall x\, \exists y\, C(x, y, \vec{a})$ with $C(x, y)$ bounded and $\vec{a} \in \mathbf{L}_\kappa$, then there exists $\rho < \kappa$ such that $\vec{a} \in \mathbf{L}_\rho$ and $\mathbf{L}_\rho \models \forall x\, \exists y\, C(x, y, \vec{a})$.

In essence, admissible proof theory is a gathering of cut-elimination and collapsing techniques that can handle infinitary calculi of set theory with Σ and/or Π_2 reflection rules, and thus lends itself to ordinal analyses of theories of the form **KP**+ *"there are x many admissibles"* or **KP**+ *"there are many admissibles"*.

A theory on the verge of admissible proof theory is **KPM**, designed to axiomatize essential features of a recursively Mahlo universe of sets. An admissible ordinal κ is said to be recursively Mahlo if it satisfies Π_2-reflection in the above sense but with the extra condition that the reflecting set $\mathbf{L}_\rho$ be admissible as well. The ordinal representation [25] for **KPM** is built on the assumption that there exists a Mahlo cardinal. The novel feature of over previous work is that there are two layers of collapsing functions. The ordinal analysis for **KPM** was carried out in [26]. A different approach to **KPM** using ordinal diagrams is due to Arai [1].

The means of admissible proof theory are too weak to deal with the next level of reflection having three alternations of quantifiers, i.e. Π_3-reflection.

2.5. Rewards of ordinal analysis Results that have been achieved through ordinal analysis mainly fall into four groups: (1) Consistency of subsystems of classical second order arithmetic and set theory relative to constructive theories, (2) reductions of theories formulated as conservation theorems, (3) combinatorial independence results, and (4) classifications of provable functions and ordinals. A detailed account of these results has been given in [31], section 3. An example where ordinal representation systems led to a new combinatorial result was Friedman's extension of Kruskal's Theorem, EKT, which asserts that finite trees are well-quasi-ordered under gap embeddability (see [39]). The gap condition imposed on the embeddings is directly related to an ordinal notation system that was used for the analysis of Π^1_1 comprehension. The principle EKT played a crucial role in the proof of the graph minor theorem of Robertson and Seymour (see [16]).

Theorem 2.1 (Robertson, Seymour). *For any infinite sequence $G_0, G_1, G_2, \ldots$ of finite graphs there exist $i < j$ so that G_i is isomorphic to a minor of G_j.*

3. Beyond admissible proof theory

Gentzen fostered hopes that with sufficiently large constructive ordinals one could establish the consistency of analysis, i.e., $\mathbf{Z_2}$. The purpose of this section is to report on the next major step in analyzing fragments of $\mathbf{Z_2}$. This is obviously the ordinal

analysis of the system (Π^1_2-**CA**).[1] The strength of (Π^1_2-**CA**) dwarfs that of (Π^1_1-**AC**). The treatment of Π^1_2 comprehension posed formidable technical challenges (see [30], [32], [33]). Other approaches to ordinal analysis of systems above Π^1_1-**AC** are due to Arai (see [1], [2]) who uses ordinal diagrams and finite deductions, and Carlson [11] who employs patterns of resemblance.

In the following, we will gradually slice Π^1_2 comprehension into degrees of reflection to achieve a sense of scale. There is no way to describe this comprehension simply in terms of admissibility except that on the set-theoretic side, Π^1_2 comprehension corresponds to Σ_1 separation, i.e. the scheme of axioms

$$\exists z(z = \{x \in a : \phi(x)\})$$

for all Σ_1 formulas ϕ. The precise relationship is as follows:

Theorem 3.1. **KP** + Σ_1 *separation and* (Π^1_2-**CA**) + **BI** *prove the same sentences of second order arithmetic.*

The ordinals κ such that $\mathbf{L}_\kappa \models$ **KP** + Σ_1-*Separation* are familiar from ordinal recursion theory.

Definition 3.2. An admissible ordinal κ is said to be *nonprojectible* if there is no total κ-recursive function mapping κ one-one into some $\beta < \kappa$, where a function $g\colon \mathbf{L}_\kappa \to \mathbf{L}_\kappa$ is called *κ-recursive* if it is Σ definable in $\mathbf{L}_\kappa$.

The key to the 'largeness' properties of nonprojectible ordinals is that for any nonprojectible ordinal κ, $\mathbf{L}_\kappa$ is a limit of Σ_1-elementary substructures, i.e. for every $\beta < \kappa$ there exists a $\beta < \rho < \kappa$ such that $\mathbf{L}_\rho$ is a Σ_1-elementary substructure of $\mathbf{L}_\kappa$, written $\mathbf{L}_\rho \prec_1 \mathbf{L}_\kappa$.

Such ordinals satisfying $\mathbf{L}_\rho \prec_1 \mathbf{L}_\kappa$ have strong reflecting properties. For instance, if $\mathbf{L}_\rho \models C$ for some set-theoretic sentence C (containing parameters from $\mathbf{L}_\rho$), then there exists a $\gamma < \rho$ such that $\mathbf{L}_\gamma \models C$. This is because $\mathbf{L}_\rho \models C$ implies $\mathbf{L}_\kappa \models \exists \gamma\, C^{\mathbf{L}_\gamma}$, hence $\mathbf{L}_\rho \models \exists \gamma\, C^{\mathbf{L}_\gamma}$ using $\mathbf{L}_\rho \prec_1 \mathbf{L}_\kappa$.

The last result makes it clear that an ordinal analysis of Π^1_2 comprehension would necessarily involve a proof-theoretic treatment of reflections beyond those surfacing in admissible proof theory. The notion of stability will be instrumental.

Definition 3.3. α is *δ-stable* if $\mathbf{L}_\alpha \prec_1 \mathbf{L}_{\alpha+\delta}$.

For our purposes we need refinements of this notion, the simplest being provided by:

Definition 3.4. $\alpha > 0$ *is said to be* *Π_n-reflecting* if $\mathbf{L}_\alpha \models \Pi_n$-reflection. By Π_n-reflection we mean the scheme $C \to \exists z[\,\mathrm{Tran}(z) \wedge z \neq \emptyset \wedge C^z]$, where C is Π_n, and $\mathrm{Tran}(z)$ expresses that z is a transitive set.

[1] For more background information see [42], p. 259, [15], p. 362, [24], p. 374.

Π_n-reflection for all n suffices to express one step in the $\prec_1$ relation.

Lemma 3.5 (cf. [34], 1.18). $\mathbf{L}_\kappa \prec_1 \mathbf{L}_{\kappa+1}$ iff κ is Π_n-reflecting for all n.

The step of analyzing Kripke–Platek set theory augmented by Π_n-reflection rules was taken in [29]; the ordinal representation system for Π_3-reflection employed a weakly compact cardinal.

A further refinement of the notion of δ-stability will be addressed next.

Definition 3.6. κ is said to be δ-Π_n-reflecting if whenever $C(u, \vec{x})$ is a set-theoretic Π_n formula, $a_1, \ldots, a_r \in \mathbf{L}_\kappa$ and $\mathbf{L}_{\kappa+\delta} \models C[\kappa, a_1, \ldots, a_n]$, then there exists $\kappa_0, \delta_0 < \kappa$ such that $a_1, \ldots, a_r \in \mathbf{L}_{\kappa_0}$ and $\mathbf{L}_{\kappa_0+\delta_0} \models C[\kappa_0, a_1, \ldots, a_n]$.

Putting the previous definition to work, one gets:

Corollary 3.7. If κ is $\delta + 1$-Σ_1-reflecting, then, for all n, κ is δ-Σ_n-reflecting.

At this point let us return to proof theory to explain the need for even further refinements of the preceding notions. Recall that the first nonprojectible ordinal ρ is a limit of smaller ordinals ρ_n such that $\mathbf{L}_{\rho_n} \prec_1 \mathbf{L}_\rho$. In the ordinal representation system $\mathcal{OR}$ for Π^1_2-**CA**, there will be symbols $\mathfrak{E}_n$ and $\mathfrak{E}_\omega$ for ρ_n and ρ, respectively. The associated infinitary proof system will have rules

$$(\mathrm{Ref}_{\Sigma(\mathbb{L}_{\mathfrak{E}_n+\delta})}) \quad \frac{\Gamma \Rightarrow \Delta, C(\vec{s})^{\mathbb{L}_{\mathfrak{E}_n+\delta}}}{\Gamma \Rightarrow \Delta, (\exists z \in \mathbb{L}_{\mathfrak{E}_n})(\exists \vec{x} \in \mathbb{L}_{\mathfrak{E}_n})[\mathrm{Tran}(z) \wedge C(\vec{x})^z]},$$

where $C(\vec{x})$ is a Σ formula, $\vec{s}$ are set terms of levels $< \mathfrak{E}_n + \delta$, and $\delta < \mathfrak{E}_\omega$. These rules suffice to bring about the embedding $\mathbf{KP} + \Sigma_1$-Separation into the infinitary proof system, but reflection rules galore will be needed to carry out cut-elimination. For example, there will be "many" ordinals $\pi, \delta \in \mathcal{OR}$ that play the role of δ-Π_{n+1}-reflecting ordinals by virtue of corresponding reflection rules in the infinitary calculus.

4. A large cardinal notion

An important part of ordinal analysis is the development of ordinal representation systems. Extensive ordinal representation systems are difficult to understand from a purely syntactical point of view, often to such an extent that it makes no sense to present an ordinal representation system without giving some kind of semantic interpretation. Large cardinals have been used quite frequently in the definition procedure of strong ordinal representation systems, and large cardinal notions have been an important source of inspiration. In the end, they can be dispensed with, but they add an intriguing twist to the relation between set theory and proof theory. The advantage of working in a strong set-theoretic context is that we can build models without getting buried under complexity considerations.

Such systems are usually generated from collapsing functions. However, from now on we prefer to call them *projection functions* since they will no longer bear any resemblance to Mostowski's collapsing function. In [33], the projection functions needed for the ordinal analysis of Π^1_2 have been construed as inverses to certain partial elementary embeddings. In this final section we shall indicate a model for the projection functions, employing rather sweeping large cardinal axioms, in that we shall presume the existence of certain cardinals, featuring a strong form of indescribability, dubbed *shrewdness*.

To be able to eliminate reflections of the type described in Definition 3.6 requires projection functions which can project intervals $[\kappa, \kappa + \delta]$ of ordinals down below κ.

Definition 4.1. Let $V = \bigcup_{\alpha \in ON} V_\alpha$ be the cumulative hierarchy of sets, i.e.

$$V_0 = \emptyset, \quad V_{\alpha+1} = \{X : X \subseteq V_\alpha\}, \quad V_\lambda = \bigcup_{\xi<\lambda} V_\xi \text{ for limit ordinals } \lambda.$$

Let $\eta > 0$. A cardinal κ is *η-shrewd* if for all $P \subseteq V_\kappa$ and every set-theoretic formula $F(v_0, v_1)$, whenever

$$V_{\kappa+\eta} \models F[P, \kappa],$$

then there exist $0 < \kappa_0, \eta_0 < \kappa$ such that

$$V_{\kappa_0+\eta_0} \models F[P \cap V_{\kappa_0}, \kappa_0].$$

κ is *shrewd* if κ is η-shrewd for every $\eta > 0$.

Let $\mathcal{F}$ be a collection of formulae. A cardinal κ is *η-$\mathcal{F}$-shrewd* if for all $P \subseteq V_\kappa$ and every $\mathcal{F}$-formula $H(v_0, v_1)$, whenever

$$V_{\kappa+\eta} \models H[P, \kappa],$$

then there exist $0 < \kappa_0, \eta_0 < \kappa$ such that

$$V_{\kappa_0+\eta_0} \models H[P \cap V_{\kappa_0}, \kappa_0].$$

We will also consider a notion of shrewdness with regard to a given class.

Let $\mathbf{U}$ be a fresh unary predicate symbol. Given a language $\mathcal{L}$ let $\mathcal{L}(\mathbf{U})$ denote its extension by $\mathbf{U}$. If $\mathcal{A}$ is a class we denote by $\langle V_\alpha; \mathcal{A}\rangle$ the structure $\langle V_\alpha; \in; \mathcal{A} \cap V_\alpha\rangle$.

For an $\mathcal{L}_{\text{set}}(\mathbf{U})$-sentence ϕ, let the meaning of "$\langle V_\alpha; \mathcal{A}\rangle \models \phi$" be determined by interpreting $\mathbf{U}(t)$ as $t \in \mathcal{A} \cap V_\alpha$.

Definition 4.2. Assume that $\mathcal{A}$ is a class. Let $\eta > 0$. A cardinal κ is *$\mathcal{A}$-η-shrewd* if for all $P \subseteq V_\kappa$ and every formula $F(v_0, v_1)$ of $\mathcal{L}_{\text{set}}(\mathbf{U})$, whenever

$$\langle V_{\kappa+\eta}; \mathcal{A}\rangle \models F[P, \kappa],$$

then there exist $0 < \kappa_0, \eta_0 < \kappa$ such that

$$\langle V_{\kappa_0+\eta_0}; \mathcal{A}\rangle \models F[P \cap V_{\kappa_0}, \kappa_0].$$

κ is $\mathcal{A}$-*shrewd* if κ is $\mathcal{A}$-η-shrewd for every $\eta > 0$.

Likewise, for $\mathcal{F}$ a collection of formulae in a language $\mathcal{L}(\mathbf{U})$, we say that a cardinal κ is $\mathcal{A}$-η-$\mathcal{F}$-*shrewd* if for all $P \subseteq V_\kappa$ and every $\mathcal{F}$-formula $H(v_0, v_1)$, whenever

$$\langle V_{\kappa+\eta}; \mathcal{A}\rangle \models H[P, \kappa],$$

then there exist $0 < \kappa_0, \eta_0 < \kappa$ such that

$$\langle V_{\kappa_0+\eta_0}; \mathcal{A}\rangle \models H[P \cap V_{\kappa_0}, \kappa_0].$$

Corollary 4.3. If κ is $\mathcal{A}$-δ-shrewd and $0 < \eta < \delta$, then κ is $\mathcal{A}$-η-shrewd.

There are similarities between the notions of η-shrewdness and η-indescribability (see [12], Ch. 9, §4). However, it should be noted that if κ is η-indescribable and $\rho < \eta$, it does not necessarily follow that κ is also ρ-indescribable (see [12], 9.4.6).

A reason for calling the above cardinals *shrewd* is that if there is a shrewd cardinal κ in the universe, then, loosely speaking, for any notion of large cardinal N which does not make reference to the totality of all ordinals, if there exists an N-cardinal then the least such cardinal is below κ. So for instance, if there are measurable and shrewd cardinals in the universe, then the least measurable is smaller than the least shrewd cardinal.

To situate the notion of shrewdness with regard to consistency strength in the usual hierarchy of large cardinals, we recall the notion of a subtle cardinal.

Definition 4.4. A cardinal κ is said to be *subtle* if for any sequence $\langle S_\alpha : \alpha < \kappa\rangle$ such that $S_\alpha \subseteq \alpha$ and C closed and unbounded in κ, there are $\beta < \delta$ both in C satisfying

$$S_\delta \cap \beta = S_\beta.$$

Since subtle cardinals are not covered in many of the standard texts dealing with large cardinals, we mention the following facts (see [22], §20):

Remark 4.5. Let $\kappa(\omega)$ denote the first ω-Erdös cardinal.

(i) $\{\pi < \kappa(\omega) : \pi \text{ is subtle}\}$ is stationary in $\kappa(\omega)$.

(ii) 'Subtlety' relativises to $\mathbf{L}$, i.e. if π is subtle, then $\mathbf{L} \models$ "π is subtle".

Lemma 4.6. Assume that π is a subtle cardinal and that $\mathcal{A} \subseteq V_\pi$. Then for every $B \subseteq \pi$ closed and unbounded in π there exists $\kappa \in B$ such that

$$\langle V_\pi; \mathcal{A}\rangle \models \text{"}\kappa \text{ is } \mathcal{A}\text{-shrewd"}.$$

Corollary 4.7. Assume that π is a subtle cardinal. Then there exists a cardinal $\kappa < \pi$ such that κ is η-shrewd for all $\eta < \pi$.

Analytic difference rings

Thomas Scanlon*

Abstract. Generalizing and synthesizing earlier work on the model theory of valued difference fields and on the model theory of valued fields with analytic structure, we prove Ax–Kochen–Eršov style relative completeness and relative quantifier elimination theorems for a theory of valuation rings with analytic and difference structure. Specializing our results to the case of $W[\mathbb{F}_p^{\mathrm{alg}}]$, the ring of Witt vectors of the algebraic closure of the field with p elements, given together with the relative Frobenius and the Tate algebras as analytic structure, we develop a model theoretic account of Buium's p-differential functions. In so doing, we derive a uniform p-adic version of the Manin–Mumford conjecture.

Mathematics Subject Classification (2000). Primary 03C10, 03C60, 12J10; Secondary 11D45, 11G10, 12H10, 13K05.

Keywords. Ax–Kochen–Eršov principle, difference ring, p-differential function, Witt vectors, abelian varieties, Manin–Mumford conjecture.

1. Introduction

If (K, v) is a complete valued field and $f(x_1, \ldots, x_n) = \sum a_\alpha x^\alpha \in K[[x_1, \ldots, x_n]]$ is a formal power series over K for which $v(a_\alpha) \to \infty$ as $|\alpha| \to \infty$, then f defines a function $\mathcal{O}_K^n \to K$. Considering a formal first-order language rich enough to express the field structure, the binary relation $v(x) \leq v(y)$ and the functions coming from such convergent power series, one has a natural logical setting for studying nonarchimedian analysis. If one includes in addition a unary function symbol σ to denote a field automorphism which respects the valuation in the sense that $v(x) = v(\sigma(x))$ universally and respects the analytic structure in the sense that $\sigma(f(x)) = f^\sigma(\sigma(x))$ where f^σ denotes the effect of applying σ to the coefficients of f, then one has a strong enough language to study analytic difference rings, the central object of consideration in this paper.

While we have several motivations to study these structures, two stand out most prominently. First, following the seminal work of Ax and Kochen [1], [2], [3] and Eršov on the model theory of valued fields, a great many results showing that valued fields considered in ever more complicated languages have very elegant theories have been proven. With this work we amalgamate two different strands of the model theory of enriched valued fields. Namely, we show that the theories of valued fields with analytic structure and of valued difference fields may be unified. Further unification is

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

certainly possible. Routine modifications of the proofs presented here should suffice to combine analytic and differential structure, or more generally D-structure, while other extensions will require the development of genuinely new methods. Secondly, we wish to give a model theoretic account of Buium's theory of p-differential geometry and thereby deduce uniformities in Diophantine geometry through applications of the compactness theorem and appropriate quantifier elimination theorems.

Let us recall a little of the theory of p-differential operators. For p a prime number a p-derivation δ on a commutative ring R is a function $\delta\colon R \to R$ satisfying

- $\delta(1) = 0$,
- the functional equation $\delta(x+y) = \delta(x) + \delta(y) + \Phi_p(x, y)$ where $\Phi_p(X, Y) \in \mathbb{Z}[X, Y]$ is the integral polynomial $\frac{1}{p}(X^p + Y^p - (X+Y)^p)$, and
- the functional equation $\delta(xy) = y^p\delta(x) + x^p\delta(y) + p\delta(x)\delta(y)$.

Given a p-derivation $\delta\colon R \to R$ one can define a ring endomorphism $\sigma\colon R \to R$ by the equation $\sigma(x) := x^p + p\delta(x)$. Conversely, if p is not a zero divisor in R and $\tau\colon R \to R$ is an endomorphism lifting the Frobenius in the sense that $\tau(x) \equiv x^p \pmod{p}$ for all $x \in R$, then $\tilde{\delta}\colon R \to R$ defined by $\tau(x) = x^p + p\tilde{\delta}(x)$ is a p-derivation.

As with differential algebra, there is a p-differential geometry associated to the category of rings with p-derivations. At the naïve level, one can consider sets defined by the vanishing of p-differential polynomials, expressions of the form $P(\boldsymbol{x}, \ldots, \delta^n(\boldsymbol{x}))$ where P is a polynomial, as the basic affine sets. In the case that the underlying rings are domains, this p-differential geometry is essentially the same as the corresponding difference algebraic geometry coming from difference equations involving σ and there is already a well developed model theoretic approach to this subject [7], [8]. However, a richer geometry more in line with that of Kolchin's differential algebraic geometry may be obtained by p-adically completing the rings of p-differential polynomials. Indeed, Buium notes that to globalize p-differential geometry one must consider these p-adically complete rings of operators. The fundamental functions in this theory, the p-differential functions, locally have the form $F(\boldsymbol{x}, \ldots, \delta^n\boldsymbol{x})$ where $\boldsymbol{x} = (x_1, \ldots, x_m)$ and F is given by p-adically convergent power series in $(n+1)m$ variables. Buium shows that many arithmetically interesting functions on the $R := W[\mathbb{F}_p^{\mathrm{alg}}]$-rational points of schemes over R may be expressed locally as p-differential functions where one takes $\delta := \frac{1}{p}(x^p - \sigma(x))$ with $\sigma\colon R \to R$ the Witt–Frobenius, the unique lifting of the Frobenius automorphism to an automorphism of the Witt vectors.

One sees from the above local description of p-differential functions, that every p-differential function over R may be expressed as a term in the language with function symbols for p-adically convergent power series over R, the Witt–Frobenius, and the restricted division function $D_p\colon R \to R$ defined by $D_p(x) := \frac{x}{p}$ if $x \in pR$ and $D_p(x) := 0$ otherwise. Conversely, if one were to regard all p-differential functions as definable, then all of the above basic functions would be definable as

well. Consequently, the logic of Buium's p-differential functions is that of the first-order structure of the Witt vectors of the algebraic closure of the field of p elements with a function symbol for the Witt–Frobenius and for all p-adic analytic functions.

Even though the goal of understanding p-differential functions guides our work, we must consider structures of a more abstract nature in order to prove our results sufficiently uniformly in order to derive any useful information about p-differential geometry. We achieve these results by axiomatizing the notion of an analytic difference structure on a valued field and then proving relative completeness and relative quantifier elimination theorems for analytic difference rings in the style of the Ax–Kochen–Eršov theorems for pure valued fields.

The essential tool in our analysis is a uniform version of the Weierstraß division theorem. Fortunately for us, this theorem is already known in the case of most interest to us [20]. Using the uniform Weierstraß division theorem we are able to assign an order-degree to an analytic difference equation with respect to which we may carry out inductive proofs.

The present author previously considered the ring $W[\mathbb{F}_p^{\mathrm{alg}}]$ simply as a difference ring in [17], [5] where a simple axiomatization was presented and a quantifier simplification theorem was proven. However, since difference polynomials are intrinsically finitistic objects, we were able to consider more complicated degree relations and worked with a version of Hensel's lemma unavailable in the analytic difference context. The restrictions imposed by considering simultaneously analytic and difference structure have forced us to employ an ostensibly weaker form of Hensel's lemma which miraculously suffices.

This paper is organized as follows. In Section 2 we introduce our basic axioms for analytic difference rings and establish some of the fundamental results about these structures. In Section 3 we state and prove our Ax–Kochen–Eršov theorems for analytically difference henselian rings. In Section 4 we recall the theory of p-differential functions in detail and apply our results of Section 3 to prove a uniform version of the Manin–Mumford conjecture.

2. Foundations of analytic and difference structure

We begin this section by recalling that a *difference ring* (R, σ) is a commutative (unital) ring R given together with a distinguished ring endomorphism $\sigma : R \to R$. While we shall usually consider rings for which σ is an automorphism, we do not insist upon this condition in our definition of the term difference ring. The model theory of difference fields, namely fields given together with a distinguished endomorphism, and, hence, also of difference domains, has been described by Chatzidakis and Hrushovski [7] and in all characteristics by Chatzidakis, Hrushovski, and Peterzil [8].

For us, a valued difference field is a valued field (K, v) given together with a distinguished automorphism $\sigma : K \to K$ which respects the valuation in the sense

that the equality $v(\sigma(x)) = v(x)$ holds universally. The model theory of valued difference fields has been developed by Bélair, Macintyre and Scanlon [17], [5].

As mentioned in the introduction, an analytic difference ring is simply the ring of integers of a valued difference field given together with analytic functions for which the distinguished automorphism respects the analytic structure. For a *fixed* complete valuation ring it is easy enough to say what one means by analytic structure. However, if one wishes to express the axioms for the theory of such a ring in a first-order language, it is necessary to formulate "analytic structure" more abstractly. Moreover, even if one is only interested in complete rings, to compare the theories of these rings as analytic structures one requires a uniform language.

We adapt van den Dries' treatment of analytic Ax–Kochen–Eršov theorems [19] and its refinements by van den Dries, Haskell, Macpherson, Lipshitz and Robinson [20], [15] to the valued difference field setting. While we could restrict our attention to such rings of analytic functions as $\mathbb{Z}[[t]]\langle X_1, \ldots, X_n\rangle$ or $W[\mathbb{F}_p^{\mathrm{alg}}]\langle X_1, \ldots, X_n\rangle$ without sacrificing the examples of greatest interest, we work with potentially more general rings in order to separate the work on the model theory of analytic functions from difference algebra.

Definition 2.1. A *pre-notion of analyticity*, $\mathcal{A}$, is given by the data of a commutative ring R and a doubly-indexed sequence of subrings $\mathcal{A}_{m,n} \subseteq R[\boldsymbol{X}][[\boldsymbol{Y}]]$ of the ring of formal power series in the n variables $\boldsymbol{Y} = (Y_1, \ldots, Y_n)$ over the polynomial ring in the m variables $\boldsymbol{X} = (X_1, \ldots, X_m)$ over R for which

1. $\mathcal{A}_{0,0} = R$,
2. if $m \leq m'$ and $n \leq n'$, then $\mathcal{A}_{m,n}$ is a subring of $\mathcal{A}_{m',n'}$ via the natural inclusion, and
3. $\mathcal{A}$ is closed under compositions as far as this makes sense.

Definition 2.2. Given a pre-notion of analyticity $\mathcal{A}$, an $\mathcal{A}$-analytic structure on a valuation ring $\mathcal{O}$ with maximal ideal $\mathfrak{m}$ is given by a sequence of homomorphisms $I_{m,n}\colon \mathcal{A}_{m,n} \to \mathrm{Functions}(\mathcal{O}^m \times \mathfrak{m}^n, \mathcal{O})$ which respect the compositional identities in $\mathcal{A}$, the identities coming from the inclusions $\mathcal{A}_{m,n} \hookrightarrow \mathcal{A}_{m',n'}$, and send the variables X_i and Y_i to the obvious projection maps.

Remark 2.3. If R itself is a complete valuation ring and $\mathcal{A}_{m,n} = R[\boldsymbol{X}][[\boldsymbol{Y}]]$, then the usual interpretation of the elements of $\mathcal{A}_{m,n}$ gives R an $\mathcal{A}$-analytic structure.

Remark 2.4. In the definition of $\mathcal{A}$-analytic structure, it is not really necessary that $\mathcal{O}$ be a valuation ring and $\mathfrak{m}$ its maximal ideal. However, this is the only case we consider in our applications.

Remark 2.5. Given a pre-notion of analyticity $\mathcal{A}$ and $\mathcal{L}$ a first-order language for valued fields containing (at least) a sort symbol $\mathcal{O}$ for the valuation ring and a sort symbol $\mathfrak{m}$ for the maximal ideal of the valuation ring we may naturally expand $\mathcal{L}$ to $\mathcal{L}(\mathcal{A})$ by new function symbols where for each $f \in \mathcal{A}_{m,n}$ we have a function

symbol, also denoted f, of domain sort $\mathcal{O}^m \times \mathfrak{m}^n$ and range sort $\mathcal{O}$. The condition that a particular interpretation of $\mathcal{A}$ on a valuation ring defines an $\mathcal{A}$-analytic structure may be expressed as a first-order theory in $\mathcal{L}(\mathcal{A})$.

Before we can give our conditions on when a pre-notion of analyticity is actually a notion of analyticity, we must recall some of the basic formalism of quotient operators on valuation rings and leading term structures. In what follows, we use the symbol $\mathcal{Q}$ for our quotient operators even though "D" is more common in the literature.

Definition 2.6. Let (K, v) be a valued field with valuation ring $\mathcal{O} := \mathcal{O}_{K,v}$ having the maximal ideal $\mathfrak{m} := \mathfrak{m}_{K,v}$. We define two operators $\mathcal{Q}_0$ and $\mathcal{Q}_1$ on $\mathcal{O}^2$ by $\mathcal{Q}_0(x, y) := \frac{x}{y}$ if $v(x) \geq v(y) \neq \infty$ and $\mathcal{Q}_0(x, y) = 0$ otherwise while $\mathcal{Q}_1(x, y) := \frac{x}{y}$ if $v(x) > v(y)$ and is zero otherwise.

Remark 2.7. As shown in the work of Denef and van den Dries [9] and Lipshitz and Robinson [15], for example, quantifier elimination for certain valuation rings considered with analytic structure may be obtained in languages possessing $\mathcal{Q}_0$ and $\mathcal{Q}_1$ as primitives, but not without these operators.

Definition 2.8. Given a pre-notion of analyticity $\mathcal{A}$ and a first-order language of valuation rings $\mathcal{L}$ as in Remark 2.5, the language $\mathcal{L}^{\mathcal{Q}}(\mathcal{A})$ is the expansion of $\mathcal{L}(\mathcal{A})$ by the function symbol $\mathcal{Q}_0$ and $\mathcal{Q}_1$ of domain sort $\mathcal{O}^2$ and range sorts $\mathcal{O}$ and $\mathfrak{m}$, respectively. Given a valuation ring with $\mathcal{A}$-analytic structure there is a natural expansion of the structure to an $\mathcal{L}^{\mathcal{Q}}(\mathcal{A})$-structure.

We recall now the formalism of leading terms and angular components.

Definition 2.9. Let (K, v) be a valued field and $t \in \mathcal{O} = \mathcal{O}_{K,v}$ be a fixed nonzero element of the ring integers of K. For each natural number n, we define the n^{th} leading terms of K relative to K to be the multiplicative monoid $\ell_{n,t}(K) := K/(1 + t^n\mathfrak{m})$. We write $\ell_{n,t}(K)^* := \ell_{n,t}(K) \smallsetminus \{0\}$. We write $r_{n,t}(K) := \mathcal{O}/t^n\mathfrak{m}$. If t is understood we write simply $\ell_n(K)$ for $\ell_{n,t}(K)$ and $r_n(K)$ for $r_{n,t}(K)$ We write $\ell_n \colon K \to \ell_n(K)$ for the natural quotient map and $\pi_n \colon \mathcal{O} \to r_n(K)$ for the reduction map.

Remark 2.10. While $\ell_n(K)^*$ is naturally a group, it carries additional structure. For instance, the valuation map $v \colon K \to \Gamma_K \cup \{\infty\}$ descends to a map on $\ell_n(K)$ which we continue to denote by v. More importantly, addition leaves a trace on $\ell_n(K)$ in the form of a ternary predicate $\tilde{+}_n := \{(x, y, z) \in \ell_n(K)^3 \mid \exists \tilde{x}, \tilde{y}, \tilde{z} \in K\ \tilde{x} + \tilde{y} = \tilde{z}, \ell_n(\tilde{x}) = x, \ell_n(\tilde{y}) = y, \text{ and } \ell_n(\tilde{z}) = z\}$. In the sequel we shall require that $\ell_n(K)$ remember more structure from K. In particular, we insist that the leading terms remember analytic identities. That is, for each $\mathcal{L}^{\mathcal{Q}}(\mathcal{A})$-term $f(x_1, \ldots, x_m)$ the image of $\{(x_1, \ldots, x_m, y) \in K^{m+1} \mid f(\boldsymbol{x}) = y\}$ under ℓ_n is to be described by an m-ary predicate on ℓ_n.

Remark 2.11. The image of $\mathcal{O}^\times$ in $\ell_n(K)$ may be identified with $r_n(K)^\times$ and the valuation exact sequence $1 \longrightarrow \mathcal{O}^\times \longrightarrow K^\times \xrightarrow{v} \Gamma_K \longrightarrow 0$ descends to $1 \longrightarrow r_n(K)^\times \longrightarrow \ell_n(K)^* \xrightarrow{v} \Gamma_K \longrightarrow 0$.

Remark 2.12. If $t \in \mathcal{O}^\times$ is a unit, then the leading term structures $\ell_{n,t}(K)$ are all identical.

Remark 2.13. In our intended applications we take $t = p$, the residue characteristic, or $t = 1$ when the residue characteristic is zero. In fact, we shall impose this requirement with our axioms.

Remark 2.14. One can consider leading term structures relative to other ideals in $\mathcal{O}_K$ and we shall use $\ell_\infty(K) := K/(1+t^\infty\mathfrak{m})$ where $t^\infty\mathfrak{m} := \{x \in \mathcal{O} \mid (\forall n \in \mathbb{Z}_+)v(x) > v(t^n)\}$. One cannot access $\ell_\infty(K)$ directly in first-order logic, but when the field K is $\aleph_1$-compact, $\ell_\infty(K) = \varprojlim \ell_n(K)$ so that it may be approached from first-order data. Note that the ring $\mathcal{O}(K)\left[\frac{1}{t}\right]$ is a valuation ring whose residue field is $r_\infty(K)\left[\frac{1}{\pi_\infty(t)}\right]$. We refer to the corresponding coarsened valuation as v_∞.

Remark 2.15. In the work of Basarab and Kuhlmann [4], [14], leading term structures are called "additive-multiplicative congruences" or "amc structures."

Leading term structures already live definably in valued fields, but the way in which they nontrivially combine the value group and certain residue rings can complicate their analysis. By working with angular component functions one can treat these parts separately.

Definition 2.16. An *angular component function of level n* is a section $\mathrm{ac}_n : \ell_n(K)^* \to r_n(K)^\times$ of the valuation sequence. A *system of angular component functions* is a sequence $\{\mathrm{ac}_n\}_{n=0}^\infty$ where ac_n is an angular component function of level n and these functions commute with the obvious quotient maps between the leading term and residue sorts.

Remark 2.17. As with the leading terms, we shall require that the angular component functions preserve more than just the multiplicative structure.

Remark 2.18. While angular components need not exist in general, they do if (K, v) is sufficiently saturated. Thus, possibly at the cost of replacing (K, v) with an elementarily equivalent structure, we may assume that we have angular component functions.

Let us now fix once and for all a background language $\mathcal{L}$ and theory of valued fields, T_{VF}. We take $\mathcal{L}$ to be a many sorted language having sort symbols VF for the valued field itself, $\mathcal{O}$ for the valuation ring, $\mathfrak{m}$ for the maximal ideal of the valuation ring, Γ for the value group, r_n for the residue rings of Definition 2.9 and $r_n^\times$ for the units in the residue ring, and ℓ_n for the leading terms. The sorts are connected by the inclusion maps $\mathfrak{m} \hookrightarrow \mathcal{O} \hookrightarrow \mathrm{VF}$, $r_n^\times \hookrightarrow r_n$ and $r_n^\times \hookrightarrow \ell_n$, the valuation maps $v\colon \mathrm{VF} \to \Gamma$ and $v\colon \ell_n \to \Gamma$, the reduction maps $\pi_n\colon \mathcal{O} \to r_n$ and $\pi_{m,n}\colon r_m \to r_n$, and the leading term maps $\ell_n\colon \mathrm{VF} \to \ell_n$ and $\ell_{m,n}\colon \ell_m \to \ell_n$. The sorts VF, $\mathcal{O}$, and r_n come equipped with a copy of the language of rings while Γ is presented in the language of ordered abelian groups and the ℓ_n sorts each have a binary multiplication

operation and a ternary predicate for addition as described above. If we wish to include angular component functions, then expand the language to $\mathcal{L}(\{\mathrm{ac}_n\})$.

We axiomatize the theory of valued fields, T_{VF}, in $\mathcal{L}$ with the usual axioms asserting that if $M \models T$, then $\mathrm{VF}(M)$ is a field and that $v\colon \mathrm{VF}(M) \to \Gamma(M)$ is a valuation, and that all of the other sorts are interpreted as expected. That is, the inclusion maps $\mathfrak{m}(M) \hookrightarrow \mathcal{O}(M) \hookrightarrow \mathrm{VF}(M)$ are really inclusions and identify their images with the elements of positive valuation and of nonnegative valuation, respectively, the valuation maps are surjective, and the residue ring sorts and leading term sorts really give the residue rings and leading terms, *et cetera*. The one nontrivial point here is that we require $\ell_n(M)$ to be $\mathrm{VF}(M)/(1+\mathfrak{m}(M))$ ($r_n(M)$ to be $\mathcal{O}(M)/\mathfrak{m}(M)$, respectively) if the residue characteristic is zero and to be $\mathrm{VF}(M)/(1+p^n\mathfrak{m}(M))$ ($\mathcal{O}(M)/p^n\mathfrak{m}(M)$, respectively) when the residue characteristic is $p > 0$. This condition may be expressed by a set of first-order sentences. Of course, if we work in $\mathcal{L}(\{\mathrm{ac}_n\})$, then our theory $T_{\mathrm{VF}}(\mathrm{ac})$ expresses that the angular component function symbols are interpreted as angular components.

When we expand to $\mathcal{L}^{\mathcal{Q}}$ our theory $T_{\mathrm{VF}}^{\mathcal{Q}}$ includes axioms expressing the definitions of $\mathcal{Q}_0$ and $\mathcal{Q}_1$. Given a pre-notion of analyticity $\mathcal{A}$, we require of the expanded language $\mathcal{L}(\mathcal{A})$ not only that there be function symbols for the elements on $\mathcal{A}$ but that there be predicates on the leading term sorts corresponding to these functions. Given any $\mathcal{L}$-theory $T \supseteq T_{\mathrm{VF}}$ of valued fields, the theory $T(\mathcal{A})$ is obtained from T by adjoining the axioms expressing that the valuation ring has $\mathcal{A}$-analytic structure and that the new predicates on the leading terms are interpreted correctly.

Remark 2.19. For the main theorems of this paper we require that the valued fields under consideration have characteristic zero.

We need to say a little about affinoids before finishing the definition of a notion of analyticity. If $M \models T_{\mathrm{VF}}(\mathcal{A})$ is a valuation ring with $\mathcal{A}$-analytic structure and (K', v') is an algebraic extension of $\mathrm{VF}(M)$ with an extension of the valuation v, then there is a unique way to extend the $\mathcal{A}$-analytic structure to K'. Indeed, it is enough to see this in the case that K' is a finite extension of $\mathrm{VF}(M)$. Fixing a basis for $\mathcal{O}(K')$ over $\mathcal{O}(M)$, one can identify $\mathcal{O}(K')$ with $\mathcal{O}(M)^{[K:\mathrm{VF}(M)]}$. In so doing, one can expand the action of the $\mathcal{A}$-analytic functions in terms of this basis as well. In particular, if $K' = \mathrm{VF}(M)^{\mathrm{alg}}$ is the algebraic closure of $\mathrm{VF}(M)$, then $(K', v) \models T_{\mathrm{VF}}(\mathcal{A})$.

Definition 2.20. Let $M \models T_{\mathrm{VF}}(\mathcal{A})$ be a valuation ring with $\mathcal{A}$-analytic structure and fix an extension v' of v to $K' := \mathrm{VF}(M)^{\mathrm{alg}}$. A S subset of $\mathcal{O}(K')$ is said to be an *affinoid over* M if there are $\gamma_1, \ldots, \gamma_n \in \Gamma(M)$ and $a_1, \ldots, a_n \in \mathcal{O}(M)$ with $\gamma_1 > \gamma_i$ for $i \neq 1$ and $S = \{z \in \mathcal{O}(K') \mid v(z-a_1) \geq \gamma_1 \ \wedge \ \bigwedge_{i=2}^{n} v(z-a_i) \leq \gamma_i\}$. An affinoid set in M is the intersection of an affinoid set over M with $\mathcal{O}(M)$.

With the background on valued fields in place we are now ready to describe when a pre-notion of analyticity is actually a notion of analyticity.

Definition 2.21. Fix some theory $T \supseteq T_{\mathrm{VF}}$ of valued fields. A *notion of analyticity* (*relative to* T) is a pre-notion of analyticity, $\mathcal{A}$, for which Weierstraß division holds uniformly in the following sense. If $M \models T(\mathcal{A})$ and $t(x)$ is an $\mathcal{L}^{\mathcal{Q}}(\mathcal{A})_M$-term in the single $\mathcal{O}$-variable x, then there are finitely many affinoid subsets $F_1, \ldots, F_n$ of $\mathcal{O}(M)$ for which $\mathcal{O}(M) = \bigcup F_i$ and for each i there is a rational function $R_i(X)$ over $\mathcal{O}(M)$ having no poles in F_i and $\mathcal{L}(\mathcal{A})_M$-terms $E_i(x)$ and $E_i^{-1}(x)$ for which $E_i(x)E_i^{-1}(x) \equiv 1$ on F_i and $t(x) = E_i(x)R_i(x)$ at all but finitely many points of F_i.

Remark 2.22. That the rings of convergent power series over complete DVRs give a notion of analyticity is proven by van den Dries, Haskell and Macpherson in [20]. (Combine Proposition 4.1 with Corollary 3.4 noting that Proposition 4.1 is still general even though it is in Section 4 where the authors claim to specialize to the case of the p-adics.)

Remark 2.23. In our applications, we restrict attention to valued fields of characteristic zero. Thus, the theory T in Definition 2.21 will be T_{VF} together with the set of sentences asserting that the valued field itself has characteristic zero.

Remark 2.24. The condition of uniform Weierstraß division may be expressed more syntactically in that the parameters for the term $t(x)$ may be given as a tuple of variables $\boldsymbol{y}$ and then the affinoids, the rational functions, and the units $E(x)$ vary uniformly with $\boldsymbol{y}$.

If R is any ring and $\sigma : R \to R$ is an automorphism, then σ extends to an automorphism $\sigma : R[\boldsymbol{X}][[\boldsymbol{Y}]] \to R[\boldsymbol{X}][[\boldsymbol{Y}]]$ of the power series ring over the polynomial ring over R. For $f \in R[\boldsymbol{X}][[\boldsymbol{Y}]]$ we write the f^{σ} for the result of applying σ to f.

Definition 2.25. A *notion of difference analyticity* (relative to T as in Definition 2.21), $(\mathcal{A}, \sigma)$, is given by a notion of analyticity $\mathcal{A}$ and an automorphism $\sigma : \mathcal{A}_{0,0} \to \mathcal{A}_{0,0}$ which induces an automorphism on each $\mathcal{A}_{m,n}$.

Definition 2.26. Given a notion of difference analyticity $(\mathcal{A}, \sigma)$ (relative to T), an $\mathcal{A}$-analytic difference ring is a model $M \models T(\mathcal{A})$ given together with a distinguished automorphism $\sigma : M \to M$ which preserves the valuation in the sense that $v(\sigma(x)) = v(x)$ universally and respects the $\mathcal{A}$-analytic structure in the sense that $\sigma(f(\boldsymbol{x})) = f^{\sigma}(\sigma(\boldsymbol{x}))$ for any $\mathcal{A}$-function f.

The condition of being an $\mathcal{A}$-analytic difference ring is clearly axiomatizable in $\mathcal{L}(\mathcal{A}, \sigma)$, the expansion of the language of valuation rings with $\mathcal{A}$-analytic structure by a symbol for an automorphism.

As in the study of difference algebra, terms in $\mathcal{L}^{\mathcal{Q}}(\mathcal{A}, \sigma)$ may be expressed using terms from $\mathcal{L}^{\mathcal{Q}}(\mathcal{A})$ applied to prolongations, sequences of the form $\boldsymbol{\sigma}(\boldsymbol{x}) = (\boldsymbol{x}, \sigma(\boldsymbol{x}), \ldots, \sigma^n(\boldsymbol{x}))$. That is, if $t = t(\boldsymbol{x}) = t(x_1, \ldots, x_m)$ is an $\mathcal{L}^{\mathcal{Q}}(\mathcal{A}, \sigma)$ term, then we can find an $\mathcal{L}^{\mathcal{Q}}(\mathcal{A})$ term $\tilde{t} = \tilde{t}(x_{0,1}, \ldots, x_{0,m}; \ldots; x_{n,1}, \ldots, x_{n,m})$ so that relative to the theory of $\mathcal{A}$-analytic difference rings we have $t(\boldsymbol{x}) = \tilde{t}(\boldsymbol{\sigma}(\boldsymbol{x}))$. We define the *order* of t to be the least m for which such a $\tilde{t}$ exists. It should be noted that

the order of t when computed in a fixed $\mathcal{A}$-analytic difference ring may be different from the order when computed relative to the theory of $\mathcal{A}$-analytic difference rings. In our applications, when we speak of *order* we mean *order relative to a given structure*.

Fix an $\mathcal{A}$-analytic difference ring M and $A \subseteq M$ a substructure for which $\mathcal{O}(A)$ generates A. If $a \in \mathcal{O}(M)$ and for some $\mathcal{L}^{\mathcal{Q}}(\mathcal{A}, \sigma)_A$ term $t(x)$ over A we have $t(a) = 0$ but $t(x) \not\equiv 0$ in a neighborhood of a, then we can find such a term of minimal possible order, n, and define the *order of a over A*, $\operatorname{ord}(a/A)$, to be that minimal order. By the uniform Weierstraß division theorem, we may write $t(x)$ as $E(\sigma^n(x))R(\sigma^n(x))$ where R is a rational function over the $\mathcal{L}^{\mathcal{Q}}(\mathcal{A})$-structure A' generated by A and $a, \ldots, \sigma^{n-1}(a)$ having no poles near $\sigma^n(a)$ and E is an $\mathcal{L}(\mathcal{A})$ term over A' which is a unit near $\sigma^n(a)$. Thus, there is actually a nonzero polynomial over A' which vanishes at $\sigma^n(a)$. We define the *degree of a over A*, $\deg(a/A)$, to be the minimal degree, d, of such a polynomial. We combine these data in the pair $(\operatorname{ord}, \deg)(a/A) := (\operatorname{ord}(a/A), \deg(a/A))$ and order them lexicographically.

As with pure valued fields and some theories of valued fields with additional structure, the model companions of theories of $\mathcal{A}$-analytic difference rings are obtained by adjoining variants of Hensel's lemma (and an axiom about the existence of constants) to the theory. Unfortunately, the usual proof of Hensel's lemma breaks down when applied to $\mathcal{L}^{\mathcal{Q}}(\mathcal{A}, \sigma)$ terms as the quotient operators may introduce discontinuities. However, these terms do define generically continuous functions and if one stays within the correct domain of continuity, Newton approximation techniques do work.

Proposition 2.27. *Suppose that M is an $\mathcal{A}$-analytic difference ring and let $p_0, \ldots, p_d$ be a finite sequence of $\mathcal{L}^{\mathcal{Q}}(\mathcal{A})_M$ terms with parameters from M and variables $x_0, \ldots, x_{n-1}$. Write $P(x) = \sum_{i=0}^{d} p_i(\boldsymbol{\sigma}(x))(\sigma^n(x))^i$. Abusing notation, we write $P'(x) = \sum i p_i(\boldsymbol{\sigma}(x))(\sigma^n(x))^{i-1}$. Assume that $a \in \mathcal{O}(M)$ with $v(P(a)) > 2v(P'(a))$ and that for any $\varepsilon \in \mathcal{O}(M)$ with $v(\varepsilon) \geq v(P(a)) - v(P'(a))$ one has $\ell_0(p_i(a+\varepsilon)) = \ell_0(p_i(a))$ for $i \leq d$. Then there is some $b \in \mathcal{O}(M)$ with $v(b-a) \geq v(P(a)) - v(P'(a))$ and $v(P(b)) > v(P(a))$.*

Proof. A variant of the usual proof applies. Indeed, let $\eta := \sigma^{-n}(\mathcal{Q}_0(-P(a), P'(a)))$ and set $b := a + \eta$. From our hypotheses, $v(a-b) = v(P(a)) - v(P'(a))$ and computing $P(b)$ we have

$$\begin{aligned} P(b) &= \sum p_i(a+\eta)(\sigma^n(a+\eta))^i \\ &= \sum_{i=0}^{d} p_i(a)[1+\xi_i] \sum_{j=0}^{i} \binom{i}{j} \sigma^n(a)^{i-j} \sigma^n(\eta)^j \quad \text{where } v(\xi_i) > 0 \\ &\equiv P(a) + P'(a)\sigma^n(\eta) \pmod{P(a)\mathfrak{m}(M)} \\ &\equiv 0 \pmod{P(a)\mathfrak{m}(M)} \end{aligned}$$

□

Corollary 2.28. *With the hypotheses as in Proposition 2.27, there is a maximal pseudoconvergent sequence $\{b_\alpha\}$ from $\mathcal{O}(M)$ with $b_0 = a$ and $v(P(b_\alpha))$ increasing*

with α. If in addition $\mathcal{O}(M)$ is maximally complete, then $b := \lim b_\alpha$ exists and $P(b) = 0$.

We convert the last part of this corollary into our version of henselianity for $\mathcal{A}$-analytic difference rings.

Definition 2.29. We say that the $\mathcal{A}$-analytic difference ring M is $\mathcal{A}$-analytically difference henselian if the conclusion of Corollary 2.28 holds for M. That is, given a sequence of $\mathcal{L}^{\mathcal{Q}}(\mathcal{A})_M$ terms $p_0, \ldots, p_d$ with variables $x_0, \ldots, x_{n-1}$ writing $P(x) = \sum p_i(\boldsymbol{\sigma}(x), \boldsymbol{a})\sigma^n(x)^i$ if $a \in \mathcal{O}(M)$ has the property that $v(P(a)) > 2v(P'(a))$ while for any $\varepsilon \in \mathcal{O}(M)$ with $v(\varepsilon) \geq v(P(a)) - v(P'(a))$ we have $\ell_0(p_i(\boldsymbol{\sigma}(a))) = \ell_0(p_i(\boldsymbol{\sigma}(a + \varepsilon)))$ for $i \leq d$, then there is some $b \in \mathcal{O}(M)$ with $P(b) = 0$ and $v(b - a) \geq v(P(a)) - v(P'(a))$.

Remark 2.30. It should be noted that even when there are no quotient operators, and even in the case of difference polynomials, the continuity hypothesis is nontrivial.

Visibly, the condition of being $\mathcal{A}$-analytically difference henselian is first-order expressible. In axiomatizing the theory of $\mathcal{A}$-analytically difference henselian rings, $T_{\mathcal{A}\text{-DH}}$, we impose two additional requirements beyond those of Definition 2.29. First, we insist that every model of $T_{\mathcal{A}\text{-DH}}$ be of characteristic zero. Secondly, we demand that the valued field have enough constants in the sense that for every element of the value group there is some element of the field fixed by σ and having that valuation. This last condition can be ostensibly weakened by requiring the existence of σ-fixed elements of each valuation only at the level of the leading terms. For the remainder of this paper, when we speak of an $\mathcal{A}$-analytically difference henselian ring we mean a model of $T_{\mathcal{A}\text{-DH}}$ where $(\mathcal{A}, \sigma)$ is some notion of difference analyticity.

3. AKE theorems for analytically difference henselian rings

In this section we state and prove our main relative completeness and quantifier elimination theorems for $\mathcal{A}$-analytically difference henselian rings. As with much of the earlier work on pure valued fields and on algebraic valued difference and differential fields (but, remarkably, unlike most previous work on the model theory of analytic functions on valued fields) we prove our results by employing a model theoretic test for completeness and quantifier elimination involving extensions of partial isomorphisms.

Simply put, our theorem is that for a fixed notion of difference analyticity, $(\mathcal{A}, \sigma)$, the theory $T_{\mathcal{A}\text{-DH}}$ of $\mathcal{A}$-analytically difference henselian rings is complete and eliminates quantifiers relative to the leading term sorts, and even, resplendently so. As we expect the meaning here of relativity and resplendence may require some explanation, we describe these terms now before announcing our theorem in its official formulation.

Given a many sorted language $\mathcal{L}$ and a nonempty set Σ of $\mathcal{L}$-sort symbols, the restriction of $\mathcal{L}$ to Σ, $(\mathcal{L} \restriction \Sigma)$, is the language having sort symbols Σ and as basic function, relation, and constant symbols exactly those from $\mathcal{L}$ which refer only to sorts in Σ. That is, a function symbol f of $\mathcal{L}$ is a function symbol of $(\mathcal{L} \restriction \Sigma)$ just in case its domain sort is a sequence of sorts from Σ and its range sort belongs to Σ while a relation symbol of $\mathcal{L}$ belongs to the restricted language if its field sort is a sequence of elements of Σ and an $\mathcal{L}$-constant symbol is an $(\mathcal{L} \restriction \Sigma)$-constant if its sort belongs to Σ. If M is an $\mathcal{L}$-structure, then the restriction of M to Σ is simply the $(\mathcal{L} \restriction \Sigma)$-structure $(M \restriction \Sigma)$ consisting of the M-interpretation of the sorts in Σ and the nonlogical $(\mathcal{L} \restriction \Sigma)$-symbols.

Definition 3.1. Given a many sorted language $\mathcal{L}$ and a nonempty set Σ of $\mathcal{L}$-sort symbols we say that the $\mathcal{L}$-theory T is *complete relative to* Σ if for any model $M \models T$ the theory $T \cup \mathrm{Th}_{(\mathcal{L}\restriction\Sigma)}(M \restriction \Sigma)$ is complete.

To discuss relative quantifier elimination we need to recall Morleyization. Given a language $\mathcal{L}$, the Morleyization $\mathcal{L}^{\mathrm{Mor}}$ of $\mathcal{L}$ is obtained by adjoining to $\mathcal{L}$ a new relation symbol $R_\phi(x_1, \ldots, x_n)$ for each $\mathcal{L}$-formula ϕ with the free variables $x_1, \ldots, x_n$. The $\mathcal{L}^{\mathrm{Mor}}$-theory $T_{\mathcal{L}}^{\mathrm{Mor}}$ is defined by

$$T_{\mathcal{L}}^{\mathrm{Mor}} := \{\forall x_1 \cdots \forall x_n (R_\phi(\boldsymbol{x}) \leftrightarrow \phi(\boldsymbol{x})) \mid \phi \text{ an } \mathcal{L}\text{-formula}\}$$

On general grounds, any extension of $T_{\mathcal{L}}^{\mathrm{Mor}}$ in $\mathcal{L}^{\mathrm{Mor}}$ eliminates quantifiers.

Definition 3.2. Given a many sorted language $\mathcal{L}$ and a nonempty set Σ of $\mathcal{L}$-sort symbols we say that the $\mathcal{L}$-theory T *eliminates quantifiers relative to* Σ if the theory $T \cup T^{\mathrm{Mor}}_{(\mathcal{L}\restriction\Sigma)}$ eliminates quantifiers in $\mathcal{L} \cup (\mathcal{L} \restriction \Sigma)^{\mathrm{Mor}}$.

We mentioned that our theorems hold resplendently. We employ this enhancement of the theorem when discussing angular components. Essentially, by resplendent relative completeness (respectively, resplendent relative quantifier elimination) we mean that relative completeness (respectively, relative quantifier elimination) continues to hold even after arbitrarily enriching the sorts to which we relativize.

Definition 3.3. Let $\mathcal{L}$ be a many sorted language and Σ a nonempty set of $\mathcal{L}$-sort symbols. We say that the $\mathcal{L}$-theory T is resplendently complete relative to Σ (respectively, resplendently eliminates quantifiers relative to Σ) if for any expansion $\mathcal{L}' \supseteq (\mathcal{L} \restriction \Sigma)$ having only Σ as sort symbols and any $\mathcal{L}'$-theory T' the theory $T \cup T'$ is complete relative to Σ (respectively, eliminates quantifiers relative to Σ).

With this general nonsense on many sorted languages in place we may now state our main theorem.

Theorem 3.4. *The theory $T_{\mathcal{A}\text{-DH}}$ of $\mathcal{A}$-analytically difference henselian rings is resplendently complete relative to the leading terms sorts and resplendently eliminates quantifiers relative to the leading terms.*

Using general results on the existence of angular components, we deduce a stronger relative completeness theorem from Theorem 3.4.

Theorem 3.5. *The theory $T_{\mathcal{A}\text{-DH}}$ of $\mathcal{A}$-analytically difference henselian rings is complete relative to the value group and residue ring sorts.*

As a particular application of Theorem 3.5 we see that if $k \hookrightarrow k'$ is an extension of algebraically closed fields of characteristic p, then the corresponding extension of rings of Witt vectors, $W[k] \hookrightarrow W[k']$, is elementary in the language $\mathcal{L}(\mathcal{A}, \sigma)$ where $\mathcal{A}_{m,n} = W[k][\boldsymbol{X}][[\boldsymbol{Y}]]$ and σ is interpreted as the Witt–Frobenius. We shall expand on this observation and exploit it in Section 4.

As is our wont, we shall prove Theorem 3.4 by converting it into a statement about extending isomorphisms and then actually proving the statement on extensions by considering the cases of residue field, totally ramified, and immediate extensions separately. Some of these steps require merely routine modifications to the proofs in the algebraic setting, but others are considerably trickier.

The reader should consult Section 7 of [17] or Theorem 8.4.1 of [11] for a discussion of why the following technical theorem is equivalent to Theorem 3.4.

Theorem 3.6. *Let $\mathcal{L}'$ be an expansion of the restriction of $\mathcal{L}^{\mathcal{Q}}(\mathcal{A}, \sigma)$ to the leading term sorts, $(\mathcal{L}^{\mathcal{Q}}(\mathcal{A}, \sigma) \restriction \mathrm{LT})$, having no new sort symbols. Suppose that M_1 and M_2 are two saturated $\mathcal{A}$-analytically difference henselian rings each of the same cardinality $> (|\mathcal{L}'|^{\aleph_0})^+$ considered in the language $\mathcal{L}^{\mathcal{Q}}(\mathcal{A}, \sigma) \cup \mathcal{L}'^{\mathrm{Mor}}$. Suppose moreover that $(M_1 \restriction \mathrm{LT}) \equiv_{\mathcal{L}'} (M_2 \restriction \mathrm{LT}) \models T^{\mathrm{Mor}}_{\mathcal{L}'}$. Suppose that $A_1 \subseteq M_1$ and $A_2 \subseteq M_2$ are two small (of cardinality at most $|\mathcal{L}'|$) substructures of M_1 and M_2 for which $\mathcal{O}(A_i)$ generates A_i and that $f\colon A_1 \to A_2$ is an isomorphism of $\mathcal{L}^{\mathcal{Q}}(\mathcal{A}, \sigma) \cup (\mathcal{L}')^{\mathrm{Mor}}$-structures. If $a \in \mathcal{O}(M_1)$ is any element, then there is an extension of f to an isomorphism between the substructure of M_1 generated by A_1 and a, $A_1\langle a\rangle$, and a substructure of M_2.*

Throughout the remainder of this section we concentrate on proving Theorem 3.6, and, hence, also Theorem 3.4. In the course of this proof we shall reduce the problem to other statements with stronger hypotheses. As these restrictions are established, we shall display our new hypotheses as boxed statements.

As M_1 and M_2 are saturated of the same cardinality and $(M_1 \restriction \mathrm{LT})$ and $(M_2 \restriction \mathrm{LT})$ are elementarily equivalent, they are actually isomorphic. Since the map $f\colon A_1 \to A_2$ is an isomorphism of $\mathcal{L}^{\mathcal{Q}}(\mathcal{A}, \sigma) \cup (\mathcal{L}')^{\mathrm{Mor}}$-structures, and, each $(M_i \restriction \mathrm{LT})$ eliminates quantifiers, the restrictions of these structures to the leading terms are actually isomorphic over f. Let us fix such an isomorphism $\tilde{f}\colon (M_1 \restriction \mathrm{LT}) \to (M_2 \restriction \mathrm{LT})$ and thereby arrive at our first reduction.

$$\boxed{\begin{array}{c}\tilde{f} \cup f\colon A_1 \cup (M_1 \restriction \mathrm{LT}) \to A_2 \cup (M_2 \restriction \mathrm{LT}) \text{ is an isomorphism of} \\ \mathcal{L}^{\mathcal{Q}}(\mathcal{A}, \sigma) \cup (\mathcal{L}')^{\mathrm{Mor}}\text{-structures.}\end{array}}$$

We fix now $N_1 \preceq M_1$ and $N_2 \preceq M_2$ two $|\mathcal{L}'|^+$-compact elementary substructures each of cardinality less than that of M_1 for which $A_1\langle a\rangle \subseteq N_1$ and $A_2 \subseteq N_2$. Our hypotheses on the saturation of M_1 and M_2 and on their cardinalities ensure that such structures exists. In the course of our construction of an extension of f we shall initially extend inside N_1 taking values in N_2 until N_i is an immediate extension of A_i and then we extend f to a maximal immediate extension of N_1 inside M_1.

With the next lemma we show that the map f may be extended so as to add new elements to the residue ring $r_\infty(A_1)$.

Lemma 3.7. *Let $a \in r_\infty(N_1)$. Suppose that* $(\mathrm{ord}, \deg)(a/r_\infty(A_1)) = (m, d)$. *Let $\tilde{p}_0, \ldots, \tilde{p}_d$ be $\mathcal{L}^{\mathcal{Q}}(\mathcal{A})_{A_1}$ terms in the variables $x_0, \ldots, x_{n-1}$ for which the reductions under π_∞, $p_i = \pi_\infty(\tilde{p}_i)$, give well-defined functions at $(a, \sigma(a), \ldots, \sigma^{m-1}(a))$ and $P(a) = \sum p_i(\boldsymbol{\sigma}(a))(\sigma^m(a))^i = 0$. Let $\tilde{P} = \sum \tilde{p}_i(\boldsymbol{\sigma}(x))(\sigma^m(x))^i$. Then there are elements $\tilde{a} \in \mathcal{O}(N_1)$ and $\tilde{b} \in \mathcal{O}(N_2)$ for which $\tilde{P}(\tilde{a}) = 0$, $\tilde{P}^f(\tilde{b}) = 0$, $\pi_\infty(\tilde{a}) = a$, $\tilde{f}(a) = \pi_\infty(\tilde{b})$, and f extends to an isomorphism defined on the structure $A_1\langle\tilde{a}\rangle$ which has no new elements in its value group taking $\tilde{a}$ to $\tilde{b}$.*

Proof. Let $a' \in \mathcal{O}(N_1)$ be any lifting of a. By our minimality assumption, $P'(a) \neq 0$. As $P(a) = 0$ in $r_\infty(N_1)$, we see that, $2v(\tilde{P}'(a')) < v(\tilde{P}(a'))$. Moreover, because the terms $p_i(\boldsymbol{\sigma}(x))$ are well-defined at a, their leading terms do not depend on the choice of a'. Hence, as N_1 is $\mathcal{A}$-analytically difference henselian, there is some $\tilde{a}$ lifting a and satisfying $\tilde{P}(\tilde{a}) = 0$. Likewise, using $\aleph_1$-compactness of N_2 we can find $\tilde{b} \in \mathcal{O}(N_2)$ with $\tilde{P}^f(\tilde{b}) = 0$ and $\pi_\infty(\tilde{b}) = \tilde{f}(a)$.

We argue by induction on $n \leq m$ that if Q is a term of order n, then $\tilde{f}(\ell_\infty(Q(\tilde{a}))) = \ell_\infty(Q^f(\tilde{b}))$. By the uniform Weierstraß property, we may express Q near $\tilde{a}$ as $E(\sigma^n(\tilde{a}))R(\sigma^n(\tilde{a}))$ where E is given by an $\mathcal{L}(\mathcal{A})$ term over the $\mathcal{L}^{\mathcal{Q}}(\mathcal{A})$-structure generated by A_1 and $\tilde{a}, \ldots, \sigma^{n-1}(\tilde{a})$ and is a unit near $\sigma^n(\tilde{a})$ and R is a rational function over the same structure having no poles near $\sigma^n(a)$. In the case that $n = m$, we may assume that the degrees of the numerator and denominator of R are less than d. By induction, the ∞-leading terms of the parameters for E and R are under control. As the quotient operators are not applied to $\sigma^n(a)$ in E and E is a unit near $\sigma^n(a)$, its ∞-leading term is determined by that of $\sigma^n(\tilde{a})$. Write $R(\sigma^n(\tilde{a})) = S(\sigma^n(\tilde{a}))/T(\sigma^n(\tilde{a}))$ where S and T are polynomials. Write $S = c\tilde{S}$ where $v(c)$ is equal to the Gauß valuation of S. Then $\pi_\infty\tilde{S}$ gives a nonvanishing polynomial at $\sigma^n(a)$ as either $n < \mathrm{ord}(a/r_\infty(A_1))$ or $\deg \pi_\infty(\tilde{S}) < \deg(a/r_\infty(A_1))$. Thus, $\ell_\infty(\tilde{S}(\tilde{a})) = \pi_\infty(\tilde{S})(a)$. Applying the same reasoning to T, we conclude the induction and, hence, also the proof of this lemma. □

Repeatedly applying Lemma 3.7 we can extend f so that $r_\infty(A_i) = r_\infty(N_i)$. However, we delay doing this until we have achieved $\Gamma(A_i) = \Gamma(N_i)$.

With the following steps we enlarge the value group of A_1. Before actually adding new elements to the value group, we extend f so that its domain has enough constants.

Lemma 3.8. *If $c \in \mathcal{O}(A_1)$, then f extends to some $A_1\langle\varepsilon\rangle \subseteq N_1$ where $v(\varepsilon) = v(c)$, $\sigma(\varepsilon) = \varepsilon$, and $\Gamma(A_1) = \Gamma(A_1\langle\varepsilon\rangle)$.*

Proof. Take $\zeta \in \mathcal{O}(N_1)$ with $\sigma(\zeta) = \zeta$ and $v(\zeta) = v(c)$. Such an element exists by our axiom that $\mathcal{A}$-analytically difference henselian rings have enough constants. Set $\eta := \mathcal{Q}_0(\varepsilon, c)$. Then η is a nonzero solution to the linear difference equation $\sigma(X) - \mathcal{Q}(c, \sigma(c))X = 0$, even upon reduction to $r_\infty(N_1)$. Thus, there are infinitely many solutions to $\sigma(X) - \pi_\infty(\mathcal{Q}(c, \sigma(c))X = 0$ in $r_\infty(N_1)$ and by $|\mathcal{L}'|^+$-compactness, at least $|\mathcal{L}'|^+$ many solutions. In particular, there some solution a which is not algebraic over $r_\infty(A_1)$. Let $\tilde{a}$ and $\tilde{b}$ be given by Lemma 3.7 applied to $\tilde{P}(X) = \sigma(X) - \pi_\infty(\mathcal{Q}(c, \sigma(c))$. Set $\varepsilon := \tilde{a} \cdot c$. □

Iterating this construction so as to consider all the elements of the value group of A_1, we may suppose that A_1 and A_2 have enough constants.

A_1 and A_2 have enough constants

For purely ramified extensions we consider the cases of algebraic and transcendental extensions separately.

Lemma 3.9. *If $\varepsilon \in \mathcal{O}(N_1)$, $\sigma(\varepsilon) = \varepsilon$, $\varepsilon^n =: \zeta \in \mathcal{O}(A_1)$, and $mv(\varepsilon) \notin \Gamma(A_1)$ for $m < n$, then f extends to $A_1\langle\varepsilon\rangle$.*

Proof. That there is some $\eta \in N_2$ fixed by σ with $\eta^n = f(\zeta)$ and that the map extending f sending ε to η preserves the valued difference structure is already known from the algebraic case. As noted in Section 2, the $\mathcal{A}$-analytic structure extends uniquely to algebraic extensions. □

We extend now to transcendental expansions of the value group.

Lemma 3.10. *If $\varepsilon \in \mathcal{O}(N_1)$ is fixed by σ and $nv(\varepsilon) \notin \Gamma(A_1)$ for all $n \in \mathbb{Z}_+$, then there is some $\eta \in \mathcal{O}(N_2)$ also fixed by σ with $\tilde{f}(\ell_\infty(\varepsilon)) = \ell_\infty(\eta)$ for which f extends to $A_1\langle\varepsilon\rangle$ via $\varepsilon \mapsto \eta$.*

Proof. Let $\zeta \in \mathcal{O}(N_2)$ be any element with $\ell_\infty(\zeta) = \tilde{f}(\ell_\infty(\varepsilon))$ and let $P(X) = \sigma(X) - X$. Then $v(P(\zeta)) > v(\zeta) > 0 = v(P'(\zeta))$ as the leading term of ζ is a constant. Indeed, we even have $v_\infty(P(\zeta)) > v_\infty(\zeta)$ where v_∞ is the coarsened valuation. It follows that if $\xi \in \mathcal{O}(N_2)$ with $v(\xi) \geq v(P(\zeta))$, then $\ell_\infty(-(\zeta + \xi)) = \ell_\infty(-\zeta)$. Hence, our version of Hensel's lemma applies and we can find some $\eta \in \mathcal{O}(N_2)$ with $\ell_\infty(\eta) = \ell_\infty(\zeta) = \tilde{f}(\ell_\infty(\varepsilon))$ and $\sigma(\eta) = \eta$.

Since $\sigma(\varepsilon) = \varepsilon$, every element of $\mathcal{O}(A_1\langle\varepsilon\rangle)$ can be expressed as an $\mathcal{L}^{\mathcal{Q}}(\mathcal{A})_{A_1}$ term applied to ε. Likewise, the same is true of η with A_1 replaced by A_2. So, it suffices to show that if $t(x)$ is an $\mathcal{L}^{\mathcal{Q}}(\mathcal{A})_{A_1}$ term, then $\tilde{f}(\ell_\infty(t(\varepsilon))) = \ell_\infty(t^f(\eta))$.

Using uniform Weierstraß division to express $t(x)$ as $E(x)R(x)$ where E is an $\mathcal{L}(\mathcal{A})_{A_1}$ term which is a unit near ε and $R(x)$ is a rational function over $\mathcal{O}(A_1)$, we see that $\ell_\infty(E(\varepsilon))$ depends just on $\ell_\infty(\varepsilon)$ and if $R(x) = \big(\sum a_i x^i\big)/\big(\sum b_j x^j\big)$, then $\ell_\infty(R(\varepsilon)) = \ell_\infty(a_{i_0})\ell_\infty(\varepsilon)^{i_0 - j_0}\ell_\infty(b_{j_0})$ where $v(a_{i_0}) + i_0 v(\varepsilon) = \min_i v(a_i) + i v(\varepsilon)$ and $v(b_{j_0}) + j_0 v(\varepsilon) = \min_j v(b_j) + j v(\varepsilon)$. □

Applying Lemmata 3.9 and 3.10 repeatedly, alternating the rôles of N_1 and N_2, we may extend f so that $\Gamma(A_i) = \Gamma(N_i)$ for $i \in \{0, 1\}$. Once this has been achieved, we may apply Lemma 3.7 repeatedly to extend f so that N_i is an immediate extension of A_i.

Let us state this result as our second reduction.

$$\boxed{N_i \text{ is an immediate extension of } A_i \text{ for } i \in \{0, 1\}}$$

Fix now $\widehat{N}_1$ a maximal immediate extension of N_1 in M_1 and a maximal immediate extension $\widehat{N}_2$ of N_2 in M_2. We shall actually extend f to $\widehat{N}_1$.

Working by induction in $\widehat{N}_1$ we may assume that a has the least possible (ord, deg) over A_1 of new elements of N_1. That is:

$$\boxed{\begin{array}{c}\text{If } b \in \mathcal{O}(N_1) \text{ and } (\text{ord}, \deg)(b/A_1) < (n, d) := (\text{ord}, \deg)(a/A_1),\\ \text{then } b \in \mathcal{O}(A_1).\end{array}}$$

Working by induction further we may assume that whenever we have a pseudo-convergent solution to a low (ord, deg) $\mathcal{A}$-analytic difference equation over A_1 in N_1, then we have an actual solution.

$$\boxed{\begin{array}{c}\text{If } Q(x) = \sum_{i=0}^{e} q_i(x, \sigma(x), \ldots, \sigma^{m-1}(x))(\sigma^m(x))^i \text{ where } (m, e) < (n, d) \text{ and}\\ \text{each } q_i \text{ is an } \mathcal{L}^{\mathcal{Q}}(\mathcal{A})_{A_1} \text{ term and } \{x_\alpha\} \text{ is a pseudosolution to } Q \text{ in the sense that}\\ v(Q(x_\alpha)) \text{ is increasing with } \alpha \text{ and Hensel's lemma applies at each } \alpha, \text{ then there}\\ \text{is some } b \in \mathcal{O}(\widehat{N}_1) \text{ with } x_\alpha \text{ pseudoconverging to } b \text{ and } Q(b) = 0.\end{array}}$$

We fix now a maximal pseudoconvergent approximation $\{x_\alpha\}$ to a from $\mathcal{O}(A_1)$ and $P(X) = \sum_{i=0}^{d} p_i(\boldsymbol{\sigma}(X))(\sigma^n(X))^i$ a minimal equation for a over A_1. We shall show the following.

1. For Q of lower complexity than that of P (that is, Q is a polynomial in $\sigma^n(X)$ of degree less than d having coefficients which are $\mathcal{L}^{\mathcal{Q}}(\mathcal{A}, \sigma)_{A_1}$ terms of order less than n) we have $\ell_\infty(Q(a)) = \ell_\infty(Q(x_\alpha))$ for $\alpha \gg 0$.

2. Indeed, we shall show that $v_\infty(Q(a) - Q(x_\alpha)) > v(Q(a)) + v(a - x_\alpha)$ for $\alpha \gg 0$.

3. Possibly replacing P with a refinement, Hensel's lemma applies along $\{x_\alpha\}$.

4. There is some $b \in M_2$ for which $\{f(x_\alpha)\}$ is a pseudoconvergent approximation and $P(b) = 0$.

It follows that we may extend f by sending a to b and that our inductive stipulations on f and $\widehat{N}_1$ continue to hold.

We work by induction on $m = \text{ord}(Q)$ to prove the first of these points.

We observe first that if U is an $\mathcal{L}^{\mathcal{Q}}(\mathcal{A}, \sigma)_{A_1}$ term of order less than m, then for $\alpha \gg 0$ we have $v(a - x_\alpha) > v(\sigma^m(a) - U(a))$. Indeed, take α large enough so that the valuation inequality stated in Part 2 above holds for U. Assuming that

$v(\sigma^m(a)-U(a)) \geq v(a-x_\alpha) = v(\sigma^m(x_\alpha-a))$, then we have $v(\sigma^m(x_\alpha)-U(x_\alpha)) = v((\sigma^m(a)-U(a))+(\sigma^m(x_\alpha-a))+(U(x_\alpha)-U(a))) \geq v(a-x_\alpha)$. Hensel's lemma then applies to produce some y_α with $\sigma^m(y_\alpha) = U(y_\alpha)$ and $v(y_\alpha - x_\alpha) \geq v(a-x_\alpha)$. But then by the boxed reduction above, the sequence $\{y_\alpha\}$, and hence also $\{x_\alpha\}$ has a pseudolimit in $\widehat{N}_1$ contradicting its maximality.

The point of this observation is that any affinoid defined over the $\mathcal{L}^{\mathcal{Q}}(\mathcal{A})$-structure generated by A_1 and $a, \ldots, \sigma^{m-1}(a)$ containing $\sigma^m(a)$ also contains points of the form $\sigma^m(x_\alpha)$.

Near $\sigma^m(a)$ we can write

$$Q(x) = E(a, \ldots, \sigma^{m-1}(a); \sigma^m(x))R(a, \ldots, \sigma^{m-1}(a); \sigma^m(x))$$

where the quotient operators are not applied to $\sigma^m(x)$ in E and E is a unit near a and R is a rational function in $\sigma^m(x)$ with no poles near $\sigma^m(a)$. By induction, the parameters in E and R have the same ∞-leading terms if $(a, \ldots, \sigma^{m-1}(a))$ is replaced by $(x_\alpha, \ldots, \sigma^{m-1}(x_\alpha))$ for $\alpha \gg 0$.

Since $\ell_\infty(x_\alpha) = \ell_\infty(a)$, E is a unit, and the ∞-leading terms of the coefficients of $E(x_\alpha, \ldots, \sigma^{m-1}(x_\alpha); X)$ and $E(a, \ldots, \sigma^{m-1}(a); X)$ are the same, it follows that $\ell_\infty(E(\boldsymbol{\sigma}(a))) = \ell_\infty(E(\boldsymbol{\sigma}(x_\alpha)))$. Moreover, since the quotient operator is not applied to the last variable and $v(E(\boldsymbol{\sigma}(x_\alpha))) = 0$, the usual Taylor series expansion can be used to see that $v(E(\boldsymbol{\sigma}(x_\alpha)) - E(\boldsymbol{\sigma}(a))) = \gamma + Nv(x_\alpha - a)$ for some fixed $\gamma \in v(\mathcal{O}(A_1))$.

We can write R as $U(x_0, \ldots, x_m)/V(x_0, \ldots, x_m)$ where each of U and V is a polynomial in x_m. Let us write $U = \sum u_i(x_0, \ldots, x_{m-1})x_m^i$. By induction we know, among other things, that $\ell_\infty(u_i(\boldsymbol{\sigma}(a))) = \ell_\infty(u_i(\boldsymbol{\sigma}(x_\alpha)))$ for all i and $\alpha \gg 0$. Replacing U with $\mathcal{Q}(U, c)$ where $c \in \mathcal{O}(A_1)$ and $v(c) = \min_i v(u_i(\boldsymbol{\sigma}(a)))$ we may assume that $v(u_i(\boldsymbol{\sigma}(a))) = 0$ for some i.

Write $x_\alpha = a + y_\alpha$.

Let us expand $U(x_\alpha)$.

$$\begin{aligned} U(x_\alpha) &= \sum u_i(\boldsymbol{\sigma}(a + y_\alpha)(\sigma^m(a + y_\alpha))^i \\ &= \sum_{i,j} u_i(\boldsymbol{\sigma}(a))[1 + \xi_i]\binom{i}{j}\sigma^m(a)^{i-j}\sigma^m(y_\alpha)^j \quad \text{where } v_\infty(\xi_i) > 0 \\ &= \sum_j [1 + \zeta_j]\frac{1}{j!}U^{(j)}(a)\sigma^m(y_\alpha)^j \quad \text{where } v_\infty(\zeta_j) > 0. \end{aligned}$$

For $\alpha \gg 0$, the summands on the righthand side of the equation all have different v_∞ valuations. Thus, $\ell_\infty(U(x_\alpha)) = \ell_\infty(\frac{1}{j!}U^{(j)}(a)\sigma^m(y_\alpha)^j)$ for the j which minimizes the valuation of the expression on the right. If this j is zero, then we are done. As we have reduced to the case that $v(u_i(\boldsymbol{\sigma}(a))) = 0$ for some i, it follows that the j for which the valuation is minimized must have $v_\infty(U^{(j)}(a)) = 0$. Writing $j = k + 1$, we see that Hensel's lemma applies to $U^{(k)}(X)$ along x_α so that by our inductive hypothesis the sequence x_α pseudoconverges to a solution to $U^{(k)}(x) = 0$ contradicting its maximality. Hence, $\ell_\infty(U(a)) = \ell_\infty(U(x_\alpha))$.

Repeating this calculation with V in place of U, we finish the proof of points 1. and 2.

The above calculations apply as well to the case that $U = P$. This time since $P(a) = 0$, necessarily the minimal valuation of a summand on the right is obtained for some $j > 0$. If this j is not one and even if $v_\infty(P'(a)) \neq 0$, then as above x_α pseudoconverges to a solution of some derivative of P. Thus, Hensel's lemma applies to P along x_α and we can find the requisite solution to $P^f(X) = 0$ in $\mathcal{O}(M_2)$.

Conversely, the above calculations show that if we assumed merely that $a \in \mathcal{O}(M_1)$, then there is an immediate extension of $\widehat{N}_1$ in which x_α pseudoconverges to a solution to $P(X) = 0$. Indeed, arguing by induction on $(\text{ord}, \deg)(a/\widehat{N}_1)$ we may assume that P is also a minimal equation for a over $\widehat{N}_1$. With the above calculations we never invoked the fact that a lives in an immediate extension of A_1. Therefore, $\ell_\infty(Q(a)) = \ell_\infty(Q(x_\alpha)) \in \ell_\infty(A_1)$ for each lower complexity Q.

With these observations we conclude the proof of Theorem 3.6.

4. Model theory of p-differential geometry

In this section we apply the results from Section 3 to the theory of p-differential functions obtaining amongst other theorems a uniform version of the Manin–Mumford conjecture over $W[\mathbb{F}_p^{\text{alg}}]$.

Before discussing applications to p-differential functions we verify that the Witt vectors may indeed be regarded as $\mathcal{A}$-analytic difference henselian rings.

The reader may wish to consult Section 17 of [10] for more details on the Witt vectors. Recall that there is a functor W taking a perfect field k of characteristic $p > 0$ and returning a complete valuation ring $W[k]$ whose maximal ideal is generated by p and whose residue field is naturally isomorphic to k. From the functoriality of the Witt vector construction it follows that the Frobenius automorphism $\tau : k \to k$ induces an automorphism $W(\tau) : W[k] \to W[k]$ which reduces to τ modulo p. We refer to $W(\tau)$ as the *Witt–Frobenius*. It follows from the construction of $W(\tau)$ that it preserves the p-adic valuation on $W[k]$.

There is more than one reasonable choice for the analytic structure on $W[k]$. If we fix k, then we may wish to take $\mathcal{A}_{m,n} := W[k][\boldsymbol{X}][[\boldsymbol{Y}]]$. In this way we recover the rings of convergent power series by specializing the variables ranging over the maximal ideal. If we wish to work uniformly in p, then we may prefer to use $\mathbb{Z}[\boldsymbol{X}][[\boldsymbol{Y}]]$. In any case, the uniform Weierstraß division property follows from the main results of [20].

The most natural angular component structure on the Witt vectors is defined by taking the powers of p as the constant representatives of the value group. Henceforth, when we consider the Witt vectors with angular components we insist upon this choice. Fixing a choice of $\mathcal{A}$ as in the previous paragraph, we find now that the theory of $W[k]$ in $\mathcal{L}^{\mathcal{Q}}(\mathcal{A}, \sigma, \text{ac})$ is determined by the theory of k and admits quantifier

elimination relative to k and the value group. From Theorem 3.4 we require the theories of all of the residue rings to determine the full theory of the $\mathcal{A}$-analytic difference henselian ring. In the case of the Witt vectors, the intermediate quotients $r_n(W[k]) = W[k]/p^{n+1}W[k]$ are uniformly interpretable as the k-rational points of ring schemes over k. Thus, their theories and questions about quantifier elimination for these rings are determined by k.

Let us note two consequences of this characterization of the theory of the Witt vectors as an $\mathcal{A}$-analytic difference ring. First, if $k \hookrightarrow k'$ is an elementary extension of perfect fields, then $W[k] \hookrightarrow W[k']$ is also elementary. Secondly, the residue field is orthogonal to the value group in the sense that if $X \subseteq r_0(W[k])^n \times \Gamma(W[k])^m$ is any definable set, then X is a finite Boolean combination of sets of the form $Y \times Z$ where $Y \subseteq k^n$ is definable in k and $Z \subseteq \mathbb{Z}^m$ is definable in $(\mathbb{Z}, +, 0, <)$.

Let us turn now to a model theoretic study of p-differential geometry. As we noted in the introduction, if $\sigma\colon W[k] \to W[k]$ is the Witt–Frobenius, then the operator $\delta\colon W[k] \to W[k]$ defined by $\delta(x) := \frac{1}{p}(\sigma(x) - x^p)$ is a p-derivation and the functions of the form $f(\boldsymbol{x}) = F(\boldsymbol{x}, \delta\boldsymbol{x}, \ldots, \delta^m\boldsymbol{x})$ where $\boldsymbol{x} = (x_1, \ldots, x_n)$ and F is given by a convergent power series in $n(m+1)$ variables are the p-differential functions on $W[k]^n$. We concentrate on one class of p-differential functions constructed by Buium, namely the p-differential characters on abelian varieties.

As an illustration of the method, we prove a uniform version of the Manin–Mumford conjecture for abelian varieties over $W[k]$. Recall that the Manin–Mumford conjecture (or Raynaud's theorem [16]) asserts that if A is an abelian variety over an algebraically closed field K of characteristic zero and $X \subseteq A$ is a closed subvariety, then the intersection of $X(K)$ with the torsion subgroup of $A(K)$ is a finite union of translates of the torsion subgroups of group subvarieties of A. For the purposes of giving this theorem a more quantitative form it can help to present it in terms of the Ueno locus of X.

Recall that the Ueno locus of X, $\mathrm{Ueno}(X)$, is the subvariety of X defined by $x \in \mathrm{Ueno}(X)(K)$ if and only if there is an abelian subvariety $B \leq A$ for which $x + B \subseteq X$. We shall have occasion to use the fact, noted in [13], that if the variety X varies in an algebraic family, then so does $\mathrm{Ueno}(X)$. The Manin–Mumford conjecture implies that there are only finitely many torsion points in $X(K)$ which do not lie in $\mathrm{Ueno}(X)(K)$. In fact, if one establishes this finiteness result for the number of torsion points lying on varieties outside their Ueno loci, then the Manin–Mumford statement follows formally.

With our terms defined we can state our uniform version of the Manin–Mumford conjecture.

Theorem 4.1. *Let k be an algebraically closed field of characteristic $p > 2$, S a variety (reduced, integral scheme of finite type) over $W[k]$ and $A \to S$ an abelian scheme over S. Let $X \subseteq A$ be a closed subscheme. Then there is a natural number N such that for any point $s \in S(W[k])$ the number of torsion points in $A_s(W[k])$ lying in $X_s(W[k])$ but outside of $\mathrm{Ueno}(X_s)(W[k])$ is bounded by N.*

Remark 4.2. The restriction to odd p is an artifact of our proof in that this is an hypothesis for the published theorem of Buium on the existence of p-differential characters.

Remark 4.3. Theorem 4.1 is similar to the main theorem of [18] but is incomparable in terms of its strength. The result in [18] is weaker in that one requires $A \to S$ to be a universal abelian variety over a moduli space and one obtains information only about fibres which are canonical lifts, but it is stronger in the sense that Zariski closure of the intersection of $X(W[k])$ with the set of torsion points on canonical lift fibres is described with greater precision than is possible under the hypotheses of Theorem 4.1.

As with some of the other model theoretic theorems describing the intersection of subvarieties of abelian varieties with certain special subgroups, we study intersections of varieties with certain uniformly definable groups containing the torsion groups in lieu of directly analyzing the torsion groups themselves. Unlike some of the other work, rather than offering an alternative proof of the Manin–Mumford conjecture itself, we use Raynaud's theorem to derive this uniform version.

Before recalling Buium's construction of p-differential characters on abelian varieties we highlight the crucial features of the groups obtained as the kernels of his characters that we shall exploit.

Definition 4.4. Let k be an algebraically closed field of characteristic $p > 0$. If X is a scheme over $W[k]$ and n is a natural number, then we write $\rho_n \colon X(W[k]) \to X(W[k]/p^{n+1}W[k])$ for the reduction modulo p^{n+1} map. If $n < m$, then we write $\rho_{m,n} \colon X(W[k]/p^{m+1}W[k]) \to X(W[k]/p^{n+1}W[k])$ for the intermediate reduction map. Using the Greenberg transform, $\rho_{m,n}$ may be regarded as a map of schemes over k. If $Z \subseteq X(W[k])$ is a closed subset of $X(W[k])$, then we say that Z is *finite dimensional* if for every natural number n the set $\rho_n(Z)$ is the set of k-rational points on a subvariety of $\rho_n(X(W[k])$ with respect to the identification $X(W[k]/p^{n+1}W[k])$ with the k-rational points of an algebraic variety over k and $\limsup \deg \rho_{n+1,n} \restriction (\rho_{n+1}Z)$ is finite.

At least when the characteristic of k is not two, Buium establishes that in analogy to the group homomorphisms constructed by Manin using derivations on function fields that if A is an abelian scheme over $W[k]$ of relative dimension g, then there is a group homomorphism given by a p-differential function $\mu \colon A(W[k]) \to W[k]^g$ for which the kernel, $A^\sharp(W[k])$, is finite dimensional. While the actual $A^\sharp$ groups need not vary uniformly, Buium does observe with Remark (1) on page 327 of [6] that the data required to produce group homomorphisms with finite dimensional kernels is bounded uniformly. Let us reformulate his observation as a theorem.

Theorem 4.5 (Buium). *Let k be an algebraically closed field of characteristic $p > 2$. Suppose that S is a variety (reduced, integral scheme of finite type) over $W[k]$ and that $A \to S$ is an abelian scheme over S of relative dimension g. Then there is a p-differential function $\mu \colon A(W[k]) \to W[k]^g$ such that for each $s \in S(W[k])$ the*

map $\mu_s\colon A_s(W[k]) \to W[k]^g$ is a group homomorphism for which $\ker(\mu_s)$ *is a finite dimensional proalgebraic group.*

Since the additive group is torsion free, the group $\ker(\mu_s)$ contains the torsion group $A_s(W[k])_{\mathrm{tor}}$. Moreover, since μ is a p-differential function, the group $\ker(\mu_s)$ is definable in $\mathcal{L}(\mathcal{A}, \sigma)$. In the notation of Theorem 4.1, one might like to argue that there are boundedly many points in $(X_s(W[k]) \smallsetminus \mathrm{Ueno}(X_s)(W[k])) \cap \ker(\mu_s)$ and then conclude *a fortiori* that the same is true with $\ker(\mu_s)$ replaced by the torsion subgroup of $A_s(W[k])$. Unfortunately, this stronger assertion is false in general. However, we shall establish a weak form of this boundedness statement for finite dimensional subgroups of abelian varieties from which Theorem 4.1 follows.

Theorem 4.6. *Let k be an algebraically closed field of characteristic p. Suppose that A is an abelian scheme over $W[k]$. Suppose $G \leq A(W[k])$ is a finite dimensional $\mathcal{L}(\mathcal{A}, \sigma)$-definable subgroup of $A(W[k])$. If $X \subseteq A$ is a closed subscheme, then $\rho_0((X(W[k]) \smallsetminus \mathrm{Ueno}(X)(W[k])) \cap G)$ is finite.*

Proof. If there were a counter-example to this theorem, then one could be found with $k = \mathbb{F}_p^{\mathrm{alg}}$. Indeed, by the quantifier elimination part of Theorem 3.4 the set $\rho_0((X(W[k]) \smallsetminus \mathrm{Ueno}(X)(W[k])) \cap G)$ is constructible. Hence, if it is infinite it contains a component of the form $Y(k) \smallsetminus F(k)$ where Y is an irreducible variety over k of dimension at least one and F is a proper subvariety. Since the extension $W[\mathbb{F}_p^{\mathrm{alg}}] \hookrightarrow W[k]$ is elementary, the assertion that there exist the appropriate parameters to define such an A, X, G, Y, and F is true in $W[\mathbb{F}_p^{\mathrm{alg}}]$. Likewise, if k' is an algebraically closed field of characteristic p, then because $W[\mathbb{F}_p^{\mathrm{alg}}] \hookrightarrow W[k']$ is elementary, we may transfer the counterexample from $W[\mathbb{F}_p^{\mathrm{alg}}]$ to $W[k']$. Thus, we may take k to be any algebraically closed field of characteristic p.

Let Y be as in the previous paragraph. Let $Z \subseteq Y$ be a curve with $Z(k) \cap F(k)$ finite. Translating, we may assume that Z contains the origin. Let H be the algebraic group generated by Z and let $\tilde{H} := (\rho_0^{-1} H(k)) \cap G$. Then $\tilde{H}$ is a definable, finite dimensional group for which $\rho_0((X(W[k]) \smallsetminus \mathrm{Ueno}(X)(W[k])) \cap \tilde{H})$ is infinite. Thus, we may and do assume that $G = \tilde{H}$.

We now transpose the proof of Proposition 4.4 of [12] to our unstable situation. For the moment we make use of our flexibility in the choice of k by taking k to be an algebraically closed field of characteristic p and cardinality strictly greater than that of the continuum. For each definable set $T \subseteq \ker(\rho_0 \restriction G)$, let $R_T := \{x \in Z(k) \mid (\exists g \in G)\ g + T = ((X(W[k]) \smallsetminus \mathrm{Ueno}(X)(W[k])) \cap G)_x\}$. The set R_T is a definable subset of the k-rational points of the curve Z and is thus either finite or cofinite. As $Z(k) = \bigcup_T R_T$ and there are at most continuum many such T and $|Z(k)| > 2^{\aleph_0}$, there must be some T for which R_T is cofinite. Translating T within $\ker(\rho_0 \restriction G)$, we may assume that T contains the origin. Let $S := \{x \in \ker(\rho_0 \restriction G) \mid x + T = T\}$. If $g + T$ is a fibre of $((X(W[k]) \smallsetminus \mathrm{Ueno}(X)(W[k])) \cap G)$, then $g + \overline{S} \subseteq X$ showing that g belongs to the Ueno locus of X unless S is finite, but g does not belong to the

Ueno locus of X. Thus, S must be finite. Thus, the correspondence which associates to $x \in Z(k)$ the g for which $g + T = ((X(W[k]) \setminus \mathrm{Ueno}(X)(W[k])) \cap G)_x$ is one to finite. Let $\tilde{Z}$ be the image of this correspondence in G. Note that $\tilde{Z}$ is a subset of $((X(W[k]) \setminus \mathrm{Ueno}(X)(W[k])) \cap G)$.

As the restriction of the map ρ_0 to $\tilde{Z}$ is finite to one, for $n \gg 0$ the map $\rho_{n+1,n}\colon \rho_{n+1}(\tilde{Z}) \to \rho_n(\tilde{Z})$ is a bijective morphism. Thus, we can find finitely many definable subsets $\tilde{Z}_1, \ldots, \tilde{Z}_m$ of $\tilde{Z}$ for which $\rho_n(\tilde{Z}_i)$ is always irreducible. For each such "component" if we translate $\tilde{Z}_i$ so that it contains the origin and then form the group L_i that it generates, we see that L_i is definable. Indeed, by the finite dimensionality of G the constructible sets $\rho_n(\tilde{Z}_i)$ generate an algebraic subgroup of $\rho_n(G)$ in a bounded number of steps. As the map ρ_0 is finite to one on $\tilde{Z}_i$, the same is true on L_i.

Now we use our flexibility in the choice of k to make k small: if $k = \mathbb{F}_p^{\mathrm{alg}}$, then every element of $\rho_0(L_i)$ is torsion. As the kernel of ρ_0 on L_i is finite, it follows that every element of L_i is torsion. By Raynaud's theorem, $L_i \cap ((X(W[k]) \setminus \mathrm{Ueno}(X)(W[k]))$ is finite. As this is true for each i, we conclude that the curve Z in question does not actually exist and that $\rho_0(((X(W[k]) \setminus \mathrm{Ueno}(X)(W[k])) \cap G))$ is finite after all. □

We are now in a position to complete the proof of Theorem 4.1.

Proof. Let $\mu\colon A(W[k]) \to W[k]^g$ be the p-differential function given by Theorem 4.5. By Theorem 4.6 each of the sets $\rho_0((X_s(W[k]) \setminus \mathrm{Ueno}(X_s)(W[k])) \cap \ker(\mu_s))$ is finite. By the quantifier elimination part of Theorem 3.4, this family of finite sets which *prima facie* is uniformly definable only in $W[k]$ is, in fact, uniformly definable in k. The quantifier "there exists infinitely many" may be eliminated in algebraically closed fields. Thus, there is a number B for which each of the above finite sets has cardinality at most B. Thus, the torsion points on X_s but outside the Ueno locus are contained in at most B cosets of the kernel of reduction. There is a bound $M = M(g, p)$ on the number of unramified torsion points in the kernel of reduction on an abelian scheme of relative dimension g depending just on g and p. Thus, there are at most $N := M \cdot B$ torsion points of $A_s(W[k])$ on X_s but outside the Ueno locus. □

Borel superrigidity and the classification problem for the torsion-free abelian groups of finite rank

Simon Thomas*

Abstract. In 1937, Baer solved the classification problem for the torsion-free abelian groups of rank 1. Since then, despite the efforts of many mathematicians, no satisfactory solution has been found of the classification problem for the torsion-free abelian groups of rank $n \geq 2$. So it is natural to ask whether the classification problem for the higher rank groups is genuinely difficult. In this article, I will explain how this question can be partially answered, using ideas from descriptive set theory and Zimmer's superrigidity theory.

Mathematics Subject Classification (2000). Primary 03E15, 20K15, 37A20.

Keywords. Borel equivalence relation, superrigidity, torsion-free abelian group.

1. Introduction

In this article, we shall discuss some recent work which partially explains why no satisfactory system of complete invariants has yet been found for the torsion-free abelian groups of finite rank $n \geq 2$. Recall that, up to isomorphism, the torsion-free abelian groups A of rank n are exactly the additive subgroups of the n-dimensional vector space $\mathbb{Q}^n$ which contain n linearly independent elements. Thus the classification problem for the torsion-free abelian groups of rank n can be naturally identified with the corresponding problem for

$$R(\mathbb{Q}^n) = \{A \leqslant \mathbb{Q}^n \mid A \text{ contains } n \text{ linearly independent elements}\}.$$

In 1937, Baer [3] solved the classification problem for the class $R(\mathbb{Q})$ of torsion-free abelian groups of rank 1 as follows. Let $\mathbb{P}$ be the set of primes. Suppose that $G \in R(\mathbb{Q})$ and that $0 \neq x \in G$. Then for each $p \in \mathbb{P}$, the *p-height* of x is defined to be

$$h_x(p) = \sup\{n \in \mathbb{N} \mid \text{ There exists } y \in G \text{ such that } p^n y = x\} \in \mathbb{N} \cup \{\infty\};$$

and the *characteristic* $\chi(x)$ of x is defined to be the sequence

$$\langle h_x(p) \mid p \in \mathbb{P}\rangle \in (\mathbb{N} \cup \{\infty\})^{\mathbb{P}}.$$

*Research partially supported by NSF Grants.

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

Two sequences $\chi_1, \chi_2 \in (\mathbb{N} \cup \{\infty\})^{\mathbb{P}}$ are said to *belong to the same type*, written $\chi_1 \equiv \chi_2$, iff

(a) $\chi_1(p) = \chi_2(p)$ for almost all primes p; and

(b) if $\chi_1(p) \neq \chi_2(p)$, then both $\chi_1(p)$ and $\chi_2(p)$ are finite.

Clearly $\equiv$ is an equivalence relation on $(\mathbb{N} \cup \{\infty\})^{\mathbb{P}}$. Furthermore, it is easily checked that if $G \in R(\mathbb{Q})$, then $\chi(x) \equiv \chi(y)$ for all $0 \neq x, y \in G$. Hence we can define the *type* $\tau(G)$ of G to be the $\equiv$-equivalence class containing $\chi(x)$, where x is any non-zero element of G. In [3], Baer proved that $\tau(G)$ is a complete invariant for the isomorphism problem for the rank 1 groups.

Theorem 1.1 (Baer [3]). *If $G, H \in R(\mathbb{Q})$, then $G \cong H$ iff $\tau(G) = \tau(H)$.*

However, the situation is much less satisfactory in the case of the torsion-free abelian groups of rank $n \geq 2$. In the late 1930s, Kurosh [22] and Malcev [25] found complete invariants for these groups consisting of equivalence classes of infinite sequences $\langle M_p \mid p \in \mathbb{P} \rangle$ of matrices, where each $M_p \in \mathrm{GL}_n(\mathbb{Q}_p)$. Unfortunately, as Fuchs [8] remarks in his classic textbook, the associated equivalence relation is so complicated that the problem of deciding whether two sequences are equivalent is as difficult as that of deciding whether the corresponding groups are isomorphic. It is natural to ask whether the classification problem for the higher rank groups is genuinely more difficult than that for the rank 1 groups. Of course, if we wish to show that the classification problem for the groups of rank $n \geq 2$ is intractible, it is not enough merely to prove that there are $2^{\aleph_0}$ such groups up to isomorphism: for there are $2^{\aleph_0}$ pairwise nonisomorphic groups of rank 1 and we have just seen that Baer has given a satisfactory classification for this class of groups. In this article, following Friedman-Stanley [7] and Hjorth–Kechris [14], we shall explain how to use the more sensitive notions of descriptive set theory to measure the complexity of the classification problem for the groups of rank $n \geq 2$.

The basic idea is quite simple; namely, in order to understand the relative complexity of these and other classification problems, we shall consider the question of when one classification problem can be "explicitly reduced" to another. For example, the classification problem for the rank n groups can be explicitly reduced to that for the rank $n + 1$ groups by the map

$$\begin{aligned} R(\mathbb{Q}^n) &\to R(\mathbb{Q}^{n+1}) \\ A &\mapsto A \oplus \mathbb{Q} \end{aligned}$$

in the sense that

$$A \cong B \quad \text{iff} \quad A \oplus \mathbb{Q} \cong B \oplus \mathbb{Q}.$$

Of course, this observation is neither surprising nor particularly interesting; and we shall be more concerned with the question of whether there exists an "explicit map" in the opposite direction

$$f\colon R(\mathbb{Q}^{n+1}) \to R(\mathbb{Q}^n)$$

such that

$$A \cong B \quad \text{iff} \quad f(A) \cong f(B).$$

If we drop the requirement that f should be "explicit", then such a map certainly exists: since $R(\mathbb{Q}^{n+1})$ and $R(\mathbb{Q}^n)$ both contain $2^{\aleph_0}$ groups up to isomorphism, we can simply use the Axiom of Choice to match up the isomorphism classes. However, nobody would regard such a matching as a satisfactory reduction of one classification problem to another. In order to give a precise formulation of this question, it is first necessary to discuss some of the basic notions from the theory of Borel equivalence relations.

Let $(X, \mathcal{S})$ be a measurable space; i.e. a set X equipped with a σ-algebra $\mathcal{S}$ of subsets of X. Then $(X, \mathcal{S})$ is said to be a *standard Borel space* iff there exists a complete separable metric d on X such that $\mathcal{S}$ is the σ-algebra of Borel sets of (X, d). By a classic result of Kuratowski [21], if $(X, \mathcal{S})$ is an uncountable standard Borel space, then $(X, \mathcal{S})$ is measurably isomorphic to the unit interval $[0, 1]$ equipped with its σ-algebra of Borel sets. The obvious examples of standard Borel spaces include $\mathbb{R}$, $\mathbb{C}$ and $\mathbb{Q}_p$, as well as the Cantor space

$$2^C = \{h \mid h\colon C \to 2\},$$

where C is any countably infinite set. Furthermore, identifying each subset $B \subseteq C$ with its characteristic function $\chi_B \in 2^C$, it follows that the power set $\mathcal{P}(C)$ is also a standard Borel space. Less obviously, there is a uniform way to represent classes of countable structures, such as groups, fields, graphs, etc., by the elements of suitable standard Borel spaces. For example, in order to define the standard Borel space of countable graphs, we first restrict our attention to the set $\mathcal{C}$ of graphs

$$\Gamma = \langle \mathbb{N}, E_\Gamma \rangle$$

with vertex set $\mathbb{N}$. After identifying each such graph $\Gamma \in \mathcal{C}$ with its edge relation $E_\Gamma \in \mathcal{P}(\mathbb{N} \times \mathbb{N})$, it is easily checked that $\mathcal{C}$ is a Borel subset of the standard Borel space $\mathcal{P}(\mathbb{N} \times \mathbb{N})$; and this implies that $\mathcal{C}$ is also a standard Borel space. (For example, see Kechris [20].) It should be relatively clear how to generalise the method of this example to deal with other classes of countable structures. However, in this article, we shall mainly be concerned with the classes of torsion-free abelian groups of rank $n \geq 1$ and the class of finitely generated groups; and these classes can be more conveniently represented by the following more *ad hoc* spaces.

Example 1.2. Let $n \geq 1$. Then $R(\mathbb{Q}^n)$ is a Borel subset of the standard Borel space $\mathcal{P}(\mathbb{Q}^n)$ and so $R(\mathbb{Q}^n)$ is a standard Borel space. For later use, note that the natural action of $\mathrm{GL}_n(\mathbb{Q})$ on the vector space $\mathbb{Q}^n$ induces a corresponding action on $R(\mathbb{Q}^n)$; and that if $A, B \in R(\mathbb{Q}^n)$, then $A \cong B$ iff there exists an element $\varphi \in \mathrm{GL}_n(\mathbb{Q})$ such that $\varphi[A] = B$.

Example 1.3 (Champetier [4]). The standard Borel space $\mathcal{G}$ of finitely generated groups can be defined as follows. Let F be the free group on countably many generators $X = \{x_i \mid i \in \mathbb{N}\}$. Suppose that G is a finitely generated group and that $(g_0, \ldots, g_n)$ is a finite sequence of generators. Then, by considering the homomorphism $\pi : F \to G$ defined by

$$\pi(x_i) = \begin{cases} g_i & \text{if } 0 \leq i \leq n, \\ 1 & \text{otherwise,} \end{cases}$$

we see that G can be realized as a quotient F/N, where N is a normal subgroup which contains all but finitely many elements of the basis X. (Of course, choosing a different generating sequence usually results in a different realization.) Thus we can identify $\mathcal{G}$ with the set of all such normal subgroups N of F. With this identification, $\mathcal{G}$ is a Borel subset of the standard Borel space $\mathcal{P}(F)$ and hence $\mathcal{G}$ is a standard Borel space. As in Example 1.2, the isomorphism relation on the standard Borel space of finitely generated groups is the orbit equivalence relation of a natural action of a suitable countable group. More precisely, let $\mathrm{Aut}_f(F)$ be the subgroup of $\mathrm{Aut}(F)$ generated by the elementary Nielsen transformations

$$\{\alpha_i \mid i \in \mathbb{N}\} \cup \{\beta_{ij} \mid i \neq j \in \mathbb{N}\},$$

where α_i is the automorphism sending x_i to x_i^{-1} and leaving $X \setminus \{x_i\}$ fixed; and β_{ij} is the automorphism sending x_i to $x_i x_j$ and leaving $X \setminus \{x_i\}$ fixed. Then the natural action of $\mathrm{Aut}_f(F)$ on F induces a corresponding action on the space $\mathcal{G}$ of normal subgroups of F which contain all but finitely many elements of the basis X; and if $N, M \in \mathcal{G}$ are two such normal subgroups, then $F/N \cong F/M$ iff there exists $\varphi \in \mathrm{Aut}_f(F)$ such that $\varphi[N] = M$. (For example, see Champetier [4] and Lyndon–Schupp [24].)

If X, Y are standard Borel spaces, then $f : X \to Y$ is a *Borel map* iff $f^{-1}(B)$ is Borel for every Borel subset $B \subseteq Y$. Equivalently, f is Borel iff $\mathrm{graph}(f)$ is a Borel subset of $X \times Y$. Now suppose that E, F are equivalence relations on the standard Borel spaces X, Y respectively. (For example, X and Y could be spaces of countable structures and E, F could be the corresponding isomorphism relations.) Then E is *Borel reducible* to F, written $E \leq_B F$, if there exists a Borel map $f : X \to Y$ such that

$$x E y \quad \text{iff} \quad f(x) F f(y).$$

E and F are *Borel bireducible*, written $E \sim_B F$, if both $E \leq_B F$ and $F \leq_B E$. Finally we write $E <_B F$ if both $E \leq_B F$ and $F \not\leq_B E$.

Remark 1.4. Of course, the notion of a Borel reduction $f : X \to Y$ from E to F is intended to capture the intuitive idea of an "explicit reduction" from the E-classification problem to the F-classification problem. For example, with a little practice, it is easily checked that any given explicit map $f : \mathbb{R} \to \mathbb{R}$ is Borel. On the other hand, many mathematicians are reluctant to accept that an arbitrary Borel map $f : \mathbb{R} \to \mathbb{R}$ should

be regarded as explicit. However, it is not necessary for us to address this question, since we will mainly be concerned with non-reducibility results; and for such results, it is clearly preferable to work with the broadest possible class of maps. (It is perhaps worth mentioning that the proofs of our main results actually show that there are no measurable reductions between the relevant classification problems. By a well-known theorem of Solovay [30], the existence of a non-measurable map requires an essential use of the Axiom of Choice and so such maps are certainly not explicit.)

Example 1.5. For each $n \geq 1$, let $\cong_n$ be the isomorphism relation on $R(\mathbb{Q}^n)$. Then the map

$$\begin{aligned} R(\mathbb{Q}^n) &\to R(\mathbb{Q}^{n+1}), \\ A &\mapsto A \oplus \mathbb{Q}, \end{aligned}$$

is a Borel reduction from $\cong_n$ to $\cong_{n+1}$. Hence

$$(\cong_1) \leq_B (\cong_2) \leq_B \cdots \leq_B (\cong_n) \leq_B \cdots$$

and our earlier question of whether the classification problem for the higher rank groups is genuinely more difficult than that for the rank 1 groups can be interpreted as the question of whether $(\cong_1) <_B (\cong_2)$.

Before discussing the solution of this problem, it will be helpful to give a brief account of some of the theory of countable Borel equivalence relations. (A detailed development of this theory can be found in Jackson–Kechris–Louveau [17].) If X is a standard Borel space, then a *Borel equivalence relation* on X is an equivalence relation $E \subseteq X^2$ which is a Borel subset of X^2. The Borel equivalence relation E is said to be *countable* iff every E-equivalence class is countable. Most of the Borel equivalence relations that we shall consider in this article arise from group actions as follows. Let G be an *lcsc* group; i.e. a locally compact second countable group. Then a *standard Borel G-space* is a standard Borel space X equipped with a Borel action $(g, x) \mapsto g \cdot x$ of G on X. The corresponding G-orbit equivalence relation on X, which we shall denote by E_G^X, is a Borel equivalence relation. In fact, by Kechris [19], E_G^X is Borel bireducible with a countable Borel equivalence relation. Conversely, by Feldman–Moore [6], if E is an arbitrary countable Borel equivalence relation on the standard Borel space X, then there exists a countable group G and a Borel action of G on X such that $E = E_G^X$.

Example 1.6. As we pointed out in Examples 1.2 and 1.3, the isomorphism relations on the spaces $R(\mathbb{Q}^n)$ of torsion-free abelian groups of rank n and the space $\mathcal{G}$ of finitely generated groups are the orbit equivalence relations of natural actions of suitable countable groups. These actions are easily seen to be Borel and so each of these isomorphism relations is a countable Borel equivalence relation.

With respect to Borel reducibility, the least complex countable Borel equivalence relations are those which are *smooth*; i.e. those countable Borel equivalence relations E on a standard Borel space X for which there exists a Borel function $f : X \to Y$

into a standard Borel space Y such that $x\,E\,y$ iff $f(x) = f(y)$. Equivalently, the countable Borel equivalence relation E on X is smooth iff the quotient X/E is a standard Borel space. (Here X/E denotes the set of E-classes equipped with the quotient Borel structure.)

Example 1.7. The isomorphism relation on the standard Borel space of countable divisible abelian groups is smooth. To see this, recall that if A is a countable divisible abelian group, then $A = D \oplus T$, where T is the torsion subgroup and D is torsion-free. Let $r_0(A) \in \mathbb{N} \cup \{\infty\}$ be the rank of D; and for each prime p, let $r_p(A) \in \mathbb{N} \cup \{\infty\}$ be the rank of the p-component T_p of T. Then the invariant

$$\rho(A) = (r_0(A), r_2(A), r_3(A), \ldots, r_p(A), \ldots)$$

determines A up to isomorphism.

Next in complexity come those countable Borel equivalence relations E which are Borel bireducible with the *Vitali equivalence relation* E_0 defined on $2^{\mathbb{N}}$ by $x\,E_0\,y$ iff $x(n) = y(n)$ for almost all n. More precisely, by Harrington–Kechris–Louveau [12], if E is a countable Borel equivalence relation, then E is nonsmooth iff $E_0 \leq_B E$. Furthermore, by Dougherty–Jackson–Kechris [5], if E is a countable Borel equivalence relation on a standard Borel space X, then the following three properties are equivalent:

(1) $E \leq_B E_0$.

(2) E is *hyperfinite*; i.e. there exists an increasing sequence

$$F_0 \subseteq F_1 \subseteq \cdots \subseteq F_n \subseteq \cdots$$

of finite Borel equivalence relations on X such that $E = \bigcup_{n \in \mathbb{N}} F_n$. (Here an equivalence relation F is said to be *finite* iff every F-equivalence class is finite.)

(3) There exists a Borel action of $\mathbb{Z}$ on X such that $E = E^X_{\mathbb{Z}}$.

Example 1.8. As is easily checked, Baer's classification of the rank 1 groups implies that $(\cong_1) \sim_B E_0$.

It turns out that there is also a most complex countable Borel equivalence relation E_∞, which is *universal* in the sense that $F \leq_B E_\infty$ for every countable Borel equivalence relation F; and, furthermore, $E_0 <_B E_\infty$. (Clearly this universality property uniquely determines E_∞ up to Borel bireducibility.) E_∞ has a number of natural realisations in many areas of mathematics, including algebra, topology and recursion theory. (See Jackson–Kechris–Louveau [17].) For example, E_∞ is Borel bireducible with both the isomorphism relation for finitely generated groups [36] and the isomorphism relation for fields of finite transcendence degree [37].

For many years, it was an open problem whether there existed infinitely many countable Borel equivalence relations E such that $E_0 <_B E <_B E_\infty$. This problem

was finally resolved by Adams–Kechris [2], who used Zimmer's superrigidity theory [38] to show that there are actually $2^{\aleph_0}$ such relations E up to Borel bireducibility. More recently, Hjorth–Kechris [15] have found an "elementary" proof of this result; i.e. a proof which requires no more background than the standard measure theory and functional analysis which should be known by every mathematician.

Returning to our discussion of the complexity of the isomorphism relation $\cong_n$ on the standard Borel space $R(\mathbb{Q}^n)$ of torsion-free abelian groups of rank n, we now see that

$$(\cong_1) \leq_B (\cong_2) \leq_B \cdots \leq_B (\cong_n) \leq_B \cdots \leq_B E_\infty.$$

In [14], Hjorth–Kechris conjectured that $(\cong_2) \sim_B E_\infty$; in other words, the classification problem for the torsion-free abelian groups of rank 2 is already as complex as that for arbitrary finitely generated groups. Of course, if true, this would have completely explained the failure to find a satisfactory system of complete invariants for the torsion-free abelian groups of rank $n \geq 2$, since nobody expects such a system to exist for the class of finitely generated groups. In [13], Hjorth provided some initial evidence for this conjecture by proving that the classification problem for the higher rank groups is indeed genuinely more difficult than that for the rank 1 groups.

Theorem 1.9 (Hjorth [13]). $(\cong_1) <_B (\cong_2)$.

However, the conjecture appeared considerably less plausible after Adams–Kechris [2] used Zimmer's superrigidity theory [38] to prove that

$$(\cong_1^*) <_B (\cong_2^*) <_B \cdots <_B (\cong_n^*) <_B \cdots$$

where $(\cong_n^*)$ is the restriction of the isomorphism relation to the class of *rigid* torsion-free abelian groups $A \in R(\mathbb{Q}^n)$. Here an abelian group A is said to be rigid if its only automorphisms are the obvious ones: $a \mapsto a$ and $a \mapsto -a$. In particular, it follows that none of the isomorphism relations $\cong_n^*$ is a universal countable Borel equivalence relation. Soon afterwards, making essential use of the earlier work of Hjorth [13] and Adams–Kechris [2], Thomas [31] proved the corresponding result for the isomorphism relation $\cong_n$ on the class $R(\mathbb{Q}^n)$ of all torsion-free abelian groups of rank n.

Theorem 1.10 (Thomas [31]). $(\cong_n) <_B (\cong_{n+1})$ *for all* $n \geq 2$.

Corollary 1.11. $(\cong_n) <_B (E_\infty)$ *for all* $n \geq 1$.

Unfortunately, while Theorem 1.10 shows that the relative complexity of the classification problem for the torsion-free abelian groups of rank n increases strictly with the rank n, it says little about the absolute complexity of these problems. In particular, it fails to answer the following:

Question 1.12. Is the classification problem for the torsion-free abelian groups of rank 2 "genuinely difficult"?

While it is difficult to imagine giving a precise formulation of Question 1.12, it certainly includes the question of whether $\cong_2$ is an immediate successor of $\cong_1$ with respect to Borel reducibility. In other words, does there exist a Borel equivalence relation E such that

$$(\cong_1) <_B E <_B (\cong_2)?$$

In seeking such an equivalence relation E, it is natural to consider the classification problem for various restricted classes of torsion-free abelian groups.

Definition 1.13. For each prime p and $n \geq 1$, let $R^p(\mathbb{Q}^n)$ be the standard Borel space of all p-local subgroups $A \leqslant \mathbb{Q}^n$ of rank n and let $\cong_n^p$ be the isomorphism relation on $R^p(\mathbb{Q}^n)$.

Here an abelian group A is said to be *p-local* iff A is q-divisible for all primes $q \neq p$. Of course, if an abelian group A is q-divisible for all primes q, then A is divisible and we have already seen that the divisible abelian groups are easily classified. Consequently, all of the complexity of the classification problem for the p-local groups is concentrated in the single prime p. In Thomas [31], it was shown that if the prime p is fixed, then

$$(\cong_1^p) <_B (\cong_2^p) <_B \cdots <_B (\cong_n^p) <_B \cdots .$$

But this left open the more natural question of whether the classification problem for the p-local torsion-free abelian groups of a *fixed* rank $n \geq 2$ was strictly easier than the classification problem for arbitrary torsion-free abelian groups of rank n. (It is trivial that $(\cong_1^p) <_B (\cong_1)$, since there are only two p-local groups of rank 1 up to isomorphism; namely, $\mathbb{Q}$ and $\mathbb{Z}_{(p)} = \{a/b \in \mathbb{Q} \mid b \text{ is relatively prime to } p\}$.) This question was partially answered in Thomas [33], where it was shown that if $n \geq 3$ and $p \neq q$ are distinct primes, then $\cong_n^p$ and $\cong_n^q$ are incomparable with respect to Borel reducibility. Of course, this implies that if $n \geq 3$, then $(\cong_n^p) <_B (\cong_n)$ for each prime p. Unfortunately, the argument in Thomas [33] made essential use of the fact that if $n \geq 3$, then $\mathrm{SL}_n(\mathbb{Z})$ is a Kazhdan group; and, consequently, the problem remained open when $n = 2$. This case was finally dealt with in Hjorth–Thomas [16], which ultimately depends upon the fact that $\mathrm{SL}_2(\mathbb{Z})$ satisfies a weak form of the Kazhdan property; namely, $\mathrm{SL}_2(\mathbb{Z})$ has Property (τ) with respect to its family of congruence subgroups. (For example, see Lubotzky [23].)

Theorem 1.14 (Hjorth–Thomas [16]). *If $p \neq q$ are distinct primes, then the classification problems for the p-local and q-local torsion-free abelian groups of rank 2 are incomparable with respect to Borel reducibility.*

Since it was already known [31] that $(\cong_1) <_B (\cong_2^p)$, it follows that

$$(\cong_1) <_B (\cong_2^p) <_B (\cong_2)$$

for each prime p; and hence there exists an infinite antichain of countable Borel equivalence relations which lie strictly between $(\cong_1)$ and $(\cong_2)$. With a little more effort,

it is possible to show that there are uncountably many countable Borel equivalence relations E such that

$$(\cong_1) <_B E <_B (\cong_2).$$

(It should be pointed out that the proof of the following result makes essential use of the work of Kurosh–Malcev [22], [25], which was so unfairly dismissed earlier in this section.)

Definition 1.15. If $P \subseteq \mathbb{P}$ is a set of primes, then an abelian group A is said to be *P-local* iff A is q-divisible for all primes $q \notin P$.

For example, an abelian group A is $\emptyset$-local iff A is divisible; while, on the other hand, every abelian group is $\mathbb{P}$-local. Clearly the class of P-local abelian groups is included in the class of Q-local groups iff $P \subseteq Q$.

Theorem 1.16 (Thomas [35]). *Let $n \geq 2$. If P, Q are sets of primes, then the classification problem for the P-local torsion-free abelian groups of rank n is Borel reducible to that for the Q-local groups of rank n iff $P \subseteq Q$.*

In particular, there exists an infinite chain $\{R_m \mid m \in \mathbb{N}\}$ of countable Borel equivalence relations such that

$$(\cong_1) <_B R_0 <_B R_1 <_B \cdots <_B R_m <_B \cdots <_B (\cong_2);$$

and so $\cong_2$ is very far from being an immediate successor of $\cong_1$ with respect to Borel reducibility.

Remark 1.17. It should be mentioned that $\mathrm{Id}_{\mathbb{R}}$, E_0 is the only known example (up to Borel bireducibility) of a pair of countable Borel equivalence relations E, F such that F is an immediate successor of E with respect to $\leq_B$. On the other hand, there are currently no countable Borel equivalence relations E with $E_0 \leq_B E <_B E_\infty$ for which it is known that no such countable Borel equivalence relation F exists.

2. Superrigidity

In this section, we shall discuss the orbit equivalence superrigidity theorems of Zimmer [38] and Furman [9], together with the corresponding Borel superrigidity theorems of Adams–Kechris [1], [2] and Thomas [32], [34]. Then, in the next section, we shall explain how to apply Borel superrigidity to the study of the classification problem for the torsion-free abelian groups of finite rank.

Recall that, by Feldman–Moore [6], if E is a countable Borel equivalence relation on the standard Borel space X, then there exists a countable group Γ and a Borel action of Γ on X such that $E = E_\Gamma^X$ is the corresponding orbit equivalence relation. However, it should be pointed out that the group Γ cannot be canonically recovered from E; and it is usually very difficult to determine whether two given Borel actions

of a pair Γ, Λ of countable groups give rise to Borel bireducible orbit equivalence relations. Consequently, the fundamental question in the study of countable Borel equivalence relations concerns the extent to which the data (X, E_Γ^X) determines the group Γ and its action on X. In order for there to be any chance of recovering Γ from this data, it is necessary to assume the following extra hypotheses:

(i) Γ acts *freely* on X; i.e. $\gamma \cdot x \neq x$ for all $1 \neq \gamma \in \Gamma$ and $x \in X$.

(ii) There exists a Γ-invariant probability measure μ on X.

For example, by Dougherty–Jackson–Kechris [5], if (i) holds and (ii) fails, then for any countable group $\Lambda \supseteq \Gamma$, there exists a free Borel action of Λ on X such that $E_\Lambda^X = E_\Gamma^X$. If Γ is finite, then E_Γ^X is smooth and so we shall suppose throughout this section that Γ is infinite. In this case, μ is necessarily nonatomic (i.e. $\mu(\{x\}) = 0$ for every $x \in X$) and it follows that the probability space (X, μ) is measurably isomorphic to the unit interval $[0, 1]$ equipped with its Lebesgue measure.

It is also natural to assume that the following "indecomposability hypothesis" holds:

(iii) Γ acts *ergodically* on (X, μ); i.e. every Γ-invariant Borel subset of X has measure 0 or 1.

Thus, even when working in the purely Borel setting, it is useful to focus our attention on those orbit equivalence relations which arise from free ergodic actions of countable groups on probability spaces.

Example 2.1. Let Γ be any countable group. Then the shift action of Γ on 2^Γ is defined by

$$(\gamma \cdot h)(\delta) = h(\gamma^{-1}\delta), \quad \gamma, \delta \in \Gamma,\ h \in 2^\Gamma.$$

Let μ be the usual product probability measure on 2^Γ. Then μ is Γ-invariant and Γ acts ergodically on $(2^\Gamma, \mu)$. (For example, see Hjorth–Kechris [15].) Furthermore, letting

$$(2)^\Gamma = \{h \in 2^\Gamma \mid \gamma \cdot h \neq h \text{ for all } 1 \neq \gamma \in \Gamma\}$$

be the free part of the action, it is easily checked that $\mu((2)^\Gamma) = 1$.

Now suppose that Γ, Λ are countable groups with free ergodic Borel actions on the probability spaces (X, μ), (Y, ν) respectively. Then, by Dougherty–Jackson–Kechris [5], the corresponding countable Borel equivalence relations E_Γ^X and E_Λ^Y are Borel bireducible iff there exist Borel complete sections $A \subseteq X$, $B \subseteq Y$ such that the restricted equivalence relations are isomorphic via a Borel bijection

$$f : (A,\ E_\Gamma^X \restriction A) \cong (B,\ E_\Lambda^Y \restriction B).$$

Here, for example, $A \subseteq X$ is said to be a *complete section* of E_Γ^X iff A intersects every E_Γ^X-class. In particular, it follows that $\mu(A), \nu(B) > 0$. However, there is no

reason to suppose that f preserves the corresponding "rescaled" probability measures μ_A, ν_B on A, B respectively, defined by $\mu_A(Z) = \mu(Z)/\mu(A)$, etc. If we add the requirement that the map f should also be measure-preserving, then we pass from the purely Borel setting into the richer measure-theoretic setting, where the fundamental question now concerns the extent to which the data (X, E_Γ^X, μ) determines the group Γ and its action on X.

Definition 2.2. With the above hypotheses, the actions of Γ, Λ on (X, μ), (Y, ν) are said to be *weakly orbit equivalent* iff there exist Borel subsets $A \subseteq X$, $B \subseteq Y$ with $\mu(A), \nu(B) > 0$ such that the restricted equivalence relations are isomorphic via a measure-preserving Borel bijection

$$f\colon (A,\ E_\Gamma^X \restriction A,\ \mu_A) \cong (B,\ E_\Lambda^Y \restriction B,\ \nu_B).$$

If $\mu(A) = \nu(B) = 1$, then the actions are said to be *orbit equivalent*.

Warning 2.3. At first glance, it might appear that weak orbit equivalence implies Borel bireducibility. However, this is not the case. In the measure-theoretic setting, sets and maps are only considered modulo measure zero sets; and, in particular, the Borel sets A, B in Definition 2.2 are not required to be complete sections.

Definition 2.4. The actions of Γ, Λ on (X, μ), (Y, ν) are said to be *isomorphic* iff there exist

- invariant Borel subsets $X_0 \subseteq X$, $Y_0 \subseteq Y$ with $\mu(X_0) = \nu(Y_0) = 1$,
- a measure-preserving Borel bijection $f\colon X_0 \to Y_0$, and
- a group isomorphism $\varphi\colon \Gamma \to \Lambda$

such that $f(\gamma \cdot x) = \varphi(\gamma) \cdot f(x)$ for all $\gamma \in \Gamma$ and $x \in X_0$.

If the actions of Γ, Λ on (X, μ), (Y, ν) are isomorphic, then they are clearly orbit equivalent. The strongest conceivable superrigidity theorem would say that, conversely, if the actions are (weakly) orbit equivalent, then they are necessarily isomorphic. Of course, in order for anything like this to be true, it is necessary to impose strong hypotheses on the groups involved. For example, Ornstein–Weiss [27] have shown that if Γ and Λ are amenable groups, then any free ergodic actions of Γ, Λ are orbit equivalent.

Definition 2.5. Let G be an lcsc group and let m be a fixed Haar measure on G. Then a subgroup $\Gamma \leqslant G$ is a *lattice* iff Γ is discrete and the covolume $m(G/\Gamma)$ is finite.

Suppose now that Γ is a lattice in a connected simple Lie group G such that $\mathbb{R}\text{-rank}(G) \geq 2$. For example, we can take $\Gamma = \mathrm{SL}_n(\mathbb{Z})$ and $G = \mathrm{SL}_n(\mathbb{R})$ for any $n \geq 3$. Then, while the lattice Γ is not uniquely determined by (X, E_Γ^X, μ), Zimmer's orbit equivalence superrigidity theorem says that this data does uniquely determine

the ambient Lie group G. More precisely, suppose that G_0 and G_1 are connected centerless simple Lie groups of $\mathbb{R}$-rank at least 2 and that Γ_0, Γ_1 are lattices in G_0, G_1 respectively. (In order to keep our account as transparent as possible, we shall mainly focus on the case of lattices in connected *centerless* simple Lie groups.) Suppose that Γ_0, Γ_1 have free ergodic Borel actions on the probability spaces (X_0, μ_0) and (X_1, μ_1). Then, for each $0 \leq i \leq 1$, there is a naturally associated induced action of G_i on the standard Borel space

$$\widehat{X}_i = X_i \times (G_i/\Gamma_i)$$

with invariant ergodic probability measure $\widehat{\mu}_i = \mu_i \times m_i$, where m_i is the Haar probability measure on G_i/Γ_i.

Theorem 2.6 (Zimmer [38]). *With the above hypotheses, if the actions of* Γ_0, Γ_1 *on* (X_0, μ_0), (X_1, μ_1) *are weakly orbit equivalent, then the induced actions of* G_0, G_1 *on* $(\widehat{X}_0, \widehat{\mu}_0)$, $(\widehat{X}_1, \widehat{\mu}_1)$ *are isomorphic. In particular,* $G_0 \cong G_1$.

Unfortunately, there are many examples of lattices Γ_0, Γ_1 with free ergodic Borel actions on probability spaces (X_0, μ_0), (X_1, μ_1) for which there exists a Borel reduction $f : X_0 \to X_1$ from $E_{\Gamma_0}^{X_0}$ to $E_{\Gamma_1}^{X_1}$ such that $\mu_1(f[X_0]) = 0$; and hence Zimmer's orbit equivalence superrigidity theorem cannot be directly applied in the purely Borel setting. However, it was an important insight of Adams–Kechris [2] that it is possible to apply Zimmer's more fundamental cocycle superrigidity theorem. (The notion of a cocycle will not be defined in this article. Clear accounts of the theory of cocycles can be found in Zimmer [38] and Adams–Kechris [2]. In particular, Adams–Kechris [2] provides a convenient introduction to the basic techniques and results in this area, written for the non-expert in the ergodic theory of groups.)

Theorem 2.7 (Adams–Kechris [2]). *With the above hypotheses, if* $E_{\Gamma_0}^{X_0} \leq_B E_{\Gamma_1}^{X_1}$, *then* G_0 *is involved in* G_1*; i.e. there exist Lie subgroups* $N \trianglelefteq H \leqslant G_1$ *such that* $G_0 \cong H/N$. *Consequently, if* $E_{\Gamma_0}^{X_0} \sim_B E_{\Gamma_1}^{X_1}$, *then* $G_0 \cong G_1$.

Corollary 2.8 (Adams–Kechris [2]). *There exist infinitely many countable Borel equivalence relations up to Borel bireducibility.*

In fact, by considering Borel actions of suitable S-arithmetic groups for various (possibly infinite) sets of primes S, Adams–Kechris [2] were able to prove that there are $2^{\aleph_0}$ such relations up to Borel bireducibility.

Corollary 2.9 (Adams–Kechris [2]). *There exist countable Borel equivalence relations which are incomparable with respect to Borel reducibility.*

The methods introduced by Adams–Kechris [2] are suitable for distinguishing between orbit equivalence relations of the form E_Γ^X and E_Λ^Y, where Γ and Λ are lattices in nonisogeneous higher rank semisimple Lie groups. More generally, they can be used to show that the countable Borel equivalence relations arising from suitably

chosen actions of "large" linear groups cannot be Borel reducible to those arising from the actions of "smaller" linear groups. For example, as we shall see in the next section, a variant of Theorem 2.7 can be used to prove that if $n \geq 2$, then the orbit equivalence relation arising from the action of $\mathrm{GL}_{n+1}(\mathbb{Q})$ on the standard Borel space $R(\mathbb{Q}^{n+1})$ of torsion-free abelian groups of rank $n+1$ is not Borel reducible to that arising from the action of $\mathrm{GL}_n(\mathbb{Q})$ on $R(\mathbb{Q}^n)$; in other words, $(\cong_{n+1}) \not\leq_B (\cong_n)$. Since we have already observed that $(\cong_n) \leq_B (\cong_{n+1})$, this implies that $(\cong_n) <_B (\cong_{n+1})$; i.e. that the complexity of the classification problem for the torsion-free abelian groups of rank n increases strictly with the rank n.

However, the methods of Adams–Kechris [2] are not as well-suited for those problems which involve distinguishing between orbit equivalence relations arising from different actions of the same countable group; e.g. the isomorphism relations for the p-local torsion-free abelian groups of rank 2, which arise as the orbit equivalence relations of the actions of $\mathrm{GL}_2(\mathbb{Q})$ on the standard Borel spaces $R^p(\mathbb{Q}^2)$. The next breakthrough occurred when Adams [1], by combining the use of Zimmer's cocycle superrigidity theorem with Ratner's measure classification theorem [29], developed a method for distinguishing between the orbit equivalence relations arising from suitably chosen actions of (not necessarily distinct) lattices Γ, Δ in the same higher rank semisimple Lie group G. (This idea had already been successfully exploited in the measure-theoretic setting by Zimmer [39] and Furman [9].) It quickly became clear that Adams' techniques were applicable to a wide range of natural problems concerning countable Borel equivalence relations. For example, combining the ideas of Adams [1] and Gefter–Golodets [10], it is straightforward to show that if $n \geq 3$, then the orbit equivalence relations arising from the following uncountable family of $\mathrm{SL}_n(\mathbb{Z})$-actions are pairwise incomparable with respect to Borel reducibility.

Example 2.10 (Gefter–Golodets [10]). Fix some integer $n \geq 2$ and for each nonempty set $\emptyset \neq J \subseteq \mathbb{P}$ of primes, let

$$K_n(J) = \prod_{p \in J} \mathrm{SL}_n(\mathbb{Z}_p),$$

where $\mathbb{Z}_p$ is the ring of p-adic integers. Then $K_n(J)$ is a compact group and we can regard $\mathrm{SL}_n(\mathbb{Z})$ as a subgroup of $K_n(J)$ via the diagonal embedding. Let μ_J be the Haar probability measure on $K_n(J)$ and let E_J be the orbit equivalence relation arising from the free action of $\mathrm{SL}_n(\mathbb{Z})$ on $K_n(J)$ via left translations. By the Strong Approximation Theorem [28], $\mathrm{SL}_n(\mathbb{Z})$ is a dense subgroup of $K_n(J)$ and this implies that $\mathrm{SL}_n(\mathbb{Z})$ acts ergodically on $(K_n(J), \mu_J)$.

Theorem 2.11 (Thomas [32]). *Fix some integer $n \geq 3$. If $J_0 \neq J_1$ are distinct nonempty subsets of $\mathbb{P}$, then E_{J_0} and E_{J_1} are incomparable with respect to Borel reducibility.*

The measure-theoretic analogue of this result was proved earlier by Gefter–Golodets [10], who showed that for distinct $J_0 \neq J_1$, the actions of $\mathrm{SL}_n(\mathbb{Z})$ on $(K_n(J_0), \mu_{J_0})$

and $(K_n(J_1), \mu_{J_1})$ are not weakly orbit equivalent. More recently, Furman [9] has shown that for many free ergodic actions of lattices Γ on probability spaces (X, μ), both the group Γ and its action on X are "almost uniquely determined" by the orbit equivalence relation E_Γ^X and the measure μ. More precisely, in our particular case, Furman's result takes the following form. (It is easily seen that if $J_0 \neq J_1$, then the actions of $\mathrm{SL}_n(\mathbb{Z})$ on $(K_n(J_0), \mu_{J_0})$ and $(K_n(J_1), \mu_{J_1})$ are not virtually isomorphic. Thus the following result is strictly stronger than that of Gefter–Golodets [10].)

Theorem 2.12 (Furman [9]). *Let $n \geq 3$ and let J be a nonempty subset of $\mathbb{P}$. Suppose that Λ is an* arbitrary *countable group with a free ergodic action on the probability space (Y, ν). If the actions of $\mathrm{SL}_n(\mathbb{Z})$, Λ on the probability spaces $(K_n(J), \mu_J)$, (Y, ν) are weakly orbit equivalent, then:*

(a) *$\mathrm{SL}_n(\mathbb{Z})$ and Λ are virtually isomorphic; and*

(b) *the actions of $\mathrm{SL}_n(\mathbb{Z})$, Λ on the probability spaces $(K_n(J), \mu_J)$, (Y, ν) are virtually isomorphic.*

Here two countable groups G_0, G_1 are said to be *virtually isomorphic* iff there exist subgroups $H_i \leqslant G_i$ of finite index and finite normal subgroups $N_i \trianglelefteq H_i$ for $i = 0, 1$ such that $H_0/N_0 \cong H_1/N_1$; and the free ergodic actions of G_0, G_1 on the probability spaces (X_0, μ_0), (X_1, μ_1) are said to be *virtually isomorphic* iff, after passing to ergodic components, the induced actions of H_0/N_0, H_1/N_1 on the factor spaces $(X_0, \mu_0)/N_0$, $(X_1, \mu_1)/N_1$ are isomorphic.

No analogues of Furman's results have yet been proved in the purely Borel setting, where all of the currently known superrigidity results impose very restrictive conditions on both the domain and the range of the relevant Borel bireduction. However, it seems reasonable to conjecture that the corresponding strengthening of Theorem 2.11 also holds in this setting.

Conjecture 2.13. The conclusion of Theorem 2.12 remains true if *weak orbit equivalence* is replaced by *Borel bireducibility*.

It is not known whether the analogue of Theorem 2.11 also holds when $n = 2$. Here the main obstacle is the failure of Zimmer's cocycle superrigidity theorem for the low rank Lie group $\mathrm{SL}_2(\mathbb{R})$. For the same reason, it is also not known whether or not these $\mathrm{SL}_2(\mathbb{Z})$-actions are (weakly) orbit equivalent. Since $\mathrm{SL}_2(\mathbb{Z})$ contains the free group F_2 on two generators as a subgroup of finite index, a positive solution of the following problem would also provide uncountably many "natural" F_2-actions which are pairwise neither Borel bireducible nor weakly orbit equivalent. Currently only three nonsmooth F_2-actions are known up to Borel bireducibility. On the other hand, in the measure-theoretic setting, Gaboriau–Popa [11] have recently constructed uncountably many F_2-actions which are pairwise not weakly orbit equivalent.

Conjecture 2.14. If $J_0 \neq J_1$ are distinct nonempty sets of primes, then the actions of $\mathrm{SL}_2(\mathbb{Z})$ on $(K_2(J_0), \mu_{J_0})$ and $(K_2(J_1), \mu_{J_1})$ are neither comparable with respect to Borel bireducibility nor weakly orbit equivalent.

We obtain a more manageable problem if we replace the lattice $\mathrm{SL}_2(\mathbb{Z})$ by

$$\Gamma_S = \mathrm{SL}_2(\mathbb{Z}[1/p_1, \ldots, 1/p_t]),$$

where $S = \{p_1, \ldots, p_t\}$ is a nonempty finite set of primes. Of course, Γ_S is no longer a lattice in $\mathrm{SL}_2(\mathbb{R})$. However, if we identify Γ_S with its image under the diagonal embedding into

$$G = \mathrm{SL}_2(\mathbb{R}) \times \mathrm{SL}_2(\mathbb{Q}_{p_1}) \times \cdots \times \mathrm{SL}_2(\mathbb{Q}_{p_t}),$$

then Γ_S is a lattice in G and Zimmer's cocycle superrigidity theorem holds for G. Furthermore, by Margulis–Tomanov [26], the analogue of Ratner's measure classification theorem also holds for G. For each nonempty (possibly infinite) set of primes J such that $S \cap J = \emptyset$, let E_S^J be the orbit equivalence relation arising from the action of Γ_S on

$$K_2(J) = \prod_{p \in J} \mathrm{SL}_2(\mathbb{Z}_p)$$

by left translations, where Γ_S is regarded as a subgroup of $K_2(J)$ via the diagonal embedding.

Theorem 2.15 (Thomas [34]). *Suppose that S_0, S_1 are nonempty finite sets of primes and that J_0, J_1 are nonempty (possibly infinite) sets of primes such that $S_0 \cap J_0 = S_1 \cap J_1 = \emptyset$. If $(J_0, S_0) \neq (J_1, S_1)$, then $E_{S_0}^{J_0}$ and $E_{S_1}^{J_1}$ are incomparable with respect to Borel reducibility.*

The proof of Theorem 2.15 easily extends to the more general situation of Γ_S-actions on homogeneous $K_2(J)$-spaces. For example, it is well-known that the compact group $\mathrm{SL}_2(\mathbb{Z}_p)$ acts transitively on the projective line $\mathbb{Q}_p \cup \{\infty\}$ over the field of p-adic numbers.

Theorem 2.16 (Thomas [34]). *Suppose that p, q are primes and that S, T are finite nonempty sets of primes such that $p \notin S$, $q \notin T$. If $(p, S) \neq (q, T)$, then the orbit equivalence relations of Γ_S, Γ_T on the projective lines $\mathbb{Q}_p \cup \{\infty\}$, $\mathbb{Q}_q \cup \{\infty\}$ are incomparable with respect to Borel reducibility.*

As we shall see in the next section, a variant of Theorem 2.16 can be used to prove that if $p \neq q$ are distinct primes, then the classification problems for the p-local and q-local torsion-free abelian groups of rank 2 are incomparable with respect to Borel reducibility.

3. The classification problem for the torsion-free abelian groups of finite rank

In this final section, we shall explain how to apply Borel superrigidity to the study of the classification problem for the torsion-free abelian groups of finite rank. First we shall

sketch the proof of Theorem 1.10, which says that the complexity of the isomorphism relation $\cong_n$ for the torsion-free abelian groups of rank n increases strictly with the rank n. This will be followed by a sketch of the proof of Theorem 1.14, which says that if $p \neq q$ are distinct primes, then the classification problems for the p-local and q-local torsion-free abelian groups of rank 2 are incomparable with respect to Borel reducibility.

Recall that for each $m \geq 1$, the isomorphism relation $\cong_m$ is precisely the orbit equivalence relation arising from the natural action of $\mathrm{GL}_m(\mathbb{Q})$ on the standard Borel space $R(\mathbb{Q}^m)$ of torsion-free abelian groups of rank m. In the last section, we saw that if Γ is a lattice in a higher rank centerless simple Lie group G and Γ has a free ergodic action on the probability space (X, μ), then the orbit equivalence relation E_Γ^X "encodes" the ambient Lie group G. More precisely, suppose that Λ is also a lattice in a centerless simple Lie group H and that Λ has a free ergodic action on the probability space (Y, ν). By Theorem 2.7, if $E_\Gamma^X \leq_B E_\Lambda^Y$, then G is involved in H; and, in particular, it follows that $\dim G \leq \dim H$. This certainly suggests that the orbit equivalence relation of $\mathrm{GL}_{n+1}(\mathbb{Q})$ on $R(\mathbb{Q}^{n+1})$ should not be Borel reducible to the orbit equivalence relation of $\mathrm{GL}_n(\mathbb{Q})$ on $R(\mathbb{Q}^n)$. Unfortunately, we cannot apply Theorem 2.7 directly to our situation, since:

(i) $\mathrm{GL}_m(\mathbb{Q})$ is not a lattice.

(ii) There does not exist a $\mathrm{GL}_m(\mathbb{Q})$-invariant probability measure on $R(\mathbb{Q}^m)$.

(iii) $\mathrm{GL}_m(\mathbb{Q})$ does not act freely on $R(\mathbb{Q}^m)$.

Fortunately, none of these difficulties is insurmountable. Suppose that $n \geq 2$ and that $f : R(\mathbb{Q}^{n+1}) \to R(\mathbb{Q}^n)$ is a Borel reduction from $\cong_{n+1}$ to $\cong_n$. First, following the example of Hjorth [13] and Adams–Kechris [2], we shall use the following result to deal with points (i) and (ii).

Theorem 3.1 (Hjorth [13]). *For each $m \geq 2$, there exists a nonatomic $\mathrm{SL}_m(\mathbb{Z})$-invariant ergodic probability measure μ on $R(\mathbb{Q}^m)$.*

In fact, Hjorth [13] has shown that for each prime $p \in \mathbb{P}$, there exists a nonatomic $\mathrm{SL}_m(\mathbb{Z})$-invariant ergodic probability measure μ_p on $R(\mathbb{Q}^m)$ which concentrates on the Borel subspace $R^p(\mathbb{Q}^m)$ of p-local groups. Later in this section, we shall sketch a proof of this result in the special case when $m = 2$.

Continuing the proof of Theorem 1.10, let E be the orbit equivalence relation arising from the action of the subgroup $\mathrm{SL}_{n+1}(\mathbb{Z})$ of $\mathrm{GL}_{n+1}(\mathbb{Q})$ on $R(\mathbb{Q}^{n+1})$. Then we can regard f as a countable-to-one Borel homomorphism from E to $\cong_n$; and Theorem 1.10 is an easy consequence of the following result. (As we shall see, most of our effort during the proof of Theorem 3.3 will go into dealing with point (iii).)

Definition 3.2. If E, F are equivalence relations on the standard Borel spaces X, Y, then the Borel map $f : X \to Y$ is a *Borel homomorphism* from E to F iff

$$x E y \text{ implies } f(x) F f(y) \quad \text{for all } x, y \in X.$$

Theorem 3.3 (Thomas [32]). *Let $m \geq 3$ and let X be a standard Borel $\mathrm{SL}_m(\mathbb{Z})$-space with an invariant ergodic probability measure μ. Suppose that $1 \leq n < m$ and that $f\colon X \to R(\mathbb{Q}^n)$ is a Borel homomorphism from $E^X_{\mathrm{SL}_m(\mathbb{Z})}$ to $\cong_n$. Then there exists an $\mathrm{SL}_m(\mathbb{Z})$-invariant Borel subset M with $\mu(M) = 1$ such that f maps M into a single $\cong_n$-class.*

Hence, letting μ be a nonatomic $\mathrm{SL}_{n+1}(\mathbb{Z})$-invariant ergodic probability measure on $R(\mathbb{Q}^{n+1})$, there exists an $\mathrm{SL}_{n+1}(\mathbb{Z})$-invariant Borel subset $M \subseteq R(\mathbb{Q}^{n+1})$ with $\mu(M) = 1$ such that f maps M into a single $\cong_n$-class $\mathcal{C}$. However, this is impossible, since $f^{-1}(\mathcal{C})$ consists of only countably many $\mathrm{SL}_{n+1}(\mathbb{Z})$-orbits. Hence $(\cong_n) <_B (\cong_{n+1})$ for all $n \geq 2$.

Next we shall sketch the proof of Theorem 3.3. Suppose that $m \geq 3$ and that X is a standard Borel $\mathrm{SL}_m(\mathbb{Z})$-space with an invariant ergodic probability measure μ. Suppose further that $1 \leq n < m$ and that $f\colon X \to R(\mathbb{Q}^n)$ is a Borel homomorphism from $E^X_{\mathrm{SL}_m(\mathbb{Z})}$ to $\cong_n$. We shall make use of the following variant of Theorem 2.7, which is a straightforward consequence of Zimmer's cocycle superrigidity theorem [38] and the ideas of Adams–Kechris [2].

Theorem 3.4 (Thomas [31]). *Let $m \geq 3$ and let X be a standard Borel $\mathrm{SL}_m(\mathbb{Z})$-space with an invariant ergodic probability measure μ. Suppose that $H \leqslant G(\mathbb{Q})$, where G is an algebraic $\mathbb{Q}$-group such that $\dim G < m^2 - 1$, and that H acts freely on the standard Borel H-space Y. If $f\colon X \to Y$ is a Borel homomorphism from $E^X_{\mathrm{SL}_m(\mathbb{Z})}$ to E^Y_H, then there exists an $\mathrm{SL}_m(\mathbb{Z})$-invariant Borel subset $M \subseteq X$ with $\mu(M) = 1$ such that f maps M into a single H-orbit.*

As we mentioned earlier, the action of $\mathrm{GL}_n(\mathbb{Q})$ on $R(\mathbb{Q}^n)$ is not free: in fact, for each $A \in R(\mathbb{Q}^n)$, the stabilizer of A in $\mathrm{GL}_n(\mathbb{Q})$ is precisely the automorphism group $\mathrm{Aut}(A)$ of A. Thus we are not yet in a position to apply Theorem 3.4.

Remark 3.5. This is actually a serious problem. The proof of Theorem 3.4 makes essential use of Zimmer's cocycle superrigidity theorem; and if H does not act freely on Y, then it impossible to define the associated cocycle on which the proof depends.

From now on, let $A_x = f(x) \in R(\mathbb{Q}^n)$. Roughly speaking, our strategy will be as follows. Suppose that there exists a Borel subset $X_0 \subseteq X$ with $\mu(X_0) = 1$ and a *fixed* subgroup $L \leqslant \mathrm{GL}_n(\mathbb{Q})$ such that $\mathrm{Aut}(A_x) = L$ for all $x \in X_0$. Then the equivalence relation $\cong_n \restriction f(X_0)$ will be induced by a free action of the quotient group $H = N_{\mathrm{GL}_n(\mathbb{Q})}(L)/L$ on the Borel subset

$$Y = \{A \in R(\mathbb{Q}^n) \mid \mathrm{Aut}(A) = L\}$$

of $R(\mathbb{Q}^n)$. Hence, provided that the quotient group H is isomorphic to a subgroup of an algebraic $\mathbb{Q}$-group $G(\mathbb{Q})$ with $\dim G < m^2 - 1$, we can apply Theorem 3.4. But why should X_0 and L exist? Imagine for the moment that there are only countably many possibilities for the subgroup $\mathrm{Aut}(A_x) \leqslant \mathrm{GL}_n(\mathbb{Q})$. Then there exists a Borel subset

$Z \subseteq X$ with $\mu(Z) > 0$ and a fixed subgroup $L \leqslant \mathrm{GL}_n(\mathbb{Q})$ such that $\mathrm{Aut}(A_x) = L$ for all $x \in Z$. Since $\mathrm{SL}_m(\mathbb{Z})$ acts ergodically on (X, μ), it follows that

$$X_0 = \{\gamma \cdot x \mid \gamma \in \mathrm{SL}_m(\mathbb{Z}) \text{ and } x \in Z\}.$$

has μ-measure 1. Let $g\colon X \to \mathrm{SL}_m(\mathbb{Z})$ be a Borel function such that $g(x) \cdot x \in Z$ for all $x \in X_0$. Then, replacing f by the Borel homomorphism f' defined by $f'(x) = f(g(x) \cdot x)$, we can suppose that $\mathrm{Aut}(A_x) = L$ for all $x \in X_0$.

Unfortunately, this approach does not work, since there are uncountably many possibilities for the subgroup $\mathrm{Aut}(A_x) \leqslant \mathrm{GL}_n(\mathbb{Q})$. In order to get around this difficulty, we shall shift our attention from the isomorphism relation on $R(\mathbb{Q}^n)$ to the coarser relation of quasi-isomorphism. This relation was first introduced in Jónsson [18], where it was shown that the class of torsion-free abelian groups of finite rank has a better decomposition theory with respect to quasi-isomorphism than with respect to isomorphism. This decomposition theory will not concern us in this article. Rather we shall exploit the fact that much of the number-theoretical complexity of finite rank torsion-free abelian groups is lost when they are only considered up to quasi-isomorphism; and this turns out to be enough to ensure that there are only countably many possibilities for the group of quasi-automorphisms of $A \in R(\mathbb{Q}^n)$.

Definition 3.6. If $A, B \in R(\mathbb{Q}^n)$, then A and B are said to be *quasi-equal*, written $A \approx_n B$, iff $A \cap B$ has finite index in both A and B.

Definition 3.7. If $A, B \in R(\mathbb{Q}^n)$, then A and B are said to be *quasi-isomorphic* iff there exists $\varphi \in \mathrm{GL}_n(\mathbb{Q})$ such that $\varphi[A] \approx_n B$.

It is easily checked that $\approx_n$ is a countable Borel equivalence relation on $R(\mathbb{Q}^n)$. For each $A \in R(\mathbb{Q}^n)$, let $[A]$ be the $\approx_n$-class containing A. We shall consider the induced action of $\mathrm{GL}_n(\mathbb{Q})$ on the set of $\approx_n$-classes. In order to describe the setwise stabilizer in $\mathrm{GL}_n(\mathbb{Q})$ of a $\approx_n$-class $[A]$, it is first necessary to introduce the notions of a quasi-endomorphism and a quasi-automorphism. If $A \in R(\mathbb{Q}^n)$, then a linear transformation $\varphi \in \mathrm{Mat}_n(\mathbb{Q})$ is said to be a *quasi-endomorphism* of A iff there exists an integer $m > 0$ such that $m\varphi[A] \leqslant A$. In other words, φ is a quasi-endomorphism of A iff there exists an integer $m > 0$ such that $m\varphi \in \mathrm{End}(A)$. It is easily checked that the collection $\mathrm{QE}(A)$ of quasi-endomorphisms of A is a $\mathbb{Q}$-subalgebra of $\mathrm{Mat}_n(\mathbb{Q})$; and, of course, this implies that there are only countably many possibilities for $\mathrm{QE}(A)$. A linear transformation $\varphi \in \mathrm{Mat}_n(\mathbb{Q})$ is said to be a *quasi-automorphism* of A iff φ is a unit of the $\mathbb{Q}$-algebra $\mathrm{QE}(A)$; and the group of quasi-automorphisms of A is denoted by $\mathrm{QAut}(A)$.

Lemma 3.8 (Thomas [31]). *If $A \in R(\mathbb{Q}^n)$, then* $\mathrm{QAut}(A)$ *is the setwise stabilizer of* $[A]$ *in* $\mathrm{GL}_n(\mathbb{Q})$.

In particular, there are only countably many possibilities for the setwise stabilizer of $[A]$ in $\mathrm{GL}_n(\mathbb{Q})$. Hence, arguing as above, we can suppose that there exists a Borel

subset $X_0 \subseteq X$ with $\mu(X_0) = 1$ and a fixed subgroup $L \leqslant \mathrm{GL}_n(\mathbb{Q})$ such that L is the setwise stabilizer of $[A_x]$ for all $x \in X_0$; and this implies that the quotient group $H = N_{\mathrm{GL}_n(\mathbb{Q})}(L)/L$ acts freely on the corresponding set $Y = \{[A] \mid \mathrm{QAut}(A) = L\}$ of $\approx_n$-classes.

Lemma 3.9 (Thomas [31]). *There is an algebraic $\mathbb{Q}$-group G with* $\dim G < m^2 - 1$ *such that $H \leqslant G(\mathbb{Q})$.*

Consequently, we are now positioned to apply Theorem 3.4 … except for one last complication. Unfortunately, the equivalence relation $\approx_n$ is not smooth and this means that Y is not a standard Borel space. However, this turns out not to be a serious difficulty. As shown in Thomas [31], the equivalence relation $\approx_n$ is hyperfinite (which is only slightly more complicated than smooth) and Theorem 3.4 is easily extended to cover induced free actions on quotients of standard Borel spaces by hyperfinite equivalence relations.

Remark 3.10. The above argument does not go through in the case when $n = 1$ because of the failure of Zimmer's cocycle superrigidity theorem for the low rank Lie group $\mathrm{SL}_2(\mathbb{R})$. However, as we mentioned earlier, this case had already been dealt with by Hjorth [13], who gave a completely elementary proof that $(\cong_1) <_B (\cong_2)$, based upon the fact that $\mathrm{GL}_1(\mathbb{Q}) = \mathbb{Q}^*$ is amenable and $\mathrm{GL}_2(\mathbb{Q})$ is nonamenable.

In the remainder of this section, we shall sketch the proof of Theorem 1.14. This involves trying to understand the orbit equivalence relation $\cong_2^p$ of the classical group $\mathrm{GL}_2(\mathbb{Q})$ on the highly non-classical space $R^p(\mathbb{Q}^2)$ of p-local torsion-free abelian groups of rank 2. Fortunately, using the invariants of Kurosh–Malcev [22], [25], it is possible to replace $R^p(\mathbb{Q}^2)$ by a much more intelligible space.

Definition 3.11. For each prime p, let E_p be the orbit equivalence relation arising from the natural action of $\mathrm{GL}_2(\mathbb{Q})$ on the projective line $\mathbb{Q}_p \cup \{\infty\}$ over the field of p-adic numbers.

Theorem 3.12 (Thomas [31]). $(\cong_2^p) \sim_B (E_p)$.

Thus Theorem 1.14 is an immediate consequence of the following result.

Theorem 3.13 (Hjorth–Thomas [16]). *If $p \neq q$ are distinct primes, then the orbit equivalence relations E_p, E_q of* $\mathrm{GL}_2(\mathbb{Q})$ *on the projective lines $\mathbb{Q}_p \cup \{\infty\}$, $\mathbb{Q}_q \cup \{\infty\}$ are incomparable with respect to Borel reducibility.*

Sketch proof of Theorem 3.12. Following Kurosh–Malcev [22], [25], we shall describe how to assign points $V_A \in \mathbb{Q}_p \cup \{\infty\}$ to the p-local groups

$$\{A \in R^p(\mathbb{Q}^2) \mid A \ncong \mathbb{Q} \oplus \mathbb{Q},\ \mathbb{Z}_{(p)} \oplus \mathbb{Z}_{(p)}\}$$

such that:

- $A \cong B$ iff the corresponding points V_A, V_B lie in the same $\mathrm{GL}_2(\mathbb{Q})$-orbit;

- for each point $V \in \mathbb{Q}_p \cup \{\infty\}$, there exists a corresponding group A such that $V_A = V$.

The result then follows easily from the fact that there are only countably many groups $A \in R^p(\mathbb{Q}^2)$ such that $A \cong \mathbb{Q} \oplus \mathbb{Q}, \mathbb{Z}_{(p)} \oplus \mathbb{Z}_{(p)}$.

It is first necessary to discuss the p-adic completion $\widehat{A}$ of each p-local group $A \in R^p(\mathbb{Q}^2)$, which is defined as follows. For the remainder of this proof, we shall regard $\mathbb{Q}^2$ as an additive subgroup of the 2-dimensional vector space $\mathbb{Q}_p^2$ over the field of p-adic numbers; and we shall regard $\mathrm{GL}_2(\mathbb{Q})$ as a subgroup of $\mathrm{GL}_2(\mathbb{Q}_p)$. For each $A \in R^p(\mathbb{Q}^2)$, let $\widehat{A} = \mathbb{Z}_p \otimes A$; i.e. $\widehat{A}$ is the subgroup of $\mathbb{Q}_p^2$ consisting of all finite sums

$$\gamma_1 a_1 + \gamma_2 a_2 + \cdots + \gamma_t a_t,$$

where $\gamma_i \in \mathbb{Z}_p$ and $a_i \in A$ for $1 \leq i \leq t$. Then, while A usually has a very complex structure, $\widehat{A}$ always decomposes into a direct sum of copies of $\mathbb{Z}_p$ and $\mathbb{Q}_p$. In fact, assuming that $A \ncong \mathbb{Q} \oplus \mathbb{Q}, \mathbb{Z}_{(p)} \oplus \mathbb{Z}_{(p)}$, there exist elements $\mathbf{v}_A, \mathbf{w}_A \in \widehat{A}$ such that

$$\widehat{A} = \mathbb{Q}_p \mathbf{v}_A \oplus \mathbb{Z}_p \mathbf{w}_A.$$

(See Fuchs [8].) Let $V_A = \mathbb{Q}_p \mathbf{v}_A$. If $A \cong B$, then there exists $\varphi \in \mathrm{GL}_2(\mathbb{Q})$ such that $\varphi[A] = B$. This implies that $\varphi[\widehat{A}] = \widehat{B}$ and it follows easily that $\varphi[V_A] = V_B$. Conversely, suppose that there exists $\varphi \in \mathrm{GL}_2(\mathbb{Q})$ such that $\varphi[V_A] = V_B$. Since the nontrivial proper $\mathbb{Z}_p$-submodules of $\mathbb{Q}_p$ are precisely $\{p^\ell \mathbb{Z}_p \mid \ell \in \mathbb{Z}\}$, after composing φ with a suitable transformation $v \mapsto p^\ell v$ if necessary, we can suppose that $\varphi[\widehat{A}] = \widehat{B}$. Since $\widehat{A} \cap \mathbb{Q}^2 = A$ and $\widehat{B} \cap \mathbb{Q}^2 = B$, it follows that $\varphi[A] = B$. Thus the $\mathrm{GL}_2(\mathbb{Q})$-orbit of the point $V_A \in \mathbb{Q}_p \cup \{\infty\}$ is a complete invariant for those $A \in R^p(\mathbb{Q}^2)$ such that $A \ncong \mathbb{Q} \oplus \mathbb{Q}, \mathbb{Z}_{(p)} \oplus \mathbb{Z}_{(p)}$. □

Remark 3.14. It is now easy to prove that for each prime $p \in \mathbb{P}$, there exists a nonatomic $\mathrm{SL}_2(\mathbb{Z})$-invariant ergodic probability measure μ_p on $R(\mathbb{Q}^2)$ which concentrates on the Borel subspace $R^p(\mathbb{Q}^2)$ of p-local groups. We have just seen how to assign a corresponding point $V_A \in \mathbb{Q}_p \cup \{\infty\}$ to each $A \in R^p(\mathbb{Q}^2)$ such that $A \ncong \mathbb{Q} \oplus \mathbb{Q}, \mathbb{Z}_{(p)} \oplus \mathbb{Z}_{(p)}$. Conversely, for each point $V \in \mathbb{Q}_p \cup \{\infty\}$, there exists a corresponding group A such that $V_A = V$. In fact, there exist countably many such groups. However, if we restrict our attention to the $\mathrm{SL}_2(\mathbb{Z})$-invariant Borel subset $X(\mathbb{Q}^2)$ consisting of those $A \in R^p(\mathbb{Q}^2)$ such that

(i) $A \ncong \mathbb{Q} \oplus \mathbb{Q}, \mathbb{Z}_{(p)} \oplus \mathbb{Z}_{(p)}$,

(ii) $\mathbb{Z}_{(p)}^2 \leqslant A$ and $\mathbb{Z}_{(p)}^2 \not\leqslant pA$,

then we obtain a one-to-one correspondence. In summary, the map

$$\begin{aligned} X(\mathbb{Q}^m) &\to \mathbb{Q}_p \cup \{\infty\}, \\ A &\mapsto V_A, \end{aligned}$$

is a Borel bijection satisfying $\varphi[V_A] = V_{\varphi[A]}$ for all $\varphi \in \mathrm{SL}_2(\mathbb{Z})$ and $A \in X(\mathbb{Q}^2)$. Hence the result follows from the observation that there exists a nonatomic $\mathrm{SL}_2(\mathbb{Z})$-invariant ergodic probability measure ν_p on $\mathbb{Q}_p \cup \{\infty\}$. To see this, recall that the compact group $K = \mathrm{SL}_2(\mathbb{Z}_p)$ acts transitively on $\mathbb{Q}_p \cup \{\infty\}$. Hence, letting L be the stabilizer in K of some point of $\mathbb{Q}_p \cup \{\infty\}$, we can identify the K-spaces $\mathbb{Q}_p \cup \{\infty\}$ and K/L. Let ν_p be the Haar probability measure on K/L. Since $\mathrm{SL}_2(\mathbb{Z})$ is a dense subgroup of K, it follows that ν_p is the unique $\mathrm{SL}_2(\mathbb{Z})$-invariant probability measure on K/L and hence $\mathrm{SL}_2(\mathbb{Z})$ acts ergodically on $(K/L, \nu_p)$.

The above argument easily generalizes to show that for all $m \geq 2$, there exists a nonatomic $\mathrm{SL}_m(\mathbb{Z})$-invariant ergodic probability measure μ_p on $R(\mathbb{Q}^m)$ which concentrates on the Borel subspace consisting of those $A \in R^p(\mathbb{Q}^m)$ such that $\dim A/pA = 1$. (For example, see Thomas [31].)

Finally we shall sketch the proof of Theorem 3.13. Recall that if $S = \{p_1, \ldots, p_t\}$ is a nonempty finite set of primes, then

$$\Gamma_S = \mathrm{SL}_2(\mathbb{Z}[1/p_1, \ldots, 1/p_t]).$$

Also let $\Gamma_\emptyset = \mathrm{SL}_2(\mathbb{Z})$. As we shall see, Theorem 3.13 is an easy consequence of the following variant of Theorem 2.16, together with a crucial result of Hjorth [16].

Theorem 3.15 (Thomas [34]). *Suppose that $p \neq q$ are distinct primes and that S is a (possibly empty) finite set of primes. Let*

- *E_1 be the orbit equivalence relation induced by the action of $\mathrm{SL}_2(\mathbb{Z}[1/q])$ on $\mathbb{Q}_p \cup \{\infty\}$, and*
- *E_2 be the orbit equivalence relation induced by the action of Γ_S on $\mathbb{Q}_q \cup \{\infty\}$.*

If $f : \mathbb{Q}_p \cup \{\infty\} \to \mathbb{Q}_q \cup \{\infty\}$ is a Borel homomorphism from E_1 to E_2, then there exists a μ_p-measure 1 subset which is mapped to a single E_2-class.

Remark 3.16. The basic theme of Borel superigidity theory is that, under suitably strong hypotheses, every nontrivial Borel homomorphism is a "slight perturbation" of a virtual homomorphism of the corresponding measure-preserving permutation groups. In the statement of Theorem 3.15, the group $\mathrm{SL}_2(\mathbb{Z}[1/q])$ was chosen because its actions on $\mathbb{Q}_p \cup \{\infty\}$ and $\mathbb{Q}_q \cup \{\infty\}$ are extremely incompatible; namely, while $\mathrm{SL}_2(\mathbb{Z}[1/q])$ preserves the p-adic probability measure on $\mathbb{Q}_p \cup \{\infty\}$, there are no $\mathrm{SL}_2(\mathbb{Z}[1/q])$-invariant probability measures on $\mathbb{Q}_q \cup \{\infty\}$.

Sketch proof of Theorem 3.13. Suppose that $f : \mathbb{Q}_p \cup \{\infty\} \to \mathbb{Q}_q \cup \{\infty\}$ is a Borel reduction between the orbit equivalence relations induced by the $\mathrm{GL}_2(\mathbb{Q})$-actions. Then we can regard f as a countable-to-one Borel homomorphism between the $\mathrm{SL}_2(\mathbb{Z}[1/q])$-action on $\mathbb{Q}_p \cup \{\infty\}$ and the $\mathrm{GL}_2(\mathbb{Q})$-action on $\mathbb{Q}_q \cup \{\infty\}$. Using a suitable Cocycle Reduction Theorem of Hjorth [16], we can "adjust" f to obtain a

countable-to-one Borel homomorphism $f' \colon \mathbb{Q}_p \cup \{\infty\} \to \mathbb{Q}_q \cup \{\infty\}$ between the orbit equivalence relation induced by the $\mathrm{SL}_2(\mathbb{Z}[1/q])$-action on $\mathbb{Q}_p \cup \{\infty\}$ and the orbit equivalence relation induced by the Γ_S-action on $\mathbb{Q}_q \cup \{\infty\}$ for some finite set of primes S, which contradicts Theorem 3.15. □

In view of Remark 1.17, it would be interesting to know whether $\cong_2^p$ is an immediate successor of $\cong_1$ with respect to $\leq_B$. Equivalently:

Question 3.17. Let E_p be the orbit equivalence relation arising from the action of $\mathrm{GL}_2(\mathbb{Q})$ on the projective line $\mathbb{Q}_p \cup \{\infty\}$ over the field of p-adic numbers. Does there exist a (countable) Borel equivalence relation E such that $E_0 <_B E <_B E_p$?

Quiver algebras, weighted projective lines, and the Deligne–Simpson problem

William Crawley-Boevey

Abstract. We describe recent work on preprojective algebras and moduli spaces of their representations. We give an analogue of Kac's Theorem, characterizing the dimension types of indecomposable coherent sheaves over weighted projective lines in terms of loop algebras of Kac–Moody Lie algebras, and explain how it is proved using Hall algebras. We discuss applications to the problem of describing the possible conjugacy classes of sums and products of matrices in known conjugacy classes.

Mathematics Subject Classification (2000). Primary 16G20, 14H60, 15A24.

Keywords. Quiver, Kac–Moody Lie algebra, preprojective algebra, weighted projective line, parabolic bundle, loop algebra, Hall algebra, Deligne–Simpson problem.

Introduction

Preprojective algebras were introduced by Gelfand and Ponomarev, and in a deformed version by Crawley-Boevey and Holland. They arose in the theory of representations of quivers, but have interesting links with Kleinian singularities, Kac–Moody Lie algebras and noncommutative symplectic geometry. In the first part of this article, §1, we survey some of the results we have obtained in the last ten years concerning these algebras, and moduli spaces of their representations.

The Deligne–Simpson problem asks about the existence of matrices in given conjugacy classes, with product the identity, and no common invariant subspace. Some time ago it became clear that our work on preprojective algebras solves an additive analogue. To solve the original problem, one needs to pass to a new setup, in which representations of quivers are replaced by coherent sheaves on weighted projective lines (or parabolic bundles), and representations of the preprojective algebra are replaced by logarithmic connections. We discuss all this in §4.

A key ingredient in the theory of preprojective algebras is Kac's Theorem, describing the possible dimension vectors of indecomposable representations of quivers. In the new setup, one needs an analogue of Kac's Theorem for weighted projective lines. We discuss it in §2, and outline a proof via Hall algebras in §3.

In the rest of this introduction we recall some basic facts about representations of quivers. A *quiver* Q, or more precisely (I, Q, h, t), consists of finite sets I and Q

Proceedings of the International Congress of Mathematicians, Madrid, Spain, 2006

of vertices and arrows, and maps $h, t\colon Q \to I$, assigning to each arrow its head and tail vertices. We fix a base field K, algebraically closed unless otherwise indicated. By a *representation* X of Q, one means the assignment of a vector space X_v for each vertex v, and a linear map $X_{t(a)} \to X_{h(a)}$ for each arrow a. There are natural notions of homomorphisms between representations, sub-representations, etc.

The *path algebra* KQ has basis the paths $a_1a_2\dots a_n$ in Q of length $n \geq 1$, with $t(a_i) = h(a_{i+1})$ for all i, and a *trivial path* of length 0 for each vertex v. It is an associative algebra, with the product of two paths given by their concatenation, if this makes sense, and otherwise zero, and the sum of the trivial paths is a multiplicative identity. The category of representations of Q is equivalent to the category of left KQ-modules, so one can use homological algebra, composition series, the Krull–Remak–Schmidt Theorem, and so on.

We now assume for simplicity that Q has no oriented cycles, in which case KQ is finite dimensional, although many results hold without this restriction.

Let $\mathfrak{g}$ be the Kac–Moody Lie algebra given by the symmetric generalized Cartan matrix $(a_{uv})_{u,v\in I}$ which has diagonal entries 2, and off-diagonal entries given by minus the number of arrows in Q between u and v, in either direction. Thus $\mathfrak{g}$ is generated over $\mathbb{C}$ by e_v, f_v, h_v ($v \in I$) with relations

$$\begin{cases} [h_u, h_v] = 0, \quad [e_u, f_v] = \delta_{uv} h_v, \\ [h_u, e_v] = a_{uv} e_v, \quad [h_u, f_v] = -a_{uv} f_v, \\ (\operatorname{ad} e_u)^{1-a_{uv}}(e_v) = 0, \quad (\operatorname{ad} f_u)^{1-a_{uv}}(f_v) = 0 \quad (\text{if } u \neq v), \end{cases} \tag{1}$$

where δ is the Kronecker delta function. The root lattice Γ of $\mathfrak{g}$ is the free additive group on symbols α_v ($v \in I$), it grades $\mathfrak{g}$, with $\deg e_v = \alpha_v$, $\deg f_v = -\alpha_v$ and $\deg h_v = 0$, and the set of roots is $\Delta = \{0 \neq \alpha \in \Gamma \mid \mathfrak{g}_\alpha \neq 0\}$. Recall that there are real roots, obtained from the simple roots α_u by a sequence of reflections $s_v(\alpha) = \alpha - (\alpha, \alpha_v)\alpha_v$, where $(-,-)$ is the symmetric bilinear form on Γ with $(\alpha_u, \alpha_v) = a_{uv}$, and there may also be imaginary roots. Defining $p(\alpha) = 1 - \frac{1}{2}(\alpha, \alpha)$, the real roots have $p(\alpha) = 0$, and the imaginary roots have $p(\alpha) > 0$.

Gabriel's Theorem [19] asserts that a quiver Q has only finitely many indecomposable representations if and only if $\mathfrak{g}$ is of finite type, i.e. the underlying graph of Q is a Dynkin diagram (of type ADE). In this case the map sending a representation to its dimension vector

$$\underline{\dim}\, X = \sum_{v\in I} (\dim X_v)\alpha_v \in \Gamma$$

gives a 1-1 correspondence between indecomposable representations and positive roots. Kac's Theorem [26], [27] extends this to $\mathfrak{g}$ of arbitrary type: the dimension vectors of indecomposable representations are exactly the positive roots, there is a unique indecomposable for each real root, infinitely many for each imaginary root.

1. Preprojective algebras

The *preprojective algebra* of a quiver Q is the algebra

$$\Pi(Q) = K\bar{Q}\Big/\Big(\sum_{a\in Q}(aa^* - a^*a)\Big),$$

where the *double* $\bar{Q}$ of Q is obtained by adjoining a reverse arrow a^* for each arrow $a \in Q$. In the finite type case it is isomorphic, as a KQ-module, to the direct sum of one copy of each indecomposable representation of Q. In general, it is isomorphic to the direct sum of the indecomposable representations of Q that are *preprojective*, meaning that some power of the Coxeter functor, or equivalently of the Auslander–Reiten translation $D\mathrm{Tr}$, sends them to a projective KQ-module.

Preprojective algebras first appeared in unpublished work of I. M. Gelfand and V. A. Ponomarev, in a lecture delivered by A. V. Roiter at the Second International Conference on Representations of Algebras (Ottawa, 1979). See [45] for a discussion about variations on this definition. Note also that work by Riedtmann [40] contains parallel ideas.

Given $\lambda = (\lambda_v)_{v\in I} \in K^I$, Crawley-Boevey and Holland [15] have introduced the *deformed preprojective algebra*, $\Pi^\lambda(Q)$, in which the relation is replaced by

$$\sum_{a\in Q}(aa^* - a^*a) - \lambda, \tag{2}$$

where λ is identified with the corresponding linear combination of trivial paths.

Up to isomorphism, these algebras do not depend on the orientation of Q. They are related to some elementary symplectic geometry. Choosing bases for the vector spaces, representations of Q of dimension vector $\alpha = \sum_v n_v\alpha_v$ are given by elements of the space

$$\mathrm{Rep}(Q,\alpha) = \bigoplus_{a\in Q}\mathrm{Mat}_{n_{h(a)}\times n_{t(a)}}(K),$$

and isomorphism classes correspond to orbits of the group

$$\mathrm{GL}(\alpha) = \prod_{v\in I}\mathrm{GL}_{n_v}(K)$$

acting by conjugation. The space of representations of $\bar{Q}$ can then be identified with a cotangent bundle

$$\mathrm{Rep}(\bar{Q},\alpha) \cong \mathrm{Rep}(Q,\alpha)\times\mathrm{Rep}(Q,\alpha)^* \cong T^*\,\mathrm{Rep}(Q,\alpha).$$

This has a natural symplectic structure, and associated to the action of $\mathrm{GL}(\alpha)$ there is a moment map

$$\mu_\alpha\colon \mathrm{Rep}(\bar{Q},\alpha)\to\mathrm{gl}(\alpha),\quad x\mapsto\Big(\sum_{\substack{a\in Q\\ h(a)=v}}x_ax_{a^*} - \sum_{\substack{a\in Q\\ t(a)=v}}x_{a^*}x_a\Big)_{v\in I}.$$

Identifying λ with a central element of $\mathrm{gl}(\alpha)$, there is a quotient

$$N_Q(\lambda, \alpha) = \mu_\alpha^{-1}(\lambda) /\!\!/ \mathrm{GL}(\alpha),$$

a 'symplectic quotient', or 'Marsden–Weinstein reduction'. Here the double slash denotes the affine variety that classifies closed orbits of $\mathrm{GL}(\alpha)$ on $\mu_\alpha^{-1}(\lambda)$. Now the elements of this fibre are exactly the representations of $\overline{Q}$ satisfying (2), so $N_Q(\lambda, \alpha)$ classifies isomorphism classes of semisimple representations of $\Pi^\lambda(Q)$ of dimension vector α.

Since the trace of $\mu_\alpha(x)$ is always zero, if there is a representation of $\Pi^\lambda(Q)$ of dimension vector $\alpha = \sum n_v \alpha_v$, then $\lambda \cdot \alpha = \sum \lambda_v n_v$ must be zero. If Q is a Dynkin diagram, then $\Pi^\lambda(Q)$ is finite-dimensional, and this argument shows that for generic λ it is even the zero algebra.

The case when Q is an extended Dynkin diagram, or equivalently when $\mathfrak{g}$ is an affine Lie algebra, appeared in work of Kronheimer [29], made more explicit by Cassens and Slodowy [6]. If δ is the minimal positive imaginary root, then $N_Q(0, \delta)$ is the corresponding Kleinian surface singularity, and the spaces $N_Q(\lambda, \delta)$, for suitably varying λ, give its semiuniversal deformation. The key idea of [15] is that the deformed preprojective algebras $\Pi^\lambda(Q)$, for unrestricted λ, give a larger family of deformations of the Kleinian singularity, the general one being noncommutative.

Theorem 1 (Crawley-Boevey and Holland [15]). *Suppose Q is an extended Dynkin diagram, and e is the trivial path corresponding to an extending vertex for Q. Then $\mathcal{O}^\lambda = e\Pi^\lambda(Q)e$ is a noetherian domain of Gelfand–Kirillov dimension 2, Auslander-Gorenstein and Cohen–Macaulay. Moreover, it is commutative if and only if $\lambda \cdot \delta = 0$, and if so, it is isomorphic to the coordinate ring of $N_Q(\lambda, \delta)$.*

For some further work on the $\mathcal{O}^\lambda$, see [1], [4], [24]. Returning to the general case, to decide when $N_Q(\lambda, \alpha)$ is nonempty, one needs to know whether or not there is a representation of $\Pi^\lambda(Q)$ of dimension vector α. It is not hard to show that a representation X of Q is in the image of the projection $\mu_\alpha^{-1}(\lambda) \to \mathrm{Rep}(Q, \alpha)$, so is the restriction of a representation of $\Pi^\lambda(Q)$, if and only if the dimension vector β of each indecomposable direct summand of X satisfies $\lambda \cdot \beta = 0$. With Kac's Theorem, this gives the following.

Theorem 2 ([7]). *The space $N_Q(\lambda, \alpha)$ is nonempty, or equivalently there is a representation of $\Pi^\lambda(Q)$ of dimension vector α, if and only if α can be written as a sum of positive roots $\alpha = \beta + \gamma + \cdots$ with $\lambda \cdot \beta = \lambda \cdot \gamma = \cdots = 0$.*

More difficult is the following.

Theorem 3 ([7]). *There is a simple representation of $\Pi^\lambda(Q)$ of dimension vector α if and only if α is a positive root, $\lambda \cdot \alpha = 0$, and $p(\alpha) > p(\beta) + p(\gamma) + \cdots$ for any nontrivial decomposition of α as a sum of positive roots $\alpha = \beta + \gamma + \cdots$ with $\lambda \cdot \beta = \lambda \cdot \gamma = \cdots = 0$.*

We have also shown [8], [9] that if K has characteristic zero and $N_Q(\lambda, \alpha)$ is nonempty, then it is an irreducible normal variety. Bocklandt and Le Bruyn [2], [30] have obtained further results in this direction. See [14] for more about the link with noncommutative symplectic geometry.

There are more general moduli spaces $N_Q(\lambda, \alpha)_\theta$, depending on suitable stability data $\theta \in \mathbb{Z}^I$. Examples of these are the 'quiver varieties' used by Nakajima to construct integrable representations of Lie algebras and quantum groups, see his ICM talk [36] (and [7]). Note that over $\mathbb{C}$, the moduli spaces are special cases of hyper-Kähler quotients, and by a standard trick of changing the complex structure, $N_Q(0, \alpha)_\theta$ is homeomorphic to $N_Q(\theta, \alpha)$.

We now give an application of these ideas. When working over a finite field, it is natural to consider representations of Q which are *absolutely indecomposable*, meaning that they remain indecomposable over the algebraic closure of the field. Kac showed that up to isomorphism, the number such representations of dimension vector α is polynomial in the size q of the field, of the form $a_\alpha(q)$ for some $a_\alpha \in \mathbb{Z}[t]$. He conjectured that a_α has non-negative coefficients, and that the constant term is the root multiplicity $\dim \mathfrak{g}_\alpha$. In partial answer we have the following.

Theorem 4 (Crawley-Boevey and Van den Bergh [17]). *If $\alpha = \sum_{v \in I} n_v \alpha_v$ is indivisible, meaning that the n_v have no common divisor, then a_α has non-negative coefficients, and the constant term is the root multiplicity* $\dim \mathfrak{g}_\alpha$.

We explain the positivity. Since α is indivisible, one can fix $\lambda \in \mathbb{Z}^I$ with $\lambda \cdot \alpha = 0$ but $\lambda \cdot \beta \neq 0$ for all $0 < \beta < \alpha$. The argument of Theorem 2 shows that the number of points in $N_Q(\lambda, \alpha)$, over a field with q elements and sufficiently large characteristic, is $q^{p(\alpha)} a_\alpha(q)$, and then if $N_Q(\lambda, \alpha)$ had been a projective variety, the Weil conjectures would have given positivity. However, $N_Q(0, \alpha)_\lambda$ is sufficiently close to being projective for the Weil conjectures to apply to it, and by the hyper-Kähler trick, the cohomologies of $N_Q(0, \alpha)_\lambda$ and $N_Q(\lambda, \alpha)$ are isomorphic when the base field is the algebraic closure of a finite field of sufficiently large characteristic. Moreover, it is possible to ensure that this isomorphism is compatible with Frobenius maps, so that $N_Q(\lambda, \alpha)$ is good enough.

2. Weighted projective lines

In this section we give an analogue of Kac's Theorem for weighted projective lines. When studying representations of finite-dimensional associative algebras, quivers tell one about *hereditary* algebras, i.e. those with global dimension ≤ 1. One of the breakthroughs in this area was the discovery by Brenner and Butler [5], [23] of algebras A that are 'tilted' from a hereditary algebra H. In Happel's language [22], there is a derived equivalence $D^b(\operatorname{mod} A) \simeq D^b(\operatorname{mod} H)$, which is useful since in $D^b(\operatorname{mod} H)$ any indecomposable object is a shift of a module.

Geigle and Lenzing [20] realized that there are other algebras, including Ringel's 'canonical algebras' [42], which aren't necessarily tilted from hereditary algebras, but are tilted from suitable hereditary abelian categories. See Reiten's ICM talk [39] for further progress in this direction.

We concentrate on Geigle and Lenzing's categories. A *weighted projective line* $\mathbb{X}$ is specified by giving a collection of distinct points $D = (a_1, \dots, a_k)$ in the projective line $\mathbb{P}^1$ over K, and a *weight sequence* $\boldsymbol{w} = (w_1, \dots, w_k)$, that is, a sequence of positive integers. The category, $\operatorname{coh}\mathbb{X}$, of coherent sheaves on $\mathbb{X}$, can be defined as the quotient of the category of finitely generated $\boldsymbol{L}(\boldsymbol{w})_+$-graded $S(\boldsymbol{w}, D)$-modules by the Serre subcategory of finite length modules. Here $\boldsymbol{L}(\boldsymbol{w})$ is the additive group with generators $\vec{x}_1, \dots, \vec{x}_k, \vec{c}$ and relations $w_1\vec{x}_1 = \cdots = w_k\vec{x}_k = \vec{c}$, partially ordered, with positive cone $\boldsymbol{L}(\boldsymbol{w})_+ = \mathbb{N}\vec{c} + \sum_{i=1}^{k} \mathbb{N}\vec{x}_i$, and

$$S(\boldsymbol{w}, D) = K[u, v, x_1, \dots, x_k]/(x_i^{w_i} - \lambda_i u - \mu_i v),$$

where $a_i = [\lambda_i : \mu_i] \in \mathbb{P}^1$, with grading $\deg u = \deg v = \vec{c}$ and $\deg x_i = \vec{x}_i$. Geigle and Lenzing showed that $\operatorname{coh}\mathbb{X}$ is a hereditary abelian category; the free module gives a structure sheaf $\mathcal{O}$, and shifting the grading gives twists $E(\vec{x})$ for any sheaf E and $\vec{x} \in \boldsymbol{L}(\boldsymbol{w})$; also, every sheaf is the direct sum of a 'torsion-free' sheaf, with a filtration by sheaves of the form $\mathcal{O}(\vec{x})$, and a finite-length 'torsion' sheaf.

Let $Q_{\boldsymbol{w}}$ be the star-shaped quiver whose vertex set I consists of a central vertex $*$, and vertices, denoted ij or i, j, for $1 \le i \le k$, $1 \le j < w_i$, and with arrows $* \leftarrow i1 \leftarrow i2 \leftarrow \cdots$ for all i. The appropriate Lie algebra to consider is the loop algebra $L\mathfrak{g} = \mathfrak{g}[t, t^{-1}]$, where $\mathfrak{g}$ is the Kac–Moody algebra associated $Q_{\boldsymbol{w}}$, or, better, an extension $\mathcal{L}\mathfrak{g}$ with generators e_{vr}, f_{vr}, h_{vr} ($v \in I$, $r \in \mathbb{Z}$) and c subject to the relations

$$\begin{cases} c \text{ central}, \quad [e_{vr}, e_{vs}] = 0, \quad [f_{vr}, f_{vs}] = 0, \\ [h_{ur}, h_{vs}] = r a_{uv}\, \delta_{r+s,0}\, c, \quad [e_{ur}, f_{vs}] = \delta_{uv} \left(h_{v,r+s} + r\, \delta_{r+s,0}\, c\right), \\ [h_{ur}, e_{vs}] = a_{uv} e_{v,r+s}, \quad [h_{ur}, f_{vs}] = -a_{uv} f_{v,r+s}, \\ (\operatorname{ad} e_{u0})^{1-a_{uv}}(e_{vs}) = 0, \quad (\operatorname{ad} f_{u0})^{1-a_{uv}}(f_{vs}) = 0 \quad (\text{if } u \ne v), \end{cases} \tag{3}$$

see [35]. The root lattice for either algebra is $\hat{\Gamma} = \Gamma \oplus \mathbb{Z}\delta$, with $\deg e_v t^r = \deg e_{vr} = \alpha_v + r\delta$, $\deg f_v t^r = \deg f_{vr} = -\alpha_v + r\delta$, $\deg h_v t^r = \deg h_{vr} = r\delta$ and $\deg c = 0$, and the set of roots for either algebra is

$$\hat{\Delta} = \{\alpha + r\delta \mid \alpha \in \Delta, r \in \mathbb{Z}\} \cup \{r\delta \mid 0 \ne r \in Z\}.$$

The real roots are $\alpha + r\delta$ with α real. (If $\mathfrak{g}$ is of finite type, $\mathcal{L}\mathfrak{g}$ is the corresponding affine Lie algebra, and if $\mathfrak{g}$ is of affine type, $\mathcal{L}\mathfrak{g}$ is a toroidal algebra.)

The Grothendieck group $K_0(\operatorname{coh}\mathbb{X})$ was computed by Geigle and Lenzing, and following Schiffmann [46] it can be identified with $\hat{\Gamma}$. Now $K_0(\operatorname{coh}\mathbb{X})$ is partially ordered, with the positive cone being the classes of objects in $\operatorname{coh}\mathbb{X}$, and this gives a partial ordering on $\hat{\Gamma}$.

Theorem 5 ([12]). *If $\mathbb{X}$ is a weighted projective line, there is an indecomposable coherent sheaf on $\mathbb{X}$ of type $\phi \in \hat{\Gamma}$ if and only if ϕ is a positive root. There is a unique indecomposable for a real root, infinitely many for an imaginary root.*

We remark that there is a classification of the indecomposables if $\mathfrak{g}$ is of finite type [20], or affine type [32]. The latter is essentially equivalent to the classification for tubular algebras, see Ringel's ICM talk [41], [42].

Lenzing [31, §4.2] showed that the category of torsion-free sheaves on $\mathbb{X}$ is equivalent to the category of (quasi) parabolic bundles on $\mathbb{P}^1$ of weight type $(D, \boldsymbol{w})$, that is, vector bundles $\pi : E \to \mathbb{P}^1$ equipped with a flag of vector subspaces

$$\pi^{-1}(a_i) \supseteq E_{i1} \supseteq \cdots \supseteq E_{i,w_i-1}$$

for each i. This equivalence is not unique, but it can be chosen so that if E is a parabolic bundle, then $[E] = \underline{\dim}\, E + (\deg E)\delta$, where the dimension vector is

$$\underline{\dim}\, E = n_*\alpha_* + \sum_{i=1}^{k} \sum_{j=1}^{w_i-1} n_{ij}\alpha_{ij} \in \Gamma,$$

with $n_* = \operatorname{rank} E$ and $n_{ij} = \dim E_{ij}$. This is necessarily *strict*, meaning that $n_* \geq n_{i1} \geq n_{i2} \geq \cdots \geq n_{i,w_i-1} \geq 0$. We can now restate Theorem 5 as follows (see [11]). For each $d \in \mathbb{Z}$ there is an indecomposable parabolic bundle of dimension vector α and degree d if and only if α is a strict root for $\mathfrak{g}$. There is a unique indecomposable for a real root, infinitely many for an imaginary root.

3. Hall algebras

In this section we explain the proof of Theorem 5. Let $\mathcal{C}$ be an abelian category that is *finitary*, meaning that its Hom and Ext spaces are finite sets. The *Hall algebra* of $\mathcal{C}$, over a commutative ring Λ, is the free Λ-module

$$H_\Lambda(\mathcal{C}) = \bigoplus_{Z \in \operatorname{iso}\mathcal{C}} \Lambda u_Z,$$

with basis the symbols u_Z, where Z runs through $\operatorname{iso}\mathcal{C}$, a set of representatives of the isomorphism classes of $\mathcal{C}$. It is an associative algebra with product

$$u_X u_Y = \sum_{Z \in \operatorname{iso}\mathcal{C}} F_{XY}^Z u_Z,$$

where F_{XY}^Z is the number of subobjects Z' of Z with $Z' \cong Y$ and $Z/Z' \cong X$. In case $\mathcal{C}$ is the category of finite abelian groups, or finite abelian p-groups, this notion is due to Steinitz [47] and Hall [21]. The current interest in Hall algebras stems from the discovery by Ringel [44] of a relationship between quantum groups and Hall algebras

for categories of representations of finite-dimensional hereditary algebras over finite fields. This quickly influenced the development of canonical bases, see Lusztig's ICM talk [34].

How to recover the underlying Lie algebra? Ringel [43] realized, for finite type hereditary algebras over a finite field K, that if one uses a ring Λ in which $|K| = 1$, and ind $\mathcal{C}$ is the set of indecomposables in iso $\mathcal{C}$, then the u_Z with $Z \in \operatorname{ind} \mathcal{C}$ generate a Lie subalgebra of $H_\Lambda(\mathcal{C})$ with bracket

$$[u_X, u_Y] = \sum_Z (F^Z_{XY} - F^Z_{YX}) u_Z.$$

To get at something resembling a semisimple Lie algebra, not just its positive part, there is a construction of Peng and Xiao [25], [38], in which one starts not with an abelian category, but with a triangulated K-category that is 2-*periodic*, meaning that the shift functor T satisfies $T^2 = 1$.

Let $\mathbb{X}$ be a weighted projective line over a finite field K, whose marked points are all defined over K. The category $\operatorname{coh} \mathbb{X}$ is still defined and well-behaved, and Schiffmann [46] has studied its Hall algebra. Applying the construction of Peng and Xiao to the orbit category $\mathcal{R}_\mathbb{X} = D^b(\operatorname{coh} \mathbb{X})/(T^2)$, one obtains a Lie algebra with triangular decomposition

$$L_\Lambda(\mathcal{R}_\mathbb{X}) = \Big(\bigoplus_{X \in \operatorname{ind} \operatorname{coh} \mathbb{X}} \Lambda u_X \Big) \oplus (\Lambda \otimes_\mathbb{Z} \hat{\Gamma}) \oplus \Big(\bigoplus_{X \in \operatorname{ind} \operatorname{coh} \mathbb{X}} \Lambda u_{TX} \Big),$$

where Λ is still a commutative ring in which $|K| = 1$. We have the following result.

Theorem 6 ([12]). *$L_\Lambda(\mathcal{R}_\mathbb{X})$ contains elements e_{vr}, f_{vr}, h_{vr} ($v \in I$, $r \in \mathbb{Z}$) and c satisfying the relations* (3) *for $\mathcal{L}\mathfrak{g}$.*

The elements are explicitly given: $c = -1 \otimes \delta$, $e_{*,r} = u_{\mathcal{O}(r\vec{c})}$, $f_{*,r} = -u_{T\mathcal{O}(-r\vec{c})}$, and the $e_{ij,r}$ and $f_{ij,r}$ are all of the form u_X or $-u_{TX}$ for suitable indecomposable torsion sheaves X. See also [33], where elliptic Lie algebra generators are found in $L_\Lambda(\mathcal{R}_\mathbb{X})$ for $\mathfrak{g}$ of affine type.

Concerning the proof of Theorem 5, the main problem is to show that the number of indecomposables of type $\phi = \alpha + r\delta$ is the same as the number of type $s_v(\alpha) + r\delta$. By arguments already used in the proof of Kac's Theorem, one reduces to counting numbers of indecomposables for weighted projective lines over finite fields, so dimensions of root spaces of $L_\Lambda(\mathcal{R}_\mathbb{X})$. A standard argument in the theory of complex Lie algebras, using sl_2-triples (e, f, h), shows that the root multiplicities for roots related by a reflection are equal. Now Theorem 6 provides such triples, and although the argument uses the fact that the base field has characteristic zero, for example it involves the operator $\exp(\operatorname{ad} e)$ with $\operatorname{ad} e$ acting locally nilpotently, it works if Λ is a field of sufficiently large characteristic, and this can be arranged by taking the finite field K to be sufficiently large.

4. The Deligne–Simpson problem

Given invertible matrices in known conjugacy (i.e. similarity) classes, what can one say about the conjugacy class of their product? More symmetrically, given conjugacy classes $C_1, \dots, C_k$ in $\mathrm{GL}_n(\mathbb{C})$, is there a solution to the equation

$$A_1 A_2 \dots A_k = 1 \tag{4}$$

with $A_i \in C_i$? The additive analogue asks for a solution to the equation

$$A_1 + A_2 + \dots + A_k = 0, \tag{5}$$

where the conjugacy classes may now be in $\mathrm{gl}_n(\mathbb{C})$. In full generality these problems seem to be open, but there are partial results, see for example [37]. The former arises when studying linear ODEs

$$\frac{d^n f}{dz^n} + c_1(z)\frac{d^{n-1} f}{dz^{n-1}} + \dots + c_n(z) f = 0 \tag{6}$$

whose coefficients are rational functions of z. If $D = \{a_1, \dots, a_k\}$ is the set of singular points of the coefficients in $\mathbb{P}^1$, the monodromy of (6) is a representation in $\mathrm{GL}_n(\mathbb{C})$ of the fundamental group of the punctured Riemann sphere $\mathbb{P}^1 \setminus D$, and the presentation of this group as $\langle g_1, \dots, g_k \mid g_1 g_2 \dots g_k = 1 \rangle$, where g_i is a suitable loop around a_i, shows how equation (4) arises.

To fix the conjugacy classes we choose a weight sequence $\boldsymbol{w} = (w_1, \dots, w_k)$, and a collection of complex numbers $\xi = (\xi_{ij})$ $(1 \le i \le k,\ 1 \le j \le w_i)$ with $(A_i - \xi_{i1}1)(A_i - \xi_{i2}1) \dots (A_i - \xi_{i,w_i}1) = 0$ for $A_i \in C_i$. Clearly, if one wishes one can take w_i to be the degree of the minimal polynomial of A_i, and $\xi_{i1}, \dots, \xi_{i,w_i}$ to be its roots. Let $Q_{\boldsymbol{w}}$ be the quiver associated to $\boldsymbol{w}$ as in §2, let I be its vertex set, let $\mathfrak{g}$ be the corresponding Kac–Moody Lie algebra, and let Γ be its root lattice. The C_i determine an element $\alpha = \sum_v n_v \alpha_v \in \Gamma$, with $n_* = n$ and

$$n_{ij} = \mathrm{rank}(A_i - \xi_{i1}1)(A_i - \xi_{i2}1) \dots (A_i - \xi_{ij}1)$$

for $A_i \in C_i$, and conversely $\boldsymbol{w}$, ξ, and α determine the C_i. We define

$$\xi^{[\beta]} = \prod_{i=1}^{k} \prod_{j=1}^{w_i} \xi_{ij}^{m_{i,j-1} - m_{ij}}, \quad \xi * [\beta] = \sum_{i=1}^{k} \sum_{j=1}^{w_i} \xi_{ij}(m_{i,j-1} - m_{ij}),$$

for $\beta = \sum m_v \alpha_v$, with the convention that $m_{i0} = m_*$ and $m_{i,w_i} = 0$. Theorem 2, applied to a deformed preprojective algebra $\Pi^\lambda(Q_{\boldsymbol{w}})$, gives the following.

Theorem 7 ([11]). *There is a solution to $A_1 + \dots + A_k = 0$ with A_i in the closure $\overline{C_i}$ of C_i if and only if α can be written as a sum of positive roots $\alpha = \beta + \gamma + \dots$ with $\xi * [\beta] = \xi * [\gamma] = \dots = 0$.*

A solution to equation (4) or (5) is *irreducible* if the A_i have no common invariant subspace. Theorem 3 gives the following.

Theorem 8 ([10]). *There is an irreducible solution to $A_1+\cdots+A_k=0$ with $A_i \in C_i$ if and only if α is a positive root, $\xi*[\alpha]=0$, and $p(\alpha) > p(\beta)+p(\gamma)+\cdots$ for any nontrivial decomposition of α as a sum of positive roots $\alpha=\beta+\gamma+\cdots$ with $\xi*[\beta]=\xi*[\gamma]=\cdots=0$.*

What about the multiplicative equation? By the Riemann–Hilbert correspondence, any solution arises as the monodromy of the differential equation given by a logarithmic connection on a vector bundle for $\mathbb{P}^1$. (Note that a Fuchsian ODE (6), as hoped for in Hilbert's 21st problem in his 1900 ICM talk, will not suffice, nor will a Fuchsian system of linear differential equations, or equivalently a logarithmic connection on a trivial vector bundle, as discussed by Bolibruch in his ICM talk [3].) Now a theorem of Weil [49] asserts that a vector bundle on a compact Riemann surface has a holomorphic connection if and only if its indecomposable direct summands have degree 0. There is an analogous theorem for parabolic bundles and compatible logarithmic connections, see [11], and, using it, Theorem 5 implies the following.

Theorem 9 ([11]). *There is a solution to $A_1 \ldots A_k = 1$ with $A_i \in \overline{C_i}$ if and only if α can be written as a sum of positive roots $\alpha=\beta+\gamma+\cdots$ with $\xi^{[\beta]}=\xi^{[\gamma]}=\cdots=1$.*

The *Deligne–Simpson problem*, see [28], asks when there is an irreducible solution to (4) with $A_i \in C_i$. By considering multiplicative analogues of preprojective algebras, Crawley-Boevey and Shaw deduce the following from Theorem 9.

Theorem 10 (Crawley-Boevey and Shaw [16]). *For there to be an irreducible solution to $A_1 \ldots A_k = 1$ with $A_i \in C_i$ it is sufficient that α be a positive root, $\xi^{[\alpha]}=1$, and $p(\alpha) > p(\beta)+p(\gamma)+\cdots$ for any nontrivial decomposition of α as a sum of positive roots $\alpha=\beta+\gamma+\cdots$ with $\xi^{[\beta]}=\xi^{[\gamma]}=\cdots=1$.*

The condition in the theorem has now also been shown to be necessary [13]. For some recent work related to multiplicative preprojective algebras, see [18] and [48].

Zeta functions of groups and rings

Marcus du Sautoy and Fritz Grunewald

Abstract. We report on progress and problems concerning the analytical behaviour of the zeta functions of groups and rings. We also describe how these generating functions are special cases of adelic cone integrals for which our results hold.

Mathematics Subject Classification (2000). Primary 20E07, 11M41; Secondary 20F18, 17B30, 11M45.

Keywords. Zeta functions, nilpotent groups, rings, elliptic curves, analytic continuation, functional equations.

1. Introduction

Whenever a counting problem pertaining to some mathematical object Λ produces a sequence of non-negative integers $a_\Lambda(n)$ $(n = 1, 2, \dots)$ we can hope to gain information by incorporating our sequence into a generating function. There are various ways of doing this, for example as coefficients of power series, sums representing automorphic functions and Dirichlet series. Sometimes there is a natural choice of a generating function dictated by the recursive properties of the sequence $a_\Lambda(n)$. We report here on counting problems where the choice of a Dirichlet series seems to be appropriate.

We consider first two counting problems relating to a finitely generated group G. Write $[G : H]$ for the index of a subgroup $H \leq G$ and let

$$a_G^<(n) := |\{\, H \leq G \mid [G : H] = n \,\}|, \quad a_G^\lhd(n) := |\{\, H \lhd G \mid [G : H] = n \,\}| \quad (1)$$

be the number of subgroups or normal subgroups of index precisely n in G. The numbers $a_G^<(n)$ all being finite we call

$$\zeta_G^<(s) := \sum_{n=1}^{\infty} a_G^<(n)\, n^{-s} = \sum_{H \leq_f G} [G : H]^{-s} \quad (2)$$

the *subgroup zeta function* of G. The symbol $H \leq_f G$ indicates that the summation is over all subgroups H of finite index in G. Similarly, we define

$$\zeta_G^\lhd(s) := \sum_{n=1}^{\infty} a_G^\lhd(n)\, n^{-s} = \sum_{H \lhd_f G} [G : H]^{-s} \quad (3)$$

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

to be the *normal subgroup zeta function* of G. When we intend to address both types of zeta functions simultaneously we write $\zeta_G^*(s)$ for $\zeta_G^<(s)$ or $\zeta_G^\lhd(s)$.

For the second type of counting problem we consider a ring R, which is for our purposes an abelian group R carrying a biadditive product. Let us write $S \leq R$ if S is a subring of R and $\mathfrak{a} \trianglelefteq R$ if $\mathfrak{a}$ is a left ideal of R. Let

$$a_R^<(n) := |\{\, S \leq R \mid [R : S] = n \,\}|, \quad a_R^\lhd(n) := |\{\, \mathfrak{a} \trianglelefteq R \mid [R : \mathfrak{a}] = n \,\}| \tag{4}$$

be the numbers of these subobjects of R which have index $n \in \mathbb{N}$ in the additive group of R. The numbers counting subrings are finite if the additive group of R is finitely generated. The numbers counting ideals are all finite under the weaker hypothesis that the ring R is finitely generated. Given these circumstances define the *subring zeta function* or the *ideal zeta function* to be respectively

$$\zeta_R^<(s) := \sum_{n=1}^{\infty} a_R^<(n)\, n^{-s}, \quad \zeta_R^\lhd(s) := \sum_{n=1}^{\infty} a_R^\lhd(n)\, n^{-s}. \tag{5}$$

Again we write $\zeta_R^*(s)$ for $\zeta_R^<(s)$ or $\zeta_R^\lhd(s)$.

While the study of the zeta functions of a finitely generated group was only begun in [27], the ideal zeta function of a ring has the Riemann zeta function ($R = \mathbb{Z}$) or more generally the Dedekind zeta function of the ring of integers in a number field as special cases (see [32]).

We wish to consider the Dirichlet series (2), (3), (5) not only as formal sums but as series converging in a non-empty subset of the complex numbers. By general theory this subset may be taken to be a right half-plane. In fact, this convergence condition will be satisfied if and only if the coefficients in the series (2), (3), (5) grow at most polynomially in n, more precisely if and only if there are $t,\ c^* \in \mathbb{R}$ such that $a_G^*(n) \leq c^* n^t$ respectively $a_R^*(n) \leq c^* n^t$ holds for all $n \in \mathbb{N}$. In this case we will say that G has *polynomial subgroup* or *normal subgroup growth*, the ring R will be said to have *polynomial subring* or *ideal growth*. For finitely generated groups G there is the following beautiful characterisation of this property by A. Lubotzky, A. Mann and D. Segal (see [36]).

Theorem 1.1. *Let G be a finitely generated residually finite group. Then G has polynomial subgroup growth if and only if G has a subgroup of finite index which is soluble and of finite rank.*

A group G is called residually finite if for every non-trivial $g \in G$ there is a subgroup H of finite index in G with $g \notin H$. Of course, this assumption is natural for Theorem 1.1 to hold. A group G is said to be of finite rank $r \in \mathbb{N}$ if every finitely generated subgroup of G can be generated by at most r elements.

In the following we shall assume that

- either $\Lambda = G$ is an infinite finitely generated torsion-free nilpotent group,
- or $\Lambda = R$ is a ring with additive group isomorphic to $\mathbb{Z}^d$ for some $d \in \mathbb{N}$.

We shall denote the set of isomorphism classes of such objects by $\mathcal{T}$.

Finitely generated torsion-free nilpotent groups satisfy the growth condition in Theorem 1.1. Their classification up to isomorphism is intimately connected with the reduction theory for arithmetic groups (see [24]). In addition there are connections between special classes of nilpotent groups and certain diophantine problems including the question of equivalence classes of integral quadratic forms ([25]). See [26] for a panorama of finitely generated torsion-free nilpotent groups. The class of rings in $\mathcal{T}$ contains all rings of integers in number fields and also (for example) the integer versions of the simple Lie algebras over $\mathbb{C}$.

For $\Lambda \in \mathcal{T}$ the zeta functions share a number of features in common with the Dedekind zeta function of a number field. Before we report the story let us mention some examples. Considering $\mathbb{Z}^d$ ($d \in \mathbb{N}$) as a direct product of infinite cyclic groups we find $\zeta^*_{\mathbb{Z}^d}(s) = \zeta(s)\zeta(s-1)\dots\zeta(s-d+1)$ where

$$\zeta(s) = \zeta^<_{\mathbb{Z}}(s) = \zeta^\lhd_{\mathbb{Z}}(s) = \sum_{n=1}^{\infty} n^{-s} = \prod_p \frac{1}{1-p^{-s}}$$

is the Riemann zeta function. A more elaborate example concerns the discrete Heisenberg group H_3, that is the group of strictly upper triangular 3×3-matrices with integer entries. The group H_3 is a torsion-free, nilpotent group of class 2 generated by two elements. The following formulas are proved in [46], see also [27].

$$\zeta^<_{H_3}(s) = \frac{\zeta(s)\zeta(s-1)\zeta(2s-2)\zeta(2s-3)}{\zeta(3s-3)}, \quad \zeta^\lhd_{H_3}(s) = \zeta(s)\zeta(s-1)\zeta(3s-2). \tag{6}$$

For an interesting example of the zeta function of a ring we can consider $sl_2(\mathbb{Z})$, the additive group of integer 2×2-matrices of trace 0 with the usual Lie bracket. The following formula was finally proved in [21] after contributions in [29], [5], [6]

$$\zeta^<_{sl_2(\mathbb{Z})}(s) = P(2^{-s})\frac{\zeta(s)\zeta(s-1)\zeta(2s-2)\zeta(2s-1)}{\zeta(3s-1)} \tag{7}$$

where $P(x)$ is the rational function $P = (1+6x^2-8x^3)/(1-x^3)$.

All these examples of zeta functions of members of $\mathcal{T}$ have three distinctive properties (evident from the formulas given):

- they converge in some right halfplane of $\mathbb{C}$,
- they decompose similarly to the Riemann or Dedekind zeta function as an Euler product of some rational expression in p^{-s} taken over all primes p,
- they have a meromorphic continuation to $\mathbb{C}$.

We believe that these three properties already justify the name zeta function for the corresponding generating function. A fourth property of the Dedekind zeta function, the global functional equation (see [32]) is hardly conceivable looking at formulas (6), (7).

Let us define now what will be the Euler factors of the zeta function of a general $\Lambda \in \mathcal{T}$. For a prime p we set:

$$\zeta^*_{\Lambda,p}(s) := \sum_{k=0}^{\infty} a^*_\Lambda(p^k)\, p^{-ks}. \tag{8}$$

This expression can be considered as a function in the variable $s \in \mathbb{C}$ or equally as a power series in p^{-s}.

In [27] the following theorem is established.

Theorem 1.2. *For $\Lambda \in \mathcal{T}$ the following hold.*

(i) *The Dirichlet series $\zeta^*_\Lambda(s)$ converges in some right half-plane of $\mathbb{C}$.*

(ii) *The Dirichlet series $\zeta^*_\Lambda(s)$ decomposes as an Euler product*

$$\zeta^*_\Lambda(s) = \prod_p \zeta^*_{\Lambda,p}(s), \tag{9}$$

where the product is to be taken over all primes p.

(iii) *The power series $\zeta^*_{\Lambda,p}(s)$ are rational functions in p^{-s}. That is, for each prime p there are polynomials $Z^*_p,\ N^*_p \in \mathbb{Z}[x]$ such that $\zeta^*_{\Lambda,p}(s) = Z^*_p(p^{-s})/N^*_p(p^{-s})$ holds. The polynomials $Z^*_p,\ N^*_p$ can be chosen to have bounded degree as p varies.*

An explicit determination of the local Euler factors (that is of the polynomials $Z^*_p,\ N^*_p$) of the zeta functions has been carried out in many cases including infinite families of examples. The methods range from ingenious elementary arguments to the use of algebraic geometry (resolving singularities). In several cases computer assistance was used (see [51]). See Section 6 for a selection of these examples. The database [52] collects comprehensive information on many examples treated so far. In very few cases the zeta function could be described by a closed formula in terms of the Riemann zeta function like in (6) or (7).

Note that, as a consequence of Theorem 1.2, the series (2), (3) and (5) converge to holomorphic functions in some right half-plane of $\mathbb{C}$. In fact the coefficients in (2), (3) and (5) are non-negative, hence by a well known theorem of E. Landau there is $\alpha \in \mathbb{R} \cup \{-\infty\}$ such that the series in question converges (absolutely and locally uniformly) for $s \in \mathbb{C}$ with $\mathrm{Re}(s) > \alpha$ and diverges if $\mathrm{Re}(s) < \alpha$. This α is called the *abscissa of convergence* of the series.

We wish to report the following theorem which collects together the main results of [13].

Theorem 1.3. *For $\Lambda \in \mathcal{T}$ the following hold.*

(i) *The abscissa of convergence α^*_Λ of $\zeta^*_\Lambda(s)$ is a rational number.*

(ii) *There is a $\delta > 0$ such that $\zeta^*_\Lambda(s)$ can be meromorphically continued to the region $\{\, s \in \mathbb{C} \mid \mathrm{Re}(s) > \alpha^*_\Lambda - \delta \,\}$.*

(iii) *The line $\{\, s \in \mathbb{C} \mid \mathrm{Re}(s) = \alpha^*_\Lambda \,\}$ contains at most one pole of $\zeta^*_\Lambda(s)$ (at the point $s = \alpha^*_\Lambda$).*

We define b^*_Λ to be the order of the pole of $\zeta^*_\Lambda(s)$ in $s = \alpha^*_\Lambda$. Using another theorem of E. Landau we find $b^*_\Lambda \geq 1$. Theorem 1.3 has as an immediate consequence:

Corollary 1.1. *Let Λ be in $\mathcal{T}$. Let*

$$s^*_\Lambda(N) := \sum_{n=1}^{N} a^*_\Lambda(n) \quad (N \in \mathbb{N}) \tag{10}$$

be the summatory function of the counting function a^*_Λ. We have

$$s^*_\Lambda(N) \sim c^*_\Lambda N^{\alpha^*_\Lambda} \log(N)^{b^*_\Lambda - 1} \tag{11}$$

with $c^*_\Lambda \in \mathbb{R}$.

The formula (11) means that the right hand side divided by the left hand side tends to 1 as N tends to infinity. The corollary follows from Theorem 1.3 using Tauber theory (see [38]). Note that the third property of the zeta function is essential for this application. Note also that c^*_Λ is equal to the lowest coefficient of the Laurent series representing ζ^*_Λ near the pole in $s = \alpha^*_\Lambda$.

Having defined the new invariants $\alpha^*_\Lambda \in \mathbb{Q}$, $b^*_\Lambda \in \mathbb{N}$ and $c^*_\Lambda \in \mathbb{R}$ for every Λ in $\mathcal{T}$ we are lead to

Problem 1.1. Relate $\alpha^*_\Lambda, b^*_\Lambda, c^*_\Lambda \in \mathbb{R}$ to structural properties of Λ.

This problem is solved when Λ is the ring of integers of a number field for the ideal zeta function. In this case $\alpha^\triangleleft_\Lambda = b^\triangleleft_\Lambda = 1$ and the value of $c^\triangleleft_\Lambda$ is given by Dirichlet's class number formula (see [32]). In the general case we have only the very scarce information reported in later sections. The following asymptotic relations can be read off from formulas (6) and (7), they reveal the values of our invariants.

$$s^<_{H_3}(N) \sim \frac{\zeta(2)^2}{2\zeta(3)} N^2 \log(N), \quad s^<_{sl_2(\mathbb{Z})}(N) \sim \frac{20\zeta(2)^2\zeta(3)}{31\zeta(5)} N^2 \tag{12}$$

The examples above illustrate that α^*_Λ can often be any natural number. However examples described in Section 6 show that $5/2$ and $7/2$ are also possible values of α^*_Λ. Considering $\mathbb{Z}^d$ ($d \in \mathbb{N}$) as a ring we have $\zeta^\triangleleft_{\mathbb{Z}^d}(s) = \zeta(s)^d$ and hence $b^\triangleleft_{\mathbb{Z}^d} = d$. Examples from Section 6 illustrate that b^*_Λ can take the values 1, 2, 3, 4. In fact, the Heisenberg group H_3 has $b^<_{H_3} = 2$. This is most of the knowledge we so far have on

Problem 1.2. What is the range of the pairs $(\alpha^*_\Lambda, b^*_\Lambda)$ as Λ varies over $\mathcal{T}$?

Problem 1.2 has many more concrete variants, let us mention one of them. Define $\mathbf{S}^*_{\text{group}} := \{\alpha^*_G\} \subset \mathbb{R}$ to be the set of abscissas of convergence of the subgroup or normal subgroup zeta functions as G varies over all finitely generated torsion-free nilpotent groups. Define $\mathbf{S}^*_{\text{ring}} := \{\alpha^*_R\} \subset \mathbb{R}$ similarly as R varies over all rings in $\mathcal{T}$. Let us briefly explain the proof of

Proposition 1.1. *The set* $\mathbf{S}^{<}_{\text{group}} \subset \mathbb{R}$ *is discrete, that is below any real number there are only finitely many members of* $\mathbf{S}^{<}_{\text{group}}$.

Let G be a torsion-free nilpotent group and G^{ab} its abelianisation. Let $h(G)$ be the Hirsch-length of G, that is the maximal number of infinite cyclic factors appearing in a composition series of G. A simple argument shows $h(G^{\text{ab}}) \leq \alpha^*_G \leq h(G)$. These two inequalities have been improved in several directions (see [27] and [42]). An unpublished result of D. Segal gives the lower bound

$$\big(3 - \sqrt{2}\big)h(G) - \frac{1}{2} \leq \alpha^{<}_G. \tag{13}$$

The main result of [4] implies that once we fix the Hirsch-length of G there is a universal denominator which all denominators of local zeta functions of nilpotent groups of that Hirsch-length have to divide. The results of Sections 2 and 3 together with (13) prove Proposition 1.1. The results of [4] apply also to the normal subgroup zeta function and to the zeta functions of rings, but a replacement for (13) has not been found. So we raise

Problem 1.3. Are the sets $\mathbf{S}^{\lhd}_{\text{group}}$, $\mathbf{S}^{<}_{\text{ring}}$ and $\mathbf{S}^{\lhd}_{\text{ring}}$ discrete? If not, what are their accumulation points?

Are $\Lambda_1,\ \Lambda_2 \in \mathcal{T}$ isomorphic if their zeta functions agree? Questions of this nature are traditionally called isospectrality problems. Examples of non-isomorphic rings of integers $R_1,\ R_2$ in number fields with $\zeta^{\lhd}_{R_1}(s) = \zeta^{\lhd}_{R_2}(s)$ are contained in [44]. The two finitely generated nilpotent groups (of class 2) G_1, G_2 described in Example 4 of Section 6 are not isomorphic but have isomorphic profinite completions. Hence $\zeta^{<}_{G_1}(s) = \zeta^{<}_{G_2}(s)$, $\zeta^{\lhd}_{G_1}(s) = \zeta^{\lhd}_{G_2}(s)$ both hold. These examples show that the isospectrality problem in general has a negative answer. But there remains:

Problem 1.4. Suppose that $\zeta^*_{\Lambda_1}(s) = \zeta^*_{\Lambda_2}(s)$ holds for both or at least one of the possibilities $* \in \{<, \lhd\}$ for $\Lambda_1,\ \Lambda_2 \in \mathcal{T}$. Which structural invariants of Λ_1 and Λ_2 are the same? For example, are the profinite completions of Λ_1 and Λ_2 isomorphic?

For a more extensive discussion of isospectrality problems see [12]. This paper also contains an example of a group G which satisfies $\zeta^{<}_G(s) = \zeta^{<}_{\mathbb{Z}^2}$ but which does not have the same profinite completion as $\mathbb{Z}^2$. The group G is one of the plane crystallographic groups, it has $\mathbb{Z}^2$ as a subgroup of index 2 but it is not nilpotent.

In this survey we mainly discuss properties of the zeta functions of groups and rings. There are many topics not treated here, see [20] and [10] for relations to other subjects. Connections to the by now vast field of subgroup growth are not treated here. For this see the surveys [34] and [35].

In Sections 2, 3 we describe the proofs of Theorems 1.2 and 1.3. As a first step the Euler factors $\zeta^*_{\Lambda,p}(s)$ are described as certain p-adic integrals. These are evaluated by the methods of p-adic integration. Having obtained explicit formulas we multiply the (global) Euler product by an Artin L-function to enlarge its region of

convergence. Section 4 discusses the variation with p of the Euler factors. Certain functional equations of the Euler factors are the subject of Section 5. Section 6 contains examples. In Section 7 we describe variations on the zeta function theme.

2. p-adic formalism

While the proof of the first two items of Theorem 1.2 is elementary, the third requires an expression for the local Euler factor $\zeta^*_{\Lambda,p}(s)$ (p a prime) of the zeta function $\zeta^*_\Lambda(s)$ in terms of a certain p-adic integral. We shall briefly explain this procedure in the case when $\Lambda = R \in \mathcal{T}$ is a ring and $* = \lhd$. For more details see [27] Section 3 or [13].

Let p be a prime. We write $\mathbb{Q}_p$ for the field of p-adic numbers and $\mathbb{Z}_p$ for its ring of integers. For $x \in \mathbb{Q}_p$ we define $v_p(x)$ to be the p-adic valuation of x and $|x|_p$ to be the normalised p-adic absolute value. We write $\mathrm{Tr}_d(\mathbb{Z})$, $\mathrm{Tr}_d(\mathbb{Z}_p)$ ($d \in \mathbb{N}$) for the space of upper triangular $d \times d$-matrices with entries in $\mathbb{Z}$ respectively $\mathbb{Z}_p$. We think of $\mathrm{Tr}_d(\mathbb{Z}_p)$ being identified with $\mathbb{Z}_p^{d(d+1)/2}$.

Let $R \in \mathcal{T}$ be a ring (with additive group isomorphic to $\mathbb{Z}^d$) and p a prime. We fix a $\mathbb{Z}$-basis of R. Analysing the conditions for the rows of an upper triangular matrix (in $\mathrm{Tr}_d(\mathbb{Z})$) to be a triangular basis of an ideal in R, we find polynomials

$$f_1,\ g_1, \ldots,\ f_l, \quad g_l \in \mathbb{Z}[x_{11}, \ldots, x_{dd}] \tag{14}$$

such that

$$\mathcal{M}^\lhd(R) := \{\, x \in \mathrm{Tr}_d(\mathbb{Z}) \mid f_1(x) \mid g_1(x), \ldots,\ f_l(x) \mid g_l(x) \,\} \tag{15}$$

is exactly the set of upper triangular matrices with entries in $\mathbb{Z}$ for which the rows generate an ideal in R. Here we write $a \mid b$ if the integer a divides the integer b. We now use our $\mathbb{Z}$-basis of R also as a $\mathbb{Z}_p$-basis of $\mathbb{Z}_p \otimes_\mathbb{Z} R$. We conclude that

$$\mathcal{M}^\lhd(R,\, p) := \{\, x \in \mathrm{Tr}_d(\mathbb{Z}_p) \mid v_p(f_i(x)) \le v_p(g_i(x)) \text{ for } i = 1, \ldots, l \,\} \tag{16}$$

is exactly the set of upper triangular matrices with entries in $\mathbb{Z}_p$ for which the rows additively generate an ideal in $\mathbb{Z}_p \otimes_\mathbb{Z} R$.

The map $\mathfrak{a} \to \mathfrak{a} \cap R$ sets up a one to one correspondence between the ideals of index p^n ($n \in \mathbb{N}$) in $\mathbb{Z}_p \otimes_\mathbb{Z} R$ and ideals of the same index in R. An exercise in p-adic integration shows that

$$\zeta^\lhd_{R,p}(s) = (1 - p^{-1})^{-d} \int_{\mathcal{M}^\lhd(R,p)} |x_{11}|_p^{s-n} |x_{22}|_p^{s-n+1} \ldots |x_{dd}|_p^{s-1}\, dx \tag{17}$$

holds for every prime p with dx the normalised Haar measure on $\mathrm{Tr}_d(\mathbb{Z}_p) = \mathbb{Z}_p^{d(d+1)/2}$. The same approach applies to the subring zeta function of a ring $R \in \mathcal{T}$. See Section 3 of [27] or Section 5 of [13] for more details.

A similar, slightly more elaborate, analysis yields polynomials (14) in $d(d+1)/2$ variables such that formula (17) holds in case $\Lambda = G$ is a finitely generated torsion-free nilpotent group. For more details see Section 2 of [27] and Section 5 of [13]. Here, due to the use of Lie ring methods, finitely many primes have to be excluded. The natural number d has to be taken to be the Hirsch-length of G.

The proof in [27] of the rationality of these p-adic integrals relied on observing that $\mathcal{M}^*(\Lambda, p)$ are definable subsets in the language of fields. One can then apply a theorem of Denef [1] which establishes the rationality of definable p-adic integrals. Denef's proof relies on an application of Macintyre's quantifier elimination for the theory of $\mathbb{Q}_p$ which simplifies in a generally mysterious way the description of definable subsets like $\mathcal{M}^*(\Lambda, p)$. In the next section we shall report on a concrete formula computing integrals like (17) which replaces the use of the model theoretic black box in the proof of the rationality.

3. p-adic and adelic cone integrals

We define here certain Euler products with factors given by p-adic integrals which are generalized versions of the p-adic integrals occurring in formula (17). We then analyze the analytical properties of these Euler products.

Let m be a natural number. A collection of polynomials

$$\mathcal{D} = (f_0, g_0; f_1, g_1, \ldots, f_l, g_l) \quad (f_0, g_0, f_1, g_1, \ldots, f_l, g_l \in \mathbb{Q}[x_1, \ldots, x_m]) \tag{18}$$

is called cone integral data. We associate to $\mathcal{D}$ the following closed subset of $\mathbb{Z}_p^m$ (p a prime)

$$\mathcal{M}(\mathcal{D}, p) := \{ x \in \mathbb{Z}_p^m \mid v_p(f_i(x)) \leq v_p(g_i(x)) \text{ for } i = 1, \ldots, l \} \tag{19}$$

and a p-adic integral with conventions as in Section 2:

$$Z_{\mathcal{D}}(s, p) = \int_{\mathcal{M}(\mathcal{D}, p)} |f_0(x)|_p^s \, |g_0(x)|_p \, dx. \tag{20}$$

Note that Section 2 shows that the local zeta functions of the $\Lambda \in \mathcal{T}$ are special cases of the $Z_{\mathcal{D}}(s, p)$. The p-adic integral (20) is easily seen to exist for $s \in \mathbb{C}$ with sufficiently large real part. It can be expressed as a power series $Z_{\mathcal{D}}(s) = \sum_{i=0}^{\infty} a_{p,i} \, p^{-is}$ with non-negative integer coefficients and $a_{p,0} \neq 0$. In fact, a result of Denef [1] says that the power series in (20) is rational in p^{-s}. Given the cone integral data $\mathcal{D}$ we can define $Z_{\mathcal{D}}(s, p)$ for every prime p. We use this to define an Euler product

$$Z_{\mathcal{D}}(s) = \prod_p (a_{p,0}^{-1} \cdot Z_{\mathcal{D}}(s, p)) \tag{21}$$

which we call the *global* or *adelic cone integral*. In fact, with appropriate normalisation of measures, $Z_{\mathcal{D}}(s)$ can be defined as an adelic integral (see [39] for a special case).

Special cases of the p-adic integrals (20) appear in [28]. We use an adaptation of a method to calculate p-adic integrals from [1] and [2] to show:

Proposition 3.1. *Let $\mathcal{D} = (f_0, g_0; f_1, g_1, \ldots, f_l, g_l)$ be cone integral data. Define the polynomial $F(x) := \prod_{i=0}^{l} f_i(x)g_i(x)$. Let (Y, h) be a resolution of singularities over $\mathbb{Q}$ of F. Let E_i $(i \in T)$ be the irreducible components defined over $\mathbb{Q}$ of the reduced scheme $(h^{-1}(D))_{\mathrm{red}}$ where $D = \mathrm{Spec}(\mathbb{Q}[x]/F)$. Then the following hold.*

(i) *There exist rational functions $P_I(X, Y) \in \mathbb{Q}(X, Y)$ for each $I \subset T$ with the property that for almost all p:*

$$Z_{\mathcal{D}}(s) = \sum_{I \subset T} c_{p,I}\, P_I(p, p^{-s}) \tag{22}$$

where $c_{p,I} = |\{a \in \bar{Y}(\mathbb{F}_p) \mid a \in E_i \text{ if and only if } i \in I\}|$ and $\bar{Y}$ is the reduction mod p of the scheme Y.

(ii) *There is a closed polyhedral cone $\mathfrak{C} \subset \mathbb{R}^t_{\geq 0}$ where $t = |T|$ and a decomposition of $\mathfrak{C}$ into open simplicial pieces which we denote by R_k $(k \in \{0, 1, \ldots, w\})$. We arrange that $R_0 = (0, \ldots, 0)$ and $R_1, \ldots, R_q$ are the one-dimensional pieces. For each $k \in \{0, 1, \ldots, w\}$ let $M_k \subset \{1, \ldots, q\}$ denote the one-dimensional pieces in the closure of R_k. Then there are positive integers A_j, B_j for $j \in \{1, \ldots, q\}$ such that for almost all primes p:*

$$Z_{\mathcal{D}}(s) = \sum_{k=0}^{w} (p-1)^{I_k}\, p^{-m}\, c_{p,I_k} \prod_{j \in M_k} \frac{p^{-(A_j s + B_j)}}{1 - p^{-(A_j s + B_j)}} \tag{23}$$

where I_k is the subset of T defined so that $i \in T \setminus I_k$ if and only if the i-th coordinate is zero for all elements of R_k.

The study of p-adic integrals like (20) has been initiated by J. Igusa. His fundamental results are documented in [28]. The references in [28] provide access to the vast literature on this subject. Previous to the results documented here the global or adelic versions (21) have only received attention in special cases (see [39]). Using various methods from analytic number theory and arithmetic geometry we show in [13] that Proposition 3.1 implies:

Corollary 3.1. *Let $\mathcal{D} = (f_0, g_0; f_1, g_1, \ldots, f_l, g_l)$ be cone integral data. Suppose $Z_{\mathcal{D}}(s)$ is not the constant function.*

(i) *The abscissa of convergence $\alpha = \alpha_{\mathcal{D}}$ of $Z_{\mathcal{D}}(s) = \sum_{n=1}^{\infty} a_n n^{-s}$ is a rational number.*

(ii) *$Z_{\mathcal{D}}(s)$ has a meromorphic continuation to $\mathrm{Re}(s) > \alpha - \delta$ for some $\delta > 0$.*

(iii) *The line $\{ s \in \mathbb{C} \mid \mathrm{Re}(s) = \alpha_\Lambda \}$ contains only one pole of $\zeta_{\mathcal{D}}(s)$ at $s = \alpha_\Lambda$.*

In fact, we multiply $Z_{\mathcal{D}}(s)$ by the Artin L-function corresponding to the permutation representation of the absolute Galois group of $\mathbb{Q}$ on the irreducible components of the E_i $(i \in T)$ appearing in Proposition 3.1. Using the estimates of Hasse and

Weil for the number of points on algebraic varieties over finite fields on the c_{p,I_k} in formula (23) we can analyse the analytic properties of the product of $Z_{\mathcal{D}}(s)$ with its Artin L-function near the abscissa of convergence of $Z_{\mathcal{D}}(s)$.

Theorem 1.3 is a consequence of this corollary together with the discussion in Section 2.

Following classical analytic number theory it is natural to ask how far the adelic cone integrals $Z_{\mathcal{D}}(s)$ can be meromorphically continued to the left. The analysis of special cases shows that often natural boundaries arise as one continues to the left (see [11]). That is, in these cases, poles or zeroes of the continued function accumulate densely to the points of a vertical line in $\mathbb{C}$. Beyond this line no continuation is possible. The following problems seem to be of interest.

Problem 3.1. Find all cone integral data $\mathcal{D}$ such that $\zeta_{\mathcal{D}}(s)$ has a meromorphic continuation to $\mathbb{C}$, or at least give sufficient conditions for this to happen.

Problem 3.2. Find all $\Lambda \in \mathcal{T}$ such that $\zeta_{\Lambda}(s)$ has a meromorphic continuation to $\mathbb{C}$, or at least give sufficient conditions for this to happen.

Problem 3.3. Show that either $\zeta_{\mathcal{D}}(s)$ has a meromorphic continuation to $\mathbb{C}$ or that there is some rational number $\beta_{\mathcal{D}}$ such that the line $\{ s \in \mathbb{C} \mid \mathrm{Re}(s) = \beta_{\Lambda} \}$ is a natural boundary.

In [14] and [16] we attempt, partially successfully, to replace the zeta function by a ghost zeta function which has more amenable analytic properties but which has Euler factors which are in a specific sense near to those of the original zeta function.

The process of continuation to the left ties up the Dirichlet series $\zeta_{\mathcal{D}}(s)$ with the zeta functions defined by A. Weil and R. Langlands for smooth $\mathbb{Q}$-defined projective algebraic varieties. Let us report on a special example. Let $y^2-x^3-ax-b\,(a,\ b \in \mathbb{Q})$ be a polynomial representing an elliptic curve E. Define

$$Z_{E,p}(s) := \int_{\mathbb{Z}_p^2} |y^2 - x^3 - ax - b|_p^s \, dx, \quad Z_E(s) := \prod_p (\lambda_p^{-1} Z_{E,p}(s)) \qquad (24)$$

with appropriate normalisation factors λ_p. We have shown in [17] that the Dirichlet series $Z_E(s)$ converges for $\mathrm{Re}(s) > 0$. Moreover when attempting to continue $Z_E(s)$ to the left, the symmetric power L-functions attached to E arise. It is conjectured that these symmetric power L-functions can all be meromorphically continued to $\mathbb{C}$.[1] If this is true then $Z_E(s)$ can be meromorphically continued to the region $\mathrm{Re}(s) > -3/2$. Results of J. P. Serre concerning the Sato–Tate conjecture for E then imply that the line $\mathrm{Re}(s) = -3/2$ is a natural boundary beyond which no continuation is possible.

[1] Note added in proof: these conjectures have recently been proved.

4. The local factors: variation with p

The behaviour of the local factors as we vary p is one of the other major problems in the field. If we consider formula (6) we easily see that

$$\zeta_{H_3,p}(s) = \frac{W_1(p, p^{-s})}{W_2(p, p^{-s})} \tag{25}$$

where W_1, W_2 can be given without reference to the prime p as polynomials $W_1(X, Y) = (1 - Y)(1 - XY)(1 - X^2Y^2)(1 - X^3Y^2)$, $W_2(X, Y) = 1 - X^3Y^3$. Groups with this property are said to have *uniform subgroup* or *normal subgroup growth*. In [27] it is proved that a finitely generated free nilpotent group of class 2 has both uniform subgroup and normal subgroup growth. As revealed in [7] the following problem ties up intimately with classification problems of finite p-groups, in particular with Higman's PORC-conjecture.

Problem 4.1. Show that every finitely generated free nilpotent group has both uniform subgroup and normal subgroup growth.

We can also consider a similar variety of problems for rings. We define *uniform subring* or *ideal growth* as above in the group case and raise

Problem 4.2. Show that the following Lie rings have uniform subring and ideal growth.

- Free nilpotent Lie rings of finite $\mathbb{Z}$-rank,
- $sl_n(\mathbb{Z})$ ($n \in \mathbb{N}$) or any other integer version of a simple Lie algebra over $\mathbb{C}$.

Let us now consider the Heisenberg group H_3 with entries from the ring of integers of a quadratic number field. The behaviour of the local factors of its zeta functions depends on how p behaves in the number field [27]. That is formulas like (25) hold, but finitely many pairs of polynomials are needed to describe the variation of the local factor of the zeta function with p. Groups with this property are said to have *finitely uniform subgroup* or *normal subgroup growth*. There is a similar concept in the case of rings.

For a long time this was the only type of variation with p which was known. Our explicit formula however takes the subject away from the behaviour of primes in number fields to the problem of counting points modulo p on a variety, a question which is in general wild and far from the uniformity predicted by all previous examples seen in [27]. Two papers [8] and [9] by the first author contain the following example of a class two nilpotent group of Hirsch length 9 whose zeta function depends on counting points mod p on the elliptic curve $y^2 = x^3 - x$. Define

$$G = \left\langle \begin{matrix} x_1,\ x_2,\ x_3,\ x_4,\ x_5,\ x_6, \\ y_1,\ y_2,\ y_3 \end{matrix} \;\middle|\; \begin{matrix} [x_1, x_4] = y_3,\ [x_1, x_5] = y_1, [x_1, x_6] = y_2, \\ [x_2, x_4] = y_2, [x_2, x_6] = y_1,\ [x_3, x_4] = y_1, \\ [x_3, x_5] = y_3 \end{matrix} \right\rangle \tag{26}$$

with the convention that commutators not mentioned are equal to 1. By [9] there exist rational functions $P_1(X, Y)$, $P_2(X, Y) \in \mathbb{Q}(X, Y)$ such that for almost all primes p

$$\zeta^{\triangleleft}_{G,p}(s) = P_1(p, p^{-s}) + |E(\mathbb{F}_p)|P_2(p, p^{-s}), \tag{27}$$

where E is the elliptic curve $y^2 = x^3 - x$. In [9] this formula is used to show that G is not finitely uniform. To see where the elliptic curve is hidden in the above presentation, take the determinant of the 3×3 matrix (a_{ij}) with entries $a_{ij} = [x_i, x_{j+3}]$ and you will get the projective version of E.

Formula (23) shows that the variation type with p of the Euler factors $\zeta_{\mathcal{D},p}(s)$ ($\mathcal{D}$ cone condition data) is that of functions counting points on a $\mathbb{Q}$-defined algebraic variety modulo primes p. But might their be further restrictions once we consider the Euler factors $\zeta_{\Lambda,p}(s)$ for $\Lambda \in \mathcal{T}$?

Problem 4.3. Let V be a $\mathbb{Q}$-defined algebraic variety. Is there $\Lambda_V \in \mathcal{T}$ such that there are rational functions $P_1(X, Y)$, $P_2(X, Y) \in \mathbb{Q}(X, Y)$ such that for almost all primes p

$$\zeta_{\Lambda_V,p}(s) = P_1(p, p^{-s}) + |V(\mathbb{F}_p)|P_2(p, p^{-s}) \tag{28}$$

holds?

The consideration of zeta functions obtained by motivic integration (see [18]) sheds some light on this new dialogue between groups and rings and questions of arithmetic geometry.

5. Functional equations of the local factors

There is another remarkable feature of many of the rational functions representing the local zeta function of nilpotent groups: they satisfy a certain palindromic symmetry. Let us explain this in the case of the normal subgroup zeta function of $F_{2,3}$, the free nilpotent group of class two on three generators. The group $F_{2,3}$ is torsion-free and has Hirsch-length 6. From [27] we know that

$$\zeta^{\triangleleft}_{F_{2,3},p}(s) = \left.\frac{1 + X^3Y^3 + X^4Y^3 + X^6Y^5 + X^7Y^5 + X^{10}Y^8}{(1-Y)(1-XY)(1-X^2Y)(1-X^8Y^5)(1-X^6Y^9)}\right|_{X=p,\, Y=p^{-s}} \tag{29}$$

holds for every prime p. Let us replace p by p^{-1} (and p^{-s} by p^s) in this expression. Indicating this replacement by $p \to p^{-1}$, we find:

$$\zeta^{\triangleleft}_{F_{2,3},p}(s)|_{p\to p^{-1}} = p^{15-9s}\zeta^{\triangleleft}_{F_{2,3},p}(s). \tag{30}$$

This phenomenon was found in all examples of all finitely generated nilpotent groups of class 2 and Lie rings of nilpotency class 2 where explicit computations have been done. We pose here the

Problem 5.1. Let G be a nilpotent group of class 2 and Hirsch-length h. Assume that the quotient of G modulo its center (which is abelian) has torsion-free rank m. Show that

$$\zeta^{<}_{G,p}(s)|_{p\to p^{-1}} = (-1)^d\, p^{\frac{h(h-1)}{2}-hs}\, \zeta^{<}_{G,p}(s), \tag{31}$$

$$\zeta^{\lhd}_{G,p}(s)|_{p\to p^{-1}} = (-1)^d\, p^{\frac{h(h-1)}{2}-(h+m)s}\, \zeta^{\lhd}_{G,p}(s) \tag{32}$$

hold for almost all primes p.

In [48] C. Voll is able to answer Problem 5.1 affirmatively for the special case of local zeta functions counting normal subgroups of torsion-free class 2 nilpotent groups which have a centre of $\mathbb{Z}$-rank 2 by giving explicit formulas for the local zeta functions in this case. C. Voll [49] and P. Paajanen [40], [43] and [41] have also confirmed the functional equation for the normal subgroup zeta function in more general settings by analysing the geometry of the Pfaffian hypersurface associated to presentations of class 2 nilpotent groups. Note however that the functional equation for zeta functions of nilpotent groups is not a completely general phenomenon. The Lie ring $\mathfrak{L}_W$ introduced in Example 3 of the next section has nilpotency class 3. The Euler factors of the ideal counting zeta function do not satisfy a functional equation, although the Euler factors of the subring zeta function do have such a symmetry.

Problem 5.1 should be seen in connection with a result of Denef and Meuser [2] who prove that the rational expression (in p^{-s}) corresponding to the Igusa-type p-adic integral

$$Z_{\{g_0,\,1\},p}(s) := \int_{\mathbb{Z}_p^m} |g_0(x)|_p^s\, dx \tag{33}$$

satisfy a functional equation if $g_0 \in \mathbb{Z}_p[x_1,\ldots,x_m]$ is absolutely irreducible and defines a smooth projective hypersurface over the finite field $\mathbb{F}_p$. A key role in their proof is played by the functional equation satisfied by the algebraic geometric zeta function for this hypersurface proved by A. Weil.

In [48] C. Voll uses the functional equation for the local zeta functions of elliptic curves to prove that the zeta function (27) of the nilpotent group encoding an elliptic curve in its presentation has a functional equation of the type predicted by (31). The paper [31] of B. Klopsch and C. Voll treats interesting new counting problems related to orthogonal and unitary groups over finite fields which arose in the study of functional equations.

The only counterexamples to the functional equations for zeta functions of groups and rings relate to counting normal subgroups in groups or ideals in rings. We therefore raise the following:

Problem 5.2. Let Λ be in $\mathcal{T}$. Show that there are rational numbers a, b and c such that

$$\zeta^{<}_{\Lambda,p}(s)|_{p\to p^{-1}} = (-1)^c\, p^{as+b}\, \zeta^{<}_{\Lambda,p}(s) \tag{34}$$

for almost all primes p.

In his thesis [51] L. Woodward analyses a general setting in which certain cone integrals are conjectured to have functional equations which could generalise the result of Denef and Meuser. The cone integral data has to satisfy what Woodward calls a homogeneity condition, namely $\deg(g_i) = \deg(f_i) + 1$ for $i = 1, \ldots, l$. The cone integrals describing zeta functions counting all subgroups or subrings satisfy this homogeneity condition in contrast to the normal subgroup and ideal zeta functions. Using results of Stanley on functional equations of polyhedral cones Woodward can prove the functional equation in the special case that all the polynomials of the cone integral data are monomials.

6. Examples

This section contains a brief description of the information obtained so far on the zeta functions of several series of Lie rings. We also describe the pair of finitely generated nilpotent groups which solves the isospectrality problem negatively.

Example 1. Let $\mathfrak{F}(2, n)$ be the free nilpotent Lie ring of class two on $n \in \mathbb{N}$ $(n \geq 2)$ generators. This Lie ring has $\mathbb{Z}$-rank $h(n) = n + n(n+1)/2$. Note that the Lie ring of the Heisenberg group H_3 is isomorphic to $\mathfrak{F}(2, 2)$. An explicit formula for the Euler factors of the ideal zeta function is given by C. Voll in [48] (see [40] for special cases). From these

$$\alpha^{\triangleleft}_{\mathfrak{F}(2,n)} = \max \left\{ n, \frac{\left(\frac{n(n-1)}{2} - j\right)(n+j)+1}{h(n)-j} \;\middle|\; j = 1, \ldots, \frac{n(n-1)}{2} - 1 \right\} \quad (35)$$

can be deduced. This formula shows that for $n \geq 5$, the abscissa of convergence of the global ideal zeta function is greater than n and is usually not an integer. However, sometimes it may just happen to be an integer. The only n in the range $5 \leq n \leq 200$ for which this happens is $n = 26$. Furthermore the ideal growth of $\mathfrak{F}(2, n)$ is uniform and the Euler factors $\zeta_{\mathfrak{F}(2,n),p}$ satisfy the functional equation of Problem 5.1 (see [50]).

Example 2. Let n be a natural number with $n \geq 2$. Define $\mathfrak{G}(n)$ to be the Lie ring

$$\mathfrak{G}(n) := \langle\, z,\ x_1, \ldots, x_{n-1},\ y_1, \ldots, y_{n-1} \mid [z, x_i] = y_i \ (i = 1, \ldots, n-1) \,\rangle. \quad (36)$$

Our convention again is that all commutators between the generators not mentioned are equal to 0. Hence $\mathfrak{G}(n)$ has nilpotency class two and $\mathbb{Z}$-rank $2n - 1$. D. Grenham [22] has determined explicit formulas for the ideal zeta functions of $\mathfrak{G}(n)$ for $n = 2, 3, 4, 5$. Let us report his formula in case $n = 4$. Define $W_4(X, Y)$ to be the rational function

$$W_4(X, Y) := \frac{1 + X^4Y^3 + X^5Y^3 + X^8Y^5 + X^9Y^5 + X^{18}Y^8}{(1-Y)(1-XY)(1-X^2Y)(1-X^3Y)(1-X^6Y^3)(1-X^{10}Y^5)}. \quad (37)$$

Grenham's formula reads as

$$\zeta^{\triangleleft}_{\mathfrak{G}(4),p}(s) = W_4(X, Y)|_{X=p,\, Y=p^{-s}}. \tag{38}$$

From this it is immediately clear that $\mathfrak{G}(4)$ has uniform ideal growth. Also $\alpha^{\triangleleft}_{\mathfrak{G}(4)} = 4$ and $b^{\triangleleft}_{\mathfrak{G}(4)} = 1$ can be read off. Further analysis of the numerator in (37) shows that the global zeta function $\zeta^{\triangleleft}_{\mathfrak{G}(4)}(s)$ has a natural boundary at $\mathrm{Re}(s) = 9/5$ (see [11]).

Using methods of algebraic geometry C. Voll [49] has developed a closed formula for $\zeta^{\triangleleft}_{\mathfrak{G}(n),p}(s)$ which holds for every $n \geq 2$ and every prime p. This formula shows that $\mathfrak{G}(n)$ has uniform ideal growth for every $n \geq 2$, it also confirms the conjectures from Section 5 concerning functional equations of the Euler factors. Also, for $n \geq 6$ the abscissa of convergence $\alpha^{\triangleleft}_{\mathfrak{G}(n)}$ is greater than n, and it is in general not an integer. Indeed, if $6 \leq n \leq 200$, the abscissa of convergence is an integer if and only if $n = 2N^2 + 6N + 5$ for some integer N.

D. Grenham [22] has also studied the subring zeta function of $\mathfrak{G}(n)$. We cite from [22] the following pole orders:

$$b^{<}_{\mathfrak{G}(3)} = 2, \quad b^{<}_{\mathfrak{G}(4)} = 2, \quad b^{<}_{\mathfrak{G}(5)} = 3. \tag{39}$$

The corresponding abscissas of convergence are

$$\alpha^{<}_{\mathfrak{G}(3)} = 3, \quad \alpha^{<}_{\mathfrak{G}(4)} = 4, \quad \alpha^{<}_{\mathfrak{G}(5)} = 5. \tag{40}$$

Example 3. The following example of a Lie ring played an important role in the development of the conjectures from Section 5 concerning functional equations of the Euler factors. Define

$$\mathfrak{L}_W := \langle\, z,\ w_1,\ w_2,\ x_1,\ x_2,\ y \mid [z, w_1] = x_1,\ [z, w_2] = x_2,\ [z, x_1] = y \,\rangle. \tag{41}$$

This Lie ring has nilpotency class 3 and $\mathbb{Z}$-rank 6. It was discovered and extensively studied by L. Woodward in [51]. The Lie ring $\mathfrak{L}_W$ has uniform subring and ideal growth but only the local subring counting zeta function satisfies a functional equation. We further report from [51]:

$$\alpha^{<}_{\mathfrak{L}_W} = 3,\ b^{<}_{\mathfrak{L}_W} = 4, \quad \alpha^{\triangleleft}_{\mathfrak{L}_W} = 3,\ b^{\triangleleft}_{\mathfrak{L}_W} = 1. \tag{42}$$

The global zeta function $\zeta^{<}_{\mathfrak{L}_W}(s)$ has a natural boundary at $\mathrm{Re}(s) = 17/7$ whereas $\zeta^{\triangleleft}_{\mathfrak{L}_W}(s)$ has a natural boundary at $\mathrm{Re}(s) = 7/6$.

Example 4. In [23] it is proved that the following two finitely generated nilpotent groups

$$G_1 = \left\langle \begin{array}{c} g_1, g_2, g_3, g_4, \\ z_1,\ z_2 \end{array} \;\middle|\; \begin{array}{c} [g_1, g_2] = 1,\ [g_3, g_4] = 1,\ [g_1, g_3] = z_1, \\ [g_1, g_4] = z_2,\ [g_2, g_3] = z_2,\ [g_2, g_4] = z_1^{-5} \end{array} \right\rangle, \tag{43}$$

$$G_2 = \left\langle \begin{array}{c} g_1, g_2, g_3, g_4, \\ z_1,\ z_2 \end{array} \;\middle|\; \begin{array}{c} [g_1, g_2] = 1,\ [g_3, g_4] = 1,\ [g_1, g_3] = z_1, \\ [g_1, g_4] = z_2,\ [g_2, g_3] = z_1^{-1} z_2^2,\ [g_2, g_4] = z_1^{-3} z_2 \end{array} \right\rangle \tag{44}$$

have the same profinite completion but are not isomorphic. It follows that both their zeta functions are the same. Both groups have Hirsch-length equal to 6 and are of nilpotency class 2. These groups come as special cases of an infinite series of l-tuples ($l \geq 2$) of examples of such groups arising from a number theoretic setting.

7. Variation

We have put the emphasis on counting subgroups or normal subgroups in nilpotent groups and on counting subrings or ideals in rings, however our results extend in a number of other directions.

(1) Variants of our zeta functions have been considered which count only subgroups with some added feature, for example characteristic subgroups or subgroups of a finitely generated torsion-free nilpotent group G which are isomorphic to G. Theorems 1.2 and 1.3 hold in this case and for many of these variants. In fact, there is always a p-adic formalism like in Section 2 which reduces Theorem 1.3 to Corollary 3.1 (see [27]). The paper [19] relates the zeta functions counting subgroups of G which are isomorphic to G to zeta functions defined by A. Weil for $\mathbb{Q}$-defined linear algebraic groups.

(2) The rationality result of Theorem 1.2 also holds for finitely generated nilpotent groups which are not necessarily torsion-free. In fact, the first author proved in [3] that this result extends to all finitely generated soluble groups of finite rank.

(3) In [12] it is proved that all crystallographic groups or more generally all finitely generated groups which contain an abelian subgroup of finite index have zeta functions which have a meromorphic continuation to all of $\mathbb{C}$. This is done by relating these zeta functions to zeta functions of orders in central simple $\mathbb{Q}$-algebras.

(4) The local zeta functions of the classical groups (see [14], [13]) can be expressed as p-adic cone integrals and our results apply to the corresponding Euler product.

(5) Let $g(n, c, d)$ be the number of finite nilpotent groups of size n, of nilpotency class bounded by c and generated by at most d elements. In [7] the zeta function

$$\zeta_{\mathcal{N}(c,d)}(s) := \sum_{n=1}^{\infty} g(n, c, d) n^{-s} \tag{45}$$

is shown to be expressible as the Euler product of p-adic cone integrals. Hence our results apply and give asymptotic results for the partial sums of the $g(n, c, d)$. The formalism of zeta functions has been applied successfully in [7] to solve conjecture **P**, which had appeared in connection with periodicity in trees connected with the classification problem for finite p-groups in terms of coclass.

(6) Thinking of Hilbert's basis theorem we might expect a connection between the ideal counting zeta function of a ring R and that of the polynomial ring $R[x]$ over R. This expectation is confirmed by a beautiful formula of D. Segal [45] which holds for Dedekind rings R.

(7) The formalism of zeta functions has been used to count representations of arithmetic and p-adic analytic groups in the papers [37] of B. Martin and A. Lubotzky, [30] of A. Jaikin-Zapirain and [33] of M. Larsen and A. Lubotzky.

On differential graded categories

Bernhard Keller

Abstract. Differential graded categories enhance our understanding of triangulated categories appearing in algebra and geometry. In this survey, we review their foundations and report on recent work by Drinfeld, Dugger–Shipley, Toën, Toën–Vaquié, and others.

Mathematics Subject Classification (2000). Primary 18E30; Secondary 16D90.

Keywords. Homological algebra, derived category, homotopy category, derived functor, Hochschild cohomology, K-theory, Morita theory, non-commutative algebraic geometry.

1. Introduction

1.1. Triangulated categories and dg categories. Derived categories were invented by Grothendieck–Verdier in the early sixties in order to formulate Grothendieck's duality theory for schemes, *cf.* [69]. Today, they have become an important tool in many branches of algebraic geometry, in algebraic analysis, non-commutative algebraic geometry, representation theory, mathematical physics .... In an attempt to axiomatize the properties of derived categories, Grothendieck–Verdier introduced the notion of a triangulated category. For a long time, triangulated categories were considered too poor to allow the development of more than a rudimentary theory. This vision has changed in recent years [112], [113], but the fact remains that many important constructions of derived categories cannot be performed with triangulated categories. Notably, tensor products and functor categories formed from triangulated categories are no longer triangulated. One approach to overcome these problems has been the theory of derivators initiated by Heller [63] and Grothendieck [59], *cf.* also [75], at the beginning of the nineties. Another, perhaps less formidable one is the theory of differential graded categories (= dg categories), together with its cousin, the theory of A_∞-categories.

Dg categories already appear in [86]. In the seventies, they found applications [130], [35] in the representation theory of finite-dimensional algebras. The idea to use dg categories to 'enhance' triangulated categories goes back at least to Bondal–Kapranov [21], who were motivated by the study of exceptional collections of coherent sheaves on projective varieties.

The synthesis of Koszul duality [11], [12] with Morita theory for derived categories [124] was the aim of the study of the unbounded derived category of a dg category in [76].

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

It is now well-established that invariants like K-theory, Hochschild (co-)homology and cyclic homology associated with a ring or a variety 'only depend' on its derived category. However, in most cases, the derived category (even with its triangulated structure) is not enough to compute the invariant, and the datum of a triangle equivalence between derived categories is not enough to construct an isomorphism between invariants (*cf.* Dugger–Shipley's [38] results results in Section 3.9). Differential graded categories provide the necessary structure to fill this gap. This idea was applied to K-theory by Thomason–Trobaugh [152] and to cyclic homology in [78], [80].

The most useful operation which *can be performed* on triangulated categories is the passage to a Verdier quotient. It was therefore important to lift this operation to the world of differential graded categories. This was done implicitly in [80] but explicitly, by Drinfeld, in [34].

In a certain sense, differential graded categories and differential graded functors contain too much information and the main problem in working with them consists in 'discarding what is irrelevant'. It now appears clearly that the best tool for doing this are Quillen model categories [121]: They provide a homotopy theoretic framework which allows simple, yet precise statements and rigorous but readable proofs. Building on the techniques of [34], a suitable model structure on the category of small differential graded categories was constructed in [146]. Starting from this structure, Toën has given a new approach to Morita theory for dg categories [155]. In their joint work [156], Toën and Vaquié have applied this to the construction of moduli stacks of objects in dg categories, and notably in categories of perfect complexes arising in geometry and representation theory.

Thanks to [155], [87] and to recent work by Tamarkin [148], we are perhaps getting closer to answering Drinfeld's question [34]: *What do DG categories form?*

1.2. Contents. After introducing notations and basic definitions in Section 2 we review the derived category of a dg category in Section 3. This is the first opportunity to practice the language of model categories. We present the structure theorems for algebraic triangulated categories which are compactly generated or, more generally, well-generated. We conclude with a survey of recent important work by Dugger and Shipley on topological Morita equivalence for dg categories. In Section 4, we present the homotopy categories of dg categories and of 'triangulated' dg categories following Toën's work [155]. The most important points are the description of the mapping spaces of the homotopy category via quasi-functors (Theorem 4.3), the closed monoidal structure (Theorem 4.5) and the characterization of dg categories of finite type (Theorem 4.12). We conclude with a summary of the applications to moduli problems. In the final Section 5, we present the most important invariance results for K-theory, Hochschild (co-)homology and cyclic homology. The derived Hall algebra presented in Section 5.6 is a new invariant due to Toën [153]. Its further development might lead to significant applications in representation theory.

Acknowledgments. I thank Bertrand Toën, Henning Krause, Brooke Shipley and Gonçalo Tabuada for helpful comments on previous versions of this article.

2. Definitions

2.1. Notations. Let k be a commutative ring, for example a field or the ring of integers $\mathbb{Z}$. We will write $\otimes$ for the tensor product over k. Recall that a *k-algebra* is a k-module A endowed with a k-linear associative multiplication $A \otimes_k A \to A$ admitting a two-sided unit $1 \in A$. For example, a $\mathbb{Z}$-algebra is just a (possibly non-commutative) ring. A *k-category* $\mathcal{A}$ is a 'k-algebra with several objects' in the sense of Mitchell [106]. Thus, it is the datum of a class of objects $\mathrm{obj}(\mathcal{A})$, of a k-module $\mathcal{A}(X, Y)$ for all objects X, Y of $\mathcal{A}$, and of k-linear associative composition maps

$$\mathcal{A}(Y, Z) \otimes \mathcal{A}(X, Y) \to \mathcal{A}(X, Z), \quad (f, g) \mapsto fg$$

admitting units $\mathbf{1}_X \in \mathcal{A}(X, X)$. For example, we can view k-algebras as k-categories with one object. The category $\mathrm{Mod}\, A$ of right A-modules over a k-algebra A is an example of a k-category with many objects. It is also an example of a *k-linear* category, *i.e.* a k-category which admits all finite direct sums.

A *graded k-module* is a k-module V together with a decomposition indexed by the positive and the negative integers:

$$V = \bigoplus_{p \in \mathbb{Z}} V^p.$$

The *shifted module* $V[1]$ is defined by $V[1]^p = V^{p+1}$, $p \in \mathbb{Z}$. A *morphism* $f : V \to V'$ of graded k-modules of degree n is a k-linear morphism such that $f(V^p) \subset V^{p+n}$ for all $p \in \mathbb{Z}$. The *tensor product* $V \otimes W$ of two graded k-modules V and W is the graded k-module with components

$$(V \otimes W)^n = \bigoplus_{p+q=n} V^p \otimes W^q, \quad n \in \mathbb{Z}.$$

The *tensor product* $f \otimes g$ of two maps $f : V \to V'$ and $g : W \to W'$ of graded k-modules is defined using the *Koszul sign rule*: We have

$$(f \otimes g)(v \otimes w) = (-1)^{pq} f(v) \otimes g(w)$$

if g is of degree p and v belongs to V^q. A *graded k-algebra* is a graded k-module A endowed with a multiplication morphism $A \otimes A \to A$ which is graded of degree 0, associative and admits a unit $1 \in A^0$. We identify 'ordinary' k-algebras with graded k-algebras concentrated in degree 0. We write $\mathcal{G}(k)$ for the *category of graded k-modules*.

A *differential graded* ($= dg$) *k-module* is a $\mathbb{Z}$-graded k-module V endowed with a *differential* d_V, *i.e.* a map $d_V : V \to V$ of degree 1 such that $d_V^2 = 0$. Equivalently, V is a *complex* of k-modules. The *shifted dg module* $V[1]$ is the shifted graded module endowed with the differential $-d_V$. The *tensor product* of two dg k-modules is the graded module $V \otimes W$ endowed with the differential $d_V \otimes \mathbf{1}_W + \mathbf{1}_V \otimes d_W$.

2.2. Differential graded categories. A *differential graded* or *dg category* is a k-category $\mathcal{A}$ whose morphism spaces are dg k-modules and whose compositions

$$\mathcal{A}(Y, Z) \otimes \mathcal{A}(X, Y) \to \mathcal{A}(X, Z)$$

are morphisms of dg k-modules.

For example, dg categories with one object may be identified with *dg algebras*, *i.e.* graded k-algebras endowed with a differential d such that the Leibniz rule holds:

$$d(fg) = d(f)g + (-1)^p f\, d(g)$$

for all $f \in A^p$ and all g. In particular, each ordinary k-algebra yields a dg category with one object. A typical example with several objects is obtained as follows: Let B be a k-algebra and $\mathcal{C}(B)$ the category of complexes of right B-modules

$$\cdots \longrightarrow M^p \xrightarrow{d_M} M^{p+1} \longrightarrow \cdots, \quad p \in \mathbb{Z}\,.$$

For two complexes L, M and an integer $n \in \mathbb{Z}$, we define $\mathcal{H}om(L, M)^n$ to be the k-module formed by the morphisms $f\colon L \to M$ of graded objects of degree n, *i.e.* the families $f = (f^p)$ of morphisms $f^p\colon L^p \to M^{p+n}$, $p \in \mathbb{Z}$, of B-modules. We define $\mathcal{H}om(L, M)$ to be the graded k-module with components $\mathcal{H}om(L, M)^n$ and whose differential is the commutator

$$d(f) = d_M \circ f - (-1)^n f \circ d_L.$$

The *dg category* $\mathcal{C}_{\mathrm{dg}}(B)$ has as objects all complexes and its morphisms are defined by

$$\mathcal{C}_{\mathrm{dg}}(B)(L, M) = \mathcal{H}om(L, M).$$

The composition is the composition of graded maps.

Let $\mathcal{A}$ be a dg category. The *opposite dg category* $\mathcal{A}^{\mathrm{op}}$ has the same objects as $\mathcal{A}$ and its morphisms are defined by

$$\mathcal{A}^{\mathrm{op}}(X, Y) = \mathcal{A}(Y, X);$$

the composition of $f \in \mathcal{A}^{\mathrm{op}}(Y, X)^p$ with $g \in \mathcal{A}^{\mathrm{op}}(Z, Y)^q$ is given by $(-1)^{pq} gf$. The *category* $Z^0(\mathcal{A})$ has the same objects as $\mathcal{A}$ and its morphisms are defined by

$$(Z^0\mathcal{A})(X, Y) = Z^0(\mathcal{A}(X, Y)),$$

where Z^0 is the kernel of $d\colon \mathcal{A}(X, Y)^0 \to \mathcal{A}(X, Y)^1$. The *category* $H^0(\mathcal{A})$ has the same objects as $\mathcal{A}$ and its morphisms are defined by

$$(H^0(\mathcal{A}))(X, Y) = H^0(\mathcal{A}(X, Y)),$$

where H^0 denotes the 0th homology of the complex $\mathcal{A}(X, Y)$. For example, if B is a k-algebra, we have an isomorphism of categories

$$Z^0(\mathcal{C}_{\mathrm{dg}}(B)) = \mathcal{C}(B)$$

and an isomorphism of categories

$$H^0(\mathcal{C}_{\mathrm{dg}}(B)) = \mathcal{H}(B),$$

where $\mathcal{H}(B)$ denotes the *category of complexes up to homotopy*, *i.e.* the category whose objects are the complexes and whose morphisms are the morphisms of complexes modulo the morphisms f homotopic to zero, *i.e.* such that $f = d(g)$ for some $g \in \mathcal{H}om(L, M)^{-1}$. The *homology category* $H^*(\mathcal{A})$ is the graded category with the same objects as $\mathcal{A}$ and morphisms spaces $H^*\mathcal{A}(X, Y)$.

2.3. The category of dg categories. Let $\mathcal{A}$ and $\mathcal{A}'$ be dg categories. A *dg functor* $F\colon \mathcal{A} \to \mathcal{A}'$ is given by a map $F\colon \mathrm{obj}(\mathcal{A}) \to \mathrm{obj}(\mathcal{A}')$ and by morphisms of dg k-modules

$$F(X, Y)\colon \mathcal{A}(X, Y) \to \mathcal{A}(FX, FY), \quad X, Y \in \mathrm{obj}(\mathcal{A}),$$

compatible with the composition and the units. The *category of small dg categories* dgcat_k has the small dg categories as objects and the dg functors as morphisms. Note that it has an initial object, the empty dg category $\emptyset$, and a final object, the dg category with one object whose endomorphism ring is the zero ring. The *tensor product* $\mathcal{A} \otimes \mathcal{B}$ of two dg categories has the class of objects $\mathrm{obj}(\mathcal{A}) \times \mathrm{obj}(\mathcal{B})$ and the morphism spaces

$$(\mathcal{A} \otimes \mathcal{B})((X, Y), (X', Y')) = \mathcal{A}(X, X') \otimes \mathcal{B}(Y, Y')$$

with the natural compositions and units.

For two dg functors $F, G\colon \mathcal{A} \to \mathcal{B}$, the *complex of graded morphisms* $\mathcal{H}om(F, G)$ has as its nth component the module formed by the families of morphisms

$$\phi_X \in \mathcal{B}(FX, GX)^n$$

such that $(Gf)(\phi_X) = (\phi_Y)(Ff)$ for all $f \in \mathcal{A}(X, Y)$, $X, Y \in \mathcal{A}$. The differential is induced by that of $\mathcal{B}(FX, GX)$. The set of *morphisms* $F \to G$ is by definition in bijection with $Z^0\mathcal{H}om(F, G)$.

Endowed with the tensor product, the category dgcat_k becomes a symmetric tensor category which admits an internal Hom-functor, *i.e.*

$$\mathrm{Hom}(\mathcal{A} \otimes \mathcal{B}, \mathcal{C}) = \mathrm{Hom}(\mathcal{A}, \mathcal{H}om(\mathcal{B}, \mathcal{C})),$$

for $\mathcal{A}, \mathcal{B}, \mathcal{C} \in \mathrm{dgcat}_k$, where $\mathcal{H}om(\mathcal{B}, \mathcal{C})$ has the dg functors as objects and the morphism space $\mathcal{H}om(F, G)$ for two dg functors F and G. The unit object is the dg category associated with the k-algebra k.

A *quasi-equivalence* is a dg functor $F\colon \mathcal{A} \to \mathcal{A}'$ such that

1) $F(X, Y)$ is a quasi-isomorphism for all objects X, Y of $\mathcal{A}$, and

2) the induced functor $H^0(F)\colon H^0(\mathcal{A}) \to H^0(\mathcal{A}')$ is an equivalence.

Note that neither the tensor product nor the internal Hom-functor respect the quasi-equivalences, a source of technical difficulties.

3. The derived category of a dg category

3.1. Dg modules. Let $\mathcal{A}$ be a small dg category. A *left dg $\mathcal{A}$-module* is a dg functor

$$L\colon \mathcal{A} \to \mathcal{C}_{\mathrm{dg}}(k)$$

and a *right dg $\mathcal{A}$-module* a dg functor

$$M\colon \mathcal{A}^{\mathrm{op}} \to \mathcal{C}_{\mathrm{dg}}(k).$$

Equivalently, a right dg $\mathcal{A}$-module M is given by complexes $M(X)$ of k-modules, for each $X \in \mathrm{obj}(\mathcal{A})$, and by morphisms of complexes

$$M(Y) \otimes \mathcal{A}(X, Y) \to M(X)$$

compatible with compositions and units. The *homology* $H^*(M)$ of a dg module M is the induced functor

$$H^*(\mathcal{A}) \to \mathcal{G}(k), \quad X \mapsto H^*(M(X))$$

with values in the category $\mathcal{G}(k)$ of graded k-modules (*cf.* 2.1). For each object X of $\mathcal{A}$, we have the right module *represented by* X

$$X^\wedge = \mathcal{A}(?, X).$$

The *category of dg modules* $\mathcal{C}(\mathcal{A})$ has as objects the dg $\mathcal{A}$-modules and as morphisms $L \to M$ the morphisms of dg functors (*cf.* 2.3). Note that $\mathcal{C}(\mathcal{A})$ is an abelian category and that a morphism $L \to M$ is an epimorphism (respectively a monomorphism) iff it induces surjections (respectively injections) in each component of $L(X) \to M(X)$ for each object X of $\mathcal{A}$. A morphism $f\colon L \to M$ is a *quasi-isomorphism* if it induces an isomorphism in homology.

We have $\mathcal{C}(\mathcal{A}) = Z^0(\mathcal{C}_{\mathrm{dg}}(\mathcal{A}))$, where, in the notations of 2.3, the dg category $\mathcal{C}_{\mathrm{dg}}(\mathcal{A})$ is defined by

$$\mathcal{C}_{\mathrm{dg}}(\mathcal{A}) = \mathcal{H}om(\mathcal{A}^{\mathrm{op}}, \mathcal{C}_{\mathrm{dg}}(k)).$$

We write $\mathcal{H}om(L, M)$ for the complex of morphisms from L to M in $\mathcal{C}_{\mathrm{dg}}(\mathcal{A})$. For each $X \in \mathcal{A}$, we have a natural isomorphism

$$\mathcal{H}om(X^\wedge, M) \xrightarrow{\sim} M(X). \tag{1}$$

The *category up to homotopy of dg $\mathcal{A}$-modules* is

$$\mathcal{H}(\mathcal{A}) = H^0(\mathcal{C}_{\mathrm{dg}}(\mathcal{A})).$$

The isomorphism (1) yields isomorphisms

$$\mathcal{H}(\mathcal{A})(X^\wedge, M[n]) \xrightarrow{\sim} H^n(\mathcal{H}om(X^\wedge, M)) \xrightarrow{\sim} H^n M(X), \tag{2}$$

where $n \in \mathbb{Z}$ and $M[n]$ is the *shifted dg module* $Y \mapsto M(Y)[n]$.

If $\mathcal{A}$ is the dg category with one object associated with a k-algebra B, then a dg $\mathcal{A}$-module is the same as a complex of B-modules. More precisely, we have $\mathcal{C}(\mathcal{A}) = \mathcal{C}(B)$, $\mathcal{C}_{\mathrm{dg}}(\mathcal{A}) = \mathcal{C}_{\mathrm{dg}}(B)$ and $\mathcal{H}(\mathcal{A}) = \mathcal{H}(B)$. In this case, if X is the unique object of $\mathcal{A}$, the dg module $X^\wedge$ is the complex formed by the free right B-module of rank one concentrated in degree 0.

3.2. The derived category, resolutions. The *derived category* $\mathcal{D}(\mathcal{A})$ is the localization of the category $\mathcal{C}(\mathcal{A})$ with respect to the class of quasi-isomorphisms. Thus, its objects are the dg modules and its morphisms are obtained from morphisms of dg modules by formally inverting [53] all quasi-isomorphisms. The projection functor $\mathcal{C}(\mathcal{A}) \to \mathcal{D}(\mathcal{A})$ induces a functor $\mathcal{H}(\mathcal{A}) \to \mathcal{D}(\mathcal{A})$ and the derived category could equivalently be defined as the localization of $\mathcal{H}(\mathcal{A})$ with respect to the class of all quasi-isomorphisms. Note that from this definition, it is not clear that the morphism classes of $\mathcal{D}(\mathcal{A})$ are sets or that $\mathcal{D}(\mathcal{A})$ is an additive category.

Call a dg module P *cofibrant* if, for every surjective quasi-isomorphism $L \to M$, every morphism $P \to M$ factors through L. For example, for an object X of $\mathcal{A}$, the dg module $X^\wedge$ is cofibrant. Call a dg module I *fibrant* if, for every injective quasi-isomorphism $L \to M$, every morphism $L \to I$ extends to M. For example, if E is an injective cogenerator of the category of k-modules and X an object of $\mathcal{A}$, the dg module $\mathcal{H}om(\mathcal{A}(X, ?), E)$ is fibrant.

Proposition 3.1. a) *For each dg module M, there is a quasi-isomorphism $\mathbf{p}M \to M$ with cofibrant $\mathbf{p}M$ and a quasi-isomorphism $M \to \mathbf{i}M$ with fibrant $\mathbf{i}M$.*

b) *The projection functor $\mathcal{H}(\mathcal{A}) \to \mathcal{D}(\mathcal{A})$ admits a fully faithful left adjoint given by $M \mapsto \mathbf{p}M$ and a fully faithful right adjoint given by $M \mapsto \mathbf{i}M$.*

One can construct $\mathbf{p}M$ and $\mathbf{i}M$ explicitly, as first done in [5] (*cf.* also [76]). We call $\mathbf{p}M \to M$ a *cofibrant resolution* and $M \to \mathbf{i}M$ a *fibrant resolution* of M. According to b), these resolutions are functorial in the category up to homotopy $\mathcal{H}(\mathcal{A})$ and we can compute morphisms in $\mathcal{D}(\mathcal{A})$ via

$$\mathcal{H}(\mathcal{A})(\mathbf{p}L, M) = \mathcal{D}(\mathcal{A})(L, M) = \mathcal{H}(\mathcal{A})(L, \mathbf{i}M).$$

In particular, for an object X of $\mathcal{A}$ and a dg module M, the isomorphisms (2) yield

$$\mathcal{D}(\mathcal{A})(X^\wedge, M[n]) \xrightarrow{\sim} \mathcal{H}(\mathcal{A})(X^\wedge, M[n]) \xrightarrow{\sim} H^n M(X) \tag{3}$$

since $X^\wedge$ is cofibrant. The embedding $\mathcal{D}(\mathcal{A}) \to \mathcal{H}(\mathcal{A})$ provided by $\mathbf{p}$ also shows that the derived category is additive.

If $\mathcal{A}$ is associated with a k-algebra B and M is a right B-module considered as a complex concentrated in degree 0, then $\mathbf{p}M \to M$ is a projective resolution of M and $M \to \mathbf{i}M$ an injective resolution. The proposition is best understood in the language of Quillen model categories [121]. We refer to [45] for a highly readable introduction and to [66], [65] for in-depth treatments. The proposition results from the following theorem, proved using the techniques of [66, 2.3].

Theorem 3.2. *The category $\mathcal{C}(\mathcal{A})$ admits two structures of Quillen model category whose weak equivalences are the quasi-isomorphisms:*

1) *The* projective *structure, whose fibrations are the epimorphisms. For this structure, each object is fibrant and an object is cofibrant iff it is a cofibrant dg module.*
2) *The* injective *structure, whose cofibrations are the monomorphisms. For this structure, each object is cofibrant and an object is fibrant iff it is a fibrant dg module.*

For both structures, two morphisms are homotopic iff they become equal in the category up to homotopy $\mathcal{H}(\mathcal{A})$.

3.3. Exact categories, Frobenius categories. Recall that an *exact category* in the sense of Quillen [120] is an additive category $\mathcal{E}$ endowed with a distinguished class of sequences

$$0 \longrightarrow A \xrightarrow{i} B \xrightarrow{p} C \longrightarrow 0\ ,$$

where i is a kernel of p and p a cokernel of i. We will state the axioms these sequences have to satisfy using the terminology of [52]: The morphisms p are called deflations, the morphisms i inflations and the pairs (i, p) conflations. The axioms are:

Ex0 The identity morphism of the zero object is a deflation.

Ex1 The composition of two deflations is a deflation.

Ex2 Deflations are stable under base change.

Ex2′ Inflations are stable under cobase change.

As shown in [74], these axioms are equivalent to Quillen's and they imply that if $\mathcal{E}$ is small, then there is a fully faithful functor from $\mathcal{E}$ into an abelian category $\mathcal{E}'$ whose image is an additive subcategory closed under extensions and such that a sequence of $\mathcal{E}$ is a conflation iff its image is a short exact sequence of $\mathcal{E}'$. Conversely, one easily checks that an extension closed full additive subcategory $\mathcal{E}$ of an abelian category $\mathcal{E}'$ endowed with all conflations which become exact sequences in $\mathcal{E}'$ is always exact. The fundamental notions and constructions of homological algebra, and in particular the construction of the derived category, naturally extend from abelian to exact categories, *cf.* [107] and [77].

A *Frobenius category* is an exact category $\mathcal{E}$ which has enough injectives and enough projectives and where the class of projectives coincides with the class of injectives. In this case, the *stable category* $\underline{\mathcal{E}}$ obtained by dividing $\mathcal{E}$ by the ideal of morphisms factoring through a projective-injective carries a canonical structure of triangulated category, *cf.* [62], [60], [85], [57]. We write $\bar{f}$ for the image in $\underline{\mathcal{E}}$ of a morphism f of $\mathcal{E}$. The suspension functor S of $\underline{\mathcal{E}}$ is obtained by choosing a conflation

$$0 \longrightarrow A \longrightarrow IA \longrightarrow SA \longrightarrow 0$$

for each object A. Each triangle is isomorphic to a standard triangle $(\bar{\imath}, \bar{p}, \bar{e})$ obtained by embedding a conflation (i, p) into a commutative diagram

$$\begin{array}{ccccccccc} 0 & \longrightarrow & A & \xrightarrow{i} & B & \xrightarrow{p} & C & \longrightarrow & 0 \\ & & \mathbf{1}\downarrow & & \downarrow & & \downarrow e & & \\ 0 & \longrightarrow & A & \longrightarrow & IA & \longrightarrow & SA & \longrightarrow & 0. \end{array}$$

3.4. Triangulated structure. Let $\mathcal{A}$ be a small dg category. Define a sequence

$$0 \longrightarrow L \xrightarrow{i} M \xrightarrow{p} N \longrightarrow 0$$

of $\mathcal{C}(\mathcal{A})$ to be a *conflation* if there is a morphism $r \in \mathcal{H}om(M, L)^0$ such that $ri = \mathbf{1}_L$ or, equivalently, a morphism $s \in \mathcal{H}om(N, M)$ such that $ps = \mathbf{1}_N$.

Lemma 3.3. a) *Endowed with these conflations, $\mathcal{C}(\mathcal{A})$ becomes a Frobenius category. The resulting stable category is canonically isomorphic to $\mathcal{H}(\mathcal{A})$. The suspension functor is induced by the shift $M \mapsto M[1]$.*

b) *Endowed with the suspension induced by that of $\mathcal{H}(\mathcal{A})$ and the triangles isomorphic to images of triangles of $\mathcal{H}(\mathcal{A})$ the derived category $\mathcal{D}(\mathcal{A})$ becomes a triangulated category. Each short exact sequence of complexes yields a canonical triangle.*

3.5. Compact objects, Brown representability. Let $\mathcal{T}$ be a triangulated category admitting arbitrary coproducts. Since the adjoint of a triangle functor is a triangle functor [85], the coproduct of triangles is then automatically a triangle. Moreover, $\mathcal{T}$ is *idempotent complete* [18], *i.e.* each idempotent endomorphism of an object of $\mathcal{T}$ is the composition of a section with a retraction. An object C of $\mathcal{T}$ is *compact* if the functor $\mathcal{T}(C, ?)$ commutes with arbitrary coproducts, *i.e.* for each family (X_i) of objects of $\mathcal{T}$, the canonical morphism

$$\coprod \mathcal{T}(C, X_i) \to \mathcal{T}\Big(C, \coprod X_i\Big)$$

is invertible. The triangulated category $\mathcal{T}$ is *compactly generated* if there is a set $\mathcal{G}$ of compact objects G such that an object X of $\mathcal{T}$ vanishes iff we have $\mathcal{T}(G, X) = 0$ for each $G \in \mathcal{G}$.

Theorem 3.4 (Characterization of compact objects [152], [108]). *An object of $\mathcal{T}$ is compact iff it is a direct factor of an iterated extension of copies of objects of $\mathcal{G}$ shifted in both directions.*

Theorem 3.5 (Brown representability [25], [1], [109]). *If $\mathcal{T}$ is compactly generated, a cohomological functor $F\colon \mathcal{T}^{\mathrm{op}} \to \mathrm{Mod}\,\mathbb{Z}$ is representable iff it takes coproducts of $\mathcal{T}$ to products of* $\mathrm{Mod}\,\mathbb{Z}$.

A set of objects $\mathcal{G}$ *symmetrically generates* $\mathcal{T}$ [95] if we have

1) an object X of $\mathcal{T}$ vanishes iff $\mathcal{T}(G, X) = 0$ for each $G \in \mathcal{G}$, and
2) there is a set of objects $\mathcal{G}'$ such that a morphism $f: X \to Y$ of $\mathcal{T}$ induces surjections $\mathcal{T}(G, X) \to \mathcal{T}(G, Y)$ for all $G \in \mathcal{G}$ iff it induces injections $\mathcal{T}(Y, G') \to \mathcal{T}(X, G')$ for all $G' \in \mathcal{G}'$.

If $\mathcal{G}$ compactly generates $\mathcal{T}$, then we can take for $\mathcal{G}'$ the set of objects G' defined by

$$\mathcal{T}(?, G') = \mathrm{Hom}_k(\mathcal{T}(G, ?), E), \quad G \in \mathcal{G}$$

where E is an injective cogenerator of the category of k-modules. Thus, in this case, $\mathcal{G}$ also symmetrically generates $\mathcal{T}$.

Theorem 3.6 (Brown representability for the dual [111], [95]). *If $\mathcal{T}$ is symmetrically generated, a homological functor $F: \mathcal{T} \to \mathrm{Mod}\,\mathbb{Z}$ is corepresentable iff it commutes with products.*

Let $\mathcal{A}$ be a small dg category. The derived category $\mathcal{D}(\mathcal{A})$ admits arbitrary coproducts and these are induced by coproducts of modules. Thanks to the isomorphisms

$$\mathcal{D}(\mathcal{A})(X^\wedge[n], M) \xrightarrow{\sim} H^{-n}M(X) \tag{4}$$

obtained from (3), each dg module $X^\wedge[n]$, where X is an object of $\mathcal{A}$ and n an integer, is compact. The isomorphism (4) also shows that a dg module M vanishes in $\mathcal{D}(\mathcal{A})$ iff each morphism $X^\wedge[n] \to M$ vanishes. Thus the set $\mathcal{G}$ formed by the $X^\wedge[n]$, $X \in \mathcal{A}$, $n \in \mathbb{Z}$, is a set of compact generators for $\mathcal{D}(\mathcal{A})$. The *triangulated category* $\mathrm{tria}(\mathcal{A})$ *associated with* $\mathcal{A}$ is the closure in $\mathcal{D}(\mathcal{A})$ of the set of representable functors $X^\wedge$, $X \in \mathcal{A}$, under shifts in both directions and extensions. The *category of perfect objects* $\mathrm{per}(\mathcal{A})$ the closure of $\mathrm{tria}(\mathcal{A})$ under passage to direct factors in $\mathcal{D}(\mathcal{A})$. The above theorems yield the

Corollary 3.7. *An object of $\mathcal{D}(\mathcal{A})$ is compact iff it lies in* $\mathrm{per}(\mathcal{A})$. *A cohomological functor $\mathcal{D}(\mathcal{A})^{\mathrm{op}} \to \mathrm{Mod}\,k$ is representable iff it takes coproducts of $\mathcal{D}(\mathcal{A})$ to products of* $\mathrm{Mod}\,k$. *A homological functor $\mathcal{D}(\mathcal{A}) \to \mathrm{Mod}\,k$ is corepresentable iff it commutes with products.*

3.6. Algebraic triangulated categories. Let $\mathcal{T}$ be a k-linear triangulated category. We say that $\mathcal{T}$ is *algebraic* if it is triangle equivalent to $\underline{\mathcal{E}}$ for some k-linear Frobenius category $\mathcal{T}$. It is easy to see that each subcategory of an algebraic triangulated category is algebraic. We will see below that each Verdier localization of an algebraic triangulated category is algebraic (if we neglect a set-theoretic problem). Moreover, categories of complexes up to homotopy are algebraic, by 3.4. Therefore, 'all' triangulated categories occurring in algebra and geometry are algebraic. Non algebraic triangulated categories appear naturally in topology (*cf.* also Section 3.9): For instance, in the homotopy category of 2-local spectra, the identity morphism of the

cone over twice the identity of the sphere spectrum is of order four, but in each algebraic triangulated category, the identity of the cone on twice the identity of an object is of order two at most. A general method to prove that a triangulated category obtained from a suitable stable Quillen model category is not algebraic is to show that its [123] Hom-functor enriched in spectra does not factor through the canonical functor from the derived category of abelian groups to the homotopy category of spectra.

We wish to show that 'all' algebraic triangulated categories can be described by dg categories. Let $\mathcal{T}$ be a triangulated category and $\mathcal{G}$ a full subcategory. We make $\mathcal{G}$ into a graded category $\mathcal{G}_{gr}$ by defining

$$\mathcal{G}_{gr}(G, G') = \bigoplus_{n\in\mathbb{Z}} \mathcal{T}(G, S^n G').$$

We obtain a natural functor $\overline{F}$ from $\mathcal{T}$ to the category of graded $\mathcal{G}_{gr}$-modules by sending an object Y of $\mathcal{T}$ to the $\mathcal{G}_{gr}$-module

$$X \mapsto \bigoplus_{n\in\mathbb{Z}} \mathcal{T}(X, S^n Y)$$

Theorem 3.8 ([76]). *Suppose that $\mathcal{T}$ is algebraic. Then there is a dg category $\mathcal{A}$ such that $H^*(\mathcal{A})$ is isomorphic to $\mathcal{G}_{gr}$ and a triangle functor*

$$F\colon \mathcal{T} \to \mathcal{D}(\mathcal{A})$$

such that the composition $H^* \circ F$ is isomorphic to $\overline{F}$. Moreover,

a) *F induces an equivalence from $\mathcal{T}$ to* $\mathrm{tria}(\mathcal{A})$ *iff $\mathcal{T}$ coincides with its smallest full triangulated subcategory containing $\mathcal{G}$;*

b) *F induces an equivalence from $\mathcal{T}$ to* $\mathrm{per}(\mathcal{A})$ *iff $\mathcal{T}$ is idempotent complete* (cf. *Section* 3.5) *and equals the closure of $\mathcal{G}$ under shifts in both directions, extensions and passage to direct factors;*

c) *F is an equivalence $\mathcal{T} \xrightarrow{\sim} \mathcal{D}(\mathcal{A})$ iff $\mathcal{T}$ admits arbitrary coproducts and the objects of $\mathcal{G}$ form a set of compact generators for $\mathcal{T}$.*

Examples arise from commutative and non-commutative geometry: A. Bondal and M. Van den Bergh show in [19] that if X is a quasi-compact quasi-separated scheme, then the (unbounded) derived category $\mathcal{T} = \mathcal{D}_{qc}(X)$ of complexes of $\mathcal{O}_X$-modules with quasi-coherent homology admits a single compact generator G and that moreover, $\mathrm{Hom}(G, G[n])$ vanishes except for finitely many n. Thus $\mathcal{T}$ is equivalent to the derived category of a dg category with one object whose endomorphism ring has bounded homology.

R. Rouquier shows in [131] (*cf.* also [96]) that if X is a quasi-projective scheme over a perfect field k, then the derived category of coherent sheaves over X admits a generator as a triangulated category (as in part b) and, surprisingly, that it is even of 'finite dimension' as a triangulated category: each object occurs as a direct factor of

an object which admits a 'resolution' of bounded length by finite sums of shifts of the generator. Thus, the bounded derived category of coherent sheaves is equivalent to $\mathrm{per}(\mathcal{A})$ for a dg category with one object whose endomorphism ring satisfies a strong regularity condition.

In [17], J. Block describes the bounded derived category of complexes of sheaves with coherent homology on a complex manifold X as the category $H^0(\mathcal{A})$ associated with a dg category constructed from the Dolbeault dg algebra $(A^{0,\bullet}(X), \bar{\partial})$. This can be seen as an instance of a), where, for $\mathcal{G}$, we can take for example the category of coherent sheaves (*i.e.* complexes concentrated in degree 0). Note however that the term 'perfect derived category' is used with a different meaning in [17].

In the independently obtained [40], W. Dwyer and J. Greenlees give elegant descriptions via dg endomorphism rings of categories of complete, respectively torsion, modules. Their results are applied in a unifying study of duality phenomena in algebra and topology in [41].

One of the original motivations for the theorem was D. Happel's description [60], [61] of the bounded derived category of a finite-dimensional associative algebra of finite global dimension as the stable category of a certain Frobenius category. This in turn was inspired by Bernstein–Gelfand–Gelfand's [16] and Beilinson's [9] descriptions of the derived category of coherent sheaves on projective space.

A vast generalization of the theorem to non-additive contexts [137] is due to S. Schwede and B. Shipley [139], *cf.* also Section 3.9 below.

3.7. Well-generated algebraic triangulated categories. A triangulated category $\mathcal{T}$ is *well-generated* [112], [94] if it admits arbitrary coproducts and a *good set of generators* $\mathcal{G}$, *i.e.* $\mathcal{G}$ is stable under shifts in both directions and satisfies

1) an object X of $\mathcal{T}$ vanishes iff $\mathcal{T}(G, X) = 0$ for each $G \in \mathcal{G}$,
2) there is a cardinal α such that each $G \in \mathcal{G}$ is α-*compact*, *i.e.* for each family of objects X_i, $i \in I$, of $\mathcal{T}$, each morphism
$$X \to \bigoplus_{i \in I} X_i$$
factors through a subsum $\bigoplus_{i \in J} X_i$ for some subset J of I of cardinality strictly smaller than α,
3) for each family of morphisms $f_i \colon X_i \to Y_i$, $i \in I$, of $\mathcal{T}$ which induces surjections
$$\mathcal{T}(G, X_i) \to \mathcal{T}(G, Y_i)$$
for all $G \in \mathcal{G}$ and all $i \in I$, the sum of the f_i induces surjections
$$\mathcal{T}(G, \bigoplus X_i) \to \mathcal{T}(G, \bigoplus Y_i)$$
for all $G \in \mathcal{G}$.

Clearly each compactly generated triangulated category is well-generated. A. Neeman proves in [112] that the Brown representability theorem holds for well-generated triangulated categories. This is one of the main reasons for studying them. Another important result of [112] is that if $\mathcal{T}$ is well-generated and $\mathcal{S} \to \mathcal{T}$ is a localization (*i.e.* a fully faithful triangle functor admitting a left adjoint whose kernel is generated by a *set* of objects) then $\mathcal{S}$ is well-generated. Thus each localization of a compactly generated triangulated category is well-generated and in particular, so is each localization of the derived category of a small dg category.

Here is another class of examples: Let $\mathcal{B}$ be a Grothendieck abelian category, *e.g.* the category of modules on a ringed space. Then, by the Popescu–Gabriel theorem [118], [101], $\mathcal{B}$ is the localization of the category of Mod A of A-modules over some ring A. One can deduce from this that the unbounded derived category of the abelian category $\mathcal{B}$ (*cf.* [51], [151], [71]) is a localization of $\mathcal{D}(A)$ and thus is well-generated.

Theorem 3.9 ([119]). *Let $\mathcal{T}$ be an algebraic triangulated category. Then $\mathcal{T}$ is well-generated iff it is a localization of $\mathcal{D}(\mathcal{A})$ for some small dg category $\mathcal{A}$. Moreover, if $\mathcal{T}$ is well-generated and $\mathcal{U} \subset \mathcal{T}$ a full small subcategory such that, for each $X \in \mathcal{T}$, we have*

$$X = 0 \Leftrightarrow \mathcal{T}(U, S^n X) = 0 \text{ for all } n \in \mathbb{Z} \text{ and } U \in \mathcal{U},$$

then there is an associated localization $\mathcal{T} \to \mathcal{D}(\mathcal{A})$ for some small dg category $\mathcal{A}$ with $H^*(\mathcal{A}) = \mathcal{U}_{gr}$.

3.8. Morita equivalence. Let $\mathcal{A}$ and $\mathcal{B}$ be small dg categories. Let X be an $\mathcal{A}$-$\mathcal{B}$-*bimodule*, *i.e.* a dg $\mathcal{A}^{\mathrm{op}} \otimes \mathcal{B}$-module X. Thus X is given by complexes $X(B, A)$, for all A in $\mathcal{A}$ and B in $\mathcal{B}$, and morphisms of complexes

$$\mathcal{B}(A, A') \otimes X(B, A) \otimes \mathcal{A}(B', B) \to X(B', A').$$

For each dg $\mathcal{B}$-module M, we obtain a dg $\mathcal{A}$-module

$$GM = \mathcal{H}om(X, M)\colon A \mapsto \mathcal{H}om(X(?, A), M).$$

The functor $G\colon \mathcal{C}(\mathcal{B}) \to \mathcal{C}(\mathcal{A})$ admits a left adjoint $F\colon L \mapsto L \otimes_{\mathcal{A}} X$. These functors do not respect quasi-isomorphisms in general, but they form a Quillen adjunction (*cf.* Section 3.9) and their derived functors

$$\mathbf{L}F\colon L \mapsto F(\mathbf{p}L) \quad \text{and} \quad \mathbf{R}G\colon M \mapsto G(\mathbf{i}M)$$

form an adjoint pair of functors between $\mathcal{D}(\mathcal{A})$ and $\mathcal{D}(\mathcal{B})$.

Lemma 3.10 ([76]). *The functor $\mathbf{L}F\colon \mathcal{D}(\mathcal{A}) \to \mathcal{D}(\mathcal{B})$ is an equivalence if and only if*

a) *the dg $\mathcal{B}$-module $X(?, A)$ is perfect for all A in $\mathcal{A}$,*

b) *the morphism*

$$\mathcal{A}(A, A') \to \mathcal{H}om(X(?, A), X(?, A'))$$

is a quasi-isomorphism for all A, A' in $\mathcal{A}$, and

c) *the dg $\mathcal{B}$-modules $X(?, A)$, $A \in \mathcal{A}$, form a set of (compact) generators for $\mathcal{D}(\mathcal{B})$.*

For example, if $E\colon \mathcal{A} \to \mathcal{B}$ is a dg functor, then $X(B, A) = \mathcal{B}(B, E(A))$ defines a dg bimodule so that the above functor G is the restriction along E. Then the lemma shows that $\mathbf{R}G$ is an equivalence iff E is a quasi-equivalence. We loosely refer to the functor $\mathbf{L}F$ associated with a dg $\mathcal{A}$-$\mathcal{B}$-bimodule as a *tensor functor*.

Theorem 3.11 ([76]). *The following are equivalent:*

1) *There is an equivalence $\mathcal{D}(\mathcal{A}) \to \mathcal{D}(\mathcal{B})$ given by a composition of tensor functors and their inverses.*

2) *There is a dg subcategory $\mathcal{G}$ of $\mathcal{C}(\mathcal{B})$ formed by cofibrant dg modules such that the objects of $\mathcal{G}$ form a set of compact generators for $\mathcal{D}(\mathcal{B})$ and there is a chain of quasi-equivalences*

$$\mathcal{A} \leftarrow \mathcal{A}' \to \cdots \leftarrow \mathcal{G}' \to \mathcal{G}$$

linking $\mathcal{A}$ to $\mathcal{G}$.

We say that $\mathcal{A}$ and $\mathcal{B}$ are *dg Morita equivalent* if the conditions of the theorem are satisfied. In this case, there is of course a triangle equivalence $\mathcal{D}(\mathcal{A}) \to \mathcal{D}(\mathcal{B})$. In general, the existence of such a triangle equivalence is not sufficient for $\mathcal{A}$ and $\mathcal{B}$ to be dg Morita equivalent, *cf.* Section 3.9. The following theorem is therefore remarkable:

Theorem 3.12 (Rickard [124]). *Suppose that $\mathcal{A}$ and $\mathcal{B}$ have their homology concentrated in degree* 0*. Then the following are equivalent:*

1) *$\mathcal{A}$ and $\mathcal{B}$ are dg Morita equivalent.*

2) *There is a triangle equivalence $\mathcal{D}(\mathcal{A}) \to \mathcal{D}(\mathcal{B})$.*

3) *There is a full subcategory $\mathcal{T}$ of $\mathcal{D}(\mathcal{B})$ such that*

   a) *the objects of $\mathcal{T}$ form a set of compact generators of $\mathcal{D}(\mathcal{B})$,*

   b) *we have $\mathcal{D}(\mathcal{B})(T, T'[n]) = 0$ for all $n \neq 0$ and all T, T' of $\mathcal{T}$,*

   c) *there is an equivalence $H^0(\mathcal{A}) \xrightarrow{\sim} \mathcal{T}$.*

We refer to [76] or [36] for this form of the theorem. A subcategory $\mathcal{T}$ satisfying a) and b) in 3) is called a *tilting subcategory*, a concept which generalizes that of a tilting module. We refer to [122], [3] for the theory of tilting, from which this theorem arose and which provides huge classes of examples from the representation theory of finite-dimensional algebras and finite groups as well as from algebraic geometry, *cf.* also the appendix to [113] and [88], [125], [132].

3.9. Topological Morita equivalence. In recent years, Morita theory has been vastly generalized from algebraic triangulated categories to stable model categories in work due to S. Schwede and B. Shipley. This is based on the category of symmetric spectra as constructed in [67] (*cf.* [46] for a different construction of a symmetric monoidal model category for the category of spectra). We refer to [136] for an excellent exposition of these far-reaching results and their surprising applications in homotopy theory. In work by D. Dugger and B. Shipley [38], *cf.* also [37], [39], this 'topological Morita theory' has been applied to dg categories. We briefly describe their results and refer to [141] for a highly readable, more detailed survey.

The main idea is to replace the monoidal base category, the derived category of abelian groups $\mathcal{D}(\mathbb{Z})$, by a more fundamental category: the 'derived category of the category of sets', *i.e.* the homotopy category of spectra. To preserve higher homotopical information, one must not, of course, work at the level of derived categories but has to introduce model categories. So instead of considering $\mathcal{D}(\mathbb{Z})$, one considers its model category $\mathcal{C}(\mathbb{Z})$ of complexes of abelian groups and replaces it by a convenient model of the category of spectra: the category of symmetric spectra, which one might imagine as 'complexes of abelian groups up to homotopy'. We refer to [67] or [136] for the precise definition. As shown in [67], symmetric spectra form a *symmetric* monoidal category which carries a compatible Quillen model structure and whose homotopy category is equivalent to the homotopy category of spectra of Bousfield and Friedlander [24]. The tensor product is the *smash product* $\wedge$ and the unit object is the *sphere spectrum* $\mathbb{S}$. The unit object is cofibrant and the smash product induces a monoidal structure on the homotopy category of symmetric spectra. The *Eilenberg–MacLane functor* H is a lax monoidal functor from the category of complexes $\mathcal{C}(k)$ to the category of symmetric spectra such that the homology groups of a complex C become isomorphic to the homotopy groups of HC. Since H is lax monoidal, if A is a dg $\mathbb{Z}$-algebra, then HA is naturally an algebra in the category of symmetric spectra and if M is an A-module, then HM becomes an HA-module. More generally, if $\mathcal{A}$ is a dg category over $\mathbb{Z}$, then $H\mathcal{A}$ becomes a *spectral category*, *i.e.* a category enriched in symmetric spectra, *cf.* [138], [140]. Each $\mathcal{A}$-module M then gives rise to a *spectral module* HM over $H\mathcal{A}$. The spectral modules over a spectral category form a Quillen model category [140].

Recall that if $\mathcal{L}$ and $\mathcal{M}$ are Quillen model categories, a *Quillen adjunction* is given by a pair of adjoint functors $L\colon \mathcal{L} \to \mathcal{M}$ and $R\colon \mathcal{M} \to \mathcal{L}$ such that L preserves cofibrations and R fibrations. Such a pair induces an adjoint pair between the homotopy categories of $\mathcal{L}$ and $\mathcal{M}$. If the induced functors are equivalences, then (L, R) is a *Quillen equivalence*. The model categories $\mathcal{L}$ and $\mathcal{M}$ are *Quillen equivalent* if they are linked by a chain of Quillen equivalences.

It was shown by A. Robinson [129], *cf.* also [139], that for an ordinary ring R, the unbounded derived category of R-modules is equivalent to the homotopy category of spectral modules over HR. This result is generalized and refined as follows:

Theorem 3.13 (Shipley [140]). *If $\mathcal{A}$ is a dg category over $\mathbb{Z}$, the model categories of dg $\mathcal{A}$-modules and of spectral modules over $H\mathcal{A}$ are Quillen equivalent.*

This allows us to define two small dg categories $\mathcal{A}$ and $\mathcal{B}$ to be *topologically Morita equivalent* if their categories of spectral modules are Quillen equivalent.

Proposition 3.14 ([38]). *Let $\mathcal{A}$ and $\mathcal{B}$ be two dg rings. Then statement* a) *implies* b) *and* b) *implies* c):

a) *$\mathcal{A}$ and $\mathcal{B}$ are dg Morita equivalent.*

b) *$\mathcal{A}$ and $\mathcal{B}$ are topologically Morita equivalent.*

c) *$\mathcal{D}(\mathcal{A})$ is triangle equivalent to $\mathcal{D}(\mathcal{B})$.*

It is remarkable that in general, these implications are strict. Examples which show this were obtained in recent joint work by D. Dugger and B. Shipley [38], *cf.* also [141]. To show that c) does not imply b), they invoke Schlichting's example [135]: Let p be an odd prime. The module categories over $A' = \mathbb{Z}/p^2$ and $B' = (\mathbb{Z}/p)[\varepsilon]/\varepsilon^2$ are Frobenius categories. Their stable categories are triangle equivalent (both are equivalent to the category of $\mathbb{Z}/p$-vector spaces with the identical suspension and the split triangles) but the K-theories associated with the stable module categories are not isomorphic. Since K-theory is preserved under topological Morita equivalence (*cf.* Section 5.2 below), the dg algebras A and B associated (*cf.* Section 3.6) with the canonical generators (corresponding to the one-dimensional vector space over $\mathbb{Z}/p$) of the stable categories of A' and B' cannot be topologically Morita equivalent.

To show that b) does not imply a), Dugger and Shipley consider two dg algebras A and B with homology isomorphic to $\mathbb{Z}/2 \oplus \mathbb{Z}/2[2]$. The isomorphism classes of such algebras in the homotopy category of dg $\mathbb{Z}$-algebras are parametrized by the Hochschild cohomology group $HH^4_{\mathbb{Z}}(\mathbb{Z}/2, \mathbb{Z}/2)$. Their isomorphism classes in the homotopy category of $\mathbb{S}$-algebras are parametrized by the topological Hochschild cohomology group $THH^4_{\mathbb{S}}(\mathbb{Z}/2, \mathbb{Z}/2)$ as shown in [97]. The computation of the Hochschild cohomology group $HH^4_{\mathbb{Z}}(\mathbb{Z}/2, \mathbb{Z}/2)$ is elementary and, thanks to Franjou–Lannes–Schwartz' work [50], the topological Hochschild cohomology algebra

$$THH^*_{\mathbb{S}}(\mathbb{Z}/2, \mathbb{Z}/2)$$

is known. Dugger–Shipley then conclude by exhibiting a non-trivial element in the kernel of the canonical map

$$\Phi\colon HH^4_{\mathbb{Z}}(\mathbb{Z}/2, \mathbb{Z}/2) \to THH^4_{\mathbb{S}}(\mathbb{Z}/2, \mathbb{Z}/2).$$

The explicit description of the two algebras is given in [140], [36], [38]. The appearance of torsion in these examples is unavoidable: for dg algebras over the rationals, statements a) and b) above are equivalent [38].

4. The homotopy category of small dg categories

4.1. Introduction. Invariants like K-theory, Hochschild homology, cyclic homology… naturally extend from k-algebras to dg categories (*cf.* Section 5). In analogy with the case of ordinary k-algebras, these extended invariants are preserved under dg Morita equivalence. However, unlike the module category over a k-algebra, the derived category of a dg category, even with its triangulated structure, does not contain enough information to compute the invariant (*cf.* the examples in Section 3.9). Our aim in this section is to present a category obtained from that of small dg categories by 'inverting the dg Morita equivalences'. It could be called the 'homotopy category of enhanced (idempotent complete) triangulated categories' [20] or the 'Morita homotopy category of small dg categories' Hmo, as in [145]. Invariants like K-theory and cyclic homology factor through the Morita homotopy category.

The Morita homotopy category very much resembles the category of small, idempotent complete, triangulated categories. In particular, it admits 'dg quotients' [34], which correspond to Verdier localizations. Like these, they are characterized by a universal property. The great advantages of the Morita homotopy category over that of small triangulated categories are that moreover, it admits *all* (*homotopy*) *limits and colimits* (like any homotopy category of a Quillen model category) and is *monoidal and closed*.

The Morita homotopy category Hmo is a full subcategory of the localization Hqe of the category of small dg categories with respect to the quasi-equivalences. The first step is therefore to analyze the larger category Hqe. Its morphism spaces are revealed by Toën's theorem 4.3 below.

4.2. Inverting quasi-equivalences. Let k be a commutative ring and dgcat_k the category of small dg k-categories as in Section 2.2. An analogue of the following theorem for simplicial categories is proved in [15].

Theorem 4.1 ([146]). *The category* dgcat_k *admits a structure of cofibrantly generated model category whose weak equivalences are the quasi-equivalences and whose fibrations are the dg functors* $F\colon \mathcal{A} \to \mathcal{B}$ *which induce componentwise surjections* $\mathcal{A}(X,Y) \to \mathcal{B}(FX,FY)$ *for all* X, Y *in* $\mathcal{A}$ *and such that, for each isomorphism* $v\colon F(X) \to Z$ *of* $H^0(\mathcal{B})$*, there is an isomorphism* u *of* $H^0(\mathcal{A})$ *with* $F(u) = v$.

This shows in particular that the *localization* Hqe of dgcat_k with respect to the quasi-equivalences has small Hom-sets and that we can compute morphisms from $\mathcal{A}$ to $\mathcal{B}$ in the localization as morphisms modulo homotopy from a cofibrant replacement $\mathcal{A}_{\mathrm{cof}}$ of $\mathcal{A}$ to $\mathcal{B}$ (note that all small dg categories are fibrant). In general, the cofibrant replacement $\mathcal{A}_{\mathrm{cof}}$ is not easy to compute with but if $\mathcal{A}(X,Y)$ is cofibrant in $\mathcal{C}(k)$ and the unit morphisms $k \to \mathcal{A}(X,X)$ admit retractions in $\mathcal{C}(k)$ for all objects X, Y of $\mathcal{A}$, for example if k is a field, then for $\mathcal{A}_{\mathrm{cof}}$, we can take the category with the same objects as $\mathcal{A}$ and whose morphism spaces are given by the 'reduced cobar-bar construction', *cf. e.g.* [34], [84]. The homotopy relation is then the one of [80, 3.3].

However, the morphism sets in the localization are much better described as follows: Consider two dg categories $\mathcal{A}$ and $\mathcal{B}$. If necessary, we replace $\mathcal{A}$ by a quasi-equivalent dg category so as to achieve that $\mathcal{A}$ is *k-flat*, *i.e.* the functor $\mathcal{A}(X, Y)\otimes?$ preserves quasi-isomorphisms for all X, Y of $\mathcal{A}$ (for example, we could take a cofibrant replacement of $\mathcal{A}$). Let $\mathrm{rep}(\mathcal{A}, \mathcal{B})$ be the full subcategory of the derived category $\mathcal{D}(\mathcal{A}^{\mathrm{op}} \otimes \mathcal{B})$ of $\mathcal{A}$-$\mathcal{B}$-bimodules formed by the bimodules X such that the tensor functor

$$? \overset{L}{\otimes}_{\mathcal{A}} X \colon \mathcal{D}(\mathcal{A}) \to \mathcal{D}(\mathcal{B})$$

takes the representable $\mathcal{A}$-modules to objects which are isomorphic to representable $\mathcal{B}$-modules. In other words, we require that $X(?, A)$ is quasi-isomorphic to a representable $\mathcal{B}$-module for each object A of $\mathcal{A}$. We call such a bimodule a *quasi-functor* since it yields a genuine functor

$$H^0(\mathcal{A}) \to H^0(\mathcal{B}).$$

We think of $\mathrm{rep}(\mathcal{A}, \mathcal{B})$ as the 'category of representations up to homotopy of $\mathcal{A}$ in $\mathcal{B}$'.

Theorem 4.2 (Toën [155]). *The morphisms from $\mathcal{A}$ to $\mathcal{B}$ in the localization of* dgcat_k *with respect to the quasi-equivalences are in natural bijection with the isomorphism classes of* $\mathrm{rep}(\mathcal{A}, \mathcal{B})$.

The theorem has been in limbo for some time, *cf.* [78, 2.3], [80], [34]. It is due to B. Toën, as a corollary of a much more precise statement: Recall from [66, Ch. 5] that each model category $\mathcal{M}$ admits a mapping space bifunctor

$$\mathrm{Map} \colon \mathrm{Ho}(\mathcal{M})^{\mathrm{op}} \times \mathrm{Ho}(\mathcal{M}) \to \mathrm{Ho}(\mathrm{Sset})$$

such that we have, for example, the natural isomorphisms

$$\pi_0(\mathrm{Map}(X, Y)) = \mathrm{Ho}(\mathcal{M})(X, Y).$$

The spaces Map may also be viewed as the morphism spaces in the Dwyer–Kan localization [44], [42], [43] of $\mathcal{M}$ with respect to the class of weak equivalences, *cf.* [43], [65]. Now let $\mathcal{R}(\mathcal{A}, \mathcal{B})$ be the category with the same objects as $\mathrm{rep}(\mathcal{A}, \mathcal{B})$ and whose morphisms are the quasi-isomorphisms of dg bimodules. Thus, the category $\mathcal{R}(\mathcal{A}, \mathcal{B})$ is a non-full subcategory of the category of dg bimodules $\mathcal{C}(\mathcal{A}^{\mathrm{op}} \otimes \mathcal{B})$.

Theorem 4.3 (Toën [155]). *There is a canonical weak equivalence of simplicial sets between* $\mathrm{Map}(\mathcal{A}, \mathcal{B})$ *and the nerve of the category* $\mathcal{R}(\mathcal{A}, \mathcal{B})$.

The theorem allows one to compute the homotopy groups of the *classifying space* $|\mathrm{dgcat}|$ *of dg categories*, which is defined as the nerve of the category of quasi-equivalences between dg categories. Of course, the connected components of this space are in bijection with the isomorphism classes of Hqe. Now let $\mathcal{A}$ be a small dg category. Then the fundamental group of $|\mathrm{dgcat}|$ at $\mathcal{A}$ is the group of automorphisms

of $\mathcal{A}$ in Hqe (*cf.* [120]). For example, if $\mathcal{A}$ is the category of bounded complexes of projective B-modules over an ordinary k-algebra B, then this group is the derived Picard group of B as studied in [133], [82], [166]. For the higher homotopy groups, we have the

Corollary 4.4 ([155]). a) *The group* $\pi_2(|\mathrm{dgcat}|, \mathcal{A})$ *is the group of invertible elements of the dg center of* $\mathcal{A}$ (= *its zeroth Hochschild cohomology group*).

b) *For* $i \geq 2$, *the group* $\pi_i(|\mathrm{dgcat}|, \mathcal{A})$ *is the* $(2-i)$*-th Hochschild cohomology of* $\mathcal{A}$.

4.3. Closed monoidal structure. As we have observed in Section 2.2, the category dgcat_k admits a tensor product $\otimes$ and an internal Hom-functor $\mathcal{H}om$. If $\mathcal{A}$ is cofibrant, then the functor $\mathcal{A}\otimes ?$ preserves weak equivalences so that the localization Hqe inherits a tensor product $\overset{L}{\otimes}$. However, the tensor product of two cofibrant dg categories is not cofibrant in general (in analogy with the fact that the tensor product of two non-commutative free algebras is not non-commutative free in general). By the adjunction formula

$$\mathcal{H}om(\mathcal{A}, \mathcal{H}om(\mathcal{B}, \mathcal{C})) = \mathcal{H}om(\mathcal{A} \otimes \mathcal{B}, \mathcal{C}),$$

it follows that even if $\mathcal{A}$ is cofibrant, the functor $\mathcal{H}om(\mathcal{A}, ?)$ cannot preserve weak equivalences in general and thus will not induce an internal Hom-functor in Hqe. Nevertheless, we have the

Theorem 4.5 ([34], [155]). *The monoidal category* $(\mathrm{Hqe}, \overset{L}{\otimes})$ *admits an internal* Hom-*functor* $\mathcal{RH}om$. *For two dg categories* $\mathcal{A}$ *and* $\mathcal{B}$ *such that* $\mathcal{A}$ *is* k*-flat, the dg category* $\mathcal{RH}om(\mathcal{A}, \mathcal{B})$ *is isomorphic in* Hqe *to the dg category* $\mathrm{rep}_{\mathrm{dg}}(\mathcal{A}, \mathcal{B})$, i.e. *the full subcategory of the dg category of* $\mathcal{A}$-$\mathcal{B}$*-bimodules whose objects are those of* $\mathrm{rep}(\mathcal{A}, \mathcal{B})$ *and which are cofibrant as bimodules.*

Thus we have equivalences (we suppose $\mathcal{A}$ k-flat)

$$H^0(\mathcal{RH}om(\mathcal{A}, \mathcal{B})) = H^0(\mathrm{rep}_{\mathrm{dg}}(\mathcal{A}, \mathcal{B})) \xrightarrow{\sim} \mathrm{rep}(\mathcal{A}, \mathcal{B}).$$

In terms of the internal Hom-functor $\mathcal{H}om$ of dgcat_k, we have

$$H^0(\mathcal{RH}om(\mathcal{A}, \mathcal{B})) = H^0(\mathcal{H}om(\mathcal{A}, \mathcal{B}))[\Sigma^{-1}],$$

where Σ is the set of morphisms $\phi\colon F \to G$ such that $\phi(A)$ is invertible in $H^0(\mathcal{B})$ for all objects A of $\mathcal{A}$, *cf.* [78].

Yet another description can be given in terms of A_∞-functors: Let $\mathcal{A}$ be a dg category such that the morphism spaces $\mathcal{A}(A, A')$ are cofibrant in $\mathcal{C}(k)$ and the unit maps $k \to \mathcal{A}(A, A)$ admit retractions in $\mathcal{C}(k)$ for all objects A, A' of $\mathcal{A}$. Then the dg category $\mathcal{RH}om(\mathcal{A}, \mathcal{B})$ is quasi-equivalent to the A_∞-category of (strictly unital) A_∞-functors from $\mathcal{A}$ to $\mathcal{B}$, *cf.* [91], [98], [104], [84]. Since $\mathcal{B}$ is a dg category, this A_∞-category is in fact a dg category.

An important point of classical Morita theory is that for two rings B, C, there is an equivalence between the category of B-C-bimodules and the category of coproduct preserving functors from the category of B-modules to that of C-modules (note that here and in what follows, we need to consider 'large' categories and should introduce universes to make our statements rigorous…). Similarly, if $\mathcal{A}$ is a small k-flat dg category, we consider the large dg category $\mathcal{D}_{\mathrm{dg}}(\mathcal{A})$: it is the full dg subcategory of $\mathcal{C}_{\mathrm{dg}}(\mathcal{A})$ whose objects are all the cofibrant dg modules. Thus we have an equivalence of categories

$$\mathcal{D}(\mathcal{A}) = H^0(\mathcal{D}_{\mathrm{dg}}(\mathcal{A})).$$

This shows that if $\mathcal{B}$ is another dg category, then each quasi-functor X in

$$\mathrm{rep}(\mathcal{D}_{\mathrm{dg}}(\mathcal{A}), \mathcal{D}_{\mathrm{dg}}(\mathcal{B}))$$

gives rise to a functor $\mathcal{D}(\mathcal{A}) \to \mathcal{D}(\mathcal{B})$. We say that the quasifunctor X *preserves coproducts* if this functor preserves coproducts.

Theorem 4.6 ([155]). *There is a canonical isomorphism in* Hqe

$$\mathcal{D}_{\mathrm{dg}}(\mathcal{A}^{\mathrm{op}} \otimes \mathcal{B}) \xrightarrow{\sim} \mathcal{RH}om_{\mathrm{c}}(\mathcal{D}_{\mathrm{dg}}(\mathcal{A}), \mathcal{D}_{\mathrm{dg}}(\mathcal{B})),$$

where $\mathcal{RH}om_{\mathrm{c}}$ denotes the full subcategory of $\mathcal{RH}om$ formed by the coproduct preserving quasifunctors.

If we apply this theorem to $\mathcal{B} = \mathcal{A}$ and compare the endomorphism algebras of the identity functors on both sides, we see that the Hochschild cohomology (*cf.* Section 5.4 below) of the small dg category $\mathcal{A}$ coincides with the Hochschild cohomology of the large dg category $\mathcal{D}_{\mathrm{dg}}(\mathcal{A})$, which is quite surprising. An analogous result for Grothendieck abelian categories (in particular, module categories) is due to T. Lowen and M. Van den Bergh [102].

4.4. Dg localizations, dg quotients, dg-derived categories. Let $\mathcal{A}$ be a small dg category. Let S be a set of morphisms of $H^0(\mathcal{A})$. Let us say that a morphism $R\colon \mathcal{A} \to \mathcal{B}$ of Hqe *makes S invertible* if the induced functor

$$H^0(\mathcal{A}) \to H^0(\mathcal{B})$$

takes each $s \in S$ to an isomorphism.

Theorem 4.7 ([155]). *There is a morphism $Q\colon \mathcal{A} \to \mathcal{A}[S^{-1}]$ of* Hqe *such that Q makes S invertible and each morphism R of* Hqe *which makes S invertible uniquely factors through Q.*

We call $\mathcal{A}[S^{-1}]$ the *dg localization of $\mathcal{A}$ at S*. Note that it is unique up to unique isomorphism in Hqe. It is constructed in [155] as a homotopy pushout

$$\begin{array}{ccc} \coprod_{s\in S} I & \longrightarrow & \mathcal{A} \\ \downarrow & & \downarrow \\ \coprod_{s\in S} k & \longrightarrow & \mathcal{A}[S^{-1}], \end{array}$$

where I denotes the dg k-category freely generated by one arrow $f\colon 0 \to 1$ of degree 0 with $df = 0$ and left vertical arrow is induced by the morphisms $I \to k$ which sends f to 1. The universal property of $Q\colon \mathcal{A} \to \mathcal{A}[S^{-1}]$ admits refined forms, namely, Q induces an equivalence of categories

$$\mathrm{rep}(\mathcal{A}[S^{-1}], \mathcal{B}) \xrightarrow{\sim} \mathrm{rep}_S(\mathcal{A}, \mathcal{B}),$$

an isomorphism of Hqe

$$\mathrm{rep}_{\mathrm{dg}}(\mathcal{A}[S^{-1}], \mathcal{B}) \xrightarrow{\sim} \mathrm{rep}_{\mathrm{dg},S}(\mathcal{A}, \mathcal{B}),$$

and a weak equivalence of simplicial sets

$$\mathrm{Map}(\mathcal{A}[S^{-1}], \mathcal{B}) \xrightarrow{\sim} \mathrm{Map}_S(\mathcal{A}, \mathcal{B}).$$

Here rep_S and $\mathrm{rep}_{\mathrm{dg},S}$ denote the full subcategories of quasi-functors whose associated functors $H^0(\mathcal{A}) \to H^0(\mathcal{B})$ make S invertible and Map_S the union of the connected components containing these quasi-functors.

An important variant is the following: Let $\mathcal{N}$ be a set of objects of $\mathcal{A}$. Let us say that a morphism $Q\colon \mathcal{A} \to \mathcal{B}$ of Hqe *annihilates* $\mathcal{N}$ if the induced functor

$$H^0(\mathcal{A}) \to H^0(\mathcal{B})$$

takes all objects of $\mathcal{N}$ to zero objects (*i.e.* objects whose identity morphism vanishes in $H^0(\mathcal{B})$).

Theorem 4.8 ([80], [34]). *There is a morphism $Q\colon \mathcal{A} \to \mathcal{A}/\mathcal{N}$ of* Hqe *which annihilates $\mathcal{N}$ and is universal among the morphisms annihilating $\mathcal{N}$.*

We call $\mathcal{A}/\mathcal{N}$ the *dg quotient of $\mathcal{A}$ by $\mathcal{N}$*. If $\mathcal{A}$ is k-flat (*cf.* Section 4.2), then $\mathcal{A}/\mathcal{N}$ admits a beautiful simple construction [34]: One adjoins to $\mathcal{A}$ a contracting homotopy for each object of $\mathcal{N}$. The general case can be reduced to this one or treated using orthogonal subcategories [80]. The dg quotient has refined universal properties analogous to those of the dg localization. In particular, the morphism $\mathcal{A} \to \mathcal{A}/\mathcal{N}$ induces an equivalence [34]

$$\mathrm{rep}(\mathcal{A}/\mathcal{N}, \mathcal{B}) \to \mathrm{rep}_{\mathcal{N}}(\mathcal{A}, \mathcal{B}),$$

where $\mathrm{rep}_{\mathcal{N}}$ denotes the full subcategory of quasi-functors whose associated functors $H^0(\mathcal{A}) \to H^0(\mathcal{B})$ annihilate $\mathcal{N}$.

Dg quotients yield functorial dg versions of Verdier localizations [160]. For example, if $\mathcal{E}$ is a small abelian (or, more generally, exact) category, we can take for $\mathcal{A}$ the dg category of bounded complexes $\mathcal{C}^b_{\mathrm{dg}}(\mathcal{E})$ over $\mathcal{E}$ and for $\mathcal{N}$ the dg category of bounded acyclic complexes $\mathcal{A}c^b_{\mathrm{dg}}(\mathcal{E})$. Then we obtain the *dg-derived category*

$$\mathcal{D}^b_{\mathrm{dg}}(\mathcal{E}) = \mathcal{C}^b_{\mathrm{dg}}(\mathcal{E})/\mathcal{A}c^b_{\mathrm{dg}}(\mathcal{E})$$

so that we have

$$\mathcal{D}^b(\mathcal{E}) = H^0(\mathcal{D}^b_{\mathrm{dg}}(\mathcal{E})).$$

More generally, every localization pair [80] (= Frobenius pair [134]) gives rise to a dg category. After taking the necessary set-theoretic precautions, we also obtain a dg-derived category

$$\mathcal{D}_{\mathrm{dg}}(\mathcal{E}) = \mathcal{C}_{\mathrm{dg}}(\mathcal{E})/\mathcal{A}c_{\mathrm{dg}}(\mathcal{E})$$

which refines the *unbounded* derived category of a k-linear Grothendieck abelian category $\mathcal{E}$. For a quasi-compact quasi-separated scheme X, let us write $\mathcal{D}_{\mathrm{dg}}(X)$ for $\mathcal{D}_{\mathrm{dg}}(\mathcal{E})$, where $\mathcal{E}$ is the Grothendieck abelian category of quasi-coherent sheaves on X. The following theorem shows that dg functors between dg derived categories are much more closely related to geometry than triangle functors between derived categories, *cf.* [23], [114].

Theorem 4.9 ([155]). *Let X and Y be quasi-compact separated schemes over k such that X is flat over* Spec k. *Then we have a canonical isomorphism in* Hqe

$$\mathcal{D}_{\mathrm{dg}}(X \times_k Y) \xrightarrow{\sim} \mathcal{R}\mathcal{H}om_{\mathrm{c}}(\mathcal{D}_{\mathrm{dg}}(X), \mathcal{D}_{\mathrm{dg}}(Y)),$$

where $\mathcal{R}\mathcal{H}om_{\mathrm{c}}$ denotes the full subcategory of $\mathcal{R}\mathcal{H}om$ formed by the coproduct preserving quasi-functors. Moreover, if X and Y are smooth and projective over Spec k, *we have a canonical isomorphism in* Hqe

$$\mathrm{par}_{\mathrm{dg}}(X \times_k Y) \xrightarrow{\sim} \mathcal{R}\mathcal{H}om(\mathrm{par}_{\mathrm{dg}}(X), \mathrm{par}_{\mathrm{dg}}(Y))$$

where $\mathrm{par}_{\mathrm{dg}}$ *denotes the full dg subcategory of $\mathcal{D}_{\mathrm{dg}}$ whose objects are the perfect complexes.*

4.5. Pretriangulated dg categories. Let $\mathcal{A}$ be a small dg category. We say that $\mathcal{A}$ is *pretriangulated* or *exact* if the image of the Yoneda functor

$$Z^0(\mathcal{A}) \to \mathcal{C}(\mathcal{A}), \quad X \mapsto X^\wedge$$

is stable under shifts in both directions and extensions (in the sense of the exact structure of Section 3.4). Equivalently, for all objects X, Y of $\mathcal{A}$ and all integers n, the object $X^\wedge[n]$ is isomorphic to $X[n]^\wedge$ and the cone over a morphism $f^\wedge\colon X^\wedge \to Y^\wedge$ is isomorphic to $C(f)^\wedge$ for unique objects $X[n]$ and $C(f)$ of $Z^0(\mathcal{A})$. If $\mathcal{A}$ is exact, then $Z^0(\mathcal{A})$ becomes a Frobenius subcategory of $\mathcal{C}(\mathcal{A})$ and $H^0(\mathcal{A})$ a triangulated subcategory of $\mathcal{H}(\mathcal{A})$. If $\mathcal{B}$ is an exact dg category and $\mathcal{A}$ an arbitrary dg category, then $\mathcal{H}om(\mathcal{A}, \mathcal{B})$ is exact (whereas $\mathcal{A} \otimes \mathcal{B}$ is not, in general).

If $\mathcal{A}$ is an arbitrary small dg category, there is a universal dg functor

$$\mathcal{A} \to \mathrm{pretr}(\mathcal{A})$$

to a pretriangulated dg category $\mathrm{pretr}(\mathcal{A})$, *i.e.* a functor inducing an equivalence

$$\mathcal{H}om(\mathcal{A}, \mathcal{B}) \xrightarrow{\sim} \mathcal{H}om(\mathrm{pretr}(\mathcal{A}), \mathcal{B})$$

for each exact dg category $\mathcal{B}$. The dg category $\mathrm{pretr}(\mathcal{A})$ is the *pretriangulated hull of* $\mathcal{A}$ constructed explicitly in [21], *cf.* also [34], [145].

For any dg category $\mathcal{A}$, the category $H^0(\mathrm{pretr}(\mathcal{A}))$ is equivalent to the triangulated subcategory of $\mathcal{H}\mathcal{A}$ generated by the representable dg modules. The functor pretr preserves quasi-equivalences and induces a left adjoint to the inclusion of the full subcategory of exact dg categories into the homotopy category Hqe. If $\mathcal{B}$ is pretriangulated, then so is $\mathcal{RH}om(\mathcal{A}, \mathcal{B})$ for each small dg category $\mathcal{A}$ and we have

$$\mathcal{RH}om(\mathrm{pretr}(\mathcal{A}), \mathcal{B}) \xrightarrow{\sim} \mathcal{RH}om(\mathcal{A}, \mathcal{B}).$$

4.6. Morita fibrant dg categories, exact sequences. A dg functor $F\colon \mathcal{A} \to \mathcal{B}$ between small dg categories is a *Morita morphism* if it induces an equivalence $\mathcal{D}(\mathcal{B}) \to \mathcal{D}(\mathcal{A})$. Each quasi-equivalence is a Morita morphism (*cf.* Section 3.8) and so is the canonical morphism $\mathcal{A} \to \mathrm{pretr}(\mathcal{A})$ from $\mathcal{A}$ to its pretriangulated hull.

Theorem 4.10 ([145]). *The category* dgcat_k *admits a structure of cofibrantly generated model category whose weak equivalences are the Morita morphisms and whose cofibrations are the same as those of the canonical model structure on* dgcat_k (cf. *Theorem* 4.1).

A dg category $\mathcal{A}$ is *Morita fibrant* (or *triangulated* in the terminology of [156]) iff it is fibrant with respect to this model structure. This is the case iff the canonical functor $H^0(\mathcal{A}) \to \mathrm{per}(\mathcal{A})$ is an equivalence iff $\mathcal{A}$ is pretriangulated and $H^0(\mathcal{A})$ is idempotent complete (*cf.* Section 3.5). We write $\mathcal{A} \to \mathrm{per}_{\mathrm{dg}}(\mathcal{A})$ for a fibrant replacement of $\mathcal{A}$ and then have

$$\mathrm{per}(\mathcal{A}) = H^0(\mathrm{per}_{\mathrm{dg}}(\mathcal{A})).$$

We write Hmo *for the localization* of dgcat_k with respect to the Morita morphisms. Then the functor $\mathcal{A} \mapsto \mathrm{per}_{\mathrm{dg}}(\mathcal{A})$ yields a right adjoint of the quotient functor $\mathrm{Hqe} \to \mathrm{Hmo}$ and induces an equivalence from Hmo onto the subcategory of Morita fibrant dg categories in Hqe, *cf.* [145]. The category Hmo is pointed: The dg category with one object and one morphism is both initial and terminal. Moreover, Hmo admits all finite coproducts (they are induced by the disjoint unions) and these are isomorphic to products.

Let

$$\mathcal{A} \xrightarrow{I} \mathcal{B} \xrightarrow{P} \mathcal{C} \tag{5}$$

be a sequence of Hqe such that $PI = 0$ in Hmo.

Theorem 4.11. *The following are equivalent:*

i) *In* Hmo, *I is a kernel of P and P a cokernel of I.*

ii) *The morphism I induces an equivalence of* $\mathrm{per}(\mathcal{A})$ *onto a thick subcategory of* $\mathrm{per}(\mathcal{B})$ *and P induces an equivalence of the idempotent closure* [8] *of the Verdier quotient with* $\mathrm{per}(\mathcal{C})$.

iii) *The functor I induces an equivalence of $\mathcal{D}(\mathcal{A})$ with a thick subcategory of $\mathcal{D}(\mathcal{B})$ and P identifies the Verdier quotient with $\mathcal{D}(\mathcal{C})$.*

The theorem is proved in [80]. The equivalence of ii) and iii) is a consequence of Thomason–Trobaugh's localization theorem [152], [108], [112]. We say that (5) is an *exact sequence* of Hmo if the conditions of the theorem hold. For example, if X is a quasi-compact quasi-separated scheme, $U \subset X$ a quasi-compact open subscheme and $Z = X \setminus U$, then the sequence

$$\mathrm{par}_{\mathrm{dg}}(X \text{ on } Z) \longrightarrow \mathrm{par}_{\mathrm{dg}}(X) \longrightarrow \mathrm{par}_{\mathrm{dg}}(U)$$

is an exact sequence of Hmo by the results of [152, Sect. 5], where $\mathrm{par}_{\mathrm{dg}}(X)$ denotes the dg quotient of the category of perfect complexes (viewed as a full dg subcategory of the category of complexes of $\mathcal{O}_X$-modules) by its subcategory of acyclic perfect complexes and $\mathrm{par}_{\mathrm{dg}}(X \text{ on } Z)$ the full subcategory of perfect complexes supported on Z.

4.7. Dg categories of finite type. Let $\mathcal{M}$ be a cofibrantly generated model category and I a small category. Recall that the category of functors $\mathcal{M}^I$ is again a cofibrantly generated model category (with the componentwise weak equivalences). Thus, the diagonal functor $\mathrm{Ho}(\mathcal{M}) \to \mathrm{Ho}(\mathcal{M}^I)$ admits a left adjoint, the *homotopy colimit functor*, and a right adjoint, the *homotopy limit functor*. An object X of $\mathcal{M}$ is *homotopically finitely presented* if, for each filtered direct system Y_i, $i \in I$, of $\mathcal{M}$, the canonical morphism

$$\mathrm{hocolim}\, \mathrm{Map}(X, Y_i) \to \mathrm{Map}(X, \mathrm{hocolim}\, Y_i)$$

is a weak equivalence of simplicial sets. The category $\mathcal{M}$ is *homotopically locally finitely presented* if, in $\mathrm{Ho}(\mathcal{M})$, each object is the homotopy colimit of a filtered direct system (in $\mathcal{M}$) of homotopically finitely presented objects.

For example [64], the category of dg algebras is homotopically locally finitely presented and a dg algebra is homotopically finitely presented iff, in the homotopy category, it is a retract of a non-commutative free graded algebra $k\langle x_1, \ldots, x_n\rangle$ endowed with a differential such that dx_i belongs to $k\langle x_1, \ldots, x_{i-1}\rangle$ for each $1 \leq i \leq n$. A dg category is *of finite type* if it is dg Morita equivalent to a homotopically finitely presented dg algebra.

Theorem 4.12 ([156]). *The category of small dg categories endowed with the canonical model structure whose weak equivalences are the Morita morphisms is homotopically locally finitely presented and a dg category is homotopically finitely presented iff it is of finite type.*

A dg category $\mathcal{A}$ is called *smooth* if the bimodule $(X, Y) \mapsto \mathcal{A}(X, Y)$ is perfect in $\mathcal{D}(\mathcal{A}^{\mathrm{op}} \overset{L}{\otimes} \mathcal{A})$. This property is invariant under dg Morita equivalence. The explicit

description of the homotopically finitely presented dg algebras shows that a dg category of finite type is smooth. Conversely [156], a dg category $\mathcal{A}$ is of finite type if it is smooth and *proper*, *i.e.* dg Morita equivalent to a dg algebra whose underlying complex of k-modules is perfect.

4.8. Moduli of objects in dg categories. Let T be a small dg category. In [156], B. Toën and M. Vaquié introduce and study the D^--stack (in the sense of [157]) of objects in T. By definition, this D^--stack is the functor

$$\mathcal{M}_T : \text{Scalg} \to \text{Sset}$$

which sends a simplicial commutative k-algebra A to the simplicial set

$$\text{Map}(T^{\text{op}}, \text{per}_{\text{dg}}(NA)),$$

where NA is the commutative dg k-algebra obtained from A by the Dold–Kan equivalence. They show that if T is a dg category of finite type, then this D^--stack is locally geometric and locally of finite presentation. Moreover, if $E : T \to \text{per}_{\text{dg}}(k)$ is a k-point of $\mathcal{M}_T$, then the tangent complex of $\mathcal{M}_T$ at E is given by

$$\mathcal{T}_{\mathcal{M}_T, E} \xrightarrow{\sim} \mathcal{RH}om(E, E)[1].$$

In particular, if E is quasi-isomorphic to a representable $x^\wedge$, then we have

$$\mathcal{T}_{\mathcal{M}_T, E} \xrightarrow{\sim} T(x, x)[1].$$

It follows that the restriction of $\mathcal{M}_T$ to the category of commutative k-algebras is a locally geometric ∞-stack in the sense of C. Simpson [144]. Here are three consequences derived from these results in [156]:

1) If T is a dg category over a field k and is smooth, proper and Morita fibrant, then the sheaf associated with the presheaf

$$R \mapsto \text{Aut}_{\text{Hqe}_R}(T \otimes_k R),$$

on the category of commutative k-algebras is a group scheme locally of finite type over k (*cf.* [166] for the case where T is an algebra).

2) If X is a smooth proper scheme over a commutative ring k, then the ∞-stack of perfect complexes on X is locally geometric.

3) If A is a (non-commutative) k-algebra over a field k, then the ∞-stack of bounded complexes of finite-dimensional A-modules is locally geometric if either A is the path algebra of a finite quiver or a finite-dimensional algebra of finite global dimension.

4.9. Dg orbit categories. Let $\mathcal{A}$ be a dg category and $F\colon \mathcal{A} \to \mathcal{A}$ an automorphism of $\mathcal{A}$ in Hqe. Let us assume for simplicity that F is given by a dg functor $\mathcal{A} \to \mathcal{A}$. The *dg orbit category* $\mathcal{A}/F^{\mathbb{Z}}$ has the same objects as $\mathcal{A}$ and the morphisms defined by

$$(\mathcal{A}/F^{\mathbb{Z}})(X, Y) = \bigoplus_{d\in\mathbb{Z}} \operatorname{colim}_n \mathcal{A}(F^n X, F^{n+d} Y).$$

The projection functor $P\colon \mathcal{A} \to \mathcal{A}/F^{\mathbb{Z}}$ is endowed with a canonical morphism $\phi\colon PF \to P$ which becomes invertible in $H^0(\mathcal{A}/F^{\mathbb{Z}})$ and the pair (P, ϕ) is the solution of a universal problem, *cf.* [83]. The category $H^0(\mathcal{A})/F^{\mathbb{Z}}$ is defined analogously. It is isomorphic to $H^0(\mathcal{A}/F^{\mathbb{Z}})$ and can be thought of as the 'category of orbits' of the functor F acting in $H^0(\mathcal{A})$.

Let us now assume that k is a field. Let Q be a quiver (= oriented graph) whose underlying graph is a Dynkin graph of type A, D or E. Let $\operatorname{mod} kQ$ be the abelian category of finite-dimensional representations of Q over k (*cf. e.g.* [52], [4]). Let $\mathcal{A} = \mathcal{D}^b_{\mathrm{dg}}(\operatorname{mod} Q)$ and $F\colon \mathcal{A} \to \mathcal{A}$ an automorphism in Hqe. We say that F *acts properly* if no indecomposable object of $\mathcal{D}^b(\operatorname{mod} kQ)$ is isomorphic to its image under F. For example, if Σ is the *Serre functor* of $\mathcal{A}$, defined by the bimodule

$$(X, Y) \mapsto \mathcal{H}om_k(\mathcal{A}(Y, X), k),$$

then Σ acts properly and, more generally, if S is the suspension functor, then $S^{-d}\Sigma$ acts properly for each $d \in \mathbb{N}$ unless Q is reduced to a point.

Theorem 4.13 ([83]). *If F acts properly, the orbit category $\mathcal{D}^b_{\mathrm{dg}}(\operatorname{mod} kQ)/F^{\mathbb{Z}}$ is Morita fibrant and thus $\mathcal{D}^b(\operatorname{mod} kQ)/F^{\mathbb{Z}}$ is canonically triangulated.*

In the particular case where $F = S^{-d}\Sigma$, the triangulated category $H^0(\mathcal{A}/F^{\mathbb{Z}})$ is Calabi–Yau [91] of CY-dimension d (*cf.* [83]). For $d = 1$, the category $H^0(\mathcal{A}/F^{\mathbb{Z}})$ is equivalent to the category of finite-dimensional projective modules over the preprojective algebra (*cf.* [56], [31], [128]) associated with the Dynkin graph underlying Q. For $d = 2$, one obtains the *cluster category* associated with the Dynkin graph. This category was introduced in [27] for type A and in [6] in the general case. It serves in the representation-theoretic approach (*cf. e.g.* [6], [26], [55]) to the study of cluster algebras [47], [48], [13], [49]. It seems likely [2] that if k is algebraically closed, the theorem yields almost all Morita fibrant dg categories whose associated triangulated categories have finite-dimensional morphism spaces and only finitely many isoclasses of indecomposables. In particular, those among these categories which are Calabi–Yau of fixed CY-dimension $d \gg 0$ are expected to be parametrized by the simply laced Dynkin diagrams.

5. Invariants

5.1. Additive invariants. Let Hmo_0 be the category with the same objects as Hmo and where morphisms $\mathcal{A} \to \mathcal{B}$ are given by elements of the Grothendieck group of

the triangulated category rep($\mathcal{A}$, $\mathcal{B}$). The composition is induced from that of Hmo. The category Hmo_0 is additive and endowed with a canonical functor $\mathrm{Hmo} \to \mathrm{Hmo}_0$ (*cf.* [22] for a related construction). One can show [145] that a functor F defined on Hmo with values in an additive category factors through $\mathrm{Hmo} \to \mathrm{Hmo}_0$ iff for each exact dg category $\mathcal{A}$ endowed with full exact dg subcategories $\mathcal{B}$ and $\mathcal{C}$ which give rise to a semi-orthogonal decomposition $H^0(\mathcal{A}) = (H^0(\mathcal{B}), H^0(\mathcal{C}))$ in the sense of [21], the inclusions induce an isomorphism $F(\mathcal{B}) \oplus F(\mathcal{C}) \xrightarrow{\sim} F(\mathcal{A})$. We then say that *$F$ is an additive invariant*. The most basic additive invariant is given by $F\mathcal{A} = K_0(\mathrm{per}\,\mathcal{A}))$. In Hmo_0, it becomes a corepresentable functor: $K_0(\mathrm{per}(\mathcal{A})) = \mathrm{Hmo}_0(k, \mathcal{A})$. As we will see below, the K-theory spectrum and all variants of cyclic homology are additive invariants. This is of interest since non-isomorphic objects of Hmo can become isomorphic in Hmo_0. For example, if k is an algebraically closed field, each finite-dimensional algebra of finite global dimension becomes isomorphic to a product of copies of k in Hmo_0 (*cf.* [78]) but it is isomorphic to such a product in Hmo only if it is semi-simple.

5.2. *K*-theory. Let $\mathcal{A}$ be a small dg k-category. Its K-theory $K(\mathcal{A})$ is defined by applying Waldhausen's construction [161] to a suitable category with cofibrations and weak equivalences: here, the category is that of perfect $\mathcal{A}$-modules, the cofibrations are the morphisms $i : L \to M$ of $\mathcal{A}$-modules which admit retractions as morphisms of graded $\mathcal{A}$-modules (*i.e.* the inflations of Section 3.4) and the weak equivalences are the quasi-isomorphisms. This construction can be improved so as to yield a functor K from dgcat_k to the homotopy category of spectra. As in [152], from Waldhausen's results [161] one then obtains the following

Theorem 5.1. a) [36] *The map $\mathcal{A} \mapsto K(\mathcal{A})$ yields a well-defined functor on* Hmo.

b) *Applied to the bounded dg-derived category $\mathcal{D}^b_{\mathrm{dg}}(\mathcal{E})$ of an exact category $\mathcal{E}$, the K-theory defined above agrees with Quillen K-theory.*

c) *The functor $\mathcal{A} \mapsto K(\mathcal{A})$ is an additive invariant. Moreover, each short exact sequence $\mathcal{A} \to \mathcal{B} \to \mathcal{C}$ of* Hmo (cf. *Section* 4.6) *yields a long exact sequence*

$$\cdots \longrightarrow K_i(\mathcal{A}) \longrightarrow K_i(\mathcal{B}) \longrightarrow K_i(\mathcal{C}) \longrightarrow \cdots \longrightarrow K_0(\mathcal{B}) \longrightarrow K_0(\mathcal{A}).$$

Part a) can be improved on: In fact, D. Dugger and B. Shipley show in [36] that K-theory is even preserved under *topological* Morita equivalence. Part c) can be improved on by defining *negative K-groups* and showing that the exact sequence extends indefinitely to the right. We refer to [134] for the most recent results, which include the case of dg categories. By combining part a) with Rickard's theorem 3.12, one obtains the invariance of the K-theory of rings under triangle equivalences between their derived categories. By combining a) and b), one obtains the invariance of the K-theory of abelian categories under equivalences between their derived categories which come from isomorphisms of Hmo (or, more generally, from topological Morita equivalences). In fact, according to A. Neeman's results [110] the K-theory of an

abelian category is even determined by the underlying triangulated category of its derived category, *cf.* [113] for a survey of his work.

Of course, any invariant defined for small triangulated categories applied to the perfect derived category yields an invariant of small dg categories. For example, Balmer–Witt groups (*cf.* [7] for a survey), defined for dg categories $\mathcal{A}$ endowed with a suitable involution $\mathcal{A} \xrightarrow{\sim} \mathcal{A}^{\mathrm{op}}$ in Hmo, yield such invariants.

5.3. Hochschild and cyclic homology. Let $\mathcal{A}$ be a small k-flat k-category. Following [106] the *Hochschild chain complex* of $\mathcal{A}$ is the complex concentrated in homological degrees $p \geq 0$ whose pth component is the sum of the

$$\mathcal{A}(X_p, X_0) \otimes \mathcal{A}(X_p, X_{p-1}) \otimes \mathcal{A}(X_{p-1}, X_{p-2}) \otimes \cdots \otimes \mathcal{A}(X_0, X_1),$$

where $X_0, \ldots, X_p$ range through the objects of $\mathcal{A}$, endowed with the differential

$$d(f_p \otimes \ldots \otimes f_0) = f_{p-1} \otimes \cdots \otimes f_0 f_p + \sum_{i=1}^{p} (-1)^i f_p \otimes \cdots \otimes f_i f_{i-1} \otimes \cdots \otimes f_0.$$

Via the cyclic permutations

$$t_p(f_{p-1} \otimes \cdots \otimes f_0) = (-1)^p f_0 \otimes f_{p-1} \otimes \cdots \otimes f_1$$

this complex becomes a precyclic chain complex and thus gives rise [77, Sect. 2] to a *mixed complex* $C(\mathcal{A})$ in the sense of [72], *i.e.* a dg module over the dg algebra $\Lambda = k[B]/(B^2)$, where B is of degree -1 and $dB = 0$. As shown in [72], all variants of cyclic homology [100] only depend on $C(\mathcal{A})$ considered in $\mathcal{D}(\Lambda)$. For example, the cyclic homology of $\mathcal{A}$ is the homology of the complex $C(\mathcal{A}) \overset{L}{\otimes}_{\Lambda} k$.

If $\mathcal{A}$ is a k-flat differential graded category, its mixed complex is the sum-total complex of the bicomplex obtained as the natural re-interpretation of the above complex. If $\mathcal{A}$ is an arbitrary dg k-category, its Hochschild chain complex is defined as the one of a k-flat (*e.g.* a cofibrant) resolution of $\mathcal{A}$.

Theorem 5.2 ([79], [80]). a) *The map* $\mathcal{A} \mapsto C(\mathcal{A})$ *yields an additive functor* $\mathrm{Hmo}_0 \to \mathcal{D}(\Lambda)$. *Moreover, each exact sequence of* Hmo (cf. *Section* 4.6) *yields a canonical triangle of* $\mathcal{D}(\Lambda)$.

b) *If A is a k-algebra, there is a natural isomorphism* $C(A) \xrightarrow{\sim} C(\mathrm{per}_{\mathrm{dg}}(A))$.

c) *If X is a quasi-compact separated scheme, there is a natural isomorphism* $C(X) \xrightarrow{\sim} C(\mathrm{par}_{\mathrm{dg}}(X))$, *where $C(X)$ is the cyclic homology of X in the sense of* [99], [163] *and* $\mathrm{par}_{\mathrm{dg}}(X)$ *the dg category defined in Section* 4.6.

The second statement in a) may be viewed as an excision theorem analogous to [164]. We refer to the recent proof [28] of Weibel's conjecture [162] on the vanishing of negative K-theory for an application of the theorem. The brave new algebra description of *topological* Hochschild (co-)homology [142] would suggest that it is

also preserved under topological Morita equivalence but no reference seems to exist as yet.

The endomorphism algebra $\mathcal{RH}om_\Lambda(k,k)$ is quasi-isomorphic to $k[u]$, where u is of degree 2 and $d(u)=0$. It acts on $C(\mathcal{A}) \overset{L}{\otimes}_\Lambda k$ and this action is made visible in the isomorphism

$$C(\mathcal{A}) \overset{L}{\otimes}_\Lambda k = C(\mathcal{A}) \otimes k[u]$$

where u is of degree 2 and the differential on the right hand complex is given by

$$d(x \otimes f) = d(x) \otimes f + (-1)^{|x|} xB \otimes uf.$$

The following 'Hodge–de Rham conjecture' is true for the dg category of perfect complexes on a smooth projective variety or over a finite-dimensional algebra of finite global dimension. It is wide open in the general case.

Conjecture 5.3 ([33], [90]). *If $\mathcal{A}$ is a smooth proper dg category over a field k of characteristic 0, then the homology of $C(\mathcal{A}) \otimes k[u]/(u^n)$ is a flat $k[u]/(u^n)$-module for all $n \geq 1$.*

5.4. Hochschild cohomology. Let $\mathcal{A}$ be a small cofibrant dg category. Its cohomological Hochschild complex $C(\mathcal{A},\mathcal{A})$ is defined as the product-total complex of the bicomplex whose 0th column is

$$\prod \mathcal{A}(X_0, X_0),$$

where X_0 ranges over the objects of $\mathcal{A}$, and whose pth column, for $p \geq 1$, is

$$\prod \mathcal{H}om_k(\mathcal{A}(X_{p-1}, X_p) \otimes \mathcal{A}(X_{p-2}, X_{p-1}) \otimes \cdots \otimes \mathcal{A}(X_0, X_1), \mathcal{A}(X_0, X_p))$$

where $X_0, \ldots, X_p$ range over the objects of $\mathcal{A}$. The horizontal differential is given by the Hochschild differential. This complex carries rich additional structure: As shown in [58], it is a B_∞-algebra, *i.e.* its bar construction carries, in addition to its canonical differential and comultiplication, a natural *multiplication* which makes it into a dg bialgebra. The B_∞-structure contains in particular the cup product and the Gerstenhaber bracket, which both descend to the Hochschild cohomology

$$HH^*(\mathcal{A},\mathcal{A}) = H^*C(\mathcal{A},\mathcal{A}).$$

The Hochschild cohomology is naturally interpreted as the homology of the complex

$$\mathcal{H}om(\mathbf{1}_\mathcal{A}, \mathbf{1}_\mathcal{A})$$

computed in the dg category $\mathcal{RH}om(\mathcal{A},\mathcal{A})$, where $\mathbf{1}_\mathcal{A}$ denotes the identity functor of $\mathcal{A}$ (*i.e.* the bimodule $(X,Y) \mapsto \mathcal{A}(X,Y)$). Then the cup product corresponds to the composition (whereas the Gerstenhaber bracket has no obvious interpretation). Each

$c \in HH^n(\mathcal{A}, \mathcal{A})$ gives rise to morphisms $cM\colon M \to M[n]$ of $\mathcal{D}(\mathcal{A})$, functorial in $M \in \mathcal{D}(\mathcal{A})$. Another interpretation links the Hochschild cohomology of $\mathcal{A}$ to the derived Picard group and to the higher homotopy groups of the category of quasi-equivalences between dg categories, *cf.* Section 4.2.

A natural way of obtaining the B_∞-algebra structure on $C(\mathcal{A}, \mathcal{A})$ is to consider the A_∞-category of A_∞-functors from $\mathcal{A}$ to itself [91], [98], [104]. Here, the B_∞-algebra $C(\mathcal{A}, \mathcal{A})$ appears as the endomorphism algebra of the identity functor (*cf.* [84]).

Note that $C(\mathcal{A}, \mathcal{A})$ is not functorial with respect to dg functors. However, if $F\colon \mathcal{A} \to \mathcal{B}$ is a fully faithful dg functor, it clearly induces a restriction map

$$F^*\colon C(\mathcal{B}, \mathcal{B}) \to C(\mathcal{A}, \mathcal{A})$$

and this map is compatible with the B_∞-structure. This can be used to construct [81] a morphism

$$\phi_X\colon C(\mathcal{B}, \mathcal{B}) \to C(\mathcal{A}, \mathcal{A})$$

in the homotopy category of B_∞-algebras associated with each dg $\mathcal{A}$-$\mathcal{B}$-bimodule X such that the functor

$$? \overset{L}{\otimes}_{\mathcal{A}} X\colon \operatorname{per}(\mathcal{A}) \to \mathcal{D}\mathcal{B}$$

is fully faithful. If moreover the functor $X \overset{L}{\otimes}_{\mathcal{B}} ?\colon \operatorname{per}(\mathcal{B}^{\mathrm{op}}) \to \mathcal{D}(\mathcal{A}^{\mathrm{op}})$ is fully faithful, then ϕ_X is an isomorphism. In particular, the Hochschild complex becomes a functor

$$\mathrm{Hmo}_{\mathrm{ff}}^{\mathrm{op}} \to \mathrm{Ho}(B_\infty),$$

where $\mathrm{Ho}(B_\infty)$ is the homotopy category of B_∞-algebras and $\mathrm{Hmo}_{\mathrm{ff}}$ the (non-full) subcategory of Hmo whose morphisms are the quasi-functors $X \in \operatorname{rep}(\mathcal{A}, \mathcal{B})$ such that

$$? \overset{L}{\otimes}_{\mathcal{A}} X\colon \operatorname{per}(\mathcal{A}) \to \operatorname{per}(\mathcal{B})$$

is fully faithful. We refer to [102] for the closely related study of the Hochschild complex of an abelian category.

Let us suppose that k is a field of characteristic 0. Endowed with the Gerstenhaber bracket the Hochschild complex $C(\mathcal{A}, \mathcal{A})$ becomes a differential graded Lie algebra and this Lie algebra 'controls the deformations of the A_∞-category $\mathcal{A}$', *cf. e.g.* [93]. Here the A_∞-structures (m_n), $n \geq 0$, may have a non-trivial term m_0. Some (but not all) Hochschild cocycles also correspond to deformations of $\mathcal{A}$ as an object of Hmo. To be precise, let $k[\varepsilon]$ be the algebra of dual numbers and consider the reduction functor

$$R\colon \mathrm{Hmo}_{k[\varepsilon]} \to \mathrm{Hmo}_k, \quad \mathcal{B} \mapsto \mathcal{B} \overset{L}{\otimes}_{k[\varepsilon]} k.$$

A *first order Morita deformation* of $\mathcal{A}$ is a pair $(\mathcal{A}', \phi)$ formed by a dg $k[\varepsilon]$-category $\mathcal{A}'$ and an isomorphism $\phi\colon R\mathcal{A}' \to \mathcal{A}$ of Hmo_k. An equivalence between such deformations is given by an isomorphism $\psi\colon \mathcal{A}' \to \mathcal{A}''$ such that $\phi' R\psi = \phi$. Then one can show [54] that the equivalence classes of first order Morita deformations of $\mathcal{A}$ are in

natural bijection with the classes $c \in HH^2(\mathcal{A}, \mathcal{A})$ such that the induced morphism $cP\colon P \to P[2]$ is nilpotent in $H^*\mathcal{H}om(P, P)$ for each perfect $\mathcal{A}$-module P. If $\mathcal{A}$ is proper or, more generally, if $H^n\mathcal{A}(?, X)$ vanishes for $n \gg 0$ for all objects X of $\mathcal{A}$, then this condition holds for all Hochschild 2-cocycles c. On the other hand, if $\mathcal{A}$ is given by the dg algebra $k[u, u^{-1}]$, where u is of degree 2 and $du = 0$, then it does not hold for the cocycle $u \in HH^2(\mathcal{A}, \mathcal{A})$.

5.5. Fine structure of the Hochschild complexes. The Hochschild cochain complex of a dg category carries a natural homotopy action of the little squares operad. This is the positive answer to a question by P. Deligne [29] which has been obtained, for example, in [105], [92], [14].... Hochschild cohomology acts on Hochschild homology and this action comes from a homotopy action of the Hochschild cochain complex, viewed as a homotopy algebra over the little squares, on the Hochschild chain complex. This is the positive answer to a series of conjectures due to B. Tsygan [158] and Tamarkin–Tsygan [149]. It has recently been obtained by B. Tsygan and D. Tamarkin [159]. Together, the two Hochschild complexes endowed with these structures yield a *non-commutative calculus* [150] analogous to the differential calculus on a smooth manifold. The link with classical calculus on smooth commutative manifolds is established through M. Kontsevich's formality theorem [89], [147] for Hochschild cochains and in [143] (*cf.* also [32]) for Hochschild chains.

Clearly, these finer structures on the Hochschild complexes are linked to the category of dg categories and its simplicial enrichment given by the Dwyer–Kan localization as developed in [155]. At the end of the introduction to [155], the reader will find a more detailed discussion of these links, *cf.* also [87]. A precise relationship is announced in [148].

5.6. Derived Hall algebras. Let $\mathcal{A}$ be a *finitary* abelian category, *i.e.* such that the underlying sets of $\mathcal{A}(X, Y)$ and $\mathrm{Ext}^1(X, Y)$ are finite for all objects X, Y of $\mathcal{A}$. The *Ringel–Hall algebra* $\mathcal{H}(\mathcal{A})$ is the free abelian group on the isomorphism classes of $\mathcal{A}$ endowed with the multiplication whose structure constants are given by the Hall numbers f^Z_{XY}, which count the number of subobjects of Z isomorphic to X and such that Z/X is isomorphic to Y, *cf.* [30] for a survey. Thanks to Ringel's famous theorem [126], [127], for each simply laced Dynkin diagram Δ, the *positive part* of the Drinfeld–Jimbo quantum group $U_q(\Delta)$ (*cf. e.g.* [73], [103]) is obtained as the (generic, twisted) Ringel–Hall algebra of the abelian category of finite-dimensional representations of a quiver $\vec{\Delta}$ with underlying graph Δ. Since Ringel's discovery, it was first pointed out by Xiao [165], *cf.* also [70], that an extension of the construction of the Ringel–Hall algebra to the derived category of the representations of $\vec{\Delta}$ might yield the *whole* quantum group. However, if one tries to mimic the construction of $\mathcal{H}(\mathcal{A})$ for a triangulated category $\mathcal{T}$ by replacing short exact sequences by triangles one obtains a multiplication which fails to be associative, *cf.* [70], [68]. It is remarkable that nevertheless, as shown by Peng–Xiao [115], [116], [117], the commutator associated with this multiplication yields the correct Lie algebra.

A solution to the problem of constructing an associative multiplication from the triangles has recently been proposed by B. Toën in [153]. He obtains an explicit formula for the structure constants ϕ_{XY}^Z of an associative multiplication on the rational vector space generated by the isomorphism classes of any triangulated category $\mathcal{T}$ which appears as the perfect derived category $\mathrm{per}(T)$ of a proper dg category T over a finite field k. The resulting $\mathbb{Q}$-algebra is the *derived Hall algebra* $\mathcal{DH}(T)$ *of* T. The formula for the structure constants reads as follows:

$$\phi_{XY}^Z = \sum_f |\operatorname{Aut}(f/Z)|^{-1} \prod_{i>0} |\operatorname{Ext}^{-i}(X, Z)|^{(-1)^i} |\operatorname{Ext}^{-i}(X, X)|^{(-1)^{i+1}},$$

where f ranges over the set of orbits of the group $\mathrm{Aut}(X)$ in the set of morphisms $f\colon X \to Z$ whose cone is isomorphic to Y, and $\mathrm{Aut}(f/Z)$ denotes the stabilizer of f under the action of $\mathrm{Aut}(X)$. The proof of associativity is inspired by methods from the study of higher moduli spaces [157], [155], [156] and by the homotopy theoretic approach to K-theory [120]. From the formula, it is immediate that $\mathcal{DH}(T)$ is preserved under triangle equivalences $\mathrm{per}(T) \xrightarrow{\sim} \mathrm{per}(T')$. Another consequence is that if $\mathcal{A}$ is the heart of a non-degenerate t-structure [10] on $\mathrm{per}(T)$, then the Ringel–Hall algebra of $\mathcal{A}$ appears as a subalgebra of $\mathcal{DH}(T)$. The derived Hall algebra of the derived category of representations of $\vec{\Delta}$ over a finite field appears closely related to the constructions of [70]. Its precise relation to the quantum group $U_q(\Delta)$ remains to be investigated.

Notice that like the K_0-group, the derived Hall algebra only depends on the underlying triangulated category of $\mathrm{per}(T)$. One would expect that geometric versions of the derived Hall algebra, as defined in [154, 3.3] will depend on finer data.

Derived equivalences and finite dimensional algebras

Raphaël Rouquier

Abstract. We discuss the homological algebra of representation theory of finite dimensional algebras and finite groups. We present various methods for the construction and the study of equivalences of derived categories: local group theory, geometry and categorifications.

Mathematics Subject Classification (2000). 20C20, 18E30, 16E10.

Keywords. Derived categories, finite groups, representations, algebraic groups, categorification, homological dimension.

1. Introduction

This paper discusses derived equivalences, their construction and their use, for finite dimensional algebras, with a special focus on finite group algebras.

In a first part, we discuss Broué's abelian defect group conjecture and its ramifications. This is one of the deepest problem in the representation theory of finite groups. It is part of local representation theory, which aims to relate characteristic p representations of a finite group with representations of local subgroups (normalizers of non-trivial p-subgroups). We have taken a more functorial viewpoint in the definition of classical concepts (defect groups, subpairs,...).

In § 2.1.4, we present Alperin's conjecture, which gives a prediction for the number of simple representations, and Broué's conjecture, which is a much more precise prediction for the derived category, but does apply only to certain blocks (those with abelian defect groups).

We discuss in § 2.2 various types of equivalences that arise and present the crucial problem of lifting stable equivalences to derived equivalences.

In § 2.3, we present some local methods. We give a stronger version of the abelian defect group conjecture that can be approached inductively and reduced to the problem explained above of lifting stable equivalences to derived equivalences. Roughly speaking, in a minimal counterexample to that refinement of the abelian defect conjecture, there is a stable equivalence. Work of Rickard suggested to impose conditions on the terms of the complexes: they should be direct summands of permutation modules. We explain that one needs also to put conditions on the maps, that make the complexes look like complexes of chains of simplicial complexes.

There is no understanding on how to construct candidates complexes who would provide the derived equivalences expected by the abelian defect group conjecture in general. For finite groups of Lie type (in non-describing characteristic), we explain

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

(§ 2.4) Broué's idea that such complexes should arise as complexes of cohomology of Deligne–Lusztig varieties. We describe (§ 2.4.2) the Jordan decomposition of blocks (joint work with Bonnafé), as conjectured by Broué: Morita equivalences between blocks are constructed from the cohomology of Deligne–Lusztig varieties. For GL_n, every block is shown to be Morita equivalent to a unipotent block. This provides some counterpart to the Jordan decomposition of characters (Lusztig). In § 2.4.3 and 2.4.4, we explain the construction of complexes in the setting of the abelian defect conjecture. There are some delicate issues related to the choice of the Deligne–Lusztig variety and the extension of the action of the centralizer of a defect group to that of the normalizer. This brings braid groups and Hecke algebras of complex reflection groups.

In § 2.5, we explain how to view the problem of lifting stable equivalences to derived equivalences as a non-commutative version of the birational invariance of derived categories of Calabi–Yau varieties.

In § 2.6, we describe a class of derived equivalences which are filtered shifted Morita equivalences (joint work with Chuang). We believe these are the building bricks for most equivalences and the associated combinatorics should be interesting.

Part § 3 is devoted to some invariants of derived equivalences. In § 3.1, we explain a functorial approach to outer automorphism groups of finite dimensional algebras and deduce that their identity component is preserved under various equivalences. This functorial approach is similar to that of the Picard group of smooth projective schemes and we obtain also an invariance of the identity component of the product of the Picard group by the automorphism group, under derived equivalence.

In § 3.2, we explain how to transfer gradings through derived or stable equivalences. As a consequence, there should be very interesting gradings on blocks with abelian defect. This applies as well to Hecke algebras of type A in characteristic 0, where we obtain gradings which should be related to geometrical gradings.

Finally, in § 3.3, we explain the notion of dimension for triangulated categories, in particular for derived categories of algebras and schemes. This applies to answer a question of Auslander on the representation dimension and a question of Benson on Loewy length of group algebras.

Part § 4 is devoted to "categorifications". Such ideas have been advocated by I. Frenkel and have already shown their relevance in the work of Khovanov [57] on knot invariants. Our idea is that "classical" structures have natural higher counterparts. These act as symmetries of categories of representations or of sheaves.

In § 4.1, we explain the construction with Chuang of a categorification of $\mathfrak{sl}_2$ and we develop the associated "2-representation theory". There is an action on the sum of module categories of symmetric groups, and we deduce the existence of derived equivalences between blocks with isomorphic defect groups, using the general theory that provides a categorification of the adjoint action of the Weyl group. This applies as well to general linear groups, and gives a solution to the abelian defect group conjecture for symmetric and general linear groups.

In § 4.2, we define categorifications of braid groups. This is based on Soergel's bimodules.

I thank Cédric Bonnafé, Joe Chuang and Hyohe Miyachi for useful comments on a preliminary version of this paper.

2. Broué's abelian defect group conjecture

2.1. Introduction

2.1.1. Blocks. Let ℓ be a prime number. Let $\mathcal{O}$ be the ring of integers of a finite extension K of the field $\mathbb{Q}_\ell$ of ℓ-adic numbers and k its residue field.

Let G be a finite group. Modular representation theory is the study of the categories $\mathcal{O}G$-mod and kG-mod (finitely generated modules). The decomposition of Spec $Z(\mathcal{O}G)$ into connected components corresponds to the decomposition $Z(\mathcal{O}G) = \prod_b Z(\mathcal{O}G)b$, where b runs over the set of primitive idempotents of $Z(\mathcal{O}G)$ (the *block idempotents*). We have corresponding decompositions in *blocks* $\mathcal{O}G = \prod_b \mathcal{O}Gb$ and $\mathcal{O}G$-mod $= \bigoplus_b \mathcal{O}Gb$-mod.

Remark 2.1. One assumes usually that K is big enough so that KG is a product of matrix algebras over K (this will be the case if K contains the e-th roots of unity, where e is the exponent of G). Descent methods often allow a reduction to that case.

2.1.2. Defect groups. A *defect group* of a block $\mathcal{O}Gb$ is a minimal subgroup D of G such that $\mathrm{Res}^G_D = \mathcal{O}Gb \otimes_{\mathcal{O}Gb} -\colon D^b(\mathcal{O}Gb) \to D^b(\mathcal{O}D)$ is faithful (*i.e.*, injective on Hom's). Such a subgroup is an ℓ-subgroup and it is unique up to G-conjugacy.

The *principal block* $\mathcal{O}Gb_0$ is the one through which the trivial representation factors. Its defect groups are the Sylow ℓ-subgroups of G.

Defect groups measure the representation type of the block:

- kGb is simple if and only if $D = 1$.
- kGb-mod has finitely many indecomposable objects (up to isomorphism) if and only if the defect groups are cyclic.
- kGb is tame (*i.e.*, indecomposable modules are classifiable in a reasonable sense) if and only if the defect groups are cyclic or $\ell = 2$ and defect groups are dihedral, semi-dihedral or generalized quaternion groups.

2.1.3. Brauer correspondence. Let $\mathcal{O}Gb$ be a block and D a defect group. There is a unique block idempotent c of $\mathcal{O}N_G(D)$ such that the restriction functor $\mathrm{Res}^G_D = c\mathcal{O}Gb \otimes_{\mathcal{O}Gb} -\colon D^b(\mathcal{O}Gb) \to D^b(\mathcal{O}N_G(D)c)$ is faithful.

This correspondence provides a bijection between blocks of $\mathcal{O}G$ with defect group D and blocks of $\mathcal{O}N_G(D)$ with defect group D.

2.1.4. Conjectures. We have seen in § 2.1.3 that $D^b(\mathcal{O}G)$ embeds in $D^b(\mathcal{O}N_G(D)c)$. The *abelian defect conjecture* asserts that, when D is abelian, the categories are actually equivalent (via a different functor):

Conjecture 2.2 (Broué). If D is abelian, there is an equivalence $D^b(\mathcal{O}Gb) \xrightarrow{\sim} D^b(\mathcal{O}N_G(D)c)$.

A consequence of the conjecture is an isometry $K_0(KGb) \xrightarrow{\sim} K_0(KN_G(D)c)$ with good arithmetical properties (a *perfect isometry*). Note that the conjecture also carries homological information: if $\mathcal{O}Gb$ is the principal block and the equivalence sends the trivial module to the trivial module, we deduce that the cohomology rings of G and $N_G(D)$ are isomorphic, a classical and easy fact. It is unclear whether there should be some canonical equivalence in Conjecture 2.2.

Local representation theory is the study of the relation between modular representations and local structure of G. Alperin's conjecture asserts that the number of simple modules in a block can be computed in terms of local structure.

Conjecture 2.3 (Alperin). Assume $D \neq 1$. Then,

$$\text{rank } K_0(kGb) = \sum_{\mathcal{S}} (-1)^{l(\mathcal{S})+1} \text{ rank } K_0(kN_G(\mathcal{S})c_{\mathcal{S}})$$

where $\mathcal{S}$ runs over the conjugacy classes of chains of subgroups $1 < Q_1 < Q_2 < \cdots < Q_n \leq_G D, l(\mathcal{S}) = n \geq 1$ and $c_{\mathcal{S}}$ is the sum of the block idempotents of $N_G(\mathcal{S})$ corresponding to b.

Remark 2.4. We have stated here Knörr–Robinson's reformulation of the conjecture [58]. Note that the conjecture is expected to be compatible with ℓ-local properties of character degrees, equivariance, rationality (Dade, Robinson, Isaacs, Navarro). When D is abelian, Alperin's conjecture (and its refinements) follows immediately from Broué's conjecture. It would be extremely interesting to find a common refinement of Alperin and Broué's conjectures. For principal blocks, it should contain the description of the cohomology ring as stable elements in the cohomology ring of a Sylow subgroup.

2.2. Various equivalences. Let A and B be two symmetric algebras over a noetherian commutative ring $\mathcal{O}$.

2.2.1. Definitions. Let M be a bounded complex of finitely generated (A, B)-bimodules which are projective as A-modules and as right B-modules. Assume there is an (A, A)-bimodule R and a (B, B)-bimodule S with

$$M \otimes_B M^* \simeq A \oplus R \text{ as complexes of } (A, A)\text{-bimodules},$$
$$M^* \otimes_A M \simeq B \oplus S \text{ as complexes of } (B, B)\text{-bimodules}.$$

We say that M induces a

- *Morita equivalence* if M is concentrated in degree 0 and $R = S = 0$;
- *Rickard equivalence* if R and S are homotopy equivalent to 0 as complexes of bimodules;
- *derived equivalence* if R and S are acyclic;
- *stable equivalence* (of Morita type) if R and S are homotopy equivalent to bounded complexes of projective bimodules.

Note that Morita $\Rightarrow$ Rickard $\Rightarrow$ stable and Rickard $\Rightarrow$ derived. Note also that if there is a complex inducing a stable equivalence, then there is a bimodule inducing a stable equivalence. Finally, Rickard's theory says that if there is a complex inducing a derived equivalence, then there is a complex inducing a Rickard equivalence.

The definitions amount to requiring that $M \otimes_B -$ induces an equivalence

- (Morita) B-mod $\xrightarrow{\sim} A$-mod,
- (Rickard) $K^b(B\text{-mod}) \xrightarrow{\sim} K^b(A\text{-mod})$,
- (derived) $D^b(B) \xrightarrow{\sim} D^b(A)$,
- (stable) $B\text{-}\overline{\text{mod}} \xrightarrow{\sim} A\text{-}\overline{\text{mod}}$ (assuming $\mathcal{O}$ regular)

where $K^b(A\text{-mod})$ is the homotopy category of bounded complexes of objects of A-mod and $A\text{-}\overline{\text{mod}}$ is the stable category, additive quotient of A-mod by modules of the form $A \otimes_{\mathcal{O}} V$ with $V \in \mathcal{O}$-mod (it is equivalent to $D^b(A)/A$-perf when $\mathcal{O}$ is regular).

2.2.2. Stable equivalences. Stable equivalences arise fairly often in modular representation theory. For example, assume the Sylow ℓ-subgroups of G are TI, *i.e.*, given P a Sylow ℓ-subgroup, then $P \cap gPg^{-1} = 1$ for all $g \in G - N_G(P)$. Then, $M = \mathcal{O}G$ induces a stable equivalence between $\mathcal{O}G$ and $\mathcal{O}N_G(P)$, the corresponding functor is restriction (this is an immediate application of Mackey's formula). This restricts to a stable equivalence between principal blocks. Unfortunately, we do not know how to derive much numerical information from a stable equivalence.

A classical outstanding conjecture in representation theory of finite dimensional algebras is

Conjecture 2.5 (Alperin–Auslander). Assume $\mathcal{O}$ is an algebraically closed field. If A and B are stably equivalent, then they have the same number of isomorphism classes of simple non-projective modules.

A very strong generalization of Conjecture 2.5 is

Question 2.6. Let A and B be blocks with abelian defect groups and M a complex of (A, B)-bimodules inducing a stable equivalence. Assume K is big enough. Does there exist $\tilde{M}$ a complex of (A, B)-bimodules inducing a Rickard equivalence and such that M and $\tilde{M}$ are isomorphic in $(A \otimes B^{\text{opp}})\text{-}\overline{\text{mod}}$?

As will be explained in § 2.3.3, this is the key step for an inductive approach to Broué's conjecture.

Remark 2.7. There are examples of blocks with non abelian defect for which Question 2.6 has a negative answer, for example A the principal block of Suz(8), $\ell = 2$, and B the principal block of the normalizer of a Sylow 2-subgroup (TI case), cf. [17, §6]. A major problem with Question 2.6 and with Conjecture 2.2 is to understand the relevance of the assumption that the defect groups are abelian. Cf. § 3.2.2 for a possible idea.

2.3. Local theory. In an ideal situation, equivalences would arise from permutation modules or more generally, from chain complexes of simplicial complexes X acted on by the groups under consideration. Then, taking fixed points on X by an ℓ-subgroup Q would give rise to equivalences between blocks of the centralizers of Q. We would then have a compatible system of equivalences, corresponding to subgroups of the defect group. At the level of characters, Broué defined a corresponding notion of "isotypie" [17]: values of characters at ℓ-singular elements are related.

2.3.1. Subpairs. We explain here some classical facts.

A kG-module of the form $k\Omega$ where Ω is a G-set is a permutation module. An ℓ-permutation module is a direct summand of a permutation module and we denote by kG-lperm the corresponding full subcategory of kG-mod.

Suppose that Q is an ℓ-subgroup of G. We define the functor $\mathrm{Br}_Q\colon kG\text{-lperm} \to k(N_G(Q)/Q)\text{-lperm}$: $\mathrm{Br}_Q(M)$ is the image of M^Q in $M_Q = M/\sum_{x\in Q}(x-1)M$. If $M = k\Omega$, then $k(\Omega^Q) \xrightarrow{\sim} \mathrm{Br}_Q(M)$: the Brauer construction extends the fixed point construction on sets to ℓ-permutation modules. Note that this works only because Q is an ℓ-group and k has characteristic ℓ.

To deal with non principal blocks, we need to use Alperin–Broué's subpairs. A subpair of G is a pair (Q, e), where Q is an ℓ-subgroup of G and e a block idempotent of $kC_G(Q)$. If we restrict to the case where e is a principal block, we recover theory of ℓ-subgroups of G.

A maximal subpair is of the form (D, b_D), where D is a defect group of a block kGb and b_D is a block idempotent of $kC_G(D)$ such that $b_D c \neq 0$ (we say that (D, b_D) is a b-subpair). Fix such a maximal subpair. The $(kG, kN_G(D, b_D))$-bimodule $bkGb_D$ has, up to isomorphism, a unique indecomposable direct summand X with $\mathrm{Br}_{\Delta D}(X) \neq 0$. Here, we put $\Delta D = \{(x, x^{-1})\}_{x\in D} \leq D \times D^{\mathrm{opp}}$. More generally, given $\phi\colon Q \to R$, we put $\Delta_\phi(Q) = \{(x, \phi(x)^{-1})\}_{x\in Q} \leq Q \times R^{\mathrm{opp}}$.

We define the Brauer category $\mathcal{B}r(D, b_D)$: its objects are subpairs (Q, b_Q) with $Q \leq D$ and $b_Q \mathrm{Br}_{\Delta Q}(X) \neq 0$, and $\mathrm{Hom}((Q, b_Q), (R, b_R))$ is the set of $f \in \mathrm{Hom}(Q, R)$ such that there is $g \in G$ with $(Q^g, b_Q^g) \in \mathcal{B}r(D, b_D)$ and $f(x) = g^{-1}xg$ for all $x \in Q$.

Let $M \in kG$-lperm indecomposable. A vertex-subpair of M is a subpair (Q, b_Q) maximal such that $b_Q \mathrm{Br}_Q(M) \neq 0$ (such a subpair is unique up to conjugacy).

2.3.2. Splendid equivalences. Let G and H be two finite groups and b and b' two block idempotents of kG and kH.

The following Theorem [86], [92] shows that a stable equivalence corresponds to "local" Rickard equivalences, for complexes of ℓ-permutation modules.

Theorem 2.8. *Let M be an indecomposable complex of ℓ-permutation (kGb, kHb')-bimodules. Then M induces a stable equivalence between kGb and kHb' if and only if given (D, b_D) a maximal b-subpair, there is a maximal b'-subpair $(D', b'_{D'})$, an isomorphism $\phi\colon D \xrightarrow{\sim} D'$ inducing an isomorphism $\mathcal{B}r(D, b_D) \xrightarrow{\sim} \mathcal{B}r(D', b'_{D'})$ such that*

- *The indecomposable modules occurring in M have vertex-subpairs of the form $(\Delta_\phi(Q), b_Q \otimes b'_{\phi(Q)})$ for some $(Q, b_Q) \in \mathcal{B}r(D, b_D)$, with $(\phi(Q), b'_{\phi(Q)}) = \phi(Q, b_Q)$.*
- *For $1 \neq Q \leq D$, then $b_Q \cdot \mathrm{Br}_{\Delta_\phi Q}\, M \cdot b'_{\phi(Q)}$ induces a Rickard equivalence between $kC_G(Q)b_Q$ and $kC_H(Q)b'_{\phi(Q)}$, where $(Q, b_Q) \in \mathcal{B}r(D, b_D)$ and $(\phi(Q), b'_{\phi(Q)}) = \phi(Q, b_Q)$.*

Remark 2.9. In [83], Rickard introduced a notion of splendid equivalences for principal blocks (complexes of ℓ-permutation modules with diagonal vertices), later generalized by Harris [46] and Linckelmann [65]. Such equivalences were shown to induce equivalences for blocks of centralizers. In these approaches, an isomorphism between the defect groups of the two blocks involved was fixed a priori and vertex-subpairs were assumed to be "diagonal" with respect to the isomorphism. Theorem 2.8 shows it is actually easier and more natural to work with no a priori identification, and the property on vertex-subpairs is actually automatically satisfied.

The second part of the theorem (local Rickard equivalences $\Rightarrow$ stable equivalence) generalizes results of Alperin and Broué and is related to work of Bouc and Linckelmann.

Finally, a more general theory (terms need not be ℓ-permutation modules) has been constructed by Puig ("basic equivalences") [78].

Rickard proposed the following strengthening of Conjecture 2.2:

Conjecture 2.10. If D is abelian, there is a complex of ℓ-permutation modules inducing a Rickard equivalence between $\mathcal{O}Gb$ and $\mathcal{O}N_G(D)c$.

To the best of my knowledge, in all cases where Conjecture 2.2 is known to hold, then, Conjecture 2.10 is also known to hold.

Conjecture 2.10 is known to hold when D is cyclic [79], [62], [85]. In that case, one can construct a complex with length 2, but the longer complex originally constructed by Rickard might be more natural. The conjecture holds also when $D \simeq (\mathbb{Z}/2)^2$ [82], [63], [85]. In both cases, the representation type is tame. Note that there is no other ℓ-group P for which Conjecture 2.10 is known to hold for all $D \simeq P$.

Conjecture 2.10 holds when G is ℓ-solvable [35], [75], [47], when G is a symmetric group or a general linear group (cf. § 4.1; the describing characteristic case $G = \mathrm{SL}_2(\ell^n)$ is solved in [70]) and when G is a finite group of Lie type and $\ell \mid (q-1)$ (cf. § 2.4.3). There are many additional special groups for which the conjecture is known to hold (work of Gollan, Hida, Holloway, Koshitani, Kunugi, Linckelmann, Marcus, Miyachi, Okuyama, Rickard, Turner, Waki), cf. http://www.maths.bris.ac.uk/~majcr/adgc/adgc.html.

2.3.3. Gluing. Theorem 2.8 suggests an inductive approach to Conjecture 2.10: one should solve the conjecture for local subgroups (say, $C_G(Q)$, $1 \neq Q \leq D$) and glue the corresponding Rickard complexes. This would give rise to a complex inducing a stable equivalence, leaving us with the core problem of lifting a stable equivalence to a Rickard equivalence. Unfortunately, complexes are not rigid enough to allow gluing. This problem can be solved by using complexes endowed with some extra structure [86], [92]. The idea is to use complexes that have the properties of chain complexes of simplicial complexes: the key point is the existence of compatible splittings of the Brauer maps $M^Q \to M(Q)$. One can build an exact category of ℓ-permutation modules with compatible splittings of the Brauer maps. The subcategory of projective objects turns out to have a very simple description in terms of sets, and we use only this category. For simplicity, we restrict here to the case of principal blocks.

Let G be a finite group, ℓ a prime number, k an algebraically closed field of characteristic ℓ, b the principal block idempotent of kG, D a Sylow ℓ-subgroup of G and c the principal block idempotent of $H = N_G(D)$. We assume D is abelian. We denote by $Z_\ell(G)$ the Sylow ℓ-subgroup of $Z(G)$ and put $Z = \Delta Z_\ell(G)$.

Let G' be a finite group containing G as a normal subgroup, let $H' = N_{G'}(D)$ and $F = G'/G \xrightarrow{\sim} H'/H$. We assume F is an ℓ'-group, we put $N = \{(g,h) \in G' \times H'^{\mathrm{opp}} \mid (gG, hH^{\mathrm{opp}}) \in \Delta F\}$ and $\overline{N} = N/Z$.

Let $\mathcal{E}$ be the category of $\overline{N}$-sets whose point stabilizers are contained in $\Delta D/Z$. Let $\tilde{\mathcal{E}}$ be the Karoubian envelop of the linearization of $\mathcal{E}$ (objects are pairs (Ω, e) where Ω is a $\overline{N}$-set and e an idempotent of the monoid algebra of $\mathrm{End}_{\overline{N}}(\Omega)$). We have a faithful functor $\tilde{\mathcal{E}} \to k\overline{N}$-lperm, $(\Omega, e) \mapsto k(\Omega, e) := k\Omega e$.

We are now ready to state a further strengthening of Conjecture 2.2. For the inductive approach, it is important to take into account central ℓ-subgroups and ℓ'-automorphism groups.

Conjecture 2.11. There is a complex C of objects of $\tilde{\mathcal{E}}$ such that $\mathrm{Res}^{\overline{N}}_{G \times H^{\mathrm{opp}}} k(C)$ induces a Rickard equivalence between kGb and kHc.

We can also state a version of Question 2.6, for the pair (G', G):

Question 2.12. Let C be a complex of objects of $\tilde{\mathcal{E}}$ such that $\mathrm{Res}^{\overline{N}}_{G \times H^{\mathrm{opp}}} k(C)$ induces a stable equivalence between kGb and kHc. Is there a bounded complex

R of finitely generated projective $\bar{N}$-modules and a morphism $f\colon R \to k(C)$ such that $\mathrm{Res}^{\bar{N}}_{G\times H^{\mathrm{opp}}}\mathrm{cone}(f)$ induces a Rickard equivalence between kGb and kHc?

The following theorem reduces (a suitable version of) the abelian defect conjecture to (a suitable version of) the problem of lifting stable equivalences to Rickard equivalences.

Theorem 2.13. *Assume Question* 2.12 *has a positive answer for* $(N_{G'}(Q), C_G(Q))$ *for all non trivial subgroups* Q *of* D. *Then Conjecture* 2.11 *holds.*

The proof goes by building inductively (on the index of Q in D) a system of complexes for $N_{G'}(Q)$ and gluing them together. The key point is that, given a finite group Γ, the category of Γ-sets whose point stabilizers are non-trivial p-subgroups is locally determined. This allows us to manipulate objects of $\tilde{\mathcal{E}}$ as "sheaves".

2.4. Chevalley groups. We explain Broué's idea that complexes of cohomology of certain varieties should give rise to derived equivalences, for finite groups of Lie type.

2.4.1. Deligne–Lusztig varieties. Let $\boldsymbol{G}$ be a connected reductive algebraic group defined over a finite field and let F be an endomorphism of $\boldsymbol{G}$, a power F^d of which is a Frobenius endomorphism defining a structure over a finite field $\mathbb{F}_{q^d}$ for some $q \in \mathbb{R}_{>0}$. Let $G = \boldsymbol{G}^F$ be the associated finite group.

Let ℓ be a prime number with $\ell \nmid q$, K a finite extension of $\mathbb{Q}_l$, and $\mathcal{O}$ its ring of integers. We assume K is big enough.

Let $\boldsymbol{L}$ be an F-stable Levi subgroup of $\boldsymbol{G}$, $\boldsymbol{P}$ be a parabolic subgroup with Levi complement $\boldsymbol{L}$, and let $\boldsymbol{U}$ be the unipotent radical of $\boldsymbol{P}$. We define the Deligne–Lusztig variety

$$Y_{\boldsymbol{U}} = \{g\boldsymbol{U} \in \boldsymbol{G}/\boldsymbol{U} \mid g^{-1}F(g) \in \boldsymbol{U}\cdot F(\boldsymbol{U})\},$$

a smooth affine variety with a left action of $\boldsymbol{G}^F$ and a right action of $\boldsymbol{L}^F$ by multiplication. The corresponding complex of cohomology $R\Gamma_c(Y_{\boldsymbol{U}}, \mathcal{O})$ induces the Deligne–Lusztig induction functor $R^{\boldsymbol{G}}_{\boldsymbol{L}\subset\boldsymbol{P}}\colon D^b(\mathcal{O}\boldsymbol{L}^F) \to D^b(\mathcal{O}\boldsymbol{G}^F)$.

The effect of these functors on characters (*i.e.*, K_0's after extension to K) is a central tool for Deligne–Lusztig and Lusztig's construction of irreducible characters of G. It is important to also consider the finer invariant $\tilde{R}\Gamma_c(Y_{\boldsymbol{U}}, \mathcal{O})$, an object of $K^b(\mathcal{O}(\boldsymbol{G}^F \times (\boldsymbol{L}^F)^{\mathrm{opp}})\text{-lperm})$ which is quasi-isomorphic to $R\Gamma_c(Y_{\boldsymbol{U}}, \mathcal{O})$ [81], [87].

We put $X_{\boldsymbol{U}} = Y_{\boldsymbol{U}}/\boldsymbol{L}^F$ and denote by $\pi\colon Y_{\boldsymbol{U}} \to X_{\boldsymbol{U}}$ the quotient map.

Remark 2.14. One could use ordinary cohomology instead of the compact support version. One can conjecture that the two versions are interchanged by Alvis–Curtis duality: $(R\Gamma_c(Y_{\boldsymbol{U}}, \mathcal{O}) \otimes^{\boldsymbol{L}}_{\mathcal{O}\boldsymbol{L}^F} -) \circ D_{\boldsymbol{L}}$ and $D_{\boldsymbol{G}} \circ (R\Gamma(Y_{\boldsymbol{U}}, \mathcal{O})) \otimes^{\boldsymbol{L}}_{\mathcal{O}\boldsymbol{L}^F} -)$ should differ by a shift. This is known in the Harish-Chandra case, *i.e.*, when $\boldsymbol{P}$ is F-stable [24].

Let $\boldsymbol{T}_0 \subset \boldsymbol{B}_0$ be a pair consisting of an F-stable maximal torus and an F-stable Borel subgroup of $\boldsymbol{G}$. Let $\boldsymbol{U}_0$ be the unipotent radical of $\boldsymbol{B}_0$ and let $W = N_{\boldsymbol{G}}(\boldsymbol{T}_0)/\boldsymbol{T}_0$.

Let B^+ (resp. B) be the braid monoid (resp. group) of W. The canonical map $B^+ \to W$ has a unique section $w \mapsto \boldsymbol{w}$ that preserves lengths (it is not a group morphism!). We fix an F-equivariant morphism $\tau\colon B \to N_{\boldsymbol{G}}(\boldsymbol{T}_0)$ that lifts the canonical map $N_{\boldsymbol{G}}(\boldsymbol{T}_0) \to W$ [99]. Given $w \in W$, we put $\dot{w} = \tau(\boldsymbol{w})$. Let w_0 be the longest element of W and let $\pi = \boldsymbol{w}_0^2$, a central element of B.

Assume $\boldsymbol{L}$ above is a torus. We give a different model for $Y_{\boldsymbol{U}}$. Let $w \in W$ and $h \in \boldsymbol{G}$ such that $h^{-1}F(h) = \dot{w}$ and $\boldsymbol{U} = h\boldsymbol{U}_0h^{-1}$. Let

$$Y(w) = \{g\boldsymbol{U}_0 \in \boldsymbol{G}/\boldsymbol{U}_0 \mid g^{-1}F(g) \in \boldsymbol{U}_0\dot{w}\boldsymbol{U}_0\},$$

a variety with a left action of G and a right action of $\boldsymbol{T}_0^{wF}$ by multiplication. We have $\boldsymbol{L} = h\boldsymbol{T}_0h^{-1}$ and conjugation by h induces an isomorphism $\boldsymbol{L}^F \xrightarrow{\sim} \boldsymbol{T}_0^{wF}$. Right multiplication by h induces an isomorphism $Y_{\boldsymbol{U}} \xrightarrow{\sim} Y(w)$ compatible with the actions of G and $\boldsymbol{L}^F$. We have $\dim Y(w) = l(w)$. We write $Y_F(w)$ when the choice of F is important.

Given $w_1, \dots, w_r \in W$, we put

$$\begin{aligned} Y(w_1, \dots, w_r) = \{&(g_1\boldsymbol{U}_0, \dots, g_r\boldsymbol{U}_0) \in (\boldsymbol{G}/\boldsymbol{U}_0)^r \mid \\ &g_1^{-1}g_2 \in \boldsymbol{U}_0\dot{w}_1\boldsymbol{U}_0, \dots, g_{r-1}^{-1}g_r \in \boldsymbol{U}_0\dot{w}_{r-1}\boldsymbol{U}_0 \text{ and } g_r^{-1}F(g_1) \in \boldsymbol{U}_0\dot{w}_r\boldsymbol{U}_0\}. \end{aligned}$$

Up to a transitive system of canonical isomorphisms, $Y(w_1, \dots, w_r)$ depends only on the product $b = \boldsymbol{w}_1 \cdots \boldsymbol{w}_r \in B^+$ and we denote that variety by $Y(b)$ [36], [22].

2.4.2. Jordan decomposition. As a first step in his classification of (complex) irreducible characters of finite groups of Lie type, Lusztig established a *Jordan decomposition* of characters.

Let $(\boldsymbol{G}^*, F^*)$ be Langlands dual to $(\boldsymbol{G}, F)$. Then Lusztig defined a partition of the set $\mathrm{Irr}(G)$ of irreducible characters of G:

$$\mathrm{Irr}(G) = \coprod_{(s)} \mathrm{Irr}(G, (s))$$

where (s) runs over conjugacy classes of semi-simple elements of $(\boldsymbol{G}^*)^{F^*}$. The elements in $\mathrm{Irr}(G, 1)$ are the *unipotent characters*.

Furthermore, Lusztig constructed a bijection

$$\mathrm{Irr}(G, (s)) \xrightarrow{\sim} \mathrm{Irr}((C_{\boldsymbol{G}^*}(s)^*)^F, 1) \tag{1}$$

(assuming $C_{\boldsymbol{G}^*}(s)$ is connected). So, an irreducible character corresponds to a pair consisting of a semi-simple element in the dual and a unipotent character of the dual of the centralizer of that semi-simple element.

Broué and Michel [21] showed that the union of series corresponding to classes with a fixed ℓ'-part is a union of blocks: let t be a ℓ'-element of $(\boldsymbol{G}^*)^{F^*}$ and let

$$\mathrm{Irr}(G, (t))_\ell = \coprod_{(s)} \mathrm{Irr}(G, (s))$$

where (s) runs over conjugacy classes of semi-simple elements of $(\boldsymbol{G}^*)^{F^*}$ whose ℓ'-part is conjugate to t. Then $\mathrm{Irr}(G, (t))_\ell$ is a union of ℓ-blocks, and we denote by $B(G^F, (t))$ the corresponding factor of $\mathcal{O}G^F$.

Broué [18] conjectured that the decomposition (1) arises from a Morita equivalence (cf. also [48]). More, precisely, we have the following theorem [11, Theorem B'] obtained in joint work with C. Bonnafé (cf. also [23] for a detailed exposition). This was conjectured by Broué who gave a proof when t is regular [18].

Theorem 2.15 (Jordan decomposition of blocks). *Assume $C_{\boldsymbol{G}^*}(t)$ is contained in an F^*-stable Levi subgroup $\boldsymbol{L}^*$ of $\boldsymbol{G}^*$ with dual $\boldsymbol{L} \leq \boldsymbol{G}$. Let $\boldsymbol{P}$ be a parabolic subgroup of $\boldsymbol{G}$ with Levi complement $\boldsymbol{L}$ and unipotent radical $\boldsymbol{U}$. Let $d = \dim X_{\boldsymbol{U}}$ and let $\mathcal{F}_t = \pi_* \mathcal{O} \otimes_{\mathcal{O}\boldsymbol{L}^F} B(\boldsymbol{L}^F, (t))$.*

Then $H_c^i(X_{\boldsymbol{U}}, \mathcal{F}_t) = 0$ for $i \neq d$ and $H_c^d(X_{\boldsymbol{U}}, \mathcal{F}_t)$ induces a Morita equivalence between $B(G, (t))$ and $B(\boldsymbol{L}^F, (t))$.

The theorem reduces the study of blocks of finite groups of Lie type to the case of those associated to a quasi-isolated element t. When $\boldsymbol{L}^* = C_{\boldsymbol{G}^*}(t)$ is a Levi subgroup of $\boldsymbol{G}^*$, then $B(\boldsymbol{L}^F, (t))$ is isomorphic to $B(\boldsymbol{L}^F, 1)$.

As shown by Broué, the key point is the statement about the vanishing of cohomology. When $\boldsymbol{L}$ is a torus, this is [37, Theorem 9.8]. For the general case, two difficulties arise: there are no known good smooth compactifications of the varieties $X_{\boldsymbol{U}}$ and the locally constant sheaf $\mathcal{F}_t$ has wild ramification. We solve these issues as follows. Let $\overline{X}$ be the closure of $X_{\boldsymbol{U}}$ in $\boldsymbol{G}/\boldsymbol{P}$. We construct new varieties of Deligne–Lusztig type and commutative diagrams

$$\begin{array}{ccc} X_i & \xrightarrow{j_i} & Y_i \\ {\scriptstyle f_i'}\downarrow & & \downarrow{\scriptstyle f_i} \\ X_{\boldsymbol{U}} & \xrightarrow[j]{} & \overline{X} \end{array}$$

where Y_i is smooth, $Y_i - X_i$ is a divisor with normal crossings, and f_i is proper. We also construct tamely ramified sheaves $\mathcal{F}_i$ on X_i with the following properties:

- $\mathcal{F}_t$ is in the thick subcategory of the derived category of constructible sheaves on $\boldsymbol{X}_{\boldsymbol{U}}$ generated by the $Rf_{i*}'\mathcal{F}_i$
- $(Rj_{i*}\mathcal{F}_i)_{|f_i^{-1}(\overline{X} - X_{\boldsymbol{U}})} = 0$.

The first property follows from the following generation result of the derived category of a finite group of Lie type [11, Theorem A]:

Theorem 2.16. *The category of perfect complexes for $B(G, (t))$ is generated, as a thick subcategory, by the $R_{\boldsymbol{T}\subset\boldsymbol{B}}^{\boldsymbol{G}} B(\boldsymbol{T}^F, (t))$, where $\boldsymbol{T}$ runs over the F-stable maximal tori of $\boldsymbol{G}$ such that $t \in \boldsymbol{T}^*$ and $\boldsymbol{B}$ runs over the Borel subgroups of $\boldsymbol{G}$ containing $\boldsymbol{T}$.*

Remark 2.17. Note that the corresponding result for derived categories is true, under additional assumptions on $\boldsymbol{G}$ [13]: this is related to Quillen's Theorem, we need every elementary abelian ℓ-subgroup of G to be contained in an F-stable torus of $\boldsymbol{G}$.

Remark 2.18. Note that the Morita equivalence of Theorem 2.15 is not splendid in general. This issue is analyzed in [13].

Example 2.19. Let $\boldsymbol{G} = \mathrm{GL}_n(\overline{\mathbb{F}}_q)$ and $F\colon (x_{ij})_{1\le i,j\le n} \mapsto (x_{ij}^q)_{i,j}$. We have $G = \mathrm{GL}_n(\mathbb{F}_q)$, $\boldsymbol{G} = \boldsymbol{G}^*$ and $F^* = F$. Centralizers of semi-simple elements are Levi subgroups, so Theorem 2.15 gives a Morita equivalence between any block of a general linear group over $\mathcal{O}$ and a unipotent block.

2.4.3. Abelian defect conjecture. Let b be a block idempotent of $\mathcal{O}G$. Let (D, b_D) be a maximal b-subpair, let $H = N_G(D, b_D)$ and let $\boldsymbol{L} = C_{\boldsymbol{G}}(D)$. We assume D is abelian and $\boldsymbol{L}$ is a Levi subgroup of $\boldsymbol{G}$ (these are satisfied if $\ell \nmid |W|$).

Broué conjectured that the sought-for complex in Conjecture 2.10 should arise from Deligne–Lusztig varieties ([17, p. 81], [20, §1], [19, §VI]):

Conjecture 2.20 (Broué). There is a parabolic subgroup $\boldsymbol{P}$ of $\boldsymbol{G}$ with Levi complement $\boldsymbol{L}$ and unipotent radical $\boldsymbol{U}$, and a complex C inducing a Rickard equivalence between $\mathcal{O}Gb$ and $\mathcal{O}Hb_D$ such that $\mathrm{Res}_{G\times(\boldsymbol{L}^F)^{\mathrm{opp}}} C$ is isomorphic to $\tilde{R}\Gamma_c(Y_{\boldsymbol{U}}, \mathcal{O})b_D$.

This conjecture 2.20 is known to hold [76] when there is a choice of an F-stable parabolic subgroup $\boldsymbol{P}$ (case $\ell \mid (q-1)$). Then $Y_{\boldsymbol{U}}$ is 0-dimensional and the Deligne–Lusztig induction is the Harish-Chandra induction. The key steps in the proof are:

- Produce an action of the reflection group $H/\boldsymbol{L}^F$ from a natural action of the associated Hecke algebra. One needs to show that certain obstructions vanish.
- Identify a 2-cocycle of $H/\boldsymbol{L}^F$ with values in $\mathcal{O}^\times$.
- Compute the dimension of the KG-endomorphism ring.

2.4.4. Regular elements. As a first step, one should make Conjecture 2.20 more precise by specifying $\boldsymbol{P}$ and by defining the extension of the action of $C_G(D)$ to an action of H on $\tilde{R}\Gamma_c(Y_U, \mathcal{O})b_D$. These issues are partly solved and I will explain the best understood case where $\boldsymbol{L} = \boldsymbol{T}$ is a torus and $\mathcal{O}Gb$ is the principal block (cf. [22]). Assume as well $\ell \nmid (q-1)$. To simplify, assume further that F acts trivially on W ("split" case).

Note that $\boldsymbol{T}$ defines a conjugacy class $\mathcal{C}$ of W and the choice of $\boldsymbol{P}$ amounts to the choice of $w \in \mathcal{C}$ (defined from $\boldsymbol{P}$ as in § 2.4.1). Since $\boldsymbol{T} = C_{\boldsymbol{G}}(D)$, it follows that elements in $\mathcal{C}$ are Springer-regular. There is $w_d \in \mathcal{C}$ such that $(\boldsymbol{w}_d)^d = \pi$, where $d > 1$ is the order of w_d (a "good" regular element).

Given $w \in W$, we have a purely inseparable morphism

$$Y(w, w^{-1}w_0, w_0ww_0, w_0w^{-1}) \to Y(w^{-1}w_0, w_0ww_0, w_0w^{-1}, w)$$
$$(x_1, x_2, x_3, x_4) \mapsto (x_2, x_3, x_4, F(x_1)).$$

Via the canonical isomorphisms, this induces an endomorphism of $Y(\pi)$. This extends to an action of B^+ on $Y(\pi)$.

There is an embedding of $Y_F(w_d)$ as a closed subvariety of $Y_{F^d}(w_d, \dots, w_d)$ (d terms) given by

$$x \mapsto (x, F(x), \dots, F^{d-1}(x)).$$

The action of $C_{B^+}(\boldsymbol{w}_d)$ on $Y_{F^d}(\pi)$ restricts to an action on $Y_F(w_d)$. It induces an action of $C_B(\boldsymbol{w}^d)$ on $\tilde{R}\Gamma_c(Y(\boldsymbol{w}_d), \mathcal{O})$.

The group $H/C_G(D) \simeq C_W(w_d)$ is a complex reflection group and we denote by B_d its braid group. There is a morphism $B_d \to C_B(\boldsymbol{w}_d)$, uniquely defined up to conjugation by an element of the pure braid group of $C_W(w_d)$ (it is expected to be an isomorphism, and known to be such in a number of cases [8]).

Now, the conjecture is that, up to homotopy, the action of $\mathcal{O}(\boldsymbol{T}_0^{w_d F} \rtimes B_d)$ on $\tilde{R}\Gamma_c(Y(w_d), \mathcal{O})b_D$ induces an action of the quotient algebra $\mathcal{O}Hc$ and the resulting object is a splendid Rickard complex:

Conjecture 2.21. There is a complex $C \in K^b((\mathcal{O}Gb) \otimes (\mathcal{O}Hb_D)^{\mathrm{opp}}\text{-lperm})$, unique up to isomorphism, with the following properties:

- There is a surjective morphism $f\colon \mathcal{O}\boldsymbol{T}_0^{w_d F} \rtimes B_d \to \mathcal{O}Hb_D$ extending the inclusion $\boldsymbol{T}_0^{w_d F} \subset H$ such that
  - f^*C and $\tilde{R}\Gamma_c(Y(w_d), \mathcal{O})b_D$ are isomorphic in $D^b((\mathcal{O}\boldsymbol{T}_0^{w_d F} \rtimes B_d) \otimes (\mathcal{O}H)^{\mathrm{opp}})$,
  - the map $kB_d \to kC_W(w_d)$ deduced from f by applying $k \otimes_{\mathcal{O}\boldsymbol{T}_0^{w_d F}} -$ is the canonical map.
- C is isomorphic to $\tilde{R}\Gamma_c(Y(w_d), \mathcal{O})b_D$ in $K^b((\mathcal{O}G) \otimes (\mathcal{O}C_G(D))^{\mathrm{opp}}\text{-lperm})$.

Furthermore, such a complex C induces a Rickard equivalence between $\mathcal{O}Gb$ and $\mathcal{O}Hb_D$.

The most crucial and difficult part in that conjecture is to show that we have no non-zero shifted endomorphisms of the complex ("disjunction property"), either for the action of G or for that H.

Conjecture 2.21 is known to hold when $l(w_d) = 1$ [87] and for GL_n and $d = n$ [12]. In the first case, we use good properties of cohomology of curves and prove disjunction for the action of G. In the second case, we study the variety $D(\boldsymbol{U}_0)^F \backslash Y(w_d)$ and prove disjunction for the action of H. This works only for GL_n, for we rely on the fact that induced Gelfand–Graev representations generate the category of projective modules.

Remark 2.22. When $\ell \mid (q-1)$ (case $d = 1$), one can formulate a version of Conjecture 2.21 using the variety $Y(\pi)$ [22, Conjectures 2.15].

Remark 2.23. The version "over K" of Conjecture 2.21 is open, even after restricting to unipotent representations (= applying the functor $K \otimes_{KT^{w_d F}} -$). The action of KB_d on $H_c^*(Y(w_d), K)$ should factor through an action of the Hecke algebra of

$C_W(w_d)$, for certain parameters. This is known in some cases: for $d = 1$ [22], [39], when $d = 2$ (work of Lusztig [67] and joint work with Digne and Michel [39]) and in some other cases [38]. The disjunction property is known for w_d a Coxeter element [66], for GL_n and $d = n - 1$ [38] and in most rank 2 groups [39].

2.5. Local representation theory as non-commutative birational geometry. It is expected that birational Calabi–Yau varieties should have equivalent derived categories (cf. [15]). We view Question 2.6 as a non-commutative version: one can expect that "sufficiently nice" Calabi–Yau triangulated categories are determined by (not too small) quotients. We explain here how this analogy can be made precise, in the setting of McKay's correspondence, via Koszul duality.

2.5.1. 2-elementary abelian defect groups. Let P be an elementary abelian 2-group. Let k be a field of characteristic 2 and $V = P \otimes_{\mathbb{F}_2} k$. Let E be a group of odd order of automorphisms of P. The algebras $kP \rtimes E$ and $\Lambda(V) \rtimes E$ are isomorphic.

Koszul duality (cf. eg [53]) gives an equivalence

$$D^b((\Lambda(V) \rtimes E)\text{-modgr}) \xrightarrow{\sim} D^b_{E \times \boldsymbol{G}_m}(V).$$

2.5.2. McKay's correspondence. Let V be a finite-dimensional vector space over k and E a finite subgroup of $\mathrm{GL}(V)$ of order invertible in k. Recall the following conjecture (independence of the crepant resolution):

Conjecture 2.24 (McKay's correspondence). If $X \to V/E$ is a crepant resolution, then $D^b(X) \simeq D^b_E(V)$.

The conjecture is known to hold when $\dim V = 3$ [16], [14] (in dimension 3, the Hilbert scheme of E-clusters on V is a crepant resolution). It is also known when V is a symplectic vector space and E respects the symplectic structure [9]. See [15, §2.2] for more details.

Examples in dimension > 3 where $E - \mathrm{Hilb}\, V$ is smooth are rare. An infinite family of examples is provided by the following theorem of Sebestean [95]:

Theorem 2.25. *Let $n \geq 2$, let k be a field containing a primitive $(2^n - 1)$-th root of unity ζ and let E be the subgroup of $\mathrm{SL}_n(k)$ generated by the diagonal matrix with entries $(\zeta, \zeta^2, \ldots, \zeta^{2^{n-1}})$. Assume $2^n - 1$ is invertible in k.*

Then $E - \mathrm{Hilb}(\boldsymbol{A}^n_k)$ is a smooth crepant resolution of $\boldsymbol{A}^n_k/E$ and there is an equivalence $D^b_E(\boldsymbol{A}^n_k) \xrightarrow{\sim} D^b(E - \mathrm{Hilb}(\boldsymbol{A}^n_k))$.

The diagonal action of $\boldsymbol{G}_m$ on $\boldsymbol{A}^n_k$ induces an action on $E - \mathrm{Hilb}(\boldsymbol{A}^n_k)$ and the equivalence is equivariant for these actions.

Let $G = \mathrm{SL}_2(2^n)$, let P be the subgroup of strict upper triangular matrices (a Sylow 2-subgroup), and let E be the subgroup of diagonal matrices. The action of E on $P \otimes_{\mathbb{F}_2} \overline{\mathbb{F}}_2$ coincides with the one in Theorem 2.25. Combining the solution of

Conjecture 2.2 for G (Okuyama, [70]) and § 3.2.2, the Koszul duality equivalence, and Theorem 2.25, we deduce a geometric realization of modular representations of $\mathrm{SL}_2(2^n)$ in natural characteristic:

Corollary 2.26. *There is a grading on the principal* 2*-block* A *of* $\overline{\mathbb{F}}_2 G$ *and an equivalence* $D^b(A\text{-modgr}) \xrightarrow{\sim} D^b_{\boldsymbol{G}_m}(E - \mathrm{Hilb}\, \boldsymbol{A}^n_k)$.

Remark 2.27. It should be interesting to study homotopy categories of sheaves on singular varieties and their relation to derived categories of crepant resolutions.

2.6. Perverse Morita equivalences. In this part, we shall describe joint work with J. Chuang [30].

2.6.1. Definitions. Let $\mathcal{A}$, $\mathcal{A}'$ be two abelian categories. We assume every object has a finite composition series. Let $\mathcal{S}$ (resp. $\mathcal{S}'$) be the set of isomorphism classes of simple objects of $\mathcal{A}$ (resp. $\mathcal{A}'$).

Definition 2.28. An equivalence $F\colon D^b(\mathcal{A}) \xrightarrow{\sim} D^b(\mathcal{A}')$ is perverse if there is

- a filtration $\emptyset = \mathcal{S}_0 \subset \mathcal{S}_1 \subset \cdots \subset \mathcal{S}_r = \mathcal{S}$,
- a filtration $\emptyset = \mathcal{S}'_0 \subset \mathcal{S}'_1 \subset \cdots \subset \mathcal{S}'_r = \mathcal{S}'$,
- and a function $p\colon \{1, \ldots, r\} \to \mathbb{Z}$,

such that

- F restricts to equivalences $D^b_{\mathcal{A}_i}(\mathcal{A}) \xrightarrow{\sim} D^b_{\mathcal{A}'_i}(\mathcal{A}')$,
- $F[-p(i)]$ induces equivalences $\mathcal{A}_i/\mathcal{A}_{i-1} \xrightarrow{\sim} \mathcal{A}'_i/\mathcal{A}'_{i-1}$.

where $\mathcal{A}_i$ (resp. $\mathcal{A}'_i$) is the Serre subcategory of $\mathcal{A}$ (resp. $\mathcal{A}'$) generated by $\mathcal{S}_i$ (resp. $\mathcal{S}'_i$).

An important point is that $\mathcal{A}'$ is determined, up to equivalence, by $\mathcal{A}$, $\mathcal{S}_\bullet$ and p.

2.6.2. Symmetric algebras. Let A be a symmetric finite dimensional algebra and $\mathcal{A} = A$-mod.

We explain how to construct a perverse equivalence, given any $\mathcal{S}_\bullet$ and p (this cannot be done in general for a nonsymmetric algebra A).

Let I be a subset of $\mathcal{S}$. Given $V \in \mathcal{S}$, let P_V be a projective cover of V, let V_I be the largest quotient of P_V all of which composition factors are in I and let $Q_V \to \ker(P_V \to V_I)$ be a projective cover. We put $T_{A,V}(I) = P_V$ if $V \in S - I$, $T_{A,V}(I) = 0 \to Q_V \to P_V \to 0$ if $V \in I$ (where Q_V is in degree 0) and $T_A(I) = \bigoplus_V T_{A,V}(I)$, a tilting complex.

Let $\mathcal{T}$ be the set of isomorphism classes of families $(T_V)_{V\in S}$, where T_V is an indecomposable bounded complex of finitely generated projective A-modules and $\bigoplus_{V\in S} T_V$ is a tilting complex.

We denote by $\mathcal{P}(\mathcal{S})$ the set of subsets of $\mathcal{S}$. We define an action of $\mathrm{Free}(\mathcal{P}(\mathcal{S})) \rtimes \mathfrak{S}(\mathcal{S})$ on $\mathcal{T}$. The symmetric group acts by permutation of indices and $I \subset \mathcal{S}$ sends $(T_V)_V$ to $(T'_V)_V$ given by $T'_V = F^{-1}(T_{B,V}(I))$, where $B = \mathrm{End}_{D^b(A)}(\bigoplus_V T_V)$ and $F = R\,\mathrm{Hom}^\bullet_A(\bigoplus_V T_V, -)\colon D^b(A) \xrightarrow{\sim} D^b(B)$.

Fix now $\mathcal{S}_\bullet$ a filtration of $\mathcal{S}$ and $p\colon \mathcal{S} \to \mathbb{Z}$. We put

$$(T_V)_V = \mathcal{S}_r^{p(r)} \mathcal{S}_{r-1}^{p(r-1)-p(r)} \dots \mathcal{S}_1^{p(1)-p(2)}((P_V)_V),$$

$T = \bigoplus_V T_V$, $A' = \mathrm{End}_{D^b(A)(T)}$ and $F = R\,\mathrm{Hom}^\bullet_A(T, -)$. Then, F is perverse with respect to $\mathcal{S}_\bullet$ and p.

Remark 2.29. One might ask whether all derived equivalences between finite dimensional symmetric algebras are compositions of perverse equivalences, or at least, if two derived equivalent symmetric algebras can be related by a sequence of perverse equivalences. Many of the derived equivalences in block theory are known to be compositions of perverse equivalences and it would be interesting to see if this is also the case for those of [70].

Remark 2.30. One can expect the equivalences predicted in Conjecture 2.20 will be perverse. The filtration should be provided by Lusztig's a-function.

We expect the action of $\mathrm{Free}(\mathcal{P}(\mathcal{S})) \rtimes \mathfrak{S}(\mathcal{S})$ on $\mathcal{T}$ relates to Bridgeland's space of stability conditions [15, §4].

Remark 2.31. The considerations above are interesting for Calabi–Yau algebras of positive dimension. Given I a subset of $\mathcal{S}$, one obtains a torsion theory that needs not always come from a tilting complex. When $r = 2$ and $|\mathcal{S}_2 - \mathcal{S}_1| = 1$, tilting has been known in string theory as Seiberg duality.

3. Invariants

Invariants of triangulated categories and dg-categories are discussed in [55, §6]. We discuss here some more elementary invariants, used to study finite dimensional algebras.

3.1. Automorphisms of triangulated categories

3.1.1. Rings. Let k be a commutative ring and A be a k-algebra. We denote by $\mathrm{Pic}(A)$ the group of isomorphism classes of invertible (A, A)-bimodules and by $\mathrm{DPic}(A)$ the group of isomorphism classes of invertible objects of the derived category of (A, A)-bimodules: this is the part of the automorphism group of $D(A\text{-Mod})$ that comes from standard equivalences. By Rickard's Theorem, $\mathrm{DPic}(A)$ is invariant under derived equivalences.

The following Proposition has been observed by many people (Rickard, Roggenkamp–Zimmermann, [93, Proposition 3.3], [103, Proposition 3.4],…).

Proposition 3.1. *If A is local, then* $\mathrm{DPic}(A) = \mathrm{Pic}(A) \times \langle A[1] \rangle$.

Given R a flat commutative Z-algebra, there is a canonical morphism $\mathrm{DPic}(A) \to \mathrm{DPic}(A \otimes_Z R)$ (joint work with A. Zimmermann [93, §2.4]). If R is faithfully flat over Z, the kernel of that map is contained in $\mathrm{Pic}(A)$. This is the key point for the following (cf. [103, Proposition 3.5] and [93, Proposition 3.3]):

Theorem 3.2. *Assume A is commutative and indecomposable. Then* $\mathrm{DPic}(A) = \mathrm{Pic}(A) \times \langle A[1] \rangle$.

3.1.2. Invariance of automorphisms. Let A be a finite dimensional algebra over an algebraically closed field k. We denote by $\mathrm{Aut}(A)$ the group of automorphisms of A. This is an algebraic group and we denote by $\mathrm{Inn}(A)$ its closed subgroup of inner automorphisms. We put $\mathrm{Out}(A) = \mathrm{Aut}(A)/\mathrm{Inn}(A)$. We have a morphism of groups $\mathrm{Aut}(A) \to \mathrm{Pic}(A)$, $\alpha \mapsto [A_\alpha]$, where $A_\alpha = A$ as a left A-module and the right action of $a \in A$ is given by right multiplication by $\alpha(a)$. It induces an injective morphism $\mathrm{Out}(A) \to \mathrm{Pic}(A)$.

The following result [91] gives a functorial interpretation of Out, to be compared with the functorial interpretation of $\mathrm{Pic}(X)$ for a smooth projective variety X.

Theorem 3.3. *The functor from the category of affine varieties over k to groups that sends X to the set of isomorphism classes of $(A \otimes A^{\mathrm{opp}} \otimes \mathcal{O}_X)$-modules that are locally free of rank 1 as $(A \otimes \mathcal{O}_X)$ and as $(A^{\mathrm{opp}} \otimes \mathcal{O}_X)$-modules is represented by* $\mathrm{Out}(A)$.

The following theorem [91] shows the invariance of Out^0, the identity component of Out, under certain equivalences. In the case of Morita equivalences, it goes back to Brauer, and for derived equivalences, it has been obtained independently by Huisgen-Zimmermann and Saorín [49]. In these cases, it follows easily from Theorem 3.3 while, for stable equivalences, some work is needed to get rid globally of projective direct summands.

Theorem 3.4. *Let B be a finite dimensional k-algebra and let C be a bounded complex of finitely generated (A, B)-bimodules inducing a derived equivalence or a stable equivalence (in which case we assume A and B are self-injective). Then there is a unique isomorphism of algebraic groups $\sigma : \mathrm{Out}^0(A) \xrightarrow{\sim} \mathrm{Out}^0(B)$ such that $A_\alpha \otimes_A C \simeq C \otimes_B B_{\sigma(\alpha)}$ for all $\alpha \in \mathrm{Out}^0(A)$.*

Yekutieli [104] deduces that $\mathrm{DPic}(A)$ has a structure of a locally algebraic group, with connected component $\mathrm{Out}^0(A)$.

3.1.3. Coherent sheaves. The following result [91] is a variant of Theorem 3.4.

Theorem 3.5. *Let X and Y be two smooth projective schemes over an algebraically closed field k. An equivalence $D^b(X) \xrightarrow{\sim} D^b(Y)$ induces an isomorphism* $\mathrm{Pic}^0(X) \rtimes \mathrm{Aut}^0(X) \xrightarrow{\sim} \mathrm{Pic}^0(Y) \rtimes \mathrm{Aut}^0(Y)$.

This implies in particular that if A and B are derived equivalent abelian varieties, then there is a symplectic isomorphism $\hat{A} \times A \xrightarrow{\sim} \hat{B} \times B$ (and the converse holds as well [71], [74]).

3.1.4. Automorphisms of stable categories and endo-trivial modules. Let A be a finite dimensional self-injective algebra over an algebraically closed field k. We denote by $\mathrm{StPic}(A)$ the group of isomorphism classes of invertible objects of $(A \otimes A^{\mathrm{opp}})$-$\overline{\mathrm{mod}}$.

Let P be an ℓ-group and k a field of characteristic ℓ. A finitely generated kP-module L is an *endo-trivial* module if $L \otimes_k L^* \simeq k$ in kP-$\overline{\mathrm{mod}}$ or equivalently, if $\mathrm{End}_{kP\text{-}\overline{\mathrm{mod}}}(L) = k$ [25]. Note that the classification of endo-trivial modules has been recently completed [27] (the case where P is abelian goes back to [34]).

Let $\mathcal{T}(kP)$ be the group of isomorphism classes of indecomposable endo-trivial modules. We have an injective morphism of groups

$$\mathcal{T}(kP) \to \mathrm{StPic}(kP),\ [L] \mapsto [\mathrm{Ind}_{\Delta P}^{P \times P^{\mathrm{opp}}} L].$$

This extends to an isomorphism $\mathcal{T}(kP) \times \mathrm{Out}(kP) \xrightarrow{\sim} \mathrm{StPic}(kP)$ ([64, §3] and [26, §2]).

Let Q be an ℓ-group. A stable equivalence of Morita type kP-$\overline{\mathrm{mod}} \xrightarrow{\sim} kQ$-$\overline{\mathrm{mod}}$ induces an isomorphism $\mathcal{T}(kP) \xrightarrow{\sim} \mathcal{T}(kQ)$. It actually forces the algebras kP and kQ to be isomorphic ([64, §3], [26, Corollary 2.4]). It is an open question whether this implies that P and Q are isomorphic.

Theorem 3.6 ([26, Theorem 3.2]). *Let P be an abelian ℓ-group and E a cyclic ℓ'-group acting freely on P. We put $G = P \rtimes E$. Then* $\mathrm{StPic}(kG) = \mathrm{Pic}(kG) \cdot \langle \Omega \rangle$. *In particular, the canonical morphism* $\mathrm{TrPic}(kG) \to \mathrm{StPic}(kG)$ *is surjective.*

Remark 3.7. Let A be a block over k of a finite group, with defect group isomorphic to P and $N_G(P)/P$ acting as E on P. From Theorem 3.6, one deduces [26, Corollary 4.4] via a construction of Puig [77], that a stable equivalence of Morita type between A and kG lifts to a Rickard equivalence if and only if A and kG are Rickard equivalent if and only if they are splendidly Rickard equivalent. In particular, for blocks with abelian defect group D such that $N_G(D, b_D)/C_G(D)$ is cyclic, then Conjecture 2.2 implies Conjecture 2.10.

3.2. Gradings. In this section, we describe results of [91].

3.2.1. Transfer of gradings. We assume we are in the situation of Theorem 3.4. Assume A is graded, *i.e.*, there is a morphism $\boldsymbol{G}_m \to \mathrm{Aut}(A)$. The induced morphism $\boldsymbol{G}_m \to \mathrm{Out}^0(A)$ induces a morphism $\boldsymbol{G}_m \to \mathrm{Out}^0(B)$. There exists a lift to a morphism $\boldsymbol{G}_m \to \mathrm{Aut}^0(B)$, and this corresponds to a grading on B. There is a grading on (an object isomorphic to) C that makes it into a complex of graded (A, B)-bimodules and it induces an equivalence between the appropriate graded categories.

Let A be a self-injective indecomposable graded algebra, let n be the largest integer such that $A_n \neq 0$, and let $C \in \mathbb{Z}[q, q^{-1}]$ be the graded Cartan matrix of A.

If A is non-negatively graded and the Cartan matrix of A_0 has non-zero determinant, then $\deg \det(C) = nr$, where r is the number of simple A-modules. As a consequence, one gets a positive solution of a "non-negatively graded" version of Conjecture 2.5:

Proposition 3.8. *Let A and B be two indecomposable self-injective non-negatively graded algebras. Assume A_0 has finite global dimension and there is a graded stable equivalence of Morita type between A and B. Then A and B have the same number of simple modules.*

Remark 3.9. Let A be a non-negatively graded indecomposable self-injective algebra with A_0 of finite global dimension. Let B be a stably equivalent self-injective algebra. One could hope that there is a compatible grading on B that is non-negative, but this is not possible in general. It would be still be very interesting to see if this can be achieved if the grading on A is "tight" in the sense of Cline–Parshall–Scott, *i.e.*, if $\bigoplus_{j \leq i} A_j = (JA)^i$ (cf. the gradings in § 3.2.2).

3.2.2. Blocks with abelian defect. Let P be an abelian ℓ-group and k an algebraically closed field of characteristic ℓ. The algebra kP is (non-canonically) isomorphic to the graded algebra associated to the radical filtration of kP. Fixing such an isomorphism provides a grading on kP. Let E be an ℓ'-group of automorphisms of P. Then the isomorphism above can be made E-equivariant and we obtain a structure of graded algebra on $kP \rtimes E$ extending the grading on kP and with kE in degree 0. Given a central extension of E by $k^\times$, this construction applies as well to the twisted group algebra $k_*P \rtimes E$.

Let A be a block of a finite group over k with defect group D. Then there is E and a central extension as above such that the corresponding block of $N_G(D)$ is Morita equivalent to $k_*D \rtimes E$ [60]. So, Conjecture 2.2 predicts there are interesting gradings on A. In the inductive approach to Conjecture 2.11, there is a stable equivalence of Morita type between A and $k_*D \rtimes E$, and we can provide A with a grading compatible with the equivalence (but we do not know if the grading can be chosen to be non-negative).

Remark 3.10. The gradings on blocks with abelian defect should satisfy some Koszulity properties (cf. [73], as well as work of Chuang). Turner [101] expects that gradings will even exist for blocks of symmetric groups with non abelian defect.

Remark 3.11. Using the equivalences in § 4.1, we obtain gradings on blocks of abelian defect of symmetric groups and on blocks of Hecke algebras over $\mathbb{C}$. One can expect the corresponding graded Cartan matrices to be given in terms of Kazhdan–Lusztig polynomials. So, the equivalences carry some "geometric meaning".

3.3. Dimensions

3.3.1. Definition and bounds. Let us explain how to associate a dimension to a triangulated category $\mathcal{T}$ (cf. [88]). For the derived category of a finite dimensional algebra, this is related to the Loewy length and to the global dimension, none of which are invariant under derived equivalences.

Given $\mathcal{U}_1$ and $\mathcal{U}_2$ two subcategories of $\mathcal{T}$, we denote by $\mathcal{U}_1 * \mathcal{U}_2$ the smallest full subcategory of $\mathcal{T}$ closed under direct summands and containing the objects M such that there is a distinguished triangle

$$M_1 \to M \to M_2 \rightsquigarrow$$

with $M_i \in \mathcal{U}_i$. Given $M \in \mathcal{T}$, we denote by $\langle M \rangle$ the smallest full subcategory of $\mathcal{T}$ containing M and closed under direct summands, direct sums, and shifts. Finally, we put $\langle M \rangle_0 = 0$ and define inductively $\langle M \rangle_i = \langle M \rangle_{i-1} * \langle M \rangle$.

The dimension of $\mathcal{T}$ is defined to be the smallest integer $d \geq 0$ such that there is $M \in \mathcal{T}$ with $\mathcal{T} = \langle M \rangle_{d+1}$ (we set $\dim \mathcal{T} = \infty$ if there is no such d). The notion of finite-dimensionality corresponds to Bondal–Van den Bergh's property of being strongly finitely generated [10].

Given a right coherent ring A, then $\dim D^b(A) \leq \operatorname{gldim} A$ (cf. [59, Proposition 2.6] and [88, Propositions 7.4 and 7.24]).

Let A be a finite dimensional algebra over a field k. Denote by $J(A)$ the Jacobson radical of A. The Loewy length of A is the smallest integer $d \geq 1$ such that $J(A)^d = 0$. We have $\dim D^b(A) < \text{Loewy length}(A)$.

Let X be a separated scheme of finite type over a perfect field k.

Theorem 3.12. *We have* $\dim D^b(X) < \infty$.

- *If X is reduced, then* $\dim D^b(X) \geq \dim X$.
- *If X is smooth and quasi-projective, then* $\dim D^b(X) \leq 2 \dim X$.
- *If X is smooth and affine, then* $\dim D^b(X) = \dim X$.

There does not seem to be any known example of a smooth projective variety X with $\dim D^b(X) > \dim X$, although this is expected to happen, for example when X is an elliptic curve (note nevertheless that $\dim D^b(\boldsymbol{P}^n) = n$).

Note that a triangulated category with finitely many indecomposable objects up to isomorphism has dimension 0. This applies to $D^b(kQ)$, where Q is a quiver of type ADE. This applies also to the orbit categories constructed by Keller (cf. [55, §4.9], [54, §8.4]). They depend on a positive integer d, and they are Calabi–Yau of dimension d.

When $\mathcal{T}$ is compactly generated, the property for $\mathcal{T}^c$ to be finite-dimensional can be viewed as a counterpart of having "finite global dimension".

3.3.2. Representation dimension. Auslander [5] introduced a measure for how far an algebra is from being representation finite. The example of exterior algebras below shows that this notion is pertinent. Let A be a finite dimensional algebra. The representation dimension of A is $\inf\{\mathrm{gldim}(A \oplus A^* \oplus M)\}_{M \in A\text{-mod}}$. This is known to be finite [50].

In [89], we show that this notion is related to the notion of dimension for associated triangulated categories. For example, $\dim D^b(A) \leq \mathrm{repdim}\, A$.

Let A be a non semi-simple self-injective k-algebra. We have

$$2 + \dim A\text{-}\overline{\mathrm{mod}} \leq \mathrm{repdim}\, A \leq \text{Loewy length}(A)$$

(the second inequality comes from [5, §III.5, Proposition]).

The following theorem is obtained by computing $\dim \Lambda(k^n)\text{-}\overline{\mathrm{mod}}$ via Koszul duality. It gives the first examples of algebras with representation dimension > 3.

Theorem 3.13. *Let n be a positive integer. We have* $\mathrm{repdim}\, \Lambda(k^n) = n + 1$.

Remark 3.14. One can actually show more quickly [59] that the algebra with quiver

and relations $x_i x_j = x_j x_i$ has representation dimension $\geq n$, using that its derived category is equivalent to $D^b(\boldsymbol{P}^n)$ [6].

Using the inequality above, one obtains the following theorem, which solves the prime 2 case of a conjecture of Benson.

Theorem 3.15. *Let G be a finite group and k a field of characteristic* 2. *If G has a subgroup isomorphic to $(\mathbb{Z}/2)^n$, then $n <$* Loewy length(kG).

4. Categorifications

This chapter discusses the categorifications of two structures, which are related to derived equivalences. We hope these categorifications will eventually lead to the construction of four-dimensional quantum field theories (as advocated in [33]), via the construction of appropriate tensor structures.

4.1. $\mathfrak{sl}_2$

4.1.1. Abelian defect conjecture for symmetric and general linear groups. Let G be a symmetric group and B an ℓ-block of kG with defect group D. Assume D is abelian and let $w = \log_\ell |D|$. In 1992, a three steps strategy was proposed for Conjecture 2.10 (inspired by the simpler character-theoretic part [84]):

- Rickard equivalence between $k(\mathbb{Z}/\ell \rtimes \mathbb{Z}/(\ell-1)) \wr \mathfrak{S}_w$ and the principal block of $k\mathfrak{S}_\ell \wr \mathfrak{S}_w$;
- Morita equivalence between the principal block of $k\mathfrak{S}_\ell \wr \mathfrak{S}_w$ and B_w;
- Rickard equivalence between B_w and B.

Here, B_w is a certain ℓ-block of symmetric groups (a "good block"). Scopes [94] has constructed a number of Morita equivalences between blocks of symmetric groups. For fixed w, there are only finitely many classes of blocks of symmetric groups up to Scopes equivalence, and B_w is defined to be the largest block that is not Scopes equivalent to a smaller block.

The first equivalence is deduced from an equivalence between the principal blocks of $\mathfrak{S}_\ell$ and $\mathbb{Z}/\ell \rtimes \mathbb{Z}/(\ell-1)$ via Clifford theory [68].

The second equivalence was established by Chuang and Kessar [28], the functor used is a direct summand of the induction functor.

The third equivalence is part of the general problem, raised by Broué, of constructing Rickard equivalences between two blocks of symmetric groups with isomorphic defect groups (equivalently, with same local structure). Rickard [80] constructed complexes of bimodules that he conjectured would solve that problem, generalizing Scopes construction (case where the complex has only one non-zero term). Rickard proved the invertibility of his complexes when they have two non-zero terms. The general case has proven difficult to handle directly.

Remark 4.1. The same strategy applies for general linear groups (in non-describing characteristic). Theorem 2.15 reduces the study to unipotent blocks. Step 2 above was handled in [69], [100]. As pointed out by H. Miyachi, this generalizes Puig's result [76] ($\mathrm{GL}_n(q)$, $\ell \mid (q-1)$).

Remark 4.2. "Good" blocks of symmetric groups have "good" properties. After the Morita equivalence theorem of [28], their properties were first analyzed by Miyachi [69], in the more complicated case of general linear groups: decomposition matrices and radical series of Specht modules were determined in the abelian defect case, by a direct analysis of the wreath product. As a consequence, decomposition matrices were known for good blocks of Hecke algebras in characteristic zero. For good blocks of symmetric groups with abelian defect, as well as for Hecke algebras in characteristic zero, a direct computation of the decomposition numbers is given in [52] (cf. also [51] for earlier results in that direction) and another approach is the determination of the relevant part of the canonical/global crystal basis [31], [32], [61].

For blocks of symmetric groups with non abelian defect, the decomposition matrices can be described in terms of decomposition matrices of smaller symmetric groups and remarkable structural properties are conjectured by Turner [101], [102], [72]. Good blocks have also been used by Fayers for the classification of irreducible Specht modules [40] and to show that blocks of weight 3 have decomposition numbers 0 or 1 (for $\ell > 3$) [41].

4.1.2. Fock spaces. Let us recall the Lie algebra setting for symmetric group representations (cf. e.g. [4]). Let $M = \bigoplus_{n\geq 0} \mathbb{Q} \otimes_{\mathbb{Z}} K_0(\mathbb{C}\mathfrak{S}_n\text{-mod})$. The complex irreducible representations of the symmetric group $\mathfrak{S}_n$ are parametrized by partitions of n and we obtain a basis of M parametrized by all partitions. We view M as a Fock space, with an action of $\hat{\mathfrak{sl}}_\ell$ and we recall a construction of this action, for the generators e_a and f_a (where $a \in \mathbb{F}_\ell$).

We have a decomposition

$$\mathrm{Res}^{\mathbb{F}_\ell\mathfrak{S}_n}_{\mathbb{F}_\ell\mathfrak{S}_{n-1}} = \bigoplus_{a\in\mathbb{F}_\ell} F_a,$$

where $F_a(M)$ is the generalized a-eigenspace of $X_n = (1,n)+(2,n)+\cdots+(n-1,n)$. Taking classes in K_0 and summing over all n, we obtain endomorphisms f_a of

$$V = \bigoplus_{n\geq 0} \mathbb{Q} \otimes_{\mathbb{Z}} K_0(\mathbb{F}_\ell\mathfrak{S}_n\text{-mod}).$$

Using induction, we obtain similarly endomorphisms e_a (adjoint to the f_a). The decomposition lifts to a decomposition of $\mathrm{Res}^{\mathbb{Z}_\ell\mathfrak{S}_n}_{\mathbb{Z}_\ell\mathfrak{S}_{n-1}}$ and we obtain endomorphisms e_a and f_a of M. The decomposition map $M \to V$ and the Cartan map $\bigoplus_{n\geq 0} \mathbb{Q} \otimes_{\mathbb{Z}} K_0(\mathbb{F}_\ell\mathfrak{S}_n\text{-proj}) \to M$ are morphisms of $\hat{\mathfrak{sl}}_\ell$-modules. The image of the Cartan map is the irreducible highest weight submodule L of M generated by $[\emptyset]$.

Let us note two important properties relating the module structure of V and the modular representation theory of symmetric groups:

- The decomposition of V into weight spaces corresponds to the block decomposition.
- Two blocks have isomorphic defect groups if and only if they are in the same orbit under the adjoint action of the affine Weyl group $\tilde{A}_{\ell-1}$.

In order to prove that two blocks of symmetric groups with isomorphic defect groups are derived equivalent, it is enough to consider a block and its image by a simple reflection s_a of $\tilde{A}_{\ell-1}$ (this involves only the $\mathfrak{sl}_2$-subalgebra generated by e_a and f_a). This is the situation in which Rickard constructed his complexes Θ_a.

Remark 4.3. These constructions extend to Hecke algebras of symmetric groups over $\mathbb{C}$, at an ℓ-th root of unity (here, $\ell \geq 2$ can be an arbitrary integer). In that situation, the classes of the indecomposable projective modules form the canonical/global crystal basis of L (Lascoux–Leclerc–Thibon's conjecture, proven by Ariki [3], cf. also [43]).

4.1.3. $\mathfrak{sl}_2$-categorifications. We describe here joint work with J. Chuang [29] (cf. also [90] for a survey and [44], [45], [7], [42] for related work). This is the special case of a more general theory under construction for Kac–Moody algebras.

Let k be an algebraically closed field and $\mathcal{A}$ a k-linear abelian category all of whose objects have finite composition series.

An $\mathfrak{sl}_2$-categorification on $\mathcal{A}$ is the data of

- (E, F) a pair of adjoint exact functors $\mathcal{A} \to \mathcal{A}$,
- $X \in \mathrm{End}(E)$, $T \in \mathrm{End}(E^2)$, $q \in k^\times$, and $a \in k$ (with $a \neq 0$ if $q \neq 1$)

satisfying the following properties:

- $[E]$ and $[F]$ give rise to a locally finite representation of $\mathfrak{sl}_2$ on $K_0(\mathcal{A})$,
- for S a simple object of $\mathcal{A}$, $[S]$ is a weight vector,
- F is isomorphic to a left adjoint of E,
- $(T\mathbf{1}_E) \circ (\mathbf{1}_E T) \circ (T\mathbf{1}_E) = (\mathbf{1}_E T) \circ (T\mathbf{1}_E) \circ (\mathbf{1}_E T)$,
- $(T + \mathbf{1}_{E^2}) \circ (T - q\mathbf{1}_{E^2}) = 0$,
- $T \circ (\mathbf{1}_E X) \circ T = \begin{cases} q(X\mathbf{1}_E) & \text{if } q \neq 1, \\ X\mathbf{1}_E - T & \text{if } q = 1, \end{cases}$
- $X - a\mathbf{1}_E$ is locally nilpotent.

From that data, we define two truncated powers $E^{(n,\pm)}$ (non-canonically isomorphic), using an affine Hecke algebra action on E^n. Following Rickard, we construct a complex Θ with terms $E^{(i,-)}F^{(j,+)}$.

The following theorem is proved by reduction to the case of "minimal categorifications", which are naturally associated to simple representations of $\mathfrak{sl}_2$.

Theorem 4.4. *Θ gives rise to self-equivalences of $K^b(\mathcal{A})$ and $D^b(\mathcal{A})$. This categorifies the action of $\left(\begin{smallmatrix} 0 & 1 \\ -1 & 0 \end{smallmatrix}\right)$ on $K_0(\mathcal{A})$.*

Remark 4.5. The self-equivalence Θ is perverse (cf. § 2.6), and this is a crucial point in the proof.

The construction of § 4.1.2 provides a structure of $\mathfrak{sl}_2$-categorification on $\mathcal{A} = \bigoplus_{n\geq 0} \overline{\mathbb{F}}_\ell \mathfrak{S}_n$-mod (for a given $a \in \mathbb{F}_\ell$). From the previous theorem, we deduce

Corollary 4.6. *Two blocks of symmetric groups with isomorphic defect groups are splendidly Rickard equivalent.*

Conjecture 2.10 *holds for blocks of symmetric groups.*

This corollary has a counterpart for $\mathrm{GL}_n(\mathbb{F}_q)$ and $\ell \nmid q$.

Remark 4.7. In general, there is a decomposition $\mathcal{A} = \bigoplus_\lambda \mathcal{A}_\lambda$ coming from the weight space decomposition of $K_0(\mathcal{A})$. There is a categorification of $[e, f] = h$ in the form of isomorphisms $EF_{|\mathcal{A}_\lambda} \xrightarrow{\sim} FE_{|\mathcal{A}_\lambda} \oplus \mathrm{Id}_{\mathcal{A}_\lambda}^{\oplus \lambda}$ (for $\lambda \geq 0$).

Remark 4.8. One can give a definition of $\mathfrak{sl}_2$-categorifications for triangulated categories and the definition above becomes a theorem that says that there is an induced categorification on $K^b(\mathcal{A})$ (and on $D^b(\mathcal{A})$).

Remark 4.9. One can also construct $\mathfrak{sl}_2$-categorifications on category $\mathcal{O}$ for $\mathfrak{gl}_n(\mathbb{C})$ and for rational representations of $\mathrm{GL}_n(\overline{\mathbb{F}}_p)$. One deduces from Theorem 4.4 that blocks with the same stabilizers under the affine Weyl groups are derived equivalent (a conjecture of Rickard).

Remark 4.10. The endomorphism X has different incarnations: Jucys–Murphy element, Casimir,….

Remark 4.11. It is expected that the functors Θ_a constructed for $a \in \mathbb{F}_\ell$ provide an action of the affine braid group $B_{\tilde{A}_{\ell-1}}$ on $\bigoplus_n D^b(\mathbb{F}_\ell \mathfrak{S}_n)$.

4.2. Braid groups

4.2.1. Definition. We present here a categorification of braid groups associated to Coxeter groups, following [90]. This should be useful for the study of categories of representations of semi-simple Lie algebras, affine Lie algebras, simple algebraic groups over an algebraically closed field,... On the other hand, work of Khovanov [56] shows its relevance for invariants of links (type A), cf. also [98].

Let (W, S) be a Coxeter group, with S finite. Let V be its reflection representation over $\mathbb{C}$ and let B_W be the braid group of W. Let $A = \mathbb{C}[V]$. Given $s \in S$, let $F_s = 0 \to A \otimes_{A^s} A \xrightarrow{\text{mult}} A \to 0$, where A is in degree 1. This is an invertible object of $K^b(A \otimes A)$. Given two decompositions of an element of B_W in a product of the generators and their inverses, we construct a canonical isomorphism between the corresponding products of F_s. The system of isomorphism coming from the various decompositions of an element $b \in B_W$ is transitive and, taking its limit, we obtain an element $F_b \in K^b(A \otimes A)$. The full subcategory of $K^b(A \otimes A)$ with objects the F_b's defines a strict monoidal category $\mathcal{B}_W$.

We expect that there is a simple presentation of $\mathcal{B}_W$ by generator and relations (or rather of a related 2-category involving subsets of S). This should be related to the vanishing of certain Hom-spaces, for example $\mathrm{Hom}_{K^b(A\otimes A)}(F_b, F_{b'}^{-1}[i])$ should be 0 when b and b' are the canonical lifts of distinct elements of W.

Remark 4.12. The bimodules obtained by tensoring the $A \otimes_{A^s} A$ are Soergel's bimodules. Soergel showed they categorify the Hecke algebra of W. He also conjectured that the indecomposable objects correspond to the Kazhdan–Lusztig basis of W [96], [97].

Remark 4.13. When W is finite, one can expect that there is a construction of $\mathcal{B}_W$ that does not depend on the choice of S. Such a construction might then make sense for complex reflection groups.

4.2.2. Representations and geometry. Let $\mathfrak{g}$ be a complex semi-simple Lie algebra with Weyl group W and let $\mathcal{O}_0$ be the principal block of its category $\mathcal{O}$. It has been widely noticed that there is a weak action of B_W on $D^b(\mathcal{O})$, using wall-crossing

functors. We show that there is a genuine action of B_W on $D^b(\mathcal{O}_0)$ and there is a much more precise statement: there is a monoidal functor from $\mathcal{B}_W$ to the category of self-equivalences of $D^b(\mathcal{O}_0)$. This has a counterpart for the derived category of B-equivariant sheaves on the flag variety (in which case the genuine action of the braid group goes back to [36]). These actions are compatible with Beilinson–Bernstein's equivalence. Conversely, a suitable presentation of $\mathcal{B}_W$ by generators and relations should provide a quick proof of that equivalence (and of affine counterparts), in the spirit of Soergel's construction. The representation-theoretic and the geometrical categories should be viewed as two realizations of the same "2-representation" of $\mathcal{B}_W$. Also, this approach should give a new proof of the results of [2] comparing quantum groups at roots of unity and algebraic groups in characteristic p.

Algorithmic and asymptotic properties of groups

Mark Sapir*

Abstract. This is a survey of the recent work in algorithmic and asymptotic properties of groups. I discuss Dehn functions of groups, complexity of the word problem, Higman embeddings, and constructions of finitely presented groups with extreme properties (monsters).

Mathematics Subject Classification (2000). Primary 20F65; Secondary 20F10.

Keywords. Turing machine, S-machine, Dehn function, Higman embedding, conjugacy problem, amenable group.

1. Introduction

Although the theory of infinite groups is very rich and full of powerful results, there are very few results having more influence on group theory and surrounding areas of mathematics (especially geometry and topology) as the following five.

- The Boone–Novikov theorem about existence of finitely presented groups with undecidable word problem [8], [35].
- The Higman theorem about embeddability of recursively presented groups into finitely presented groups [28];
- The Adian–Novikov solution of the Burnside problem [36].
- Gromov's theorem about groups with polynomial growth [23].
- Olshanskii and his students' theorems about existence of groups with all proper subgroups cyclic (Tarski monsters), and other finitely generated groups with extreme properties [38].

In this paper, I am going to survey the last ten years of my work on the topics related to these results.

Acknowledgement. Most of the work surveyed here is joint with J.-C. Birget, C. Druţu, V. Guba, A. Olshanskii and E. Rips. I am very grateful to them for cooperation.

2. *S*-machines

Recall that a Turing machine, say, with one tape is a triple (Y, Q, Θ) where Y is a tape alphabet, Q is the set of states, Θ is a set of commands (transitions) of the form $\theta = [U \to V]$ where U has the form vqu and V has the form $v'q'u'$. Here u, v, u' and v' are words in the tape alphabet, $q, q' \in Q$. A *configuration* of the Turing machine is a word wqw' where w, w' are words in the tape letters, q is a state letter. To apply the command $[U \to V]$ to a configuration, one has to replace U by V.

In order to specify a Turing machine with many tapes, one needs several disjoint sets of state letters. A *configuration* of the machine is a word of the form $u_1q_1u_2 \dots u_Nq_Nu_{N+1}$ where q_i are state letters, u_i are words in tape letters. Of course one needs to separate tapes. That can be done by using the special symbols (endmarkers) marking the beginning and the end of each tape. But these symbols can be treated as state letters as well. Every transition has the form $[U_1 \to V_1, \dots, U_N \to V_N]$, where $[U_i \to V_i]$ is a transition of a 1-tape machine.

Among all configurations of a machine M, one chooses one *accept* configuration W. Then a configuration W_1 is called *accepted* if there exists a *computation* $W_1 \to W_2 \to \dots \to W_n = W$ where each step consists in application of a command of W.

Recall that the time function of a (non-deterministic) Turing machine is the smallest function $f(n)$ such that every accepted input w of size at most n requires at most $f(n)$ steps of the machine to be accepted.

The "common denominator" of the proofs of most of the results I am reviewing here is the notion of an S-machine that I introduced in [50]. Roughly speaking, S-machines make building groups with prescribed properties as easy as programming a Turing machine.

Essentially, an S-machine is simply an HNN-extension of a free group, although not every HNN-extension of a free group is an S-machine.

Let us start with an example that we shall call the *Miller machine*. It is the famous group of C. Miller [34]. Let $G = \langle X \mid R \rangle$ be a finitely presented group. The Miller machine is the group $M(G)$ generated by $X \cup \{q\} \cup \{\theta_x \mid x \in X\} \cup \{\theta_r \mid r \in R\}$ subject to the following relations

$$\theta x = x\theta, \quad \theta_x xq = qx\theta_x, \quad \theta_r q = qr\theta_r$$

where θ is any letter in $\Theta = \{\theta_x \mid x \in X\} \cup \{\theta_r \mid r \in R\}$. Clearly, this is an HNN-extension of the free group $\langle X, q\rangle$ with free letters $\theta \in \Theta$. The main feature of $M(G)$ discovered by Miller is that $M(G)$ *has undecidable conjugacy problem provided* G *has undecidable word problem.* In fact it is easy to see that qw is conjugated to q in $M(G)$ if and only if $w = 1$ in G.

To see that $M(G)$ can be viewed as a machine, consider any word uqv where u, v are words in $X \cup X^{-1}$. If we conjugate uqv by θ_r, we get the word $uqrv$ because $\theta_r q = qr\theta_r$ and θ_r commutes with u and v (here and below we do not distinguish words that are freely equal). Hence conjugation by θ_r amounts to executing

a command $[q \to qr]$. Similarly, conjugation by θ_x amounts to executing a command $[q \to x^{-1}qx]$. If u ends with x, then executing this command means moving q one letter to the left. Thus conjugating words of the form uqv by θ's and their inverses, we can move the "head" q to the left and to the right, and insert relations from R.

The work of the Miller machine $M(G)$ can be drawn in the form of a diagram (see Figure 1) that we call a *trapezium*. It is a tessellation of a disc. Each cell corresponds to one of the relations of the group. The bottom layer of cells in Figure 1 corresponds to the conjugation by θ_x, the next layer corresponds to the conjugation by θ_r, etc. These layers are the so-called θ*-bands*. The bottom side of the boundary of the trapezium is labeled by the first word in the computation (uqv), the top side is labeled by the last word in the computation (q), the left and the right sides are labeled by the *history of computation*, the sequence of θ's and their inverses corresponding to the commands used in the *computation* $uqv \to \cdots \to q$. The words written on the top and bottom sizes of the θ-bands are the intermediate words in the computation. We shall always assume that they are freely reduced.

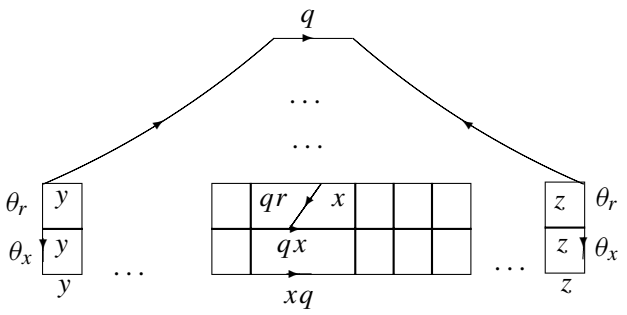

Figure 1. Trapezium of the Miller machine for a deduction $uqv \to \cdots \to q$. Here $u = y \dots x$, $v = \dots z$.

The Miller machine has one tape and one state letter. General S-machines can have many tapes and many state letters. Here is a formal definition.

Let $F(Q, Y)$ be the free group generated by two sets of letters $Q = \bigcup_{i=1}^{N} Q_i$ and $Y = \bigcup_{i=1}^{N-1} Y_i$ where Q_i are disjoint and non-empty (below we always assume that $Q_{N+1} = Q_1$, and $Y_N = Y_0 = \emptyset$).

The set Q is called the set of q-letters, the set Y is called the set of a-letters.

In order to define an HNN-extension, we consider also a collection Θ of N-tuples of θ-letters. Elements of Θ are called *rules*. The components of θ are called *brothers* $\theta_1, \dots, \theta_N$. We always assume that all brothers are different. We set $\theta_{N+1} = \theta_1$, $Y_0 = Y_N = \emptyset$.

With every $\theta \in \Theta$, we associate two sequences of elements in $F(Q \cup Y)$: $B(\theta) = [U_1, \dots, U_N]$, $T(\theta) = [V_1, \dots, V_N]$, and a subset $Y(\theta) = \cup Y_i(\theta)$ of Y, where $Y_i(\theta) \subseteq Y_i$.

The words U_i, V_i satisfy the following restriction:

(*) For every $i = 1, \dots, N$, the words U_i and V_i have the form

$$U_i = v_{i-1} k_i u_i, \quad V_i = v'_{i-1} k'_i u'_i$$

where $k_i, k'_i \in Q_i$, u_i and u'_i are words in the alphabet $Y_i^{\pm 1}$, v_{i-1} and v'_{i-1} are words in the alphabet $Y_{i-1}^{\pm 1}$.

Now we are ready to define an S-machine $\mathcal{S}$ by generators and relations. The generating set X of the S-machine $\mathcal{S}$ consists of all q-, a- and θ-letters. The relations are:

$$U_i \theta_{i+1} = \theta_i V_i, \ i = 1, \dots, s, \quad \theta_j a = a \theta_j$$

for all $a \in Y_j(\theta)$. The first type of relations will be called (q, θ)-*relations*, the second type (a, θ)-*relations*.

Sometimes we will denote the rule θ by $[U_1 \to V_1, \dots, U_N \to V_N]$. This notation contains all the necessary information about the rule except for the sets $Y_i(\theta)$. In most cases it will be clear what these sets are: they are usually equal to either Y_i or $\emptyset$. By default $Y_i(\theta) = Y_i$.

Every S-rule $\theta = [U_1 \to V_1, \dots, U_s \to V_s]$ has an inverse $\theta^{-1} = [V_1 \to U_1, \dots, V_s \to U_s]$; we set $Y_i(\theta^{-1}) = Y_i(\theta)$.

Remark 2.1. Every S-machine is indeed an HNN-extension of the free group $F(Y, Q)$ with finitely generated associated subgroups. The free letters are θ_1 for every $\theta \in \Theta$. We leave it as an exercise to find the associated subgroups.

Every Turing machine T can be considered as an S-machine $S'(T)$ in the natural way: the generators of the free group are all tape letters and all state letters. The commands of the Turing machine are interpreted as rules of the S-machine. The main problem in that conversion is the following: there is a much bigger freedom in applying S-rules than in executing the corresponding commands of the Turing machine. Indeed, the Turing machine is in general not *symmetric* (i.e. if $[U \to V]$ is a command of the Turing machine then $[V \to U]$ is usually not) while every S-machine is symmetric. Another difference is that Turing machines work only with positive words, and S-machines work with arbitrary group words. Hence the language accepted by $S'(T)$ is usually much bigger than the language accepted by T.

Nevertheless, it can be proved that if T is symmetric, and a computation $w_1 \to w_2 \to \cdots$ of the S-machine $S'(T)$ involves only positive words, then that is a computation of T.

This leads to the following idea of converting any Turing machine T into an S-machine $S(T)$. First we construct a symmetric Turing machine T' that is equivalent to T (recognizes the same language). That is a fairly standard Computer Science trick (see [50]): the machine T' first guesses a computation of T, then executes it,

then erases all the tapes. Note that the time function and the space function of T' are equivalent to the time function of T.

The second step is to compose the S-machine $S'(T')$ with a machine that checks positivity of a word. That machine starts working after every step of $S'(T')$. That is if an application of a rule of $S'(T')$ gives a non-positive (reduced) word then the checking machine does not allow the machine $S'(T')$ to proceed to the next step.

There are several checking machines. One of them – the *adding machine* – is very simple but its time function is exponential (see [42]). Another one is very complicated but it has a quadratic time function (see [50]).

Here is the definition of the adding machine. We present it here also in order to show an example of a program of an S-machine. It is not difficult to program an S-machine, but it does require some practice.

Let A be a finite set of letters. Let the set A_1 be a copy of A. It will be convenient to denote A by A_0. For every letter $a_0 \in A_0$, a_1 denotes its copy in A_1. The set of state letters of the adding machine $Z(A)$ is $P_1 \cup P_2 \cup P_3$ where $P_1 = \{L\}$, $P_2 = \{p(1), p(2), p(3)\}$, $P_3 = \{R\}$. The set of tape letters is $Y_1 \cup Y_2$ where $Y_1 = A_0 \cup A_1$ and $Y_2 = A_0$.

The adding machine $Z(A)$ has the following rules (there a is an arbitrary letter from A) and their inverses. The comments explain the meanings of these rules.

- $r_1(a) = [L \to L,\ p(1) \to a_1^{-1} p(1) a_0,\ R \to R]$.

  Comment. The state letter $p(1)$ moves left searching for a letter from A_0 and replacing letters from A_1 by their copies in A_0.

- $r_{12}(a) = [L \to L,\ p(1) \to a_0^{-1} a_1 p(2),\ R \to R]$.

  Comment. When the first letter a_0 of A_0 is found, it is replaced by a_1, and p turns into $p(2)$.

- $r_2(a) = [L \to L,\ p(2) \to a_0 p(2) a_0^{-1},\ R \to R]$.

  Comment. The state letter $p(2)$ moves toward R.

- $r_{21} = [L \to L,\ p(2) \to p(1),\ R \to R]$, $Y_1(r_{21}) = Y_1$, $Y_2(r_{21}) = \emptyset$.

  Comment. $p(2)$ and R meet, the cycle starts again.

- $r_{13} = [L \to L,\ p(1) \to p(3),\ R \to R]$, $Y_1(r_{13}) = \emptyset$, $Y_2(r_{13}) = A_0$.

  Comment. If $p(1)$ never finds a letter from A_0, the cycle ends, $p(1)$ turns into $p(3)$; p and L must stay next to each other in order for this rule to be executable.

- $r_3(a) = [L \to L,\ p(3) \to a_0 p(3) a_0^{-1},\ R \to R]$, $Y_1(r_3(a)) = Y_2(r_3(a)) = A_0$.

  Comment. The letter $p(3)$ returns to R.

The underlying algorithm of the adding machine is simple: the machine starts with a word $Lwp(1)R$, where w is a word in $A \cup A^{-1}$, L, $p(1)$, R are state letters. It

considers the sequence of indexes of the letters in w as a binary number. The initial number is 0. The machine proceeds by adding 1 to this number until it produces $2^n - 1$ where n is the length of the word (each cycle of the machine adds a 1). After that, the machine returns the word to its initial state (all indexes are 0). If the initial word contained a negative letter, the state letter of the adding machine never becomes $p(3)$.

To compose a checking machine Z with an S-machine $\mathcal{S}$ means inserting state letters of Z between any two consecutive state letters of $\mathcal{S}$, and changing the rules of $\mathcal{S}$ in an appropriate way: every rule of $\mathcal{S}$ "turns on" the checking machines. After they finish their work, $\mathcal{S}$ can apply another rule (provided the word is still positive). If Z is a checking machine then the composition of $\mathcal{S}$ and Z is denoted by $\mathcal{S} \circ Z$.

The following results from [50] are very important for the applications. The equivalence of S-machines, their time functions, space functions, etc. are defined as for ordinary Turing machines.

We say that two increasing functions $f, g\colon \mathbb{Z}_+ \to \mathbb{Z}_+$ are equivalent if

$$\frac{1}{C} g\left(\frac{n}{C}\right) - Cn \le f(n) \le Cg(Cn) + Cn \tag{1}$$

for some constant C. We are not going to distinguish equivalent functions in this note. Thus $n^{3.2}$ is the same as $5n^{3.2}$ but different from $n^{3.2} \log n$.

Theorem 2.2 (Sapir, [50]). *Let T be a Turing machine. Then there exists an S-machine $\mathcal{S}$ that is polynomially equivalent to T. Moreover the time function of $\mathcal{S}$ is equivalent* (*in the sense of* (1)) *to the cube of the time function of T, the space function of $\mathcal{S}$ is equivalent to the time function of T.*

Moreover, one can use Miller's machines to simulate any Turing machine.

Theorem 2.3 (Sapir, [45]). *For every Turing machine T there exists a finitely presented group G such that the Miller machine $M(G)$ is polynomially equivalent to T.*

Thus any Turing machine can be effectively simulated by an S-machine with one tape and only one state letter.

3. Dehn functions and the word problem

3.1. The definition. Let $G = \langle X \mid R \rangle$ be a finitely presented group. We shall always assume that $X = X^{-1}$, R is a collection of words in the alphabet X closed under taking inverses and cyclic shifts, i.e. if $r \in R$, $r \equiv ab$ then $r^{-1} \in R$ and $ba \in R$.

The word problem in G asks, given a word w in X (i.e. a product of generators of G), whether w is equal to 1 in G. Clearly, the word problem in all "ordinary" groups is algorithmically decidable. For example, if the group is linear, then in order to check if $w = 1$, one can just multiply matrices representing the generators of G in the order of their appearance in w.

About 70 years ago, van Kampen noticed that $w = 1$ in G if and only if one can tessellate a disc with boundary labeled by w by tiles (cells) whose boundaries are labeled by words in R.

That tessellation is called a *van Kampen* diagram for w. It is also sometimes called *Dehn* or *disc* diagram of w. For example, the trapezium in Figure 1 is a van Kampen diagram over the S-machine $M(G)$ with boundary label $huqvh^{-1}q^{-1}$ where h is the history of the computation.

For every $w = 1$ in G, the area $\mathrm{a}(w)$ is the smallest number of cells in the van Kampen diagram for w, or the simplicial area of the (null-homotopic) loop labeled by w in the Cayley complex Cayley(G, X). Combinatorially, that is the smallest number of factors in any representation of w as a product of conjugates of the words from R. From the logic point of view, that is the length of the shortest "proof" that $w = 1$ in G (steps of the "proof" are insertions of relations from R into W).

It is easy to see that the word problem in G is decidable if and only if the area of a word w representing 1 in G is bounded from above by a recursive function in the length of w. Madlener and Otto [33] and, independently, Gersten [19] introduced a very basic characteristic of the algorithmic complexity of a group G, the Dehn function $\delta_G(n)$ of G: *it is the smallest function $d(n)$ such that the area of a word w of length $\leq n$ representing* 1 *in G does not exceed $d(n)$*. Of course $\delta_G(n)$ depends on the choice of generating set X. But Dehn functions corresponding to different generating sets are *equivalent* in the sense of (1). Similarly, one can introduce the *isodiametric function* of G by looking at the diameter of van Kampen diagrams instead of their areas.

For example, the area of the trapezium in Figure 1 is approximately $|h|$ times the length of the longest θ-band in that trapezium, that can be interpreted as the product of the time of the computation by its space. That observation is the key to converting properties of the S-machine into the properties of the Dehn function.

3.2. The description. Dehn functions reflect in an easy and natural way both geometric and algorithmic properties of a group, so it is natural to ask which functions appear as Dehn functions of groups.

The first observation is not difficult.

Theorem 3.1 (See [50, Theorem 1.1]). *Every Dehn function of a finitely presented group G is* (*equivalent to*) *the time function of a Turing machine solving* (*non-deterministically*) *the word problem in G.*

The proof of this theorem in [50] is more complicated than it should have been. An easier proof can be obtained by using [45, Lemma 1].

Not every increasing function can be equivalent to a time function of a Turing machine. For example, if a time function $f(n)$ does not exceed a recursive function then it must be recursive. On the other hand, any "natural" function is the time function of a Turing machine. In particular, if $f(n)$ can be computed in time $\leq f(n)$ then $f(n)$ is the time function of a deterministic Turing machine computing $f(n)$.

By a theorem proved by Gromov and Olshanskii among others, every finitely presented group with subquadratic Dehn function is in fact hyperbolic, so its Dehn function is linear. It is possible to deduce from a result of Kapovich and Kleiner [29] that if the Dehn function is subquadratic even on an infinite subset of natural numbers then the group is still hyperbolic. Dehn functions of nilpotent groups are bounded by a polynomial [5]. Another source of groups with polynomial Dehn function is the class of groups with simply connected asymptotic cones (Gromov, [24]). Moreover if the asymptotic cones are simply connected then the isodiametric function of the group is linear.

Recall that the asymptotic cone of a group G (see [24], [16] or [18]) is the ultralimit (or Gromov–Hausdorff limit) of a sequence X/d_i where X is a Cayley graph of G, $\lim d_i = \infty$, X/d_i is the metric space X with distance function divided by d_i [23]. Asymptotic cones capture "global" geometric properties of the group G.

Of a particular interest are groups with quadratic Dehn function. That class of groups includes the classes of automatic groups and CAT(0)-groups. Higher dimensional Heisenberg groups [3], [43] and some solvable non-virtually nilpotent groups [17] also have quadratic Dehn functions. That class contains more complicated groups as well. The most striking example so far is the R. Thompson group

$$F = \langle x_0, x_1 \mid x_1^{x_0^2} = x_1^{x_0 x_1}, x_1^{x_0^3} = x_1^{x_0^2 x_1} \rangle$$

where $a^b = b^{-1}ab$. Recall that F is the group of all piecewise linear increasing self-homeomorphisms of the unit interval with finitely many dyadic singular points and all slopes powers of 2. Guba showed in [25] that F has a quadratic Dehn function. One of the most interesting unsolved problems about this class is whether $\mathrm{SL}_n(\mathbb{Z})$ belongs to it for $n \geq 4$.

A very non-trivial result of Bridson and Groves [11] shows that every cyclic extension of a finitely generated free group has quadratic Dehn function. On the other hand, Olshanskii and I proved [42] that HNN extensions of free groups having undecidable conjugacy problem must have Dehn function at least $n^2 \log n$. Together with the result of Bridson and Groves it gives another proof of decidability of the conjugacy problem for cyclic extensions of free groups [7].

It is still unknown whether every group with quadratic Dehn function has decidable conjugacy problem. Olshanskii and I gave a "quasi-proof" of that in [42].

I think that it is most probable that the class of Dehn functions $\geq n^2 \log n$ is as wide as the class of time functions of Turing machines. The next theorem confirms that conjecture in the case of Dehn functions $\geq n^4$.

Theorem 3.2 (See [50]). 1. *Let $\mathcal{D}_4$ be the set of all Dehn functions $d(n) \geq n^4$ of finitely presented groups. Let $\mathcal{T}_4$ be the set of time functions $t(n) \geq n^4$ of arbitrary Turing machines. Let $\mathcal{T}^4$ be the set of superadditive functions which are fourth powers of time functions. Then*

$$\mathcal{T}^4 \subseteq \mathcal{D}_4 \subseteq \mathcal{T}_4.$$

2. *For every time function $T(n)$ of a non-deterministic Turing machine with superadditive $T^4(n)$ there exists a finitely presented group G with Dehn function $T^4(n)$ and the isodiametric function $T^3(n)$.*

Recall that a function f is superadditive if $f(n+m) \geq f(m) + f(n)$ for any m, n. The question of whether all Dehn functions are superadditive is one of the unsolved mysteries of the subject. Together with Victor Guba [26], we proved that *the Dehn function of any non-trivial free product is superadditive.* Thus if there are non-superadditive Dehn functions then there are groups G such that G and $G * \mathbb{Z}$ have different Dehn functions!

Theorem 3.2 has many corollaries. For example, it implies that the *isoperimetric spectrum*, i.e. the set of α's such that $\lfloor n^\alpha \rfloor$ is a Dehn function, contains all numbers $\alpha \geq 4$ whose n-th digit can be computed by a deterministic Turing machine in time less than 2^{2^n}. All "constructible" numbers (rational numbers, algebraic numbers, values of elementary functions at rational points, etc.) satisfy this condition. On the other hand, Theorem 3.1 implies that if α is in the isoperimetric spectrum then the n-th digit of α can be computed in time $\leq 2^{2^{2^n}}$ (see [50] for details). The difference in the number of 2's in these expressions, is the difference between P and NP in Computer Science (if $P = NP$ then there should be two 2's in both expressions).

Note that before [50] has been submitted to Annals of Mathematics (in 1997), only a discrete set of non-integer numbers in the isoperimetric spectrum was known [10]. By the time the paper appeared in print (2002), that set increased by a dense subset in $[2, \infty)$ [9]. Groups in [10] with Dehn functions $\lfloor n^\alpha \rfloor$, $\alpha \notin \mathbb{N}$, have easier presentations than groups based on S-machines having the same Dehn functions, but the construction in [10], [9] is far from universal, and one cannot expect anything like Theorem 3.2 proved using their methods.

Other applications of Theorem 3.2 are:

- the first example of a finitely presented group with NP-complete word problem,
- examples of finitely presented groups with easy word problem (solvable in quadratic time) and arbitrary large (recursive) Dehn functions.

3.3. The proof. Here is how our construction from [50] works. Take any Turing machine M. Let M' be the symmetric Turing machine described above. Let $S(M')$ be the S-machine obtained as a composition of $S'(M')$ with a positivity checking S-machine from [50] working in quadratic time. The time function of $S(M')$ is T^3 and the space function is T where T is the time function of M. We can assume that the accepting configuration of $S(M')$ is some fixed word W of the form $k_1 w_1 k_2 w_2 \dots k_N$ where $N > 8$ (for some small cancellation reasons) and all w_i are copies of each other written in disjoint alphabets and containing no tape letters. That can be achieved by taking N copies of the initial Turing machine and making all of them work in parallel. Finally add one *hub* relation $W = 1$ to the S-machine $S(M')$. The resulting

group $G(M)$ has Dehn function T^4 provided T^4 is superadditive, and isodiametric function T^3.

The main idea of the proof is the following. Take the standard trapezium corresponding to a computation $W_1 \to \cdots \to W_n = W$, identify its left and right sides (which have the same label). The resulting diagram has one hole with boundary label W. Insert the cell corresponding to the hub relation $W = 1$ into the hole. The result is a van Kampen diagram, called a *disc corresponding to the equality* $W_1 = 1$. The area of that diagram is equal to the area of the trapezium (plus 1). So it is equivalent to the product of the time of the computation by its space. The diameter of the disc with perimeter $\leq n$ is the time of the computation. Hence the worst area we can get is T^4, and the worst diameter is T^3. That gives the lower bound of the Dehn function and the isodiametric function. The upper bound is obtained by using certain surgeries on van Kampen diagrams. It turns out that every van Kampen diagram over the group $G(M)$ can be decomposed into a few discs and a diagram whose area is at most cubic (with respect to the perimeter of the original diagram). Thus if the area of a van Kampen diagram is large then most of the area is concentrated in the discs. It turns out also that the sum of the perimeters of the discs does not exceed a constant multiple of the perimeter of the diagram. This gives the desired upper bound of T^4 for the Dehn function (it is in this part of the proof where the superadditivity of T^4 is used) and T^3 for the isodiametric function.

3.4. The Dehn functions of *S*-machines and chord diagrams. It is easy to see that the Dehn function of an S-machine is at most cubic. Indeed, every van Kampen diagram with perimeter of length n over the presentation of an S-machine is covered by θ-bands that start and end on the boundary. There are also q-bands composed of (q, θ)-cells, and a-bands composed of the commutativity (a, θ)-cells. It can be proved that every θ-band intersects a q-band (an a-band) at most once. Hence the total number of (q, θ)-cells is at most n^2. Every other cell is an (a, θ)-cell. Each a-band starts on the boundary of the diagram or on the boundary of a (q, θ)-cell, so the total number of such bands is at most n^2 and the length of each of them is at most n. Hence the total area is at most n^3.

It was conjectured by Rips and myself that the Dehn function of an S-machine should in fact depend on the program of the S-machine. We thought that S-machines should provide examples of groups with Dehn functions strictly between n^2 and n^3. It turned out to be the case. In particular, Olshanskii and I proved in [42] that if $\mathcal{A}$ is any S-machine accepting language L, then the composition $\mathcal{A} \circ Z(A)$ of $\mathcal{A}$ and the adding machine has Dehn function at most $n^2 \log n$ and accepts the same language L. Hence we get the following result.

Theorem 3.3 ([42]). *There exists an S-machine with undecidable conjugacy problem and Dehn function* $n^2 \log n$.

The idea of analyzing van Kampen diagrams over S-machines is to show that if the area of a diagram is large then "most" of the area is inside large subtrapezia, and then

analyze trapezia (i.e. computations of the S-machines). Note that in a trapezium, every θ-band intersects every q-band, thus the band structure of a trapezium is somewhat regular. In order to analyze irregular diagrams, Olshanskii introduced a measure of irregularity, the *dispersion*. In fact, the dispersion is an invariant of the *cord diagram* associated with every van Kampen diagram over an S-machine: the role of chords is played by the θ-bands (T-chords) and the q-bands (Q-chords). It is similar to a Vassiliev invariant of knots.

As I mentioned before, $n^2 \log n$ is the smallest Dehn function of an HNN extension of a free group with undecidable conjugacy problem. If the undecidability condition is dropped, one can construct Dehn functions strictly between n^2 and $n^2 \log n$. In particular, Olshanskii [40] constructed an *S-machine with non-quadratic Dehn function bounded from above by a quadratic function on arbitrary long intervals.* This gives the first example of a finitely presented group with two non-homeomorphic asymptotic cones [41]: *one of the asymptotic cones of this group is simply connected, and another one is not.*

Non-finitely presented groups with "very many" asymptotic cones are constructed in [18] using completely different methods.

Theorem 3.4 (Druţu, Sapir [18]). *There exist finitely generated groups with continuously many* (*maximal theoretically possible if the Continuum Hypothesis is true* [32]) *non-homeomorphic asymptotic cones.*

It is very interesting whether one can replace "finitely generated" by "finitely presented" in Theorem 3.4. One can try to use Higman embeddings from Section 4 to construct such examples.

3.5. Non-simply connected asymptotic cones. Note that Theorem 3.2 gave some of the first examples of groups with polynomial Dehn function and non-simply connected asymptotic cones because their Dehn functions can be polynomial (if the original Turing machine had polynomial time function) while their isodiametric functions are not linear. The first examples of groups with polynomial (cubic) Dehn functions, linear isodiametric functions and non-simply connected asymptotic cones were given in [44]. That answered a question of Druţu from [16].

The groups in [44] are S-machines. The easiest example is this:

$$G = \langle \theta_1, \theta_2, a, k \mid a^{\theta_i} = a, k^{\theta_i} = ka, i = 1, 2 \rangle.$$

The S-machine has one tape letter, one state letter and two rules $[k \to ka]$ (and their inverses).

There is also an S-machine with Dehn function $n^2 \log n$ satisfying the same asymptotic properties. Note that $n^2 \log n$ cannot be lowered to n^2 because of a result of Papasoglu [49]: *all groups with quadratic Dehn functions have simply connected asymptotic cones.*

If a group has non-simply connected asymptotic cone, it is natural to ask what is its fundamental group. We do not know what are the fundamental groups of asymptotic

cones of S-machines. These groups may provide some interesting invariants of S-machines and Turing machines, so it is worthwhile studying them.

The following theorem gives a partial answer to the question of what kind of groups can be fundamental groups of asymptotic cones of finitely generated groups.

Theorem 3.5 ([18]). *For every countable group C there exists an asymptotic cone of a finitely generated group G whose fundamental group is isomorphic to the free product of continuously many copies of C.*

The proof does not use S-machines but uses some small cancellation arguments. It would be interesting to find finitely presented groups with similar "arbitrary" fundamental groups of asymptotic cones. Perhaps the Higman embeddings discussed in the next section will help solving that problem. Another very interesting problem (due to Gromov [24]) is whether there exists an asymptotic cone of a finitely generated group with non-trivial but at most countable fundamental group.

4. Higman embeddings

The flexibility of S-machines allowed us to construct several versions of Higman embeddings (embeddings of recursively presented groups into finitely presented ones) preserving certain properties of the group.

4.1. An easy construction. The easiest known construction of a Higman embedding is the following. Let H be a recursively presented group $\langle X \mid R\rangle$. Then the set of all words in $X \cup X^{-1}$ that are equal to 1 in H is recursively enumerable. Hence we can assume that R consists of all these words. Then there exists an S-machine recognizing R. More precisely, for every word w in X, it starts with a word $q_1 w q_2 q_3 \dots q_m$ and ends with a word $\bar q_1 \bar q_2 \dots \bar q_m$ if and only if $w \in R$.

Again, as in the proof of Theorem 3.2, we consider $N > 8$ copies of this S-machine and assume that the input of the S-machine $\mathcal{S}$ has the form

$$K(w) = k_1 q_1 w q_2 \dots q_m k_2 q_1' w' q_2' \dots q_m' k_3 \dots k_{N+1}$$

and the accepting configuration

$$W = k_1 \bar q_1 \bar q_2 \dots \bar q_m k_2 \bar q_1' \dots k_{N+1}.$$

Here $w', w'', \dots$ are copies of w written in disjoint alphabets.

Let G be the group constructed as in the proof of Theorem 3.2 (see Section 3.3) by imposing the hub relation $W = 1$ on $\mathcal{S}$. Then the word $K(w)$ is equal to 1 in G if and only if $w \in R$.

Consider now another S-machine $\mathcal{S}'$ with input configuration

$$K'(w) = k_1 q_1 q_2 \dots q_m k_2 q_1' w' q_2' \dots q_m' k_3 \dots k_{N+1}.$$

That machine works exactly like $\mathcal{S}$ in the part of the word between k_2 and k_{N+1}, and does nothing in the part between k_1 and k_2. Let G' be the group obtained by imposing the relation $W = 1$ on S'. Then $K'(w) = 1$ in G' if and only if $w \in R$.

Finally consider the amalgamated product $\mathcal{G} = G *_A G'$ where A is generated by all state and tape letters that appear in $K'(W)$. In that group, for every $w \in R$, both $K(w) = 1$ and $K'(w) = 1$. Hence $w = 1$. Thus there exists a natural homomorphism from H into $\mathcal{G}$. It is possible (and not too hard) to prove that this homomorphism is injective. Hence H is inside a finitely presented group G.

Another version of embedding used in [6] employs the so called *Aanderaa trick* [1]: instead of the amalgamated product, we used an HNN extension (see also the survey [45]).

Ones the embedding is established, it is important to understand which properties of a group H can be preserved.

4.2. Dehn functions and quasi-isometric Higman embeddings. First results have been obtained by Clapham [12] and Valiev [53] (see [46] for the history of these results): they proved that the solvability (even recursively enumerable degree) of the word problem and the level in the polynomial hierarchy of the word problem is preserved under some versions of Higman embedding.

In [6], Birget, Olshanskii, Rips and the author of this paper obtained a much stronger result.

Theorem 4.1 ([6]). *Let H be a finitely generated group with word problem solvable by a non-deterministic Turing machine with time function $\leq T(n)$ such that $T(n)^4$ is superadditive. Then H can be embedded into a finitely presented group G with Dehn function $\leq n^2 T(n^2)^4$ in such a way that H has bounded distortion in G.*

This theorem immediately implies the following characterization of groups with word problem in *NP*.

Theorem 4.2 ([6]). *A finitely generated group H has word problem in NP if and only if H is embedded quasi-isometrically into a finitely presented group with polynomial Dehn function.*

Note that the "if" part of this theorem is trivial: if a finitely generated group is a (not necessarily quasi-isometric) subgroup of a group with polynomial Dehn function, its word problem is in *NP*. The converse part is highly non-trivial, although one can prove that the embedding described in Section 4.1 satisfies the desired properties (in [6], we used the Aanderaa trick).

From the logic point of view, Theorem 4.2 means that for every (arbitrary clever) algorithm solving the word problem in a finitely generated group, there exists a finitely presented group $G > H$ such that the word problem in H (and, moreover, in G) can be solved by the Miller machine $M(G)$ in approximately the same time as the initial algorithm.

4.3. Preserving the solvability of the conjugacy problem. The conjugacy problem turned out to be much harder to preserve under embeddings. Collins and Miller [14] and Gorjaga and Kirkinskiĭ[20] proved that even subgroups of index 2 of finitely presented groups do not inherit solvability or unsolvability of the conjugacy problem.

In 1976 D. Collins [31] posed the following question (Problem 5.22): *Does there exist a version of the Higman embedding theorem in which the degree of unsolvability of the conjugacy problem is preserved?* In [46], [47] we solved this problem affirmatively. In particular, we proved the following results.

Theorem 4.3 ([46]). *A finitely generated group H has solvable conjugacy problem if and only if it is Frattini embedded into a finitely presented group G with solvable conjugacy problem.*

Theorem 4.4 ([47]). *Every countable recursively presented group with solvable word and power problems is embeddable into a finitely presented group with solvable conjugacy and power problem.*

Recall that a subgroup H of a group G is Frattini embedded in G if every two elements of H that are conjugate in G are also conjugate inside H. We say that G has solvable *power problem* if there exists an algorithm which, given u, v in G says if $v = u^n$ for some $n \neq 0$.

Theorem 4.4 is a relatively easy application of Theorem 4.3.

The construction in [46] is much more complicated than in [6]. First we embed H into a finitely presented group H_1 preserving the solvability of the word problem. Then we use the Miller S-machine $M(H_1)$ to solve the word problem in H. In order to overcome technical difficulties, we needed certain parts of words appearing the computation to be always positive. The standard positivity checkers do not work because they are S-machines as well, and can insert negative letters! So we used some ideas from the original Boone–Novikov proofs. That required introducing new generators, x-letters (in addition to the a-, q-, and θ-letters in S-machines) and Baumslag–Solitar relations. In addition, to analyze the conjugacy problem in G, we had to consider annular diagrams which are more complicated than van Kampen disc diagrams. Different types of annular diagrams (spirals, roles, etc.) required different treatment.

We do not have any reduction of the complexity of the conjugacy problem in H to the complexity of the conjugacy problem in G. In particular, solving the conjugacy problem in G, in some cases required solving systems of equations in free groups (i.e. the Makanin–Razborov algorithm).

5. Non-amenable finitely presented groups

One of the most important applications of S-machines and Higman embeddings so far was the construction of a finitely presented counterexample to the von Neumann

problem, i.e. a finitely presented non-amenable group without non-Abelian free subgroups [48].

5.1. Short history of the problem. Hausdorff [27] proved in 1914 that one can subdivide the 2-sphere minus a countable set of points into 3 parts A, B, C, such that each of these three parts can be obtained from each of the other two parts by a rotation, and the union of two of these parts can be obtained by rotating the third part. This implied that one cannot define a finitely additive measure on the 2-sphere which is invariant under the group SO(3). In 1924 Banach and Tarski [4] generalized Hausdorff's result by proving, in particular, that in $\mathbb{R}^3$, every two bounded sets A, B with non-empty interiors can be decomposed $A = \bigcup_{i=1}^n A_i$, $B = \bigcup_{i=1}^n B_i$ such that A_i can be rotated to B_i, $i = 1, \ldots, n$ (the so called Banach–Tarski paradox). Von Neumann [54] was first who noticed that the cause of the Banach–Tarski paradox is not the geometry of $\mathbb{R}^3$ but an algebraic property of the group SO(3). He introduced the concept of an amenable group (he called such groups "measurable") as a group G which has a left invariant finitely additive measure μ, $\mu(G) = 1$, noticed that if a group is amenable then any set it acts upon freely also has an invariant measure and proved that a group is not amenable provided it contains a free non-Abelian subgroup. He also showed that groups like $\mathrm{PSL}(2, \mathbb{Z})$, $\mathrm{SL}(2, \mathbb{Z})$ contain free non-Abelian subgroups. So analogs of Banach–Tarski paradox can be found in $\mathbb{R}^2$ and even $\mathbb{R}$ (for a suitable group of "symmetries"). Von Neumann showed that the class of amenable groups contains Abelian groups, finite groups and is closed under taking subgroups, extensions, and infinite unions of increasing sequences of groups. Day [15] and Specht [51] showed that this class is closed under homomorphic images. The class of groups without free non-Abelian subgroups is also closed under these operations and contains Abelian and finite groups.

The problem of existence of non-amenable groups without non-Abelian free subgroups probably goes back to von Neumann and became known as the "von Neumann problem" in the fifties. Probably the first paper where this problem was formulated was the paper by Day [15]. It is also mentioned in the monograph by Greenleaf [21] based on his lectures given in Berkeley in 1967. Tits [52] proved that every non-amenable matrix group over a field of characteristic 0 contains a non-Abelian free subgroup. In particular every semisimple Lie group over a field of characteristic 0 contains such a subgroup.

First counterexamples to the von Neumann problem were constructed by Olshanskii [37]. He proved that the Tarsky monsters, both torsion-free and torsion (see [38]), are not amenable. Later Adian [2] showed that the non-cyclic free Burnside group of odd exponent $n \geq 665$ with at least two generators (that is the group given by the presentation $\langle a_1, \ldots, a_m \mid u^n = 1$, where u runs over all words in the alphabet $\{a_1, \ldots, a_m\}\rangle$) is not amenable.

Both Olshanskii's and Adian's examples are not finitely presented: in the modern terminology these groups are inductive limits of word hyperbolic groups, but they are not hyperbolic themselves. Since many mathematicians are mostly interested

in groups acting "nicely" on manifolds, it is natural to ask if there exists a finitely presented non-amenable group without non-Abelian free subgroups. This question was explicitly formulated, for example, by Grigorchuk in [31] and by Cohen in [13]. This question is one of a series of similar questions about finding finitely presented "monsters", i.e. groups with unusual properties. Probably the most famous problem in that series is the (still open) problem about finding a finitely presented infinite torsion group. Other similar problems ask for finitely presented divisible group (group where every element has roots of every degree), finitely presented Tarski monster, etc. In each case a finitely generated example can be constructed as a limit of hyperbolic groups (see [38]), and there is no hope to construct finitely presented examples as such limits.

One difficulty in constructing a finitely presented non-amenable group without free non-Abelian subgroups is that there are "very few" known finitely presented groups without free non-Abelian subgroups. Most non-trivial examples are solvable or "almost" solvable (see [30]), and so they are amenable. The only previously known example of a finitely presented group without free non-Abelian subgroups for which the problem of amenability is non-trivial, is R. Thompson's group F (for the definition of F look in Section 3.2). The question of whether F is not amenable was formulated by R. Geoghegan in 1979. A considerable amount of work has been done to answer this question but it is still open.

5.2. The result. Together with A. Olshanskii, we proved the following theorem.

Theorem 5.1 ([48]). *For every sufficiently large odd n, there exists a finitely presented group $\mathcal{G}$ which satisfies the following conditions.*

1. *$\mathcal{G}$ is an ascending HNN extension of a finitely generated infinite group of exponent n.*

2. *$\mathcal{G}$ is an extension of a non-locally finite group of exponent n by an infinite cyclic group.*

3. *$\mathcal{G}$ contains a subgroup isomorphic to a free Burnside group of exponent n with 2 generators.*

4. *$\mathcal{G}$ is a non-amenable finitely presented group without free non-cyclic subgroups.*

Notice that parts 1 and 3 of Theorem 5.1 immediately imply part 2. By a theorem of Adian [2], part 3 implies that $\mathcal{G}$ is not amenable. Thus parts 1 and 3 imply part 4.

Note that the first example of a finitely presented group which is a cyclic extension of an infinite torsion group was constructed by Grigorchuk [22]. But the torsion subgroup in Grigorchuk's group does not have a bounded exponent and his group is amenable (it was the first example of a finitely presented amenable but not elementary amenable group).

5.3. The proof. Let us present the main ideas of our construction. We first embed the free Burnside group $B(m, n) = \langle \mathcal{B} \rangle$ of odd exponent $n \gg 1$ with $m > 1$ generators $\{b_1, \dots, b_m\} = \mathcal{B}$ into a finitely presented group $\mathcal{G}' = \langle \mathcal{C} \mid \mathcal{R} \rangle$ where $\mathcal{B} \subset \mathcal{C}$. This is done as in Section 4.1 using an S-machine recognizing all words of the form u^n. The advantage of S-machines is that such an S-machine can be easily and explicitly constructed (see [45]). Then we take a copy $\mathcal{A} = \{a_1, \dots, a_m\}$ of the set $\mathcal{B}$, and a new generator $\boldsymbol{t}$, and consider the group given by generators $\mathcal{C} \cup \mathcal{A}$ and the following three sets of relations:

(1) the set $\mathcal{R}$ of the relations of the finitely presented group $\mathcal{G}'$ containing $B(m, n)$;

(2) (u-relations) $y = u_y$, where u_y, $y \in \mathcal{C}$, is a certain word in $\mathcal{A}$ these words satisfy a very strong small cancellation condition; these relations make $\mathcal{G}'$ (and $B(m, n)$) embedded into a finitely presented group generated by $\mathcal{A}$;

(3) ($\boldsymbol{t}$-relations) $\boldsymbol{t}^{-1} a_i \boldsymbol{t} = b_i$, $i = 1, \dots, m$; these relations make $\langle \mathcal{A} \rangle$ a conjugate of its subgroup of exponent n (of course, the group $\langle \mathcal{A} \rangle$ gets factorized).

The resulting group $\mathcal{G}$ is obviously generated by the set $\mathcal{A} \cup \{\boldsymbol{t}\}$ and is an ascending HNN extension of its subgroup $\langle \mathcal{A} \rangle$ with the stable letter $\boldsymbol{t}$. Every element in $\langle \mathcal{A} \rangle$ is a conjugate of an element of $\langle \mathcal{B} \rangle$, so $\langle \mathcal{A} \rangle$ is an m-generated group of exponent n. This immediately implies that $\mathcal{G}$ is an extension of a group of exponent n (the union of increasing sequence of subgroups $\boldsymbol{t}^s \langle \mathcal{A} \rangle \boldsymbol{t}^{-s}$, $s = 1, 2, \dots$) by a cyclic group.

Hence it remains to prove that $\langle \mathcal{A} \rangle$ contains a copy of the free Burnside group $B(2, n)$.

In order to prove that, we construct a list of defining relations of the subgroup $\langle \mathcal{A} \rangle$. As we have pointed out, the subgroup $\langle \mathcal{A} \cup \mathcal{C} \rangle = \langle \mathcal{A} \rangle$ of $\mathcal{G}$ clearly satisfies all *Burnside relations* of the form $v^n = 1$. Thus we can add all Burnside relations

(4) $v^n = 1$ where v is a word in $\mathcal{A} \cup \mathcal{C}$

to the presentation of group $\mathcal{G}$ without changing the group.

If Burnside relations were the only relations in $\mathcal{G}$ among letters from $\mathcal{B}$, the subgroup of $\mathcal{G}$ generated by $\mathcal{B}$ would be isomorphic to the free Burnside group $B(m, n)$ and that would be the end of the story. Unfortunately there are many more relations in the subgroup $\langle \mathcal{B} \rangle$ of $\mathcal{G}$. Indeed, take any relation $r(y_1, \dots, y_s)$, $y_i \in \mathcal{C}$, of $\mathcal{G}$. Using u-relations (2), we can rewrite it as $r(u_1, \dots, u_s) = 1$ where $u_i \equiv u_{y_i}$. Then using $\boldsymbol{t}$-relations, we can substitute each letter a_j in each u_i by the corresponding letter $b_j \in \mathcal{B}$. This gives us a relation $r' = 1$ which will be called a relation *derived* from the relation $r = 1$, the operator producing derived relations will be called the $\boldsymbol{t}$-*operator*. We can apply the $\boldsymbol{t}$-operator again and again producing the second, third, ..., derivatives $r'' = 1, r''' = 1, \dots$ or $r = 1$. We can add all *derived relations*

(5) $r' = 1, r'' = 1, \dots$ for all relations $r \in \mathcal{R}$

to the presentation of $\mathcal{G}$ without changing $\mathcal{G}$.

Now consider the group H generated by $\mathcal{C}$ subject to the relations (1) from $\mathcal{R}$, the Burnside relations (4) and the derived relations (5). The structure of the relations of H immediately implies that H contains subgroups isomorphic to $B(2, n)$. Thus it is enough to show that the natural map from H to $\mathcal{G}$ is an embedding.

The idea is to consider two auxiliary groups. The group $\mathcal{G}_1$ generated by $\mathcal{A} \cup \mathcal{C}$ subject to the relations (1) from $\mathcal{R}$, u-relations (2), the Burnside relations (4), and the derived relations (5). It is clear that $\mathcal{G}_1$ is generated by $\mathcal{A}$ and is given by relations (1) and (5) where every letter $y \in \mathcal{C}$ is replaced by the corresponding word u_y in the alphabet $\mathcal{A}$ plus all Burnside relations (4) in the alphabet $\mathcal{A}$. Let L be the normal subgroup of the free Burnside group $B(\mathcal{A}, n)$ (freely generated by $\mathcal{A}$) generated as a normal subgroup by all relators (1) from $\mathcal{R}$ and all derived relators (5) where letters from $\mathcal{C}$ are replaced by the corresponding words u_y. Then $\mathcal{G}_1$ is isomorphic to $B(\mathcal{A}, n)/L$.

Consider the subgroup U of $B(\mathcal{A}, n)$ generated (as a subgroup) by $\{u_y \mid y \in \mathcal{C}\}$. The words u_y, $y \in \mathcal{C}$, are chosen in such a way that the subgroup U is a free Burnside group freely generated by u_y, $y \in \mathcal{C}$, and it satisfies the *congruence extension* property, namely every normal subgroup of U is the intersection of a normal subgroup of $B(\mathcal{A}, n)$ with U.

All defining relators of $\mathcal{G}_1$ are inside U. Since U satisfies the congruence extension property, the normal subgroup $\bar{L}$ of U generated by these relators is equal to $L \cap U$. Hence $U/\bar{L}$ is a subgroup of $B(\mathcal{A}, n)/L = \mathcal{G}_1$. But by the choice of U, there exists a (natural) isomorphism between U and the free Burnside group $B(\mathcal{C}, n)$ generated by $\mathcal{C}$, and this isomorphism takes $\bar{L}$ to the normal subgroup generated by relators from $\mathcal{R}$ and the derived relations (5). Therefore $U/\bar{L}$ is isomorphic to H (since, by construction, H is generated by $\mathcal{C}$ subject to the Burnside relations, relations from $\mathcal{R}$ and derived relations)! Hence H is a subgroup of $\mathcal{G}_1$. Let $\mathcal{G}_2$ be the subgroup of H generated by $\mathcal{B}$.

Therefore we have

$$\mathcal{G}_1 \geq H \geq \mathcal{G}_2.$$

Notice that the map $a_i \to b_i$, $i = 1, \ldots, m$, can be extended to a homomorphism $\phi_{1,2} \colon \mathcal{G}_1 \to \mathcal{G}_2$. Indeed, as we mentioned above $\mathcal{G}_1$ is generated by $\mathcal{A}$ subject to Burnside relations, all relators from $\mathcal{R}$ and all derived relators (5) where letters from $\mathcal{C}$ are replaced by the corresponding words u_y. If we apply $\phi_{1,2}$ to these relations, we get Burnside relations and derived relations which hold in $\mathcal{G}_2 \leq H$.

The main technical statement of the paper shows that $\phi_{1,2}$ is an isomorphism, that is for every relation $w(b_1, \ldots, b_m)$ of $\mathcal{G}_2$ the relation $w(a_1, \ldots, a_m)$ holds in $\mathcal{G}_1$. This implies that the HNN extension $\langle \mathcal{G}_1, \boldsymbol{t} \mid \boldsymbol{t}^{-1}\mathcal{G}_1\boldsymbol{t} = \mathcal{G}_2 \rangle$ is isomorphic to $\mathcal{G}$. Indeed, this HNN extension is generated by $\mathcal{G}_1$ and $\boldsymbol{t}$, subject to relations (1), (2), (4), (5) of $\mathcal{G}_1$ plus relations (3). So this HNN extension is presented by relations (1)–(5) which is the presentation of $\mathcal{G}$. Therefore $\mathcal{G}_1$ is a subgroup of $\mathcal{G}$, hence H is a subgroup of $\mathcal{G}$ as well.

The proof of the fact that $\phi_{1,2}$ is an isomorphism requires a detailed analysis of the group H. This group can be considered as a factor-group of the group H' generated by $\mathcal{C}$ subject to the relations (1) from $\mathcal{R}$ and derived relations (5) over the normal subgroup generated by Burnside relations (4). In other words, H is the *Burnside factor* of H'.

Burnside factors of free groups have been studied extensively starting with the celebrated paper by Adian and Novikov [36]. Later Olshanskii developed a geometric method of studying these factors in [38]. These methods were extended to arbitrary hyperbolic groups in [39]

The main problem we face in this paper is that H' is "very" non-hyperbolic. In particular, the set of relations $\mathcal{R}$ contains many commutativity relations, so H' contains non-cyclic torsion-free Abelian subgroups which cannot happen in a hyperbolic group.

We use a weak form of relative hyperbolicity that does hold in H'. In order to roughly explain this form of relative hyperbolicity used in the proof, consider the following example. Let $P = F_A \times F_B$ be the direct product of two free groups of rank m. Then the Burnside factor of P is simply $B(m,n) \times B(m,n)$. Nevertheless the theory of [38] cannot be formally applied to P. Indeed, there are arbitrarily thick rectangles corresponding to relations $u^{-1}v^{-1}uv = 1$ in the Cayley graph of P so diagrams over P are not A-maps in the terminology of [38] (i.e. they do not look like hyperbolic spaces). But one can obtain the Burnside factor of P in two steps. First we factorize F_A to obtain $Q = B(m,n) \times F_B$. Since F_A is free, we can simply use [38] to study this factor.

Now we consider all edges labeled by letters from A in the Cayley graph of Q as 0-edges, i.e. edges of length 0. As a result the Cayley graph of Q becomes a hyperbolic space (a tree). This allows us to apply the theory of A-maps from [38] to obtain the Burnside factor of Q. In fact Q is weakly relatively hyperbolic in the sense of our paper [48], i.e. it satisfies conditions (Z1), (Z2), (Z3) from the paper. The class of groups satisfying these conditions is very large and includes groups corresponding to S-machines considered in [48].

Recall that set $\mathcal{C}$ consists of tape letters, state letters, and command letters. In different stages of the proof some of these letters become 0-letters.

Trapezia corresponding to computations of the S-machine play central role in our study of the Burnside factor H of H'. As in [38], the main idea is to construct a graded presentation $\mathcal{R}'$ of the Burnside factor H of H' where longer relations have higher ranks and such that every van Kampen diagram over the presentation of H' has the so called property A from [38]. In all diagrams over the graded presentation of H, cells corresponding to the relations from $\mathcal{R}$ and derived relations are considered as 0-cells or cells of rank $1/2$, and cells corresponding to Burnside relations from the graded presentation are considered as cells of ranks 1, 2,.... So in these van Kampen diagrams "big" Burnside cells are surrounded by "invisible" 0-cells and "small" cells.

The main part of property A from [38] is the property that if a diagram over $\mathcal{R}'$ contains two Burnside cells Π_1, Π_2 connected by a rectangular *contiguity* subdia-

gram Γ of rank 0 where the sides contained in the contours of the two Burnside cells are "long enough" then these two cells cancel, that is the union of Γ, Π, Π' can be replaced by a smaller subdiagram. This is a "graded substitute" to the classic property of small cancellation diagrams (where contiguity subdiagrams contain no cells).

In our case, contiguity subdiagrams of rank 0 turn out to be trapezia (after we clean them of Burnside 0-cells), so properties of contiguity subdiagrams can be translated into properties of the machine $\mathcal{S}$.

A unified approach to computations with permutation and matrix groups

Ákos Seress*

Abstract. We survey algorithms to compute with large finite permutation and matrix groups. Particular attention will be given to handling both types of groups with similar methods, using structural properties to answer even basic questions such as the order of the input group.

Mathematics Subject Classification (2000). Primary 20B40; Secondary 20B15.

Keywords. Computational group theory, permutation group algorithm, matrix group algorithm.

1. Introduction

There are two basic methods to input a group into a computer: (a) by a presentation, using abstract generators and relations, and (b) by a "concrete" representation as a permutation group or matrix group, defined by a set of generating permutations or matrices. In this survey, we are concerned with groups given as in (b), and with black-box groups (see Definition 3.1), which are a common generalization of permutation and matrix groups. We shall concentrate on the basic questions how to determine the order of the input group G, how to set up a data structure to test membership in G, and how to compute a composition series. For readers interested in a broader range of topics, we recommend our brief survey [47] describing all areas of computational group theory and the more thorough coverage in the recent book [29]. Two monographs providing a comprehensive coverage of the subareas finitely presented groups and permutation groups are [51] and [48], respectively.

Given a set X of permutations or of invertible matrices over a finite field, X generates a finite group G so the undecidability issues related to generator-relator presentations and to infinite matrix groups do not arise. However, $|G|$ can be exponentially large in terms of the input length, so brute-force methods like listing all elements of G are out of question and we have to design efficient algorithms to deal with G.

There are two widely accepted notions of efficiency. On one hand, in practice, it means that we obtain results in reasonable time in the actual computations we perform. On the other hand, in theory, efficiency means fast asymptotic running time. Historically, group computations developed on these two tracks separately,

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

but in the last fifteen years or so the two approaches have started to converge. This convergence is not surprising. As we deal with larger and larger inputs, only those practical methods that are asymptotically efficient survive; conversely, the rigorous complexity analysis inspires new algorithms that may have practical implementations. This unification of theory and practice is one of the aspects the title of this paper refers to. Implementations of asymptotically fast algorithms are finding their way into *GAP* [28] and MAGMA [19], the two large computer algebra systems for group computations.

There are two other aspects of unification. One of them is within the matrix group setting. As we shall discuss in Section 3, there are two approaches to matrix group computations and we shall mention the recent efforts to combine them. The other aspect is the uniform treatment of permutation groups and matrix groups, by breaking them into manageable pieces as the image and kernel of appropriate group homomorphisms. This approach is the standard one for matrix groups, but a recently developed data structure enables us to handle both types of groups the same way.

The most recent ICM talk about computational group theory was given eight years ago, by Bill Kantor [30]. His major emphasis was the use of the classification of finite simple groups (CFSG) in the topic and the handling of simple groups. We shall also report the latest developments in simple group management, but this paper is more focused on the *reduction* to the simple group case. There are interesting and deep mathematical problems in both subareas, although the management of simple groups requires mostly group theoretical arguments while the reduction to the simple group case uses a mixture of group theoretic, combinatorial and computer science (design of data structures) methods. Consequences of CFSG are required in the analysis of many reduction algorithms as well.

2. Permutation groups

The fundamental data structures for computation with permutation groups were introduced by Sims [50]; they are called base and strong generating set (SGS). A *base* of $G \leq \mathrm{Sym}(\Omega)$ is a sequence of points $B = (\beta_1, \ldots, \beta_m)$ from Ω such that the pointwise stabiliser $G_B = 1$. A base B naturally defines a subgroup chain

$$G = G^{[1]} \geq G^{[2]} \geq \cdots \geq G^{[m]} \geq G^{[m+1]} = 1$$

where $G^{[i]} := G_{(\beta_1,\ldots,\beta_{i-1})}$ is the pointwise stabilizer of $\{\beta_1, \ldots, \beta_{i-1}\}$. The base is called *non-redundant* if $G^{[i+1]}$ is a proper subgroup of $G^{[i]}$ for all $i \leq m$. For a non-redundant base B, we have $\log |G|/\log N \leq |B| \leq \log |G|$, where $|\Omega| = N$. (As usual in complexity theory, we write logarithms to base 2.)

A *strong generating set* (SGS) for G relative to B is a generating set S for G with the property that

$$\langle S \cap G^{[i]} \rangle = G^{[i]}, \quad \text{for } 1 \leq i \leq m+1.$$

Given $G = \langle X \rangle \leq \mathrm{Sym}(\Omega)$, Sims's algorithm constructs a non-redundant base B and an SGS S relative to B. Once S is known, it is easy to construct (right) transversals T_i

for $G^{[i]}$ mod $G^{[i+1]}$. Crucially, $|T_i| \leq N$ is "small". For all γ in the orbit $\beta_i^{G^{[i]}}$, the transversal T_i contains some $r_\gamma \in G^{[i]}$ with $\beta_i^{r_\gamma} = \gamma$. These transversals can be used to compute $|G| = \prod_{i=1}^{m} |T_i|$ and to factor any $g \in G$ as a product $g = r_m \dots r_1$, for some $r_i \in T_i$. This factorization is unique and it can be done by an efficient algorithm called *sifting*. First, we take $r_1 \in T_1$ such that $\beta_1^g = \beta_1^{r_1}$. Then $g_2 := gr_1^{-1} \in G^{[2]}$, and we can take $r_2 \in T_2$ such that $\beta_2^{g_2} = \beta_2^{r_2}$, etc. Sifting can be used to test membership in G. For details, we refer to [48, Ch. 4].

Sims's algorithm is based on elementary group theory. The running time of the asymptotically fastest versions is $O(|X|N^2 \log^c |G|)$ for some absolute constant c. A factor N can be shaved off the running time by randomization:

Theorem 2.1 ([7]). *Given $G = \langle X \rangle \leq \mathrm{Sym}(\Omega)$ with $|\Omega| = N$, a base B and an SGS relative to B can be computed in $O(|X|N \log^c |G|)$ time, by a Monte Carlo algorithm with an arbitrarily small positive but fixed upper bound on the probability of incorrect output.*

Recall that a randomized algorithm is called *Monte Carlo* if there is a chance of an incorrect output but an upper bound for the probability of error can be prescribed by the user. On the contrary, a *Las Vegas* algorithm never returns an incorrect answer but it may report failure with probability bounded by the user.

The algorithm in Theorem 2.1 is still elementary. The quadratic $O(N^2)$ bottlenecks are broken by randomization, and by combinatorial tricks like working with base images instead of full permutations or to test membership in certain large subsets of G without listing those subsets. If $\log |G|$ is bounded from above by a polylogarithmic, $\log^c N$, function of N then the running time is a *nearly linear*, $O((|X|N) \log^{c'} (|X|N))$, function of the input length $|X|N$. This motivated the following definition. An infinite family $\mathcal{G}$ of permutation groups is called *small-base* if every group $G \in \mathcal{G}$ of degree m satisfies $\log |G| < \log^c m$ for some fixed constant c. Important families of groups are small-base, including all permutation representations of non-alternating simple groups.

The algorithm in Theorem 2.1 is also practical. In *GAP*, currently permutation group computations are based on an implementation of this algorithm. The certainty of a correct answer, if desired, is obtained by a quadratic algorithm of Sims that checks the correctness of a base and SGS (see [48, Section 8.2]).

For arbitrary inputs, where $\log |G|$ may become comparable to N, no deterministic version of Sims's algorithm is known to run faster than $O(N^5 + |X|N^2)$. Fortunately, ideas from a purely theoretical development come to the rescue. In [9], an algorithm is described to handle permutation groups in the parallel computational model NC. Informally, in NC we can work with polynomially many, n^c, processors, but we have only polylogarithmic, $\log^c n$, time in terms of the input length n. Note that sifting is inherently sequential (we have to know the coset representatives $r_1, \dots, r_i$ before r_{i+1} can be computed in a factorization $g = r_m \dots r_1$) so a Sims-based approach may work in NC only for small-base groups. The algorithm in [9] is based on entirely different

principles, exploring the structure of the input group G. By the time it computes $|G|$, it also obtains a composition series for G. Some of these ideas were also used in the more realistic domain of sequential computations to break the long-standing $O(N^5)$ barrier:

Theorem 2.2 ([10]). *Given $G = \langle X \rangle \leq \mathrm{Sym}(\Omega)$ with $|\Omega| = N$, there is a deterministic algorithm with $O(N^4 \log^c N + |X|N^2)$ running time to compute $|G|$ and to set up a data structure for testing membership in G.*

The algorithm in Theorem 2.2 detects all large alternating composition factors of G and handles them by special methods, while the rest of the group is handled using Sims's ideas.

How can we detect large alternating sections in a permutation group? Combinatorial reduction (action on orbits, and then action on blocks of imprimitivity) leads to primitive permutation groups. At that point, we invoke a consequence of CFSG [20]: any primitive permutation group $H \leq \mathrm{Sym}(\Delta)$ of degree n is a small-base group, unless $n = \binom{m}{k}^r$ for some positive integers m, k, r and Δ can be identified with r-tuples of k-sets of an m-element set, $A_m^r \leq H \leq S_m \wr S_r$, and H acts naturally on these sequences in the so-called product action of wreath products. Such an H is called a *group of Cameron type* in [10]. In this very special situation, [10] gives a combinatorial algorithm to construct a collection Σ of mr subsets of Δ so that H acts on Σ in the natural imprimitive action of wreath products.

The input group G is handled by a recursive procedure. We define a homomorphism $\varphi\colon G \to \mathrm{Sym}(\Delta)$ for some Δ, process $\mathrm{Im}(\varphi)$, obtain generators for $\mathrm{Ker}(\varphi)$, and process $\mathrm{Ker}(\varphi)$. If G is transitive then Δ is an orbit and $\mathrm{Im}(\varphi)$ is the restriction of G to this orbit; and if G is transitive but imprimitive then Δ is a block system and $\mathrm{Im}(\varphi)$ is the action on this block system. When the recursion arrives to a primitive group then we test whether it is of Cameron type. If not, then Sims's base-SGS method is used to process it. If it is of Cameron type then a further homomorphism is constructed to the natural imprimitive action. The full alternating and symmetric groups A_m and S_m, encountered in their natural action on m points, are handled by combinatorial methods, as a special case of the constructive recognition of almost simple groups (see Section 3.1).

We finish this section by announcing a Las Vegas upgrade of Theorem 2.1.

Theorem 2.3 ([32], [33]). *Given $G = \langle X \rangle \leq \mathrm{Sym}(\Omega)$ with $|\Omega| = N$ and G having no composition factors of Lie type ${}^2G_2$ and ${}^2F_4$, a base and SGS for G can be computed in $O(|X|N \log^c |G|)$ time, by a Las Vegas algorithm with an arbitrarily small but fixed positive upper bound on the probability of incorrect output.*

Although the statements of Theorems 2.1 and 2.3 are similar, the proofs are based on entirely different principles. The algorithm in Theorem 2.3 computes a composition series for G by a Monte Carlo algorithm, recognizes constructively the composition factors (see Section 3.1), and then uses the isomorphisms set up by the recognition algorithms to write a presentation for G. Evaluation of this presentation verifies

the correctness of the entire computation. The groups ${}^2G_2(q)$ have to be excluded because currently it is not known that they have short presentations suitable for the time requirement of this application; the groups ${}^2F_4(q)$ are excluded because the known constructive recognition algorithm is not fast enough.

There is a large library of Monte Carlo algorithms that run in nearly linear time for small-base inputs (see [48, Ch. 5 and 6]). The significance of Theorem 2.3 is that if the initial base-SGS computation is correct for some input group G then all of these nearly linear-time algorithms are *automatically upgraded to Las Vegas*.

Summarizing, we saw that the basic tasks of finding the order and setting up membership testing in permutation groups can be performed by elementary methods in polynomial time, but randomization and the structural exploration of the input group provide much faster algorithms.

3. Matrix groups

The basic problems for matrix groups over finite fields, such as membership and order, seem to be much harder than the corresponding problems for permutation groups. The fundamental difference is that there is no longer, in general, a decreasing sequence of subgroups from G to 1 in which all successive indices are small; this makes an analogue of Sims' base-SGS approach infeasible. For permutation groups, the natural divide-and-conquer approach leads to primitive groups, and those groups can be reduced to symmetric groups or else they are small-base groups. In contrast, a large variety of primitive irreducible matrix groups has order $\exp(\Omega(d^2))$ (here d is the dimension of the matrices). Finally, even for 1×1 matrices, the problems are closely related to discrete logarithm computations.

For later use, we define two versions of the discrete logarithm problem:

(DL1) Given $a, b \in \mathrm{GF}(q)^*$, determine whether $a \in \langle b \rangle$.

(DL2) Given $a, b \in \mathrm{GF}(q)^*$, determine whether $a \in \langle b \rangle$. If the answer is yes then find an exponent x such that $a = b^x$.

Finding the order of $G = \langle X \rangle \leq \mathrm{GL}(1, q)$ is between these two problems in difficulty: version (DL1) can be reduced to it in polynomial time, while it can be reduced to version (DL2) in polynomial time. We note that neither version of the discrete logarithm problem has at present a polynomial-time solution, although subexponential algorithms exist even for the more difficult version (DL2) [39].

Despite all the difficulties listed above, significant progress has been made recently on matrix groups and associated data structures, and currently this is the most active area of computational group theory. However, contrary to the permutation group case, it seems that randomization and a full structural exploration of the input is not only a speedup, but an essential and unavoidable tool. This means that we have to set up a

recursive scheme of homomorphisms, breaking the input into the image and kernel. This reduction bottoms out at matrix groups H that are almost simple modulo scalars. At these terminal stages of the recursion, we have to find the name of the isomorphism type of H, and then set up an identification with a standard permutation or matrix representation of this isomorphism type.

First, we discuss the methods for handling almost simple groups. For that, we need two definitions.

Definition 3.1. A *black-box group* is a group whose elements are encoded as words of length at most N over some alphabet T and some bound N. Not every word represents a group element and the same group element may be represented by more than one word. Moreover, an oracle (the "black box") performs the following three operations: given (words representing) $g, h \in G$, it can compute (a word representing) gh, g^{-1}, and it can decide whether $g = 1$.

Our definition is slightly more general than the original one [11], where only 0-1 strings of uniform lengths are allowed. The primary examples of black-box groups are permutation groups and matrix groups, but there are two other important examples. One of them is a power-conjugate presentation for a finite solvable group, where each group element has a canonical form $a_1^{e_1} a_2^{e_2} \dots a_m^{e_m}$ for a suitable generating sequence $(a_1, \dots, a_m)$. More important for our present discussion is that permutation groups G can be considered as black-box groups where the alphabet is an SGS for G (see [48, Section 5.3]). In small-base groups, group operations using words in the strong generators are asymptotically much faster than permutation multiplications. These special types of black-box groups play an important role, for example, in the proof of Theorem 2.3. In these black-box groups, we lose all information stored implicitly in the cycle structure of permutations, and algorithms can utilize only the three black-box operations defined above.

In some situations, we also consider permutation and matrix groups with their natural group operations as black-box groups, because permutation group theoretic notions like orbits or cycle structure, or geometric notions like invariant subspaces or characteristic polynomials in the matrix group case, do not help. For example, we have no better methods for generating random elements in a matrix group than creating new group elements from the given generators by multiplications and inversions, that is, by black-box operations [4], [22]. Black-box group algorithms, with the natural permutation operations, are also used in computations of normal closures, derived series, and related algorithms both in theory [23], [6] and in *GAP*.

The second definition we require is of a straight-line program (SLP). It is a data structure to circumvent problems with overly long words in generators.

Definition 3.2. Given $G = \langle X \rangle$, a *straight-line program of length m* reaching some $g \in G$ is a sequence of expressions $(w_1, \dots, w_m)$ such that for each i one of the following holds: w_i is a symbol for some element of X, $w_i = (w_j, -1)$ for some $j < i$, or $w_i = (w_j, w_k)$ for some $j, k < i$, such that, if the expressions are evaluated,

then the value of w_m is g. Here, $(w_j, -1)$ is evaluated as the inverse of the evaluated value of w_j, and (w_j, w_k) is evaluated as the product of the evaluated values of w_j and w_k.

3.1. Recognition of almost simple groups. Now we are ready to discuss matrix groups that are almost simple modulo scalars or, more generally, almost simple black-box groups. There are two basic tasks: non-constructive recognition and constructive recognition. *Non-constructive recognition* of an almost simple group means to name the isomorphism type. The first such algorithm is in [41], where it is decided whether a given group $G \leq \mathrm{GL}(d, p^e)$ contains $\mathrm{SL}(d, p^e)$. A sample of random elements is taken, and we look for elements whose order is divisible by some primitive prime divisor (ppd) of $p^{de} - 1$ and of $p^{(d-1)e} - 1$. (Recall that a *primitive prime divisor* of $p^n - 1$ is a prime $r \mid p^n - 1$ which does not divide $p^i - 1$ for any $i < n$.) If $G \geq \mathrm{SL}(d, p^e)$ then elementary estimates show that both kinds of ppd's occur frequently enough so that a small sample of random elements detects them; however, CFSG is invoked to prove that if both kinds of ppd's occur then indeed $G \geq \mathrm{SL}(d, p^e)$. Subsequently, similar algorithms were designed to recognize the other classical groups in their natural matrix representations [21], [43]. The culmination of this type of results is in [8]: given an almost simple black-box group G of Lie type and given the characteristic p of G, the isomorphism type of G can be computed. This algorithms still looks for elements whose order is divisible by various ppd's and pairs of ppd's. We note that the ppd property can be checked in the black-box group setting, without computing element orders. If we know only that a matrix group is simple of Lie type modulo scalar matrices, its characteristic can be determined by recent algorithms in [38] and [49]. All algorithms mentioned in this paragraph are Monte Carlo with polynomial running time, and have efficient implementations.

In applications in recursive schemes breaking down arbitrary matrix groups to almost simple pieces, non-constructive recognition is not sufficient; we need the more involved constructive recognition. Given an almost simple black-box group $G = \langle X \rangle$, *constructive recognition* of G is a Las Vegas algorithm that, besides naming the isomorphism type of G, computes an isomorphism $\varphi\colon G \to C$ with a standard permutation representation or (projective) matrix representation of this isomorphism type. The isomorphism φ is defined by giving the images of a new generating set $Y \leq G$. Moreover, we require that, given any $g \in G$, a short SLP reaching g from Y can be computed, and given any $h \in C$, $\varphi^{-1}(h)$ can be computed.

The first constructive recognition algorithm, for black-box groups $\mathrm{GL}(n, 2)$, was given in [24]. Subsequently, constructive recognition of all classical groups (in [32]) and exceptional groups G (in [31]) was accomplished. These algorithms require the characteristic p of G as part of the input. The rough idea is the following. Since in the black-box setting we do not have a vector space to work with, the algorithms construct a large elementary abelian p-section P of G such that the conjugation action of a maximal parabolic $H \leq G$ on P is isomorphic to the natural matrix action of H, and subsequently extend this matrix action to arbitrary elements of G. Constructive

recognition of alternating and symmetric groups is much easier [12], [13], [14]. A recent algorithm [2] recognizes constructively about half of the sporadic groups, using a generalization of Sims's sifting through subset chains instead of subgroup chains.

An exciting new method by Ryba toward the constructive recognition of some Lie-type groups is described in [45] and [46]. Let p be an odd prime, and let G be a group of untwisted Lie type defined over a field of characteristic p. Suppose further that the associated Lie algebra of G is simple. Then, given any absolutely irreducible characteristic p representation $G = \langle X \rangle$, a polynomial-time Las Vegas algorithm computes the action of the generator set X on the Chevalley basis of the Lie algebra of G. Hence the constructive recognition problem is reduced to consideration of the adjoint representation.

Ryba is currently working on the extension of this algorithm to all Lie-type groups. Although his methods are still under development, they seem to have the potential to become the major tool of constructive recognition, reducing the use of the methodology of [32], [31] only to the natural and cross-characteristic representations of Lie-type groups.

The running times of the algorithms in [32], [31] are polynomials in the rank r and the defining field size q of the Lie-type input group G. However, the length of the input may be only $O(r^2 \log q)$, so for large q the running time is exponential. An idea to overcome this difficulty is in [25], where the groups $\mathrm{SL}(2, q)$ in their standard 2×2 matrix setting are recognized in polynomial time of the input length *plus* polynomially many calls to an oracle solving version (DL2) of the discrete logarithm problem in $\mathrm{GF}(q)$. Later this algorithm was extended to arbitrary matrix representations of $\mathrm{PSL}(2, q)$ [26]. This motivated the following definition.

Definition 3.3. Let G be an almost simple group of Lie type defined over the field $\mathrm{GF}(p^l)$. We say that G is *constructively recognizable with a discrete logarithm oracle*, in short G is *CRDLO*, if for *any* quasisimple representation of G in characteristic p, G can be constructively recognized in time polynomial in the input length plus the time of polynomially many calls to a discrete logarithm oracle in $\mathrm{GF}(p^l)$. (Note that the field of definition $\mathrm{GF}(p^l)$ may be different from the field $\mathrm{GF}(p^e)$ over which the input matrices are given. Recall that a group G is called *quasisimple* if $G/Z(G)$ is simple and G equals its derived subgroup.)

Theorem 3.4 ([16], [15], [17]). *All classical groups are CRDLO.*

The algorithms of this theorem are based on [32], using an oracle to handle $\mathrm{SL}(2, q)$ subgroups. In turn, this oracle is based on the methods of [26]. The case of special linear, symplectic, and unitary groups is a more or less straightforward modification of [32], but the case of orthogonal groups involves significant additional technical difficulties.

3.2. The general case. Now we turn to the case of arbitrary matrix groups. There are two basic methods for the breakup of the input into manageable pieces (which,

in most cases, amounts to the reduction to almost simple groups). The *geometric approach*, summarized in [37], is based on Aschbacher's classification of matrix groups [3]. This classification defines eight types of geometric subgroups of $\mathrm{GL}(d, q)$, and groups $G \leq \mathrm{GL}(d, q)$ belonging to seven of these types have a naturally associated $N \lhd G$ which enables the recursive handling of G/N and N. These classes consist of reducible groups, imprimitive groups, normalizers of extraspecial groups, and so on. For example, in the case of reducible groups we can consider the homomorphism defined by the restriction to the action on an invariant subspace, and the kernel of this action. The eighth geometric category contains the classical groups in their natural representation. The groups not belonging to any of the eight geometric categories are almost simple modulo scalars. After contributions by many people (see [44] for an overview), O'Brien has a working implementation of the reduction to the almost simple case.

By contrast, the *black-box group approach*, initiated by Babai and Beals [12], tries to determine the abstract group-theoretic structure of G. Every finite group G has a series of characteristic subgroups $1 \leq M_1 \leq M_2 \leq M_3 \leq G$, where M_1 is solvable, M_2/M_1 is isomorphic to a direct product $T_1 \times \cdots \times T_k$ of nonabelian simple groups, M_3/M_2 is solvable, and G/M_3 is a permutation group, permuting the simple groups T_i. Given $G = \langle X \rangle \leq \mathrm{GL}(d, p^e)$, [5] constructs subgroups $H_1, \ldots, H_k$ such that $H_i/S_i \cong T_i$ for some solvable group S_i. Having these H_i at hand, it is possible to construct the permutation group $G/M_3 \leq S_k$, which then can be handled by permutation group methods. Moreover, using the results of [1], [8], the simple groups T_i can be non-constructively recognized.

The Babai–Beals algorithm and its extension by [1], [8] are Monte Carlo, and run in polynomial time in the input length.

Contrary to the geometric approach, [5] does not use the geometry associated with the matrix group action of G. The fact that $G \leq \mathrm{GL}(d, p^e)$ is only used when appealing to a simple consequence of [35], [27]: if T_i is of Lie type in characteristic different from p, then T_i has a permutation representation of degree polynomial in d.

These results can be extended significantly further.

Theorem 3.5 ([34]). *Given $G = \langle X \rangle \leq \mathrm{GL}(d, p^e)$, there is a Las Vegas algorithm that computes the following.*

(i) *The order of G.*

(ii) *A series of subgroups $1 = N_0 \lhd N_1 \lhd \cdots \lhd N_{m-1} \lhd N_m = G$, where N_i/N_{i-1} is a nonabelian simple group or a cyclic group for all i.*

(iii) *A presentation of G.*

(iv) *Given any $g \in \mathrm{GL}(d, p^e)$, the decision whether $g \in G$, and if $g \in G$, then a straight-line program from X, reaching g.*

The algorithm uses an oracle to solve version (DL2) of the discrete logarithm problem in fields of characteristic p and size up to p^{ed}. In the case when all composition factors of Lie type that are in characteristic p are CRDLO, the running time

is polynomial in the input length $|X|d^2e \log p$, plus the time requirement of polynomially many calls to the discrete logarithm oracle. Note that in (ii) the cyclic factors N_i/N_{i-1} may not be simple of prime order because we do not assume that we can factor large integers.

The proof proceeds by continuing the Babai–Beals algorithm when that approach bottoms out. The key idea is that, using the notation introduced in the discussion before Theorem 3.5, for those simple groups T_i that are of Lie type of characteristic p, H_i can be written in an appropriate basis in an upper triangular 3×3 block matrix form such that T_i acts in a quasisimple representation on the block $(2, 2)$. Hence the CRLDO constructive recognition algorithms can be applied. Finally, the subgroup M_1 is handled using a modification of Luks's deterministic algorithm [40] for solvable matrix groups.

The algorithms of [5] and [34] are not practical. However, [5] is a cookie jar of new ideas, which should be used in implementations. Hence, we recently started a project of designing new reduction algorithms for those Aschbacher categories where the current algorithms do not have fast asymptotic running time, combining geometric and black-box methods. This is the second level of unification mentioned in the introduction. Although this project is quite new and there is only one paper [18] in print (about the category of normalizers of extraspecial groups), algorithms for three other categories (imprimitive, tensor product, and tensor induced) are in the offing.

4. A new data structure

In this section we discuss an implementation aspect of computations with permutation and matrix groups. As we have seen in the previous sections, the asymptotically most efficient permutation group algorithms and all existing matrix group algorithms break up the input into manageable pieces. Hence, in order to implement these algorithms, we need a data structure for a recursive scheme which facilitates divide-and-conquer techniques to pass from a group G to a normal subgroup N and the factor group G/N, and then to put together the results of those two smaller computations.

In [42] we describe the design and implementation of such a data structure. This data structure opens up the possibility to handle theoretical algorithms that were considered too complicated for implementation. The homomorphism mechanism is on the black-box level, so permutation groups and matrix groups can be treated in a uniform way. Also, for any group occurring in the recursive scheme, the image of the homomorphism may be either a permutation, matrix, or black-box group, so we can switch between the different types as best suited for the particular application. Once a homomorphism $\varphi\colon H \to K$ is defined for some inner node H of the recursion tree, the computation of $\mathrm{Ker}(\varphi)$ and the combination of the results for $\mathrm{Im}(\varphi)$ and $\mathrm{Ker}(\varphi)$ are done by generic procedures, so in applications we can concentrate on finding suitable homomorphisms φ and the handling of the leaf nodes (which usually means constructive recognition of that node).

The first success story is the implementation of a randomized version of the algorithm of Theorem 2.2. All that was needed was the design and implementation of a randomized speedup for processing groups of Cameron type [36], and an implementation of constructive recognition of alternating and symmetric groups in their natural representation, as described in [48, Section 10.2.4]. The rest of the algorithm of Theorem 2.2 is done automatically by the generic recursive procedure. The final result is the first practical treatment of *all* permutation groups: for small-base inputs, the algorithm reverts to the base-SGS method with minimal overhead (and sometimes it runs faster even on small-base inputs), and on larger inputs there are very substantial savings compared to the straightforward call of the current default base-SGS computation.

The mathematical idea behind the recursion scheme is simple, but there were formidable challenges in the design of the data structure. To pull back the results from N and G/N to G, we need new data types, permutations and matrices with memory, that "remember" how they were obtained from the generators of G by storing a straight-line program (SLP). This results in conflicting requirements. On one hand, these new data types must behave like permutations or matrices, so the *existing and future permutation and matrix group algorithms can be applied to them without rewriting the library of GAP functions* and we can incorporate permutation and matrix group algorithms by other developers who may not need to know of our recursive scheme. On the other hand, the steps of the applied permutation and matrix group algorithms must be recorded in the SLP, although these algorithms are not even aware that this SLP exists. We also need a new type of homomorphism template, flexible enough to accommodate the wide variety of methods that can create factor groups. Exploring an unknown G, we may try a lot of different methods to pass to a factor group; these methods must be prioritized by an automatic method selection mechanism, while at the same time this mechanism must be transparent enough for users to change the order in which applicable methods are called if some extra information is known or suspected about G.

There is a long list of novel tricks incorporated in the new framework: for example, how to balance the recursive tree (that the branches are about the same length, speeding up traversing the tree); how to pass information to the children of a node, so each node can have its own individualized method selection process for a more efficient way to find a homomorphism from this node; and the introduction of an analogue of strong generating sets in the matrix group setting, which enables the writing of shorter straight-line programs to reach group elements. Current work concentrates on adding new homomorphism methods to the recursive scheme for the geometric subgroups in Aschbacher's classification, combining black-box and geometric methods as mentioned at the very end of the previous section, and implementing methods for the end nodes of recursion, to handle almost simple matrix and black-box groups. There will also be methods to handle solvable groups given by power-conjugate presentations, thereby including the third large category of black-box groups in the same scheme. I am quite enthusiastic about this new framework: I think we have found the tool for

the uniform treatment of permutation, matrix, and solvable groups, at the same time unifying the theoretical and practical sides of computations with these groups.

Acknowledgement. I am indebted to Bill Kantor for his very helpful comments.

Some results in noncommutative ring theory

Agata Smoktunowicz

Abstract. In this paper we survey some results on the structure of noncommutative rings. We focus particularly on nil rings, Jacobson radical rings and rings with finite Gelfand–Kirillov dimension.

Mathematics Subject Classification (2000). 16-02, 16-06, 16N40, 16N20, 16N60, 16D60, 16P90.

Keywords. Nil rings, Jacobson radical, algebraic algebras, prime algebras, growth of algebras, the Gelfand–Kirillov dimension.

1. Introduction

We present here a brief outline of results and examples related mainly to noncommutative nil rings. In this exposition rings are noncommutative and associative. A vector space R is called an algebra (or a K-algebra) if R is equipped with a binary operation

$$* : (R, R) \to R,$$

called multiplication, such that for any $a, b, c \in R$ and for any $\alpha \in K$, we have $(a + b) * c = a * c + b * c$, $a * (b + c) = a * b + a * c$, $(a * b) * c = a * (b * c)$, $\alpha(a * b) = (\alpha a) * b = a * (\alpha b)$.

It is known that simple artinian rings, commutative simple rings and simple right noetherian rings of characteristic zero have unity elements [35]. In this text, rings are usually without 1. In fact nil rings and Jacobson radical rings cannot have unity elements.

2. Nil rings

The most important question in this area is the Köthe Conjecture, first posed in 1930. Köthe conjectured that a ring R with no nonzero nil (two-sided) ideals would also have no nonzero nil one-sided ideals, [24], see also [15] and [27]. This conjecture is still open despite the attention of many noncommutative algebraists. It is a basic question concerning the structure of rings.

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

The truth of the conjecture has been established for many classes of rings: typically, one proves that for a given class of rings, the sum of all nil one-sided ideals is nil. The most famous examples of such results are the proof of the conjecture in the case of algebras over uncountable fields by Amitsur, and the fact that nil ideals are nilpotent in the class of noetherian rings, proved by Levitski, see [27]. However, as indicated above, Köthe's conjecture is still open in the general case.

An element r in a ring R is said to be *nilpotent* if $r^n = 0$ for some n. A ring R is a *nil* ring if every element of R is nilpotent, and the ring R is *nilpotent* if $R^n = 0$ for some n. A more appropriate definition in the case of infinitely generated rings is the following. A ring R is *locally nilpotent* if every finitely generated subring of R is nilpotent. A thorough understanding of nil and nilpotent rings is important for an attempt to understanding general rings.

In addition, nil rings have some applications in group theory. The following famous theorem was proved in 1964 by Golod and Shafarevich. *For every field F there exists a finitely generated nil F-algebra R which is not nilpotent* ([20]). Recall that a group G is said to be torsion (or periodic) if every $g \in G$ has a finite order. Golod used the group $1 + R$, when F has positive characteristic, to get a counterexample to the General Burnside Problem: *Let G be a finitely generated torsion group. Is G necessarily finite*?

There are many open questions concerning nil rings. As mentioned before, the most important is now known as the *Köthe Conjecture* and was posed by Köthe in 1930: if a ring R has no nonzero nil ideals, does it follow that R has no nonzero nil one-sided ideals? Köthe himself conjectured that the answer would be in the affirmative ([24], [27], [37]).

There are many assertions equivalent to the Köthe Conjecture: For example, the following are equivalent to Köthe's conjecture:

1. The sum of two right nil ideals in any ring is nil.

2. (Krempa [26]) For every nil ring R the ring of 2 by 2 matrices over R is nil.

3. (Fisher, Krempa [18]) For every ring R, R^G is nil implies R is nil (G is the group of automorphisms of R, R^G the set of G-fixed elements).

4. (Ferrero, Puczylowski [17]) Every ring which is a sum of a nilpotent subring and a nil subring must be nil.

5. (Krempa [26]) For every nil ring R the polynomial ring $R[x]$ in one indeterminate over R is Jacobson radical.

6. (Smoktunowicz [44]) For every nil ring R the polynomial ring $R[x]$ in one indeterminate over R is not left primitive.

7. (Xu [49]) The left annihilators of a single element in every complement of a nil radical in a maximal left nil ideal satisfy a.c.c.

Recall that a ring R is Jacobson radical if for every $r \in R$ there is $r' \in R$ such that $r + r' + rr' = 0$. Every nil ring is Jacobson radical. The largest ideal in a ring R, which is Jacobson radical is called the *Jacobson radical* of R. The Jacobson radical of a ring R equals the intersection of all (right) primitive ideals of R (I is a primitive ideal in R if I/R is primitive). Recall that a ring R is (right) primitive if there is a maximal right ideal Q such that $Q + I = R$ for every nonzero ideal I in R and there is $b \in R$ such that $br - r \in Q$ for every $r \in R$ ([13]).

The Köthe Conjecture is said to hold for a ring R if the ideal generated by the nil left ideals of R is nil. Köthe's conjecture holds for the class of Noetherian rings (Levitzki, [27], [32]), Goldie rings (Levitzki, [32]), rings with right Krull dimension (Lenagan [29], [15]), monomial algebras (Beidar, Fong [6]), PI rings (Rasmyslow–Kemer–Braun [14], [34], [22], [12]), algebras over uncountable fields (Amitsur [27], [36]).

There are many related results, some are indicated in the following.

Theorem 2.1 (Levitzki; [32]). *Let R be a right Noetherian ring. Then every nil one-sided ideal of R is nilpotent.*

Theorem 2.2 (Lenagan [29]). *If R has right Krull dimension, then nil subrings of R are nilpotent.*

Theorem 2.3 (Gordon, Lenagan and Robson, Gordon and Robson; [15]). *If R has right Krull dimension, then the prime radical of R is nilpotent.*

The prime radical of R is a nil ideal and is equal to the intersection of all prime ideals in R.

Theorem 2.4 (Beidar, Fong [6]). *Let X be a nonempty set, $Z = \langle X \rangle$ the free monoid on X, Y an ideal of the monoid Z, and F a field. Then the Jacobson radical of the monomial algebra $F[Z/Y]$ is locally nilpotent.*

In the case of characteristic zero the result is due to Jaspers and Puczylowski, [21]. Earlier, Belov and Gateva-Ivanova [10] showed that the Jacobson radical of a finitely generated monomial algebra over a field is nil. However, it is not true that the Jacobson radical of a finitely generated monomial algebra is nilpotent, since it was shown by Zelmanov [50] that there is a finitely generated prime monomial algebra with a nonzero locally nilpotent ideal.

Theorem 2.5 (Razmyslov–Kemer–Braun [34], [22], [12]; [14]). *If R is a finitely generated PI-algebra over a field then the Jacobson radical of R is nilpotent.*

Razmyslov [34] proved this for rings satisfying all identities of matrices, Kemer [22] for algebras over fields of characteristic zero. Later Braun [12] proved the nilpotency of the radical in any finitely generated PI algebra over a commutative noetherian ring. Amitsur has previously shown that the Jacobson radical of a finitely generated PI algebra over a field is nil.

Another famous result is the Nagata–Higman Theorem:

Theorem 2.6 (Nagata–Higman; [19]). *If A is an associative algebra of characteristic p such that $a^n = 0$ for all $a \in A$ and $p > n$ or $p = 0$ then A is nilpotent.*

For interesting results related to Nagata–Higman's theorem see [19].

A theorem of Klein [23] asserts that if R is a nil ring of bounded index then $R[x]$ is a nil ring of bounded index.

In 1956 Amitsur [27] showed that if R is a nil algebra over an uncountable field, then the polynomial ring $R[x]$ in one indeterminate over R is also nil. The situation is completely different for countable fields, as was shown by the author in 2000.

Theorem 2.7 (Smoktunowicz [43]). *For every countable field K there is a nil K-algebra N such that the polynomial ring in one indeterminate over N is not nil.*

This answers a question of Amitsur. Another important theorem by Amitsur is the following.

Theorem 2.8 (Amitsur; [27]). *Let R be a ring. Then the Jacobson radical of the polynomial ring $R[x]$ is equal to $N[x]$ for some nil ideal N of R.*

In 1956 Amitsur conjectured that if R is a ring, and $R[x]$ has no nil ideals then it is semiprimitive (i.e. the Jacobson radical of $R[x]$ is zero). This assertion is true for many important classes of rings, as mentioned above. However, the following theorem shows that this conjecture does not hold in general: *There is a nil ring N such that the polynomial ring in one indeterminate over N is Jacobson radical but not nil* ([41]). For some generalizations of this theorem see [45]. This theorem is true in a more general setting: *For every natural number n, there is a nil ring N such that the polynomial ring in n commuting indeterminates over N is Jacobson radical but not nil*.

Recall that, as shown by Krempa in [26], Köthe's conjecture is equivalent to the assertion that polynomial rings over nil rings are Jacobson radical. However, homomorphic images of polynomial rings over nil rings with nonzero kernels are often Jacobson radical, as is shown by the next result.

Theorem 2.9 (Smoktunowicz [44]). *Let R be a nil ring and $R[x]$ the polynomial ring in one indeterminate over R. Let I be an ideal in $R[x]$ and M the ideal of R generated by coefficients of polynomials from I. Then $R[x]/I$ is Jacobson radical if and only if $R[x]/M[x]$ is Jacobson radical.*

The following are interesting open questions on nil rings.

Question 1 (Latyshev, [16], pp. 12). Let A be an associative algebra with a finite number of generators and relations. If A is a nil algebra must it be nilpotent?

Question 2 (Amitsur; [33]). Let A be an associative algebra with a finite number of generators and relations. Does it follow that the Jacobson radical of A nil?

3. Algebraic algebras

The most well-known question in this area is the Kurosh Problem ([15], [36]). *Let R be a finitely generated algebra over a field F such that R is algebraic over F. Is R finite dimensional over F?*

This problem has a negative solution in general. The famous construction of Golod and Shafarevich in the 1960s produced a finitely generated nil algebra which is not nilpotent ([20]). This was then used to construct a counterexample to the Burnside Conjecture, one of the biggest outstanding problems in group theory at that time. Zelmanov was later awarded the Fields Medal for his solution of the Restricted Burnside Problem [27].

However, the Kurosh Problem is still open for the key special case of a division ring:

Question 3 (Kurosh's problem for division rings [16], [36]). Let R be a finitely generated algebra over a field F such that R is algebraic over F and R is a division ring. Does it follow that R a finite dimensional vector space over its center?

Again, as with the nil ring problems, there are many partial results. The Kurosh Problem for division rings is still open in general, but it is answered affirmatively for F finite and for F having only finite algebraic field extensions, in particular, for F algebraically closed ([36]). By Levitzki's and Kaplanski's theorem, Kurosh's conjecture is also true if there is a bound on the degree of elements in R ([15]). It is unknown whether Kurosh's problem for division rings has a positive answer in the case of algebras over uncountable fields. Also the following question is still open: Is Kurosh's conjecture true for division rings with finite Gelfand–Kirillov dimension, and in particular for division rings with quadratic growth? There are obvious connections with problems in nil rings. A nil element is obviously algebraic, and, in the converse direction, it is possible to construct an associated graded algebra connected with an algebraic algebra in such a way that the positive part is graded nil, i.e., all homogeneous elements are nil. On the other hand, the Kurosh Problem has a negative solution for rings with finite Gelfand–Kirillov dimension ([30]), for simple rings ([42]), for primitive rings ([2]), for finitely generated primitive rings ([8]), and for finitely generated algebraic primitive rings ([9]). However, a natural question arising from the general Kurosh Problem remains open:

Question 4 (Small's question). Let R be a finitely generated simple algebra with 1 over a field F such that R is algebraic over F. Is R a finite dimensional vector space over its center?

Another open question on division rings, which has been around for years, is the following:

Question 5. Let K be a field and let R be a finitely generated algebra which is a division ring. Does it follow that R is a finitely generated vector space over K?

As far as I know this question is very much open even with various conditions, like e.g. Gelfand–Kirillov dimension 2. It has been shown by Small ([38]) that a division ring which is a homomorphic image of a graded noetherian ring (of course, by a non graded ideal) must be finite dimensional. There is a similar open question concerning rings:

Question 6 ([16], p. 20). Does there exist an infinite associative division ring which is finitely generated as a ring?

4. Algebras with finite Gelfand–Kirillov dimension

The Gelfand–Kirillov dimension measures the rate at which an algebra is generated by a generating set. The GK dimension is zero for algebras which are finite dimensional and an elementary counting argument shows that the next possible dimension is one. However, Borho and Kraft showed that any real number value greater than or equal to two is possible ([25]). Bergman's famous Gap Theorem establishes that there is no algebra with GK dimension strictly between one and two ([11], see also [25]). A theorem of Small and Warfield asserts that an affine prime algebra R over a field F of GK dimension 1 is a finite module over its center, and that its center is a finitely generated F-algebra of GK dimension 1 ([40], [25]). In the special case when R is a finitely generated domain over an algebraically closed field with GK dimension 1, it follows by Small–Warfield's and Tsen's theorem (see [15]) that R is in fact commutative ([47]). A theorem of Small, Stafford and Warfield shows that a finitely generated algebra with GK dimension 1 is close to being commutative in that it must satisfy a polynomial identity ([39], [25]).

The graded case has attracted interest in the last decade or so with the development of noncommutative algebraic geometry. Here progress is being made by studying algebras with restricted conditions, including conditions on the growth of the algebras. Low GK dimension examples are obviously of interest. Since the theory is developing by analogy with the classical projective case, one typically deals with graded algebras. Thus dimensions should be increased by one compared to the ungraded case. The first interesting case is to study graded domains of GK dimension two; that is, noncommutative projective curves. This was done in a famous paper in the *Inventiones Mathematicae* by Artin and Stafford about 10 years ago. In fact Artin and Stafford described in [3] the structure of finitely graded domains in terms of algebras related to automorphisms of elliptic curves. They were able to tell when such algebras are noetherian, primitive, PI, etc. In this paper they formulated the analogue of the Bergman Gap Theorem: there should be no graded (by natural numbers) domain with GK dimension strictly between two and three, and they were able to exclude the open interval $(2, 11/5)$. The author has recently established in [46] the truth of the full conjecture.

There are several connecting threads between the three areas mentioned above. As stated earlier, nil elements are algebraic, and graded nil algebras can be constructed from algebraic algebras as associated graded rings. The Golod–Shafarevich construction yields a nil but *not* nilpotent algebra which has exponential growth and so certainly infinite GK dimension.

In recent work with Lenagan, the author has constructed an example of a finitely generated nil but not nilpotent algebra that has finite GK dimension (≤ 20). The precise growth condition dividing nilpotent and nil but not nilpotent is tantalizing. Certainly, nil algebras with GK dimension 1 are easily seen to be nilpotent. It may be that the dividing line is of quadratic growth.

In this area the following question remains open and may be considered to be a test question for new methods. Is there a finitely generated nil algebra with quadratic growth which is not nilpotent? An F-algebra R has quadratic growth if there is a constant c and a generating subspace V of R such that $\dim_F(V+V^2+\cdots+V_n) < cn^2$ for all $n > 0$. In particular GKdim $R \leq 2$.

In connection with this problem, a recent result of Bartholdi is pertinent. In 2004 Bartholdi proved the following result.

Theorem 4.1 (Bartholdi [4]). *Let K be an algebraic field extension of F_2. Then there exist a finitely generated graded K-algebra R such that all homogeneous elements of R are nil, but the algebra has a transcendental invertible element. In particular, R is graded nil but not nil. This algebra R has also a subalgebra isomorphic to the ring of 2×2 matrices over R.*

In more detail, Bartholdi showed that an affine 'recurrent transitive' algebra (without unit) constructed from Grigorchuk's group of intermediate growth is of quadratic growth. Moreover, assuming that the base field is an algebraic extension of F_2, the algebra is Jacobson radical and not nil. This algebra R was earlier studied by Ana Christina Vieira in [48], who showed that R is prime and for every non-zero two sided ideal I of R, R/I is finite-dimensional.

Another way to construct examples of finitely generated algebras was introduced by Markov and later extended by Beidar ([5]), Bell and Small ([7], [8], [32], [36]). The effect of Markov's result is to allow constructions first in infinitely generated algebras, thus simplifying the problem, and then, by using Markov's method, to bring the construction into a finitely generated algebra.

Theorem 4.2 (Markov [31]). *Let K be a field, and let R be a prime, countably generated K-algebra. Then there exists a prime K-algebra A generated by two elements x, y such that R is isomorphic to a right ideal of A, namely to xR.*

Recall that $T \subseteq R$ is a corner of an algebra R if T is a subalgebra of R and $TRT \subseteq T$. Markov's theorem was extended by Small who showed (around 1982, unpublished) that if K is a field and T is a prime, countably generated K algebra then there exists a finitely generated, prime K-algebra A such that T is a corner of A.

It is possible to apply this result in many situations. For example, in [8], Bell and Small applied the result to show that there is a finitely generated algebraic primitive algebra which is infinitely dimensional over its center. In 2003 Bell proved the following extension of Small's theorem. *Let K be a field, and let T be a prime, countably generated K-algebra of Gelfand–Kirillov dimension $\alpha < \infty$. Then there exists a finitely generated, prime K-algebra A of Gelfand–Kirillov dimension $\alpha + 2$ such that T is a corner of A* (see [7]).

Bell's theorem above is related to another question of Small: if R is a noetherian affine algebra with quadratic growth, does it follow that R is either primitive or PI? This is true in the graded case, as was shown by Artin and Stafford in 2000. According to Small, it is also true if every non-zero prime ideal in R is maximal.

An application by Bell of his theorem is the following example which is a counterexample to another question of Small. There is a prime, affine algebra with Gelfand–Kirillov dimension 2 which is not PI and not primitive. This algebra has a nonzero Jacobson radical. The following result of Lanski, Resco and Small assures that usually an affinization of a primitive ring is still primitive:

Theorem 4.3 (Lanski, Resco, Small [28]). *Let R be a prime ring. Then the following is true:*

1. *Let V be a right ideal of R. Then R is a primitive ring exactly when $V/(V \cap l(V))$ is a primitive ring, where $l(V) = \{r \in R : rV = 0\}$.*
2. *If R contains an idempotent e, then R is a primitive ring if and only if eRe is a primitive ring.*

5. Simple rings

A ring R (possibly without 1) is called simple if $R^2 \neq 0$ and R has no proper two-sided ideals. Levitzki, Jacobson, Kaplansky and others asked if there is a simple nil ring. An example of a simple ring which is a Jacobson radical ring (that is, $R = J(R)$ where $J(R)$ denotes the Jacobson radical of R) was found by Sasiada in 1961, see e.g. [15]; however, this ring is not nil. Note that the polynomial ring in one indeterminate over Sasiada's ring is left and right primitive ([44]). By Nakayama's lemma a simple Jacobson radical ring cannot be finitely generated. Since every nil ring is Jacobson radical, a simple nil ring also cannot be finitely generated. A few years ago examples of simple nil rings were constructed by the author ([15]).

Theorem 5.1 (Smoktunowicz [42]). *For every countable field K there is a simple nil algebra over K.*

Notice that all rings in that paper were graded by integers. The following natural question remains open.

Question 7. Is there a simple noncommutative nil algebra over an uncountable field?

Acknowledgements. The author is very grateful to Tom Lenagan and Lance Small for many useful suggestions, and to Tom Lenagan for his collaboration in writing Section 4.

Higher composition laws and applications

Manjul Bhargava*

Abstract. In 1801 Gauss laid down a remarkable law of composition on integral binary quadratic forms. This discovery, known as *Gauss composition*, not only had a profound influence on elementary number theory but also laid the foundations for ideal theory and modern algebraic number theory. Even today, Gauss composition remains one of the best ways of understanding ideal class groups of quadratic fields.

The question arises as to whether there might exist similar laws of composition on other spaces of forms that could shed light on the structure of other algebraic number rings and fields. In this article we present several such higher analogues of Gauss composition, and we describe how each of these composition laws can be interpreted in terms of ideal classes in appropriate rings of algebraic integers. We also discuss several applications of these composition laws, including the resolution of a critical case of the Cohen–Lenstra–Martinet heuristics, and a solution of the long-standing problem of counting the number of quartic and quintic fields of bounded discriminant. In addition, we describe the mysterious relationship between these various composition laws and the exceptional Lie groups. Finally, we discuss prospects for future work and conclude with several open questions.

Mathematics Subject Classification (2000). Primary 11R29; Secondary 11R45.

Keywords. Gauss composition, classical invariant theory, density theorems.

1. Introduction

Gauss published his seminal treatise *Disquisitiones Arithmeticae* in 1801. One of the primary subjects of this work was the (integral) *binary quadratic form*, i.e., any expression $f(x, y) = ax^2 + bxy + cy^2$ where $a, b, c \in \mathbb{Z}$.[1] The group $\mathrm{SL}_2(\mathbb{Z})$ acts naturally on the space of binary quadratic forms by linear substitution of variable: if $\gamma \in \mathrm{SL}_2(\mathbb{Z})$, then one defines

$$(\gamma \cdot f)(x, y) = f((x, y)\gamma).$$

Gauss studied this action of $\mathrm{SL}_2(\mathbb{Z})$ on binary quadratic forms f in terms of the *discriminant* $\mathrm{Disc}(f) = b^2 - 4ac$, as it is easily seen that this discriminant remains

*The author was partially supported by a Packard Fellowship. I am extremely grateful to Andrew Wiles and Peter Sarnak for their encouragement and to Jonathan Hanke, Wei Ho, and Melanie Wood for numerous helpful comments.

[1] Gauss actually considered only the forms where b is even; however, from the modern point of view it is more natural to assume a, b, c are arbitrary integers.

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

invariant under the action of $\mathrm{SL}_2(\mathbb{Z})$. In fact, one can show that *any* polynomial $P(a, b, c)$ invariant under the action of $\mathrm{SL}_2(\mathbb{Z})$ on the space of binary quadratic forms $ax^2 + bxy + cy^2$ must be a polynomial in the discriminant $b^2 - 4ac$ (see e.g. [28]).

It follows that the binary quadratic forms of any fixed discriminant D also naturally break up into orbits under the action of $\mathrm{SL}_2(\mathbb{Z})$. We say a quadratic form $ax^2 + bxy + cy^2$ is *primitive* if a, b, c are relatively prime. Then $\mathrm{SL}_2(\mathbb{Z})$ evidently preserves primitivity, so that the primitive forms of a given discriminant also break up into $\mathrm{SL}_2(\mathbb{Z})$-orbits. Gauss's remarkable discovery regarding these primitive $\mathrm{SL}_2(\mathbb{Z})$-orbits was the following:

Theorem 1.1 (Gauss). *Let $D \equiv 0$ or 1 modulo 4. Then the set of $\mathrm{SL}_2(\mathbb{Z})$-orbits of primitive binary quadratic forms having discriminant D naturally possesses the structure of a finite abelian group.*

What is particularly remarkable about this theorem is that Gauss proved this result before the notion of group formally existed! Theorem 1.1 is quite a deep fact, and has a number of beautiful interpretations. Classically, the theorem generalizes the identity of Brahmagupta [12]:

$$(x_1^2 + Dy_1^2)(x_2^2 + Dy_2^2) = x_3^2 + Dy_3^2,$$

where $x_3 = x_1x_2 + Dy_1y_2$ and $y_3 = x_1y_2 - y_1x_2$. Gauss's theorem describes all identities of the form

$$(a_1x_1^2 + b_1x_1y_1 + c_1y_1^2)(a_2x_2^2 + b_2x_2y_2 + c_2y_2^2) = (a_3x_3^2 + b_3x_3y_3 + c_3y_3^2) \quad (1)$$

where x_3 and y_3 are bilinear functions of (x_1, y_1) and (x_2, y_2) with integer coefficients. Because of the bilinearity condition on (x_3, y_3), the existence of an identity of the type (1) depends only on the $\mathrm{SL}_2(\mathbb{Z})$-equivalence classes of the three forms. Remarkably, the ensemble of all such identities turns the set of $\mathrm{SL}_2(\mathbb{Z})$-equivalence classes of primitive quadratic forms of discriminant D into a group for any eligible value of D. This is precisely the group described by Gauss in Theorem 1.1, showing in particular that the theorem is compatible with the multiplicative structure of the values taken by the forms.

In modern language, the group described in Theorem 1.1 is simply the narrow class group of the unique quadratic ring $S(D)$ of discriminant D (see Section 2.1). This connection with ideal class groups was in fact one of the original motivations for Dedekind to introduce "ideal numbers", or what are now called ideals. Thus Theorem 1.1 really lies at the foundations of modern algebraic number theory. Moreover, Gauss composition still remains one of the best methods for understanding narrow class groups of quadratic fields, and it is certainly still the best way of computing with them.

Of course, Gauss's composition law is related in this way only to field extensions of $\mathbb{Q}$ of degree two, and it would be desirable to have similar ways to understand cubic, quartic, and higher degree fields. The question thus arises: do there exist analogous

composition laws on other spaces of forms, which could be used to shed light on the structure of higher degree fields?

2. The parametrization of algebraic structures

2.1. Gauss composition and rings of rank 2. An alternate way of viewing Gauss composition is as a parametrization result. To describe this, we need some simple definitions. First, define a *ring of rank n* to be any commutative ring with identity whose underlying additive group is isomorphic to $\mathbb{Z}^n$. For example, an order in a number field of degree n is a ring of rank n. Rings of rank 2, 3, 4, 5, and 6 are called *quadratic*, *cubic*, *quartic*, *quintic*, and *sextic* rings respectively. In general, a ring $\mathcal{R}$ of rank n is said to be an *order* in a $\mathbb{Q}$-algebra K if $\mathcal{R} \otimes \mathbb{Q} = K$.

Given a ring $\mathcal{R}$ of rank n, there are two simple functions $\mathcal{R} \to \mathbb{Z}$ called the *trace* and the *norm*, denoted by Tr and N respectively. Given $\alpha \in \mathcal{R}$, we define $\mathrm{Tr}(\alpha)$ (resp. $\mathrm{N}(\alpha)$) as the trace (resp. determinant) of the linear map $\mathcal{R} \xrightarrow{\times\alpha} \mathcal{R}$ given by multiplication by α. The function $x, y \mapsto \mathrm{Tr}(xy)$ defines an inner product on $\mathcal{R}$. If $\langle \alpha_0, \ldots, \alpha_{n-1} \rangle$ is a $\mathbb{Z}$-basis of $\mathcal{R}$, then the *discriminant* $\mathrm{Disc}(\mathcal{R})$ is defined to be the determinant $\mathrm{Det}(\mathrm{Tr}(\alpha_i \alpha_j)_{0 \le i,j \le n-1})$. In basis-free terms, the discriminant of $\mathcal{R}$ is the co-volume of the lattice $\mathcal{R}$ with respect to this inner product, and forms the most important invariant of a ring of rank n. It turns out that the discriminant is always an integer congruent to 0 or 1 (mod 4).

It is easy to describe what all quadratic rings are in terms of the discriminant. Namely, for every integer D congruent to 0 or 1 modulo 4, there is a unique quadratic ring $S(D)$ having discriminant D (up to isomorphism), given by

$$S(D) = \begin{cases} \mathbb{Z}[x]/(x^2) & \text{if } D = 0, \\ \mathbb{Z} \cdot (1,1) + \sqrt{D} \cdot (\mathbb{Z} \oplus \mathbb{Z}) & \text{if } D \ge 1 \text{ is a square}, \\ \mathbb{Z}[(D + \sqrt{D})/2] & \text{otherwise.} \end{cases} \tag{2}$$

Therefore, if we denote by $\mathbb{D}$ the set of elements of $\mathbb{Z}$ that are congruent to 0 or 1 (mod 4), we may say that isomorphism classes of quadratic rings are parametrized by $\mathbb{D}$. The case $D = 0$ is called the *degenerate* case.

Gauss composition concerns the parametrization of narrow (or oriented) ideal classes in oriented quadratic rings. An *oriented* quadratic ring is a quadratic ring in which one of the two choices for a square root $\sqrt{D}$ of D has been distinguished, where D denotes the discriminant of the ring.[2] An *oriented* ideal of a nondegenerate quadratic ring S is a pair (I, ε), where I is any ideal of S having rank 2 over $\mathbb{Z}$ and $\varepsilon = \pm 1$ gives the *orientation* of I. Multiplication of oriented ideals is defined

[2]The advantage of this point of view is that any two oriented quadratic rings of the same discriminant are then canonically isomorphic; to construct this isomorphism, one simply sends the distinguished $\sqrt{D}$ in one ring to that in the other. Note that a choice of $\sqrt{D}$ amounts to a choice of generator of $\wedge^2 S$, namely $1 \wedge \left(\frac{D+\sqrt{D}}{2}\right)$ – hence the name *oriented* quadratic ring.

componentwise. Similarly, for an element $\kappa \in K = S \otimes \mathbb{Q}$, the product $\kappa \cdot (I, \varepsilon)$ is defined to be the ideal $(\kappa I, \mathrm{sgn}(N(\kappa))\varepsilon)$. Two oriented ideals (I_1, ε_1) and (I_2, ε_2) are said to be in the same *class* if $(I_1, \varepsilon_1) = \kappa \cdot (I_2, \varepsilon_2)$ for some invertible $\kappa \in K$. In practice, we will denote an oriented ideal (I, ε) simply by I, with the orientation $\varepsilon = \varepsilon(I)$ on I being understood.

In this language, Gauss composition states:

Theorem 2.1. *There is a canonical bijection between the set of* $\mathrm{SL}_2(\mathbb{Z})$*-equivalence classes of nondegenerate binary quadratic forms and the set of isomorphism classes of pairs* (S, I)*, where* S *is a nondegenerate oriented quadratic ring and* I *is an oriented ideal class of* S*.*

The map from oriented ideal classes to binary quadratic forms is easily described. Given an oriented ideal $I \subset S$, let $\langle \alpha_1, \alpha_2 \rangle$ be a correctly oriented basis of I, i.e., a basis such that the determinant of the change-of-basis matrix from $\langle 1, \sqrt{D} \rangle$ to $\langle \alpha_1, \alpha_2 \rangle$ has the same sign as $\varepsilon(I)$;[3] this determinant is called the *norm* of I and is denoted $\mathrm{N}(I)$. To the oriented ideal I, one then associates the binary quadratic form

$$Q(x, y) = \frac{\mathrm{N}(\alpha_1 x + \alpha_2 y)}{\mathrm{N}(I)}. \tag{3}$$

One readily verifies that $Q(x, y)$ is an integral binary quadratic form and that it is well-defined up to the action of $\mathrm{SL}_2(\mathbb{Z})$. What is remarkable about Theorem 2.1 is not just that every oriented ideal class of a quadratic ring yields an integral binary quadratic form, but that every integral binary quadratic form arises in this way! Another remarkable aspect of the correspondence (3) of Theorem 2.1 is that it is *discriminant-preserving*: under the bijection, the discriminant of a binary quadratic form is equal to the discriminant of the corresponding quadratic ring. That is, oriented ideal classes in $S(D)$ correspond to $\mathrm{SL}_2(\mathbb{Z})$-equivalence classes of binary quadratic forms having discriminant D.

An oriented ideal I of the oriented quadratic ring $S(D)$ is said to be *invertible* if there exists a (fractional) oriented ideal I' such that the product $I I'$ is $(S(D), +1)$. It is known that the set of invertible oriented ideals modulo multiplication by scalars forms a finite abelian group $\mathrm{Cl}^+(S(D))$, called the *oriented* (or *narrow*) *class group*.[4] One checks that invertible oriented ideals correspond to primitive forms via (3). Gauss's group structure on classes of primitive forms of discriminant D arises from the fact that the invertible oriented ideal classes of a quadratic ring $S(D)$ form a group under multiplication.

In the statement of the theorem, we have used the word "nondegenerate" to mean "nonzero discriminant". Theorem 2.1 could also be extended to zero discriminant, although this would require a rather more involved notion of "oriented ideal class", so in what follows we always restrict ourselves to the nondegenerate case.

[3] Evidently, for any basis $\langle \alpha_1, \alpha_2 \rangle$ of I, either $\langle \alpha_1, \alpha_2 \rangle$ or $\langle \alpha_2, \alpha_1 \rangle$ will be correctly oriented.

[4] The usual *class group* is a quotient of the oriented class group, and may be obtained by "forgetting" all orientations.

2.2. Parametrization and rings of rank n. In terms of Theorem 2.1, it becomes easier to see what we might mean by "generalizations" of Gauss composition. Namely, we seek an algebraic group G and a representation V, defined over $\mathbb{Z}$, such that the set $G(\mathbb{Z}) \setminus V(\mathbb{Z})$ of integral orbits are in canonical bijection with interesting algebraic objects – such as rings of rank n, modules over these rings, and maps among them. In Gauss's case, the group G is SL_2 and V is the space of binary quadratic forms, and we have seen that the integral orbits parametrize oriented ideal classes (or oriented rank 1 modules) in quadratic rings. In general, we have the following question:

Question 2.2. For what pairs (G, V) does $G(\mathbb{Z}) \setminus V(\mathbb{Z})$ parametrize rings, modules, maps, etc.?

If other such pairs (G, V) do in fact exist, where do we go about looking for them? One thing to notice about the action of $\mathrm{GL}_2(\mathbb{C})$ on the vector space of binary quadratic forms over $\mathbb{C}$ is that there is essentially one (Zariski open) orbit – i.e., any binary quadratic form of nonzero discriminant can be taken to any other such form via an element of $\mathrm{GL}_2(\mathbb{C})$. It is also possible to see this from the point of view of Gauss composition: by "base change" the proof of Theorem 2.1 shows that nondegenerate orbits over $\mathbb{C}$ must be in one-to-one correspondence with quadratic rings over $\mathbb{C}$ – which must take the form $\mathbb{C} \oplus \mathbb{C}$ – and ideal classes over such rings – which also must take the form $\mathbb{C} \oplus \mathbb{C}$ (up to isomorphism). So over $\mathbb{C}$, there is essentially just one object of the form (S, I), namely $S = I = \mathbb{C} \oplus \mathbb{C}$.

By the same argument, if we are to get a parametrization result of a simple form like Gauss composition, where objects being parametrized are rings of rank n, ideal classes, etc. (so that there is only one such nondegenerate object over $\mathbb{C}$), then the pair (G, V) must also have the property that there is just one open orbit over $\mathbb{C}$. Such representations having just one open orbit over $\mathbb{C}$ have come up for numerous authors in various contexts, and they are known as "prehomogeneous vector spaces".

Definition 2.3. A *prehomogeneous vector space* is a pair (G, V) where G is an algebraic group and V is a rational vector space representation of G such that the action of $G(\mathbb{C})$ on $V(\mathbb{C})$ has just one Zariski open orbit.

In a monumental work, Sato and Kimura [33] gave a classification of all "reduced, irreducible" prehomogeneous vector spaces. Namely, they showed that there are essentially 36 of them! A few of these 36 are in fact infinite families. In another beautiful work, Wright and Yukie [41] studied these spaces over fields and found that the K-orbits for a field K frequently correspond to field extensions of K; for example, the nondegenerate $\mathbb{Q}$-orbits on the space of binary quadratic forms are naturally in bijection with quadratic extensions of $\mathbb{Q}$. So that gives us some hope, and obtaining the answer to Question 2.2 thus translates into the following goal:

Goal 2.4. Understand $G(\mathbb{Z}) \setminus V(\mathbb{Z})$ for prehomogeneous vector spaces (G, V).

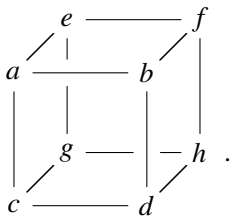
Of course, some of these spaces are quite large – thirty or more dimensions – so to just go in and analyze the integer orbits is somewhat daunting. Even Gauss's space,

which is only three-dimensional, is (as we have seen!) far from trivial. Gauss's own treatment of Gauss composition took numerous pages to describe.

To make further progress, we wish to have a different – and perhaps also simpler – perspective on Gauss composition that might lend itself more naturally to generalization to other spaces. Following [4], we give such a perspective in terms of $2 \times 2 \times 2$ cubes of integers. As we will see, the space of $2 \times 2 \times 2$ cubes not only gives an elementary description of Gauss composition, but also leads to composition laws and analogues of Theorem 2.1 for numerous other prehomogeneous vector spaces.

3. The story of the cube

Suppose we put integers on the corners of a cube:



(4)

Notice that any such cube A of integers may be sliced into two 2×2 matrices, and in essentially three different ways, corresponding to three different planes of symmetry of a cube. More precisely, the integer cube A given by (4) can be sliced into the following pairs of 2×2 matrices:

$$\begin{aligned} M_1 &= \begin{bmatrix} a & b \\ c & d \end{bmatrix}, \quad N_1 = \begin{bmatrix} e & f \\ g & h \end{bmatrix} \\ M_2 &= \begin{bmatrix} a & c \\ e & g \end{bmatrix}, \quad N_2 = \begin{bmatrix} b & d \\ f & h \end{bmatrix} \\ M_3 &= \begin{bmatrix} a & e \\ b & f \end{bmatrix}, \quad N_3 = \begin{bmatrix} c & g \\ d & h \end{bmatrix}. \end{aligned} \tag{5}$$

Now for any such slicing of the cube A into a pair (M_i, N_i) of 2×2 matrices as in (5), we may construct a binary quadratic form $Q_i(x, y)$ as follows:

$$Q_i(x, y) = -\mathrm{Det}(M_i x + N_i y). \tag{6}$$

Thus any cube A of integers gives rise to three integral binary quadratic forms. A simple computation or elementary argument shows that the discriminants of the three quadratic forms Q_1, Q_2, and Q_3 are the same! And the punchline is:

Theorem 3.1. *If a cube A gives rise to three primitive binary quadratic forms Q_1, Q_2, Q_3 via* (4)–(6)*, then Q_1, Q_2, Q_3 have the same discriminant, and the product of these three forms is the identity in the group defined by Gauss composition.*

Conversely, if Q_1, Q_2, Q_3 are any three primitive binary quadratic forms of the same discriminant whose product is the identity under Gauss composition, then there exists a cube A yielding Q_1, Q_2, Q_3 via (4)–(6).

Thus the cube story gives a very simple and complete description of Gauss composition of binary quadratic forms. In fact, Theorem 3.1 can be used to *define* Gauss composition. The situation is reminiscent of the group law on a plane elliptic curve, where the most elementary way to define the group law is to declare that three points sum to zero if and only if they lie on a common line. In the same way, we may define Gauss composition by declaring that three primitive quadratic forms multiply to the identity if and only if they arise from a common cube. A proof of Theorem 3.1 may be found in [4, Appendix].

Theorem 3.1 is useful not only because it leads to Gauss composition, but also because it leads to various additional laws of composition. First and foremost, it leads to a law of composition on the cubes themselves!

3.1. Composition of cubes. Let us begin by rephrasing Theorem 3.1 as an orbit problem. First, we note that the space of cubes may be identified with the representation $\mathbb{Z}^2 \otimes \mathbb{Z}^2 \otimes \mathbb{Z}^2$ of the group $G = \mathrm{SL}_2(\mathbb{Z}) \times \mathrm{SL}_2(\mathbb{Z}) \times \mathrm{SL}_2(\mathbb{Z})$; this representation is a prehomogeneous vector space. The identification is made as follows: if we use $\langle v_1, v_2 \rangle$ to denote the standard basis of $\mathbb{Z}^2$, then the cube described by (4) is simply

$$\begin{aligned} &a\, v_1 \otimes v_1 \otimes v_1 + b\, v_1 \otimes v_2 \otimes v_1 + c\, v_2 \otimes v_1 \otimes v_1 + d\, v_2 \otimes v_2 \otimes v_1 \\ &+ e\, v_1 \otimes v_1 \otimes v_2 + f\, v_1 \otimes v_2 \otimes v_2 + g\, v_2 \otimes v_1 \otimes v_2 + h\, v_2 \otimes v_2 \otimes v_2 \end{aligned}$$

as an element of $\mathbb{Z}^2 \otimes \mathbb{Z}^2 \otimes \mathbb{Z}^2$. In terms of the cubical representation (4), the three factors of $\mathrm{SL}_2(\mathbb{Z})$ in G act by row operations, column operations, and the "other direction" operations respectively.

Theorem 3.1 may be viewed as describing the nondegenerate orbits of $\mathbb{Z}^2 \otimes \mathbb{Z}^2 \otimes \mathbb{Z}^2$ under the action of G in terms of triples of oriented ideal classes whose "product" is the identity class. To state this description more precisely, we need just two simple definitions. First, we call a triple (I_1, I_2, I_3) of oriented fractional ideals in $S \otimes \mathbb{Q}$ *balanced* if $I_1 I_2 I_3 \subseteq S$ and $\mathrm{N}(I_1)\mathrm{N}(I_2)\mathrm{N}(I_3) = 1$. Also, we define two balanced triples (I_1, I_2, I_3) and (I_1', I_2', I_3') of oriented ideals of S to be *equivalent* if $I_1 = \kappa_1 I_1'$, $I_2 = \kappa_2 I_2'$, and $I_3 = \kappa_3 I_3'$ for some invertible elements $\kappa_1, \kappa_2, \kappa_3 \in S \otimes \mathbb{Q}$. For example, if S is the full ring of integers in a quadratic field, then an equivalence class of balanced triples means simply a triple of oriented ideal classes whose product is the principal class.

Our Theorem 3.1 on cubes may then be stated as the solution to an orbit problem as follows:

Theorem 3.2. *There is a canonical bijection between the set of nondegenerate G-orbits on the space $\mathbb{Z}^2 \otimes \mathbb{Z}^2 \otimes \mathbb{Z}^2$ of $2 \times 2 \times 2$ integer cubes and the set of isomorphism classes of pairs $(S, (I_1, I_2, I_3))$, where S is a nondegenerate oriented quadratic ring and (I_1, I_2, I_3) is an equivalence class of balanced triples of oriented ideals of S.*

As with Theorem 3.2, we may consider those orbits that correspond solely to *invertible* oriented ideal classes. Let us say a cube A is *projective* if the three oriented ideal classes associated to A in Theorem 3.2 are invertible (i.e., if they are projective as modules). Equivalently, A is projective if the associated three binary quadratic forms Q_i are each primitive.

Let us define the *discriminant* $\mathrm{Disc}(A)$ of a cube A to be the discriminant of any one of the three binary quadratic forms Q_i arising from it. Then Theorem 3.2 is discriminant-preserving: under the bijection, the discriminant of a cube is equal to the discriminant of the corresponding quadratic ring.

We can now describe composition of cubes. It is most easily stated in terms of ideal classes. Recall that Gauss composition can be viewed as multiplication of oriented ideal classes in a fixed quadratic ring S:

$$(S, I) \circ (S, I') = (S, II').$$

When restricted to invertible ideal classes of a fixed quadratic ring $S = S(D)$ (i.e., primitive binary quadratic forms having a fixed discriminant D), this yields the oriented class group $\mathrm{Cl}^+(S(D))$.

Analogously, composition of cubes can be viewed as multiplication of equivalence classes of balanced triples of oriented ideals:

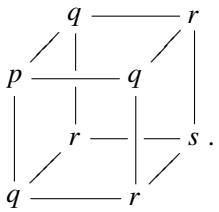
$$(S, (I_1, I_2, I_3)) \circ (S, (I_1', I_2', I_3')) = (S, (I_1I_1', I_2I_2', I_3I_3')).$$

When restricted to invertible ideal classes of a fixed quadratic ring (i.e., projective cubes having a fixed discriminant), this yields the group $\mathrm{Cl}^+(S) \times \mathrm{Cl}^+(S)$, since the last ideal class is determined by the first two. Thus Gauss composition yields $\mathrm{Cl}^+(S)$, while composition of cubes gives $\mathrm{Cl}^+(S) \times \mathrm{Cl}^+(S)$. A surprising consequence of this result is that the number of orbits of projective cubes having a given discriminant D is always a square number.

3.2. Composition of binary cubic forms. The law of composition of cubes now also leads to a number of further composition laws on various other spaces. First, let us consider the space of triply-symmetric cubes, which is equivalent to the space of binary cubic forms $px^3 + 3qx^2y + 3rxy^2 + sy^3$: indeed, just as one often expresses a binary quadratic form $px^2 + 2qxy + ry^2$ as the symmetric 2×2 matrix

$$\begin{bmatrix} p & q \\ q & r \end{bmatrix},$$

one may naturally express a binary cubic form $px^3 + 3qx^2y + 3rxy^2 + sy^3$ via the triply-symmetric $2 \times 2 \times 2$ matrix



(7)

If we use $\mathrm{Sym}^3\mathbb{Z}^2$ to denote the space of binary cubic forms with triplicate central coefficients, then the above association of $px^3 + 3qx^2y + 3rxy^2 + sy^3$ with the cube (7) corresponds to the natural inclusion

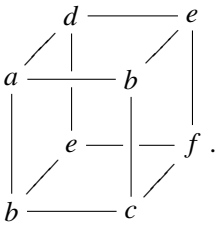
$$\iota\colon \mathrm{Sym}^3\mathbb{Z}^2 \to \mathbb{Z}^2 \otimes \mathbb{Z}^2 \otimes \mathbb{Z}^2$$

of the space of triply-symmetric cubes into the space of cubes. The space of binary cubic forms under the action of $\mathrm{SL}_2(\mathbb{Z})$ also yields a prehomogeneous vector space.

We call a binary cubic form $C(x, y) = px^3 + 3qx^2y + 3rxy^2 + sy^3$ *projective* if the corresponding triply-symmetric cube $\iota(C)$ given by (7) is projective. It turns out that the $\mathrm{SL}_2(\mathbb{Z})$-orbits on such binary cubic forms having a fixed discriminant D also then inherit a law of composition from the space of cubes, leading to a group structure when restricted to projective forms. It is not hard to guess what this group should be related to. Namely, projective triply-symmetric cubes correspond to a balanced triple of ideals (I, I, I) in $S(D)$, where the three ideals are in fact the same. Thus $I \cdot I \cdot I$ is the identity ideal class, implying that orbits of binary cubic forms essentially correspond to 3-torsion elements in the oriented class group $\mathrm{Cl}^+(S)$. (The precise 3-torsion group one obtains is discussed in [4].) Thus the symmetrization procedure allows us to isolate a certain arithmetic part of the class group.

An interesting consequence of this result is that the number of orbits of projective binary cubic forms having a given discriminant D is always a power of three!

3.3. Composition of pairs of binary quadratic forms. The group law on binary cubic forms of discriminant D was obtained by imposing a triple-symmetry condition on the group of $2 \times 2 \times 2$ cubes of discriminant D. Rather than imposing a threefold symmetry, one may instead impose only a twofold symmetry. This leads to cubes taking the form



(8)

That is, these cubes can be sliced (along a certain fixed plane) into two 2×2 symmetric matrices and therefore can naturally be viewed as a pair of binary quadratic forms $(ax^2 + 2bxy + cy^2, dx^2 + 2exy + fy^2)$.

If we use $\mathbb{Z}^2 \otimes \mathrm{Sym}^2\mathbb{Z}^2$ to denote the space of pairs of integer-matrix binary quadratic forms, then the above association of $(ax^2+2bxy+cy^2, dx^2+2exy+fy^2)$ with the cube (8) corresponds to the natural inclusion map

$$\jmath : \mathbb{Z}^2 \otimes \mathrm{Sym}^2\mathbb{Z}^2 \to \mathbb{Z}^2 \otimes \mathbb{Z}^2 \otimes \mathbb{Z}^2.$$

The lattice $\mathbb{Z}^2 \otimes \mathrm{Sym}^2\mathbb{Z}^2$ under the action of $\mathrm{SL}_2(\mathbb{Z}) \times \mathrm{SL}_2(\mathbb{Z})$ again yields a prehomogeneous vector space.

As in the case of binary cubic forms, we call a pair of binary quadratic forms *projective* if the corresponding doubly-symmetric cube $\jmath(C)$ given by (8) is projective. Again, the projective pairs of binary quadratic forms having a fixed discriminant D inherit a group structure. Since such elements correspond to balanced triples of ideals (I_1, I_3, I_3) where the last two ideals are the same, one sees that the group thus obtained is again simply the group $\mathrm{Cl}^+(S(D))$ since I_3 determines I_1. That is, not only do binary quadratic forms of a fixed discriminant D give rise to the oriented class group of $S(D)$, but so do *pairs* of binary quadratic forms!

3.4. Further parametrization spaces for quadratic rings. The discussions above illustrate that once we have a law of composition on the space of cubes, then various other of its invariant and covariant spaces also inherit a law of composition; Gauss composition is indeed just one of these.

Symmetrization is one procedure that allows us to generate new prehomogenous vector spaces with composition; this was the subject of Sections 3.2 and 3.3. The determinant trick (6) to produce Gauss composition is another. There are several other operations too that play an important role, such as *skew-symmetrization*, *symplectization*, *hermitianization*, and *dualization*, and each procedure is found to have both invariant-theoretic and number-theoretic meaning, yielding numerous further analogues of Theorem 2.1 involving higher rank rings, higher rank modules, as well as noncommutative rings such as quaternion and octonion algebras. Further details may be found in [4] and [8].

4. Cubic analogues of Gauss composition

In the previous section, we discussed various generalizations of Gauss composition that were found to be closely related to the ideal class groups of quadratic rings. In this section, we show how similar ideas can be used to obtain genuine "cubic analogues" of Gauss composition, i.e., composition laws on appropriate spaces of forms so that the resulting groups are related to the class groups of *cubic rings*.

The fundamental object in our treatment of quadratic composition was the space of $2 \times 2 \times 2$ cubes of integers. It turns out that the fundamental object for cubic

composition is the space of $2\times3\times3$ boxes of integers, and yields exactly what is needed for a cubic analogue of Gauss's theory. The action of $\mathrm{GL}_2(\mathbb{Z}) \times \mathrm{SL}_3(\mathbb{Z}) \times \mathrm{SL}_3(\mathbb{Z})$ on $2 \times 3 \times 3$ integer boxes is again a prehomogeneous vector space, and the orbits correspond in a natural way to cubic rings and ideal classes in those rings. Before the resulting cubic analogues of Gauss composition can be described, it is necessary first to understand how cubic rings are parametrized.

4.1. The parametrization of cubic rings. In Section 2.1, we saw that quadratic rings are parametrized up to isomorphism by their discriminants. This is not so for cubic rings; indeed, there may sometimes be several nonisomorphic cubic rings having the same discriminant. The correct object parametrizing cubic rings – i.e., rings free of rank 3 as $\mathbb{Z}$-modules – was first determined by Delone–Faddeev in their beautiful 1964 treatise on cubic irrationalites [21]. They showed that cubic rings are in bijective correspondence with $\mathrm{GL}_2(\mathbb{Z})$-equivalence classes of integral binary cubic forms $ax^3 + bx^2y + cxy^2 + dy^3$, as follows.

Given a binary cubic form $f(x, y) = ax^3+bx^2y+cxy^2+dy^3$ with $a, b, c, d \in \mathbb{Z}$, we associate to f the ring $R(f)$ having $\mathbb{Z}$-basis $\langle 1, \omega, \theta\rangle$ and multiplication table

$$\begin{aligned} \omega\theta &= -ad \\ \omega^2 &= -ac + b\omega - a\theta \\ \theta^2 &= -bd + d\omega - c\theta. \end{aligned} \tag{9}$$

One easily verifies that $\mathrm{GL}_2(\mathbb{Z})$-equivalent binary cubic forms then yield isomorphic rings, and conversely, that every isomorphism class of ring R can be represented in the form $R(f)$ for a unique binary cubic form f, up to such equivalence. Thus we may say that isomorphism classes of cubic rings are parametrized by $\mathrm{GL}_2(\mathbb{Z})$-equivalence classes of integral binary cubic forms. An easy calculation using (9) shows that the discriminant $\mathrm{Disc}(R(f))$ is equal to the discriminant $\mathrm{Disc}(f)$ of the binary cubic form f, where $\mathrm{Disc}(f) = b^2c^2 - 4ac^3 - 4b^3d + 18abcd - 27a^2d^2$ is the unique polynomial invariant for the action of $\mathrm{GL}_2(\mathbb{Z})$ on binary cubic forms. We thus obtain:

Theorem 4.1 ([21]). *There is a canonical bijection between the set of* $\mathrm{GL}_2(\mathbb{Z})$*-equivalence classes of integral binary cubic forms and the set of isomorphism classes of cubic rings, by the association*

$$f \leftrightarrow R(f).$$

Moreover, $\mathrm{Disc}(f) = \mathrm{Disc}(R(f))$.

We say a cubic ring is *nondegenerate* if it has nonzero discriminant (equivalently, if it is an order in an étale cubic algebra over $\mathbb{Q}$). Similarly, a binary cubic form is *nondegenerate* if it has nonzero discriminant (equivalently, if it has distinct roots in $\mathbb{P}^1(\mathbb{Q})$). The discriminant equality in Theorem 4.1 implies, in particular, that isomorphism classes of nondegenerate cubic rings correspond bijectively with equivalence classes of nondegenerate integral binary cubic forms.

4.2. Cubic composition and 2 × 3 × 3 boxes. Imitating Section 3.1, for a cubic ring R let us say a pair (I, I') of fractional R-ideals in $K = R \otimes \mathbb{Q}$ is *balanced* if $II' \subseteq R$ and $N(I)N(I') = 1$. Furthermore, we say two such balanced pairs (I_1, I_1') and (I_2, I_2') are *equivalent* if there exist invertible elements $\kappa, \kappa' \in K$ such that $I_1 = \kappa I_2$ and $I_1' = \kappa' I_2'$. For example, if R is the full ring of integers in a cubic field then an equivalence class of balanced pairs of ideals is simply a pair of ideal classes that are inverse to each other in the ideal class group.

The analogue of Theorem 3.2 in the theory of cubic composition states that $\mathrm{GL}_2(\mathbb{Z}) \times \mathrm{SL}_3(\mathbb{Z}) \times \mathrm{SL}_3(\mathbb{Z})$-classes of $2 \times 3 \times 3$ integer boxes correspond to equivalence classes of balanced pairs of ideals in cubic rings.

Theorem 4.2. *There is a canonical bijection between the set of nondegenerate* $\mathrm{GL}_2(\mathbb{Z}) \times \mathrm{SL}_3(\mathbb{Z}) \times \mathrm{SL}_3(\mathbb{Z})$*-orbits on the space* $\mathbb{Z}^2 \otimes \mathbb{Z}^3 \otimes \mathbb{Z}^3$ *and the set of isomorphism classes of pairs* $(R, (I, I'))$*, where* R *is a nondegenerate cubic ring and* (I, I') *is an equivalence class of balanced pairs of ideals of* R*.*

How does one recover the cubic ring R from a $2 \times 3 \times 3$ box of integers? A $2 \times 3 \times 3$ box may be viewed (by an appropriate slicing) as a pair (A, B) of 3×3 matrices. Then $f(x, y) = \mathrm{Det}(Ax - By)$ is a binary cubic form. The ring R is simply the cubic ring $R(f)$ associated to f via Theorem 4.1.

If we define the *discriminant* $\mathrm{Disc}(A, B)$ of (A, B) as $\mathrm{Disc}(\mathrm{Det}(Ax - By))$, then one shows again that this discriminant is the unique polynomial invariant for the action of $\mathrm{GL}_2(\mathbb{Z}) \times \mathrm{SL}_3(\mathbb{Z}) \times \mathrm{SL}_3(\mathbb{Z})$ on $2 \times 3 \times 3$ boxes. By the method of recovering R from (A, B) above, we see again that the bijection of Theorem 4.2 preserves discriminants.

We may now describe composition of $2 \times 3 \times 3$ boxes. Given a binary cubic form f, let $(\mathbb{Z}^2 \otimes \mathbb{Z}^3 \otimes \mathbb{Z}^3)(f)$ denote the set of all elements $(A, B) \in \mathbb{Z}^2 \otimes \mathbb{Z}^3 \otimes \mathbb{Z}^3$ such that $\mathrm{Det}(Ax - By) = f(x, y)$; all such elements correspond to the same cubic ring in Theorem 4.2. The group $\mathrm{SL}_3(\mathbb{Z}) \times \mathrm{SL}_3(\mathbb{Z})$ is seen to act naturally on the set $(\mathbb{Z}^2 \otimes \mathbb{Z}^3 \otimes \mathbb{Z}^3)(f)$ via simultaneous row and column operations on A and B; this action evidently does not change the value of $\mathrm{Det}(Ax - By)$. Moreover, one finds that two elements of $(\mathbb{Z}^2 \otimes \mathbb{Z}^3 \otimes \mathbb{Z}^3)(f)$ yield equivalent balanced pairs of ideals in $R(f)$ if and only if they are equivalent under $\mathrm{SL}_3(\mathbb{Z}) \times \mathrm{SL}_3(\mathbb{Z})$.

As with the quadratic cases of composition in Section 3, composition of $2 \times 3 \times 3$ boxes having a fixed f can now be viewed as multiplication of equivalence classes of balanced pairs of ideals in the corresponding cubic ring $R = R(f)$:

$$(R, (I, I')) \circ (R, (J, J')) = (R, (IJ, I'J')).$$

When restricted to invertible ideal classes (i.e., *projective* $2 \times 3 \times 3$ boxes), this yields the ideal class group $\mathrm{Cl}(R)$ of R, since the second ideal class is determined by the first (as they are inverses to each other). Thus composition of $\mathrm{SL}_3(\mathbb{Z}) \times \mathrm{SL}_3(\mathbb{Z})$-equivalence classes of projective $2 \times 3 \times 3$ boxes yields the class groups of cubic rings, in complete analogy with Gauss composition in the quadratic case.

To summarize:

- In the case of binary quadratic forms, the unique SL_2-invariant is the discriminant D, which classifies orders in quadratic fields. The primitive classes having a fixed value of D form a group under a certain natural composition law. This group is naturally isomorphic to the narrow class group of the corresponding quadratic order.
- In the case of $2\times3\times3$ integer boxes, the unique $\mathrm{SL}_3\times\mathrm{SL}_3$-invariant is the binary cubic form f, which classifies orders in cubic fields. The projective classes having a fixed value of f form a group under a certain natural composition law. This group is naturally isomorphic to the ideal class group of the corresponding cubic order.

Thus the composition law on the space of $2 \times 3 \times 3$ integer cubes is really the cubic analogue of Gauss composition.

4.3. Cubic composition and pairs of ternary quadratic forms. Just as we were able to impose a symmetry condition on $2 \times 2 \times 2$ matrices to obtain information on the exponent 3-parts of class groups of quadratic rings, we can impose a symmetry condition on $2 \times 3 \times 3$ matrices to obtain information on the exponent 2-parts of class groups of cubic rings. The "symmetric" elements in $\mathbb{Z}^2 \otimes \mathbb{Z}^3 \otimes \mathbb{Z}^3$ are the elements of $\mathbb{Z}^2 \otimes \mathrm{Sym}^2\mathbb{Z}^3$, i.e., pairs (A, B) of symmetric 3×3 integer matrices, which may be viewed as pairs (A, B) of integral ternary quadratic forms. The action of $\mathrm{GL}_2(\mathbb{Z}) \times \mathrm{SL}_3(\mathbb{Z})$ on pairs of ternary quadratic forms is again a prehomogeneous vector space.

The cubic form invariant f and the *discriminant* $\mathrm{Disc}(A, B)$ of (A, B) may be defined in the identical manner; we have $f(x, y) = \mathrm{Det}(Ax - By)$ and $\mathrm{Disc}(A, B) = \mathrm{Disc}(\mathrm{Det}(Ax - By))$. We say an element $(A, B) \in \mathbb{Z}^2 \otimes \mathrm{Sym}^2\mathbb{Z}^3$ is *projective* if it is projective as a $2 \times 3 \times 3$ box.

As in the case of binary cubic forms and symmetric cubes (see Section 3.2), the space of pairs of ternary quadratic forms also inherits a law of composition from the space of $2 \times 3 \times 3$ boxes. Again, the restriction to symmetric classes isolates a certain arithmetic part of the class group. Namely, symmetric projective $2 \times 3 \times 3$ boxes yield pairs of the form $(R, (I, I))$ where the two ideals are in fact the same. Thus $I \cdot I$ is the identity ideal class of R, so we see that $\mathrm{GL}_2(\mathbb{Z}) \times \mathrm{SL}_3(\mathbb{Z})$-orbits of pairs of integer-matrix ternary quadratic forms essentially parametrize 2-torsion elements in the class groups of cubic rings (see [5] for further details).

This parametrization has several interesting consequences. For example, it implies that the number of equivalence classes of projective pairs (A, B) of ternary quadratic forms having a given binary cubic $\mathrm{Det}(Ax - By)$ is always a power of 2!

The parametrization also enables one to prove the first known case of the Cohen–Martinet heuristics for class groups, namely for the average size of the 2-torsion subgroup in the class groups of cubic fields. This average number of 2-torsion elements turns out to be 5/4 for real cubic fields and 3/2 for complex cubic fields. In particular,

this implies that at least 75% of totally real cubic fields, and at least 50% of complex cubic fields, have odd class number. Further details may be found in [9]. The case of narrow class groups can also be handled by generalizations of these arguments (to appear in future work).

5. The parametrization of quartic and quintic rings

The composition laws and results of the previous two sections depended heavily on the simple but beautiful parametrizations of quadratic and cubic rings given by (2) and (9) respectively. Namely, we saw that quadratic rings are parametrized by integers congruent to 0 or 1 (mod 4), while cubic rings are parametrized by $\mathrm{GL}_2(\mathbb{Z})$-equivalence classes of binary cubic forms.

It has been a long-time open question to determine whether analogous parametrizations exist for rings of rank 4. The ideas of the previous sections, together with a theory of *resolvent rings*, lead to a parametrization of quartic rings that is just as complete as in the quadratic and cubic cases. These "resolvent rings" are so named because they form natural integral models of the resolvent fields occurring in the classical literature; see [6] for further details.

This perspective leads one to show that the analogous objects parametrizing quartic rings are essentially *pairs of integer-valued ternary quadratic forms*, up to integer equivalence. To make a precise statement, let $(\mathbb{Z}^2 \otimes \mathrm{Sym}^2\mathbb{Z}^3)^*$ denote the space of pairs of ternary quadratic forms having integer coefficients. Then we have:

Theorem 5.1. *There is a canonical bijection between the set of* $\mathrm{GL}_2(\mathbb{Z}) \times \mathrm{SL}_3(\mathbb{Z})$*-orbits on the space* $(\mathbb{Z}^2 \otimes \mathrm{Sym}^2\mathbb{Z}^3)^*$ *of pairs of integer-valued ternary quadratic forms and the set of isomorphism classes of pairs* (Q, R)*, where* Q *is a quartic ring and* R *is a cubic resolvent ring of* Q*.*

A cubic resolvent ring of a quartic ring Q is a cubic ring R equipped with a certain natural quadratic mapping $Q \to R$. It turns out that all quartic rings have at least one cubic resolvent ring; moreover, for "most" quartic rings (e.g., for maximal quartic rings) this cubic resolvent ring is in fact unique. Thus every quartic ring arises in Theorem 5.1, and the theorem yields a bijection on the quartic rings of primary interest to algebraic number theorists, namely the maximal orders in quartic fields.

The theory of resolvent rings used in [6] to prove Theorem 5.1 makes heavy use of many of the formulae arising in the solution to the quartic equation. The same ideas also yield a purely ring-theoretic interpretation of the Delone–Faddeev parametrization of cubic rings, using formulae arising in the classical solution to the cubic equation.

Since the quintic equation is known to be "unsolvable", it may then seem that such parametrization methods could not extend beyond the quartic. However, there has been a lot of literature on the quintic equation, and some of the formulae that arise

in these works – although they fail to "solve" the quintic equation – can nevertheless be adapted to develop a completely analogous theory for parametrizing quintic rings! It turns out that quintic rings are essentially parametrized by *quadruples of quinary alternating bilinear forms*, i.e., quadruples of 5×5 skew-symmetric integer matrices.

Let $\mathbb{Z}^4 \otimes \wedge^2\mathbb{Z}^5$ denote the space of quadruples of 5×5 skew-symmetric integer matrices. Then the parametrization result for quintic rings is as follows.

Theorem 5.2. *There is a canonical bijection between the set of* $\mathrm{GL}_4(\mathbb{Z}) \times \mathrm{SL}_5(\mathbb{Z})$*-orbits on the space* $\mathbb{Z}^4 \otimes \wedge^2\mathbb{Z}^5$ *of quadruples of* 5×5 *skew-symmetric integer matrices and the set of isomorphism classes of pairs* (R, S)*, where* R *is a quintic ring and* S *is a sextic resolvent ring of* R*.*

A *sextic resolvent ring* of a quintic ring R is a sextic ring S equipped with a certain natural mapping $R \to \wedge^2 S$ which seems to have been missed in the classical literature on the quintic equation. The notion of sextic resolvent ring yields a natural integral model for the sextic resolvent fields studied by Cayley and Klein. As in the quartic case, one finds that all quintic rings have a sextic resolvent, and maximal quintic rings have exactly one sextic resolvent ring. Thus Theorem 5.2 yields a bijection on maximal orders in quintic fields!

These parametrization results have an important application to determining the density of discriminants of number fields of degree less than or equal to five, which we discuss in the next section.

Because of the classification of prehomogeneous vector spaces, one can show that parametrizations of the *same type* cannot exist for rings of rank $n > 5$. This is in agreement with the classification of group stabilizers by Sato–Kimura [33], and with the classification of orbits over fields by Wright–Yukie [41]. Thus parametrizations of this type end with the quintic.

6. Counting number fields of low degree

Number fields – i.e., field extensions of the rational numbers of finite degree – are perhaps the most fundamental objects in algebraic number theory, yet very little is known about their distribution with respect to basic invariants.

The most fundamental numerical invariant of a degree n number field K is its *discriminant* $\mathrm{Disc}(K)$. The quantity $\mathrm{Disc}(K)$ is defined as $\mathrm{Disc}(O_K)$, where O_K denotes the unique maximal ring of rank n contained in K (equivalently, O_K is the ring of algebraic integers in K). A fundamental theorem of Minkowski states that, up to isomorphism, there can be only finitely many number fields having any given discriminant D. The question thus arises: how many? The number of number fields of discriminant D fluctuates with D in a seemingly random manner, so that obtaining an exact answer would be rather unwieldy. Nevertheless, it is still natural to ask whether one can understand the answer on average. That is, how many number fields do we expect having discriminant D?

It is natural to refine the latter question by considering each degree and each associated Galois group separately. For the remainder of this section, we fix the degree to be n and consider the degree n number fields whose Galois closures have Galois group S_n, which is in some sense the "generic" case. We now consider successive cases of n, starting with the simplest case, namely

***n* = 1.** There is only one degree 1 number field, namely the field $\mathbb{Q}$ of rational numbers, and its discriminant is 1. Thus we expect zero degree 1 number fields per discriminant as the discriminant tends to infinity. □

***n* = 2.** The case $n = 2$ is also not difficult to handle. Recall that, for each nonsquare discriminant D, there is a unique quadratic order having discriminant D. Maximal orders correspond to discriminants that are not square multiples of other discriminants, so that maximality essentially amounts to a squarefree condition on D.[5] It is known that the probability that a number is squarefree is $6/\pi^2$; it follows that we expect about $6/\pi^2 \approx .607\ldots$ quadratic fields per discriminant. □

In the 1960s, the cases $n = 1$ and $n = 2$ apparently provided enough evidence for the following bold folk conjecture to come into existence. The origin of this conjecture seems to be unknown.

Conjecture 6.1. Let $N_n(X)$ denote the number of S_n-number fields of degree n having absolute discriminant at most X. Then

$$c_n = \lim_{X\to\infty} \frac{N_n(X)}{X}$$

exists, and is positive for $n \geq 2$.

That is, we expect about c_n S_n-number fields of degree n per discriminant, where c_n is some positive constant when $n > 1$. One question that immediately arose from the circulation of this conjecture was: what should the value of c_n be? Evidently $c_1 = 0$ and $c_2 = 6/\pi^2$, but no general formula for the value of c_n was known.

***n* = 3.** Some further data as to the nature of c_n was provided in the seminal 1970 work of Davenport and Heilbronn [20], who explicitly determined the value of c_3. A key ingredient in their work was the parametrization of cubic orders by $\mathrm{GL}_2(\mathbb{Z})$-equivalence classes of binary cubic forms (see Section 4.1).

To count the number of $\mathrm{GL}_2(\mathbb{Z})$-equivalence classes of binary cubic forms having absolute discriminant less than X, Davenport constructed a fundamental domain $\mathcal{F}$ for the action of $\mathrm{GL}_2(\mathbb{Z})$ on the four-dimensional real vector space V of binary cubic

[5] The precise condition is that the number be squarefree and 1 (mod 4) or be four times an integer that is 2 or 3 (mod 4). So it is not quite a squarefree condition at 2. Nevertheless, the density of such numbers is still $6/\pi^2$! This is *not* a coincidence, but is part of a general phenomenon occurring in all degrees and at all primes dividing the degree, which may be explained via certain "mass formulae" arising in work of Serre. More details may be found in [11].

forms over $\mathbb{R}$. The number of cubic orders having absolute discriminant at most X is then simply the number of integer points in the region $\mathcal{F}_X$, where

$$\mathcal{F}_X = \mathcal{F} \cap \{v \in V : |\mathrm{Disc}(v)| \leq X\}.$$

This region is seen to have finite volume, namely $(\pi^2/18)X$.

Now given any region $\mathcal{R}$ in n-dimensional Euclidean space, it is very natural to approximate the number of integer lattice points in $\mathcal{R}$ by the Euclidean volume $\mathrm{Vol}(\mathcal{R})$. Such an approximation will be particularly good if the region is compact and somewhat "round-looking" in the sense that its boundaries are smooth, and there are no serious "spikes" or "tentacles" jutting out of the region.

However, if the region is noncompact or it possesses thin, long tentacles or spikes, then all bets are off. For example, one may have a region with a tentacle thinning as it runs off to infinity, which has finite volume yet contains an infinite number of lattice points. Or one could have a region with one infinitely long tentacle, which has arbitrarily large (finite or infinite) volume yet contains *no* lattice points! It is easy to draw pictures even in two-dimensional space that illustrate each of these unruly scenarios. For such "bad" regions, there may be little correlation between the volume and the number of lattice points lying within.

Let us consider again Davenport's domain $\mathcal{F}_X$. If this subset of V were compact and round, we could then conclude that the number of lattice points within is essentially $(\pi^2/18)X$. However, the region $\mathcal{F}_X$ is not compact. Although we do not attempt to draw this region here – as it is four-dimensional – it is nevertheless easy to visualize roughly what this region looks like. Namely, $\mathcal{F}_X$ is relatively round-looking, but there is a single problematic tentacle going off to infinity (arising from the fact that $\mathrm{SL}_2(\mathbb{Z}) \setminus \mathrm{SL}_2(\mathbb{R})$ is noncompact). Thus, to make any conclusions regarding the number of lattice points in $\mathcal{F}_X$, it is necessary to deal with this tentacle.

What Davenport shows is that although this tentacle (or *cusp*) contains a very large number of lattice points, nearly all of these lattice points are *reducible* cubic forms; i.e., they correspond to cubic rings sitting not in a cubic field, but in the direct sum of $\mathbb{Q}$ and a quadratic field. Only a negligible number of irreducible points are found to lie in the cusp. Meanwhile, the lattice points in the main body of the region and away from the cusps correspond almost entirely to irreducible points, i.e., orders in cubic fields; only a negligible number of points in this main body are reducible.[6]

It follows that, as $X \to \infty$, one may approximate the number of irreducible points in $\mathcal{F}_X$ by the volume of the main body of the region. As the above cusps are found to have negligible volume, we conclude that the number of irreducible points in $\mathcal{F}_X$ is $(\pi^2/18)X$, where the error is $o(X)$. We therefore obtain

Theorem 6.2. *The number of cubic orders* (*in cubic fields*) *having absolute discriminant at most X is asymptotic to $(\pi^2/18)X$ as $X \to \infty$.*

[6]Here, by negligible, we mean "$o(X)$".

To pass from such cubic orders to maximal cubic orders (and thus to cubic fields) requires a delicate sieve, which was carried out in the remarkable work of Davenport–Heilbronn. The result of this sieve is:

Theorem 6.3 (Davenport–Heilbronn [20]). *The number of cubic fields having absolute discriminant at most X is asymptotic to $(1/3\zeta(3))X$ as $X \to \infty$, where $\zeta(s)$ denotes the Riemann zeta function.*

Thus Davenport and Heilbronn showed, in sum, that $c_3 = \frac{1}{3\zeta(3)} \approx .277\ldots$. That is, we expect approximately .277 cubic fields per discriminant. □

It has been a long-time open problem to extend Davenport–Heilbronn's theorem to $n = 4$, i.e., to gain an understanding of quartic number fields in the same way. Having now obtained a parametrization of quartic orders, it is natural to try and proceed in a manner analogous to Davenport–Heilbronn.

***n* = 4.** As discussed in Section 5, quartic orders are parametrized by pairs of integer-coefficient ternary quadratic forms, modulo the action of the group $\mathrm{GL}_2(\mathbb{Z}) \times \mathrm{SL}_3(\mathbb{Z})$. In analogy with Davenport–Heilbronn's work, we construct a fundamental domain $\mathcal{F}$ for the action of $\mathrm{GL}_2(\mathbb{Z}) \times \mathrm{SL}_3(\mathbb{Z})$ on the space V of pairs of real-coefficient ternary quadratic forms. Then $\mathcal{F}$ is a certain region in the 12-dimensional real vector space V, and quartic rings are seen to correspond to lattice points inside the fundamental domain $\mathcal{F}$.

In order to understand the number of quartic orders (and eventually quartic fields) having absolute discriminant at most X, we therefore wish to count the number of integer points inside the region $\mathcal{F}_X$, where the region $\mathcal{F}_X$ is as usual defined by $\mathcal{F} \cap \{v \in V : |\mathrm{Disc}(v)| \leq X\}$. However, the region $\mathcal{F}_X$ is not so simple; indeed, the geometry of this fundamental domain is significantly more complicated than the analogous region considered by Davenport and Heilbronn. For one thing, the dimension is now twelve instead of four! Moreover, there are now three major cusps or tentacles rather than one, and the cross sections of these cusps lie in several dimensions. If these cusps did not exist, and $\mathcal{F}_X$ were compact, it would be an easy matter to estimate the number of integer points in $\mathcal{F}_X$.

It takes quite a bit of hard work to deal with the cusps, but in the end, what happens with these cusps is quite beautiful. All three cusps contain *many* points (i.e., at least on the order of X in number). However, essentially all the lattice points in the first cusp are found to be "reducible": they correspond to quartic rings that lie in the direct sum of two quadratic fields instead of a single quartic field. The second cusp also consists almost entirely of "reducible" points! These points correspond to orders lying in the direct sum of $\mathbb{Q}$ and a cubic field (or some other étale cubic algebra) rather than a quartic field. In the third cusp, another very interesting phenomenon occurs, namely the lattice points inside almost entirely correspond to orders in quartic fields whose Galois closure has Galois group D_4 (the dihedral group of order 8) rather than S_4! Meanwhile, the main body of the region away from the cusps is shown to consist

almost entirely (i.e., up to $o(X)$) of the lattice points that correspond to orders in S_4-quartic fields.[7]

As a result, to count orders in S_4-quartic fields (i.e., "S_4-quartic orders"), one may simply count lattice points in the region $\mathcal{F}_X$ with its tentacles cut off. This region is then compact, and is sufficiently round for one to deduce that the number of lattice points inside this region is essentially its volume, which is computed to be $(5\zeta(2)^2\zeta(3)/24)X$. It follows (in conjunction with Theorem 5.1) that the number of pairs (Q, R), where Q is an S_4-quartic order of discriminant at most X and R is a cubic resolvent ring of Q, is asymptotic to $(5\zeta(2)^2\zeta(3)/24)X$ as $X \to \infty$.

Finally, one shows that counting quartic rings just once each – i.e., without weighting by the number of cubic resolvents – affects this final answer simply by a factor of $\zeta(5)$. We obtain:

Theorem 6.4. *The number of S_4-quartic orders having absolute discriminant at most X is asymptotic to $\frac{5\zeta(2)^2\zeta(3)}{24\,\zeta(5)}\,X$ as $X \to \infty$.*

To count only the maximal orders in S_4-quartic fields again requires a fairly delicate sieve. The end result of this sieve is:

Theorem 6.5. *The number of S_4-quartic fields having absolute discriminant at most X is asymptotic to $\frac{5}{24}\prod_p(1 + p^{-2} - p^{-3} - p^{-4}) \cdot X$ as $X \to \infty$.*

Thus $c_4 = \frac{5}{24}\prod_p(1 + p^{-2} - p^{-3} - p^{-4}) \approx .253\ldots$; that is, we expect about .253 S_4-quartic fields per discriminant. □

Theorem 6.5 has a number of interesting consequences. First, it is related to the proof of the case of the Cohen–Lenstra–Martinet class group heuristics mentioned at the end of Section 4.3. Second, in conjunction with the work of Baily [1] and Cohen–Diaz–Olivier [13] on D_4-fields, Theorem 6.5 implies that when all quartic fields are ordered by the size of their discriminants, a positive proportion of them *do not* have Galois group S_4! In fact, "only" about 90.644% have Galois group S_4, while the remaining correspond to the Galois group D_4 (0% have any of the other possible Galois groups). This is interesting because it is in direct opposition to the situation for polynomials, where Hilbert's irreducibility theorem implies that if integer polynomials of degree n are ordered by the size of their coefficients, then 100% will have Galois group S_n.

***n* = 5.** Last but not least, the parametrization results described in the previous section also allow one to asymptotically determine the number of quintic fields of bounded discriminant. This represents the first instance where one can count *unsolvable* extensions.

[7] In practice, to simplify the details, we perform all these computations using not one but several fundamental domains $\mathcal{F}_X \subset \mathbb{R}^{12}$, but the spirit of the argument remains unchanged. The details of this "averaging" method may be found in [9] and [10].

We have shown that quintic rings correspond to the $\mathrm{GL}_4(\mathbb{Z}) \times \mathrm{SL}_5(\mathbb{Z})$-orbits on quadruples of 5×5 skew-symmetric integer matrices. Following the cases $n = 3$ and $n = 4$, we begin by constructing a fundamental domain for the action of $\mathrm{GL}_4(\mathbb{Z}) \times \mathrm{SL}_5(\mathbb{Z})$ on the corresponding forty-dimensional real vector space V. We wish to understand the number of integer points in $\mathcal{F}_X$, where as before $\mathcal{F}_X = \mathcal{F} \cap \{v \in V : |\mathrm{Disc}(v)| \leq X\}$. This turns out to be significantly more difficult than the corresponding problem in the cubic and quartic cases. Besides being highly non-compact, the forty-dimensional fundamental domain $\mathcal{F}_X$ has an intriguingly complex system of numerous high-dimensional tentacles and cusps!

But in the end these cusps too exhibit a surprisingly beautiful structure, and can be handled in much the same way as in the cubic and quartic cases. Namely, we cut up this system of cusps into a finite number (approximately 160) of sub-cusps, all of which run off to infinity and thus present a problematic tentacle-type scenario. In each one of these 160 sub-cusps, one shows either that there are a negligible number of points within, *or* that essentially all points in that tentacle are reducible in a certain way. In this aspect, these cusps are very similar to those occurring in the cases $n = 3$ and $n = 4$ – the difference being only that there are *many* more of them this time!

Lastly, one shows that 100% of the points in the main body of the region correspond to orders in S_5-quintic fields. By computing the volume of this main body, and then sieving down to the maximal quintic orders (for details on these tasks, see [10]), one finally obtains the following theorem.

Theorem 6.6. *The number of quintic fields having absolute discriminant at most X is asymptotic to $\frac{13}{120} \prod_p (1 + p^{-2} - p^{-4} - p^{-5}) \cdot X$ as $X \to \infty$.*

Therefore $c_5 = \frac{13}{120} \prod_p (1 + p^{-2} - p^{-4} - p^{-5}) \approx .149\ldots$, and so there are about .149 quintic fields per discriminant on average. □

***n* ≥ 6?** Given the success in the cases $n \leq 5$, the question is only too tempting: what happens for $n \geq 6$? We put forth the following conjecture:

Conjecture 6.7. We have

$$c_n = \frac{r_2(S_n)}{2 \cdot n!} \prod_p \Big(\sum_{k=0}^{n} \frac{q(k, n-k) - q(k-1, n-k+1)}{p^k} \Big) \tag{10}$$

where $q(i, j)$ denotes the number of partitions of i into at most j parts, and $r_2(S_n)$ denotes the number of 2-torsion elements in S_n.

That is, we conjecture that the number of S_n-number fields per discriminant will be c_n on average, where c_n is given as in (10).

Conjecture 6.7 was obtained by combining global heuristics with new mass formulae for étale extensions of local fields inspired by work of Serre [36]. It is readily checked that Conjecture 6.7 agrees with the values of c_n now proven for $n = 1$ through 5. For further details on this conjecture and the related mass formulae, see [11]. The proofs of the conjecture for $n = 3$, 4, and 5 may be found in [20], [9], and [10] respectively.

7. Related and future work

The composition and parametrization laws described in Sections 3–5 all turn out to be closely related to certain exceptional Lie groups. More precisely, let E be an exceptional Lie group and let P be a maximal parabolic of E. If we write $E = GU$, where G is the Levi factor and U is the unipotent radical at P, then the group G acts naturally (by conjugation) on the abelianized unipotent radical $V = U/[U, U]$. For appropriate choices of E and P, we find that we obtain precisely the prehomogeneous vector spaces (G, V) underlying the composition laws and parametrizations described in Sections 3–5. For example, the first case we considered in Section 3 was the space of $2 \times 2 \times 2$ cubes, and this representation of $\mathrm{SL}_2(\mathbb{Z}) \times \mathrm{SL}_2(\mathbb{Z}) \times \mathrm{SL}_2(\mathbb{Z})$ arises in this way when E is the exceptional Lie group of type D_4 and P is the Heisenberg parabolic.

This remarkable connection with Lie groups in fact appears to run much further – see [4, §4] and [5, §4] – and needs exploration, perhaps in connection with automorphic forms on these groups in the sense of Gan–Gross–Savin [26] and in the subsequent work of Lucianovic [31] and Weissman [38]. The reduction-theoretic aspect of some of the exceptional representations that arise in this way and their relation to noncommutative rings has been the subject of study in the recent work of Krutelevich.

The parametrization results described in Sections 3–5 for commutative rings extend to a large extent also to many noncommutative rings such as quaternions, octonions, and higher rank division algebras (see [8]). Many of these parametrizations of noncommutative rings and modules were discovered by applying certain number-theoretic operations (mentioned in Section 3.4) to parametrizations involving quadratic and cubic rings, indicating that there is a great deal of number theory lurking behind noncommutative – and even nonassociative! – rings such as the octonions. These number-theoretic connections beg for further investigation.

We note that the spaces underlying these various parametrizations also come equipped with a theory of zeta functions. Zeta functions associated to prehomogeneous vector spaces were first introduced by Sato and Shintani [34], and were further developed by Datskovsky, Wright, Yukie, and others. In particular, Datskovsky and Wright [16] used such zeta functions to give an alternative proof of Davenport–Heilbronn's theorem, which applies over an arbitrary number field or function field. The more difficult quartic analogue of their work was initiated by Yukie [42], and could eventually lead to an alternative method for counting quartic fields. The problem of understanding the relationship between the various parametrizations discussed here and the associated zeta functions is intriguing and deserves further investigation, both in the commutative and noncommutative cases.

Regarding commutative rings, the problem of finding parametrizations for rings of rank > 5 is a very interesting one. Although we have already noted that commutative rings cannot be parametrized by prehomogeneous vector spaces beyond the quintic case, there may be other ways to accomplish the task, such as through the study of

integer points on certain special varieties. This is a central problem in the theory, and of importance not only algebraically but also with respect to understanding the distribution of algebraic number rings and fields of higher degree.

As to our Conjecture 6.7 on counting S_n-number fields having fixed degree n and absolute discriminant less than X, even the correct order of growth (i.e., $O(X)$) is not known. The best general bounds known for $n \geq 6$ are due to Ellenberg and Venkatesh [24], who prove a bound of $O(X^{n^\varepsilon})$. Conjectures for the density of discriminants of degree n number fields having a specified Galois group G (yielding the expected orders of growth but not the constants) have been suggested by Malle [32]. These conjectures have been proven for many specific cases of G, including S_n for $n \leq 5$ (see Section 6), abelian groups (Wright [40]), D_4 (Cohen–Diaz–Olivier [13]), and certain nilpotent groups (Klüners–Malle [30]). The constants $c(G)$ in these conjectures for $G \neq S_n$ are unknown in general, even conjecturally, although there has been some recent progress. If the case $G = S_n$ is any indication, the constants $c(G)$ likely contain a great deal of arithmetic information.

One important ingredient in the case $G = S_n$ in determining the corresponding constants $c_n = c(S_n)$ was the development of mass formulae that count étale extensions of local fields by appropriate weights (see [11]). How these mass formulae change with G is an intriguing question, and several interesting cases and families of finite groups G have been treated by Kedlaya [29] and more recently by Wood. The manner in which these various local mass formulae glue together globally to give the global constants $c(G)$ is still an open question.

The counting arguments described in Section 6 can be taken much further, leading e.g. to further information on the distribution of class numbers, narrow class numbers, units, and regulators of cubic rings and fields. They can also be used to obtain information on the discriminant density of noncommutative rings such as quaternion and octonion rings, and modules over these rings. Finally, results analogous to those described in this survey can be obtained for ring and field extensions not just over $\mathbb{Z}$ and $\mathbb{Q}$ but over more general base rings. These directions too must be investigated, and we hope to treat them further in future work.

Hecke orbits as Shimura varieties in positive characteristic

Ching-Li Chai*

Abstract. Let p be a prime number, and let $\mathcal{M}$ be a modular variety of PEL type over $\overline{\mathbb{F}}_p$ which classifies abelian varieties in characteristic p with extra symmetries of a fixed PEL type. Consider the p-divisible group with extra symmetries consisting of all p-power torsions of the universal abelian scheme over $\mathcal{M}$. The locus in $\mathcal{M}$ corresponding to a fixed isomorphism type of a p-divisible group with extra symmetry is called a *leaf* by F. Oort. Each leaf is a smooth locally closed subvariety of the modular variety $\mathcal{M}$ which is stable under all prime-to-p Hecke correspondences on $\mathcal{M}$. Oort conjectured that every Hecke orbit is dense in the leaf containing it. Tools fashioned for this conjecture include (a) rigidity, (b) global monodromy, and (c) canonical coordinates. The theory of canonical coordinates generalizes the classical Serre–Tate coordinates; it asserts that locally at the level of jet-spaces, every leaf is built up from p-divisible formal groups through a finite family of fibrations in a canonical way. The Hecke orbit conjecture is affirmed when $\mathcal{M}$ is a Siegel modular variety classifying principally polarized abelian varieties of a fixed dimension, and also when $\mathcal{M}$ is a Hilbert modular variety classifying abelian varieties with real multiplications. The proof of the Siegel case, joint with F. Oort, uses the irreducibility of non-supersingular leaves in Hilbert modular varieties due to C.-F. Yu. That proof relies heavily on a special property of Siegel modular varieties: The set of $\overline{\mathbb{F}}_p$-rational points of a Siegel modular variety $\mathcal{A}_{g,n}$ is filled up by $\overline{\mathbb{F}}_p$-rational points of Hilbert modular varieties contained in $\mathcal{A}_{g,n}$. Possible directions for further progress include Tate-linear subvarieties and p-adic monodromy. The title of this article suggests that each leaf deserves to be viewed as a Shimura variety in characteristic p in its own right.

Mathematics Subject Classification (2000). Primary 14K10; Secondary 11G10.

Keywords. Shimura variety, Hecke correspondence, moduli, leaf, Barsotti–Tate group, abelian variety, monodromy.

1. Introduction

Let p be prime number and let $k \supset \mathbb{F}_p$ be an algebraically closed field fixed throughout this article; the field k will serve as the base field of modular varieties. The reader may want to take $k = \overline{\mathbb{F}}_p$.

We are interested in Hecke symmetries on the reduction to k of a Shimura variety. Because the theory of integral models of Shimura varieties are not fully developed yet, we will restrict to a small class of Shimura varieties, call modular varieties of PEL

*Partially supported by NSF grant DMS04-00482.

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

type. Such a modular variety classifies abelian varieties with prescribed polarization and endomorphisms of a fixed type.

We will further restrict our attention to the prime-to-p Hecke symmetries. Since these symmetries come from finite étale isogeny correspondences for the universal abelian scheme over a modular variety $\mathcal{M}$, they preserve all p-adic invariants of geometric fibers of the universal Barsotti–Tate group on $\mathcal{M}$. Familiar examples of p-adic invariants include the p-rank and the Newton polygon. In 1999 F. Oort had the insight that if one uses "the mother of all p-adic invariants", namely the isomorphism class of the geometric fibers of the universal Barsotti–Tate group, then instead of a stratification of $\mathcal{M}$ by a finite number of subvarieties, one gets a decomposition of $\mathcal{M}$ into an infinite number of smooth locally closed subvarieties. In [30] these subvarieties are called *central leaves*, which we simplify to *leaves* here. In general the leaves in a given modular variety have moduli: They are parametrized by a scheme of finite type over k. Oort's Hecke orbit conjecture asserts that the leaves are determined by the Hecke symmetries: Every prime-to-p Hecke orbit is dense in the leaf containing it.

In this article we explain techniques motivated by the Hecke orbit problem: global ℓ-adic monodromy (Proposition 3.3), canonical coordinates on leaves (§4), hypersymmetric points (§5), local stabilizer principle (Proposition 6.1) and local rigidity (Theorem 6.2). The first is group-theoretic, while the rest four constitutes an effective "linearization method" of the Hecke orbit problem, which is illustrated in 6.3. The techniques developed so far are strong enough to affirm the Hecke orbit conjecture for Siegel modular varieties and Hilbert modular varieties. Advances in p-adic monodromy may lead to further progress; see §7.

In many ways a leaf in a modular variety $\mathcal{M}$ over a field of characteristic p resembles a Shimura variety in characteristic zero:

- The action of the Hecke symmetries on a leaf is topologically transitive according to the Hecke orbit Conjecture 3.2.
- By Proposition 3.3, the ℓ-adic monodromy of a leaf of positive dimension in $\mathcal{M}$ is $G(\mathbb{Q}_\ell)$, where G is a semisimple group attached to $\mathcal{M}$.
- A leaf is homogeneous in the sense that the local structure of a leaf are the same throughout the leaf, in view of the theory of canonical coordinates in §4.
- It seems plausible that a suitable parabolic subgroup P of an inner twist G' of G attached to a leaf $\mathcal{C}$ is closely related to the p-adic monodromy of $\mathcal{C}$; see §7.2. Hints of such a connection already appeared in [21].
- The theory of canonical coordinates suggests that one considers a leaf $\mathcal{C}$ as above to be "uniformized" by G'/P in a weak sense.

The above analogy depicts a scene in which a Shimura variety spawns an infinitude of morphed characteristic p replicas while reducing itself modulo p, an image that

resonates with the mantra of *Indra's Pearls*[1]. We hope that the readers find this analogy somewhat sound, or perhaps even pleasing.

2. Hecke symmetry on modular varieties

A modular varieties of PEL type classifies abelian varieties with a prescribed type of polarization, endomorphisms and level structure. To a given PEL type is associated a tower of modular varieties. A locally compact group, consisting of prime-to-p finite adelic points of a reductive algebraic group over $\mathbb{Q}$, operates on this tower; this action induces Hecke correspondences on a fixed modular variety in the tower.

2.1. PEL data. Let B be a finite dimensional semisimple algebra over $\mathbb{Q}$, let $\mathcal{O}_B$ be a maximal order of B maximal at p, and let $*$ be a positive involution on B preserving $\mathcal{O}_B$. Let V be a B-module of finite dimension over $\mathbb{Q}$, let $\langle\cdot,\cdot\rangle$ be a $\mathbb{Q}$-valued nondegenerate alternating form on V compatible with $(B,*)$, and let $h\colon \mathbb{C}\to \mathrm{End}_{B\otimes_{\mathbb{Q}}\mathbb{R}}(V\otimes_{\mathbb{Q}}\mathbb{R})$ be a $*$-homomorphism such that

$$(v,w)\ \mapsto\ \langle v, h(\sqrt{-1})w\rangle$$

defines a positive definite real-valued symmetric form on $V\otimes_{\mathbb{Q}}\mathbb{R}$. The 6-tuple $(B,*,\mathcal{O}_B,V,\langle\cdot,\cdot\rangle,h)$ is called a *PEL datum unramified at p* if B is unramified at p and there exists a self-dual $\mathbb{Z}_p$-lattice in $V\otimes_{\mathbb{Q}}\mathbb{Q}_p$ stable under $\mathcal{O}_B$.

2.2. Modular varieties of PEL type. Suppose that we are given a PEL datum $(B,*,\mathcal{O}_B,V,\langle\cdot,\cdot\rangle,h)$ unramified at p, one associates a tower of modular varieties $(\mathcal{M}_{K^p})$ indexed by the set of all compact open subgroups K^p of $G(\mathbb{A}_f^p)$, where G is the unitary group attached to the pair $(\mathrm{End}_B(V),*)$, and $\mathbb{A}_f^p=\prod'_{\ell\neq p}\mathbb{Q}_\ell$ is the ring of prime-to-p finite adeles attached to $\mathbb{Q}$. The modular variety $\mathcal{M}_{K^p}$ classifies abelian varieties A with endomorphisms by $\mathcal{O}_B$ plus prime-to-p polarization and level-structure, whose H_1 is modeled on the given PEL datum; see [20, §5] for details.

2.3. Hecke symmetries. The group $G(\mathbb{A}_f^p)$ operates on the whole projective system $(\mathcal{M}_{K^p})$. If a level subgroup K_0^p is fixed, then on the corresponding modular variety $\mathcal{M}_{K_0^p}$ the remnant from the action of $G(\mathbb{A}_f^p)$ takes the form of a family of algebraic finite étale algebraic correspondences on $\mathcal{M}_{K_0^p}$; they are known as *Hecke correspondences*.

For a given point $x\in\mathcal{M}_{K_0^p}(k)$, denote by $\mathcal{H}^p\cdot x$ the subset of $\mathcal{M}_{K_0^p}(k)$ consisting of all elements which belongs to the image of x under some prime-to-p Hecke correspondence on $\mathcal{M}_{K_0^p}$. The countable set $\mathcal{H}^p\cdot x$ is called the prime-to-p Hecke orbit of x; it is equal to the image of $G(\mathbb{A}_f^p)\cdot\tilde{x}$ in $\mathcal{M}_{K_0^p}(k)$, where $\tilde{x}\in\varprojlim_{K^p}\mathcal{M}_{K^p}(k)$ is a pre-image of x.

[1] Cf. the preface of [25].

2.4. Examples

2.4.1. Siegel modular varieties. Let $g, n \in \mathbb{N}$, $(n, p) = 1$, and $n \geq 3$. Denote by $\mathcal{A}_{g,n}$ the modular variety over k which classifies all g-dimensional principally polarized abelian varieties (A, λ) over k with a symplectic level-n structure η. Two k-points $[(A_1, \lambda_1, \eta_1)]$, $[(A_2, \lambda_2, \eta_2)]$ in $\mathcal{A}_{g,n}$ are in the same prime-to-p Hecke orbit if and only if there exists a prime-to-p quasi-isogeny β (="$\beta_2 \circ \beta_1^{-1}$")

$$\beta\colon A_1 \xleftarrow{\beta_1} A_3 \xrightarrow{\beta_2} A_2$$

defined by prime-to-p isogenies β_1 and β_2 such that β respects the principal polarizations λ_1 and λ_2 in the sense that $\beta_1^*(\lambda_1) = \beta_2^*(\lambda_2)$. The semisimple algebra B in the PEL datum is equal to $\mathbb{Q}$. The reductive group G attached to the PEL datum is the symplectic group Sp_{2g}. The modular variety attached to the principal congruence subgroup of level-n in $\mathrm{Sp}_{2g}(\mathbb{A}_f^p)$ is $\mathcal{A}_{g,n}$.

2.4.2. Hilbert modular varieties. Let $E = F_1 \times \cdots \times F_r$, where $F_1, \ldots, F_r$ are totally real number fields. Consider the PEL datum where $B = E$, $* = \mathrm{Id}_E$, and V is a free E-module of rank two. Then the reductive group attached to the PEL datum is the kernel of the composition

$$\prod_{E/\mathbb{Q}} \mathrm{GL}_2 \xrightarrow{\det} \prod_{E/\mathbb{Q}} \mathbb{G}_m \xrightarrow{\mathrm{Nm}_{E/\mathbb{Q}}} \mathbb{G}_m,$$

where $\prod_{E/\mathbb{Q}}$ denotes Weil's restriction of scalars functor from E to $\mathbb{Q}$. A typical member of the associated tower of modular varieties is $\mathcal{M}_{E,n}$, with $n \geq 3$ and $(n, p) = 1$, which classifies $[E : \mathbb{Q}]$-dimensional abelian varieties A over k, together with a ring homomorphism $\iota\colon \mathcal{O}_E = \mathcal{O}_{F_1} \times \cdots \times \mathcal{O}_{F_r} \to \mathrm{End}(A)$, an $\mathcal{O}_E$-linear level-n structure η, and an $\mathcal{O}_E$-linear polarization of A.

There are different versions of polarizations; the one in [14] is as follows. It is a positivity-preserving $\mathcal{O}_E$-linear homomorphism $\lambda\colon \mathcal{L} \to \mathrm{Hom}^{\mathrm{sym}}_{\mathcal{O}_E}(A, A^t)$ from an projective rank-one $\mathcal{O}_E$-module $\mathcal{L}$ with a notion of positivity, which induces an $\mathcal{O}_E$-linear isomorphism $\lambda\colon A \otimes_{\mathcal{O}_E} \mathcal{L} \xrightarrow{\sim} A^t$, where A^t is the dual abelian variety of A. The modular variety $\mathcal{M}_{E,n}$ is not smooth over k if any one of the totally real fields F_i is ramified above p; if so then $\mathcal{M}_{E,n}$ has moderate singularities – it is a local complete intersection.

The prime-to-p Hecke orbit of a point $[(A, \iota_A, \lambda_A, \eta_A)] \in \mathcal{M}_{E,n}(k)$ consists of all points $[(B, \iota_B, \lambda_B, \eta_B)] \in \mathcal{M}_{E,n}(k)$ such that there exists a prime-to-p $\mathcal{O}_E$-linear quasi-isogeny from A to B which preserves the polarizations.

2.4.3. Picard modular varieties. Let L be an imaginary quadratic field contained in $\mathbb{C}$ such that p is unramified in L. Let a, b be positive integers, and let $g = a + b$. For the PEL datum, we take $B = L$ with the involution induced by the

complex conjugation, a g-dimensional vector space V over L, and an L-linear complex structure $h\colon \mathbb{C} \to \mathrm{End}_{L\otimes_{\mathbb{Q}}\mathbb{R}}(V\otimes_{\mathbb{Q}}\mathbb{R})$ on $V\otimes_{\mathbb{Q}}\mathbb{R}$ satisfying the following condition: For every element $u \in L \subset \mathbb{C}$, the trace of the action of u on V_1 is equal to $au + b\bar{u}$, where $V_1 = \{v \in V\otimes_{\mathbb{Q}}\mathbb{C} : h(z)(v) = z\cdot v \text{ for all } z \in \mathbb{C}\}$. We also fix a ring homomorphism $\varepsilon\colon \mathcal{O}_L \to k$, i.e. a $\mathcal{O}_L$-algebra structure on k.

Let $n \geq 3$ be a positive integer, $(n, p) = 1$. The Picard modular variety $\mathcal{M}_{L,a,b,n}$ over k classifies $\mathcal{O}_L$-linear$g$-dimensional abelian varieties (A, ι) of signature (a, b), together with a principal polarization $\lambda\colon A \to A^t$ such that $\lambda\circ\iota(\bar{u}) = \iota(u)^t\circ\lambda$ for all $u \in \mathcal{O}_L$, and a symplectic $\mathcal{O}_L$-linear level-n structure. The signature condition above is that

$$\det_{\mathcal{O}_L\otimes_{\mathbb{Z}}k}(T\cdot\mathrm{Id} - \iota(u)|\mathrm{Lie}(A,\iota)) = (T-\varepsilon(u))^a\cdot(T-\varepsilon(u))^b \in k[T] \text{ for all } u \in \mathcal{O}_L.$$

As before the prime-to-p Hecke orbit of a point $[(A, \iota_A, \lambda_A, \eta_A)] \in \mathcal{M}_{L,a,b,n}(k)$ consists of all points $[(B, \iota_B, \lambda_B, \eta_B)] \in \mathcal{M}_{L,a,b,n}(k)$ such that there exists a prime-to-p $\mathcal{O}_L$-linear quasi-isogeny from A to B which preserves the polarizations.

3. Leaves and the Hecke orbit conjecture

3.1. Leaves in modular varieties in characteristic p

Definition 3.1. Let $\mathcal{M} = \mathcal{M}_{K_0^p}$ be a modular variety of PEL type over k as in 2.2. Let x_0 be a point in $\mathcal{M}(k)$. The *leaf* $\mathcal{C}_{\mathcal{M}}(x_0)$ in $\mathcal{M}$ passing through x_0 is the reduced locally closed subvariety of $\mathcal{M}$ over k such that $\mathcal{C}_{\mathcal{M}}(x_0)(k)$ consists of all points $x = [(A, \lambda, \iota, \eta)] \in \mathcal{C}_{\mathcal{M}}(x_0)(k)$ such that the Barsotti–Tate group (or p-divisible group) $(A[p^\infty], \lambda[p^\infty], \iota[p^\infty])$ with prescribed polarization and endomorphisms attached to x is isomorphic to that attached to x_0.

Remark. (i) The notion of leaves was introduced in [30]; it was studied later by Vasiu in [38].

(ii) In addition to being locally closed, every leaf in $\mathcal{M}$ is a smooth subvariety of $\mathcal{M}$ and is closed under all prime-to-p Hecke correspondences.

3.2. The Hecke orbit conjectures. The Hecke orbit conjecture HO, due to Oort, asserts that the decomposition of a modular variety $\mathcal{M}$ of PEL type into leaves is determined by the Hecke symmetries on $\mathcal{M}$. It is equivalent to the conjunction of the continuous version $\mathrm{HO}_{\mathrm{ct}}$ and the discrete version $\mathrm{HO}_{\mathrm{dc}}$ below.

Conjecture 3.2 (HO). Every prime-to-p Hecke orbit in a modular variety of PEL type $\mathcal{M}$ over k is dense in the leaf in $\mathcal{M}$ containing it.

Conjecture ($\mathrm{HO}_{\mathrm{ct}}$). The closure of any prime-to-p Hecke orbit in the leaf $\mathcal{C}$ containing it is an open-and-closed subset of $\mathcal{C}$, i.e. it is a union of irreducible components of the smooth variety $\mathcal{C}$.

Conjecture ($\mathrm{HO}_{\mathrm{dc}}$). Every prime-to-$p$ Hecke orbit in a leaf $\mathcal{C}$ meets every irreducible component of $\mathcal{C}$.

3.3. Global ℓ-adic monodromy. The discrete Hecke orbit conjecture is essentially an irreducibility statement, in view of the following result on global monodromy.

Proposition 3.3. *Let $\mathcal{M}$ be a modular variety of PEL type attached to a reductive group G over $\mathbb{Q}$ as in* 2.2. *Let $G^{\mathrm{sc}}_{\mathrm{der}}$ be the simply connected cover of the derived group of G. Let $x_0 \in \mathcal{M}(k)$ be a point of $\mathcal{M}$ such that the prime-to-p Hecke orbit of x_0 with respect to every simple factor of $G^{\mathrm{sc}}_{\mathrm{der}}$ is infinite. Let $Z(x_0)$ be the Zariski closure of the prime-to-p Hecke orbit of x_0 for the group $G^{\mathrm{sc}}_{\mathrm{der}}$ in the leaf $\mathcal{C}(x_0)$ in $\mathcal{M}$ containing x_0. Then $Z(x_0)$ is irreducible, and the Zariski closure of the ℓ-adic monodromy group of $Z(x_0)$ is $G_{\mathrm{der}}(\mathbb{Q}_\ell)$ for every prime number $\ell \neq p$.*

Remark. (i) A stronger version of 3.3 for Siegel modular varieties is proved in [5]. The argument in [5] works for all modular varieties of PEL type.

(ii) The irreducibility statement in Proposition 3.3 is a useful tool for proving irreducibility of a given subvariety Z of modular varieties of PEL type which are stable under the prime-to-p Hecke correspondences: It reduces the task to proving Hecke transitivity on $\pi_0(Z)$.

3.4. Some known cases of the Hecke orbit conjecture

Theorem 3.4. *The Hecke orbit conjecture* HO *holds for Siegel modular varieties.*

Theorem 3.5. *The Hecke orbit conjecture* HO *holds for Hilbert modular varieties attached to a finite product $F_1 \times \cdots \times F_r$ of totally real fields. Here the prime p may be ramified in any or all of the totally real fields $F_1, \ldots, F_r$.*

Remark. (i) Theorem 3.4 is joint work with F. Oort. Details of the proof of Theorem 3.4 will appear in a monograph with F. Oort. The proof of the continuous version $\mathrm{HO}_{\mathrm{ct}}$ in the Siegel case uses Theorem 3.5.

(ii) The proof of Theorem 3.5 is the result of joint work with C.-F. Yu; the proof of the discrete version, i.e. the irreducibility of non-supersingular leaves in Hilbert modular varieties, is the work of C.-F. Yu.

(iii) Among the methods used in the proof of Theorem 3.4, the action of the local stabilizer subgroup and the trick of using Hilbert modular subvarieties first appeared in [2], where the case of Theorem 3.4 for ordinary principally polarized abelian varieties was proved.

(iv) A detailed sketch of the proof of Theorem 3.4 can be found in [4].

4. Canonical coordinates on leaves

4.1. Classical Serre–Tate coordinates. Recall that an abelian variety A over k is *ordinary* if the Barsotti–Tate group $A[p^\infty]$ is the extension of an étale Barsotti–Tate

group by a toric Barsotti–Tate group over k. It has been more than forty years when Serre and Tate discovered that the local deformation space of an ordinary abelian variety A over k has a natural structure as a formal torus over $W(k)$ of relative dimension $\dim(A)^2$. For Siegel modular varieties, their result says that if $x = [(A, \lambda)] \in \mathcal{A}_{g,n}(k)$ is a closed point of $\mathcal{A}_{g,n}$ such that A is an ordinary abelian variety, then the formal completion $\mathcal{A}_{g,n}^{/x}$ of $\mathcal{A}_{g,n} \to \mathrm{Spec}(\mathbb{Z})$ has a natural structure as a formal torus over $W(k)$ of relative dimension $\frac{g(g+1)}{2}$, where $g = \dim(A)$. Notice that the ordinary locus of $\mathcal{A}_{g,n}$ over k is equal to the dense open stratum in the Newton polygon stratification of $\mathcal{A}_{g,n}$.

The above approach generalizes to modular variety of PEL type, to the effect that the mixed-characteristic local deformation space for a point in the dense open Newton polygon stratum of a modular variety $\mathcal{M}$ of PEL type can be built up from Barsotti–Tate groups over $W(k)$ by a system of fibrations; see [23].

There is a long-standing question as to whether one can find a reasonable theory of canonical coordinates for points outside the generic Newton polygon stratum of a modular variety of PEL type. It turns out that the answer is *yes* if one restricts to a leaf in a modular variety.

4.2. The slope filtration. The starting point is the observation that there exists a natural *slope filtration* on the restriction of the universal Barsotti–Tate group to a leaf; moreover the slope filtration gives the local moduli of a leaf.

Proposition 4.1. *Let $\mathcal{M}$ be a modular variety of PEL type over k attached to a PEL datum $(B, *, \mathcal{O}_B, V, \langle\cdot,\cdot\rangle, h)$ as in* 2.2. *Let $\mathcal{C}$ be a leaf in $\mathcal{M}$. Let $\tilde{X} \to \mathcal{C}$ be the restriction to $\mathcal{C}$ of the Barsotti–Tate group attached to the universal abelian variety.*

(i) *There exist rational numbers $\mu_1, \dots \mu_m$ with $1 \geq \mu_1 > \cdots > \mu_m \geq 0$ and Barsotti–Tate groups*

$$0 = \tilde{X}_0 \subset \tilde{X}_1 \subset \tilde{X}_2 \subset \cdots \subset \tilde{X}_m = \tilde{X}$$

over $\mathcal{C}$ such that $\tilde{Y}_i := \tilde{X}_i/\tilde{X}_{i-1}$ is a non-trivial isoclinic Barsotti–Tate group over $\mathcal{C}$ of slope μ_i for each $i = 1, \dots, m$.

(ii) *The filtration $0 = \tilde{X}_0 \subset \tilde{X}_1 \subset \tilde{X}_2 \subset \cdots \subset \tilde{X}_m = \tilde{X}$ is uniquely determined by $\tilde{X} \to \mathcal{C}$. Each subgroup $\tilde{X}_i \subseteq \tilde{X}$ is stable under the natural action of $\mathcal{O}_B \otimes_{\mathbb{Z}} \mathbb{Z}_p$.*

(ii) *For each $i = 1, \dots, r$ the Barsotti–Tate group $\tilde{Y}_i \to \mathcal{C}$ is geometrically constant, hence $\tilde{Y}_i$ is isomorphic to the twist of a constant Barsotti–Tate group by a smooth étale $\mathbb{Z}_p$-sheaf over $\mathcal{C}$.*

Remark. (i) That $\tilde{Y}_i$ is *isoclinic* of slope μ_i means that the kernel of the N-th iterate of the relative Frobenius for $\tilde{Y}_i$ is comparable to the kernel of $[p^{N\mu_i}]_{\tilde{X}_i/\tilde{X}_{i-1}}$ for all sufficiently large multiples of the denominator of μ_i.

(ii) The proof of Proposition 4.1 depends on [42] and [34].

4.3. The cascade structure. Combining Proposition 4.1 with the Serre–Tate theorem, one sees that the local moduli of a leaf $\mathcal{C}$ comes from the deformation of the slope filtration.

Let $x = [(A, \iota, \lambda, \eta)] \in \mathcal{M}(k)$ be a closed point of the modular variety $\mathcal{M}$, and let $\mathrm{Fil}_{A[p^\infty]} = (0 = X_0 \subset X_1 \subset \cdots \subset X_m = A[p^\infty])$ be the slope filtration of $A[p^\infty]$. Let $Y_i = X_i/X_{i-1}$ for $i = 1, \ldots, m$. For each pair (i, j) with $1 \le i \le j \le m$, let $\mathfrak{Def}([i, j], \iota) = \mathfrak{Def}([i, j], \iota[p^\infty])$ be the deformation functor over k of the filtered Barsotti–Tate group

$$0 \subset X_i/X_{i-1} \subset X_{i+1}/X_{i-1} \subset \cdots \subset X_j/X_{i-1}$$

with action by $\mathcal{O}_B \otimes_{\mathbb{Z}} \mathbb{Z}_p$. Each $\mathfrak{Def}([i, j], \iota)$ is a smooth formal scheme over k, and $\mathfrak{Def}([i, i], \iota) = \mathrm{Spec}(k)$ for each i. For $1 \le i < j \le m$, let $\mathfrak{DE}(i, j; \iota) = \mathfrak{DE}(i, j; \iota[p^\infty])$ be the deformation functor of the filtered Barsotti–Tate group $0 \subset Y_i \subset Y_i \times_{\mathrm{Spec}(k)} Y_j$ with action by $\mathcal{O}_B \otimes_{\mathbb{Z}} \mathbb{Z}_p$; it is a smooth formal scheme over k. Each $\mathfrak{DE}(i, j; \iota)$ has a natural structure as a smooth commutative formal group over k; the group structure comes from via Baer sum. Notice that $\mathfrak{Def}([i, i+1], \iota)$ is a torsor over $\mathfrak{DE}(i, i+1; \iota])$ for $i = 1, \ldots, m-1$.

We have a family of forgetful morphisms

$$\pi_{[i+1,j],[i,j]} : \mathfrak{Def}([i, j], \iota]) \to \mathfrak{Def}([i+1, j], \iota), \quad 1 \le i < j \le m,$$

and

$$\pi_{[i,j-1],[i,j]} : \mathfrak{Def}([i, j], \iota) \to \mathfrak{Def}([i, j-1], \iota), \quad 1 \le i < j \le m$$

such that

$$\pi_{[i+1,j-1],[i+1,j]} \circ \pi_{[i+1,j],[i,j]} = \pi_{[i+1,j-1],[i,j-1]} \circ \pi_{[i,j-1],[i,j]} \quad \text{if } i \le j-2.$$

Each morphism $\pi_{[i+1,j],[i,j]}$ is smooth, same for each $\pi_{[i,j-1],[i,j]}$.

For each pair (i, j) with $1 \le i < j \le m$, define a commutative smooth formal group

$$\pi'_{[i+1,j],[i,j]} : \mathfrak{DE}(i, [i+1, j]; \iota) \to \mathfrak{Def}([i+1, j], \iota)$$

as follows. For each Artinian local ring R over k and for each R-valued point $f : \mathrm{Spec}(R) \to \mathfrak{Def}([i+1, j], \iota)$ corresponding to a deformation

$$0 \subset \tilde{X}_{[i+1,i+1]} \subset \cdots \subset \tilde{X}_{[i+1,j]}$$

of the filtration $(0 \subset X_{i+1}/X_i \subset \cdots \subset X_j/X_i)$ over R, define the set of R-valued points of $\mathfrak{DE}(i, [i+1, j], \iota)$ over f to be the set of all isomorphism classes of extensions of $\tilde{X}_{[i+1,j]}$ by $Y_i \times_{\mathrm{Spec}(k)} \mathfrak{Def}([i+1, j], \iota)$. It is easy to see that $\pi_{[i+1,j],[i,j]}$ has a natural structure as a torsor for $\pi'_{[i+1,j],[i,j]}$. Similarly one can define a commutative formal group

$$\pi'_{[i,j-1],[i,j]} : \mathfrak{DE}([i, j-1], j; \iota) \to \mathfrak{Def}([i, j-1]$$

for $1 \le i < j \le m$ so that $\pi_{[i,j-1],[i,j]}$ has a natural structure as a torsor for $\pi'_{[i,j-1],[i,j]}$.

Consider the natural map

$$\pi_{[i,j]}\colon \mathfrak{Def}([i,j],\iota) \to \mathfrak{Def}([i+1,j],\iota) \times_{\mathfrak{Def}([i+1,j-1],\iota)} \mathfrak{Def}([i,j-1],\iota)$$

defined by the maps $\pi_{[i+1,j],[i,j]}$ and $\pi_{[i,j-1],[i,j]}$. It turns out that in a suitable sense the map $\pi_{[i,j]}$ has a natural structure as a *torsor for a biextension* of

$$\big(\mathfrak{DE}([i+1,j-1],j;\iota),\ \mathfrak{DE}(i,[i+1,j-1];\iota)\big)$$

by (the base extension to $\mathfrak{Def}([i+1,j-1],\iota)$ of) the commutative smooth formal group $\mathfrak{DE}(i,j;\iota)$ if $i \le j-2$. Notice that for the two factors of the target of the map $\pi_{[i,j]}$, the first factor $\mathfrak{Def}([i+1,j],\iota) \to \mathfrak{Def}([i+1,j-1],\iota)$ is a torsor for the group $\mathfrak{DE}([i+1,j-1],j;\iota) \to \mathfrak{Def}([i+1,j-1],\iota)$, while the second factor $\mathfrak{Def}([i,j-1],\iota) \to \mathfrak{Def}([i+1,j-1],\iota)$ is a torsor for the group $\mathfrak{DE}(i,[i+1,j-1];\iota) \to \mathfrak{Def}([i+1,j-1],\iota)$.

The formal structure of a family such as

$$\begin{aligned}\mathfrak{MDE} = \big(&\mathfrak{Def}([i,j],\iota]),\ \mathfrak{Def}([i,j],\iota), \pi_{[i+1,j],[i,j]},\\ &\pi_{[i,j-1],[i,j]}, \pi'_{[i+1,j],[i,j]}, \pi'_{[i,j-1],[i,j]}, \pi_{[i,j]}\big)\end{aligned}$$

will be called a *cascade*, following the terminology in [23], although the situation here is somewhat more complicated than [23].

When x is a point of the generic Newton polygon stratum of $\mathcal{M}$, the maximal subcascade of $\mathfrak{MDE}$ fixed by the involution induced by the polarization λ coincides with the formal completion $\mathcal{M}^{/x}$ of $\mathcal{M}$ at x. So $\mathcal{M}^{/x}$ is built up from suitable subgroups of the commutative formal groups $\mathfrak{DE}(i,j;\iota[p^\infty])$ over k through a family of fibrations; see [23].

4.4. Maximal p-divisible subcascade. Suppose that x lies outside the generic Newton polygon stratum. Then when one deforms the slope filtration, the resulting Barsotti–Tate group may fail to remain geometrically constant. It turns out that the maximal reduced closed formal subscheme of $\mathfrak{Def}([0,m];\iota)$ is in some sense the *maximal p-divisible subcascade* of the cascade $\mathfrak{MDE}$ of formal groups attached to x; the latter is built up from the maximal p-divisible formal subgroups $\mathfrak{DE}(i,j;\iota)_{\mathrm{pdiv}}$ of $\mathfrak{DE}(i,j;\iota)$, with (i,j) running through all pairs with $1 \le i < j \le m$.

The polarization λ of the abelian variety A induces an involution on the formal scheme $\mathfrak{Def}([0,m];\iota])$. and also an involution of the maximal p-divisible subcascade $\mathfrak{MDE}_{\mathrm{pdiv}}$ of the cascade of formal groups $\mathfrak{MDE}$ attached to $x \in \mathcal{M}(k)$. The maximal closed formal subscheme of the formal scheme underlying $\mathfrak{MDE}_{\mathrm{pdiv}}$ is equal to the formal completion $\mathcal{C}^{/x}$ of the leaf $\mathcal{C}$ in $\mathcal{M}$ containing x. In particular $\mathcal{C}^{/x}$ is built up from p-divisible formal groups over k through a family of fibrations.

4.5. The two slope case. Let X, Y be isoclinic Barsotti–Tate groups over k with slopes $\mu_X < \mu_Y$. Let h_X and h_Y be the height of X and Y respectively. Let $\mathfrak{DE}(X, Y)$ be the deformation functor over k of the filtration $0 = Y \subset X \times_{\mathrm{Spec}(k)} Y$; it is a commutative smooth formal group over k. Let $\mathfrak{DE}(X, Y)_{\mathrm{pdiv}}$ be the maximal p-divisible formal subgroup of the commutative smooth formal group $\mathfrak{DE}(X, Y)$ over k.

Let $\mathrm{M}(X)$ and $\mathrm{M}(Y)$ be the Cartier module of X and Y respectively. We refer to [43] for the Cartier theory. On $H_{\mathbb{Q}} := \mathrm{Hom}_{W(k)}(\mathrm{M}(X), \mathrm{M}(Y)) \otimes_{\mathbb{Z}} \mathbb{Q}$ we have a σ-linear operator F and a σ^{-1}-linear operator V on $H_{\mathbb{Q}}$ given by

$$(V \cdot h)(u) = V(h(V^{-1}u)), \quad (F \cdot h)(u) = F(h(V(u)) \quad \text{for all } h \in H_{\mathbb{Q}}, u \in \mathrm{M}(X).$$

Clearly $\mathrm{Hom}_{W(k)}(\mathrm{M}(X), \mathrm{M}(Y))$ is stable under the action of F.

Theorem 4.2. *Notation as above.*

(i) *The p-divisible formal group $\mathfrak{DE}(X, Y)_{\mathrm{pdiv}}$ is isoclinic of slope $\mu_Y - \mu_X$; its height is equal to $h_X \cdot h_Y$.*

(ii) *The Cartier module of $\mathfrak{DE}(X, Y)_{\mathrm{pdiv}}$ is naturally isomorphic to the maximal $W(k)$-submodule of $\mathrm{Hom}_{W(k)}(\mathrm{M}(X), \mathrm{M}(Y))$ which is stable under the actions of F and V.*

(iii) *Suppose that $Y = X^t$ is the Serre dual of X. Then we have a natural involution $*$ on $\mathfrak{DE}(X, X^t)_{\mathrm{pdiv}}$, and the Cartier module of the maximal formal subgroup of $\mathfrak{DE}(X, X^t)_{\mathrm{pdiv}}$ fixed under $*$ is the maximal $W(k)$-submodule of $\mathrm{Hom}_{W(k)}(\mathrm{S}^2(\mathrm{M}(X)), W(k))$ which is stable under the actions of F and V.*

Remark. (i) See [8] for a proof of Theorem 4.2.

(ii) The set of all p-typical curves in the reduced Cartier ring functor, with three compatible actions by the reduced Cartier ring over k, plays a major role in the proof.

(iii) The case when we have a maximal order $\mathcal{O}_B \otimes_{\mathbb{Z}} \mathbb{Z}_p$ in an unramified semisimple algebra $B \otimes_{\mathbb{Q}} \mathbb{Q}_p$ over $\mathbb{Q}_p$ operating on X and Y is easily deducible from Theorem 4.2.

5. Hypersymmetric points

Over a field of characteristic zero one has the notion of *special points* in modular varieties of PEL type, corresponding to abelian varieties of CM-type (or, with sufficiently many complex multiplications). On the other hand, it is well-known that every abelian variety over $\overline{\mathbb{F}}_p$ has sufficiently many complex multiplications, so one can say that every $\overline{\mathbb{F}}_p$-point of a modular variety $\mathcal{M}$ of PEL type is "special". But there are points in $\mathcal{M}$ that are more distinguished than others – they correspond to abelian varieties whose $\mathcal{O}_B$-endomorphism ring is "as big as allowed by the slope constraint".

Definition 5.1. (i) Let B be a simple algebra over $\mathbb{Q}$, and let $\mathcal{O}_B$ be an order of B. Let A be an abelian variety over k, and let $\iota\colon \mathcal{O}_B \to \mathrm{End}(A)$ be a ring homomorphism. We say that (A, ι) is a *hypersymmetric $\mathcal{O}_B$-linear abelian variety* if the canonical map $\mathrm{End}_{\mathcal{O}_B}(A) \otimes_{\mathbb{Z}} \mathbb{Z}_p \to \mathrm{End}_{\mathcal{O}_B}(A[p^\infty])$ is an isomorphism.

(ii) Let $\mathcal{M}$ be a modular variety of PEL type as in 2.2. A point $x \in \mathcal{M}(k)$ is *hypersymmetric* if the underlying $\mathcal{O}_B$-linear abelian variety (A_x, ι_x) is hypersymmetric.

Remark 5.2. (i) When $B = \mathbb{Q}$, it is easy to see that an abelian variety A over k is hypersymmetric if and only if it is isogenous to a finite product of abelian varieties $B_1 \times \cdots \times B_r$ defined over a finite field $\mathbb{F}_q$ such that the action of the Frobenius element $\mathrm{Fr}_{B_i, \mathbb{F}_q}$ on the first ℓ-adic cohomology group of B_i has at most two eigenvalues for each $i = 1, \ldots, r$, and B_i and B_j share no common slope if $i \neq j$. See [9, §2, §3].

(ii) One can use the method in [9, §5] to show that there exist hypersymmetric points on any leaf of a modular variety of PEL type over k. However one has difficulty showing the existence of hypersymmetric points on every irreducible component of a given leaf of a modular variety, without knowing or assuming the irreducibility of the leaf.

(iii) If the semisimple $\mathbb{Q}$-rank of the reductive group G attached to the PEL datum for the modular variety $\mathcal{M}$ is equal to one, then every $\overline{\mathbb{F}}_p$-point of $\mathcal{M}$ is hypersymmetric. For instance, every $\overline{\mathbb{F}}_p$-point of the modular curve is hypersymmetric. One consequence of this phenomenon is that one cannot simply substitute "special points" by "hypersymmetric points" and expect to get a reasonable formulation of the André-Oort conjecture in characteristic p; see [9, §7].

6. Action of stabilizer subgroups and rigidity

6.1. Stabilizer subgroups. Let $\mathcal{M}$ be a modular variety over k of PEL type as in 2.2. Attached to a point $x \in \mathcal{M}(k)$ corresponding to a quadruple $(A_x, \iota_x, \lambda_x, \eta_x)$ are two compact p adic groups:

- Let $\mathrm{G_x}(\mathbb{Z}_p) = \mathrm{Aut}_{\mathcal{O}_B}(A_x[p^\infty], \lambda_x[p^\infty])$. We call $G_x(\mathbb{Z}_p)$ the *local p-adic automorphism group* at x, and

- Let $\mathrm{H_x}$ be the unitary group attached to the semisimple algebra with involution $(\mathrm{End}_{\mathcal{O}_B}(A_x) \otimes_{\mathbb{Z}} \mathbb{Q}, *_x)$, where $*_x$ is the Rosati involution attached to λ_x. Let $\mathrm{H}_x(\mathbb{Z}_p)$ be the group of $\mathbb{Z}_p$-points of $\mathrm{H_x}$ with respect to the integral structure given by $\mathrm{End}(A_x)$. We call $\mathrm{H}_x(\mathbb{Z}_p)$ the *local stabilizer subgroup* at x. We have a natural embedding $\mathrm{H}_x(\mathbb{Z}_p) \hookrightarrow G_x(\mathbb{Z}_p)$.

6.2. Action on deformation space. We have a natural action of $G_x(\mathbb{Z}_p)$ on $\mathcal{M}^{/x}$, the formal completion of $\mathcal{M}^{/x}$. This action comes from the combination of

(a) a classical theorem of Serre and Tate, which states that the deformation functor for the abelian variety A_x is canonically isomorphic to the deformation functor attached to the Barsotti–Tate group $A_x[p^\infty]$, and

(b) the action of $G_x(\mathbb{Z}_p)$ on the deformation functor for the $\mathcal{O}_B$-linear Barsotti–Tate group $(A_x[p^\infty], \iota_x[p^\infty])$ by "change of marking", or "transport of structure".

The local stabilizer subgroup $\mathrm{H}_x(\mathbb{Z}_p)$ can be regarded as the p-adic completion of the stabilizer subgroup at x in the set of all prime-to-p Hecke correspondences. Consequently the *local stabilizer principle* holds:

Proposition 6.1 (Local stabilizer principle). *If Z is a closed subvariety of $\mathcal{M}$ stable under all prime-to-p Hecke correspondence and $x \in Z(k)$ is a closed point of Z, then the formal completion $Z^{/x} \subset \mathcal{M}^{/x}$ of Z at x is stable under $\mathrm{H}_x(\mathbb{Z}_p)$ for the action described in* 6.2.

The local stabilizer principle can be effectively deployed for studying Hecke-invariant subvarieties when combined with the rigidity result below.

Theorem 6.2 (Local rigidity). *Let X be a p-divisible formal group over k. Let H be a connected reductive linear algebraic subgroup over $\mathbb{Q}_p$ and let $\rho\colon H(\mathbb{Q}_p) \to (\mathrm{End}_k(X) \otimes_{\mathbb{Z}_p} \mathbb{Q}_p)^\times$ be a rational linear representation of $H(\mathbb{Q}_p)$ such that the composition of ρ with the left regular representation of $\mathrm{End}_k(X) \otimes_{\mathbb{Z}_p} \mathbb{Q}_p$ does not contain the trivial representation of $H(\mathbb{Q}_p)$ as a subquotient. Let Z be an irreducible closed formal subscheme of X. Assume that Z is stable under the natural action of an open subgroup U of $H(\mathbb{Q}_p)$ on X. Then Z is a p-divisible formal subgroup of X.*

The proof of 6.2 is elementary; see [6]. An instructive special case of 6.2 asserts that any irreducible closed formal subvariety of a formal torus over k which is stable under multiplication by $1 + p^n$ for some $n \geq 1$ is a formal subtorus.

6.3. Linearization of the Hecke orbit problem. The combination of the local stabilizer principle and local rigidity leads to an effective linearization of the Hecke orbit problem: Consider the case when $\mathcal{M}$ is a Siegel modular variety $\mathcal{A}_{g,n}$ and $x \in \mathcal{A}_{g,n}(\overline{\mathbb{F}}_p)$ corresponds to a g-dimensional principally polarized abelian variety A_x defined over $\overline{\mathbb{F}}_p$ with two slopes $\lambda < 1-\lambda$. Then the formal completion $\mathcal{C}(x)^{/x}$ at x of the leaf $\mathcal{C}(x)$ containing x has a natural structure as an isoclinic p-divisible formal group of hight $\frac{g(g+1)}{2}$ and slope $1-2\lambda$. The local stabilizer principle and Theorem 6.2 imply that the formal completion at x of the Zariski closure of the prime-to-p Hecke orbit of x is a p-divisible formal subgroup of $C(x)^{/x}$; moreover this p-divisible formal subgroup is stable under the natural action of the local stabilizer subgroup $\mathrm{H}_x(\mathbb{Z}_p)$.

Continuing the situation above, and assume that A_x is hypersymmetric in the sense of 5.1. Then the Zariski closure of the prime-to-p Hecke orbit of x coincides with the irreducible component of $\mathcal{C}(x)$ in an open neighborhood of x, because the action on the local stabilizer subgroup $\mathrm{H}_x(\mathbb{Z}_p)$ on the Cartier module of the p-divisible formal group $C(x)^{/x}$ underlies an absolutely irreducible representation of $\mathrm{H}_x(\mathbb{Q}_p)$.

6.4. Hypersymmetric points and the Hecke orbit conjecture. Let $x \in \mathcal{M}(\overline{\mathbb{F}}_p)$ be an $\overline{\mathbb{F}}_p$ point of a modular variety $\mathcal{M}$ of PEL type, and let $Z(x)$ be the Zariski closure in the leaf $\mathcal{C}(x)$ of the prime-to-p Hecke orbit of x. The argument in 6.3 shows that the continuous Hecke orbit conjecture $\mathrm{HO}_{\mathrm{ct}}$ for $Z(x)$ would follow if one can show that there exists a hypersymmetric point y in $Z(x)$.

The Hecke orbit conjecture HO for Hilbert modular varieties comes into the proof of the continuous Hecke orbit conjecture $\mathrm{HO}_{\mathrm{ct}}$ for Siegel modular varieties at this juncture. After a possibly inseparable isogeny correspondence, one can assume that the given point $x \in \mathcal{A}_{g,n}$ lies in a Hilbert modular subvariety in $\mathcal{A}_{g,n}$. After another application of the local stabilizer principle, one is reduced to the case when the abelian variety A_x has only two slopes. With the help of Theorem 3.5, one sees that $Z(x)$ contains the leaf through x in a Hilbert modular subvariety containing x, hence $Z(x)$ contains a hypersymmetric point in $\mathcal{A}_{g,n}$. See [4] for a more detailed outline of the argument.

Remark 6.3. (i) The proof of the Hecke orbit conjecture for Siegel modular varieties outlined above relies on a special property of Siegel modular varieties: For every point $x \in \mathcal{A}_{g,n}(\overline{\mathbb{F}}_p)$, there exists a Hilbert modular variety $\mathcal{M}_{E,n}$, a finite-to-one correspondence $f\colon \mathcal{M}_{E,n} \to \mathcal{A}_{g,n}$ equivariant with respect to the prime-to-p Hecke correspondences, and a point $y \in \mathcal{M}_{E,n}(\overline{\mathbb{F}}_p)$ above x. See [4, §9], labeled as the "Hilbert trick". The point is that, every $\overline{\mathbb{F}}_p$-point of $\mathcal{A}_{g,n}$ lies in a subvariety which is essentially the reduction of a "small" Shimura subvariety of positive dimension, namely a Hilbert modular variety attached to a product E of totally real fields such that $\dim_{\mathbb{Q}}(E) = g$. Here "small" means that every factor of the reductive group attached to the Shimura subvariety has semisimple $\mathbb{Q}$-rank one.

(ii) The property that every rational point over a finite field lies in the image of a small Shimura variety of positive dimension holds for modular varieties of PEL type C, but fails for modular varieties of type A and D. Consequently, the Hecke orbit conjecture for modular varieties of PEL type C is within reach by available methods, while new ideas are needed for PEL types A and D, or the reduction of general Shimura varieties.

7. Open questions and outlook

We discuss two approaches toward a proof of the Hecke orbit conjecture for Siegel modular varieties without resorting to the Hilbert trick.

7.1. Tate-linear subvarieties in leaves. For simplicity, we consider the special case of a leaf $\mathcal{C}$ in a Siegel modular variety $\mathcal{A}_{g,n}$, such that every point of $\mathcal{C}$ corresponds to a g-dimensional principally polarized abelian variety with two slopes $\lambda < 1 - \lambda$. This assumption implies that the formal completion $\mathcal{C}^{/x}$ of $\mathcal{C}$ has a natural structure

as an isoclinic p-divisible formal group with slope $1-2\lambda$ and height $\frac{g(g+1)}{2}$, for any closed point $x \in \mathcal{C}$.

An irreducible closed subvariety $Z \subset \mathcal{C}$ is said to be *Tate linear* at a closed point $x \in Z$ if the formal completion $Z^{/x}$ is a p-divisible formal subgroup of $\mathcal{C}^{/x}$. It can be shown that if Z is Tate-linear at one closed point of $\mathcal{C}$, then it is Tate-linear at every closed point of the smooth locus of Z

Remark. (i) The proof that the property of being Tate-linear propagates from one point of Z to every point of Z depends on a global version of canonical coordinates. The case when $\mathcal{C}$ is the ordinary locus of $\mathcal{A}_{g,n}$ has been documented in [7], where several issues related to the notion of Tate-linear subvarieties are addressed.

(ii) The notion of Tate-linear subvarieties is inspired by the Hecke orbit problem: Suppose that $\mathcal{M}$ is a modular variety of PEL type contained in a Siegel modular variety $\mathcal{A}_{g,n}$, and $x \in \mathcal{M}(\overline{\mathbb{F}}_p) \cap \mathcal{C}(\overline{\mathbb{F}}_p)$ is a point of $\mathcal{M}$ such that the abelian variety A_x attached to x has two slopes $\lambda < 1-\lambda$. Then the Zariski closure of the Hecke orbit $\mathcal{H}^p \cdot x$ in the leaf $\mathcal{C}_{\mathcal{M}}(x)$ is a Tate linear subvariety of $\mathcal{C}$.

Question 7.1. The most intriguing question about the notion of Tate-linear subvarieties is whether every Tate-linear subvariety of a leaf $\mathcal{C}$ in $\mathcal{A}_{g,n}$ is (an irreducible component of) the intersection of $\mathcal{C}$ with the reduction of a Shimura subvariety of $\mathcal{A}_{g,n}$ in characteristic 0.

It seems plausible that the answer is a *qualified yes*. This naive expectation will be termed the *global rigidity conjecture*.

Remark. (i) If the global rigidity conjecture is true, then the notion of Tate-linear subvarieties provides a geometric characterization for subvarieties of $\mathcal{C}$ which are equal to (an irreducible component of) the intersection of $\mathcal{C}$ with the reduction of a Shimura subvariety of $\mathcal{A}_{g,n}$.

(ii) The global rigidity conjecture should be considered as being stronger than the continuous Hecke orbit conjecture $\mathrm{HO}_{\mathrm{ct}}$: Continuing the set-up as in §7.1. Let Z be the Zariski closure in the leaf $\mathcal{C}_{\mathcal{M}}(x)$ in $\mathcal{M}$ containing x of the prime-to-p Hecke orbit in $\mathcal{M}$. Then Z is a Tate-linear subvariety, by Theorem 6.2. Moreover if the global rigidity conjecture is true, then one can deduce without difficulty that Z is a union of irreducible components of $\mathcal{C}(x)$.

7.2. *p*-adic monodromy. As we saw in 6.3, the combination of the local stabilizer principle, canonical coordinates and the local rigidity theory achieves a certain level of localization for the Hecke orbit problem. This linearization allows one to approach the Hecke orbit problem through the p-adic monodromy: Let Z be the Zariski closure of a given prime-to-p Hecke orbit $\mathcal{H}(x)$ in the leaf $\mathcal{C}$ containing $\mathcal{H}(x)$. Consider the restriction to Z of the universal Barsotti–Tate group $A[p^\infty] \to \mathcal{M}$ over the modular variety $\mathcal{M}$. Over the leaf $\mathcal{C}$, the Barsotti–Tate group $A[p^\infty] \to \mathcal{C}$ admits a *slope filtration*; the p-adic monodromy attached to the associated graded of the slope filtration of $A[p^\infty] \to \mathcal{Z}$ will be called the *naive p-adic monodromy* of $A[p^\infty] \to Z$.

Conjecture 7.2. The naive p-adic monodromy of the family $A[p^\infty] \to Z$ is "as large as possible", in the sense that the image of the naive p-adic monodromy representation is an open subgroup of the group of $\mathbb{Q}_p$-points of a suitable Levi subgroup L of an inner twist G' of G attached to Z, where G is the reductive group attached to the PEL data for $\mathcal{M}$.

Remark. (i) Conjecture 7.2 for the Zariski closure Z of an Hecke orbit implies the continuous Hecke orbit conjecture $\mathrm{HO}_{\mathrm{cont}}$.

(ii) Conjecture 7.2 is a p-adic analogue of Proposition 3.3.

(iii) As a weak converse to Conjecture 7.2, the method of the proof of Proposition 7.4 below should enable one to show that the Hecke orbit conjecture HO implies Conjecture7.2, using a hypersymmetric point as the base point.

Remark 7.3. Given an abelian scheme $A \to S$, where S a scheme over $\mathbb{F}_p$, we would like to show that the naive p-adic monodromy for $A \to S$ is "as large as possible", subject to obvious constraints, such as cycles on the family $A \to S$. As an intermediate step toward this goal, one would like to show that, when S is the spectrum of a Noetherian local integral domain and the Newton polygon of the closed fiber of $A \to S$ is different from the Newton polygon of the generic fiber, the naive p-adic monodromy for the generic fiber of $A \to S$ is *large* in a suitable sense.

When $\dim(A/S) = 1$, the above *wish* is a classical theorem of Igusa. The argument of Igusa was generalized in [3] to the case of a one-dimensional p-divisible formal group with ordinary generic fiber. The same argument applies to the case of a p-divisible formal group with ordinary generic fiber such that the dimension and the codimension are coprime; details will appear in an article with D. U. Lee.

Proposition 7.4. *Let $\mathcal{A}_{g,n}^{\mathrm{or}}$ be the ordinary locus of a Siegel modular variety $\mathcal{A}_{g,n}$ over k, where $g \geq 1$, $n \geq 3$, $(n, p) = 1$, and the base field $k \supseteq \mathbb{F}_p$ is algebraically closed. Let $A \to \mathcal{A}_{g,n}^{\mathrm{or}}$ be the universal abelian scheme over $\mathcal{A}_{g,n}^{\mathrm{or}}$. Let $A[p^\infty]_{\mathrm{et}} \to \mathcal{A}_{g,n}^{\mathrm{or}}$ be the maximal étale quotient of $A[p^\infty] \to \mathcal{A}_{g,n}^{\mathrm{or}}$; it is an étale Barsotti–Tate group of height g. Let E_0 be an ordinary elliptic curve defined over $\overline{\mathbb{F}}_p$, and let $x_0 = (A_0, \lambda_0)$, where A_0 is the product of g copies of E_0, and λ_0 is the product principal polarization on A_0. Let $\mathrm{T}_p = \mathrm{T}_p(A_0[p^\infty])_{\mathrm{et}})$ be the p-adic Tate module of the étale p-divisible group $A_0[p^\infty]_{\mathrm{et}}$; it is naturally isomorphic to the direct sum of g copies of $\mathrm{T}_p(E_0[p^\infty]_{\mathrm{et}}) \cong \mathbb{Z}_p$, so $\mathrm{GL}(\mathrm{T}_p)$ is naturally isomorphic to $\mathrm{GL}_g(\mathbb{Z}_p)$. Let $\rho\colon \pi_1(\mathcal{A}_{g,n}^{\mathrm{or}}, x_0) \to \mathrm{GL}(\mathrm{T}_p)$ be the naive p-adic monodromy representation of $A[p^\infty] \to \mathcal{A}_{g,n}^{\mathrm{or}}$. Then the image of ρ is equal to $\mathrm{GL}(\mathrm{T}_p) \cong \mathrm{GL}_g(\mathbb{Z}_p)$.*

Proof. Let $\mathcal{B}$ be the product of g copies of $\mathcal{A}_{1,n}$, diagonally embedded in $\mathcal{A}_{g,n}$. Let E_0 be an ordinary elliptic curve defined over a $\overline{\mathbb{F}}_p$, and let $x_0 = (A_0, \lambda_0)$, where A_0 is the product of g copies of E_0, and λ_0 is the product principal polarization on A_0. Let $\mathcal{O} = \mathrm{End}(E_0)$. Then $\mathcal{O} \otimes_{\mathbb{Z}} \mathbb{Z}_p \cong \mathbb{Z}_p \times \mathbb{Z}_p$, corresponding to the natural splitting of $E_0[p^\infty]$ into the product of its toric part $E_0[p^\infty]_{\mathrm{tor}}$ and its étale part $E_0[p^\infty]_{\mathrm{et}}$. So we have an isomorphism $\mathrm{End}(A_0) \cong \mathrm{M}_g(\mathcal{O})$, and a splitting $\mathrm{End}(A_0) \otimes_{\mathbb{Z}} \mathbb{Z}_p \cong$

$\mathrm{M}_g(\mathcal{O}) \times \mathrm{M}_g(\mathcal{O})$ corresponding to the splitting of $A_0[p^\infty]$ into the product its toric and étale parts. Denote by $\mathrm{pr}\colon (\mathrm{End}(A_0) \otimes_{\mathbb{Z}} \mathbb{Z}_p)^\times \to \mathrm{GL}(\mathrm{T}_p) \cong \mathrm{GL}_g(\mathbb{Z}_p)$ the projection corresponding to the action of $\mathrm{End}(A_0) \otimes_{\mathbb{Z}} \mathbb{Z}_p$ on the étale factor $A_0[p^\infty]_{\mathrm{et}}$ of $A_0[p^\infty]$. The Rosati involution $*$ on $\mathrm{End}(A_0)$ interchanges the two factors of $\mathrm{End}(A_0) \otimes_{\mathbb{Z}} \mathbb{Z}_p$. It follows that $\mathrm{U}(\mathcal{O}_{(p)} \otimes_{\mathbb{Z}} \mathbb{Z}_p, *)$ is isomorphic to $\mathrm{GL}(\mathrm{T}_p)$ under the projection map pr, therefore the image of $\mathrm{U}(\mathcal{O}_{(p)}, *)$ in $\mathrm{GL}(\mathrm{T}_p)$ is dense in $\mathrm{GL}(\mathrm{T}_p)$. Here $\mathcal{O}_{(p)} = \mathcal{O} \otimes_{\mathbb{Z}} \mathbb{Z}_{(p)}$, and $\mathbb{Z}_{(p)} = \mathbb{Q} \cap \mathbb{Z}_p$ is the localization of $\mathbb{Z}$ at the prime ideal $(p) = p\mathbb{Z}$.

By a classical theorem of Igusa, the p-adic monodromy group of the restriction to $\mathcal{B}$, i.e. $\rho(\mathrm{Im}(\pi_1(\mathcal{B}, x_0) \to \pi_1(\mathcal{A}_{g,n}, x_0)))$, is naturally identified with the product of g copies of $\mathbb{Z}_p^\times$ diagonally embedded in $\mathrm{GL}(\mathrm{T}_p) \cong \mathrm{GL}_g(\mathbb{Z}_p)$. Denote by D this subgroup of $\mathrm{GL}(\mathrm{T}_p)$.

Let $R_{(p)} = \mathrm{End}(A_0) \otimes_{\mathbb{Z}} \mathbb{Z}_{(p)} \cong \mathrm{M}_g(\mathcal{O}) \otimes_{\mathbb{Z}} \mathbb{Z}_{(p)}$. Every element $u \in R_{(p)}$ such that $u^*u = uu^* = 1$ gives rise to a prime-to-p isogeny from A_0 to itself respecting the polarization λ_0. Such an element $u \in R_{(p)}$ gives rise to

- a prime-to-p Hecke correspondence h on $\mathcal{A}_{g,n}$ having x_0 as a fixed point, and
- an irreducible component $\mathcal{B}'$ of the image of $\mathcal{B}$ under h such that $\mathcal{B}' \ni x_0$.

By the functoriality of the fundamental group, the image of the fundamental group $\pi_1(\mathcal{B}', x_0)$ of $\mathcal{B}'$ in $\pi_1(\mathcal{A}^{\mathrm{or}}_{g,n}, x_0)$ is mapped under the p-adic monodromy representation ρ to the conjugation of D by the element $\mathrm{pr}(h) \in \mathrm{GL}(\mathrm{T}_p)$. In particular, $\rho(\pi_1(\mathcal{A}^{\mathrm{or}}_{g,n}, x_0))$ is a closed subgroup of $\mathrm{GL}(\mathrm{T}_p)$ which contains all conjugates of D by elements in the image of $\mathrm{pr}\colon \mathrm{U}(E_{(p)}, *) \to \mathrm{GL}(\mathrm{T}_p)$.

Recall that the image of $\mathrm{U}(E_{(p)}, *)$ in $\mathrm{GL}(\mathrm{T}_p)$ is a dense subgroup. So the monodromy group $\rho(\pi_1(\mathcal{A}_{g,n}, x_0))$ is a closed normal subgroup of $\mathrm{GL}(\mathrm{T}_p) \cong \mathrm{GL}_g(\mathbb{Z}_p)$ which contains the subgroup D of all diagonal elements. An easy exercise in group theory shows that the only such closed normal subgroup is $\mathrm{GL}_g(\mathbb{Z}_p)$ itself. □

Remark. (i) There are at least two published proofs of Proposition 7.4 in the literature, in [15] and [16, chap. V §7] respectively.

(ii) In the proof of 7.4, one can use as the base point any element $[(A_1, \lambda)]$ of $\mathcal{A}^{\mathrm{or}}_{g,n}$ such that A_1 is separably isogenous to a product of g copies of an ordinary elliptic curve E_1 over $\overline{\mathbb{F}}_p$.

(iii) As already mentioned before, the argument of Proposition 7.4 applies to leaves in modular varieties of PEL type. Since we used a hypersymmetric point as the base point, a priori this argument applies only to those irreducible components of a given leaf which contain hypersymmetric points.

Heegner points, Stark–Heegner points, and values of L-series

Henri Darmon*

Abstract. Elliptic curves over $\mathbb{Q}$ are equipped with a systematic collection of *Heegner points* arising from the theory of complex multiplication and defined over abelian extensions of imaginary quadratic fields. These points are the key to the most decisive progress in the last decades on the Birch and Swinnerton-Dyer conjecture: an essentially complete proof for elliptic curves over $\mathbb{Q}$ of analytic rank ≤ 1, arising from the work of Gross–Zagier and Kolyvagin. In [Da2], it is suggested that Heegner points admit a host of conjectural generalisations, referred to as *Stark–Heegner points* because they occupy relative to their classical counterparts a position somewhat analogous to Stark units relative to elliptic or circular units. A better understanding of Stark–Heegner points would lead to progress on two related arithmetic questions: the explicit construction of global points on elliptic curves (a key issue arising in the Birch and Swinnerton-Dyer conjecture) and the analytic construction of class fields sought for in Kronecker's Jugendtraum and Hilbert's twelfth problem. The goal of this article is to survey Heegner points, Stark–Heegner points, their arithmetic applications and their relations (both proved, and conjectured) with special values of L-series attached to modular forms.

Mathematics Subject Classification (2000). Primary 11G05; Secondary 11G15.

Keywords. Elliptic curves, modular forms, L-series, Heegner points, Stark–Heegner points.

1. Introduction

Elliptic curves are distinguished among projective algebraic curves by the fact that they alone are endowed with the structure of a (commutative) algebraic group. The *affine* curves with this property are the additive group $\mathbb{G}_a$ and the multiplicative group $\mathbb{G}_m$. The integral points on $\mathbb{G}_a$ (taken, say, over an algebraic number field F) is a finitely generated $\mathbb{Z}$-module. The same is true for the integral points on G_m: these are the units of F, whose structure is well understood thanks to Dirichlet's unit theorem. The close parallel between units and rational points on elliptic curves is frequently illuminating. In both cases, it is the natural group law on the underlying curve which lends the associated Diophantine theory its structure and richness.

An elliptic curve E over F can be described concretely as a Weierstrass equation

*The author is grateful to NSERC, CICMA, McGill University and the Centre de Recherches Mathématiques in Montreal for their support during the writing of this paper.

Proceedings of the International Congress of Mathematicians, Madrid, Spain, 2006

in projective space

$$y^2z = x^3 + axz^2 + bz^3, \quad a, b \in F, \text{ where } \Delta := 4a^3 - 27b^2 \neq 0.$$

The group $E(F)$ of F-rational (or equivalently: integral) solutions to this equation is in bijection with the F-rational solutions of the corresponding affine equation

$$y^2 = x^3 + ax + b,$$

together with an extra "point at infinity" corresponding to $(x, y, z) = (0, 1, 0)$.

The most basic result on the structure of $E(F)$ is the *Mordell–Weil Theorem* which asserts that $E(F)$ is a finitely generated abelian group, so that there is an isomorphism of abstract groups

$$E(F) \simeq T \oplus \mathbb{Z}^r,$$

where T is the finite torsion subgroup of $E(F)$. The integer $r \geq 0$ is called the *rank* of E over F. Many questions about T are well-understood, for example:

1. There is an efficient algorithm for computing T, given E and F.

2. A deep result of Mazur [Ma] describes the possible structure of T when $F = \mathbb{Q}$ and E is allowed to vary over all elliptic curves. The size of T is bounded uniformly, by 14. Mazur's result has been generalised by Kamienny and Merel [Mer], yielding a uniform bound on the size of T when F is fixed – a bound which depends only on the degree of F over $\mathbb{Q}$.

In contrast, much about the rank remains mysterious. For example, can r become arbitrarily large, when F is fixed but E is allowed to vary? The answer is believed to be yes, but no proof is known for $F = \mathbb{Q}$ or for any other number field F.

An even more fundamental problem resides in the absence of effectivity in the proof of the Mordell–Weil theorem. Specifically, the answer to the following question is not known.

Question 1.1. Is there an algorithm which, given E, calculates the rank r of $E(F)$, and a system $P_1, \ldots, P_r$ of generators for this group modulo torsion?

A candidate for such an algorithm is Fermat's method of infinite descent, but this method is not guaranteed to terminate in a finite amount of time – it would, if the so-called *Shafarevich–Tate group* $Ш(E/\mathbb{Q})$ of E is finite, as is predicted to be the case.

Question 1.1 is also connected with the *Birch and Swinnerton-Dyer conjecture*. This conjecture relates Diophantine invariants attached to E, such as r, to the Hasse–Weil L-series $L(E, s)$ of E, a function of the complex variable s which is defined in terms of an Euler product taken over the non-archimedean places v of F. To describe this Euler product precisely, let $\mathbb{F}_v = \mathcal{O}_F/v$ denote the residue field of F at v, and write $|v| := \#\mathbb{F}_v$ for the norm of v. The elliptic curve E is said to have *good reduction*

at v if it can be described by an equation which continues to describe a smooth curve over $\mathbb{F}_v$ after reducing its coefficients modulo v. Set $\delta_v = 1$ if E has good reduction at v, and $\delta_v = 0$ otherwise. Finally, define integers a_v indexed by the places v of good reduction for E by setting

$$a_v := |v| + 1 - \#E(\mathbb{F}_v).$$

This definition is extended to the finite set of places of bad reduction for E, according to a recipe in which $a_v \in \{0, 1, -1\}$, the precise value depending on the type of bad reduction of E in an explicit way.

The L-series of E is given in terms of these invariants by

$$L(E, s) = \prod_v (1 - a_v|v|^{-s} + \delta_v|v|^{1-2s})^{-1} = \sum_{\mathfrak{n}} a_E(\mathfrak{n})|\mathfrak{n}|^{-s},$$

where the product is taken over all the non-archimedean places v of F, and the sum over the integral ideals $\mathfrak{n}$ of F. The Euler product converges absolutely for $\mathrm{Re}(s) > 3/2$, but $L(E, s)$ is expected to admit an analytic continuation to the entire complex plane. Some reasons for this expectation, and a statement of the Birch and Swinnerton-Dyer conjecture, are given in Section 2.6.

2. Elliptic curves over $\mathbb{Q}$

It is useful to first discuss elliptic curves over $\mathbb{Q}$, a setting in which a number of results currently admit more definitive formulations.

Given an elliptic curve $E/\mathbb{Q}$, let N denote its *conductor*. This positive integer, which measures the arithmetic complexity of E, is divisible by exactly the same primes as those dividing the minimal discriminant of E (the minimum being taken over all possible plane cubic equations describing E). Denote by a_n the coefficient of n^{-s} in the Hasse–Weil L-series of E:

$$L(E, s) = \prod_p (1 - a_p p^{-s} + \delta_p p^{1-2s})^{-1} = \sum_{n=1}^{\infty} a_n n^{-s}.$$

2.1. Modular parametrisations. Little can be asserted about the effective determination of $E(\mathbb{Q})$, or about the analytic behaviour of $L(E, s)$, without the knowledge that E is *modular*. Wiles's far-reaching program for proving the modularity of elliptic curves (and more general Galois representations) has been completely carried out in [BCDT] when $F = \mathbb{Q}$. One way of formulating the modularity of E is to state that the generating series

$$f_E(z) := \sum_{n=1}^{\infty} a_n e^{2\pi i n z} \tag{1}$$

is a *modular form of weight* 2 for the Hecke congruence group

$$\Gamma_0(N) := \left\{ \begin{pmatrix} a & b \\ c & d \end{pmatrix} \in \mathrm{SL}_2(\mathbb{Z}) \text{ such that } N|c \right\}.$$

This means that $f(z)$ is a holomorphic function on the Poincaré upper half-plane

$$\mathcal{H} := \{z = x + iy,\ y > 0\} \subset \mathbb{C},$$

satisfying

$$f\left(\frac{az+b}{cz+d}\right) = (cz+d)^2 f(z) \quad \text{for all } \begin{pmatrix} a & b \\ c & d \end{pmatrix} \in \Gamma_0(N), \tag{2}$$

together with suitable growth properties around the fixed points of parabolic elements of $\Gamma_0(N)$. These fixed points belong to $\mathbb{P}_1(\mathbb{Q})$, and it is useful to replace $\mathcal{H}$ by the completed upper half-plane $\mathcal{H}^* := \mathcal{H} \cup \mathbb{P}_1(\mathbb{Q})$. After suitably defining the topology and complex structure on the quotient $\Gamma_0(N)\backslash\mathcal{H}^*$, thus making it into a compact Riemann surface, the differential form $\omega_f := 2\pi i f(z)dz$ is required to extend to a holomorphic differential on this surface.

The quotient $\Gamma_0(N)\backslash\mathcal{H}^*$ can even be identified with the set of complex points of an algebraic curve defined over $\mathbb{Q}$, denoted by $X_0(N)$. This algebraic curve structure arises from the interpretation of $\Gamma_0(N)\backslash\mathcal{H}$ as classifying isomorphism classes of elliptic curves with a distinguished cyclic subgroup of order N, in which the orbit $\Gamma_0(N)\tau \in \Gamma_0(N)\backslash\mathcal{H}$ is identified with the pair $\left(\mathbb{C}/\langle 1, \tau\rangle, \left\langle \frac{1}{N} \right\rangle\right)$. A (highly singular, in general) equation for $X_0(N)$ as a plane curve over $\mathbb{Q}$ is given by the polynomial $G_N(x, y)$ of bidegree $\#\mathbb{P}_1(\mathbb{Z}/N\mathbb{Z})$, where

$$G_N(x, y) \in \mathbb{Q}[x, y] \quad \text{satisfies} \quad G_N(j(\tau), j(N\tau)) = 0, \tag{3}$$

and j is the classical modular function of level 1.

An equivalent formulation of the modularity property is that there exists a non-constant map of algebraic curves defined over $\mathbb{Q}$,

$$\Phi_E : X_0(N) \longrightarrow E, \tag{4}$$

referred to as the *modular parametrisation* attached to E. One of the attractive features of this modular parametrisation is that it can be computed by analytic means, without the explicit knowledge of an equation for $X_0(N)$ as an algebraic curve over $\mathbb{Q}$. (Such an equation, as in (3), tends to be complicated and difficult to work with numerically for all but very small values of N.)

To describe Φ_E analytically, i.e., as a map

$$\Phi_E^{\infty} : X_0(N)(\mathbb{C}) = \Gamma_0(N)\backslash\mathcal{H} \longrightarrow E(\mathbb{C}), \tag{5}$$

let $\Lambda_f \subset \mathbb{C}$ be the set of complex numbers of the form

$$\int_{\tau}^{\gamma\tau} \omega_f, \quad \text{for } \gamma \in \Gamma.$$

It can be shown that Λ_f is a lattice, and that the quotient $\mathbb{C}/\Lambda_f$ is isomorphic to an elliptic curve E_f which is defined over $\mathbb{Q}$ and is $\mathbb{Q}$-isogenous to E. (The curve E_f is sometimes called the *strong Weil curve* attached to f.) The modular parametrisation to E_f, denoted by Φ_f, is defined analytically by the rule

$$\Phi_f(\tau) = \int_{i\infty}^{\tau} 2\pi i f(z)dz = \sum_{n=1}^{\infty} \frac{a_n}{n} e^{2\pi i n\tau} \pmod{\Lambda_f}, \tag{6}$$

for all $\tau \in \Gamma_0(N)\backslash\mathcal{H} \subset X_0(N)(\mathbb{C})$. The resulting value is viewed as an element of $E_f(\mathbb{C})$ via the identification $\mathbb{C}/\Lambda_f = E_f(\mathbb{C})$.

After choosing an isogeny $\alpha\colon E_f \longrightarrow E$ defined over $\mathbb{Q}$, the parametrisation Φ_E is defined by setting $\Phi_E^{\infty} = \alpha\Phi_f$. In practice it is preferable to start with $E = E_f$, at the cost of replacing E by a curve which is isogenous to it, so that α can be chosen to be the identity. The map Φ_E^{∞} is then given directly by (6).

2.2. Heegner points. Let $K \subset \mathbb{C}$ be a quadratic imaginary field, and denote by K^{ab} its maximal abelian extension, equipped with an embedding into $\mathbb{C}$ compatible with the complex embedding of K. The following theorem, a consequence of the theory of complex multiplication, is one of the important applications of the modular parametrisation Φ_E of (5):

Theorem 2.1. *If τ belongs to $K \cap \mathcal{H}$, then $\Phi_E^{\infty}(\tau)$ belongs to $E(K^{\mathrm{ab}})$.*

Theorem 2.1 also admits a more precise formulation which describes the field of definition of $\Phi_E^{\infty}(\tau)$. Let $M_0(N) \subset M_2(\mathbb{Z})$ denote the ring of 2×2 matrices with integer entries which are upper triangular modulo N. Given $\tau \in \mathcal{H}$, the *associated order* of τ is the set of matrices in $M_0(N)$ which preserve τ under Möbius transformations, together with the zero matrix, i.e.,

$$\mathcal{O}_\tau := \left\{\gamma \in M_0(N) \text{ such that } \gamma\begin{pmatrix}\tau\\1\end{pmatrix} = \lambda_\gamma\begin{pmatrix}\tau\\1\end{pmatrix}, \text{ for some } \lambda_\gamma \in \mathbb{C}\right\}.$$

The assignment $\gamma \mapsto \lambda_\gamma$ identifies $\mathcal{O}_\tau$ with a discrete subring of $\mathbb{C}$. Such rings are isomorphic either to $\mathbb{Z}$, or to an order in a quadratic imaginary field, the latter case occurring precisely when τ generates a quadratic (imaginary) extension of $\mathbb{Q}$. In that case $\mathcal{O}_\tau$ is an order in the quadratic field $K = \mathbb{Q}(\tau)$.

Orders in quadratic fields have the peculiarity that they are completely determined by their discriminants. Write D for the discriminant of the order $\mathcal{O} = \mathcal{O}_\tau$, and let $G_D := \mathrm{Pic}(\mathcal{O})$ denote the class group of this order, consisting of isomorphism classes of projective modules of rank one over $\mathcal{O}$ equipped with the group law arising from the tensor product. A standard description identifies G_D with a quotient of the idèle class group of K:

$$G_D = \mathbb{A}_K^{\times}/\Big(K^{\times}\mathbb{C}^{\times}\mathbb{A}_{\mathbb{Q}}^{\times}\prod_{\ell}\mathcal{O}_\ell^{\times}\Big). \tag{7}$$

Here $\mathbb{A}_K^\times$ denotes the group of idèles of K, the product is taken over the rational primes ℓ, and $\mathcal{O}_\ell := \mathcal{O} \otimes \mathbb{Z}_\ell$. The group G_D also admits a more classical description which is well adapted to explicit computations, as the set of equivalence classes of primitive binary quadratic forms of discriminant D equipped with the classical Gaussian composition law. (For more details on this classical point of view, see Bhargava's lecture in these proceedings.)

If D and N are relatively prime, and $\mathcal{O}_\tau = \mathcal{O}_D$, there is a primitive integral binary quadratic form $F_\tau(x, y) = A_\tau x^2 + B_\tau xy + C_\tau y^2$ satisfying

$$F_\tau(\tau, 1) = 0, \quad B_\tau^2 - 4A_\tau C_\tau = D, \quad N \text{divides } A_\tau.$$

In particular,

$$\text{all the primes } \ell | N \text{ are split in } K/\mathbb{Q}, \tag{8}$$

and therefore the equation

$$x^2 = D \pmod{N}$$

has a solution (namely, B_τ). Fix a square root δ of D modulo N, and define

$$\mathcal{H}^D := \{\tau \in \mathcal{H} \text{ such that } \mathcal{O}_\tau = \mathcal{O}_D \text{ and } B_\tau \equiv \delta \pmod{N}\}.$$

The function which to $\tau \in \Gamma_0(N)\backslash\mathcal{H}^D$ associates the $\mathrm{SL}_2(\mathbb{Z})$-equivalence class of the binary quadratic form F_τ is a bijection. (Cf., for example, Section I.1 of [GKZ].) Through this bijection, $\Gamma_0(N)\backslash\mathcal{H}^D$ inherits a natural action of G_D via the Gaussian composition law. Denote this action by $(\sigma, \tau) \mapsto \tau^\sigma$, for $\sigma \in G_D$ and $\tau \in \Gamma_0(N)\backslash\mathcal{H}^D$.

Class field theory identifies G_D with the Galois group of an abelian extension of K, as is most readily apparent, to modern eyes, from (7). This abelian extension, denoted by H_D, is called the *ring class field* attached to $\mathcal{O}$, or to the discriminant D. When D is a fundamental discriminant, H_D is Hilbert class field of K, i.e., the maximal unramified abelian extension of K. Let

$$\mathrm{rec}\colon G_D \longrightarrow \mathrm{Gal}(H_D/K) \tag{9}$$

denote the reciprocity law map of global class field theory.

A more precise form of Theorem 2.1 is given by

Theorem 2.2. *If τ belongs to $\Gamma_0(N)\backslash\mathcal{H}^D$, then $\Phi_E^\infty(\tau)$ belongs to $E(H_D)$, and*

$$\Phi_E^\infty(\tau^\sigma) = \mathrm{rec}(\sigma)^{-1}\Phi_E^\infty(\tau), \quad \textit{for all } \sigma \in G_D.$$

The fact that Φ_E^∞ intertwines the explicit action of G_D on $\Gamma_0(N)\backslash\mathcal{H}^D$ arising from Gaussian composition with the natural action of $\mathrm{Gal}(H_D/K)$ on $E(H_D)$ gives a concrete realisation of the reciprocity map (9) of class field theory. It is a special case of the *Shimura reciprocity law*.

The points $\Phi_E^\infty(\tau)$, as τ ranges over $\mathcal{H} \cap K$ are called *Heegner points* attached to K. (Sometimes, this appellation is confined to the case where the discriminant of $\mathcal{O}_\tau$ is relatively prime to N.) Theorems 2.1 and 2.2 are of interest for the following reasons, which are discussed at greater length in Sections 2.3, 2.4, and 2.5 respectively.

1. They provide a simple, computationally efficient construction of rational and algebraic points on E.

2. They are a manifestation of the fact that we dispose of an *explicit class field theory* for imaginary quadratic fields, allowing the construction of abelian extensions of such fields from values of modular functions evaluated at quadratic imaginary arguments of the upper half-plane.

3. There are deep connections between the points $\Phi_E^\infty(\tau)$, for $\tau \in \mathcal{H}^D$, and the first derivative at $s = 1$ of the Hasse–Weil L-series $L(E/K, s)$ and of related partial L-series associated to ideal classes of K. These connections lead to new insights into the behaviour of these L-series and the Birch and Swinnerton-Dyer conjecture.

2.3. The efficient calculation of global points. The fact that the theory of complex multiplication, combined with modularity, can be used to construct rational and algebraic points on E is of interest in its own right. This was noticed and exploited by Heegner, and taken up systematically by Birch in the late 60s and early 70s [BS], [Bi].

Given any (not necessarily fundamental) discriminant D for which $\mathcal{H}^D \neq \emptyset$, let $K = \mathbb{Q}(\sqrt{D})$ and set

$$P_D := \mathrm{trace}_{H_D/\mathbb{Q}}(\Phi_E^\infty(\tau)), \quad \text{for any } \tau \in \mathcal{H}^D,$$
$$P_K := \mathrm{trace}_{H/K}(\Phi_E^\infty(\tau)), \quad \text{for any } \tau \in \mathcal{H}^D,\ D = \mathrm{Disc}(K).$$

When are the points P_D and P_K of *infinite order* (in $E(\mathbb{Q})$ and $E(K)$ respectively)? This question is part of the larger problem of efficiently constructing rational or algebraic points of infinite order on elliptic curves. It is instructive to consider this problem from the point of view of its *computational complexity*.

From the outset, one is stymied by the fact that an answer to Question 1.1 is not known. Complexity issues are therefore better dealt with by focussing on the following more special problem, which depends on the curve E and a positive real parameter h. To state this problem precisely, define the *height* of a rational number $r = a/b$ (represented, of course, in lowest terms) to be

$$\mathrm{height}(r) = \log(|ab| + 1).$$

Thus, the height of r is roughly proportional to the number of digits needed to write r down. The height of an equation is the sum of the heights of its coefficients. The height of a solution $(x_1, \ldots, x_n)$ to such an equation is taken to be the sum of the height of the x_j. (In the case of an elliptic curve, one might prefer a coordinate-free definition by taking the height of E to be the height of the minimal discriminant of E.)

It is expected that, for infinitely many E, the smallest height of a point of infinite order in $E(\mathbb{Q})$ can be at least as large as an exponential function of the height of E. In this respect, the behaviour of elliptic curves is not unlike that of Pell's equation,

where a fundamental solution to $x^2 - Dy^2 = 1$ has height roughly $O(\sqrt{D})$ if $\mathbb{Q}(\sqrt{D})$ has class number one. Of greatest relevance for complexity questions are the "worst-case" elliptic curves E for which the point of infinite order $P_{\min}$ of smallest height in $E(\mathbb{Q})$ has height which is *large* relative to the height of E, i.e., for which

$$\text{height}(P_{\min}) \gg \exp(\text{height}(E)).$$

In order to focus on these curves, and avoid technical side-issues associated with elliptic curves having non-torsion points of small height, we formulate the following problem:

Problem 2.3. Given an elliptic curve E, and a real number

$$h > \exp(\text{height}(E)), \tag{10}$$

find a point P of infinite order on E with $\text{height}(P) < h$, if it exists, or assert that no such point exists, otherwise.

Denote by $P(E, h)$ the instance of this problem associated to E and the parameter h. In light of (10), this parameter can be chosen as a natural measure of the size of the problem.

Note that $P(E, h)$ continues to make sense for *any* Diophantine equation. Even in such great generality, problem $P(E, h)$ has the virtue of possessing an algorithmic solution: a brute force search over all possible points (in the projective space in which E is embedded) of height less than h, say. Such an exhaustive search requires $O(\exp(h))$ operations to solve an instance of $P(E, h)$. The exponential complexity of the brute force approach provides a crude benchmark against which to measure other approaches, and leads naturally to the following definition.

Definition 2.4. A class $\mathcal{C}$ of Diophantine equations is said to be *solvable in polynomial time* if there exists $n \in \mathbb{N}$ and an algorithm that solves $P(E, h)$, with $E \in \mathcal{C}$, in at most $O(h^n)$ operations.

The property that $\mathcal{C}$ is solvable in polynomial time can be expressed informally by stating that the time required to find a *large* solution to any $E \in \mathcal{C}$ is *not much worse* than the time is takes to write that solution down. Thus, an (infinite) class $\mathcal{C}$ of equations being solvable in polynomial time indicates that there is a method for "zeroing in" on a solution (x_0, y_0) to any equation in $\mathcal{C}$ in a way that is qualitatively more efficient than running though all candidates of smaller height.

The prototype for a class of equations that possess a polynomial time solution in the sense of Definition 2.4 is Pell's equation. A polynomial time algorithm for finding a fundamental solution to $x^2 - Dy^2 = 1$ is given by the continued fraction method that was known to the Indian mathematicians of the 10th century (although Fermat seems to be the first to have shown its effectivity.) See [Le] for a more thorough discussion of Pell's equation from the point of view of its computational complexity.

The strong analogy that exists between Pell's equation and elliptic curves suggests that the class **ELL** of all elliptic curves over $\mathbb{Q}$ might also be solvable in polynomial time. Indeed, Fermat's method of infinite descent (applied, say, to a rational 2-isogeny η, if it exists) reduces $P(E, h)$ to d_E instances of $P(C_1, h/2), \ldots, P(C_{d_E}, h/2)$ where the C_j are principal homogeneous spaces for E, and the number d_E is related to the cardinality of the Selmer group attached to η. Applying this remark iteratively suggests that the complexity for solving $P(E, h)$ might be a polynomial of degree related to d_E. The analysis required to make this discussion precise does not appear in the literature, and it would be interesting to determine whether the method of infinite descent can be used to determine to what extent **ELL** is solvable in polynomial time (assuming, eventually, the finiteness of the Shafarevich–Tate group of an elliptic curve).

It should be stressed that the method of descent is often complicated in practice because of the mounting complexity of the principal homogeneous spaces that arise in the procedure. On the other hand, the Heegner point construction, *when it produces a point of infinite order in* $E(\mathbb{Q})$, can be used to solve $P(E, h)$ by a method that is also extremely efficient in practice. See [El2] for a discussion of this application of the Heegner point construction.

For example, let

$$E : y^2 + y = x^3 - x^2 - 10x - 20$$

be the strong Weil curve of conductor 11. (This is the elliptic curve over $\mathbb{Q}$ of smallest conductor.) The following table lists a few values of the x-coordinate of P_K for some more or less randomly chosen K. It takes a desktop computer a fraction of a second to find these x-coordinates, far less than would be required to find points of comparable height on the corresponding quadratic twist of E by a naive search.

$\mathrm{Disc}(K)$	$x(P_K)$
-139	$\frac{-208838\sqrt{-139}-3182352}{1957201}$
-211	$\frac{-11055756376\sqrt{-211}-36342577392}{29444844025}$
-259	$\frac{64238721198\sqrt{-259}-2458030017103}{992886694969}$
-1003	$\frac{-2420904161556151656963 8\sqrt{-1003}-10531813107543863542748 47}{219167070502034515453609}$

2.4. Explicit Class Field Theory. The Heegner point construction is a manifestation of an explicit class field theory for imaginary quadratic fields. Normally, this is stated in terms of the elliptic modular function j. The field

$$K^? := \bigcup_{\alpha\in\mathbb{Q},\,\tau\in K\cap\mathcal{H}} K(e^{2\pi i\alpha},\, j(\tau))$$

obtained by adjoining to the imaginary quadratic field K all the roots of unity, as well as the values $j(\tau)$ for $\tau \in K \cap \mathcal{H}$, is *almost* equal to the maximal abelian extension K^{ab} of K. More precisely, $K^{\mathrm{ab}}/K^{?}$ is an extension whose Galois group, although infinite, has exponent two. (See [Se].)

Given a negative (not necessarily fundamental) discriminant D, let $\tau_1, \ldots, \tau_h$ be representatives for $\mathcal{H}^D$ (with $N = 1$) modulo the action of $\mathrm{SL}_2(\mathbb{Z})$. Then the so-called *modular polynomial*

$$Z_D(z) := \prod_{i=1}^{h} (z - j(\tau_i)) \tag{11}$$

has rational coefficients and its splitting field is the ring class field attached to the discriminant D. One might also fix an elliptic curve E and consider the function $j_E(\tau)$ of $\tau \in \Gamma_0(N)\backslash\mathcal{H}^D$ defined as the x-coordinate of the point $\Phi_E^{\infty}(\tau)$, where the x coordinate refers, say, to a minimal Weierstrass equation for E. Let Z_D^E denote the polynomial defined as in (11) with j replaced by j_E.

For example, consider the discriminants $D = -83$, -47, and -71 of class number 3, 5 and 7 respectively. The polynomials Z_D attached to the first two of these discriminants are given by:

$$x^3 + 2691907584000x^2 - 41490055168000000x + 549755813888000000000$$

$$x^5 + 2257834125x^4 - 9987963828125x^3 + 5115161850595703125x^2 - 14982472850828613281250x + 160429296006238708496093750.$$

(The degree seven polynomial Z_{-71} has been omitted to save space, its coefficients being integers of roughly 30 digits.) The following table gives the values of the polynomials $Z_D^E(z)$ for a few elliptic curves (labelled according to the widely used conventions of the tables of Cremona [Cr2]) whose conductor is a prime that splits in $\mathbb{Q}(\sqrt{D})$, for these three discriminants.

E	$Z^E_{-83}(x)$	$Z^E_{-47}(x)$
$37A$	$x^3 + 5x^2 + 10x + 4$	$x^5 - x^4 + x^3 + x^2 - 2x + 1$
$61A$	$x^3 - 2x^2 + 2x + 1$	$x^5 - x^3 + 2x^2 - 2x + 1$
$79A$		$x^5 + 4x^4 + 3x^3 - 3x^2 - x + 1$

E	$Z^E_{-71}(x)$
$37A$	$x^7 - 2x^6 + 9x^5 - 10x^4 - x^3 + 8x^2 - 5x + 1$
$43A$	$x^7 + 2x^6 + 2x^5 + x^3 + 3x^2 + x + 1$
$79A$	$x^7 + 4x^6 + 5x^5 + x^4 - 3x^3 - 2x^2 + 1$

This data illustrates the well-known fact that in computing class fields one is often better off working with modular functions other than j (such as modular units for instance). The above data suggests (at least anecdotally) that the functions j_E can be excellent choices in certain cases. For a systematic discussion of the heights of Heegner points and of the polynomials $Z_D^E(x)$ as D varies, see [RV].

2.5. Relation with L-series. The following result of Gross and Zagier [GZ] provides a connection between Heegner points and the L-series of E over K.

Theorem 2.5. *The height of P_K is equal to an explicit non-zero multiple of $L'(E/K, 1)$.*

In particular, the point P_K is of infinite order if and only if $L'(E/K, 1) \neq 0$. This result can be exploited in two ways.

Firstly, since Heegner points are so readily computable, specific instances where the point P_K is of finite order yield non-trivial examples where $L'(E/K, 1) = 0$. The *vanishing* of the leading term in an L-series is notoriously difficult to prove numerically. The Gross–Zagier theorem makes it possible to produce elliptic curves for which, provably, $L(E, 1) = L'(E, 1) = 0$. Considerations involving the sign in the functional equation for $L(E, s)$ may even force this function to vanish to odd order, and therefore to order at least 3, at $s = 1$. (The smallest elliptic curve of prime conductor with this property has conductor 5077.) The existence of elliptic curves and modular forms whose L-series has a triple zero at $s = 1$ was exploited to great effect by Goldfeld [Go] in his effective solution of the analytic class number problem of Gauss.

Secondly, and more germane to the theme of this survey, the Gross–Zagier theorem gives a criterion for the "Heegner point method" to produce a point of infinite order on $E(K)$ or on $E(\mathbb{Q})$. This provides a neat characterization of the elliptic curves for which Heegner points lead to an efficient solution of problem $P(E, h)$.

When $\mathrm{ord}_{s=1}(L(E, s)) \geq 2$, constructing the Mordell–Weil group $E(\mathbb{Q})$ is more elusive. It is an apparent paradox of the subject that we are the least well-equipped to produce global points on elliptic curves in precisely those cases when these points are expected to be more plentiful! (On the other hand, this reflects a common occurrence in mathematics, where an object that is uniquely defined is easier to produce explicitly.)

2.6. The Birch and Swinnerton-Dyer conjecture. The Birch and Swinnerton-Dyer conjecture relates the behaviour of $L(E, s)$ at $s = 1$ to arithmetic invariants of E over $\mathbb{Q}$, such as its rank. To facilitate the subsequent exposition, we state it in a form that involves an integer parameter $r \geq 0$.

Conjecture 2.6 (BSD_r). If $\mathrm{ord}_{s=1} L(E, s) = r$, then the rank of $E(\mathbb{Q})$ is equal to r, and the Shafarevich–Tate group $Ш(E/\mathbb{Q})$ of E is finite.

The Birch and Swinnerton-Dyer conjecture predicts that $E(\mathbb{Q})$ should be infinite precisely when $L(E, 1) = 0$. (The latter condition can be easily ascertained computationally in examples, because $L(E, 1)$ is known *a priori* to belong to a specific sublattice of $\mathbb{R}$.)

Remark 2.7. The Birch and Swinnerton-Dyer conjecture (suitably generalised) is consistent with the presence of a systematic supply of algebraic points defined over certain ring class fields of imaginary quadratic fields. To elucidate this remark, we begin by noting that the Birch and Swinnerton-Dyer conjecture generalises to elliptic

curves over number fields, where it predicts that the rank of $E(F)$ is equal to the order of vanishing of $L(E/F, s)$ at $s = 1$. This L-series (and its twists $L(E/F, \chi, s)$ by abelian characters of $\mathrm{Gal}(\bar{F}/F)$) admits a functional equation relating $L(E/F, \chi, s)$ to $L(E/F, \bar{\chi}, 2 - s)$. Suppose that E is defined over $\mathbb{Q}$, that $F = K$ is a quadratic extension of $\mathbb{Q}$, and that $\chi : \mathrm{Gal}(H/K) \longrightarrow \mathbb{C}^\times$ factors through the Galois group of a ring class field H of K. Then the definition of $L(E/K, \chi, s)$ as an Euler product shows that

$$L(E/K, \chi, s) = L(E/K, \bar{\chi}, s).$$

The *sign* that appears in the functional equation of the L-series $L(E/K, \chi, s)$, denoted by $\mathrm{sign}(E/K, \chi) \in \{-1, 1\}$, therefore determines the parity of its order of vanishing $\mathrm{ord}_{s=1}(L(E/K, \chi, s))$.

When (E, K) satisfies the *Heegner hypothesis* of equation (8), it can be shown that $\mathrm{sign}(E, K) = -1$ so that $L(E/K, 1) = 0$. Moreover, the same is true of $\mathrm{sign}(E/K, \chi)$ when χ is *any* ring class character of conductor prime to N_E, so that $L(E/K, \chi, 1) = 0$ for such ring class characters. In particular, if H is a ring class field of K of discriminant prime to N_E, we find

$$\mathrm{ord}_{s=1} L(E/H, s) = \mathrm{ord}_{s=1} \Big(\prod_{\chi \in \widehat{\mathrm{Gal}(H/K)}} L(E/K, \chi, s) \Big) \geq [H : K], \tag{12}$$

so that the Birch and Swinnerton-Dyer conjecture predicts the inequality:

$$\mathrm{rank}(E(H)) \overset{?}{\geq} [H : K]. \tag{13}$$

The Gross–Zagier formula (Theorem 2.5), suitably generalised to the L-series $L(E/K, \chi, s)$ with character, as in the work of Zhang discussed in Section 3.4, makes it possible to bound the rank of $E(H)$ from below by establishing the non-triviality of certain Heegner points, and yields

Corollary 2.8. *If the inequality in* (12) *is an* equality*, then the inequality* (13) *holds.*

A short time after the proof of the Gross–Zagier formula, Kolyvagin discovered a general method for using Heegner points to bound the ranks of Mordell–Weil groups *from above.*

Theorem 2.9 (Kolyvagin). *If P_K is of infinite order, then $E(K)$ has rank one and $Ш(E/K)$ is finite.*

Crucial to Kolyvagin's proof is the fact that the Heegner point P_K does not come alone, but is part of an infinite collection of algebraic points

$$\{\Phi_E^\infty(\tau)\}_{\tau \in \mathcal{H}^D}$$

as D ranges over all discriminants of orders in K. These points are defined over abelian extensions of K and obey precise compatibility relations under the norm

maps. They are used to construct a supply of cohomology classes that can be used, under the non-triviality assumption on P_K, to bound $E(K)$ and $Ш(E/K)$, showing that the former has rank one and the latter is finite. See [Ko] (or the expositions given in [Gr3] or Chapter X of [Da2]) for the details of the argument.

In relation with Corollary 2.8 we note the following consequence of Theorem 2.9 (suitably adapted to the problem of bounding Mordell–Weil groups over ring class fields in terms of Heegner points, as in [BD1] for example)

Corollary 2.10. *If the inequality in* (12) *is an* equality*, then the inequality predicted in* (13) *is an* equality.

Theorem 2.9 completes Theorem 2.5 by relating the system of Heegner points attached to E/K to the arithmetic of E over K. When combined with Theorem 2.5, it yields the following striking evidence for the Birch and Swinnerton-Dyer conjecture.

Theorem 2.11. *Conjectures BSD_0 and BSD_1 are true for all elliptic curves over $\mathbb{Q}$.*

Sketch of proof. If $\mathrm{ord}_{s=1} L(E, s) \leq 1$, one can choose an auxiliary quadratic imaginary field K in which all the primes dividing N are split, and for which

$$\mathrm{ord}_{s=1} L(E/K, s) = 1.$$

The existence of such a K is a consequence of non-vanishing results for special values and derivatives of twisted L-series. (See the book [MM], for example, for an attractive exposition of these results.) After choosing such a K, Theorem 2.5 implies that P_K is of infinite order, since $L'(E/K, 1) \neq 0$. Theorem 2.9 then implies that P_K generates a finite index subgroup of $E(K)$, and that $Ш(E/K)$ is finite. Explicit complementary information on the action of $\mathrm{Gal}(K/\mathbb{Q})$ on the point P_K implies that the rank of $E(\mathbb{Q})$ is at most one, with equality occurring precisely when $L(E, 1) = 0$. The finiteness of $Ш(E/K)$ directly implies the finiteness of $Ш(E/\mathbb{Q})$ since the restriction map $Ш(E/\mathbb{Q}) \longrightarrow Ш(E/K)$ has finite kernel. □

Theorem 2.11 is the best evidence at present for Conjecture 2.6. We remark that almost nothing is known about this conjecture when $r > 1$.

3. Elliptic curves over totally real fields

Summarising the discussion of the previous chapter, the Heegner point construction (attached to an elliptic curve over $\mathbb{Q}$, and a quadratic imaginary field K) is appealing because it provides an elegant and efficient method for calculating global points on elliptic curves as well as class fields of imaginary quadratic fields. It also leads to a proof of Conjecture BSD_r for $r = 0$ and 1.

It is therefore worthwhile to investigate whether elliptic curves defined over a number field F other than $\mathbb{Q}$ are equipped with a similar collection of algebraic

points. The modularity property so crucial in defining Heegner points does have an analogue for elliptic curves defined over F, which is most conveniently couched in the language of automorphic representations: an elliptic curve E/F should correspond to an automorphic representation π of $\mathrm{GL}_2(\mathbb{A}_F)$, the correspondence being expressed in terms of an equality of associated L-series:

$$L(E, s) = L(\pi, s).$$

(For an explanation of these concepts, see for example [Ge] or [BCdeSGKK].)

When $F = \mathbb{Q}$, the automorphic form attached to E corresponds to a differential on a modular curve, and leads to the modular parametrisation Φ_E^∞ of (4). Unfortunately, such a geometric formulation of modularity is not always available; therefore the Heegner point construction does not carry over to other number fields without further ideas.

The number fields for which Heegner points are best understood are the *totally real fields*. Let F be such a field, of degree ν, and fix an ordering $v_1, \ldots, v_\nu$ on the real embeddings of F. For $x \in F$, write $x_j := v_j(x)$ $(1 \leq j \leq \nu)$. The v_j determine an embedding of F into $\mathbb{R}^\nu$ and an embedding of $\mathrm{SL}_2(\mathcal{O}_F)$ as a discrete subgroup of $\mathrm{SL}_2(\mathbb{R})^\nu$ with finite covolume. Given any ideal $\mathcal{N}$ of $\mathcal{O}_F$, denote by $\Gamma_0(\mathcal{N})$ the subgroup of $\mathrm{SL}_2(\mathcal{O}_F)$ consisting of matrices which are upper-triangular modulo $\mathcal{N}$.

Assume now for simplicity that F has *narrow class number one*. (The definitions to be made below need to be modified in the general case, by adopting adèlic notation which is better suited to working in greater generality but might also obscure the analogy with the classical case that we wish to draw.) A *Hilbert modular form* of parallel weight 2 and level $\mathcal{N}$ is a holomorphic function $f(z_1, \ldots, z_\nu)$ on $\mathcal{H}^\nu$ satisfying the transformation rule analogous to (2), for all matrices $\left(\begin{smallmatrix} a & b \\ c & d \end{smallmatrix}\right) \in \Gamma_0(\mathcal{N})$:

$$f\left(\frac{a_1 z_1 + b_1}{c_1 z_1 + d_1}, \ldots, \frac{a_\nu z_\nu + b_\nu}{c_\nu z_\nu + d_\nu}\right) = (c_1 z_1 + d_1)^2 \ldots (c_\nu z_\nu + d_\nu)^2 f(z_1, \ldots, z_\nu), \quad (14)$$

together with suitable growth properties around the fixed points of parabolic elements of $\Gamma_0(\mathcal{N})$, which imply in particular that f admits a Fourier expansion "near infinity"

$$f(z_1, \ldots, z_\nu) := a(0) + \sum_{\mathfrak{n} \gg 0} a(\mathfrak{n}) e(\delta^{-1}\mathfrak{n} \cdot z),$$

in which the sum is taken over all totally positive $\mathfrak{n} \in \mathcal{O}_F$, δ is a totally positive generator of the different ideal of F, and

$$e(\mathfrak{n} \cdot z) := \exp(2\pi i (\mathfrak{n}_1 z_1 + \cdots + \mathfrak{n}_\nu z_\nu)).$$

Let $N \in F$ be a totally positive generator of the conductor ideal of E over F, and let $a_E(\mathfrak{n})$ denote the coefficients in the Hasse–Weil L-series of this elliptic curve. The following conjecture is a generalisation of the Shimura–Taniyama–Weil conjecture for totally real fields (of narrow class number one)

Conjecture 3.1. The generating series analogous to (1)

$$f_E(z_1, \ldots, z_v) := \sum_{\mathfrak{n} \gg 0} a_E(\mathfrak{n}) e(\delta^{-1}\mathfrak{n} \cdot z)$$

is a modular form of parallel weight 2 and level $\mathcal{N}$.

The methods of Wiles have successfully been extended to prove many instances of Conjecture 3.1, under a number of technical hypotheses. (See [SW] [Fu] for example.) In the sequel, it will always be assumed that any elliptic curve E/F satisfies the conclusion of Conjecture 3.1, to avoid having to worry about the precise technical conditions under which this is known unconditionally. (These conditions are fluid and ever-changing, and one might hope that they will eventually be completely dispensed with. This hope is bolstered by the wealth of new ideas – which the reader can appreciate, for instance, by consulting [BCDT], [SW], or [Ki], to cite just three in a roster that is too long and rapidly evolving to give anything like a complete list – emerging from the branch of number theory devoted to generalising and extending the scope of Wiles's methods.)

The differential form $\omega_f := f(z_1, \ldots, z_v)dz_1 \ldots dz_v$ defines a $\Gamma_0(\mathcal{N})$-invariant holomorphic differential on $\Gamma_0(\mathcal{N})\backslash\mathcal{H}^v$, but these objects do not give rise to a modular parametrisation. (Indeed, the natural generalisation of modular curves are Hilbert modular varieties, which are of dimension $[F : \mathbb{Q}]$ and probably do not admit any non-constant maps to E when $F \neq \mathbb{Q}$.) To define Heegner points on $E(F)$, it becomes crucial to consider *Shimura curve* parametrisations arising from automorphic forms on certain quaternion algebras.

3.1. Shimura curve parametrisations. Let S be a set of places of odd cardinality, containing all the archimedean places of F. Associated to S there is a *Shimura curve* denoted by X_S. This curve has a canonical model over F arising from a connection between it and the solution to a moduli problem classifying abelian varieties with "quaternionic endomorphisms". (Cf. Section 1.1 of [Zh1], for example, where it is called M_K.)

For each place $v \in S$, the curve X_S also admits an explicit v-adic analytic description. Since this description is useful for doing concrete calculations with X_S, we now describe it in some detail, following a presentation that the author learned from Gross. (Cf. [Gr4].)

If $v \in S$ is an archimedean (and hence, real) place, denote by $\mathcal{H}_v$ the Poincaré upper half-plane. If v is non-archimedean, let $\mathbb{C}_v$ denote the completion of the algebraic closure of F_v, and let $\mathcal{H}_v := \mathbb{P}_1(\mathbb{C}_v) - \mathbb{P}_1(F_v)$ denote the v-adic upper half-plane. It is equipped with a natural structure as a v-adic analytic space which plays the role of the complex structure on $\mathcal{H}$ in the non-archimedean case. (See for instance Chapter IV of [Da2] for a description of this structure.)

Let B denote the quaternion algebra over F which is ramified precisely at the places of $S - \{v\}$. (Since this set of places has even cardinality, such a quaternion

algebra exists; it is unique up to isomorphism.) Identifying v with the corresponding embedding $F \longrightarrow F_v$ of F into its completion at v, there is an F_v-algebra isomorphism

$$\iota_v \colon B \otimes_v F_v \longrightarrow M_2(F_v).$$

Let R denote a maximal $\mathcal{O}_F$-order of B if v is archimedean, and a maximal $\mathcal{O}_F[1/v]$-order of B if v is non-archimedean, and write $R_1^\times$ for the group of elements of R of reduced norm 1. Then $\Gamma_v := \iota_v(R_1^\times)$ is a discrete and finite covolume (and cocompact, if $(F, S) \neq (\mathbb{Q}, \infty)$) subgroup of $\mathrm{SL}_2(F_v)$. The quotient $\Gamma\backslash\mathcal{H}_v$ is naturally equipped with the structure of a complex curve (if v is real) or of a rigid analytic curve over $\mathbb{C}_v$ (if v is non-archimedean).

Theorem 3.2. *The quotient $\Gamma\backslash\mathcal{H}_v$ is analytically isomorphic to $X_S(\mathbb{C}_v)$.*

The complex uniformisation of $X_S(\mathbb{C})$ at the real places of F follows directly from the description of X_S in terms of the solution to a moduli problem. The non-archimedean uniformisation follows from the theory of Cerednik and Drinfeld. For more details on Drinfeld's proof of Theorem 3.2 for v non-archimedean see [BC].

If $\mathcal{N}^+$ is any ideal (or totally positive element) of F prime to the places of S, one can also define a Shimura curve $X_S(\mathcal{N}^+)$ by adding "auxiliary level structure" of level $\mathcal{N}^+$.

Denote by J_S and $J_S(\mathcal{N}^+)$ the jacobian varieties of X_S and $X_S(\mathcal{N}^+)$ respectively. The relevance of these jacobians is that they are expected to parametrise certain elliptic curves over F in the same way that jacobians of modular curves uniformise elliptic curves over $\mathbb{Q}$.

More precisely, a (modular, in the sense of Conjecture 3.1) elliptic curve E over F is said to be *arithmetically uniformisable* if there exists a Shimura curve $X_S(\mathcal{M})$ and a non-constant map of abelian varieties over F, generalising (4)

$$\Phi_{S,E} \colon J_S(\mathcal{M}) \longrightarrow E. \tag{15}$$

Conjecture 3.1 leads one to expect that many (*but not all*, in general!) elliptic curves over F are arithmetically uniformisable. More precisely,

Theorem 3.3. *A modular elliptic curve E over F is arithmetically uniformisable if and only if at least one of the following conditions holds.*

1. *The degree of F over $\mathbb{Q}$ is odd;*
2. *There is a place v of F for which* $\mathrm{ord}_v(\mathcal{N})$ *is odd.*

When condition 1 is satisfied, a Shimura curve uniformising E can be taken to be of the form $X_S(\mathcal{N}_E)$, where $S = S_\infty$ is the set of archimedean places of F. If condition 1 is not satisfied, but 2 is, one can consider a Shimura curve associated to $S = \{v\} \cup S_\infty$ with a suitable choice of level structure. See [Zh1] for more details on Shimura curves and their associated modular parametrisations.

3.2. Heegner points. From now on we assume that E/F is *semistable*, and that there is a factorisation $\mathcal{N} = \mathcal{N}^+\mathcal{N}^-$ of the conductor into a product of ideals with the property that the set of places of F

$$S := \{v \text{ divides } \infty \text{ or } \mathcal{N}^-\}$$

has odd cardinality. (Placing oneself in this special situation facilitates the exposition, and does not obscure any of the essential features we wish to discuss.) This assumption implies that E is arithmetically uniformisable and occurs as a quotient of the Jacobian $J_S(\mathcal{N}^+)$ of the Shimura curve $X_S(\mathcal{N}^+)$ of the previous section. Let

$$\Phi_{S,E}^{\mathcal{N}^+}\colon \operatorname{Div}^0(X_S(\mathcal{N}^+)) \longrightarrow E \tag{16}$$

denote the Shimura curve parametrisation attached to this data.

Just like classical modular curves, the curve $X_S(\mathcal{N}^+)$ is also equipped with a collection of CM points attached to certain CM extensions of F. More precisely, let K be a quadratic extension of F satisfying:

1. For all places $v \in S$, the F_v-algebra $K \otimes_v F_v$ is a field.
2. For all places $v|\mathcal{N}^+$, the F_v-algebra $K \otimes_v F_v$ is isomorphic to $F_v \oplus F_v$.

Note that condition 1 implies in particular that K is a CM extension of F, since S contains all the archimedean places of F.

Fix an $\mathcal{O}_F$-order $\mathcal{O}$ of K, and let H denote the associated ring class field of K. There is a canonical collection $CM(\mathcal{O}) \subset X_S(\mathcal{N}^+)(H)$ associated, in essence, to solutions to the moduli problem related to $X_S(\mathcal{N}^+)$ which have "extra endomorphisms by $\mathcal{O}$." This fact allows an extension of the theory of Heegner points to the context of totally real fields.

3.3. The efficient calculation of global points. Assume for notational simplicity that $\mathcal{N}^+ = 1$. From a computational perspective, it would be useful to have efficient numerical recipes for computing the points of $CM(\mathcal{O})$ and their images in $E(H)$ under the parametrisation $\Phi_{S,E}$ of (16). Difficulties arise in calculating Heegner points arising from Shimura curve parametrisations, largely because the absence of Fourier expansions for modular forms on $\Gamma\backslash\mathcal{H}_v$ prevents one from writing down an explicit analytic formula for $\Phi_{S,E}$ analogous to (6).

The article [El1] proposes to work with Shimura curves by computing algebraic equations for them. This approach can be carried out when the group Γ arising in an archimedean uniformisation of $X_S(\mathbb{C})$ following Theorem 3.2 is contained with small index in a Hecke triangle group. Adapting the ideas of [KM] to the context of Shimura curves might also yield a more systematic approach to these types of questions. Nonetheless, it appears that an approach relying on an explicit global equation for the Shimura curve may become cumbersome, since such an algebraic equation is expected to be quite complicated for even modest values of F and S.

Alternately, one may try to exploit the non-archimedean uniformisations of $X_S(\mathbb{C}_v)$ given by Theorem 3.2. Given a non-archimedean place $v \in S$, let B and R be the quaternion algebra and Eichler order associated to S and v as in the statement of this theorem. An F-algebra embedding

$$\Psi : K \longrightarrow B$$

is said to be *optimal* relative to $\mathcal{O}$ if $\Psi(K) \cap R = \Psi(\mathcal{O})$. It can be shown that the number of distinct optimal embeddings of K into B, up to conjugation by the normaliser of $R^\times$ in $B^\times$, is equal to the class number of $\mathcal{O}$. Let h denote this class number and let $\Psi_1, \ldots, \Psi_h$ be representatives for the distinct conjugacy classes of optimal embeddings of $\mathcal{O}$ into R. Let τ_j and $\bar{\tau}_j$ denote the fixed points for $\Psi_j(K^\times)$ acting on $\mathcal{H}_v$. Then the points in $CM(\mathcal{O})$ are identified with the points τ_j, $\bar{\tau}_j$ under the identification of Theorem 3.2.

In his thesis [Gre], Matthew Greenberg exploits this explicit v-adic description of the points in $CM(\mathcal{O})$ and computes their images in $E(\mathbb{C}_v)$ analytically. The absence of cusps on X_S and of the attendant Fourier expansion of modular forms is remedied in part by an alternate combinatorial structure on $X_S(\mathbb{C}_v)$ which allows explicit v-adic analytic calculations with cusp forms on X_S. This combinatorial structure arises from the *reduction map*

$$r : \mathcal{H}_v \longrightarrow \mathcal{T}$$

on $\mathcal{H}_v$, where $\mathcal{T}$ is the *Bruhat–Tits tree* of $\mathrm{PGL}_2(F_v)$, a homogeneous tree with valency $|v| + 1$. Thanks to this structure, rigid analytic modular forms of weight two on $\Gamma\backslash\mathcal{H}_v$ admit a simple description as functions on the edges of the quotient graph $\Gamma\backslash\mathcal{T}$ satisfying a suitable harmonicity property. (For a more detailed discussion of the description of rigid analytic modular forms on $\Gamma\backslash\mathcal{H}_v$ in terms of an associated Hecke eigenfunction on the edges of the Bruhat–Tits tree, see Chapters 5 and 6 of [Da2] for example.)

Greenberg explains how the knowledge of the eigenfunction on $\Gamma\backslash\mathcal{T}$ associated to E can be parlayed into an efficient algorithm for computing the Shimura curve parametrisation $\Phi_{S,E}$ of (16), viewed as a v-adic analytic map

$$\Phi_{S,E}^v : \mathrm{Div}^0(\Gamma\backslash\mathcal{H}_v) \longrightarrow E(\mathbb{C}_v).$$

The main ingredient in Greenberg's approach is the theory of "overconvergent modular symbols" developed in [PS], adapted to the context of automorphic forms on definite quaternion algebras.

For example, setting $\omega = \frac{1+\sqrt{5}}{2}$, Greenberg considers the elliptic curve

$$E : y^2 + xy + \omega y = x^3 + (-\omega - 1)x^2 + (-30\omega - 45)x + (-111\omega - 117)$$

defined over $F = \mathbb{Q}(\sqrt{5})$. This curve has conductor $\mathcal{N} = v = (3-5\omega)$, a prime ideal above 31. Consider the CM extension $K = F(\sqrt{-\omega - 5})$ of F. It has class number two, and its Hilbert class field is equal to $H = K(i)$ (where $i = \sqrt{-1}$) by genus

theory. Letting $\tau \in \mathcal{H}_v$ be an element of $CM(\mathcal{O}_K)$, and τ' its translate by the element of order 2 in the class group of K, Greenberg computes the image of $\Phi^v_{S,E}((\tau)-(\tau'))$ in $E(K_v)$ to a v-adic accuracy of 31^{-30}, obtaining a point that agrees with the global point

$$P = \left(\frac{578\omega - 1}{90}, -\frac{27178\omega + 9701}{2700} i - \frac{668\omega - 1}{180} \right)$$

to that degree of accuracy.

The calculations of [Gre] convincingly demonstrate that Heegner points arising from Shimura curve parametrisations can be computed fairly systematically in significant examples using the Cerednik–Drinfeld theory. It would be interesting to understand whether the archimedean uniformisations described in Theorem 3.2 can be similarly exploited.

3.4. Relation with L-series. Retaining the notations of the previous section, let P be any point of $CM(\mathcal{O}) \subset X_S(H)$, and let χ be a character of $G = \mathrm{Gal}(H/K)$. Suppose for simplicity that this character is non-trivial, so that

$$D_\chi := \sum_{\sigma \in G} \chi(\sigma) P^\sigma \text{ belongs to } \mathrm{Div}^0(X_s(H)) \otimes \mathbb{C}.$$

Let P_χ denote the image of D_χ,

$$P_\chi := \Phi_{S,E}(D_\chi).$$

The Heegner point P_χ enjoys the following property analogous to the formula of Gross and Zagier.

Theorem 3.4 (Zhang). *The height of P_χ is equal to an explicit non-zero multiple of $L'(E/K, \chi, 1)$.*

The proof of Theorem 3.4, which is explained in [Zh1], [Zh2], and [Zh3], proceeds along general lines that are similar to those of [GZ] needed to handle the case $F = \mathbb{Q}$, although significant new difficulties have to be overcome in handling Shimura curve parametrisations. Note that, even when $F = \mathbb{Q}$, Zhang's theorem asserts something new since an elliptic curve over $\mathbb{Q}$ may possess, along with the usual modular curve parametrisation, a number of Shimura curve parametrisations.

3.5. The Birch and Swinnerton-Dyer conjecture. Zhang's formula has applications to the arithmetic of elliptic curves defined over totally real fields that are analogous to those of the original Gross–Zagier formula.

Theorem 3.5. *Suppose that E is arithmetically uniformisable. Then conjectures BSD_0 and BSD_1 are true for E.*

Sketch of proof. Since E is arithmetically uniformisable, there is a Shimura curve $X_S(\mathcal{M})$ parametrising E, for an appropriate $\mathcal{M}|\mathcal{N}_E$. If $\mathrm{ord}_{s=1} L(E,s) \leq 1$, one can choose as in the proof of Theorem 2.11 an auxiliary quadratic CM extension K of F in which all the primes of S are inert, those dividing $\mathcal{M}$ are split, and for which

$$\mathrm{ord}_{s=1} L(E/K, s) = 1.$$

After choosing such a K, the Heegner point P_K attached to K and the parametrisation (15) is of infinite order by Theorem 3.4. A natural extension of Kolyvagin's Theorem 2.9 to the context of totally real fields has been proved by Kolyvagin and Logachev [KL]. Their result implies that P_K generates a subgroup of $E(K)$ of finite index, and that $Ш(E/K)$ is finite. Theorem 3.5 now follows much as in the proof of Theorem 2.11. □

The proof of Theorem 3.5 sketched above breaks down for elliptic curves that are not arithmetically uniformisable in the sense of Theorem 3.3. This is the case for the elliptic curve

$$E : y^2 + xy + \varepsilon^2 y = x^3, \quad \varepsilon = \frac{5+\sqrt{29}}{2} \in \mathcal{O}_F^\times. \tag{17}$$

defined over the real quadratic field $F = \mathbb{Q}(\sqrt{29})$ and having everywhere good reduction over F.

Remark 3.6. It should be noted however that the curve E of (17) is isogenous to a quotient of the modular Jacobian $J_1(29)$, this circumstance arising from the fact that E is a $\mathbb{Q}$-curve, i.e., is isogenous to its Galois conjugate. Hence a variant of the Heegner point construction exploiting CM points on $X_1(29)$ might provide some information on the arithmetic of E.

In light of this remark, an even more puzzling example is given by the following elliptic curve discovered by R. Pinch,

$$y^2 - xy - \omega y = x^3 + (2+2\omega)x^2 + (162+3\omega)x + (71+34\omega), \quad \omega = \frac{1+\sqrt{509}}{2}, \tag{18}$$

which has everywhere good reduction over $F = \mathbb{Q}(\sqrt{509})$, and is *not* isogenous to its Galois conjugate. The curve given by (18), and any of its quadratic twists over F, are elliptic curves for which no variant of the Heegner point construction relying on CM points is known. For such elliptic curves, the strategy of proof of Theorem 3.5 runs across a fundamental barrier.

In spite of this the following theorem has been proved independently in [Lo1], [Lo2] and [TZ].

Theorem 3.7 (Longo, Tian-Zhang). *Suppose that E is any (modular) elliptic curve over a totally real field F. Then conjecture BSD_0 is true for E.*

Sketch of proof. We indicate the idea of the proof in the simplest case where E has everywhere good reduction over a real quadratic field F. Let K be any CM extension of F, and fix a rational prime p. The key fact is that, even though E is *not* arithmetically uniformisable, it is still possible to produce a sequence $X_1, \ldots, X_n, \ldots$ of Shimura curves in such a way that the Galois module given by the p^n-torsion $E[p^n]$ of E appears as a Jordan–Hölder constituent of $J_n[p^n]$, where J_n denotes the Jacobian of X_n. The Shimura curve X_n is associated to the set $S_n := \{\ell_n, \infty_1, \infty_2\}$ of places of F, for a judiciously chosen (non-archimedean) place ℓ_n of F. The existence of X_n follows from the theory of congruences between modular forms and the Jacquet–Langlands correspondence. The Heegner point attached to K and X_n can then be used to produce, following a variant of Kolyvagin's original recipe, a global cohomology class in $H^1(K, J_n[p^n])$, and, from this, a class $\kappa_n \in H^1(K, E[p^n])$. A key formula, whose proof exploits the Cerednik–Drinfeld theory of ℓ_n-adic uniformisation of X_n, relates the restriction of κ_n in the local cohomology group $H^1(K_{\ell_n}, E[p^n])$ to the special value of $L(E/K, 1)$. (More precisely, to a suitable *algebraic part*, taken modulo p^n.) In particular, if this special value is non-zero, then the class κ_n is non-trivial for n sufficiently large. (In fact, this is even so locally at ℓ_n.) This local control of the classes κ_n is enough to prove (following the lines of Kolyvagin's original argument) that the p^n-Selmer group of E over K has cardinality bounded independently of n, and therefore that $E(K)$ and the p-primary component of $Ш(E/K)$ are both finite. The same finiteness results hold *a fortiori* with K replaced by F. It is in ensuring the existence of a suitable auxiliary CM field K for which $L(E/K, 1) \neq 0$ that the non-vanishing hypothesis on $L(E/F, 1)$ made in the statement of Conjecture BSD_0 is used in a crucial way. □

A similar approach to bounding the Selmer group of E relying on congruences between modular forms was first exploited in [BD3] where it was used to prove part of the "main conjecture" of Iwasawa Theory attached to an elliptic curve $E/\mathbb{Q}$ and the anticyclotomic $\mathbb{Z}_p$-extension of an imaginary quadratic field K.

Theorem 3.7 notwithstanding, the following question retains an alluring aura of mystery.

Question 3.8. Prove Conjecture BSD_1 for elliptic curves over totally real fields that are *not* arithmetically uniformisable.

For example, let E_0 be an elliptic curve with everywhere good reduction over a real quadratic field F such as the curve given in equations (17) and (18). Let K be a quadratic extension of F which is neither totally real nor complex, i.e., an extension with one complex and two real places. Let E denote the twist of E_0 by K. It can be shown that $\mathrm{sign}(E, F) = -1$, so that $L(E/F, s)$ vanishes to odd order. Can one show that $E(F)$ is infinite, if $L'(E/F, 1) \neq 0$? This would follow from a suitable variant of Theorem 2.5 or 3.4, but it is unclear how such a variant could be proved – or even formulated precisely! – in the absence of a known Heegner point construction for E.

4. Stark–Heegner points

Question 3.8 points out one among many instances where Heegner points are not sufficient to produce algebraic points on elliptic curves, even when the presence of such points is predicted by the Birch and Swinnerton-Dyer conjecture.

The notion of *Stark–Heegner point* is meant to provide a *conjectural* remedy by proposing constructions in a number of situations lying ostensibly outside the scope of the theory of complex multiplication.

4.1. ATR extensions of totally real fields. Let F be a totally real field of narrow class number 1, as in Section 3. A quadratic extension K of F is said to be *almost totally real* (or "ATR" for short) if it has exactly one complex place, so that the remaining real places split in K/F. The field K can be viewed as a subfield of $\mathbb{C}$ via its unique complex embedding. A point in the complex upper half-plane is called an *ATR point* if it generates an ATR extension of F. Let $\mathcal{H}'$ denote the set of all ATR points on $\mathcal{H}$, relative to a fixed real place v of F. Note that $\mathcal{H}'$ is preserved under the action of the Hecke congruence group $\Gamma_0(\mathcal{N}) \subset \mathrm{SL}_2(\mathcal{O}_F)$, although, because the action of this group is not discrete, the quotient $\Gamma_0(\mathcal{N})\backslash\mathcal{H}'$ inherits no obvious topology (other than the discrete one). Let f_E denote the Hilbert modular form of level $\mathcal{N}$ associated to E in Conjecture 3.1, and write

$$\omega_f := f_E(z_1, \ldots, z_v) dz_1 \ldots dz_v$$

for the corresponding $\Gamma_0(\mathcal{N})$-invariant differential form on $\mathcal{H}^v$. The article [DL] describes a kind of *natural substitute* of the modular parametrisation attached to E, denoted

$$\Phi_E^v \colon \Gamma_0(\mathcal{N})\backslash\mathcal{H}' \longrightarrow E(\mathbb{C}). \tag{19}$$

A precise description of this map is given in Chapter VIII of [Da2] as well as in [DL]. We will not recount the details of this construction here, mentioning only that Φ_E^v is defined in terms of the periods of ω_f. It is in that sense that it can be viewed as purely analytic, even though Φ_E^v does not extend to a holomorphic or even continuous map on $\mathcal{H}$ (as is apparent from the fact that $\Gamma_0(\mathcal{N})$ acts on $\mathcal{H}$ with dense orbits). We note that the definition of Φ_E^v is quite concrete and lends itself well to computer calculations. In fact, working with the Hilbert modular form attached to E has the added computational advantage that the fourier expansion of ω_f is available as an aid to computing its periods numerically.

The main conjecture that is spelled out precisely in [DL] is that the points $\{\Phi_E^v(\tau)\}_{\tau\in\mathcal{H}'\cap K}$ belong to ring class fields of the ATR extension K of F, and that they enjoy all the properties (Shimura reciprocity law, norm compatibility relations) of classical Heegner points. This conjecture is also tested numerically and used to produce global points on the elliptic curve of equation (17) in terms of periods of the associated Hilbert modular form over $\mathbb{Q}(\sqrt{29})$. A proof of the conjectures of [DL] (an admittedly tall order, at present) would presumably lead to a solution to Question 3.8 proceeding along much the same lines as the proof of Theorems 2.11 and 3.5.

4.2. Ring class fields of real quadratic fields. We return now to the setting where E is an elliptic curve over $\mathbb{Q}$. Little changes in the analysis of Remark 2.7 when the imaginary quadratic field is replaced by a *real* quadratic field. Hence, if K is such a field and $\mathrm{sign}(E, K) = -1$, one expects the presence of a systematic collection of points defined over various ring class fields of K. This is intriguing, since the theory of complex multiplication gives no means of producing these points.

Suppose now that the conductor of E is the form $N = pM$, where p is a prime that does not divide M, so that E has multiplicative reduction at p. Let K be a *real* quadratic field satisfying the following "modified" Heegner hypothesis:

1. All the primes dividing M are split in K;
2. The prime p is inert in K.

These conditions are analogous to the ones that are imposed in the setting of classical Heegner points, with the prime p now playing the role of ∞. It can be shown that $\mathrm{sign}(E, K) = -1$, and the same holds for all twists of $L(E/K, s)$ by ring class characters of conductor prime to N. The analysis carried out in Remark 2.7 therefore shows that if H is any ring class field of K of discriminant prime to N, one has the same inequality as in (12):

$$\mathrm{ord}_{s=1}(L(E/H, s) \geq [H : K]. \tag{20}$$

The article [Da1] describes a conjectural recipe for constructing certain canonical points in $E(H)$, which is expected to yield a subgroup of finite index in $E(H)$ whenever (20) is an equality.

The idea behind the construction of [Da1] is to attach p-adic periods to f in a way which formally suggests viewing f as a "mock Hilbert modular form" on $\Gamma\backslash(\mathcal{H}_p \times \mathcal{H})$, where $\Gamma \subset \mathrm{SL}_2(\mathbb{Z}[1/p])$ is the subgroup of matrices which are upper triangular modulo M. The construction of these p-adic periods, which is described in [Da1], is essentially elementary. The main ingredient that enters in their definition is the theory of *modular symbols* associated to f, which states that the period integral

$$I_f\{r\to s\} := \frac{1}{\Omega^+}\mathrm{Re}\left(\int_r^s 2\pi i f(z)\, dz\right), \quad r, s \in \mathbb{P}_1(\mathbb{Q}) \tag{21}$$

takes *integer values* for a suitable choice of "real period" $\Omega^+ \in \mathbb{R}$, which is, up to a non-zero rational multiple, the real period in the Néron lattice of E.

Further pursuing the analogy with the setting of Section 4.1, the counterpart of the set $\mathcal{H}'$ of ATR points in $\mathcal{H}$ (associated to the real quadratic base field F and a choice of real embedding) is the collection $\mathcal{H}'_p$ of elements of $\mathcal{H}_p$ which generate a *real quadratic* extension of $\mathbb{Q}$. In particular, after fixing a p-adic embedding $K \subset \mathbb{C}_p$, the set $\mathcal{H}'_p \cap K$ is *non-empty*. Mimicking the formal aspects of the definition of the map (19) of Section 4.1, with the complex periods attached to a Hilbert modular form replaced by the (p-adic) periods on $\mathcal{H}_p \times \mathcal{H}$ attached to f, leads to the definition of a "modular parametrisation" analogous to (19)

$$\Phi_E^p\colon \Gamma\backslash\mathcal{H}'_p \longrightarrow E(\mathbb{C}_p). \tag{22}$$

Let D be the discriminant of K, and choose a $\delta \in \mathbb{Z}[1/p]$ satisfying

$$\delta^2 \equiv D \pmod{M}.$$

Let $\mathcal{F}^D$ be the set of primitive binary quadratic forms $Ax^2 + Bxy + Cy^2$ with coefficients in $Z[1/p]$, satisfying

$$B^2 - 4AC = D, \quad M|A, \quad B \equiv \delta \pmod{M}.$$

(A quadratic form is said to be *primitive* in this context if the ideal of $\mathbb{Z}[1/p]$ generated by (A, B, C) is equal to $\mathbb{Z}[1/p]$.) The group Γ acts naturally on $\mathcal{F}^D$ by "change of variables", and the quotient $\Gamma\backslash\mathcal{F}^D$ is equipped with a natural simply transitive action of the class group G_D of K arising from the Gaussian composition law. (Or rather, the Picard group of $\mathcal{O}_K[1/p]$, but these coincide since p is inert in K.) This action is completely analogous to the action of G_D on $\Gamma_0(N0\backslash\mathcal{H}^D$ (for D a negative discriminant) that is described in Section 2.2. Choose an embedding of K into $\mathbb{C}_p$, and for each quadratic form $F = [A, B, C] \in \mathcal{F}^D$, let

$$\tau = \frac{-B + \sqrt{D}}{2A} \in \mathcal{H}_p \tag{23}$$

be the corresponding element of $\mathcal{H}_p$ satisfying $F(\tau, 1) = 0$. The set $\mathcal{H}_p^D$ of all τ that arise in this way is preserved under the action of Γ, and the natural assignment given by (23) induces a bijection

$$\Gamma\backslash\mathcal{F}^D \longrightarrow \Gamma\backslash\mathcal{H}_p^D.$$

Hence the target of this bijection inherits a simply transitive action of G_D. Denote this action by $(\sigma, \tau) \mapsto \tau^\sigma$, for all $\sigma \in G_D$ and $\tau \in \mathcal{H}_p^D$. Conjectures 5.9 and 5.15 of [Da1] predict that

Conjecture 4.1. 1. For all $\tau \in \mathcal{H}_p^D$, the point $\Phi_E^p(\tau)$ is defined over H.

2. If $\chi : G_D \longrightarrow \mathbb{C}^\times$ is a complex character, then the expression

$$\sum_{\sigma \in G_D} \chi(\sigma)\Phi_E^p(\tau^\sigma) \in E(H) \otimes \mathbb{C}$$

is non-zero if and only if $L'(E/K, \chi, 1) \neq 0$. In particular, the subgroup of $E(H)$ generated by the Stark–Heegner points $\Phi_E^p(\tau)$, as $\tau \in \Gamma\backslash\mathcal{H}_p^D$, has rank $h = [H : K]$ if and only if $\mathrm{ord}_{s=1} L(E/H, s) = h$.

A proof of Conjecture 4.1 would not yield any new information about Conjecture BSD_r for $r \leq 1$, since this conjecture is already known for elliptic curves over $\mathbb{Q}$. It would, however, give a proof of some new cases of the Birch and Swinnerton-Dyer conjecture for Mordell–Weil groups over ring class fields of real quadratic fields, following a simple extension of Kolyvagin's arguments which is explained in [BD1] and in Chapter X of [Da2]. See also [BDD] for other ways in which a strengthening of

Conjecture 4.1 to modular forms with non-rational Fourier coefficients would imply new cases of Conjecture BSD_0, by adapting the ideas that are used in the proof of Theorem 3.7.

Conjecture 4.1 has been extensively tested numerically in [DG]. A significant improvement of the algorithms of [DG], based on ideas of Pollack and Stevens which grew out of their theory of overconvergent modular symbols, as mentioned in Section 3.3, is described in [DP1]. These improvements make it possible to find global points of large height on E rather efficiently. For example, the Stark–Heegner point on the elliptic curve E of conductor 11 given by the equation

$$y^2 + y = x^3 - x^2 - 10x - 20$$

attached to the field $K = \mathbb{Q}(\sqrt{101})$ can be computed to an 11-adic accuracy of 11^{-100} in a few seconds on a standard computer. It can then be "recognized" as the global point in $E(\mathbb{Q}(\sqrt{101}))$ with x-coordinate equal to

$$x = \frac{1081624136644692539667084685116849}{24684654182277032144757997152010 0}.$$

Of course, the calculation of Stark–Heegner points also has applications to explicit class field theory for real quadratic fields analogous to those described in Section 2.4 for imaginary quadratic fields. For example, let E be the unique elliptic curve over $\mathbb{Q}$ of conductor $p = 79$, defined by the Weierstrass equation

$$y^2 + xy + y = x^3 + x^2 - 2x.$$

The prime p is inert in the real quadratic field $K = \mathbb{Q}(\sqrt{401})$, which has class number five. The 5 distinct representatives in $\mathcal{H}_{79}^{401}$ can be chosen to be

$$\tau = \frac{-19 + \sqrt{401}}{2}, \quad \frac{19 - \sqrt{401}}{4}, \quad \frac{-15 + \sqrt{401}}{8}, \quad \frac{17 - \sqrt{401}}{8}, \quad \frac{-17 + \sqrt{401}}{4}.$$

The x-coordinates of the corresponding Stark–Heegner points $\Phi_E^{79}(\tau)$ (computed modulo 79^{20}) appear to satisfy the polynomial

$$x^5 - 20x^4 + 47x^3 - 31x^2 + x + 3$$

whose splitting field is indeed the Hilbert class field H of K. In fact this calculation leads to the discovery of points in $E(H)$. The analogous polynomial, for the real quadratic field $\mathbb{Q}(\sqrt{577})$ of class number seven, is

$$x^7 - 22x^6 + 74x^5 - 51x^4 - 40x^3 + 32x^2 + 2x - 1.$$

These examples are chosen at random among the hundreds of calculations that were performed in [DP1] to test the conjectures of [Da1] numerically. (More such calculations could be performed by the interested reader using the publicly available software [DP2] for calculating Stark–Heegner points, written in Magma, which is documented in [DP1].)

4.3. Beyond totally real fields?. The assumption that E is defined over a totally real field F, although it arises naturally in considering automorphic forms and their associated Shimura varieties, is not a natural one from the point of view of the Diophantine study of elliptic curves. It would be just as desirable to understand elliptic curves defined over general number fields, and to have the means of tackling conjectures BSD_0 and BSD_1 for such curves.

The simplest case arises when E is an elliptic curve defined over an *imaginary* quadratic field, denoted by F (and not K as in Section 2, since now it plays the role of the "ground field" over which E is defined). Assume for simplicity that F has class number one, and let $\mathcal{N}$ denote the conductor of E.

As in Section 3, the Shimura–Taniyama conjecture predicts that E corresponds to an automorphic form f on $\mathrm{GL}_2(F)$, which gives rise, following the description given in [Cr1], to a differential form ω_f on the *hyperbolic upper half space*

$$\mathcal{H}^{(3)} := \mathbb{C} \times \mathbb{R}^{>0}.$$

This three-dimensional real manifold is equipped with a hyperbolic metric and an action of $\mathrm{SL}_2(\mathbb{C})$ by isometries, and the differential ω_f is *invariant* under the resulting action of the subgroup $\Gamma_0(\mathcal{N}) \subset SL_2(\mathcal{O}_F)$ consisting of matrices which are upper triangular modulo $\mathcal{N}$. Congruence subgroups of $\mathrm{SL}_2(\mathcal{O}_F)$ are examples of so-called *Bianchi groups*; for information about their structure and properties and further references, see [EGM] for example.

The modular form ω_f does not give rise to a modular parametrisation of E analogous to (4). In fact, the symmetric space $\mathcal{H}^{(3)}$ is not even endowed with a natural complex structure (since it has real dimension 3); therefore the quotient $\Gamma_0(\mathcal{N})\backslash\mathcal{H}^{(3)}$ cannot be viewed as the points of a complex analytic variety, much less an algebraic one. The absence of a Shimura variety attached to f implies that one has less control on the arithmetic of this modular form. For certain f, Taylor [Ta] has been able to construct the Galois representations which the Langlands conjectures attach to f by exploiting congruences with modular forms on GSp(4) whose associated Galois representations can be found in the cohomology of the appropriate Shimura varieties. Unfortunately, global points on elliptic curves or abelian varieties, unlike p-adic Galois representations (as in the work of Taylor) or Galois cohomology classes attached to rational points (as in the proof of Theorem 3.7), do not readily lend themselves to constructions based on congruences between modular forms.

Nonetheless, the differential form ω_f comes with an attendant notion of *modular symbol* which enjoys the same integrality properties as in the classical case. (For a discussion of modular symbols attached to forms on $\mathrm{GL}_2(F)$, and their computational applications, see [Cr1], [CW].) Trifkovic [Tr] exploits this modular symbol to transpose to f the definition of the p-adic periods on $\mathcal{H}_p \times \mathcal{H}$ alluded to in Section 4.2. In this way he associates to ω_f a "modular form on $\Gamma\backslash(\mathcal{H}_\mathfrak{p} \times \mathcal{H}^{(3)})$", where

1. $\mathfrak{p}$ is a prime of K dividing $\mathcal{N} = \mathcal{M}\mathfrak{p}$ exactly;

2. $\mathcal{H}_\mathfrak{p} = \mathbb{P}_1(\mathbb{C}_p) - \mathbb{P}_1(F_\mathfrak{p})$ is the $\mathfrak{p}$-adic upper half plane (defined after choosing an embedding $F_\mathfrak{p} \subset \mathbb{C}_p$);

3. $\Gamma \subset \mathrm{SL}_2(\mathcal{O}_F[1/\mathfrak{p}])$ is the subgroup consisting of matrices which are upper triangular modulo $\mathcal{M}$.

The set $\mathcal{H}'_\mathfrak{p}$ is simply the set of $\tau \in \mathcal{H}_\mathfrak{p}$ which generate a quadratic extension of $F \subset F_\mathfrak{p}$. Trifkovic uses his $\mathfrak{p}$-adic periods to define an explicit, numerically computable map

$$\Phi_E^\mathfrak{p} \colon \Gamma\backslash\mathcal{H}'_\mathfrak{p} \longrightarrow E(\mathbb{C}_p),$$

and formulates an analogue of Conjecture 4.1 for this map, predicting that $\Phi_E^\mathfrak{p}(\tau)$ is defined over a specific ring class field of $K = F(\tau)$ for all $\tau \in \mathcal{H}'_p$.

Trifkovic has been able to gather extensive numerical evidence for his "Stark–Heegner conjectures" in this setting. Here is just one example taken among the many calculations that are reported on in [Tr]. Let E be the elliptic curve over $F = \mathbb{Q}(\sqrt{-11})$ given by the Weierstrass equation

$$y^2 + y = x^3 + \left(\frac{1-\sqrt{-11}}{2}\right)x^2 - x.$$

Its conductor is the prime $\mathfrak{p} = 6+\sqrt{-11}$ of F of norm 47. Note that E is not isogenous to its Galois conjugate, since $\mathfrak{p} \neq \bar{\mathfrak{p}}$. The quadratic extension $K = F(\sqrt{29})$ has class number 5. Trifkovic computes the five distinct Stark–Heegner points attached to the maximal order of K, as elements of $E(\mathbb{Q}_{47})$ (using the isomorphism $K_\mathfrak{p} = \mathbb{Q}_{47}$) with an accuracy of 20 significant 47-adic digits. This allows him to "guess" that the x coordinates of these Stark–Heegner points satisfy the degree 5 polynomial

$$x^5 - \left(\frac{80299+139763\sqrt{-11}}{149058}\right)x^4 + \left(\frac{-558203+71567\sqrt{-11}}{149058}\right)x^3 + \left(\frac{141709+45575\sqrt{-11}}{74529}\right)x^2 + \left(\frac{8372-7727\sqrt{-11}}{24843}\right)x + \left(\frac{-473+35\sqrt{-11}}{2366}\right)$$

whose splitting field can then be checked to be the Hilbert class field of K.

For many more calculations of this type, and a precise statement of the conjecture on which they rest, the reader is invited to consult [Tr].

4.4. Theoretical evidence. In spite of the convincing numerical evidence that has been gathered in their support, the conjectures on Stark–Heegner points suffer from the same paucity of theoretical evidence as in the setting of Stark's original conjectures on units. What little evidence there is at present can be grouped roughly under the following two rubrics:

4.4.1. Stark–Heegner points and Stark units. Many of the basic theorems and applications of elliptic curves have counterparts for units of number fields. (For instance, the Mordell–Weil theorem is analogous to Dirichlet's Unit Theorem; Lenstra's factorisation algorithm based on elliptic curves, to the Pollard $p-1$ method; to name just two examples.) The very terminology "Stark–Heegner point" is intended to convey the idea that these points are analogous to Stark units constructed from special values of L-series.

To make this sentiment precise, one can replace the cusp forms that enter into the constructions of Section 4.2 by *modular units*, or rather, their logarithmic derivatives which are Eisenstein series of weight two. Pursuing this idea, the article [DD] associates to any modular unit α on $\Gamma_0(N)\backslash\mathcal{H}$ and to $\tau \in \mathcal{H}_p' \cap K$ where K is a real quadratic field in which p is inert, an element $u(\alpha, \tau) \in K_p^\times$, which is predicted to behave like an elliptic unit defined over a ring class field of an imaginary quadratic field. More precisely, if $\mathcal{O}$ is the order associated to τ, and H denotes the corresponding ring class field of K, it is conjectured that $u(\alpha, \tau)$ belongs to $\mathcal{O}_H[1/p]^\times$ and obeys a Shimura reciprocity law formulated exactly as in Conjecture 4.1.

Section 3.1 [DD] attaches to α and to τ a ζ-function $\zeta(\alpha, \tau, s)$ which is essentially (up to a finite collection of Euler factors depending on α) the partial zeta-function attached to K and the narrow ideal class corresponding to τ. In particular, this zeta-function has a meromorphic continuation to $\mathbb{C}$ with at worst a simple pole at $s = 1$. Sections 4.1-4.3 of [DD] explain how a p-adic zeta function $\zeta_p(\alpha, \tau, s)$ can be defined by p-adically interpolating the special values of $\zeta(\alpha, \tau, k)$ at certain negative integers.

The main result of [DD], which is contained in Theorems 3.1 and 4.1 of [DD], is then

Theorem 4.2. *For all $\tau \in \mathcal{H}_p'$,*

$$\zeta(\alpha, \tau, 0) = \frac{1}{12}\,\mathrm{ord}_p(u(\alpha, \tau)); \tag{24}$$

$$\zeta_p'(\alpha, \tau, 0) = -\frac{1}{12}\log_p \mathrm{Norm}_{K_p/\mathbb{Q}_p}(u(\alpha, \tau)). \tag{25}$$

This theorem is consistent with Gross's p-adic analogue of the Stark conjectures [Gr1], [Gr2], which expresses the left hand side of (25) in terms of p-adic logarithms of the norm to $\mathbb{Q}_p$ certain global p-units in abelian extensions of K. We note that the conjecture of [DD] represents a genuine *refinement* of Gross's conjecture in the special case of ring class fields of real quadratic fields, since it gives a formula for the Gross–Stark units *as elements of* $K_p^\times$, and not just for their norms to $\mathbb{Q}_p^\times$.

Remark 4.3. A purely archimedean analogue of the setting of Theorem 4.2 is considered in [CD], leading to the conjectural construction of units in abelian extensions of an ATR extension K of a totally real field F in terms of periods of weight two Eisenstein series on the Hilbert modular group attached to F. This construction can be viewed either as the archimedean analogue of the main construction of [DD], or

as the analogue of the main construction of [DL] in which cusp forms on the Hilbert modular group are replaced by Eisenstein series. This construction (in the setting of abelian extensions of K) goes further than the original Stark conjectures by proposing a formula for the Stark units as elements of $\mathbb{C}^\times$, and not just for their *lengths* which are expressed in terms of values of L-series at $s = 0$. In other words, the formulae of [CD] capture the *arguments* as well as the absolute values of these Stark units (relative to a complex embedding of the ring class field H of K extending the unique complex embedding of K.)

Remark 4.4. The proof of Theorem 4.2 brings to light the role of the Eisenstein series of weight k and their associated periods (with k a weight which can be taken to vary p-adically) in relating the invariants $u(\alpha, \tau)$ to special values of L-functions. This suggests that the Stark–Heegner points of Section 4.2 should be related to the periods of a *Hida family* interpolating the cuspidal eigenform f in weight two.

4.4.2. The rationality of Stark–Heegner points over genus fields. Returning to the setting of Section 4.2, let K be a real quadratic field of discriminant D satisfying the auxiliary hypotheses relative to N that were mentioned in Section 4.2, and let H be its Hilbert class field. Write $G_D = \mathrm{Gal}(H/K)$ as before.

To each factorisation $D = D_1 D_2$ of D as a product of two fundamental discriminants is associated the unramified quadratic extension $L = \mathbb{Q}(\sqrt{D_1}, \sqrt{D_2}) \subset H$ of K. This field corresponds to a quadratic character

$$\chi : G_D \longrightarrow \pm 1,$$

called the *genus character* associated to the factorisation (D_1, D_2). Let χ_1 and χ_2 denote the quadratic Dirichlet characters attached to $\mathbb{Q}(\sqrt{D_1})$ and $\mathbb{Q}(\sqrt{D_2})$ respectively. Then χ, viewed as a character of the ideals of K, is characterised on ideals prime to D by the rule

$$\chi(\mathfrak{n}) = \chi_1(\mathrm{Norm}\,\mathfrak{n}) = \chi_2(\mathrm{Norm}\,\mathfrak{n}).$$

The field L is also called the *genus field* of K attached to (D_1, D_2). Let $E(L)^\chi$ denote the submodule of the Mordell–Weil group $E(L)$ on which G_D acts via the character χ.

Recall the action of G_D on $\Gamma\backslash\mathcal{H}_p^D$ arising from its identification with the class group of K. Define the point

$$P_\chi = \sum_{\sigma \in G_D} \chi(\sigma) \Phi_E^p(\tau^\sigma) \in E(K_p).$$

Conjecture 4.1 predicts that this local point belongs to $E(L)^\chi$ (after fixing an embedding $L \subset K_p$), and that it is of infinite order if and only if

$$L(E/K, \chi, s) = L(E, \chi_1, s) L(E, \chi_2, s)$$

has a simple zero at $s = 1$.

For each $m|N$ with $\gcd(m, N/m) = 1$, let w_m denote the sign of the Fricke involution at m acting on f. Note that the modified Heegner hypothesis implies that $\chi_1(-M) = \chi_2(-M)$. The main result of [BD5] is

Theorem 4.5. *Suppose that E has at least two primes of multiplicative reduction, and that $\chi_1(-M) = -w_M$.*

1. *There is a global point $\boldsymbol{P}_\chi \in E(L)^\chi$ and $t \in \mathbb{Q}^\times$ such that*

$$P_\chi = t\,\boldsymbol{P}_\chi \quad \text{in } E(K_p) \otimes \mathbb{Q}. \tag{26}$$

2. *The point $\boldsymbol{P}_\chi$ is of infinite order if and only if $L'(E/K, \chi, 1) \neq 0$.*

The proof of Theorem 4.5 relies on the connection between Stark–Heegner points and Shintani-type periods attached to Hida families alluded to in Remark 4.4, which grew out of the calculations of [DD]. A second key ingredient is the relation, made precise in [BD2] and [BD4], between classical Heegner points arising from certain Shimura curve parametrisations and the derivatives of associated two-variable anticyclotomic p-adic L-functions attached to Hida families. In a nutshell, these two ingredients are combined to express the Stark–Heegner point P_χ as a classical Heegner point, following an idea whose origins (as is explained in the introduction of [BD5]) can be traced back to Kronecker's "solution of Pell's equation" in terms of special values of the Dedekind eta-function.

Remark 4.6. A result of Gross–Kohnen–Zagier [GKZ] suggests that the position of the Stark–Heegner point P_χ in the Mordell–Weil group $E(L)^\chi$ is controlled by the Fourier coefficients of a modular form of weight $3/2$ associated to f via the Shimura lift. See [DT] where results of this type are discussed.

Galois deformations and arithmetic geometry of Shimura varieties

Kazuhiro Fujiwara*

Abstract. Shimura varieties are arithmetic quotients of locally symmetric spaces which are canonically defined over number fields. In this article, we discuss recent developments on the reciprocity law realized on cohomology groups of Shimura varieties which relate Galois representations and automorphic representations.

Focus is put on the control of ℓ-adic families of Galois representations by ℓ-adic families of automorphic representations. Arithmetic geometrical ideas and methods on Shimura varieties are used for this purpose. A geometrical realization of the Jacquet–Langlands correspondence is discussed as an example.

Mathematics Subject Classification (2000). 11F55, 11F80, 11G18.

Keywords. Galois representations, automorphic representations, Shimura variety.

1. Introduction

For a reductive group G over $\mathbb{Q}$ and a homogeneous space X under $G(\mathbb{R})$ (we assume that the stabilizer K_∞ is a maximal compact subgroup modulo center), the associated modular variety is defined by

$$M_K(G, X) = G(\mathbb{Q})\backslash G(\mathbb{A}_f) \times X/K.$$

Here $\mathbb{A}_f = \prod'_{p \text{ prime}} \mathbb{Q}_p$ (the restricted product) is the ring of finite adeles of $\mathbb{Q}$, and K is a compact open subgroup of $G(\mathbb{A}_f)$.

$M_K(G, X)$ has finitely many connected components, and any connected component is an arithmetic quotient of a Riemannian symmetric space. It is very important to view $\{M_K\}_{K \subset G(\mathbb{A}_f)}$ as a projective system as K varies, and hence as a tower of varieties. The projective limit

$$M(G, X) = \varprojlim_{K \subset G(\mathbb{A}_f)} M_K(G, X)$$

admits a right $G(\mathbb{A}_f)$-action, which reveals a hidden symmetry of this tower. At each finite level, the symmetry gives rise to Hecke correspondences. For two compact open

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

subgroups $K, K' \subset G(\mathbb{A}_f)$ and $g \in G(\mathbb{A}_f)$, g defines a correspondence $[K'gK]$: the first projection $M_{K\cap g^{-1}K'g} \to M_K$, and the second is the projection $M_{K\cap g^{-1}K'g} \to M_{g^{-1}K'g} \simeq M_{K'}$.

The Betti cohomology group $H^*_B(M_K(G, X), \mathbb{Q})$ admits the action of the Hecke algebra $H(G(\mathbb{A}_f), K)_{\mathbb{Q}}$, the convolution algebra formed by the compactly supported $\mathbb{Q}$-valued K-biinvariant functions on $G(\mathbb{A}_f)$. The characteristic function χ_{KgK} of a double coset KgK acts as correspondence $[Kg^{-1}K]$.

When all connected components of X are hermitian symmetric spaces, we call $M_K(G, X)$ a Shimura variety and denote it by $\mathrm{Sh}_K(G, X)$. The arithmetic theory was begun by Shimura, and developed in his series of articles (cf. [44], [45], [47], [48]).

Shimura varieties have the following special features[1]:

- They are quasi-projective algebraic varieties over $\mathbb{C}$ (and smooth when K is small enough).
- They are canonically defined over the number field $E(G, X)$ (Shimura's theory of canonical models). $E(G, X)$ is called the reflex field. For a field extension E' of E, $\mathrm{Sh}(G, X)_{E'}$ denotes this model as defined over E'.

Shimura established the existence of canonical models when they are moduli spaces of abelian varieties with PEL structure [48], and even in some cases which are not moduli spaces of motives (exotic models, see [47])[2]. The functoriality of the canonical models is Shimura's answer to Hilbert's 12th problem (explicit construction of class fields).

In the case of Shimura varieties, $\mathrm{Sh}(G, X)_E = \varprojlim_{K\subset G(\mathbb{A}_f)} \mathrm{Sh}_K(G, X)_E$ is canonically defined over $E = E(G, X)$, which yields more symmetries than other modular varieties. The Galois group $G_E = \mathrm{Gal}(\bar{E}/E)$ acts on the tower[3], and hence the symmetry group is enlarged to $G_E \times G(\mathbb{A}_f)$. This symmetry acts on ℓ-adic étale cohomology groups $H^*_{\text{ét}}$ instead of the Betti cohomology H^*_B. The decomposition of the cohomology groups as Galois–Hecke bimodules is *the non-abelian reciprocity law* for Shimura varieties.

Aside from Shimura varieties, let us mention one more case which plays a very important role in the p-adic study of automorphic forms. When G is $\mathbb{Q}$-compact and X is a point, Hida noticed the arithmetic importance of $M(G, X)$ [21], though it is not a Shimura variety in general. These are called Hida varieties. Hida varieties are zero-dimensional, but the action of $G(\mathbb{A}_f)$ is quite non-trivial.

2. Non-abelian class field theory

We make the reciprocity law more explicit. Let $q(G)$ be the complex dimension of $\mathrm{Sh}(G, X)$. The ℓ-adic intersection cohomology group $IH^*_{\text{ét}}(\mathrm{Sh}_K(G, X)_{\bar{E}}) =$

[1] We assume that (G, X) satisfies Deligne's axioms [11], [12] for non-connected Shimura varieties.

[2] The general solution is due to Borovoi and Milne.

[3] In the following, for a field F, the absolute Galois group $\mathrm{Gal}(\bar{F}/F)$ of F is denoted by G_F.

$IH^*_{\text{ét}}(\overline{\mathrm{Sh}(G, X)}_{\min,\overline{E}}, \overline{\mathbb{Q}}_\ell)$ of the minimal compactification $\overline{\mathrm{Sh}(G, X)}_{\min,E}$ is pure in each degree, and the most interesting part lies in the middle degree $IH^{q(G)}_{\text{ét}}$. In general, the decomposition of IH^* is understood by Arthur packets, by granting Arthur's celebrated conjectures on local and global representations of reductive groups[4]. See [32] for a conjectural description in the general case.

Let us take a simple (but still deep) example. For a totally real number field F of degree g, let $I_F = \{\iota\colon F \hookrightarrow \mathbb{R}\}$ be the set of all real embeddings (regarded as the set of infinite places of F). One chooses a quaternion algebra D central over F which is split at one $\iota_0 \in I_F$ and ramifies at the other infinite places.

$G_D = \mathrm{Res}_{F/\mathbb{Q}} D^\times$ is the Weil restriction of the multiplicative group of D, and $X_D = \mathbb{P}^1_{\mathbb{C}} \backslash \mathbb{P}^1_{\mathbb{R}} = \mathbb{C}\backslash\mathbb{R}$ is the Poincaré double half plane. The resulting $\mathrm{Sh}(G_D, X_D)$ is a system of algebraic curves, namely the modular curve for $D = M_2(\mathbb{Q})$ and Shimura curves for the other cases, which has a canonical model over $F = E(G_D, X_D)$.

We fix a field isomorphism $\overline{\mathbb{Q}}_\ell \simeq \mathbb{C}$. The decomposition of $IH^1_{\text{ét}}$ as a $G_F \times H(G(\mathbb{A}_f), K)$-module is given by

$$IH^1_{\text{ét}}(\mathrm{Sh}_K(G_D, X_D)_{\overline{F}}) = \oplus_{\pi\in\mathcal{A}_D} \rho_\pi \otimes \pi_f^K.$$

Here $\mathcal{A}_D$ is the set of irreducible cuspidal representations $\pi = \pi_f \otimes \pi_\infty$ of $G_D(\mathbb{A})$ such that the infinite part π_∞ is cohomological for the trivial coefficient and the Jacquet–Langlands correspondent $JL(\pi)$ on $\mathrm{GL}_2(\mathbb{A}_F)$ is cuspidal[5]. $\rho_\pi\colon G_F \to \mathrm{GL}_2(\overline{\mathbb{Q}}_\ell)$ is the ℓ-adic Galois representation attached to π which has the same L-function as π. The identity

$$L(s, \rho_\pi) = L(s, \pi, \mathrm{st})$$

holds, where $L(s, \rho_\pi)$ is the Artin–Hasse–Weil L-function of ρ_π, and $L(s, \pi, \mathrm{st})$ is the standard Hecke L-function of π. This identity (or rather identities between their local factors) is the *non-abelian reciprocity law* realized on $IH^1_{\text{ét}}$. The modular curve case is due to Eichler and Shimura. The Shimura curve case is due to Shimura [47], Ohta [35] and Carayol [5]. It fits into the general representation theoretical framework due to Langlands. The Langlands correspondence is a standard form of non-abelian class field theory which predicts a correspondence between Galois and automorphic representations.

In the following, we discuss the relationship between ℓ-adic families of Galois representations and ℓ-adic families of automorphic representations (with applications to the Langlands correspondence as Wiles did for elliptic curves over $\mathbb{Q}$ in his fundamental work [57]). We show how arithmetic geometrical ideas and methods on Shimura varieties are effectively used for this purpose[6].

[4]It is more natural (and sometimes more convenient because of vanishing theorems known in harmonic analysis) to introduce coefficient sheaves attached to representations of G.

[5]The finite part π_f of π is defined over $\overline{\mathbb{Q}}_\ell$ via identification $\overline{\mathbb{Q}}_\ell \simeq \mathbb{C}$.

[6]Though the viewpoint of motives is extremely important, an emphasis is put on Galois representations in this article.

3. Galois deformations and nearly ordinary Hecke algebras for GL_2

In this section F denotes a totally real field, and I_F is as in §2. Fix an ℓ-adic field E_λ with integer ring o_λ and the maximal ideal λ.

By $I_{F,\ell}$ we mean the set of all field embeddings $F \hookrightarrow \overline{\mathbb{Q}}_\ell$. $I_{F,\ell}$ is canonically identified with $\coprod_{v|\ell} I_{F_v}$, where F_v is the local field at v, and I_{F_v} is the set of all continuous embeddings $F_v \hookrightarrow \overline{\mathbb{Q}}_\ell$. $I_{F,\ell}$ is identified with I_F by the isomorphism $\overline{\mathbb{Q}}_\ell \simeq \mathbb{C}$ chosen in §2.

Let Σ be a set of finite places which contains all places dividing ℓ. Let G_Σ denote $\mathrm{Gal}(F_\Sigma/F)$, where F_Σ is the maximal Galois extension of F which is unramified outside Σ.

For $G = \mathrm{GL}_{2,F}$, Hida has produced a very big Hecke algebra in [22] by the method of cohomological ℓ-adic interpolation[7]. Let $\mathcal{X}_\Sigma^{\mathrm{gl}}$ be the maximal pro-ℓ abelian quotient of G_Σ and $\mathcal{X}_\ell^{\mathrm{loc}}$ be the pro-ℓ completion of $\prod_{v|\ell} o_v^\times$. A pair $((k_\iota)_{\iota\in I_F}, w)$ consisting of an integer vector $(k_\iota)_{\iota\in I_F}$ and an integer w is called discrete type if $k_\iota \equiv w \bmod 2$ and $k_\iota \geq 2$ for all $\iota \in I_F$. A continuous character $\chi : \mathcal{X}_\Sigma^{\mathrm{gl}} \times \mathcal{X}_\ell^{\mathrm{loc}} \to \overline{\mathbb{Q}}_\ell^\times$ is algebraic of type $((k_\iota)_{\iota\in I_F}, w)$ if the quotient $\chi/\big(\chi_{\mathrm{cycle}}^{-w} \cdot \prod_{v|\ell}\prod_{\iota\in I_{F_v}} \chi_\iota^{k_\iota-2}\big)$ is of finite order. Here χ_{cycle} is the cyclotomic character, and χ_ι is the ℓ-adic character $o_v^\times \to \overline{\mathbb{Q}}_\ell^\times$ defined via the embedding ι.

Then a nearly ordinary Hecke algebra T_Σ is a finite local $o_\lambda[[\mathcal{X}_\Sigma^{\mathrm{gl}} \times \mathcal{X}_\ell^{\mathrm{loc}}]]$-algebra having the following properties:

- T_Σ is generated by the standard Hecke operators at all finite places.
- Take an ℓ-adic integer ring $o'_{\lambda'}$. For an o_λ-algebra homomorphism $f : T_\Sigma \to o'_{\lambda'}$ such that the induced o_λ-homomorphism $o_\lambda[[\mathcal{X}_\Sigma^{\mathrm{gl}} \times \mathcal{X}_\ell^{\mathrm{loc}}]] \to o'_{\lambda'}$ defines an algebraic character of discrete type $((k_\iota)_{\iota\in I_F}, w)$, there is a cuspidal $\mathrm{GL}_2(\mathbb{A}_F)$ representation π which is defined by a holomorphic Hilbert cusp form of type $((k_\iota)_{\iota\in I_F}, w)$.
- Any cuspidal representations obtained by specializations as above are nearly ordinary, that is, the action of standard Hecke operators at $v|\ell$ are ℓ-adic units.
- T_Σ is the biggest o_λ-algebra with the above properties. T_Σ is the universal ring which connects all nearly ordinary cuspidal representations.

Assume that for some π appearing from T_Σ by a specialization, the mod λ-reduction $\bar{\rho}_\pi$ of ρ_π is absolutely irreducible. Then there is a Galois representation $\rho_{T_\Sigma} : G_\Sigma \to \mathrm{GL}_2(T_\Sigma)$ which interpolates ρ_π's for various π ℓ-adically (see [56] for the ordinary Hecke algebra: the method of pseudo-representation of Wiles). The local representation $\rho_{T_\Sigma}|_{G_{F_v}}$ for $v|\ell$ is *nearly ordinary*, that is, it has an expression

$$\rho_{T_\Sigma}|_{G_{F_v}} \simeq \begin{pmatrix} \chi_{1,v} & * \\ 0 & \chi_{2,v} \end{pmatrix}$$

[7] This method was found by Shimura in [46] in the late 1960s.

for some local characters $\chi_{i,v}\colon G_{F_v} \to T_\Sigma^\times$ $(i = 1, 2)$ which are made explicit by the universal character of $\mathcal{X}_\ell^{\mathrm{loc}}$. Also $\det\rho_{T_\Sigma}|_{\mathcal{X}_\Sigma^{\mathrm{gl}}}$ is the universal character of $\mathcal{X}_\Sigma^{\mathrm{gl}}$ twisted by $\chi_{\mathrm{cycle}}^{-1}$.

Next we introduce the deformation-theoretical viewpoint due to Mazur. Let R_Σ be the universal nearly ordinary deformation ring of $\bar\rho$. We put the nearly ordinary condition at $v|\ell$ and no restrictions at other $v \in \Sigma$. There is a canonical ring homorphism $R_\Sigma \to T_\Sigma$ which is surjective (one recovers standard Hecke operators from ρ_{T_Σ}).

Theorem 3.1. *Assume the following conditions:*

1. *ℓ is odd, and $\bar\rho|_{F(\zeta_\ell)}$ is absolutely irreducible*[8].
2. *$\bar\rho|^{\mathrm{ss}}_{G_{F_v}}$ is either indecomposable, or is a sum of distinct characters for $v|\ell$ (G_{F_v}-distinguished).*

Then the nearly ordinary Hecke algebra T_Σ is a finite $o_\lambda[[\mathcal{X}_\Sigma^{\mathrm{gl}} \times \mathcal{X}_\ell^{\mathrm{loc}}]]$-flat algebra of complete intersection and is isomorphic to the universal nearly ordinary deformation ring R_Σ.

When $F = \mathbb{Q}$, this is a fundamental result of Wiles [57] supplemented by his collaboration with Taylor [55][9]. For general F, this result is due to the author and is a special case of [18]. For a precise construction of T_Σ at a finite level, see [18]. The above version of the theorem follows easily from it.

So Hida's theory of nearly ordinary Hecke algebras for $\mathrm{GL}_{2,F}$ is almost completed when the residual representation is absolutely irreducible.

We discuss some applications of the theorem. The first application is to the modularity of Galois representations[10]. The following theorem, which is a partial contribution to the modularity of elliptic curves over F (the Taniyama–Shimura conjecture) is an example:

Theorem 3.2. *Let E be an elliptic curve over F, and let $\rho_{E,\ell}$ be the associated Galois representation on the Tate module $T_\ell(E)$. Assume the following conditions:*

1. *3 splits completely in F.*
2. *$\rho_{E,3} \mod 3$ remains absolutely irreducible over $F(\zeta_3)$.*
3. *E is semi-stable at all $v|3$ and ordinary if it admits a good reduction.*

Then there is a cuspidal representation π_E of infinity type $((2, \dots, 2), -2)$ such that $\rho_{E,\ell}$ is isomorphic to ρ_{π_E} over $\overline{\mathbb{Q}}_\ell$ for any ℓ. In particular $L(E, s) = L(s, \pi_E, \mathrm{st})$ holds for the Hasse–Weil L-function $L(E, s)$ of E.

[8] There is an exceptional case when $\ell = 5$ and $[F(\zeta_5) : F] = 2$ which is not treated in [18]. This case will be discussed on another occasion.

[9] Also with a supplement by Diamond [13] to treat some exceptional local representations.

[10] One may apply the solvable base change technique to know the modularity, so only a weaker form of Theorem 3.1 is needed. Usually $[F : \mathbb{Q}]$ becomes even after a base change, so the Mazur principle in the even degree case [17] is indispensable for this approach.

One can use other division points (5-division points, for example) to establish similar modularity results.

By the solvable base change technique, one can also deduce a quite interesting result for $\mathrm{GL}_{2,\mathbb{Q}}$. See the work of Khare and Wintenberger [30], [28] for such directions. In particular Khare proves Serre's conjecture for mod ℓ level 1 forms of $\mathbb{Q}$.

The second application is in Iwasawa theory, especially the Selmer group for the symmetric square of GL_2-representations [23]. Here we need the full form of Theorem 3.1. This theorem is also effective in solving classical problems. See [24] for such an example (Eichler's integral basis problem).

To establish Theorem 3.1, what we shall do is something like proving Weber's theorem (all abelian extensions of $\mathbb{Q}$ are cyclotomic). In our case we already have some tower of Galois extensions which is explicitly described by automorphic forms via the reciprocity law, and we would like to know that it exhausts all extensions which satisfy reasonable conditions.

Let us list the main ingredients in the proof of Theorem 3.1, which are now standard. It consists of 4 steps:

- 1st step. *Level and weight optimization.* Define some minimal Hecke algebra $T_{\min}$. It is necessary to find a minimal Σ with more restrictive minimality conditions.
- 2nd step. *Compatibility of local and global Langlands correspondences.* Define the Galois representation $\rho_{T_{\min}}\colon G_F \to \mathrm{GL}_2(T_{\min})$, and determine the local behaviour of $\rho_{T_{\min}}$, namely local restrictions $\rho_{T_{\min}}|_{G_{F_v}}$.
- 3rd step. $R = T$ *in the minimal case.* Define the minimal deformation ring $R_{\min}$ and show that $R_{\min} \simeq T_{\min}$.
- 4th step. *Reduction to the minimal case.* Show $R_\Sigma \simeq T_\Sigma$ by reducing it to the minimal case (raising the level).

The basic strategy for the third and fourth steps exists for general modular varieties $M(G, X)$, and will be discussed in the next two sections.

The first step applied to $\mathrm{GL}_{2,\mathbb{Q}}$ is Serre's ε-conjecture on the optimization of level and weights for modular $\mathrm{GL}_2(\overline{\mathbb{F}}_\ell)$-representations. This is proved in a series of works. See [40] for the related references. For general $\mathrm{GL}_{2,F}$, outside ℓ, the optimization of the level is completely understood; see [26], [27], [17] for the ramified case and the Mazur principle, [36] for the Ribet type theorem [39]. These results are enough to prove Theorem 3.1 in the nearly ordinary case. However, optimization of level and weight at $v|\ell$ is still insufficient for further progress[11]. The solvable base change technique in [50] is useful for modularity questions.

For the second step, one first constructs ρ_{T_Σ} by an ℓ-adic interpolation from various ρ_π's which appear from Shimura curves by Wiles' method of pseudo-representations [56].

[11] A very naive version of Serre's ε-conjecture is false for $F \neq \mathbb{Q}$ for trivial reasons (one can not attain a conductor which is prime to ℓ in general). Diamond has formulated a refined conjecture and is making progress.

For $\mathrm{GL}_{2,F}$, $\rho_\pi|_{G_{F_v}}$ for $v \nmid \ell$ depends only on the v-component π_v of $\pi = \otimes_w \pi_w$ and is obtained by the local Langlands correspondence for GL_{2,F_v} [5], [52]. For $v|\ell$, the Weil–Deligne representation attached to the potentially stable representation $\rho_\pi|_{G_{F_v}}$ is compatible with π_v when ρ_π comes from Shimura curves [41], [42]. However, this information is too weak to determine $\rho_\pi|_{G_{F_v}}$. For example, information on the Hodge filtration is lacking. Breuil has formulated a p-adic version of the local Langlands correspondence [2].

For general Shimura varieties, this requires a detailed study of bad reductions. For n-dimensional representations as defined by Clozel [9], compatibility outside ℓ is established. (See [20] for the semi-simplification case, and see Taylor and Yoshida [54] for the general case).

For $v|\ell$, p-adic Hodge theory is the basic tool at present, especially for general Shimura varieties.

Remark 3.3. 1. One may allow finite flat deformations at $v|\ell$ when F_v is absolutely unramified [18]. Kisin has developed a local theory for finite flat deformation which allows ramification when the residue field at v is $\mathbb{F}_\ell$, with an application to modularity theorems [31].

2. In the case of $\mathbb{Q}$, Ramakrishna and Khare [29] have found an interesting method without any reduction to the minimal case via use of special deformations, that is, by adding Steinberg type conditions at several auxiliary primes[12]. Moreover, Ramakrishna has studied various Galois deformations over $\mathbb{Q}$, which may not be modular a priori, .

When $\bar\rho$ is absolutely reducible, T_Σ is used to prove Iwasawa's main conjecture for class characters of totally real fields. Skinner and Wiles [49], [51] have obtained a modularity result even in the absolutely reducible case, by showing partial results on the relationship between the versal hull of R_Σ and T_Σ using many ideas and techniques including Taylor–Wiles systems.

4. Taylor–Wiles systems: the formalism

In [55], Taylor and Wiles have invented a marvelous argument to show a nice ring theoretical property of $T_{\min}$: $T_{\min}$ is a complete intersection in the case of modular curves. This property may seem technical at first glance, but has the very deep implication that $R_{\min}$ is $T_{\min}$ in the case they considered. The original argument by Taylor and Wiles has been improved by now; Faltings suggested the direct use of deformation rings rather than Hecke algebras, and the further refinement we now describe is due to Diamond [14] and myself.

For a number field F, let $|F|_f$ be the set of finite places of F. q_v denotes the cardinality of the residue field $k(v)$ for $v \in |F|_f$.

[12] A freeness assertion is necessary for this approach. Using this assertion, one can compute congruence modules to come back to unrestricted deformations. Technical assumptions are made on $\bar\rho$ in [29].

Let k_λ be the residue field of o_λ.

Definition 4.1. Let H be a torus over F of relative dimension d, and let X be a set of finite subsets of $|F|_f$ that contains $\emptyset$. Let R be a complete noetherian local o_λ-algebra with the residue field k_λ, and M an R-module which is finitely generated as an o_λ-module. A Taylor–Wiles system $\{R_Q, M_Q\}_{Q\in X}$ for (R, M) consists of the following data:

- For $Q \in X$ and $v \in Q$, H is split at v, and $q_v \equiv 1 \mod \ell$. We denote the ℓ-Sylow subgroup of $H(k(v))$ by Δ_v, and Δ_Q is defined as $\prod_{v\in Q} \Delta_v$ for $Q \in X$.
- For $Q \in X$, R_Q is a complete noetherian local $o_\lambda[\Delta_Q]$-algebra with the residue field k_λ, and M_Q is an R_Q-module. For $Q = \emptyset$, $(R_\emptyset, M_\emptyset) = (R, M)$.
- There is a surjection of local o_λ-algebras

$$R_Q/I_Q R_Q \to R$$

  for each non-empty $Q \in X$ [13]. Here $I_Q \subset o_\lambda[\Delta_Q]$ denotes the augmentation ideal of $o_\lambda[\Delta_Q]$.
- The homomorphism $R_Q/I_Q R_Q \to \mathrm{End}_{o_\lambda} M_Q/I_Q M_Q$ factors through R, and $M_Q/I_Q M_Q$ is isomorphic to M as an R-module.
- M_Q is free and of rank α as an $o_\lambda[\Delta_Q]$-module for a fixed $\alpha \geq 1$.

In [55], the condition that R_Q is Gorenstein and M_Q is a free R_Q-module is required.

Taylor–Wiles systems are commutative ring theoretic versions of Kolyvagin's Euler systems. The following theorem is the most important consequence of the existence of Taylor–Wiles systems.

Theorem 4.2 (Complete intersection and freeness criterion). *For a Taylor–Wiles system $\{R_Q,\ M_Q\}_{Q\in X}$ for (R, M) and a torus H of dimension d, assume the following conditions:*

1. *For any $m \in \mathbb{N}$*
$$v \in Q \Rightarrow q_v \equiv 1 \mod \ell^m$$
holds for infinitely many $Q \in X$.
2. *The cardinality r of Q is independent of $Q \in X$ for non-empty Q.*
3. *R_Q is generated by at most dr elements as a complete local o_λ-algebra for non-empty $Q \in X$.*

[13] For deformation rings, $R_Q/I_Q R_Q \simeq R$ usually holds. The condition here is relaxed so that it applies to Hecke algebras directly.

Then one has:

- (*complete intersection property*) *R is o_λ-flat and of relative complete intersection of dimension zero;*
- (*freeness*) *M is a free R-module.*

In particular, M is a faithful R-module. If we denote the image of R in $\mathrm{End}_{o_\lambda} M$ by T, we have $R \simeq T$ as a consequence of Theorem 4.2. So the complete intersection and the freeness criterion is also regarded as an *isomorphism criterion*. The Auslander–Buchsbaum formula for regular local rings plays a very important role in the proof of the theorem.

The reason why we have the complete intersection property is the following. When Q and N vary, a well chosen limit of $R_Q/m_{R_Q}^N$ tends to be a power series ring over o_λ in dr variables[14]. This is implied by condition (3) of 4.2. Usually $R = R_Q/I_Q R_Q$ holds, thus R is defined by $d \cdot \sharp Q = dr$ equations in R_Q, and hence it is a complete intersection in the limit.

If the complete intersection property and freeness both hold, then this pair of properties is inherited by descendants of (R, M). This is formulated in the following way.

Definition 4.3. 1. An admissible quintet is a quintet $(R, T, \pi, M, \langle\ ,\ \rangle)$, where R is a complete local o_λ-algebra, T is a finite flat o_λ-algebra, $\pi : R \to T$ is a surjective o_λ-algebra homomorphism, M is a faithful finitely generated T-module which is o_λ-free, and $\langle\ ,\ \rangle : M \otimes_{o_\lambda} M \to o_\lambda$ is a perfect pairing which induces $M \simeq \mathrm{Hom}_{o_\lambda}(M, o_\lambda)$ as a T-module.

2. An admissible quintet $(R, T, \pi, M, \langle\ ,\ \rangle)$ is distinguished if R is a complete intersection and M is R-free (and hence π is an isomorphism).

3. By an admissible morphism from $(R', T', \pi', M', \langle\ ,\ \rangle')$ to $(R, T, \pi, M, \langle\ ,\ \rangle)$ we mean a triple (α, β, ξ). Here $\alpha : R' \to R$, $\beta : T' \to T$ are surjective o_λ-algebra homomorphisms making the following diagram

$$\begin{array}{ccc} R' & \xrightarrow{\alpha} & R \\ {\scriptstyle \pi'}\downarrow & & \downarrow{\scriptstyle \pi} \\ T' & \xrightarrow{\beta} & T \end{array}$$

commutative, and $\xi : M \hookrightarrow M'$ is an injective T'-homomorphism onto an o_λ-direct summand. (Note that we do not assume the restriction of $\langle\ ,\ \rangle'$ to $\xi(M)$ is $\langle\ ,\ \rangle$.)

A Taylor–Wiles system gives rise to a distinguished admissible quintet for a suitably chosen pairing on M under the conditions of Theorem 4.2.

[14] In applications, R_Q is a deformation ring. This implies that the deformation functor which defines R_Q behaves as if it were unobstructed for a well-chosen limit of Q.

Assume that (α, β, ξ) is an admissible morphism from $(R', T', \pi', M', \langle\ ,\ \rangle')$ to $(R, T, \pi, M, \langle\ ,\ \rangle)$. There is an abstract criterion for $(R', T', \pi', M', \langle\ ,\ \rangle')$ to be a distinguished quintet if $(R, T, \pi, M, \langle\ ,\ \rangle)$ is distinguished.

By duality we have

$$\hat{\xi}\colon M' \simeq \mathrm{Hom}_{o_\lambda}(M', o_\lambda) \to \mathrm{Hom}_{o_\lambda}(M, o_\lambda) \simeq M$$

such that

$$\langle\, \xi(x),\ y \,\rangle' = \langle\, x,\ \hat{\xi}(y) \,\rangle \quad \text{for all } x \in M,\ y \in M'.$$

We fix an o_λ-algebra homomorphism $f_T\colon T \to o_\lambda$. We define f_R (resp. $f'_{R'}$) as $f_T \circ \pi$ (resp. $f \circ \beta \circ \pi'$).

Theorem 4.4 (abstract level raising formalism). *For an admissible morphism between admissible quintets $(R', T', \pi', M', \langle\ ,\ \rangle') \to (R, T, \pi, M, \langle\ ,\ \rangle)$, we assume the following conditions:*

1. *$(R, T, \pi, M, \langle\ ,\ \rangle)$ is distinguished.*
2. *T and T' are reduced, $M' \otimes_{o_\lambda} E_\lambda$ is $T' \otimes_{o_\lambda} E_\lambda$-free, and its rank is the same as the rank of M over T.*
3. *$\hat{\xi} \circ \xi(M) = \Delta \cdot M$ holds for some non-zero divisor Δ in T.*
4. *An inequality*

$$\begin{aligned}&\mathrm{length}_{o_\lambda} \ker f_{R'}/(\ker f_{R'})^2\\ &\quad \le \mathrm{length}_{o_\lambda} \ker f_R/(\ker f_R)^2 + \mathrm{length}_{o_\lambda} o_\lambda/\ f_T(\Delta)o_\lambda\end{aligned}$$

holds.

Then $(R', T', \pi', M', \langle\ ,\ \rangle')$ is also distinguished, that is, $R' \simeq T'$, R is a complete intersection, and M' is T'-free.

A generalization of Wiles' isomorphism criterion in [57] by Lenstra is used in the proof. Though the main two theorems in this section are a consequence of the general commutative algebra machinery, they are extremely deep. In the next section, we will see how modular varieties should yield the setup formulated in this section.

Remark 4.5. 1. The idea of an admissible quintet first appeared in the work of Ribet in [38]. $M/\hat{\xi} \circ \xi(M)$ is the congruence module.

2. The o_λ-direct summand property in Definition 4.3, (3) is an abstract form of what is known as "Ihara's Lemma".

3. $\ker f_R/(\ker f_R)^2$ is regarded as a Selmer group. When R is a complete intersection, its o_λ-length is computed and equal to $\mathrm{length}_{o_\lambda} o_\lambda/\eta_R$. Here η_R is the ideal generated by the image of 1 under $o_\lambda \xrightarrow{\hat{f}_R} \mathrm{Hom}_{o_\lambda}(R, o_\lambda) \simeq R \xrightarrow{f_R} o_\lambda$ as introduced by Wiles in [57]. Note that the finiteness of the Selmer group is a consequence of the reducedness of T (Taylor–Wiles systems do not give finiteness directly).

5. Taylor–Wiles systems: a strategy for the construction

Take a pair (G, X) which defines a modular variety, and take a finite dimensional representation $\nu\colon G \to \mathrm{Aut}_{E_\lambda} V_{E_\lambda}$ defined over E_λ. For simplicity, we assume that G is quasi-split over $\mathbb{Q}$. ν defines a $G(\mathbb{A}_f)$-equivariant local system $\mathcal{F}_\nu$ on $M(G, X)$ [15], which yields a family of local systems $\mathcal{F}_\nu^K$ on $M_K(G, X)$ at each level K. By choosing an o_λ-lattice in V_{E_λ}, $\mathcal{F}_\nu^K$ has an o_λ-structure $\mathcal{F}_{\nu,o_\lambda}^K$. We limit ourselves to the adelic action and the Hecke algebra action which respect the integral structure. Let Σ be a finite set of primes containing ℓ, and for a factorizable $K = \prod_q K_q$, K_Σ and K^Σ are defined by $K_\Sigma = \prod_{q\in\Sigma} K_q$, $K^\Sigma = \prod_{q\notin\Sigma} K_q$.

For simplicity, we only consider Hecke operators outside Σ [16]. $H(G(\mathbb{A}_f^\Sigma), K^\Sigma)_{o_\lambda}$ is the Hecke algebra formed by o_λ-valued functions on the adele group without components in Σ. Let us begin with a remark on homological algebras: $R\Gamma_B(M_K(G, X), \mathcal{F}_{\nu,o_\lambda}^K)$ belongs to $D^+(H(G(\mathbb{A}_f^\Sigma), K^\Sigma)_{o_\lambda})$, the derived category of $H(G(\mathbb{A}_f^\Sigma), K^\Sigma)_{o_\lambda}$-complexes bounded from below. This is shown by taking the canonical flasque resolution of $\mathcal{F}_{\nu,o_\lambda}^K$.

Assume that K_q is maximal and hyperspecial for $q \notin \Sigma$. Then $H(G(\mathbb{A}_f^\Sigma), K^\Sigma)_{o_\lambda} = \otimes_{q\notin\Sigma} H(G(\mathbb{Q}_q), K_q)_{o_\lambda}$ is commutative. Let m_Σ denote a maximal ideal of $H(G(\mathbb{A}_f^\Sigma), K^\Sigma)_{o_\lambda}$. Throughout this section we make the following assumption:

Assumption 5.1 (Vanishing of cohomology for $\overline{\mathbb{F}}_\ell$-coefficients). For any (sufficiently small) K,

$$H_B^i(M(G, X)_K, \mathcal{F}_{\nu,o_\lambda}^K \otimes_{o_\lambda} k_\lambda)_{m_\Sigma} = 0$$

for $i \neq q(G)$.

This type of vanishing statement is known over E_λ when the weight of ν is sufficiently regular, but for torsion coefficients it is difficult to prove a vanishing statement[17]. Moreover, we need to have a vanishing claim *which holds uniformly* in K.

Let $M_\Sigma = H_B^{q(G)}(M(G, X)_K, \mathcal{F}_{\nu,o_\lambda}^K)_{m_\Sigma}$ be the localization of the middle dimensional cohomology group at m_Σ[18]. By Assumption 5.1, it is o_λ-free.

T_Σ is defined as the image of $H(G(\mathbb{A}_f^\Sigma), K^\Sigma)_{o_\lambda}$ in M_Σ. We call it the ℓ-adic Hecke algebra.

When $M(G, X)$ is a Shimura variety $\mathrm{Sh}(G, X)$ with reflex field E, we further assume, by using the étale cohomology, that a reciprocity law of the following form for $(\mathrm{Sh}(G, X), \nu)$ holds:

$$M_\Sigma \otimes_{o_\lambda} \overline{\mathbb{Q}}_\ell \simeq \oplus_{\pi\in\Pi_\rho} V_\rho \otimes (\pi_f^K)^{a(\pi)}.$$

[15] For the center $Z(G)$ of G, the image of $Z(G)(\mathbb{Q}) \cap K$ by ν must be trivial for some K.

[16] We also need Hecke actions at Σ. At ℓ, one should use a semi-subgroup $G(\mathbb{Q}_\ell)_+$ of $G(\mathbb{Q}_\ell)$ because the full action of $G(\mathbb{Q}_\ell)$ does not preserve the lattice structure in general.

[17] In fact, there are non-zero torsion classes in general unless one puts restrictive conditions on m_Σ.

[18] Further localizations by elements in $H(G(\mathbb{A}_\Sigma), K_\Sigma)$ are necessary.

Here ${}^L G$ is the L-group of G, Π_ρ is a packet which corresponds to $\rho\colon G_E \to {}^L G(\overline{\mathbb{Q}}_\ell)$ and is cohomological for ν [19]. V_ρ is a G_E-representation defined by a finite dimensional representation of ${}^L G$ determined by ν. We try to construct a Taylor–Wiles system for (T_Σ, M_Σ).

As is suggested in the introduction, a modular variety for a given level K does not admit a symmetry by a group. To have a group action, we must use an open subgroup of $G(\mathbb{A}_f)$ which is smaller than K. Take a $\mathbb{Q}$-parabolic subgroup P of G, and a quotient torus H of P which is disjoint from the center $Z(G)$, that is, the image of $Z(G)$ in H is trivial. It is very important to have a torus which is disjoint from the center: this gives us a *geometric direction*, which, in the case of Shimura varieties, cannot be obtained from abelian extensions of the reflex field. This feature is quite different from Euler systems.

For a prime q, let $K_{P,q} = \{g \in G(\mathbb{Z}_q),\ g \bmod q \in P(\mathbb{F}_q)\}$ be a parahoric subgroup at q defined by P, and let $K_{P,H,q} = \{g \in K_{P,q},\ g \bmod q \in \ker(P(\mathbb{F}_q) \to H(\mathbb{F}_q)^\ell)\}$ be a subgroup depending on H. Here $H(\mathbb{F}_q)^\ell$ is the maximal subgroup whose order is prime to ℓ. Then $K_{P,q}/K_{P,H,q}$ is isomorphic to Δ_q, the ℓ-Sylow subgroup of $H(\mathbb{F}_q)$.

For a finite set of finite primes Q which is disjoint from Σ, one sets

$$K_{P,Q} = \prod_{q \in Q} K_{P,q} \cdot K^Q,$$

$$K_{P,H,Q} = \prod_{q \in Q} K_{P,H,q} \cdot K^Q,$$

and $\Delta_Q = \prod_{q \in Q} \Delta_q$. Since H is disjoint from the center, the natural covering

$$\pi_Q\colon \mathrm{Sh}_{K_{P,H,Q}} \to \mathrm{Sh}_{K_{P,Q}}$$

is an étale Galois covering with Galois group Δ_Q if K^Q is small enough to make group actions free. We view $R\Gamma_B(\mathrm{Sh}_{K_{P,H,Q}} \mathcal{F}_{\nu,o_\lambda}^{K_{P,H,Q}})$ as an object in

$$D^+(H(G(\mathbb{A}_f^{\Sigma \cup Q}), K^{\Sigma \cup Q})_{o_\lambda}).$$

Then we make the following simple observation (*perfect complex argument*):

Lemma 5.2. *Let $\pi\colon X \to Y$ be an étale Galois covering between finite dimensional manifolds*[20] *with Galois group G. Let $\mathcal{F}$ be a smooth Λ-sheaf on Y. Then $R\Gamma_B(X, \pi^*\mathcal{F})$ is represented by a perfect complex of $\Lambda[G]$-modules, and*

$$R\Gamma_B(X, \pi^*\mathcal{F}) \otimes^{\mathbb{L}}_{\Lambda[G]} \Lambda[G]/I_G \simeq R\Gamma_B(Y, \mathcal{F})$$

holds in $D^b(\Lambda[G])$. Here I_G is the augmentation ideal of $\Lambda[G]$, and the map is induced by the trace map.

[19] We are ignoring the role of characters of centralizer groups, endoscopy, and so on. See [32] for a precise conjectural description. Moreover, we only have information on the semi-simplification V_ρ^{ss}.

[20] These manifolds must satisfy reasonable finiteness conditions on cohomology groups, which are true for the algebraic varieties or modular varieties that we are interested in.

By Lemma 5.2, we know that $R\Gamma_B(\mathrm{Sh}_{K_{P,H,Q}}, \mathcal{F}_{\nu,o_\lambda}^{K_{P,H,Q}})$ is, in $D^b(o_\lambda[\Delta_Q])$, a perfect complex of $o_\lambda[\Delta_Q]$-modules, that is, it is quasi-isomorphic to a bounded complex of free $o_\lambda[\Delta_Q]$-modules. We assume 5.1 holds and localize at the maximal ideal m_Q of $H(G(\mathbb{A}_f^{\Sigma\cup Q}), K^{\Sigma\cup Q})_{o_\lambda}$ below m_Σ. Then

$$M_Q = H_B^{q(G)}(\mathrm{Sh}_{K_{P,H,Q}}, \mathcal{F}_{\nu,o_\lambda}^{K_{P,H,Q}})_{m_Q}$$

is $o_\lambda[\Delta_Q]$-free since it is the only non-zero cohomology of a perfect $o_\lambda[\Delta_Q]$-complex. Then $M_Q \otimes_{o_\lambda[\Delta_Q]} o_\lambda[\Delta_Q]/I_{\Delta_Q} = M_{0,Q}$. Here $M_{0,Q} = H_B^{q(G)}(\mathrm{Sh}_{K_{P,Q}}, \mathcal{F}_{\nu,o_\lambda}^{K_{P,Q}})_{m_Q}$.

We define T_Q as the image of $H(G(\mathbb{A}_f^{\Sigma\cup Q}), K^{\Sigma\cup Q})_{o_\lambda}$ in $\mathrm{End}_{o_\lambda} M_Q$. Then the expectation is that $M_{0,Q}$ is a direct sum of M for a good choice of Q, and that (T_Q, M_Q) forms a Taylor–Wiles system for (T_Σ, M_Σ) as Q varies. Hence, a system for deformation rings will be obtained for appropriate choices of deformation functors.

To relate $M_{0,Q}$ to the original M_Σ, we already need information from the Galois parameter for the Langlands (or Arthur) packets for automorphic forms which contributes to $M_{0,Q}$, since we need to remove non-spherical components from $M_{0,Q}$. Some version of the compatibility of local and global parametrizations is needed.

This program for constructing a Taylor–Wiles system, and in particular for combining the perfect complex argument and the vanishing assumption 5.1 to obtain a system, was made explicit and carried out in two special cases in [18]. One case is when (G, X) defines a Shimura curve, that is, $G = G_D$ as in §3. The Hecke actions on H_B^0 and H_B^2 are easily determined for Shimura curves, and Assumption 5.1 is true if we localize at the maximal ideals of Hecke algebras which correspond to absolutely irreducible two dimensional representations. In another case, Hida varieties are used to treat some situations which do not arise from Shimura curves.

In general, the program is very effective when G defines Hida varieties, since the vanishing assumption is trivially true. To study non-abelian class field theory, especially the question of modularity, or deformations of absolutely irreducible representations, this case is quite useful, since one can apply the Jacquet–Langlands correspondence for inner forms (assuming that it is already known) to convert the problem to a compact inner form. For unitary groups, this approach was taken by Harris and Taylor, showing the $R = T$ theorem for the n-dimensional representations of CM fields constructed by Clozel [9] under several restrictive assumptions. Arithmetic geometrical difficulties are all encoded in the compatibility of local and global Langlands correspondences outside ℓ and in the description of local monodromy at ℓ.

Unfortunately, Hida varieties do not admit any natural Galois action. Since one needs to have finer information coming from geometry, it is still an important problem to construct Taylor–Wiles systems for higher dimensional Shimura varieties.

There are several possible solutions. One solution would be to establish Assumption 5.1, that is, a vanishing theorem for $\overline{\mathbb{F}}_\ell$-coefficients. A partial solution will be given in the sequel for unitary groups with signature $(m, 1)$ by using a geometrical realization of the Jacquet–Langlands correspondence. As far as the author knows,

these unitary Shimura varieties are the only examples where the program is carried out for the middle dimensional cohomology in arbitrary higher dimensions.

For other approaches in the case of Siegel modular varieties using p-adic Hodge theory, see [34]. A Taylor–Wiles system for the Hilbert–Siegel case, especially $G\,\mathrm{Sp}_{4,\mathbb{Q}}$, has been studied by Tilouine.

Another possible solution would be to avoid the use of vanishing theorems. We have enough information about the alternating sum of cohomology groups, so in working with a suitable K_0-group of virtual Galois–Hecke bimodules instead of Galois–Hecke bimodules, Taylor–Wiles systems might work for virtual representations.

Remark 5.3. The perfect complex argument is simple but very powerful in the cohomological study of congruences between automorphic forms. There are several other uses of the perfect complex argument.

One example would be the construction of nearly ordinary Hecke algebra for GL_2, with an *exact control theorem*.

In particular for the nearly ordinary Hecke algebra T_Σ, there is a faithful T_Σ-module M_Σ with the following properties:

- M_Σ is free over $\Lambda = o_\lambda[[\mathcal{X}_\Sigma^{\mathrm{gl}} \times \mathcal{X}_\ell^{\mathrm{loc}}]]$.
- Take an algebraic character $\chi : \Lambda \to o'_{\lambda'}$ of discrete type $((k_\iota)_{\iota\in I_F}, w)$ such that $\tilde{\chi} = \chi/(\chi_{\mathrm{cycle}}^{-w} \cdot \prod_{v|\ell} \prod_{\iota\in I_{F_v}} \chi_\iota^{k_\iota-2})$ is of order prime to ℓ. $M_\Sigma \otimes_{\Lambda,\chi} o'_{\lambda'}$ is a lattice in the space of nearly ordinary forms of type $((k_\iota)_{\iota\in I_F}, w)$ with "nebencharacter" $\tilde{\chi}$. Moreover, when the degree $[F : \mathbb{Q}]$ is even[21], it is *exactly* the image of $H_B^0(M_K, \mathcal{F}^K_{((k_\iota)_{\iota\in I_F},w),o'_{\lambda'}})$. Here M_K is a Hida variety associated to a definite quaternion algebra, and $\mathcal{F}^K_{((k_\iota)_{\iota\in I_F},w),o'_{\lambda'}}$ is a smooth $o'_{\lambda'}$-sheaf on M_K (cf. [17]) which realizes the reciprocity law for forms of type $((k_\iota)_{\iota\in I_F}, w)$ over $\overline{\mathbb{Q}}_\ell$.

Another example would be the level optimization for GL_2 in a special case, which gives an interpretation of Carayol's lemma [7], [17].

6. Geometric Jacquet–Langlands correspondence

We use the strategy in Section 5 for some unitary Shimura varieties where the non-abelian reciprocity is established by Kottwitz [33], and we construct a Taylor–Wiles system for the middle dimensional cohomology group. To do this, we establish an explicit Jacquet–Langlands correspondence which preserves o_λ-lattice structures by arithmetic geometrical means, in particular by analyzing bad reductions of Shimura varieties. This is called a geometric Jacquet–Langlands correspondence. This first

[21] One uses Shimura curves when the degree is odd.

appeared in the level optimization problem mentioned in §3 in the case of modular curves. This also gives an arithmetic geometrical meaning of Hida varieties.

Let us give a simple example. Let $S_{D,K} = \mathrm{Sh}(G_D, X_D)_K$ be a Shimura curve as in §2. For a finite place v of F, assume that D is split at v, and $v \nmid \ell$. Let $\tilde{D}$ be a quaternion algebra which is definite at all infinite places, non-split at v, but has the same local invariants as D at the other finite places. $\tilde{D}$ defines a Hida variety $M_{\tilde{D}}$, and we have an isomorphism $D^\times(\mathbb{A}^v_{F,f}) \simeq \tilde{D}^\times(\mathbb{A}^v_{F,f})$ outside v.

Assume $K = \prod_u K_u$ is factorizable, and K_v is an Iwahori subgroup of GL_{2,F_v}. We set $\tilde{K}_v = o^\times_{\tilde{D}_v}$ for a maximal order $o_{\tilde{D}_v}$ of D_v, and we view $\tilde{K} = \tilde{K}_v \cdot \prod_{u\neq v} K_v$ as a subgroup of $\tilde{D}^\times(\mathbb{A}_{F,f})$.

Then we have the following geometric realization of the Jacquet–Langlands [25], and of the Shimizu [43] correspondence[22]:

Proposition 6.1. *For $\Lambda = E_\lambda$, we have a (non-canonical) isomorphism as $H(D^\times(\mathbb{A}^{\ell,v}_{F,f}), K^{\ell,v})_{o_\lambda}$-modules*

$$W_0 H^1_{\text{ét}}(S_{D,K}, \Lambda) \simeq H^0(M_{\tilde{D},\tilde{K}}, \Lambda)$$

modulo Eisenstein modules. W_0 is the weight 0 part of the weight filtration, and the decomposition with respect to the Hecke action gives the Jacquet–Langlands correspondence.

Here we view the Hida variety $M_{\tilde{D},\tilde{K}}$ as a variety over $\overline{k(v)}$, and we regard it as the set of supersingular points[23], that is, the set of points which correspond to formal o_v-modules of height 2. Since the special fiber at v of the arithmetic model of $S_{D,K}$ has two kinds of components which meet at supersingular points, the claim follows from the standard calculation of the weight filtration using the dual graph of the special fiber[24]. There is also a variant for any finite o_λ-algebra Λ, which preserves o_λ-lattice structures.

So the Jacquet–Langlands correspondence is realized on the weight filtration of local monodromy action where the Shimura variety admits a bad reduction. This is our starting point[25].

6.1. Arithmetic model of unitary Shimura varieties. As in §2, F denotes a totally real field and $[F : \mathbb{Q}] = g$. I_F is the set of the embeddings $\iota\colon F \hookrightarrow \mathbb{R}$. Take an imaginary quadratic field E_0 over $\mathbb{Q}$, and let $E = E_0 \cdot F$ be the composite field. Let $\mathrm{Gal}(E/F) = \langle\sigma\rangle$.

Let D be a central division algebra over E of dimension n^2, and let $*\colon D \to D$ be a positive involution of the second kind, that is, an involution which induces σ on E.

[22] There is also a version when D is ramified at v, which plays an essential role in [39], [36].

[23] This identification is non-canonical.

[24] The Hecke action on the set of the irreducible components is Eisenstein, and we are ignoring this part.

[25] It will be desirable to have a motivic correspondence over a global field.

We require the following condition on ι at infinity: At one infinite place $\iota_0 \in I_F$, $*$ is equivalent to $g \mapsto J^t \bar{g} J^{-1}$ with $J = \begin{pmatrix} 1_{n-1} & 0 \\ 0 & -1 \end{pmatrix}$, and it is equivalent to the standard involution $g \mapsto^t \bar{g}$ for the other $\iota \neq \iota_0$.

Let $U(D) = \{g \in D^{\mathrm{op}\times},\ g \cdot g^* = 1_D\}$ be the unitary group. Let $GU(D) = \{g \in D^{\mathrm{op}\times},\ g \cdot g^* = \nu(g) \cdot 1_D,\ \nu(g) \in \mathbb{G}_{m,F}\}$ be the group of unitary similitudes, seen as a reductive group over F.

Let $G' = \mathrm{Res}_{F/\mathbb{Q}} U(D)$ be the Weil restriction of the unitary group, and let G be the inverse image of $\mathbb{G}_{m,\mathbb{Q}}$ by $\mathrm{Res}_{F/\mathbb{Q}} GU(D) \to \mathrm{Res}_{F/\mathbb{Q}} \mathbb{G}_{m,F}$.

$$1 \to G' \to G \xrightarrow{\nu} \mathbb{G}_{m,\mathbb{Q}} \to 1.$$

We fix an embedding $E_0 \hookrightarrow \mathbb{C}$. This defines a CM-type on E, and for each $\iota\colon F \hookrightarrow \mathbb{R}$, we have identifications

$$E \otimes_{F,\iota} \mathbb{R} \simeq \mathbb{C},\ D \otimes_{F,\iota} \mathbb{R} \simeq M_n(\mathbb{C}).$$

It follows that

$$G'_{\mathbb{R}} \simeq U(n-1,1) \times U(n)^{g-1}$$

by our choice.

Define a group homomorphism

$$h_0\colon \mathrm{Res}_{\mathbb{C}/\mathbb{R}} \mathbb{G}_{m,\mathbb{C}} \to G_{\mathbb{R}}$$
$$z \mapsto h_0(z) = \left(\begin{pmatrix} z \cdot 1_{n-1} & 0 \\ 0 & \bar{z} \end{pmatrix}, z1_n, \ldots, z1_n \right).$$

The associated symmetric space

$$X = G_\infty(\mathbb{R})/K_\infty$$

(K_∞ is the centralizer of $h_0(\sqrt{-1})$) is a complex ball of dimension $n-1$.

For a compact open subgroup $K \subset G(\mathbb{A}_f)$, the corresponding Shimura variety $\mathrm{Sh}_K(G,X)$ is compact by our assumption on D, and the reflex field $E(G,X)$ is E. We view $\mathrm{Sh}_K(G,X)$ as a generalization of Shimura curves. The determination of the reciprocity law is due to Kottwitz [33], and the bad reductions have been studied especially by Rapoport and Zink [37], Harris, and Taylor [20].

The moduli interpretation of these varieties is given by Shimura. We need arithmetic models over the integers, so we consider it over $o_E \otimes_{\mathbb{Z}} \mathbb{Z}_p$ by fixing a prime p. The details are found in [20]. To avoid technical problems which arise from obstructions to the Hasse principle for G, we assume that n is odd in this exposition.

We fix a finite place w of the reflex field E of residual characteristic p. Assume p splits completely in E_0, and let $\wp$ be the place of E_0 below w. $P_\wp$ is the set of places of E which divide $\wp$.

Since p is split in E_0, the unitary group has a simpler form, and we have an isomorphism

$$G_{\mathbb{Q}_p} \simeq \mathbb{G}_{m,\mathbb{Q}_p} \times \prod_{u \in P_\wp} \mathrm{Res}_{E_u/\mathbb{Q}_p} D_u^{\mathrm{op}\times}.$$

In the following, we only consider compact open subgroups K_p of $G(\mathbb{Q}_p)$ which are of the form $\mathbb{Z}_p^\times \cdot \prod_{u\in P_\wp} K_u$ for $K_u \subset D^{\mathrm{op}\times}(E_u)$. We assume moreover that D is split at w, and we identify the w-component with $H_w = D_w^{\mathrm{op}\times} \simeq \mathrm{GL}_{n,E_w}$.

Take a maximal order o_D of D which is stable under $*$. $o_D \otimes_{\mathbb{Z}} \mathbb{Z}_p$ is identified with $\prod_{u\in P_\wp} o_{D_u} \times \prod_{u\in P_\wp} o_{D_{\sigma(u)}}$. For $u \in P_\wp$, let e_u denote the projector corresponding to o_{D_u}.

For an o_w-scheme U, let A be an abelian scheme over U of relative dimension gn^2 with o_D-multiplication. We assume that the o_D-action on the relative Lie algebra $\mathrm{Lie}A/U$ satisfies the following conditions:

1. For $u \in P_\wp$ different from w, $e_u\mathrm{Lie}A/U$ is zero.
2. $e_w\mathrm{Lie}A/U$ is a locally free o_U-module of rank n, and the o_w-action on $e_w\mathrm{Lie}A/S$ is the multiplication through $o_w \to \Gamma(U, \mathcal{O}_U)$.

By condition (1), for the p-divisible group $A[p^\infty]$, $e_uA[p^\infty]$ is an étale o_u-divisible module for $u \in P_\wp$ different from w. We denote the Tate module by $T_u(A)$.

We take a compact open subgroup $K = K_p \cdot K^p \subset G(\mathbb{A}_f)$. We assume that $K_w = \mathrm{GL}_n(o_w)$ and that K^p is sufficiently small. We denote the product $\mathbb{Z}_p^\times \cdot \prod_{u\in P_\wp, u\neq w} K_u \cdot K^p$ by K^w. Then $K = K_w \cdot K^w$ by the definition. We view D as a left D^{op}-module and denote it by V [26]. The integral structure is given by $V_{\mathbb{Z}} = o_D$.

Definition 6.2. Let U be an o_w-scheme, let A be an abelian scheme over U with o_D-multiplication which satisfies the Lie algebra conditions described above, and let $\bar{p}$ be a homogeneous polarization of A. Then $(A, \bar{p})$ is of type $(o_D, V_{\mathbb{Z}}; K)$ if the following rigidification structures are attached:

1. For any point $s \in U$, there is a polarization $\lambda \in \bar{p}$ of degree prime to p such that λ induces $*$ on D as its Rosati involution.
2. For any geometric point $\bar{s}$ of characteristic p, a class $k \mod K^w$ of o_D-linear symplectic similitudes

$$k: \prod_{u\in P_\wp, u\neq w} T_u(A)_{\bar{s}} \times T^p(A)_{\bar{s}} \simeq V_{\mathbb{Z}} \otimes \hat{\mathbb{Z}}^p.$$

Here $\pi_1(U, \bar{s})$, the étale fundamental group, is mapped to K^w.

By a standard argument, the moduli functor

$$U \mapsto \mathcal{S}h_K(U),$$

where $\mathcal{S}h_K(U)$ is the set of the isomorphism classes of polarized abelian schemes of type $(o_D, V_{\mathbb{Z}}; K)$ over U, is representable by a projective smooth scheme $\mathcal{S}h_K$ over o_w, which gives a model for $\mathrm{Sh}_K(G, X)$.

[26] With a symplectic form which we do not make precise here.

Let $\mathcal{A}^{\mathrm{univ}}$ be the universal abelian scheme over $\mathcal{S}h_K$. Then o_{D_w} acts on $e_w\mathcal{A}^{\mathrm{univ}}[p^\infty]$, and is isomorphic to $M_n(o_w)$. By Morita equivalence, this gives an o_w-divisible module $\mathcal{C}_w$ of height n on $\mathcal{S}h_K$, so that $e_w\mathcal{A}^{\mathrm{univ}}[p^\infty] \simeq \mathcal{C}_w^{\oplus n}$.

For general $K_w \subset H_w(E_w) \simeq \mathrm{GL}_n(E_w)$, we have a flat arithmetic model $\mathcal{S}h_K$ over o_w by using the notion of level structures due to Drinfeld [15].

6.2. Inductive structure. We briefly describe an inductive structure of arithmetic models in characteristic p. The inductive structure was first studied by Boyer in the function field case [1]. In our unitary case it is due to Harris and Taylor in [20].

For $N \geq 1$, set $K_N = K_{N,w} \cdot K^w$, $K_{N,w} = \ker(H_w(o_w) \to H_w(o_w/m_w^N))$, $X_N = \mathcal{S}h_{K_N}$, and $S = \operatorname{Spec} o_w$. Let s (resp. η) denote the closed (resp. generic) point of S.

For $1 \leq h \leq n$, $X_{N,s}^{[h]}$ is the set of points in the special fiber $(X_N)_s$ of X_N where the étale (resp. connected) part of $\mathcal{C}_w$ has height $n-h$ (resp. height h). $X_{N,s}^{[h]}$ is locally closed in $(X_N)_s$, and the canonical filtration on $X_{N,s}^{[h]}$

$$0 \to \mathcal{C}_w^{\mathrm{conn}} \to \mathcal{C}_w \to \mathcal{C}_w^{\text{ét}} \to 0$$

has the property that $\mathcal{C}_w^{\text{ét}}$ is étale locally isomorphic to $(E_w/o_w)^{n-h}$.

We consider the formal completion $\mathcal{X}_N^{[h]} = \hat{X}_N|_{X_{N,s}^{[h]}}$ of X_N along $X_{N,s}^{[h]}$. Note that Hecke correspondences induce correspondences on $\mathcal{X}_N^{[h]}$.

Let P_h be the standard maximal parabolic subgroup of H_w which fixes the filtration $0 \subset o_w^h \subset o_w^n$.

Define $\mathcal{Y}_N^{[h]}$ to be the subspace of $\mathcal{X}_N^{[h]}$ where the canonical filtration of $\mathcal{C}_w[m_w^N]$ is compatible with the filtration $0 \subset (m_w^{-N}/o_w)^h \subset (m_w^{-N}/o_w)^n$ via the universal Drinfeld level structure $(m_w^{-N}/o_w)^n \to \mathcal{C}_w[m_w^N]$. $P_h(o_w/m_w^N)$ acts naturally on $\mathcal{Y}_N^{[h]}$.

We consider the pro-systems of formal schemes

$$\mathcal{X}_\infty^{[h]} = \varprojlim_N \mathcal{X}_N^{[h]} \quad \text{and} \quad \mathcal{Y}_\infty^{[h]} = \varprojlim_N \mathcal{Y}_N^{[h]}.$$

Note that $H_w(o_w)$ (resp. $P_h(o_w)$)-action on $\mathcal{X}_\infty^{[h]}$ (resp. $\mathcal{Y}_\infty^{[h]}$) is extended to $H_w(E_w)$ (resp. $P_h(E_w)$).

Then the canonical morphism[27]

$$H_w(E_w) \wedge^{P_h(E_w)} \mathcal{Y}_\infty^{[h]} \to \mathcal{X}_\infty^{[h]}$$

is in fact an isomorphism by a method of Boyer ([1], [20]), that is,

$$\mathcal{X}_\infty^{[h]} \simeq H_w(E_w) \wedge^{P_h(E_w)} \mathcal{Y}_\infty^{[h]}.$$

[27] For a group G and a right (resp. left) G-space X (resp. Y), $X \wedge^G Y$ denotes the contracted product, i.e., by viewing Y as a right G-space, $X \wedge^G Y = X \times Y/G$, where G acts diagonally on $X \times Y$.

Since the space itself is "parabolically induced from P_h", then for $\Lambda = \overline{\mathbb{F}}_\ell$, we have an isomorphism of admissible modules[28]

$$\varinjlim_N H^i_c(X^{[h]}_{N,\bar{s}}, R^j\psi(\Lambda)) \simeq \mathrm{Ind}_{P_h(E_w)}^{H_w(E_w)} \varinjlim_N H^i_c(Y^{[h]}_{N,\bar{s}}, R^j\psi(\Lambda)),$$

where $Y^{[h]}_N$ is the underlying scheme of $\mathcal{Y}^{[h]}_N$. In particular for $h < n$, this implies that the $H_v(E_w)$-representations occurring in proper support cohomologies $\varinjlim_N H^i_c(X^{[h]}_{N,\bar{s}}, R^j\psi(\Lambda))$ are induced from admissible representations of $P_h(E_w)$. Admissibility follows from the finiteness of nearby cycle cohomologies.

6.3. Vanishing theorem. We take a supercuspidal representation in the sense of Vignéras

$$\bar{\pi}_w : H_w(E_w) \to \mathrm{Aut}\, V_{\bar{\pi}_w}.$$

Here $V_{\bar{\pi}_w}$ is an $\overline{\mathbb{F}}_\ell$-vector space, that is, $\bar{\pi}_w$ is admissible, irreducible and cannot be obtained by a non-trivial parabolic induction. We assume that $\bar{\pi}_w^{K_w}$ is non-zero. $\bar{\pi}_w$ corresponds to a finite dimensional irreducible representation of $H(H_w(E_w),\ K_w)_{\overline{\mathbb{F}}_\ell}$.

Theorem 6.3 (Vanishing theorem for $\overline{\mathbb{F}}_\ell$-coefficients). *For a finite place w of E of residual characteristic p, assume that p is split in E_0, D is split at w, and $p \neq \ell$. For a compact open subgroup $K = K_w \cdot K^w$, assume moreover that K_w is contained in an Iwahori subgroup and K^w is sufficiently small. Then for any o_λ-local system $\mathcal{F}^K_{\nu,o_\lambda}$ on Sh_K corresponding to a finite dimensional representation ν of G, $\bar{\pi}_w$ does not appear as a subquotient of $H^i_B(\mathrm{Sh}_K,\ \mathcal{F}^K_{\nu,o_\lambda} \otimes_{o_\lambda} \bar{k}_\lambda)$ unless $i = n-1$.*

We give a sketch of the proof. We assume $\mathcal{F}^K_{\nu,o_\lambda} = o_\lambda$, since the general case is shown similarly. We set $\Lambda = \overline{\mathbb{F}}_\ell$. By the comparison theorem, the Betti cohomology is canonically isomorphic to the étale cohomology. We reduce the vanishing theorem to:

Lemma 6.4 (Localization principle). *For $X = \mathcal{S}h_K$, the kernel and the cokernel of the canonical map*

$$\begin{aligned} H^i_{\text{ét}}(X_{\bar{\eta}}, \Lambda) \simeq H^i_{\text{ét}}(X_{\bar{s}}, R\psi(\Lambda)) &\to H^i_{\text{ét}}(X^{[n]}_{\bar{s}}, R\psi(\Lambda)|_{X^{[n]}_{\bar{s}}}) \\ &= H^0_{\text{ét}}(X^{[n]}_{\bar{s}}, R^i\psi(\Lambda)|_{X^{[n]}_{\bar{s}}}) \end{aligned}$$

do not admit $\bar{\pi}_w$ as a subquotient, that is, the supercuspidal part of the global cohomology is isomorphic to nearby cycle fibers at "supersingular points".

To show the lemma, we assume that $K_w = K_{N,w}$ for simplicity[29]. For $\alpha \geq 1$, we denote $\mathcal{S}h_{K_\alpha}$ by X_α. Note that, for $\beta \geq \alpha \geq 1$, the $K_{\alpha,w}$-invariants $H^i_{\text{ét}}(X_{\beta,\bar{\eta}}, \Lambda)^{K_{\alpha,w}}$

[28] By using the regular base change theorem in étale cohomology to compare the algebraic and the formal situation.

[29] The general case follows from the perfect complex argument. Even the assumption on K_w can be weakened.

are $H^i_{\text{ét}}(X_{\alpha,\bar\eta}, \Lambda)$ since $K_{\alpha,w}/K_{\beta,w}$ has order prime to ℓ. The same is true for the nearby cycle fibers for X_α and X_β as the group action is free on the generic fiber, so it suffices to prove that the kernel and the cokernel of the homomorphism

$$\varinjlim_\alpha H^i_{\text{ét}}(X_{\alpha,\bar\eta}, \Lambda) \to \varinjlim_\alpha H^0_{\text{ét}}(X^{[n]}_{\alpha,\bar s}, R^i\psi(\Lambda)|_{X^{[n]}_{\alpha,\bar s}})$$

do not admit $\bar\pi_w$ as a subquotient. Note that both sides are admissible $H_w(E_w)$-representations. We work modulo the Serre subcategory of admissible representations generated by non-supercuspidal representations.

Then 6.4 follows from the result in 6.2, since the contribution of the proper support cohomologies of nearby cycle sheaves from $X^{[h]}_{N,s}$ for $h < n$ is parabolically induced from P_h.

We go back to the proof of 6.3. Since the nearby cycle is perverse,

$$R^i\psi(\Lambda)_{\bar x} = 0 \quad \text{for } i > n-1,$$

so we get

$$H^i_{\text{ét}}(X_{\bar\eta}, \Lambda) = 0 \quad \text{for } i > n-1$$

by the localization principle, modulo non-supercuspidal representations. By Poincaré duality on $X_{\bar\eta}$, we have the vanishing of the cohomologies of degree strictly less than $n-1$, since the contragradient of a supercuspidal representation is again supercuspidal.

Remark 6.5. The method of this proof also gives a vanishing theorem for $\mathbb{Q}_\ell$-sheaves. The result in this case is proved by Harris [19] by using Clozel's purity lemma and the base change lift to $D^{\text{op}\times}$.

Note that $X^{[n]}_{\bar s}$ consists of a single isogeny class preserving homogeneous polarization when we assume n is odd for simplicity (see [37], chapter 6). It is classified by an inner form G_- of G which is compact modulo the center at all infinite places. $G_-(\mathbb{Q}_p)$ is $\mathbb{Q}_p^\times \cdot \tilde D_w^{\text{op}\times} \cdot \prod_{u\in P_\wp, u\neq w} D_u^{\text{op}\times}$ for a division algebra $\tilde D_w$ over E_w of invariant $\frac{1}{n}$, and $G_-(\mathbb{A}_f^p) \simeq G(\mathbb{A}_f^p)$ holds, that is, G and G_- are locally isomorphic except at w and ι_0 as chosen in 6.1. Take a compact open subgroup $K_- = K_{-,w}\cdot K^w$ of $G_-(\mathbb{A}_f)$ with $K_{-,w} = o^{\text{op}\times}_{\tilde D_w}$ for a maximal order $o_{\tilde D_w}$ of $\tilde D_w$. Then the underlying space of $X^{[n]}_{\bar s}$ is regarded as a Hida variety $M_{K_-}(G_-, X_-)$ where X_- is a point. The key point for this identification is a theorem of Drinfeld that formal o_w-modules of dimension one and height n are unique over an algebraically closed field and that the endomorphism ring is isomorphic to $o_{\tilde D_w}$. So the canonical homomorphism

$$H^{n-1}_{\text{ét}}(X_{\bar\eta}, \Lambda) \to H^0_{\text{ét}}(X^{[n]}_{\bar s}, R^{n-1}\psi(\Lambda)|_{X^{[n]}_{\bar s}})$$

connects the middle dimensional cohomologies of Shimura and Hida varieties in characteristic p, though the sheaf $R^{n-1}\psi(\Lambda)|_{X^{[n]}_{\bar s}}$ may seem to be complicated at first glance. But the sheaf is described, for $\Lambda = \mathbb{Q}_\ell$, by Drinfeld's reciprocity

law as formulated by Carayol [6] and proved by Harris and Taylor in [20]. This is the geometric Jacquet–Langlands correspondence. More precisely, *the geometric Jacquet–Langlands isomorphism* for G and G_-.

6.4. Reciprocity law and Taylor–Wiles systems for unitary Shimura varieties. For an irreducible automorphic representation π of $U_D(\mathbb{A}_F)$, Clozel shows the existence of the base change lift $\mathrm{BC}(\pi)$ to $U_D(\mathbb{A}_E) \simeq D^{\mathrm{op}\times}(\mathbb{A}_E)$ [9]. For an automorphic representation π of G, $\mathrm{BC}(\pi) = (\psi, \Pi_D)$ is defined as a representation of $\mathbb{A}_E^\times \times D^{\mathrm{op}\times}(\mathbb{A}_E)$ [20].

$H^i_B(\mathrm{Sh}_K(G, X), \overline{\mathbb{Q}}_\ell)$ is decomposed by the irreducible automorphic $G(\mathbb{A})$-representations $\pi = \pi_f \otimes \pi_\infty$ such that π_∞ is cohomological for the trivial coefficient. We denote by $H^i_B(\mathrm{Sh}_K(G, X), \overline{\mathbb{Q}}_\ell)[\mathrm{cusp}]$ the part where Π_D corresponds to a cuspidal representation Π_{GL_n} of $\mathrm{GL}_n(\mathbb{A}_E)$ by the Jacquet–Langlands correspondence[30].

We use a Galois parameter $\rho\colon G_E \to (\mathrm{GL}_1 \times \mathrm{GL}_n)(\overline{\mathbb{Q}}_\ell)$ attached to ψ and Π_{GL_n} ([9], [20]). We denote by P_ρ the set of the isomorphism classes of the $G(\mathbb{A}_f)$-representation π'_f such that there is some π as above which has π'_f as the finite part and Galois parameter ρ.

Then the reciprocity law of Kottwitz, which is strengthened by Clozel, takes the form

$$H^{n-1}_{\text{ét}}(\mathrm{Sh}_K, \overline{\mathbb{Q}}_\ell)[\mathrm{cusp}] = \oplus_{\pi_f \in P_\rho} V_{\pi_f} \otimes \pi_f,$$

where $V^{\mathrm{ss}}_{\pi_f}$ is described by ρ [31].

Once the reciprocity is established, we are ready to construct a Taylor–Wiles system along the lines in §5, since we have the desired vanishing theorem in §6. Assume that $\bar\rho\colon G_E \to (\mathrm{GL}_1 \times \mathrm{GL}_n)(\overline{\mathbb{F}}_\ell)$ is obtained from a Galois parameter which appear in the reciprocity law by mod ℓ-reduction. We assume that D is split at $w \nmid \ell$ and that $\bar\rho|_{G_{E_w}}$ defines an absolutely irreducible representation on the standard representation of GL_n. With these assumptions, the vanishing assumption 5.1 is satisfied by using Theorem 6.3. We take a finite set Q of finite places of E so that Q is disjoint from all ramifications, $q_u \equiv 1 \mod \ell$, the Frobenius image $\bar\rho(\mathrm{Fr}_u)$ at u is a regular semi-simple element for all $u \in Q$. The compatibility of local and global Langlands correspondences plays an important role here.

Then the identification of a deformation ring R of $\bar\rho$ and the Hecke algebra T, as well as the freeness of the middle dimensional cohomology group M localized at the maximal ideal of the Hecke algebra, follows in the minimal case by the standard machinery in §4 under restrictive assumptions to define an appropriate deformation problem and to control the tangent space[32].

[30] Many technical conditions are omitted here. For example, at any place u of E, D_u is either split or a division algebra to be able to apply the global Jacquet–Langlands correspondence to $D^{\mathrm{op}\times}(\mathbb{A}_E)$.

[31] It is conjectured that V_{π_f} is an irreducible G_E-representation of dimension n. It seems likely that the assertion about the dimension is a consequence of the recent progress on the fundamental lemma by Laumon and Ngo.

[32] The basic assumptions are that: $\bar\rho$ has a large image, D is split at all places dividing ℓ and where $\bar\rho$ is ramified, and there is some π giving $\bar\rho$ such that π is minimally ramified and spherical at places dividing ℓ. More technical conditions are needed.

As is already mentioned in §5, Harris and Taylor already used Hida varieties associated to unitary groups which are compact at infinity to prove $R = T$ [33]. Thus our approach here does not give new information on the deformation ring, but it gives us hope that a further investigation might be possible for the middle dimensional cohomology of Shimura varieties along the lines sketched in §5.

7. Concluding remarks

Finally, the author would like to mention an application of the geometric Jacquet–Langlands correspondence to the theory of cohomological ℓ-adic automorphic forms of Emerton [16] and Urban which is closely related to the Coleman–Mazur construction of ℓ-adic families of automorphic forms for $\mathrm{GL}_{2,\mathbb{Q}}$ [10]. Assume $G_{\mathbb{Q}_\ell}$ is split with a split maximal torus $T_{\mathbb{Q}_\ell}$. We fix $K^\ell \subset G(\mathbb{A}_f^\ell)$. Consider the projective limit

$$\mathrm{Sh}_{K^\ell}(G, X) = \varprojlim_{K_\ell \subset G(\mathbb{Q}_\ell)} \mathrm{Sh}_{K_\ell \cdot K^\ell}(G, X).$$

By the vanishing theorem, under the supercuspidality assumption mod ℓ at a finite place $w \nmid \ell$, the ℓ-adic continuous complex $R\Gamma_{\mathrm{cont}}(\mathrm{Sh}_{K^\ell}(G, X), E_\lambda)$ reduces to one module H concentrated at the middle dimension. The Jacquet module of the space of locally analytic vectors in H is seen as the set of the global sections of a coherent sheaf $\mathcal{E}_{G,K^\ell}$ on the ℓ-adic rigid analytic torus $\mathcal{T}_\ell$ whose $\widehat{\overline{\mathbb{Q}}}_\ell$-valued point is $\mathrm{Hom}_{\mathrm{cont}}(T_{\mathbb{Q}_\ell}(\mathbb{Q}_\ell)/\overline{Z(F) \cap K^\ell}, \widehat{\overline{\mathbb{Q}}}_\ell^\times)$ (the weight space).

On the other hand, for the compact twist G_- in 6.3, the cohomological construction using Hida varieties gives a coherent sheaf $\mathcal{E}_{G_-,K_-^\ell}$ on $\mathcal{T}_\ell$. The geometric Jacquet–Langlands isomorphism in 6.3 suggests that $\mathcal{E}_{G,K^\ell}$ is described explicitly by $\mathcal{E}_{G_-,K_-^\ell}$, where $K^{\ell,w}$ is identified with $K_-^{\ell,w}$, preserving Hecke actions outside w. So the geometric Jacquet–Langlands correspondence, which preserves $\mathbb{Z}_\ell$-lattice structures (or even structures over $\mathbb{Z}_\ell/\ell^n$), realizes a correspondence between cohomological ℓ-adic automorphic forms on G and G_-. The existence of such a correspondence for GL_2 and the Coleman–Mazur construction was questioned by Buzzard ([3] for the construction on the definite quaternion side), and answered by Chenevier [8].

The author would like to close this article with the following speculation: the functoriality principle for reductive groups should be true even for cohomological ℓ-adic automorphic forms.

[33] After this paper was written, Taylor [53] has shown a potential automorphy for a large class of Galois representations by developing the techniques discussed in this article. As a consequence, he proved the Sato–Tate conjecture for elliptic curves quite generally.

Generalising the Hardy–Littlewood method for primes

Ben Green*

Abstract. The Hardy–Littlewood method is a well-known technique in analytic number theory. Among its spectacular applications are Vinogradov's 1937 result that every sufficiently large odd number is a sum of three primes, and a related result of Chowla and Van der Corput giving an asymptotic for the number of 3-term progressions of primes, all less than N. This article surveys recent developments of the author and T. Tao, in which the Hardy–Littlewood method has been generalised to obtain, for example, an asymptotic for the number of 4-term arithmetic progressions of primes less than N.

Mathematics Subject Classification (2000). 11B25.

Keywords. Hardy–Littlewood method, prime numbers, arithmetic progressions, nilsequences.

1. Introduction

Godfrey Harold Hardy and John Edensor Littlewood wrote, in the 1920s, a famous series of papers *Some problems of "partitio numerorum"*. In these papers, whose content is elegantly surveyed by Vaughan [31], they developed techniques having their genesis in work of Hardy and Ramanujan on the partition function [18] to well-known questions in additive number theory such as Waring's problem and the Goldbach problem.

Papers III and V in the series, [16], [17], were devoted to the sequence of primes. In particular it was established on the assumption of the Generalised Riemann Hypothesis that every sufficiently large odd number is the sum of three primes. In 1937 Vinogradov [33] made a further substantial advance by removing the need for any unproved hypothesis.

The Hardy–Littlewood–Vinogradov method may be applied to give an asymptotic count for the number of solutions in primes p_i to any fixed linear equation

$$a_1 p_1 + \cdots + a_t p_t = b$$

in, say, the box $p_1, \ldots, p_t \leqslant N$, provided that at least 3 of the a_i are non-zero. This includes the three-primes result, and also the result that there are infinitely many

*This research was partially conducted during the period the author served as a Clay Research Fellow. He would like to express his sincere gratitude to the Clay Institute, and also to the Massachusetts Institute of Technology, where he was a Visiting Professor for the academic year 2005-06.

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

triples of primes $p_1 < p_2 < p_3$ in arithmetic progression, due to Chowla [4] and van der Corput [29].

More generally the Hardy–Littlewood method may also be used to investigate systems such as $\boldsymbol{A}\boldsymbol{p} = \boldsymbol{b}$, where $\boldsymbol{A}$ is an $s \times t$ matrix with integer entries and, potentially, $s > 1$. A natural example of such a system is given by the $(k-2) \times k$ matrix

$$\boldsymbol{A} := \begin{pmatrix} 1 & -2 & 1 & 0 & \dots & 0 & 0 & 0 \\ 0 & 1 & -2 & 1 & \dots & 0 & 0 & 0 \\ & & & & \dots & & & \\ 0 & 0 & 0 & 0 & \dots & 1 & -2 & 1 \end{pmatrix}, \tag{1}$$

in which case a solution to $\boldsymbol{A}\boldsymbol{p} = 0$ is just a k-term arithmetic progression of primes.

Here, unfortunately, the Hardy–Littlewood method falters in that it generally requires $t \geqslant 2s + 1$. In particular it cannot be used to handle progressions of length four or longer. There are certain special systems with fewer variables which *can* be handled. In this context we take the opportunity to mention a beautiful result of Balog [2], where it is shown that for any m there are distinct primes $p_1 < \cdots < p_m$ such that each number $\frac{1}{2}(p_i + p_j)$ is also prime, or in other words that the system

$$\begin{aligned} p_1 + p_2 &= 2p_{12} \\ &\vdots \\ p_{m-1} + p_m &= 2p_{m-1,m} \end{aligned} \tag{2}$$

has a solution in primes $p_1, \dots, p_m, p_{12}, \dots, p_{m-1,m}$. There is also a result of Heath-Brown [19], in which it is established that there are infinitely many four-term progressions in which three members are prime and the fourth is either a prime or a product of two primes.

The survey of Kumchev and Tolev [25] gives a detailed account of applications of the Hardy–Littlewood method to additive prime number theory.

The aim of this survey is to give an overview of recent joint work with Terence Tao [13], [14], [15]. Our aim, which has been partially successful, is to extend the Hardy–Littlewood method so that it is capable of handling a more-or-less arbitrary system $\boldsymbol{A}\boldsymbol{p} = \boldsymbol{b}$, subject to the proviso that we do not expect to be able to handle any system which secretly encodes a "binary" problem such as Goldbach or Twin Primes.

This is a large and somewhat technical body of work. Perhaps my main aim here is to give a guide to our work so far, pointing out ways in which the various papers fit together, and future directions we plan to take. A subsidiary aim is to focus as far as possible on key concepts, rather than on details. Of course, one would normally aim to do this in a survey article. However in our case we expect that many of these details will be substantially cleaned up in future incarnations of the theory, whilst the key concepts ought to remain more-or-less as they are.

I will say rather little about our paper [12] establishing that there are arbitrarily long arithmetic progressions of primes. Whilst there is considerable overlap between

that paper and the ideas we discuss here, those methods were somewhat "soft" whereas the flavour of our more recent work is distinctly "hard". We refer the reader to the survey of Tao in Volume II of these Proceedings, and also to the surveys [11], [23], [27], [28].

To conclude this introduction let me remark that the reader should not be under the impression that the Hardy–Littlewood method only applies to linear equations in primes, or even that this is the most popular application of the method. There has, for example, been a huge amount done on the circle of questions surrounding Waring's problem. For a survey see [32]. More generally there are many spectacular results where variants of the method are used to locate integer points on quite general varieties, provided of course that there are sufficiently many variables. The reader may consult Wooley's survey [34] for more information on this.

2. The Hardy–Littlewood heuristic

We have stated our interest in systems of linear equations in primes. While we are still somewhat lacking in theoretical results, there are heuristics which predict what answers we should expect in more-or-less any situation.

It is natural, when working with primes, to introduce the von Mangoldt function $\Lambda\colon \mathbb{N} \to \mathbb{R}_{\geqslant 0}$, defined by

$$\Lambda(n) := \begin{cases} \log p & \text{if } n = p^k \text{ is a prime power,} \\ 0 & \text{otherwise.} \end{cases}$$

The prime powers with $k \geqslant 2$ make a negligible contribution to any additive expression involving Λ. Thus, for example, the prime number theorem is equivalent to the statement that

$$\mathbb{E}_{n \leqslant N} \Lambda(n) = 1 + o(1).$$

Here we have used the very convenient notation of expectation from probability theory, setting $\mathbb{E}_{x \in X} := |X|^{-1} \sum_{x \in X}$ for any set X. The notation $o(1)$ refers to a quantity which tends to zero as $N \to \infty$.

We now discuss a version of the Hardy–Littlewood heuristic for systems of linear equations in primes. Here, and for the rest of the article, we restrict attention to homogeneous systems for simplicity of exposition.

Conjecture 2.1 (Hardy–Littlewood). Let $\boldsymbol{A}$ be a fixed $s \times t$ matrix with integer entries and such that there is at least one non-zero solution to $\boldsymbol{A}\boldsymbol{x} = 0$ with $x_1, \dots, x_t \geqslant 0$. Then

$$\mathbb{E}_{\substack{x_1,\dots,x_t \leqslant N \\ \boldsymbol{A}\boldsymbol{x}=0}} \Lambda(x_1) \dots \Lambda(x_t) = \mathfrak{S}(A)(1 + o(1))$$

as $N \to \infty$, where the *singular series* $\mathfrak{S}(A)$ is equal to a product of local factors $\prod_p \alpha_p$, where

$$\alpha_p := \left(\frac{p}{p-1}\right)^t \lim_{M\to\infty} \frac{\mathbb{P}(\boldsymbol{A}\boldsymbol{x} = 0, (x_1, p) = \cdots = (x_t, p) = 1 | \boldsymbol{x} \in [-M, M]^t)}{\mathbb{P}(\boldsymbol{A}\boldsymbol{x} = 0 | \boldsymbol{x} \in [-M, M]^t)}.$$

The singular series reflects "local obstructions" to having solutions to $\boldsymbol{A}\boldsymbol{x} = 0$ in primes; in the simple example $\boldsymbol{A} = \begin{pmatrix} 1 & 9 & -27 \end{pmatrix}$, where the associated equation $p_1 + 9p_2 - 27p_3 = 0$ has no solutions, one has $\alpha_3 = 0$. A more elegant formulation of the conjecture would include a "local obstruction at ∞" α_∞, in exchange for removing the hypothesis on $\boldsymbol{A}$.

Chowla and van der Corput's results concerning three-term progressions of primes confirm the prediction Conjecture 2.1 for the matrix $\boldsymbol{A} = \begin{pmatrix} 1 & -2 & 1 \end{pmatrix}$. From this it is easy to derive an *asymptotic* for the number of triples (p_1, p_2, p_3), $p_1 < p_2 < p_3 \leqslant N$, of primes in arithmetic progression.

Theorem 2.2 (Chowla, van der Corput, [4], [29]). *The number of triples of primes (p_1, p_2, p_3), $p_1 < p_2 < p_3 \leqslant N$, in arithmetic progression is*

$$\mathfrak{S}_3 N^2 \log^{-3} N(1 + o(1)),$$

where

$$\mathfrak{S}_3 := \frac{1}{2} \prod_{p \geqslant 3} \left(1 - \frac{1}{(p-1)^2}\right) \approx 0.3301.$$

The singular series $\mathfrak{S}_3$ is equal to $\frac{1}{4}\mathfrak{S}(\boldsymbol{A})$, where $\boldsymbol{A} = \begin{pmatrix} 1 & -2 & 1 \end{pmatrix}$, and is also half the twin prime constant.

Certain systems $\boldsymbol{A}\boldsymbol{p} = \boldsymbol{b}$ should be thought of as very difficult indeed, since their understanding implies an understanding of a binary problem such as the Goldbach or twin prime problem. If $\boldsymbol{A}$ has the property that every non-zero vector in its row span (over $\mathbb{Q}$) has at least three non-zero entries then there is no such reason to believe that it should be fantastically hard to solve.

Definition 2.3 (Non-degenerate systems). Suppose that s, t are positive integers with $t \geqslant s + 2$. We say that an $s \times t$ matrix $\boldsymbol{A}$ with integer entries is *non-degenerate* if it has rank s, and if every non-zero vector in its row span (over $\mathbb{Q}$) has at least three non-zero entries.

The reader may care to check that the system (1) defining a progression of length k is non-degenerate.

Our eventual goal is to prove Conjecture 2.1 for all non-degenerate systems. This goal may be subdivided into subgoals according to the value of s.

Conjecture 2.4 (Asymptotics for s simultaneous equations). Fix a value of $s \geqslant 1$ and suppose that $t \geqslant s + 2$ and that $\boldsymbol{A}$ is a non-degenerate $s \times t$ matrix. Then Conjecture 2.1 holds for the system $\boldsymbol{A}\boldsymbol{p} = 0$.

One can also formulate an appropriate conjecture for non-homogeneous systems $\boldsymbol{A}\boldsymbol{p} = \boldsymbol{b}$, and one would not expect to encounter significant extra difficulties in proving it. One might also try to count prime solutions to $\boldsymbol{A}\boldsymbol{p} = 0$ in which the primes p_i are subject to different constraints $p_i \leqslant N_i$, or perhaps are constrained to lie in a fixed arithmetic progression $p_i \equiv a_i \pmod{q_i}$. One would expect all of these extensions to be relatively straightforward.

The classical Hardy–Littlewood method can handle the case $s = 1$ of Conjecture 2.4. Our new developments have led to a solution of the case $s = 2$. In particular we can obtain an asymptotic for the number of 4-term arithmetic progressions of primes, all less than N:

Theorem 2.5 (Green–Tao [15]). *The number of quadruples of primes* (p_1, p_2, p_3, p_4), $p_1 < p_2 < p_3 < p_4 \leqslant N$, *in arithmetic progression is*

$$\mathfrak{S}_4 N^2 \log^{-4} N(1 + o(1)),$$

where

$$\mathfrak{S}_4 := \frac{3}{4} \prod_{p \geqslant 5} \left(1 - \frac{3p-1}{(p-1)^3}\right) \approx 0.4764.$$

3. The Hardy–Littlewood method for primes

The aim of this section is to describe the Hardy–Littlewood method as it would normally be applied to linear equations in primes. We will sketch the proof of Theorem 2.2, the asymptotic for the number of 3-term progressions of primes. This is equivalent to the $s = 1$ case of Conjecture 2.4 for the specific matrix $\boldsymbol{A} = \begin{pmatrix} 1 & -2 & 1 \end{pmatrix}$. Very similar means may be used to handle the general case $s = 1$ of that conjecture.

The Hardy–Littlewood method is, first and foremost, a method of harmonic analysis. The primes are studied by introducing the *exponential sum* (a kind of Fourier transform)

$$S(\theta) := \mathbb{E}_{n \leqslant N} \Lambda(n) e(\theta n)$$

for $\theta \in \mathbb{R}/\mathbb{Z}$, where $e(\alpha) := e^{2\pi i \alpha}$. It is the appearance of the circle $\mathbb{R}/\mathbb{Z}$ here which gives the Hardy–Littlewood method its alternative name. Now it is easy to check that

$$\mathbb{E}_{x_1, x_2, x_3 \leqslant N} \Lambda(x_1)\Lambda(x_2)\Lambda(x_3) 1_{x_1 - 2x_2 + x_3 = 0} = \int_0^1 S(\theta)^2 S(-2\theta)\, d\theta.$$

whence

$$\mathbb{E}_{\substack{x_1, x_2, x_3 \leqslant N \\ x_1 - 2x_2 + x_3 = 0}} \Lambda(x_1)\Lambda(x_2)\Lambda(x_3) = (2N + O(1)) \int_0^1 S(\theta)^2 S(-2\theta)\, d\theta. \qquad (3)$$

The method consists of gathering information about $S(\theta)$, and then using this formula to infer an asymptotic for the left-hand side.

The process of gathering information about $S(\theta)$ leads us to another key feature of the Hardy–Littlewood method: the realisation that one must split the set of θ into two classes, the *major arcs* $\mathfrak{M}$ in which $\theta \approx a/q$ for some small q and the *minor arcs* $\mathfrak{m} := [0, 1) \setminus \mathfrak{M}$. To see why, let us attempt some simple evaluations. First of all we note that

$$S(0) := \mathbb{E}_{n \leqslant N} \Lambda(n) = 1 + o(1),$$

this being equivalent to the prime number theorem. To evaluate $S(1/2)$, observe that almost all of the support of Λ is on odd numbers n, for which $e(n/2) = -1$. Thus

$$S(1/2) := \mathbb{E}_{n \leqslant N} \Lambda(n) e(n/2) = -1 + o(1).$$

The evaluation of $S(1/3)$ is a little more subtle. Most of the support of Λ is on n not divisible by 3, and for those n the character $e(n/3)$ takes two values according as $n \equiv 1 \,(\mathrm{mod}\ 3)$ or $n \equiv 2 \,(\mathrm{mod}\ 3)$. We have

$$\begin{aligned} S(1/3) &= e(1/3)\mathbb{E}_{n \leqslant N} 1_{n \equiv 1 \,(\mathrm{mod}\ 3)} \Lambda(n) + e(2/3)\mathbb{E}_{n \leqslant N} 1_{n \equiv 2 \,(\mathrm{mod}\ 3)} \Lambda(n) + o(1) \\ &= -1/2 + o(1), \end{aligned}$$

this being a consequence of the fact that the primes are asymptotically equally divided between the congruence classes $1 \,(\mathrm{mod}\ 3)$ and $2 \,(\mathrm{mod}\ 3)$.

In similar fashion one can get an estimate for $S(a/q)$ for small q, and indeed for $S(a/q+\eta)$ for sufficiently small η, if one uses the prime number theorem in arithmetic progressions. The set of such θ is called the *major arcs* and is denoted $\mathfrak{M}$. (The notion of "small q" might be $q \leqslant \log^A N$, for some fixed A. The notion of "small η" might be $|\eta| \leqslant \log^A N/qN$. The flexibility allowed here depends on what type of prime number theorem along arithmetic progressions one is assuming. Unconditionally, the best such theorem is due to Siegel and Walfisz and it is this theorem which leads to these bounds on q and $|\eta|$.)

Suppose by contrast that $\theta \notin \mathfrak{M}$, that is to say θ is not close to a/q with q small. We say that $\theta \in \mathfrak{m}$, the *minor arcs*. It is hard to imagine that in the sum

$$S(\sqrt{2} - 1) = \mathbb{E}_{n \leqslant N} \Lambda(n) e(n\sqrt{2}) \tag{4}$$

the phases $e(n\sqrt{2})$ could conspire with $\Lambda(n)$ to prevent cancellation. It turns out that indeed there *is* substantial cancellation in this sum. This was first proved by Vinogradov, and nowadays it is most readily established using an identity of Vaughan [30], which allows one to decompose (4) into three further sums which are amenable to estimation. We will discuss a variant of this method in §5. For the particular value $\theta = \sqrt{2} - 1$, and for other highly irrational values, one can obtain an estimate of the shape $|S(\theta)| \ll N^{-c}$ for some $c > 0$, which is quite remarkable since applying the best-known error term in the prime number theorem only allows one to estimate $S(0)$ with the much larger error $O(\exp(-C_\varepsilon \log^{3/5-\varepsilon} N))$. By defining parameters suitably (that is by taking a suitable value of the constant A in the precise definition

of $\mathfrak{M}$), one can arrange that $S(\theta)$ is always very small indeed on the minor arcs $\mathfrak{m}$, say

$$\sup_{\theta\in\mathfrak{m}} |S(\theta)| \ll \log^{-10} N. \tag{5}$$

Recall now the formula (3). Splitting the integral into that over $\mathfrak{M}$ and that over $\mathfrak{m}$, we see from Parseval's identity that

$$\left| \int_{\mathfrak{m}} S(\theta)^2 S(-2\theta)\, d\theta \right| \leqslant \sup_{\theta\in\mathfrak{m}} |S(\theta)| \int_0^1 |S(\theta)|^2\, d\theta \ll \frac{\log^{-9} N}{N}. \tag{6}$$

Thus in the effort to establish Theorem 2.2 the contribution from the minor arcs $\mathfrak{m}$ may essentially be ignored. The proof of that theorem is now reduced to showing that

$$\int_{\mathfrak{M}} S(\theta)^2 S(-2\theta)\, d\theta = (1+o(1))\frac{1}{N}\prod_{p\geqslant 3}\Big(1-\frac{1}{(p-1)^2}\Big).$$

Since one has asymptotic formulæ for $S(\theta)$ (and $S(-2\theta)$) on $\mathfrak{M}$, this is essentially just a computation, albeit not a particularly straightforward one.

It is instructive to look for the point in the above argument where we used the fact that $\boldsymbol{A}$ was non-degenerate, that is to say that our problem had at least three variables. Why can we not use the same ideas to solve the twin prime or Goldbach problems? The answer lies in the bound (6). In the twin prime problem we would be looking to bound

$$\left| \int_{\theta\in\mathfrak{m}} |S(\theta)|^2 e(2\theta) \right|,$$

and the only obvious means of doing this is via an inequality of the form

$$\left| \int_{\theta\in\mathfrak{m}} |S(\theta)|^2 e(2\theta) \right| \leqslant \sup_{\theta\in\mathfrak{m}} |S(\theta)|^c \int_0^1 |S(\theta)|^{2-c}\, d\theta.$$

Now, however, Parseval's identity does not permit one to place a bound on

$$\int_0^1 |S(\theta)|^{2-c}\, d\theta.$$

Indeed this whole endeavour is rather futile since heuristics predict that the minor arcs actually make a significant contribution to the asymptotic for twin primes.

An attempt to count 4-term progressions in primes via the circle method is beset by difficulties of a similar kind.

4. Exponential sums with Möbius

The presentation in the next two sections (and in our papers) is influenced by that in the beautiful book of Iwaniec and Kowalski [21].

In the previous section we described what is more-or-less the standard approach to solving linear equations in primes using the Hardy–Littlewood method. In [21, Ch. 19] one may find a very elegant variant in which the Möbius function μ is made to play a prominent rôle. As we saw above the behaviour of the exponential sum $S(\theta)$ was a little complicated to describe, depending as it does on how close to a rational θ is. By contrast the exponential sum

$$M(\theta) := \mathbb{E}_{n\leqslant N}\mu(n)e(\theta n)$$

has a very simple behaviour, as the following result of Davenport shows.

Proposition 4.1 (Davenport's bound). *We have the estimate*

$$|M(\theta)| \ll_A \log^{-A} N$$

uniformly in $\theta \in [0, 1)$ *for any* $A > 0$.

In fact on the GRH Baker and Harman [1] obtain the superior bound $|M(\theta)| \ll N^{-3/4+\varepsilon}$. By analogy with results of Salem and Zygmund [26] concerning random trigonometric series one might guess that the truth is that $\sup_{\theta\in[0,1)} |M(\theta)| \sim c\sqrt{\log N/N}$. This is far from known even on GRH; so far as I am aware no *lower* bound of the form $\sup_{\theta\in[0,1)} |M(\theta)|\sqrt{N} \to \infty$ is known.

Although Davenport's result is easy to describe its proof has the same ingredients as used in the analysis of $S(\theta)$. One must again divide $\mathbb{R}/\mathbb{Z}$ into major and minor arcs. On the major arcs one must once more use information equivalent to a prime number theorem along arithmetic progressions, that is to say information on the zeros of L-functions $L(s, \chi)$ close to the line $\Re s = 1$. On the minor arcs one uses an appropriate version of Vaughan's identity. One of the attractions of working with Möbius is that this identity takes a particularly simple form (see [21, Ch. 13] or [14]).

We offer a rough sketch of how Proposition 4.1 may be used as the main ingredient in a proof of Theorem 2.2, referring the reader to [21, Ch. 19] for the details. The key point is that one has the identity

$$\Lambda(n) = \sum_{d|n} \mu(d) \log(n/d).$$

One splits the sum over d into the ranges $d \leqslant N^{1/10}$ and $d > N^{1/10}$ (say), obtaining a decomposition $\Lambda = \Lambda^\sharp + \Lambda^\flat$. One has

$$S^\flat(\theta) := \mathbb{E}_{n\leqslant N}\Lambda^\flat(n)e(n\theta) = \sum_{d\leqslant N^{1/10}} \log d \sum_{N^{1/10}\leqslant k\leqslant N/d} \mu(k)e(\theta kd),$$

from which it follows easily using Davenport's bound that

$$S^\flat(\theta) \ll_A \log^{-A} N \tag{7}$$

uniformly in $\theta \in [0, 1)$.

One may then write the expression

$$\mathbb{E}_{\substack{x_1,x_2,x_3 \leqslant N \\ x_1-2x_2+x_3=0}} \Lambda(x_1)\Lambda(x_2)\Lambda(x_3)$$

as a sum of eight terms using the splitting $\Lambda = \Lambda^\sharp + \Lambda^\flat$. The basic idea is now that the main term $\prod_p \alpha_p$ in Theorem 2.2 comes from the term with three copies of $\Lambda^\sharp$, whilst the other 7 terms (each of which contains at least one $\Lambda^\flat$) provide a negligible contribution in view of (7) and simple variants of the formula (3).

We have extolled the virtues of the Möbius function by pointing to the aesthetic qualities of Davenport's bound. A more persuasive argument for focussing on it is the following basic metaprinciple of analytic number theory:

Principle (Möbius randomness law). *The Möbius function is highly orthogonal to any "reasonable" bounded function $f : \mathbb{N} \to \mathbb{C}$. That is to say*

$$\mathbb{E}_{n \leqslant N} \mu(n) f(n) = o(1),$$

and usually one would in fact expect

$$\mathbb{E}_{n \leqslant N} \mu(n) f(n) \ll N^{-1/2+\varepsilon}. \tag{8}$$

In the category "reasonable" in this context one would certainly include polynomials phases and other somewhat continuous objects, but one should exclude functions f which are closely related to the primes ($f = \mu$ and $f = \Lambda$, for example, are clearly not orthogonal to Möbius).

At a finer level than is relevant to our work, the Möbius randomness law is more reliable than other heuristics that one might formulate, for example concerning Λ. In [22] it is shown that

$$\mathbb{E}_{n \leqslant N} \Lambda(n)\lambda(n)e(-2\sqrt{n}) \sim cN^{-1/4},$$

where $\lambda(n) := n^{-11/2}\tau(n)$ is a normalised version of Ramanujan's τ-function. One could hardly be called naïve for expecting square root cancellation here.

5. Proving the Möbius randomness law

In the last section we mentioned a principle, the *Möbius randomness law,* which is very useful as a guiding principle in analytic number theory. Unfortunately it is not possible to prove the strong version (8) of the principle in any case – even when $f(n) \equiv 1$ it is equivalent to the Riemann hypothesis.

It is, however, possible to prove weaker estimates of the form

$$\mathbb{E}_{n \leqslant N} \mu(n) f(n) \ll_A \log^{-A} N, \tag{9}$$

for arbitrary $A > 0$, for a wide variety of functions f. Davenport's bound is precisely this result when $f(n) = e(\theta n)$ (and, furthermore, this result is uniform in θ). Similar statements are also known for polynomial phases and for Dirichlet characters (uniformly over all characters of a fixed conductor).

Now when it comes to proving an estimate of the form (9), one should think of there being two different classes of behaviour for f. In the first class are those f which are in a vague sense multiplicative, or linear combinations of a few multiplicative functions. Then the behaviour of $\mathbb{E}_{n\leqslant N}\mu(n)f(n)$ can be intimately connected with the zeros of L-functions. One has, for example, the formula

$$\sum_{n=1}^{\infty}\mu(n)\chi(n)n^{-s} = \frac{1}{L(s,\chi)}$$

for any fixed Dirichlet character χ. By the standard contour integration technique (Perron's formula) of analytic number theory one sees that $\mathbb{E}_{n\leqslant N}\mu(n)\chi(n)$ is small provided that $L(s,\chi)$ does not have zeros close to $\Re s = 1$. (In fact, as reported on [21, p. 124], there are complications caused by possible multiple zeros of L, and it is better to work first with the sum $\mathbb{E}_{n\leqslant N}\Lambda(n)\chi(n)$ of χ over primes.)

The need to consider zeros of L-functions can also be felt when considering *additive* characters $e(an/q)$, for relatively small q. Indeed any Dirichlet character to the modulus q may be expressed as a linear combination of such characters. Conversely any additive character $e(an/q)$ may be written as a linear combination of Dirichlet characters to moduli dividing q by using Gauss sums. By applying Siegel's theorem, which gives the best unconditional information concerning the location of zeros of $L(s,\chi)$ near to $\Re s = 1$, one obtains for any A the estimate

$$\mathbb{E}_{n\leqslant N}\mu(n)e(an/q) \ll_A \log^{-A} N,$$

uniformly for $q \leqslant \log^A N$. By partial summation the same estimate holds when a/q is replaced by $\theta = a/q + \eta$ for suitably small η, that is to say for all θ which lie in the set $\mathfrak{M}$ of major arcs.

We turn now to a completely different technique for bounding $\mathbb{E}_{n\leqslant N}\mu(n)f(n)$. Remarkably this is at its most effective when the previous technique fails, that is to say when f is somehow *far* from multiplicative.

Proposition 5.1 (Type I and II sums control sums with Möbius). *Let $f:\mathbb{N}\to\mathbb{C}$ be a function with $\|f\|_\infty \leqslant 1$, and suppose that the following two estimates hold.*

1. (Type I sums are small) *For all $D \leqslant N^{2/3}$, and for all sequences $(a_d)_{d=D}^{2D}$ with $\|a\|_{l^2[D,2D)} = 1$, we have*

$$\Big|\sum_{d=D}^{2D}\sum_{1\leqslant w<N/d} a_d f(wd)\Big| \ll_A N(\log N)^{-A-3}. \tag{10}$$

2. (Type II sums are small) *For all* D, W, $N^{1/3} \leqslant D \leqslant N^{2/3}$, $N^{1/3} \leqslant W \leqslant N/D$ *and all choices of complex sequences* $(a_d)_{d=D}^{2D}$, $(b_w)_{w=W}^{2W}$ *with* $\|a\|_{l^2[D,2D)} = \|b\|_{l^2[W,2W)} = 1$, *we have*

$$\Big|\sum_{d=D}^{2D}\sum_{W\leqslant w\leqslant 2W} a_d b_w f(wd)\Big| \ll_A N(\log N)^{-A-5}. \tag{11}$$

Then

$$\mathbb{E}_{n\leqslant N}\mu(n)f(n) \ll_A \log^{-A} N. \tag{12}$$

The reader may find a proof of this statement in [14, Ch. 6]. It is proved by decomposing the Möbius function into two parts using an identity of Vaughan [30]. When one multiplies by $f(n)$ and sums, one of these parts leads to Type I sums and the other to Type II sums. Note that there is considerable flexibility in arranging the ranges of D in which Type I and II estimates are required, but it is not important to have such flexibility in our arguments.

The statement of Proposition 5.1 may look complicated. What has been achieved, however, is the elimination of μ. Strictly speaking, one actually only *needs* Type I and II estimates for some rather specific choices of coefficients a_d, b_w whose definition involves μ. The important realisation is that it is best to forget about the precise forms of these coefficients, the general expressions (10) and (11) laying bare the important underlying information required of f.

Note that if f is close to multiplicative then there is no hope of obtaining enough cancellation in Type II sums to make use of Proposition 5.1. If f is actually completely multiplicative, for example, one may take $a_d = \overline{f(d)}$ and $b_w = \overline{f(w)}$ and there is manifestly no cancellation at all in (11). If this is not the case, however, then very often it *is* possible to verify the bounds (10) and (11). An example of this is a linear phase $e(\theta n)$ where θ lies in the minor arcs $\mathfrak{m}$, that is to say θ is not close to a/q with q small. By verifying these two estimates for such θ, one has from (12) that Davenport's bound holds when $\theta \in \mathfrak{m}$. This completes the proof of Davenport's bound, since the major arcs $\mathfrak{M}$ have already been handled using L-function technology.

To see how this is usually achieved in practice we refer the reader to [5, Ch. 24]. There the reader will see that a key device is the Cauchy–Schwarz inequality, which allows one to eliminate the arbitrary coefficients a_d, b_w.

In [14] there is also a discussion of this result. Although logically equivalent, this discussion takes a point of view which turns out to be invaluable when dealing with more complicated situations. Taking $f(n) = e(\theta n)$ in Proposition 5.1, we suppose that either (10) or (11) does not hold, that is to say that either a Type I or a Type II sum is large. We then *deduce* that θ must be close to a rational with small denominator, that is to say θ must be major arc. This *inverse* approach to bounding sums with Möbius means that there is no need to make an *a priori* definition of what a "major" or "minor" object is. In situations to be discussed later this helps enormously.

6. The insufficiency of harmonic analysis

What did we mean when we stated that the Hardy–Littlewood method was a method of harmonic analysis? In §3 we saw that there is a formula, (3), which expresses the number of 3-term progressions in a set (such as the primes) in terms of the exponential sum over that set. The following proposition is an easy consequence of a slightly generalised version of that formula:

Proposition 6.1. *Suppose that* $f_1, f_2, f_3 \colon [N] \to [-1, 1]$ *are three functions and that*

$$|\mathbb{E}_{\substack{x_1,x_2,x_3 \\ x_1-2x_2+x_3=0}} f_1(x_1) f_2(x_2) f_3(x_3)| \geqslant \delta.$$

Then for any $i = 1, 2, 3$ *we have*

$$\sup_{\theta\in[0,1)} |\mathbb{E}_{n\leqslant N} f_i(n)e(n\theta)| \geqslant (1 + o(1))\delta/2. \tag{13}$$

We think of this as a statement the effect that the linear exponentials $e(n\theta)$ form a *characteristic system* for the linear equation $x_1-2x_2+x_3 = 0$. It follows immediately from Proposition 6.1 and Davenport's bound that Möbius exhibits cancellation along 3-term APs, in the sense that

$$\mathbb{E}_{\substack{x_1,x_2,x_3 \\ x_1-2x_2+x_3=0}} \mu(x_1)\mu(x_2)\mu(x_3) \ll_A \log^{-A} N.$$

Proposition 6.1 is also useful for counting progressions in sets $A \subseteq [N]$, in which context one would take various of the f_i to equal the *balanced function* $f_A := 1_A - \alpha$ of A, where $\alpha := |A|/N$. It is easy to deduce from Proposition 6.1 the following variant, which covers this situation.

Proposition 6.2. *Suppose that* $A \subseteq [N]$ *is a set with* $|A| = \alpha N$ *and that*

$$|\mathbb{E}_{\substack{x_1,x_2,x_3 \\ x_1-2x_2+x_3=0}} 1_A(x_1)1_A(x_2)1_A(x_3) - \alpha^3| \geqslant \delta.$$

Write

$$f_A := 1_A - \alpha$$

for the balanced function of A*. Then we have*

$$\sup_{\theta\in[0,1)} |\mathbb{E}_{n\leqslant N} f_A(n)e(n\theta)| \geqslant (1 + o(1))\delta/14. \tag{14}$$

If a function f correlates with a linear exponential as in (13) or (14) then we sometimes say that f has *linear bias*.

In this section we give examples which show that the linear exponentials do not form a characteristic system for the pair of equations $x_1-2x_2+x_3 = x_2-2x_3+x_4 = 0$ defining a four-term progression. These examples show, in a strong sense, that the Hardy–Littlewood method in its traditional form *cannot* be used to study 4-term

progressions. An interesting feature of these two examples is that they were both essentially discovered by Furstenberg and Weiss [6] in the context of ergodic theory. Much of our work is paralleled in, and in fact motivated by, the work of the ergodic theory community. See the lecture by Tao in Volume II of these proceedings, or the elegant surveys of Kra [23], [24] for more discussion and references. The examples were rediscovered, in the finite setting, by Gowers [8], [10] in his work on Szemerédi's theorem.

Example 6.1 (Quadratic and generalised quadratic behaviour). Let $\alpha > 0$ be a small, fixed, real number, and define the following sets. Let A_1 be defined by

$$A_1 := \{x \in [N] : \{x^2\sqrt{2}\} \in [-\alpha/2, \alpha/2]\}$$

(here, $\{t\}$ denotes the fractional part of t, and lies in $(-1/2, 1/2]$). Define also

$$A_2 := \{x \in [N] : \{x\sqrt{2}\{x\sqrt{3}\}\} \in [-\alpha/2, \alpha/2]\}.$$

Now it can be shown (not altogether straightforwardly) that $|A_1|, |A_2| \approx \alpha N$, and furthermore that

$$\sup_{\theta\in[0,1)} |\mathbb{E}_{n\leqslant N} f_A(n)e(n\theta)| \ll N^{-c}$$

for $i = 1, 2$. Thus neither of the sets A_1, A_2 has linear bias in a rather strong sense. If the analogue of Proposition 6.2 were true for four term progressions, then, one would expect both A_1 and A_2 to have approximately $\alpha^4 N^2/6$ four-term progressions.

The set A_1, however, has considerably more 4-term APs that this in view of the identity

$$x^2 - 3(x + d)^2 + 3(x + 2d)^3 - (x + 3d)^2 = 0. \tag{15}$$

This means that if $x, x + d, x + 2d \in A_1$ then

$$\{(x + 3d)^2\sqrt{2}\} \in [-7\alpha/2, 7\alpha/2],$$

which would suggest that $x + 3d \in A_1$ with probability $\gg 1$. In fact one can show using harmonic analysis that (15) is the only relevant constraint in the sense that

$$\begin{aligned}\mathbb{P}(x + 3d \in A_1 | x, x + d, x + 2d \in A_1)& \\ \approx \mathbb{P}(y_1 - 3y_2 + 3y_3 \in [-1, 1] | y_1, y_2, y_3 \in [-1, 1]) &= 8/27.\end{aligned}$$

The number of 3-term progressions in A_1 is $\approx \alpha^3 N/4$, and so it follows that the number of 4-term progressions in A_1 is $\approx 2\alpha^3/27$.

The analysis of A_2 is rather more complicated. However one may check that if $|\{x\sqrt{3}\}|, |\{d\sqrt{3}\}| \leqslant 1/10$ and if $|\{y\sqrt{2}\{y\sqrt{3}\}\}| \leqslant \alpha/10$ for $y = x, x + d, x + 2d$, then $x + 3d \in A_2$. One can show that there are $\gg \alpha^3 N^2$ choices of x, d satisfying these constraints, and hence once again A_2 contains $\gg \alpha^3 N^2$ 4-term progressions.

7. Generalised quadratic obstructions

We saw in the last section that the set of linear exponentials $e(\theta n)$ is not a characteristic system for 4-term progressions. There we saw examples involving quadratics $n^2\theta$ and generalised quadratics $n\theta_1\{n\theta_2\}$, and these must clearly be addressed by any generalisation of Propositions 6.1 and 6.2 to 4-term APs. Somewhat remarkably, these quadratic and generalised quadratic examples are in a sense the only ones.

Proposition 7.1. *Suppose that $f_1, f_2, f_3, f_4 \colon [N] \to [-1, 1]$ are four functions and that*

$$|\mathbb{E}_{\substack{x_1,x_2,x_3,x_4 \\ x_1-2x_2+x_3=0 \\ x_2-2x_3+x_4=0}} f_1(x_1) f_2(x_2) f_3(x_3) f_4(x_4)| \geqslant \delta. \tag{16}$$

Then for any $i = 1, 2, 3, 4$ there is a generalised quadratic polynomial

$$\phi(n) = \sum_{r,s \leqslant C_1(\delta)} \beta_{rs}\{\theta_r n\}\{\theta_s n\} + \gamma_r\{\theta_r n\}, \tag{17}$$

where $\beta_{rs}, \gamma_r, \theta_r \in \mathbb{R}$, such that

$$|\mathbb{E}_{n \leqslant N} f_i(n) e(\phi(n))| \geqslant c_2(\delta).$$

We can take $C_1(\delta) \sim \exp(\delta^{-C})$ and $c_2(\delta) \sim \exp(-\delta^{-C})$.

Note that

$$\theta n^2 = 100\theta N^2 \left\{ \frac{n}{10N} \right\}^2$$

and

$$\theta_1 n\{\theta_2 n\} = 10\theta_1 N \left\{ \frac{n}{10N} \right\} \{\theta_2 n\}$$

for $n \leqslant N$, and so the phases which can be written in the form (17) do include all those which were discovered to be relevant in the preceding section.

The proof of Proposition 7.1 is given in [13]. It builds on earlier work of Gowers [8], [10]. In [13] (see also [14]) several results of a related nature are given, in which other characteristic systems for the equation $x_1 - 2x_2 + x_3 = x_2 - 2x_3 + x_4 = 0$ are given. These systems all have a "quadratic" flavour. We will discuss the family of 2-*step nilsequences*, which is perhaps the most conceptually appealing, in §9. In §11 we will mention the family of *local quadratics*, which are useful for computations involving the Möbius function. The only real merit of the generalised quadratic phases $e(\phi(n))$ discussed above is that they are easy to describe from first principles.

8. The Gowers norms and inverse theorems

The proof of Proposition 7.1 is long and complicated: there does not seem to be anything so simple as Formula (3) in the world of 4-term progressions. Very roughly

speaking one assumes that (16) holds, and then one proceeds to place more and more structure on each function f_i until eventually one establishes that f_i correlates with a generalised quadratic phase. There is a finite field setting for this argument, and we would recommend that the interested reader read this first: it may be found in [13, Ch. 5]. The ICM lecture of Gowers [9] is a fine introduction to the ideas in his paper [8], which is the foundation of our work.

There is only one part of the existing theory which we feel sure will play some rôle in future incarnations of these methods. This is the first step in the long series of deductions from (16), in which one shows that each f_i has large *Gowers norm*. For the purposes of this exposition[1] we define the Gowers U^2-norm $\|f\|_{U^2}$ of a function $f : [N] \to [-1, 1]$ by

$$\|f\|_{U^2}^4 := \mathbb{E}_{\substack{x_{00},x_{01},x_{10},x_{11}\leqslant N \\ x_{00}+x_{11}=x_{01}+x_{10}}} f(x_{00}) f(x_{01}) f(x_{10}) f(x_{11}),$$

which is a sort of average of f over two dimensional parallelograms. The U^k norm, $k \geqslant 3$, is an average of f over k-dimensional parallelepipeds. Written down formally it looks much more complicated than it is:

$$\|f\|_{U^k}^{2^k} := \mathbb{E}_{\substack{x_{0,\dots,0},\dots,x_{1,\dots,1} \\ x_{\omega(1)}+x_{\omega(2)}=x_{\omega(3)}+x_{\omega(4)}}} f(x_{0,\dots,0}) \dots f(x_{1,\dots,1}),$$

where there are 2^k variables x_ω, $\omega = (\omega_1, \dots, \omega_k) \in \{0, 1\}^k$, and the constraints range over all quadruples $(\omega^{(1)}, \omega^{(2)}, \omega^{(3)}, \omega^{(4)}) \in (\{0, 1\}^k)^4$ with $\omega^{(1)}+\omega^{(2)} = \omega^{(3)}+\omega^{(4)}$.

The Gowers U^k norm governs the behaviour of any non-degenerate system $\boldsymbol{A}\boldsymbol{x} = 0$ in which $\boldsymbol{A}$ has $(k - 1)$ rows.

Proposition 8.1 (Generalised von Neumann theorem). *Suppose that $\boldsymbol{A}$ is a non-degenerate $s \times t$ matrix with integer entries. Suppose that $f_1, \dots, f_t : [N] \to [-1, 1]$ are functions and that*

$$|\mathbb{E}_{\substack{x_1,\dots,x_t \\ \boldsymbol{A}\boldsymbol{x}=0}} f_1(x_1) \dots f_t(x_t)| \geqslant \delta.$$

Then for each $i = 1, \dots, t$ we have

$$\|f_i\|_{U^{s+1}} \geqslant c_{\boldsymbol{A}}\delta.$$

The proof involves $s + 1$ applications of the Cauchy–Schwarz inequality. In this generality, the result was obtained in [14], though the proof technique is the same as in [10]. There are results in ergodic theory of the same general type, in which "non-conventional ergodic averages" are bounded using seminorms which are analogous to the U^k-norms: see [20].

[1] In practice we do all our work on the group $\mathbb{Z}/N'\mathbb{Z}$ for some prime $N' \geqslant N$ with $N' \approx M(\boldsymbol{A})N$, where $M(\boldsymbol{A})$ is some constant depending on the system of equations $\boldsymbol{A}\boldsymbol{x} = 0$ one is interested in. One advantage of this is that the number of solutions to $\boldsymbol{A}\boldsymbol{x} = 0$ in $\mathbb{Z}/N'\mathbb{Z}$ is much easier to count than the number of solutions in $[N]$. The Gowers norms defined here differ from the Gowers norms in those settings by constant factors, so for expository purposes they may be thought of as the same. In the group setting the constant $c_{\boldsymbol{A}}$ in Proposition 8.1 is simply 1.

Taking $s = k-2$ and $\boldsymbol{A}$ as in (1), we see that in particular the Gowers U^{k-1}-norm "controls" k-term progressions. The Gowers norms are, of course, themselves defined by a system of linear equations, and so they must be studied as part of a generalised Hardy–Littlewood method with as broad a scope as we would like. The Generalised von Neumann Theorem may be regarded as a statement to the effect that in a sense they represent the *only* systems of equations that need to be studied.

The Gowers norms do not feature in the classical Hardy–Littlewood method. It is, however, possible to prove a somewhat weaker version of Proposition 6.1 by combining the case $k = 3$ of Proposition 8.1 with the following *inverse theorem*:

Proposition 8.2 (Inverse theorem for U^2). *Suppose that N is large and that $f : [N] \to [-1, 1]$ is a function with $\|f\|_{U^2} \geqslant \delta$. Then we have*

$$\sup_{\theta\in[0,1)} |\mathbb{E}_{n\leqslant N} f(n)e(n\theta)| \geqslant 2\delta^2.$$

To prove this we note the formula

$$\mathbb{E}_{x_{00},x_{01},x_{10},x_{11}} f(x_{00})f(x_{01})f(x_{10})f(x_{11})1_{x_{00}+x_{11}=x_{01}+x_{10}} = \int_0^1 |\hat{f}(\theta)|^4\, d\theta,$$

where $\hat{f}(\theta) := \mathbb{E}_{n\leqslant N} f(n)e(n\theta)$. This implies that

$$\|f\|_{U^2}^4 = (3N + O(1))\|\hat{f}\|_4^4.$$

In view of the fact that $\|\hat{f}\|_2^2 \leqslant 1/N$, this and the assumption that $\|f\|_{U^2} \geqslant \delta$ imply that

$$\|\hat{f}\|_\infty^2 \geqslant (3 + o(1))\delta^4,$$

which implies the result.

This argument should be compared to the argument in (6), to which it corresponds rather closely.

To deduce Proposition 6.1 by passing through Proposition 8.2 is rather perverse, since the derivation is longer than the one that proceeds via an analogue of (3) and it leads to worse dependencies. With our current technology, however, this is the only method which is amenable to generalisation.

Similarly, one may deduce Proposition 7.1 from Proposition 8.1 and the following result.

Proposition 8.3 (Inverse theorem for the U^3-norm). *Suppose that $f : [N] \to \mathbb{R}$ is a function for which $\|f\|_\infty \leqslant 1$ and $\|f\|_{U^3} \geqslant \delta$. Then there is a generalised quadratic phase*

$$\phi(n) = \sum_{r,s\leqslant C_1(\delta)} \beta_{rs}\{\theta_r n\}\{\theta_s n\} + \gamma_r\{\theta_r n\}, \tag{18}$$

where $\beta_{rs}, \gamma_r, \theta_r \in \mathbb{R}$, such that

$$|\mathbb{E}_{n\leqslant N} f(n)e(\phi(n))| \geqslant c_2(\delta).$$

We can take $C_1(\delta) \sim \exp(\delta^{-C})$ and $c_2(\delta) \sim \exp(-\delta^{-C})$.

This result (and variations of it involving other "quadratic families") is in fact the main theorem in [13].

As we mentioned, one may find a series of seminorms which are analogous to the Gowers norms in the ergodic-theoretic work of Host and Kra [20]. There are no such seminorms in the related work of Ziegler [35], however, and this suggests that (as in the classical case) the Gowers norms may not be completely fundamental to a generalised Hardy–Littlewood method.

9. Nilsequences

In the previous section we introduced the Gowers U^k-norms, and stated inverse theorems for the U^2- and U^3-norms. These inverse theorems provide lists of rather algebraic functions which are *characteristic* for a given system of equations $\boldsymbol{A}\boldsymbol{x} = 0$. Roughly speaking, the linear phases $e(\theta n)$ are characteristic for single linear equations in which $\boldsymbol{A}$ is a $1 \times t$ matrix. Generalised quadratic phases $e(\phi(n))$ are characteristic for pairs of linear equations in which $\boldsymbol{A}$ is a non-degenerate $2 \times t$ matrix.

These two results leave open the question of whether there is a similar list of functions which is characteristic for the U^k-norm, $k \geqslant 4$ and hence, by the Generalised von Neumann Theorem, for non-degenerate systems defined by an $s \times t$ matrix with $s \geqslant 3$. The form of Propositions 8.2 and 8.3 does not suggest a particularly natural form for such a result, however, and indeed Proposition 8.2 is already rather unnatural-looking.

To make more natural statements, we introduce a class of functions called *nilsequences*.

Definition 9.1. Let G be a connected, simply connected, k-step nilpotent Lie group. That is, the central series $G_0 := G$, $G_{i+1} = [G, G_i]$ terminates with $G_k = \{e\}$. Let $\Gamma \subseteq G$ be a discrete, cocompact subgroup. The quotient G/Γ is then called a k-step nilmanifold. The group G acts on G/Γ via the map $T_g(x\Gamma) = xg\Gamma$. If $F\colon G/\Gamma \to \mathbb{C}$ is a bounded, Lipschitz function and $x \in G/\Gamma$ then we refer to the sequence $(F(T_g^n \cdot x))_{n\in\mathbb{N}}$ as a k-step nilsequence.

By analogy with the results of Host and Kra [20] in ergodic theory, we expect the collection of $(k-1)$-step nilsequences to be characteristic for the U^k-norm. The following conjecture is one of the guiding principles of the generalised Hardy–Littlewood method.

Conjecture 9.2 (Inverse conjecture for U^k-norms). Suppose that $k \geqslant 2$ and that $f\colon [N] \to [-1, 1]$ has $\|f\|_{U^k} \geqslant \delta$. Then there is a $(k-1)$-step nilmanifold G/Γ with dimension at most $C_{1,k}(\delta)$, together with a function $F\colon G/\Gamma \to \mathbb{C}$ with $\|F\|_\infty \leqslant 1$ and Lipschitz constant at most $C_{2,k}(\delta)$ and elements $g \in G$, $x \in G/\Gamma$ such that

$$|\mathbb{E}_{n\leqslant N} f(n)F(T_g^n \cdot x)| \geqslant c_{3,k}(\delta). \tag{19}$$

We can at least be sure that Conjecture 9.2 is no more complicated than necessary, since in [13, Ch. 12] we showed that if a bounded function f correlates with a $(k-1)$-step nilsequence as in (19) then f *does* have large Gowers U^k-norm. This, incidentally, is another reason to believe that the Gowers norms play a fundamental rôle in the theory. It is not the case that correlation of a function f with a $(k-1)$-step nilsequence prohibits f from enjoying cancellation along k-term arithmetic progressions, for example. In the case $k = 3$ an example of this phenomenon is given by the function f which equals α for $1 \leqslant n \leqslant N/3$ and -1 for $N/3 < n \leqslant N$, where α is the root between 1 and 2 of $\alpha^3 - \alpha^2 + 3\alpha - 4 = 0$. This f correlates with the constant nilsequence 1 yet exhibits cancellation along 3-term progressions, as the reader may care to check.

Conjecture 9.2 seems, at first sight, to be completely unrelated to Propositions 8.2 and 8.3. However after a moment's thought one realises that a linear phase $e(\theta n)$ can be regarded as a 1-step nilsequence in which $G = \mathbb{R}$, $\Gamma = \mathbb{Z}$, $g = \theta$ and $x = 0$. Thus Proposition 8.2 immediately implies the case $k = 2$ of Conjecture 9.2.

The case $k = 3$ is proved in [13]. One first proves Proposition 8.3, and then one shows how any generalised quadratic phase $e(\phi(n))$ may be approximated by a 2-step nilsequence. Let us discuss a simple example, the *Heisenberg nilmanifold*, to convince the reader that 2-step nilsequences can give rise to "generalised quadratic" behaviour.

Example 9.1 (The Heisenberg nilmanifold). Consider

$$G := \begin{pmatrix} 1 & \mathbb{R} & \mathbb{R} \\ 0 & 1 & \mathbb{R} \\ 0 & 0 & 1 \end{pmatrix}; \quad \Gamma := \begin{pmatrix} 1 & \mathbb{Z} & \mathbb{Z} \\ 0 & 1 & \mathbb{Z} \\ 0 & 0 & 1 \end{pmatrix}.$$

Then G/Γ is a 2-step nilmanifold. By using the identification

$$(x, y, z) \equiv \begin{pmatrix} 1 & x & y \\ 0 & 1 & z \\ 0 & 0 & 1 \end{pmatrix} \Gamma,$$

we can identify G/Γ (as a set) with $\mathbb{R}^3$, quotiented out by the equivalence relations

$$(x, y, z) \sim (x + a, y + b + cx, z + c) \quad \text{for all } a, b, c \in \mathbb{Z}.$$

This can in turn be coordinatised by the cylinder $(\mathbb{R}/\mathbb{Z})^2 \times [-1/2, 1/2]$ with the identification $(x, y, -1/2) \sim (x, x + y, 1/2)$. Let $F\colon G/\Gamma \to \mathbb{C}$ be a function. We may lift this to a function $\widetilde{F}\colon G \to \mathbb{C}$, defined by $\widetilde{F}(g) := F(g\Gamma)$. In coordinates, this lift takes the form

$$\widetilde{F}(x, y, z) = F(x \pmod 1, y - [z]x \pmod 1, \{z\})$$

where $[z] = z - \{z\}$ is the nearest integer to x. Let

$$g := \begin{pmatrix} 1 & \alpha & \beta \\ 0 & 1 & \gamma \\ 0 & 0 & 1 \end{pmatrix}$$

be an element of G. Then the shift $T_g : G \to G$ is given by

$$T_g(x, y, z) = (x + \alpha, y + \beta + \gamma x, z + \gamma).$$

A short induction confirms, for example, that

$$T_g^n(0, 0, 0) = (n\alpha, n\beta + \tfrac{1}{2}n(n+1)\alpha\gamma, n\gamma).$$

Therefore if $F : G/\Gamma \to G/\Gamma$ is any Lipschitz function, written as a function $F : (\mathbb{R}/\mathbb{Z})^2 \times [-1/2, 1/2] \to \mathbb{C}$ with $F(-1/2, y, z) = F(1/2, y + z, z)$, then we have

$$F(T_g^n(0, 0, 0)) = F(n\alpha \pmod 1, n\beta + \tfrac{1}{2}n(n+1)\alpha\gamma - [n\gamma]n\alpha \pmod 1, \{n\gamma\}).$$

The term $[n\gamma]n\alpha$ which appears here certainly exhibits a sort of generalised quadratic behaviour. For a complete description of how an arbitrary generalised quadratic phase $e(\phi(n))$ can be approximated by a two-step nilsequence, we refer the reader to [13, Ch. 12].

Let us conclude this section by stating, for the reader's convenience, a result/conjecture which summarises much of our discussion so far in one place.

Theorem 9.3 (Green–Tao [13]). *We have the following two statements.*

(i) (Generalised von Neumann) *Suppose that s and t are positive integers with $s + 2 \leqslant t$. Suppose that $\boldsymbol{A}$ is a non-degenerate $s \times t$ matrix with integer entries. Suppose that $f_1, \dots, f_t : [N] \to [-1, 1]$ are functions and that*

$$|\mathbb{E}_{\substack{x_1,\dots,x_t \\ \boldsymbol{A}\boldsymbol{x}=0}} f_1(x_1) \dots f_t(x_t)| \geqslant \delta. \tag{20}$$

Then for each $i = 1, \dots, t$ we have

$$\|f_i\|_{U^{s+1}} \geqslant c_{\boldsymbol{A}}\delta.$$

(ii) (Gowers inverse result: proved for $k = 2, 3$, conjectural for $k \geqslant 4$) *Suppose that $f : [N] \to [-1, 1]$ has $\|f\|_{U^k} \geqslant \delta$. Then there is a $(k-1)$-step nilmanifold G/Γ with dimension at most $C_{1,k}(\delta)$, together with a function $F : G/\Gamma \to \mathbb{C}$ with $\|F\|_\infty \leqslant 1$ and Lipschitz constant at most $C_{2,k}(\delta)$ and elements $g \in G$, $x \in G/\Gamma$ such that*

$$|\mathbb{E}_{n \leqslant N} f(n) F(T_g^n \cdot x)| \geqslant c_{3,k}(\delta). \tag{21}$$

In particular when $s = 1$ or 2 and (20) holds for some $\boldsymbol{A}$ and some δ then for each $i = 1, \dots, t$ there is a 2-step nilsequence $(F(T_g^n \cdot x))_{n \in \mathbb{N}}$ such that

$$|\mathbb{E}_{n \leqslant N} f_i(n) F(T_g^n \cdot x)| \geqslant c_{\boldsymbol{A}}(\delta). \tag{22}$$

10. Working with the primes

Let us suppose that we wish to count four-term progressions in the primes. One might try to apply Theorem 9.3 with the functions f_i equal to the balanced function of A, the set of primes $p \leqslant N$, and then hope to rule out a correlation such as (21) for some $\delta = o(\alpha^t)$ (here, of course, $\alpha \approx \log^{-1} N$ by the prime number theorem). This would then lead to an asymptotic using various instances of (20) together with the triangle inequality.

There are two reasons why this is a hopeless strategy. First of all, the primes *do* correlate with nilsequences. In fact since all primes other than 2 are odd it is easy to see that

$$\mathbb{E}_{n \leqslant N} f_A(n) e(n/2) \approx -\alpha.$$

There is a way to circumvent this problem, which we call the W-trick. The idea is that if $W = 2 \times 3 \times \cdots \times w(N)$ is the product of the first several primes, then for any b coprime to W the set

$$A_b := \{n \leqslant N : Wn + b \text{ is prime}\}$$

does not exhibit significant bias in progressions with common difference $q \leqslant w(N)$. One can then count 4-term progressions in the primes by counting 4-term progressions in $A_{b_1} \times \ldots A_{b_4}$ for each quadruple $(b_1, \ldots, b_4) \in (\mathbb{Z}/W\mathbb{Z})^{\times 4}$ in arithmetic progression and adding.

We refer to any set A_b as a set of "W-tricked primes". In practice one is only free to take $w(N) \sim \log\log N$, since one must be able to understand the distribution of primes in progressions with common difference W (note that even on GRH one could only take $w(N) \sim c \log N$). Even assuming we could obtain optimal results concerning the correlation of the W-tricked primes with 2-step nilsequences, this information will be very weak indeed.

This highlights a more serious problem with the suggested strategy. Suppose that $A \subseteq [N]$ is a set of density α for which there is no obvious reason why A should have an unexpectedly large or small number of 4-term APs, that is to say for which we might hope to prove that

$$\mathbb{E}_{\substack{x_1,x_2,x_3,x_4 \\ x_1-2x_2+x_3=0 \\ x_2-2x_3+x_4=0}} 1_A(x_1)1_A(x_2)1_A(x_3)1_A(x_4) \approx \alpha^4. \tag{23}$$

For example, A might be the W-tricked primes less than N, in which case $\alpha \sim \frac{W}{\phi(W)} \log^{-1} N$.

We might prove (23) by writing $1_A = \alpha + f_A$, expanding as the sum of sixteen terms, and showing that fifteen of these are $o(\alpha^4)$ by appealing to Theorem 9.3, and ruling out a correlation with a 2-step nilsequence as in (22). Unfortunately we will be operating with $\delta = o(\alpha^4) \ll \log^{-4+\varepsilon} N$, and the dependence of $c_A(\delta)$ on δ is very weak, being of the form $\exp(-\delta^{-C})$. Thus we are asking to rule out the possibility

that

$$|\mathbb{E}_{n\leqslant N} f_A(n) F(T_g^n \cdot x)| \gg \exp(-\log^C N)$$

for some potentially rather large C. This is a problem, since one would never expect more than square root cancellation in any such expression. In fact for the W-tricked primes one only has a small amount (depending on $w(N)$) of potential cancellation to work with and to all intents and purposes one should not bank on having available any estimate stronger than

$$\mathbb{E}_{n\leqslant N} f_A(n) F(T_g^n \cdot x) = o(1).$$

What one really needs is a version of Proposition 16 which applies to functions which need not be bounded by 1. Then one could hope to work with the von Mangoldt function Λ instead of the far less natural characteristic function 1_A, or more accurately with W-tricked variants of the von Mangoldt function such as

$$\Lambda_{b,W}(n) := \frac{\phi(W)}{W}\Lambda(Wn + b).$$

Such a result is the main result of our forthcoming paper [15]. It would take us too far afield to say anything concerning its proof, other than that it uses one of the key tools from our paper [12] on long progressions of primes, the "ergodic transference" technology of [12, Chs. 6,7,8].

Proposition 10.1 (Transference principle, [15]). *Suppose that* $\nu\colon [N] \to \mathbb{R}^+$ *is a* pseudorandom measure. *Then*

(i) *The generalised von Neumann theorem, Theorem* 9.3 (i)*, continues to hold for functions* $f_1, \dots, f_t\colon [N] \to \mathbb{R}^+$ *such that* $|f_i(x)| \leqslant 1 + \nu(x)$ *pointwise* (*the value of* $c_{\boldsymbol{A}}$ *may need to be reduced slightly*).

(ii) *If the Gowers inverse conjecture, Theorem* 9.3 (ii)*, holds for a given value of* k *then it continues to hold for a function* f *such that* $|f(x)| \leqslant 1+\nu(x)$ *pointwise. In particular such an extension of the Gowers inverse conjecture is true when* $k = 2, 3$.

The reader may consult [12, Ch. 3] for a definition of the term *pseudorandom measure* and a discussion concerning it. For the purposes of this article the reader can merely accept that there is such a notion, and furthermore that one may construct a pseudorandom measure $\nu\colon [N] \to \mathbb{R}^+$ such that $\nu+1$ dominates any fixed W-tricked von Mangoldt function $\Lambda_{W,b}$. The construction of ν comes from sieve theoretic ideas originating with Selberg. The confirmation that ν is pseudorandom is essentially due, in a very different context, to Goldston and Yıldırım [7].

Applying these two results, one may see that Conjecture 2.1 for a given non-degenerate $s \times t$ matrix $\boldsymbol{A}$ is a consequence of the Gowers inverse conjecture in the case $k = s + 1$ together with a bound of the form

$$\mathbb{E}_{n\leqslant N}(\Lambda_{b,W}(n) - 1) F(T_g^n \cdot x) = o_{G/\Gamma,F}(1) \tag{24}$$

for every s-step nilsequence $(F(T_g^n \cdot x))_{n\in\mathbb{N}}$.

By effecting a decomposition of $\Lambda_{b,W}$ as $\Lambda_{b,W}^\sharp + \Lambda_{b,W}^\flat$ rather like that in §4, the proof of this statement may be further reduced to a similar result for the Möbius function:

Conjecture 10.2 (Möbius and nilsequences). For all $A > 0$ we have the bound

$$\mathbb{E}_{n\leqslant N}\mu(n)F(T_g^n \cdot x) \ll_{A,G/\Gamma,F} \log^{-A} N$$

for every k-step nilsequence $(F(T_g^n \cdot x))_{n\in\mathbb{N}}$.

Note that we require more cancellation (a power of a logarithm) here than in (24). This is because in passing from μ to $\Lambda_{b,W}^\flat$ one loses a logarithm in performing partial summation as in the derivation of (7). The method we have in mind to prove Conjecture 10.2, however, is likely to give this strong cancellation at no extra cost.

Conjecture 10.2 posits a rather vast generalisation of Davenport's bound. The conjecture is, of course, highly plausible in view of the Möbius randomness law.

Let us remark that the derivation of (24) from Conjecture 10.2 is not at all immediate, since one must also handle the contribution from $\Lambda_{b,W}^\sharp$. To do this one uses methods of classical analytic number theory rather similar to those of Goldston and Yıldırım [7].

11. Möbius and nilsequences

The main result of [14] is a proof of Conjecture 10.2 in the case $k = 2$. This leads, by the reasoning outlined in the previous section, to a proof of Conjecture 2.4 in the case $s = 2$.

We remarked that the classical Hardy–Littlewood method was a technique of harmonic analysis. We also highlighted the idea of dividing into major and minor arcs. We have said much on the subject of generalising the underlying harmonic analysis, but as yet there has been nothing said about a suitable extension of major and minor arcs. In this section we describe such an extension by making some remarks concerning the proof of the case $k = 2$ of Conjecture 10.2.

In §5 we discussed how bounds on Type I and II sums may be used to show that a given function f does not correlate with Möbius. Recalling our "inverse" strategy for proving Davenport's bound, one might be tempted to go straight into Proposition 5.1 with $f(n) = F(T_g^n \cdot x)$, a 2-step nilsequence, posit largeness of either a Type I or a Type II sum, and then use this to say that the nilsequence is somehow "major arc". One might then hope to handle the major nilsequences by some other method, perhaps the theory of L-functions.

Such an attempt is a little too simplistic, for the following reason. Returning to the 1-step case, note that the sum of two 1-step nilsequences is also a 1-step nilsequence (on the product nilmanifold $G_1/\Gamma_1 \times G_2/\Gamma_2$). In particular, the function

$f(n) = e(n/5) + e(n\sqrt{2})$ is a 1-step nilsequence. We know, however, that to handle correlation of Möbius with $e(n/5)$ we need to know something about L-functions, whereas we do not have an L-function method of handling $e(n\sqrt{2})$. This suggests that some sort of preliminary decomposition of the function f is in order, and such a suggestion turns out to be correct.

In the 2-step case, a nilsequence $F(T_g^n \cdot x)$ can be decomposed into *local quadratics*. These are objects of the form

$$f(n) := 1_{B_N}(n)e(\phi(n)), \tag{25}$$

where B_N is a set of the form

$$B_N := \{n : N/2 \leqslant n < N : F_1(n) \neq 0\}$$

for some 1-step nilsequence F_1 depending on F, G/Γ, g and x, and $\phi\colon B_N \to \mathbb{R}/\mathbb{Z}$ is *locally quadratic*. This means that one may unambiguously define the second derivative $\phi''(h_1, h_2)$ to equal

$$\phi(x + h_1 + h_2) - \phi(x + h_1) - \phi(x + h_2) + \phi(x)$$

for any x such that $x, x + h_1, x + h_2, x + h_1 + h_2 \in B_N$.

It turns out that for the purposes of analysing Type I and II sums the cutoff 1_{B_N} plays a subservient rôle. The phase ϕ, on the other hand, is crucial. The bulk of [14] is devoted to showing that if either a Type I or a Type II sum involving some f as in (25) is large, then ϕ is *major arc*. This is a direct analogue of the proof of Davenport's bound as phrased at the end of §5 (the "inverse" approach). Roughly speaking, ϕ is said to be major arc if $q\phi''(h_1, h_2)$ is small for some smallish q and all h_1, h_2, which in turn essentially means that ϕ is slowly varying on B_N intersected with any fixed progression $a \pmod q$. For a detailed discussion see [14]. Suffice it to say that the passage from large Type I/II sum to ϕ being major arc is long and difficult, and requires many applications of the Cauchy–Schwarz inequality to manipulate the phase ϕ into a helpful form, as well as basic tools of equidistribution such as a version of the Erdős–Turán inequality.

Recalling Proposition 5.1, one has reduced the case $s = 2$ of Conjecture 10.2 to the statement that

$$\mathbb{E}_{n \leqslant N} \mu(n) 1_{B_N}(n) e(\phi(n)) \ll_A \log^{-A} N$$

for any major arc phase ϕ. It turns out that $1_{B_N}(n)e(\phi(n))$ can, in this case, be closely approximated by a sum of linear phases $e(\theta n)$, and so we may conclude using Proposition 4.1.

Note that this analysis has the flavour of an induction on s, the step of the nilsequence we are considering. We expect to see this more clearly when addressing the general case of Conjecture 10.2 in future work.

12. Future directions

The most obvious avenue of research left open is to generalise everything we have done for $s = 2$ to the case $s \geqslant 3$. In particular we would like inverse theorems for the U^k-norms for $k \geqslant 4$, and a proof of Conjecture 10.2 for $s \geqslant 3$. We are currently working towards this goal. We expect that the methods of Gowers [10] can be adapted to achieve the inverse theorem, though this will not be straightforward. It is also very likely that the "inverse" approach to handling Type I and II sums can be adapted to the higher-step case of Conjecture 10.2, though again we do not expect this to be wholly straightforward.

It would be very desirable to have good bounds for error terms such as the $o(1)$ in Theorem 2.5. We are sure that our current estimate for the error in Theorem 2.5 is the worst that has ever featured in analytic number theory – the error term is a *completely ineffective* $o(1)$! Ultimately this is because to show that the error is less than δ one finds oneself needing to rule out a real zero of some $L(s, \chi)$, χ a primitive quadratic character to the modulus q, with $s > 1 - Cq^{-\varepsilon}$, where $\varepsilon = \varepsilon(\delta) \to 0$ as $\delta \to 0$. Siegel's theorem states that for any $\varepsilon > 0$ there is such a C, but it is, of course, not possible to specify C effectively.

It is clear that the spectre of ineffectivity does not rear its head under the assumption of GRH, and we believe that our methods lead to an error term of the form $\log^{-c} N$ in Theorem 2.5.

There are other, presumably more tractible, ways in which one might obtain an explicit error term. Improvements to the combinatorial tools used in [13], particularly advances on the circle of conjectures known as the "polynomial Freiman–Ruzsa conjecture", could be very helpful here.

We turn now to goals which lie further away. I have hinted at various places in this survey that the way in which we see nilsequences arising is very long-winded and, presumably, not the "right" way. The ergodic theorists [20], [35] do admittedly discover the rôle of these functions somewhat less painfully (albeit after setting up a good deal of notation). Nilsequences seem such natural objects, however, that there ought to be a much better way of appreciating their place in the study of systems of linear equations. Recalling that $\|f\|_{U^2}$ is essentially the L^4 norm of $\hat{f}$ one might even ask, for example,

Question 12.1. Is there a usable "formula" relating $\|f\|_{U^3}$ and certain of the "nil-fourier coefficients" $\mathbb{E}_{n \leqslant N} f(n) F(T_g^n \cdot x)$?

Such a formula would assuredly have to be very exotic on account of the vast profusion of nilsequences which might enter into consideration. The nilsequences are not naturally parametrised by anything so simple as the circle S^1, which gave its name to the classical circle method.

Let us conclude with some speculations on non-linear systems of equations, where our knowledge is at present essentially non-existent. We have seen in Conjecture 9.2 that the behaviour of an any system $\boldsymbol{A}\boldsymbol{x} = \boldsymbol{b}$, where $\boldsymbol{A}$ is non-degenerate in the sense

of Definition 2.3, should be governed by a very "hard" or "algebraic" collection of *characteristic functions,* in this case the nilsequences.

On the other hand degenerate linear systems, such as $x_1 - x_2 = 1$, do not have this property. To see this, suppose that $N = 2m$ is even and let $A \subseteq [N]$ be a set formed by setting $A \cap \{2i, 2i+1\} = \{2i\}$ or $\{2i+1\}$, these choices being independent in i for $i = 0, \ldots, m-1$. Then $|A| = N/2$, and A is indistinguishable from a truly random set by taking inner products with any conceivable "hard" character such as a linear or quadratic phase. However, A is expected to have about $N/8$ solutions to $x_1 - x_2 = 1$, whereas a random set has about twice this many.

One might call an equation or system of equations for which a "hard" characteristic system exists a *mixing* system. We do not have a precise definition of this notion. Some non-linear equations are known to be mixing – for example, the linear phases $e(\theta n)$ form a characteristic system for the equation $x_1 + x_2 = x_3^2$. Many more are not. It would be very interesting to know, for example, whether the equation $x_1x_2 - x_3x_4 = 1$ is mixing and, if so, what a characteristic system for it might be. This seems to be a very difficult question as the analysis of this equation even in very specific situations involves deep methods from the theory of automorphic forms.

Aspects géométriques du Lemme Fondamental de Langlands-Shelstad

Gérard Laumon*

Abstract. In order to compute the Hasse–Weil zeta functions of the Shimura varieties or to establish some cases of the Langlands functoriality one first needs to stabilize the Arthur–Selberg trace formula. This stabilization can be done only if some combinatorial identities between orbital integrals over p-adic reductive groups are satisfied. The series of these conjectural identities form the so-called "Fundamental Lemma". We present here some key points of the geometric approaches which have been used by Goresky, Kottwitz and MacPherson on the one hand and Ngô Bao Châu and myself one the other hand, to prove some cases of the Fundamental Lemma.

Résumé. Pour calculer les fonctions zêta de Hasse-Weil des variétés de Shimura ou pour établir certains cas de la fonctorialité de Langlands, il faut dans un premier temps stabiliser la formule des traces d'Arthur-Selberg. Cette stabilisation n'est possible que si certaines identités combinatoires entre intégrales orbitales sur les groupes réductifs p-adiques sont vérifiées. Ces identités conjecturales ont été regroupées sous la terminologie générique de "Lemme Fondamental". Nous présentons ici quelques points clé des approches géométriques utilisées par Goresky, Kottwitz et MacPherson d'une part, et Ngô Bao Châu et moi-même d'autre part, pour démontrer certains cas du Lemme Fondamental.

Mathematics Subject Classification (2000). Primary 14H60, 11F72 ; Secondary 22E35.

Keywords. Fundamental Lemma, endoscopy, Langlands functoriality.

Mots-clés. Lemme Fondamental, endoscopie, fonctorialité de Langlands.

1. Introduction

Le programme de Langlands est un faisceau de relations entre les représentations automorphes des groupes réductifs sur un corps local ou global et les représentations galoisiennes de ce même corps local ou global. Ce programme est très vaste puisqu'il contient une bonne partie de la théorie des nombres et aussi de la géométrie algébrique du fait de ses relations avec la théorie des motifs de Grothendieck, et il est donc très loin d'être achevé.

Nous nous intéressons ici à un aspect technique de ce programme. Pour calculer les fonctions zêta de Hasse-Weil des variétés de Shimura ou pour établir certains cas

*UMR 8628 du CNRS

Proceedings of the International Congress of Mathematicians, Madrid, Spain, 2006

de la fonctorialité de Langlands, il faut dans un premier temps stabiliser la formule des traces d'Arthur-Selberg (cf. [19], [12], [13] et [3]). Cette stabilisation n'est possible que si certaines identités combinatoires entre intégrales orbitales sur les groupes réductifs p-adiques sont vérifiées. Ces identités conjecturales ont été regroupées sous la terminologie générique et un peu baroque de "Lemme Fondamental".

Le Lemme Fondamental a été découvert par Labesse et Langlands dans leur travail sur la stabilisation de la formule des traces de Selberg pour SL(2) (cf. [18]). Langlands et Shelstad en ont donné une formulation générale toujours conjecturale dans [20]. Waldspurger en a ensuite formulé une variante pour les algèbres de Lie (cf. [28] et [16]) et Kottwitz et Shelstad ont donné une conjecture précise dans le cas "tordu" (cf. [17]). Pour être complet, signalons aussi les variantes "pondérée" et "pondérée tordue" du Lemme Fondamental conjecturées par Arthur (cf. [3]).

Dans certain cas il est possible de prouver le Lemme Fondamental en n'utilisant que des techniques combinatoires ou d'analyse harmonique. Cependant le cas général semble hors d'atteinte de cette manière et un recours à des techniques de la géométrie algébrique est probablement nécessaire.

Dans cet exposé nous présentons quelques points clé des approches géométriques utilisées par Goresky, Kottwitz et MacPherson d'une part, et Ngô Bao Châu et moi-même d'autre part, pour démontrer certains cas du Lemme Fondamental. Nous renvoyons aux articles originaux ([7] et [22]), à l'exposé de Ngô dans ce volume (cf. [23]) et à l'exposé Bourbaki de Dat (cf. [5]) pour plus de détails

2. Groupes réductifs

Soit F un corps local non archimédien, i.e. une extension finie de $\mathbb{Q}_p$ ou $\mathbb{F}_p((t))$. On note $\mathcal{O}_F$ l'anneau des entiers de F (la clôture intégrale de $\mathbb{Z}_p$ ou $\mathbb{F}_p[[t]]$ dans F) et $\mathfrak{p}_F$ l'idéal maximal de $\mathcal{O}_F$. Soit $\overline{F}$ une clôture algébrique de F.

Soit G un groupe (algébrique) réductif connexe sur F. On suppose que G est *quasi-déployé*, c'est-à-dire que G admet un sous-groupe de Borel défini sur F et qu'il se déploie au-dessus d'une extension finie non ramifiée $F' \subset \overline{F}$ de F. Notre groupe G est donc *non ramifié* et il existe des schémas en groupes lisses $\mathcal{G}$ sur le trait $\mathrm{Spec}(\mathcal{O}_F)$ dont la fibre générique est G et la fibre spéciale est un groupe réductif connexe sur le corps résiduel $\mathcal{O}_F/\mathfrak{p}_F$ de F. Soient $\mathcal{G}$ un tel schéma en groupes et $K = \mathcal{G}(\mathcal{O}_F) \subset G(F)$ le sous-groupe compact maximal *hyperspécial* correspondant.

Exemple 2.1. On suppose que la caractéristique résiduelle p de F est > 2. Soit F' l'extension quadratique non ramifiée de F contenue dans $\overline{F}$. On note τ l'élément non trivial du groupe de Galois $\mathrm{Gal}(F'/F)$.

On rappelle que le groupe $F^\times/\mathrm{Nr}_{F'/F}(F'^\times)$ est le groupe à deux éléments engendré par la classe de n'importe quelle uniformisante $\varpi_F \in \mathfrak{p}_F$ de F. On l'identifie à $\mathbb{Z}/2\mathbb{Z}$ dans la suite.

Un F'-espace hermitien est un espace vectoriel V de dimension finie sur F' muni d'une forme τ-sesquilinéaire symétrique non dégénérée Φ. Un tel F'-espace vectoriel hermitien (V, Φ) admet un discriminant : la classe dans $F^\times/\mathrm{Nr}_{F'/F}(F'^\times)$ du déterminant de la matrice de Φ dans une base de V. Deux F'-espaces hermitiens de même dimension sont isomorphes si et seulement s'ils ont même discriminant.

Le groupe unitaire des automorphismes

$$\mathrm{U}(V, \Phi) \subset \mathrm{Res}_{F'/F}\mathrm{Aut}_{F'}(V).$$

d'un tel F'-espace hermitien (V, Φ) est un groupe réductif connexe sur F. Il se déploie sur F' et est en fait une forme (extérieure) de $\mathrm{Aut}_{F'}(V)$ sur F. Il est quasi-déployé, et donc non ramifié, si et seulement si le discriminant de (V, Φ) est trivial. Dans ce cas, il existe des $\mathcal{O}_{F'}$-réseaux $M \subset V$ qui sont auto-duaux pour Φ au sens où le $\mathcal{O}_{F'}$-réseau

$$M^\perp = \{v \in V \mid \Phi(v, M) \subset \mathcal{O}_{F'}\} \subset V$$

est égal à M ; les sous-groupes maximaux hyperspéciaux sont alors les stabilisateurs dans $\mathrm{U}(V, \Phi)(F)$ de ces réseaux.

Soient (V, Φ) un F'-espace hermitien (V, Φ) de dimension n dont le discriminant est trivial et M un $\mathcal{O}_{F'}$-réseau auto-dual de V. On peut trouver une base de M sur $\mathcal{O}_{F'}$, qui est aussi une base de V sur F', dans laquelle la matrice de Φ est égale à la matrice Φ_n qui n'a pour seules entrées non nulles que les $(\Phi_n)_{i,n+1-i} = 1$ pour $i = 1, \ldots, n$. Tout couple formé d'un groupe unitaire non ramifié et d'une sous-groupe compact maximal hyperspécial est donc isomorphe à un groupe unitaire standard

$$\mathrm{U}(n) = \{g \in \mathrm{GL}_{F'}(n) \mid {}^t g^\tau \Phi_n g = \Phi_n\}$$

avec son sous-groupe compact maximal hyperspécial standard

$$\mathrm{U}(n)(F) \cap \mathrm{GL}(n, \mathcal{O}_{F'}).$$

Le groupe réductif $\mathrm{U}(n)$ ainsi défini admet pour groupe de Borel sur F le sous-groupe formé des $g \in \mathrm{U}(n)$ qui sont des matrices triangulaires supérieures dans $\mathrm{GL}_{F'}(n)$.

3. Intégrales orbitales

Soit $\mathfrak{g}$ l'algèbre de Lie de G qui est en particulier un espace vectoriel de dimension finie sur F. Notons $\mathrm{ad}\colon G \to \mathrm{Aut}_F(\mathfrak{g})$ la représentation adjointe de G. La classe de conjugaison d'un élément γ de $\mathfrak{g}$ est l'ensemble des $\mathrm{ad}(g)(\gamma)$ pour g parcourant $G(F)$; le centralisateur de γ est le sous-schéma en groupes $Z_G(\gamma)$ de G défini par la condition $\mathrm{ad}(g)(\gamma) = \gamma$. On rappelle que le centralisateur d'un élément régulier semi-simple de $\mathfrak{g}$ est toujours connexe.

Soit T un tore maximal de G que l'on suppose *anisotrope*, c'est-à-dire ne contenant pas de sous-tore déployé sur F non trivial, de sorte que le groupe $T(F)$ est compact. Soit $\mathfrak{t} \subset \mathfrak{g}$ l'algèbre de Lie de T.

Pour tout élément γ de $\mathfrak{t} \subset \mathfrak{g}$ qui est régulier, c'est-à-dire dont le centralisateur dans G est égal à T, toute fonction $f : \mathfrak{g} \to \mathbb{C}$ localement constante et à support compact et toute mesure de Haar $\mathrm{d}g$ sur $G(F)$, on peut former l'*intégrale orbitale* en γ de f

$$\mathrm{O}_\gamma^G(f, \mathrm{d}g) = \int_{G(F)} f(\mathrm{ad}(g^{-1})(\gamma))\,\mathrm{d}g.$$

On vérifie que l'ensemble

$$\{g \in G(F) \mid \mathrm{ad}(g^{-1})(\gamma) \in \mathrm{Supp}(f)\}$$

est compact et donc que cette intégrale orbitale converge (c'est essentiellement une somme finie).

En particulier, si K est un sous-groupe compact maximal hyperspécial de $G(F)$, si on normalise $\mathrm{d}g$ par $\mathrm{vol}(K, \mathrm{d}g) = 1$ et si $f = 1_{\mathfrak{k}}$ est la fonction caractéristique du $\mathcal{O}_F$-réseau $\mathfrak{k} \subset \mathfrak{g}$ algèbre de Lie de K, on a l'intégrale orbitale $\mathrm{O}_\gamma^G(1_{\mathfrak{k}}, \mathrm{d}g)$. Comme tous les sous-groupes compacts maximaux hyperspéciaux sont conjugués dans $G(F)$, cette intégrale orbitale ne dépend pas du choix de K et on la note simplement O_γ^G dans la suite.

Exemple 3.1 (Suite de 2.1). Soient $(E_i)_{i\in I}$ une famille finie d'extensions finies séparables de F que l'on suppose toutes totalement ramifiées pour simplifier l'exposition. On note n_i le degré de E_i sur F, E_i' l'extension composée $E_i' = E_i F'$ de F' et encore τ l'élément non trivial du groupe de Galois $\mathrm{Gal}(E_i'/E_i) \cong \mathrm{Gal}(F'/F)$.

Pour chaque $i \in I$ et chaque $c_i \in E_i^\times$, on considère le F'-espace hermitien (E_i', Φ_{i,c_i}) où

$$\Phi_{i,c_i}(x, y) = \mathrm{Tr}_{E_i'/F'}(c_i x^\tau y).$$

On note $\mu_i(c_i) \in \mathbb{Z}/2\mathbb{Z}$ son discriminant ; si n_i est premier à p, on a simplement

$$\mu_i(c_i) \equiv v_{E_i}(c_i) + n_i - 1 \pmod 2.$$

Pour chaque $c_I = (c_i)_{i\in I} \in E_I^\times$, on considère le F'-espace hermitien

$$(E_I', \Phi_{I,c_I}) = \bigoplus_{i\in I} (E_i', \Phi_{i,c_i}).$$

Son discriminant est la somme

$$\sum_{i\in I} \mu_i(c_i) \in \mathbb{Z}/2\mathbb{Z}$$

des discriminants des Φ_{i,c_i}. On note

$$G_{I,c_I} \subset \mathrm{Res}_{F'/F}\mathrm{Aut}_{F'}(E_I')$$

le F-groupe réductif des automorphismes du F'-espace hermitien (E_I', Φ_{I,c_I}).

Pour chaque $i \in I$ on note T_i le noyau de l'homomorphisme de tores

$$\mathrm{Res}_{E_i'/F}\mathbb{G}_\mathrm{m} \to \mathrm{Res}_{E_i/F}\mathbb{G}_\mathrm{m}$$

qui envoie x sur $x^\tau x$. Le tore $T_I = \prod_{i\in I} T_i$ est anisotrope sur F. Comme le tore $\prod_{i\in I} \mathrm{Res}_{E_i'/F'}\mathbb{G}_\mathrm{m}$ est de manière naturelle un tore maximal dans $\mathrm{Aut}_{F'}(E_I')$, T_I est naturellement plongé dans $\mathrm{Res}_{F'/F}\mathrm{Aut}_{F'}(E_I')$ et on a en fait

$$T_I \subset G_{I,c_I} \subset \mathrm{Res}_{F'/F}\mathrm{Aut}_{F'}(E_I')$$

pour chaque $c_I \in E_I^\times$.

Pour chaque $i \in I$, soit $\gamma_i \in \mathcal{O}_{E_i'} \subset E_i'$ qui engendre E_i' sur F' et qui vérifie

$$\gamma_i^\tau + \gamma_i = 0,$$

de sorte que $\gamma_I = (\gamma_i)_{i\in I}$ est un élément de l'algèbre de Lie $\mathfrak{t}_I = \bigoplus_{i\in I}\{x_i \in E_i' \mid x_i^\tau + x_i = 0\}$ de T_I. Pour chaque $c_I \in E_I^\times$, γ_I est un élément semi-simple de l'algèbre de Lie $\mathfrak{g}_{I,c_I}$ de G_{I,c_I} de centralisateur T_I.

Supposons de plus que pour tous $i \neq j$ dans I les polynômes minimaux $P_i(x)$ et $P_j(x)$ sur F' de γ_i et γ_j sont premiers entres eux. Alors cette classe de conjugaison semi-simple est régulière et l'intégrale orbitale $\mathrm{O}_{\gamma_I}^{G_{I,c_I}}$ admet l'interprétation concrète suivante : c'est le nombre des $\mathcal{O}_{F'}$-réseaux $M \subset E_I'$ vérifiant les deux conditions suivantes :

- $M^{\perp_{c_I}} = M$, où $M^{\perp_{c_I}} = \{x \in E_I' \mid \Phi_{I,c_I}(x, M) \subset \mathcal{O}_{F'}\}$,
- $\gamma_I M \subset M$.

4. κ-Intégrales orbitales

La classe de *conjugaison stable* d'un élément régulier $\gamma \in \mathfrak{k} \subset \mathfrak{g}$, est l'ensemble des $\gamma' \in \mathfrak{g}$ qui sont conjugués à γ dans $\overline{F} \otimes_F \mathfrak{g}$ par un élément de $G(\overline{F})$. Tout $\gamma' = \mathrm{ad}(g^{-1})(\gamma)$ stablement conjugué à γ définit un 1-cocycle

$$\sigma \mapsto g^{-1}\sigma(g),\ \mathrm{Gal}(\overline{F}/F) \to T(\overline{F}),$$

dont la classe dans $H^1(F,T) := H^1(\mathrm{Gal}(\overline{F}/F), T(\overline{F}))$ ne dépend que de la classe de $G(F)$-conjugaison de γ'. Par construction l'image de cette classe dans l'ensemble pointé $H^1(F,G) := H^1(\mathrm{Gal}(\overline{F}/F), G(\overline{F}))$ est triviale. On construit ainsi une bijection de l'ensemble des classes de $G(F)$-conjugaison dans la classe de conjugaison stable de γ (ensemble pointé par la classe de conjugaison de γ) sur le groupe fini $\mathrm{Ker}(H^1(F,T) \to H^1(F,G))$.

Le centralisateur d'un élément $\gamma' = \mathrm{ad}(g)(\gamma) \in \mathfrak{g}$ stablement conjugué à γ est le tore maximal $T' = gTg^{-1} \subset G$ stablement conjugué à T ; il est donc canoniquement isomorphe à T par l'isomorphisme $T \to T' = gTg^{-1}$ qui envoie t sur gtg^{-1},

isomorphisme qui est en fait défini sur F. Pour tout caractère $\kappa : \mathrm{Ker}(H^1(F,T) \to H^1(F,G)) \to \mathbb{C}^\times$ vu comme une fonction sur la classe de conjugaison stable de γ, on peut former la *κ-intégrale orbitale* en γ d'une fonction $f : \mathfrak{g} \to \mathbb{C}$ localement constante à support compact

$$\mathrm{O}_\gamma^{G,\kappa}(f, \mathrm{d}g) = \sum_{\gamma'} \kappa(\gamma') \mathrm{O}_{\gamma'}^G(f, \mathrm{d}g)$$

où γ' parcourt un système de représentants des classes de conjugaison dans la classe de conjugaison stable de γ. Pour le caractère trivial $\kappa = 1$ on note

$$\mathrm{SO}_{[\gamma]}^G(f, \mathrm{d}g) = \mathrm{O}_\gamma^{G,1}(f, \mathrm{d}g)$$

où $[\gamma]$ est la classe de conjugaison stable de γ, et on dit *intégrale orbitale stable* au lieu de 1-*intégrale orbitale*.

Pour $f = 1_{\mathfrak{k}}$ et $\mathrm{vol}(K, \mathrm{d}g) = 1$ où K est un sous-groupe compact maximal hyperspécial de $G(F)$, on note simplement $\mathrm{O}_\gamma^{G,\kappa}$ la κ-intégrale orbitale et $\mathrm{SO}_{[\gamma]}^G$ l'intégrale orbitale stable ; elles ne dépendent pas du choix de K.

Exemple 4.1 (Suite de 3.1). Pour tout $i \in I$ posons

$$c_i^0 = \frac{\varepsilon^{n-1}}{\frac{\mathrm{d}P_i(x)}{\mathrm{d}x}(\gamma_i) P_{I-\{i\}}(\gamma_i)} \in E_i^\times$$

où $\varepsilon \in \mathcal{O}_{F'}^\times$ est n'importe quel élément vérifiant $\varepsilon^\tau = -\varepsilon$ et où $P_J(x) = \prod_{j \in J} P_j(x)$ quel que soit $J \subset I$. On a

$$\mu_i(c_i^0) \equiv \sum_{j \in I-\{i\}} r_{ji} \pmod 2$$

où r_{ji} est la valuation du résultant des deux polynômes $P_i(x)$ et $P_j(x)$ à coefficients dans F'. Le discriminant de Φ_{I,c_I^0} est trivial et le $\mathcal{O}_{F'}$-réseau $\mathcal{O}_{F'}[\gamma] \subset E_I'$ est autodual pour Φ_{I,c_I^0}. On note simplement G_I le groupe unitaire G_{I,c_I^0}, $\mathfrak{g}_I$ son algèbre de Lie et K_I le sous-groupe maximal hyperspécial de G_I qui fixe le $\mathcal{O}_{F'}$-réseau auto-dual $\mathcal{O}_{F'}[\gamma_I]$. On peut si l'on le souhaite identifier (G_I, K_I) à $(\mathrm{U}(n), \mathrm{U}(n,F) \cap \mathrm{GL}(n, \mathcal{O}_{F'}))$ comme dans la section 2.

Pour chaque $i \in I$ fixons une uniformisante ϖ_{E_i} de E_i et donc aussi de E_i'. Notons Λ_I le noyau de l'application somme des coordonnées $\mathbb{Z}^I \to \mathbb{Z}$ et pour chaque $\lambda \in \Lambda_I$ posons $\varpi_{E_I}^{-\lambda} = (\varpi_{E_i}^{-\lambda_i})_{i \in I}$ et $c_I^\lambda = \varpi_{E_I}^{-\lambda} c_I^0$.

On a l'élément γ_I dans $\mathfrak{t}_I \subset \mathfrak{g}_I$. Pour chaque $\lambda \in \Lambda_I$, le discriminant de la forme hermitienne Φ_{I,c_I^λ} est trivial et il existe donc $x^\lambda \in \mathrm{Aut}_{F'}(E_I')(F')$ tel que $x^\lambda G_{I,c_I^\lambda}(x^\lambda)^{-1} = G_I$. On choisit un tel x^λ et on note γ_I^λ l'élément $\mathrm{ad}(x^\lambda)(\gamma_I)$ de $\mathfrak{g}_I$; la classe de conjugaison dans $\mathfrak{g}_I$ de γ_I^λ ne dépend pas du choix de x^λ (pour $\lambda = 0$ on peut bien sûr prendre $x^\lambda = 1$).

Pour tous $\lambda, \lambda' \in \Lambda_I$, les éléments γ_I^{λ} et $\gamma_I^{\lambda'}$ sont automatiquement stablement conjugués dans $\mathfrak{g}_I$. Ils sont de plus conjugués dans $\mathfrak{g}_I$ si et seulement si $\lambda \equiv \lambda' \pmod{2\Lambda_I}$.

On a donc un classe de conjugaison stable $[\gamma_I]$ bien définie dans $\mathfrak{g}_I$ et une indexation des classes de conjugaison dans cette classe de conjugaison stable par $\Lambda_I/2\Lambda_I$.

On considère l'ensemble $\mathcal{X}_{\gamma_I}$ des $\mathcal{O}_{F'}$-réseaux $M \subset E_I'$ tels qu'il existe $\lambda \in \Lambda_I$ avec

$$M^{\perp_{c_I^{\lambda}}} = M$$

ou ce qui revient au même

$$M^{\perp_{c_I^0}} = \varpi_{E_I'}^{-\lambda} M.$$

Le groupe discret Λ_I agit sur cet ensemble par

$$\lambda \cdot M = \varpi_{E_I'}^{-\lambda} M$$

et on a une application

$$\mu_{\gamma_I} : \mathcal{X}_{\gamma_I}/\Lambda_I \to \Lambda_I/2\Lambda_I$$

qui envoie l'orbite $\Lambda_I \cdot M$ sur la classe de tout λ tel que $M^{\perp_{c_I^0}} = \varpi_{E_I'}^{-\lambda} M$.

Alors, pour tout caractère κ de $\Lambda_I/2\Lambda_I$ la κ-intégrale orbitale $\mathrm{O}_{\gamma_I}^{G_I,\kappa}$ est en fait la somme

$$\sum_{\mu \in \Lambda_I/2\Lambda_I} \kappa(\mu) |\{M \in \mathcal{X}_{\gamma_I} \mid \mu_{\gamma_I}(M) = \mu\}|$$

et en particulier

$$\mathrm{SO}_{\gamma_I}^{G_I} = |\mathcal{X}_{\gamma_I}/\Lambda_I|.$$

5. Dualité de Langlands

Rappelons qu'à tout couple formé d'un groupe réductif connexe G sur un corps séparablement clos k et d'un tore maximal T de G, est associé la *donnée radicielle*

$$(X^*, R, X_*, R^\vee) = (X^*(T), R(G,T), X_*(T), R^\vee(G,T))$$

où X^* (resp. X_*) est le groupe abélien libre de rang fini des caractères (resp. co-caractères) de T et où $R \subset X^*$ (resp. $R^\vee \subset X_*$) est l'ensemble fini des racines (resp. co-racines) de T dans G.

Rappelons aussi que toute donnée radicielle $(X^*, R, X_*, R^\vee)$ formée de deux groupes abéliens libres de rangs finis en dualité et de sous-ensembles finis $R \subset X^*$ et $R^\vee \subset X_*$ vérifiant les axiomes des systèmes de racines et de co-racines, provient d'un couple (G, T) et que le couple (G, T) est uniquement déterminé par sa donnée radicielle à isomorphisme non unique près. Plus précisément, l'homomorphisme du groupe $\mathrm{Aut}(G, T)$ des automorphismes algébriques du couple (G, T) dans celui

$\mathrm{Aut}(X^*, R, X_*, R^\vee)$ des automorphismes de la donnée radicielle induit un isomorphisme

$$\mathrm{Aut}(G,T)/\mathrm{Int}(T) \xrightarrow{\sim} \mathrm{Aut}(X^*, R, X_*, R^\vee)$$

où $\mathrm{Int}\colon G \to \mathrm{Aut}(G)$ est l'homomorphisme de groupes qui associe à un élément de G l'automorphisme intérieur correspondant. L'application $\mathrm{Int}\colon N_G(T) \to \mathrm{Aut}(G,T)$ induit un monomorphisme du groupe de Weyl $W = W(G,T) = N_G(T)/T$ dans $\mathrm{Aut}(G,T)/\mathrm{Int}(T)$ que l'on note encore Int et dont le conoyau est fini.

Partant d'un couple (G,T) sur k comme ci-dessus, il existe donc un couple $(\widehat{G}, \widehat{T})$ formé d'un groupe réductif connexe $\widehat{G}$ sur $\mathbb{C}$ et d'un tore maximal de $\widehat{T}$ de $\widehat{G}$, dont la donnée radicielle est duale de celle de (G,T) au sens où

$$(X^*(\widehat{T}), R(\widehat{G},\widehat{T}), X_*(\widehat{T}), R^\vee(\widehat{G},\widehat{T})) = (X_*(T), R^\vee(G,T), X^*(T), R(G,T)).$$

Ce couple est dit le *dual de Langlands complexe* de (G,T).

Par exemple, on a les groupes duaux suivants (les tores maximaux étant des deux côtés les tores des matrices diagonales)

G	$\widehat{G}$
$\mathrm{GL}(n)$	$\mathrm{GL}(n)$
$\mathrm{PGL}(n)$	$\mathrm{SL}(n)$
$\mathrm{Sp}(2n)$	$\mathrm{SO}(2n+1)$
$\mathrm{SO}(2n)$	$\mathrm{SO}(2n)$

Si G est semi-simple et adjoint, $\widehat{G}$ est semi-simple et simplement connexe, et vice-versa. Plus généralement, si le centre de G est connexe alors le groupe dérivé de $\widehat{G}$ est simplement connexe, et vice-versa.

Si maintenant k est un corps non nécessairement séparablement clos, soit $\bar{k}$ une clôture séparable de k. Pour un groupe réductif connexe G sur k muni d'un tore maximal T sur k, on a comme précédemment la donnée radicielle

$$(X^*, R, X_*, R^\vee) = (X^*(\bar{k}\otimes_k T), R(\bar{k}\otimes_k G, \bar{k}\otimes_k T), X_*(\bar{k}\otimes_k T), R^\vee(\bar{k}\otimes_k G, \bar{k}\otimes_k T)).$$

De plus on a une action de $\mathrm{Gal}(\bar{k}/k)$ sur cette donnée radicielle et donc une action de $\mathrm{Gal}(\bar{k}/k)$ sur la donnée radicielle duale $(X_*, R^\vee, X^*, R)$, d'où un homomorphisme de groupes

$$\rho\colon \mathrm{Gal}(\bar{k}/k) \to \mathrm{Aut}(\widehat{G},\widehat{T})/\mathrm{Int}(\widehat{T}).$$

Pour tout w dans le groupe de Weyl $W = W(\bar{k}\otimes_k G, \bar{k}\otimes_k T) = W(\widehat{G},\widehat{T})$ on peut tordre ρ par w en posant

$${}^w\rho(\sigma) = \mathrm{Int}(w)\rho(\sigma)\mathrm{Int}(w^{-1})$$

quel que soit $\sigma \in \mathrm{Gal}(\bar{k}/k)$. Dire que G est quasi-déployé sur k revient à dire :

(∗) *il existe $w \in W$ tel que ${}^w\rho$ fixe une base Δ du système de racines R ou ce qui revient au même d'une base $\Delta^\vee$ du système de co-racines $R^\vee$.*

La donnée de $(\widehat{G}, \widehat{T})$ munie de l'homomorphisme ρ ci-dessus ne permet pas de retrouver le couple (G, T). Par contre, on a une bijection entre les classes d'isomorphie de couples $(G, [T])$ formés d'un groupe réductif connexe quasi-déployé sur k et d'une classe de conjugaison stable de tores maximaux de G et l'ensemble des classes d'isomorphie de triplets $(\widehat{G}, \widehat{T}, \rho)$ formés d'une groupe réductif connexe sur $\mathbb{C}$, d'un tore maximal $\widehat{T}$ et d'un homomorphisme $\mathrm{Gal}(\bar{k}/k) \to \mathrm{Aut}(\widehat{G}, \widehat{T})/\mathrm{Int}(\widehat{T})$ vérifiant $(*)$.

Exemple 5.1 (Suite de 4.1). Pour $G = \mathrm{Res}_{E'_I/F'}\mathbb{G}_\mathrm{m}$ et $T = \mathrm{Res}_{E'_I/F'}\mathbb{G}_\mathrm{m}$, on a $\widehat{G} = \mathrm{Aut}(\mathbb{C}^{\mathrm{Hom}_{F'}(E'_I, \bar{F})})$, $\widehat{T} = (\mathbb{C}^\times)^{\mathrm{Hom}_{F'}(E'_I, \bar{F})}$ et l'homomorphisme $\rho\colon \mathrm{Gal}(\bar{F}/F') \to \mathrm{Aut}(\widehat{G}, \widehat{T})/\mathrm{Int}(\widehat{T})$ envoie σ sur l'élément du groupe de Weyl

$$W(\widehat{G}, \widehat{T}) = \mathrm{Int}(\widehat{G}, \widehat{T})/\mathrm{Int}(\widehat{T}) \subset \mathrm{Aut}(\widehat{G}, \widehat{T})/\mathrm{Int}(\widehat{T})$$

défini par la permutation de $\mathrm{Hom}_{F'}(E'_I, \bar{F})$ induite par l'action de σ sur $\bar{F}$.

Dans ce cas $\mathrm{Aut}(\widehat{G}, \widehat{T})/\mathrm{Int}(\widehat{T})$ est le produit semi-direct de $W(\widehat{G}, \widehat{T})$ par l'automorphisme extérieur de $\widehat{G}$ donné par $g \to {}^{\mathrm{t}}g^{-1}$ où la transposition est relative à la base canonique de $\mathbb{C}^{\mathrm{Hom}_{F'}(E'_I, \bar{F})}$.

Pour $G = G_I$ et $T = T_I$, on a $\widehat{G} = \mathrm{Aut}(\mathbb{C}^{\mathrm{Hom}_F(E_I, \bar{F})})$, $\widehat{T} = (\mathbb{C}^\times)^{\mathrm{Hom}_F(E_I, \bar{F})}$ et l'homomorphisme $\rho\colon \mathrm{Gal}(\bar{F}/F) \to \mathrm{Aut}(\widehat{G}, \widehat{T})/\mathrm{Int}(\widehat{T})$ envoie $\sigma \in \mathrm{Gal}(\bar{F}/F') \subset \mathrm{Gal}(\bar{F}/F)$ sur l'élément du groupe de Weyl $W(\widehat{G}, \widehat{T})$ défini par la permutation de $\mathrm{Hom}_F(E_I, \bar{F}) = \mathrm{Hom}_{F'}(E'_I, \bar{F})$ induite par l'action de σ sur $\bar{F}$, et il envoie $\sigma \in \mathrm{Gal}(\bar{F}/F) - \mathrm{Gal}(\bar{F}/F')$ sur le produit de ce même élément du groupe de Weyl et de l'automorphisme extérieur ci-dessus.

Pour le groupe unitaire quasi-déployé $G = \mathrm{U}(n)$ et T le tore maximal le plus déployé formé des matrices unitaires diagonales, on a $\widehat{G} = \mathrm{GL}(n, \mathbb{C})$, $\widehat{T}$ est le tore des matrices diagonales de $\mathrm{GL}(n, \mathbb{C})$ et l'homomorphisme $\rho\colon \mathrm{Gal}(\bar{F}/F) \to \mathrm{Aut}(\widehat{G}, \widehat{T})/\mathrm{Int}(\widehat{T})$ se factorise par $\mathrm{Gal}(F'/F)$ et envoie l'élément non trivial τ sur l'automorphisme extérieur $g \mapsto \Phi_n {}^{\mathrm{t}}g^{-1} \Phi_n$.

6. Groupes endoscopiques

Soit G un groupe réductif connexe quasi-déployé sur le corps local non archimédien F muni d'un tore maximal T.

Soit $(\widehat{G}, \widehat{T})$ le groupe dual de $(\bar{F} \otimes_F G, \bar{F} \otimes_F T)$ muni de l'homomorphisme $\rho\colon \mathrm{Gal}(\bar{F}/F) \to \mathrm{Aut}(\widehat{G}, \widehat{T})/\mathrm{Int}(\widehat{T})$.

La dualité de Tate-Nakayama identifie ce groupe fini $\pi_0(\widehat{T}^{\mathrm{Gal}(\bar{F}/F)})$ au dual de Pontryagin de $H^1(F, T)$. Plus généralement la dualité de Tate-Nakayama étendue par Kottwitz identifie $H^1(F, G)$ au groupe fini $\pi_0(Z(\widehat{G})^{\mathrm{Gal}(\bar{F}/F)})$ où on a noté $Z(\widehat{G})$ le centre de $\widehat{G}$. Par suite, le dual du noyau $\mathrm{Ker}(H^1(F, T) \to H^1(F, G))$ est le quotient $\pi_0(\widehat{T}^{\mathrm{Gal}(\bar{F}/F)})/\pi_0(Z(\widehat{G})^{\mathrm{Gal}(\bar{F}/F)})$.

Pour simplifier l'exposition on suppose dans la suite que T est anisotrope de sorte que $\widehat{T}^{\mathrm{Gal}(\overline{F}/F)}$ est fini, tout comme $Z(\widehat{G})^{\mathrm{Gal}(\overline{F}/F)} \subset \widehat{T}^{\mathrm{Gal}(\overline{F}/F)}$.

Si $s \in \widehat{T}^{\mathrm{Gal}(\overline{F}/F)}$, la composante neutre $\widehat{H}$ de son centralisateur dans $\widehat{G}$ est un groupe réductif connexe qui contient le tore maximal $\widehat{T}$. La donnée radicielle de $(\widehat{H}, \widehat{T})$, qui est contenue dans celle de $(\widehat{G}, \widehat{T})$, est stable sous l'action de $\mathrm{Gal}(\overline{F}/F)$. L'homomorphisme $\rho\colon \mathrm{Gal}(\overline{F}/F) \to \mathrm{Aut}(\widehat{G}, \widehat{T})/\mathrm{Int}(\widehat{T})$ a son image contenue dans $\mathrm{Aut}(\widehat{G}, \widehat{H}, \widehat{T})/\mathrm{Int}(\widehat{T})$ et induit donc un homomorphisme

$$\rho_H\colon \mathrm{Gal}(\overline{F}/F) \to \mathrm{Aut}(\widehat{H}, \widehat{T})/\mathrm{Int}(\widehat{T}).$$

Par suite il existe un couple (unique à isomorphisme près) formé d'un groupe réductif connexe quasi-déployé H sur F et d'une classe de conjugaison stable $[T]$ de tores maximaux de H, de dual $(\widehat{H}, \widehat{T})$ avec l'homomorphisme ρ_H. Un tel couple est dit *endoscopique* pour (G, T). Tout tore S dans $[T]$ est muni d'un isomorphisme naturel avec T (ce qui justifie notre notation) et est donc anisotrope.

Exemple 6.1 (Suite de 5.1). Pour $G = G_I$ et $T = T_I$ on a T_I anisotrope et $\widehat{T}^{\mathrm{Gal}(\overline{F}/F)} = \{\pm 1\}^I \subset (\mathbb{C}^\times)^I \subset \prod_{i\in I}(\mathbb{C}^\times)^{\mathrm{Hom}_F(E_i,\overline{F})} = \widehat{T}$. Tout $s = (s_i)_{i\in I} \in \widehat{T}^{\mathrm{Gal}(\overline{F}/F)}$ définit une partition $I = I_1 \amalg I_2$ où I_1 (resp. I_2) est l'ensemble des $i \in I$ tel que $s_i = 1$ (resp. $s_i = -1$). Le groupe endoscopique défini par s est le produit de groupes unitaires $G_{I_1} \times_F G_{I_2}$, muni de la classe de conjugaison stable de tores maximaux $[T_{I_1} \times_F T_{I_2}]$.

7. Lemme Fondamental

Conjecture 7.1 (Langlands-Shelstad [20]). Soient G un groupe réductif non ramifié sur F, T un tore maximal anisotrope de G, $\gamma \in \mathfrak{t}$ un élément régulier semi-simple dans $\mathfrak{g}$ comme dans la section 3, et $s \in \widehat{T}^{\mathrm{Gal}(\overline{F}/F)}$ définissant un caractère κ de $\mathrm{Ker}(H^1(F, T) \to H^1(F, G))$ par la dualité de Tate-Nakayama comme dans la section précédente. On a la κ-intégrale orbitale $\mathrm{O}_\gamma^{G,\kappa}$, le groupe endoscopique H muni de sa classe de conjugaison stable de tore maximaux $[T]$ défini par s et l'*intégrale orbitale stable* $\mathrm{SO}^H_{[\gamma]}$.

Alors

$$\mathrm{O}_\gamma^{G,\kappa} = \varepsilon(\gamma)\mathrm{D}_H^G(\gamma)\mathrm{SO}^H_{[\gamma]}.$$

où $\varepsilon(\gamma)$ est une racine de l'unité qui est définie précisément dans [20] et où le discriminant $\mathrm{D}_H^G(\gamma)$ est défini par

$$\mathrm{D}_H^G(\gamma) = \prod_{\alpha\in R(G,T)-R(H,T)} |\alpha(\gamma)|_F^{1/2}.$$

On a noté $|a|_{\overline{F}} = q^{-v_F(a)}$ pour tout $a \in \overline{F}^\times$ où q est de nombre des élément du corps résiduel de F et $v_F\colon \overline{F}^\times \to \mathbb{Q}$ est la valuation normalisée par $v_F(\varpi_F) = 1$ pour toute uniformisante ϖ_F de F.

Remarque 7.2. (i) La racine de l'unité $\varepsilon(\gamma)$ a été calculée par Waldspurger pour les groupes classiques dans [29].

(ii) Kottwitz a montré comment pointer la classe de conjugaison stable de γ dans G à l'aide de la section de Kostant pour simplifier la définition de Langlands-Shelstad de $\varepsilon(\gamma)$ (cf. [15]).

(iii) D'après Waldspurger (cf. [30]), il suffit de démontrer le Lemme Fondamental pour F d'égales caractéristiques, c'est-à-dire $F = \mathbb{F}_q((t))$ pour un corps fini $\mathbb{F}_q$.

8. Résultats

Outre le cas particulier de SL(2) qui est à l'origine du Lemme Fondamental (cf. [18]) plusieurs cas particuliers de 7.1 ont déjà été démontrés sans recours à la géométrie algébrique : le cas de SL(n) par Waldspurger (cf. [27]), le cas de U(3) par Kottwitz d'une part (cf. [14]) et par Rogawski d'autre part (cf. [25]), et le cas de Sp(4) par Hales d'une part (cf. [9]) et Weissauer d'autre part (cf. [31]).

Par contre les deux théorèmes ci-dessous sont obtenus par voie géométrique, ce qui suppose que F soit d'égales caractéristiques (voir cependant la remarque 7.2 (iii)).

Théorème 8.1 (Goresky, Kottwitz et MacPherson [7]). *En plus des hypothèse de la conjecture* 7.1*, supposons que le tore anisotrope T est non ramifié, c'est-à-dire qu'il se déploie sur une extension finie non ramifiée de F, et que l'élément régulier semi-simple $\gamma \in \mathfrak{t}$ est d'égales valuations, c'est-à-dire que la valuation de $\alpha'(\gamma)$ ne dépende pas de la racine α de T dans G (α' est la dérivée de α). Alors*

$$\mathrm{O}_\gamma^{G,\kappa} = \varepsilon(\gamma)\mathrm{D}_H^G(\gamma)\mathrm{SO}_{[\gamma]}^H.$$

Théorème 8.2 (Laumon et Ngô [22]). *Reprenons les notations et les hypothèses de l'exemple* 4.1*. Nous avons donc le groupe réductif quasi-déployé $G = G_I$, une classe de conjugaison stable $[\gamma]$ dans $\mathfrak{g}_I$ pointée par un élément $\gamma = \gamma_I$ dans l'algèbre de Lie et un tore maximal anisotrope $T = T_I$ de G.*

Fixons une partition $I = I_1 \sqcup I_2$, notons $H = G_{I_1} \times G_{I_2}$ le groupe endoscopique correspondant et encore $[\gamma]$ la classe de conjugaison stable dans $\mathfrak{h}$ de $\gamma \in \mathfrak{t}_I = \mathfrak{t}_{I_1} \oplus \mathfrak{t}_{I_2} \subset \mathfrak{h}$.

Supposons que F soit d'égales caractéristiques $p > n$. Alors on a la relation

$$\mathrm{O}_\gamma^{\kappa} = (-1)^r q^r \, \mathrm{SO}_{[\gamma]}^H$$

où

$$r = r_{I_1,I_2} = \sum_{\substack{i_1 \in I_1 \\ i_2 \in I_2}} r_{i_1,i_2}.$$

(*On rappelle que $r_{ij} = r_{ji}$ est la valuation du résultant* $\mathrm{Res}(P_i, P_j) \in F'$ *des polynômes minimaux $P_i(x)$ et $P_j(x)$ de γ_i et γ_j.*)

9. Fibres de Springer affines

Les preuves des théorèmes 8.1 et 8.2 sont fondées sur une interprétation cohomologique des deux membres du Lemme Fondamental à l'aide de la formule des points fixes de Grothendieck-Lefschetz. Cette interprétation fait intervenir les fibres de Springer affines qui sont des analogues pour les groupes de lacets des fibres de Springer classiques.

Soient k un corps algébriquement clos et G un groupe réductif sur k. On note $G((t))$ le ind-k-schéma en groupes de lacets des $k((t))$-points de G et $G[[t]] \subset G((t))$ son sous-k-schéma en groupes des $k[[t]]$-points de G. On ne tient pas compte ici des nilpotents éventuels de ces schémas.

Le ind-k-schéma réduit quotient $X = G((t))/G[[t]]$ est appelé la *grassmannienne affine* de G ; il est réunion croissante de k-schémas projectifs. Le ind-k-schéma en groupes $G((t))$ agit par translation à gauche sur X.

Pour $G = \mathrm{GL}_k(n)$ cette grassmannienne affine n'est autre que le ind-k-schéma réduit des $k[[t]]$-réseaux dans $k((t))^n$, c'est-à-dire des sous-$k[[t]]$-modules $M \subset k((t))^n$ tels qu'il existe un entier $N \geq 0$ avec $t^N k[[t]]^n \subset M \subset t^{-N} k[[t]]^n \subset k((t))^n$.

Soit $\mathfrak{g}$ l'algèbre de Lie de G et γ un élément régulier semi-simple de $\mathfrak{g}((t)) = \mathfrak{g} \otimes_k k((t))$. La fibre de Springer affine en γ est le sous-ind-k-schéma fermé réduit X_γ de X dont l'ensemble des k-points est

$$X_\gamma(k) = \{gG(k[[t]]) \in X(k) \mid \mathrm{ad}(g^{-1})(\gamma) \in \mathfrak{g}[[t]]\}.$$

Pour que cet ensemble soit non vide il faut que, à conjugaison près on ait $\gamma \in \mathfrak{g}[[t]] = \mathfrak{g} \otimes_k k[[t]]$, ce que nous supposons dans la suite.

Pour $\mathrm{GL}_k(n)$ et $\gamma \in \mathrm{gl}(n, k[[t]])$ une matrice régulière semi-simple, la fibre de Springer affine est encore le ind-k-schéma réduit des $k[[t]]$-réseaux $M \subset k((t))^n$ tels que $\gamma M \subset M$.

Le centralisateur T de γ dans $G((t))$ est un tore maximal par hypothèse. L'action de $T \subset G((t))$ par translation à gauche sur X respecte le fermé X_γ. Le tore T contient un plus grand sous-tore de la forme $A((t))$ pour A un sous-tore de $\mathfrak{g}$ sur k (le sous-tore déployé maximal). Le groupe des co-caractères $X_*(A)$ agit librement sur X_γ par

$$\lambda \cdot gG[[t]] = \lambda(t) gG[[t]].$$

Dans [11], Kazhdan et Lusztig ont montré que X_γ est en fait un schéma localement de type fini et de dimension finie sur k, et que le quotient de X_γ par l'action libre de $X_*(A)$ ci-dessus est un k-schéma projectif, l'application quotient $X_\gamma \to X_\gamma/X_*(A)$ étant un revêtement étale galoisien de groupe de Galois $X_*(A)$.

La structure de ind-k-schéma de la grassmannienne affine X induit sur la fibre de Springer affine X_γ une structure analogue : X_γ est une réunion croissante de sous-k-schémas fermés projectifs.

Soit ℓ un nombre premier distinct de la caractéristique de k. On peut définir la cohomologie étale ℓ-adique de X_γ

$$H^i(X_\gamma, \mathbb{Q}_\ell).$$

comme la limite projective des cohomologies étales ℓ-adiques des sous-k-schémas fermés projectifs ci-dessus.

Si $k = \overline{\mathbb{F}}_q$ est la clôture algébrique d'un corps fini $\mathbb{F}_q$ et si G et γ sont définis sur ce corps fini, il en est bien entendu de même de $G((t))$, $G[[t]]$, X et X_γ. Par suite, pour tout nombre premier ℓ distinct de la caractéristique de k on a une action de l'endomorphisme de Frobenius géométrique Frob_q relatif à $\mathbb{F}_q$ sur la cohomologie étale ℓ-adique $H^i(X_\gamma, \mathbb{Q}_\ell)$.

Rappelons que si Z est un k-schéma propre sur $k = \overline{\mathbb{F}}_q$, qui est défini que $\mathbb{F}_q$, Deligne a montré que, quel que soit l'entier i, chaque valeur propre λ de Frob_q sur $H^i(Z, \mathbb{Q}_\ell)$ est un entier algébrique de poids $\leq i$, c'est-à-dire qu'il existe un entier $w(\lambda) \leq i$ tel que $|\iota(\lambda)| = q^{-w(\lambda)/2}$ pour tout plongement de $\iota\colon \mathbb{Q}(\lambda) \hookrightarrow \mathbb{C}$. On dit que la cohomologie étale ℓ-adique de Z est *pure* si pour tout entier i et toute valeur propre λ de Frob_q sur $H^i(Z, \mathbb{Q}_\ell)$, $w(\lambda) = i$ (cf. [6]). Toujours d'après Deligne c'est le cas si Z est supposé de plus lisse sur k (cf. loc. cit.). Les fibres de Springer sont des exemples de schémas propres non lisses dont la cohomologie étale ℓ-adique est pure (cf. [26]).

Cette notion de pureté garde un sens pour les fibres de Springer affines X_γ et Goresky, Kottwitz et MacPherson ont conjecturé dans [7] :

Conjecture 9.1. La cohomologie étale ℓ-adique de X_γ est pure.

Ils ont démontré cette conjecture dans un cas particulier (cf. [8]) :

Théorème 9.2 (Goresky, Kottwitz et MacPherson). *Supposons que γ est d'égales valuations, c'est-à-dire que la valuation de $\alpha'(\gamma)$ ne dépend pas de la racine α de T dans G ($\alpha'\colon \mathfrak{t} \to k((t))$ est la dérivée de α). Alors X_γ peut être pavé par des fibrés en espaces affines standard sur des variétés projectives et lisses sur k. En particulier la cohomologie étale ℓ-adique de X_γ est pure.*

10. L'approche de Goresky, Kottwitz et MacPherson

Soient toujours k une clôture algébrique d'un corps fini $\mathbb{F}_q$ et G un groupe réductif sur k que l'on suppose défini sur $\mathbb{F}_q$.

Soit $T \subset G$ un tore maximal défini sur $\mathbb{F}_q$ et $\gamma \in \mathfrak{t}[[t]]$ un élément régulier (semi-simple) dans $\mathfrak{g}((t))$ que l'on suppose rationnel sur $\mathbb{F}_q$, où bien sûr $\mathfrak{t}$ et $\mathfrak{g}$ sont les algèbres de Lie de T et G. Comme dans la section précédente on a la fibre de Springer affine

$$X_\gamma = \{gG[[t]] \mid g^{-1}\gamma g \in \mathfrak{g}[[t]]\} \subset X$$

en γ qui est laissée globalement invariante par l'action par translations à gauche du centralisateur $T((t)) \subset G((t))$ de γ. En particulier on a une action du tore $T \subset T((t))$ et du groupe des co-caractères $\Lambda = X_*(T) \cong t^{X_*(T)} \subset G((t))$ sur X qui laissent globalement invariante X_γ ; l'action de Λ sur X_γ est libre et commute à celle de T. La fibre de Springer X_γ et les actions de T et Λ sont définies sur $\mathbb{F}_q$.

Le lieu des points fixes de T agissant sur X est le fermé $X^T = T((t))/T[[t]] \subset G((t))/G[[t]] = X$ qui est automatiquement contenu dans X_γ et est donc le lieu des points fixes X_γ^T de l'action de T sur X_γ. Ce lieu est bien entendu globalement stable sous l'action de Λ et on peut l'identifier à Λ avec l'action de Λ par translation sur lui-même. La cohomologie étale ℓ-adique de $X_\gamma^T = X^T$ avec l'action induite de Λ est le $\mathbb{Q}_\ell[\Lambda]$-module $\mathbb{Q}_\ell[[\Lambda]]$.

Goresky, Kottwitz et MacPherson donnent une formule explicite pour la cohomologie étale ℓ-adique de X_γ sous l'hypothèse que cette cohomologie est pure. Ils déduisent cette formule d'une formule explicite pour la cohomologie étale ℓ-adique T-équivariante de X_γ qu'ils établissent en premier.

Avant d'énoncer leur résultat rappelons que la cohomologie étale ℓ-adique T-équivariante de $\mathrm{Spec}(k)$ avec l'action triviale de T est la $\mathbb{Q}_\ell$-algèbre graduée

$$H_T^*(\mathrm{Spec}(k), \mathbb{Q}_\ell) = \bigoplus_{n\geq 0} H_T^{2n}(\mathrm{Spec}(k), \mathbb{Q}_\ell) = \bigoplus_{n\geq 0} \mathrm{Sym}^n(X^*(T)(-1)) \otimes \mathbb{Q}_\ell,$$

où $\chi \in X^*(T)$ correspond à la classe de Chern du fibré en droites $\mathcal{L}_\chi$ sur le champ algébrique $[\mathrm{Spec}(k)/T]$, obtenu en poussant par χ le T-torseur universel. Rappelons aussi que cette $\mathbb{Q}_\ell$-algèbre graduée agit par le cup-produit sur la cohomologie étale ℓ-adique T-équivariante de tout ind-k-schéma muni d'une action de T. On a donc

$$H_T^*(X_\gamma^T, \mathbb{Q}_\ell) = \bigoplus_{n\geq 0} \mathrm{Sym}^n(X^*(T)(-1)) \otimes \mathbb{Q}_\ell[[\Lambda]]$$

en tant que $\bigoplus_{n\geq 0} \mathrm{Sym}^n(X^*(T)(-1)) \otimes \mathbb{Q}_\ell[\Lambda]$-module gradué et un homomorphisme de $\bigoplus_{n\geq 0} \mathrm{Sym}^n(X^*(T)(-1)) \otimes \mathbb{Q}_\ell[\Lambda]$-modules graduées

$$H_T^*(X_\gamma, \mathbb{Q}_\ell) \to H_T^*(X_\gamma^T, \mathbb{Q}_\ell) = \bigoplus_{n\geq 0} \mathrm{Sym}^n(X^*(T)(-1)) \otimes \mathbb{Q}_\ell[[\Lambda]].$$

de restriction au lieu des points fixes sous T. On notera par la multiplication à gauche l'action de $\mathrm{Sym}^*(X^*(T)(-1))$ et par la multiplication à droite celle de $\mathbb{Q}_\ell[\Lambda]$ pour clarifier l'exposition.

Théorème 10.1 (Goresky, Kottwitz et MacPherson). *Supposons que la cohomologie étale ℓ-adique de X_γ soit pure. Alors la flèche de restriction ci-dessus est injective et son image est formée en degré n des $f \in \mathrm{Sym}^n(X^*(T)(-1)) \otimes \mathbb{Q}_\ell[[\Lambda]]$ tels que, pour toute racine $\alpha \in X^*(T)$ de T dans G et tout entier $d = 1, 2, \ldots, v(\alpha(\gamma))$, on ait*

$$f(1-\alpha^\vee)^d \in \alpha^d \mathrm{Sym}^{n-d}(X^*(T)(-1)) \otimes \mathbb{Q}_\ell[[\Lambda]]$$

où $\alpha' : \mathfrak{t}((t)) \to k((t))$ est la dérivée de α et où $\alpha^\vee \in \Lambda$ est la co-racine correspondante.

Le théorème 8.1 résulte des théorèmes 9.2 et 10.1

11. Notre approche avec Ngô

L'idée de départ est d'essayer de déformer les fibres de Springer en espérant qu'après déformation les choses deviennent plus simples. Bien sûr nous sommes guidés par l'analogie avec la résolution simultanée de Grothendieck-Springer qui regroupe en une seule famille toutes les fibres de Springer classiques.

Les fibres de Springer affines se comportent mal du point de vue des déformations et le point clé de notre approche est de les remplacer par des objets de nature globale que sont les jacobiennes compactifiées de courbes singulières, et de manière plus proche de la théorie des groupes par les fibres du morphisme de Hitchin.

Pour rendre les choses plus transparente je me limite dans la suite au cas où $G = \mathrm{GL}_k(n)$ bien que cela ne soit pas suffisant pour notre preuve du théorème 8.2.

Se donner un élément régulier semi-simple γ de $\mathfrak{g}((t))$ équivaut à se donner un polynôme unitaire séparable $P(x) \in k((t))[x]$ de degré n, et une base du $k((t))$-espace vectoriel $k((t))[x]/(P(x))$ de dimension n. Pour que la fibre de Springer affine X_γ soit non vide il faut que $P(x) \in k[[t]][x]$; pour simplifier l'exposition on suppose dans la suite que c'est bien le cas et que $P(0) \in tk[[t]]$. On introduit alors l'anneau $R_\gamma = k[[t]][\gamma] = k[[t]][x]/(P(x))$; c'est une k-algèbre réduite, non normale, d'anneau total des fractions $\mathrm{Frac}(R_\gamma) = k((t))[x]/(P(x))$.

Pour toute k-algèbre réduite complète R isomorphe à $k[[x, y]]/(f)$ pour $f \in (x, y) \subset k[[x, y]]$ (comme l'est R_γ), on dispose d'un k-schéma en groupes commutatifs P_R et d'une "compactification" équivariante $\bar{P}_R$ de ce dernier.

Le groupe de k-points de P_R est simplement $\mathrm{Frac}(R)^\times / R^\times$ où $\mathrm{Frac}(R)$ est l'anneau total des fractions de R ; le groupe des composantes connexes de P_R est $\mathbb{Z}^I$ où I est l'ensemble des points génériques de $\mathrm{Spec}(R)$ (ou ce qui revient au même des facteurs irréductibles de f) et la composante neutre P_R^0 de P_R est un k-schéma en groupes de type fini extension d'une tore $\mathbb{G}_{\mathrm{m},k}^I / \mathbb{G}_{\mathrm{m},k}$ par un groupe unipotent. On peut voir P_R comme l'espace de modules des R-modules M libres de rang 1 munis d'un isomorphisme $\mathrm{Frac}(R) \otimes_R M \cong \mathrm{Frac}(R)$

Le k-schéma $\bar{P}_R$ est lui l'espace de modules des R-modules M de type fini sans torsion munis d'un isomorphisme $\mathrm{Frac}(R) \otimes_R M \cong \mathrm{Frac}(R)$; P_R qui est évidemment contenu dans $\bar{P}_R$, agit par produit tensoriel sur ce dernier.

Proposition 11.1 (cf. [21]). *La fibre de Springer affine X_γ est homéomorphe à $\bar{P}_{R_\gamma}$.*

Soit maintenant C une courbe réduite, connexe et projective sur k. Le k-champ algébrique de Picard $\mathrm{Pic}(C)$ de C est l'espace de modules des $\mathcal{O}_C$-Modules inversibles $\mathcal{L}$. Ce champ algébrique est lisse sur k et le produit tensoriel le munit d'une structure de champ algébrique en "groupes commutatifs".

Les composantes connexes de $\mathrm{Pic}(C)$ sont découpées par l'invariant discret $\deg(\mathcal{L}) = \chi(C, \mathcal{L}) - \chi(C, \mathcal{O}_C)$; elles sont de type fini si et seulement si C est irréductible.

Mayer et Mumford ont introduit une "compactification" équivariante de $\mathrm{Pic}(C)$ (cf. [2]). Plus précisément ils ont introduit le k-champ algébrique $\overline{\mathrm{Pic}}(C)$ des $\mathcal{O}_C$-Modules cohérents $\mathcal{F}$ sans torsion de rangs génériques tous égaux à 1. On a une immersion ouverte évidente de $\mathrm{Pic}(C) \hookrightarrow \overline{\mathrm{Pic}}(C)$ et l'action par translation de $\mathrm{Pic}(C)$ sur lui-même se prolonge en l'action de $\mathrm{Pic}(C)$ sur $\overline{\mathrm{Pic}}(C)$ induite par le produit tensoriel. En général $\overline{\mathrm{Pic}}(C)$ n'est pas lisse sur k.

Les composantes connexes de $\mathrm{Pic}(C)$ sont elles aussi découpées par le degré de $\mathcal{F}$. Elles sont de type fini que si et seulement si C est irréductible. Par contre elles ne sont pas irréductibles en général car $\mathrm{Pic}(C)$ n'est pas toujours dense dans $\overline{\mathrm{Pic}}(C)$ et la dimension de $\overline{\mathrm{Pic}}(C)$ peut être strictement plus grande que celle de $\mathrm{Pic}(C)$.

Cependant, si les singularités de C sont toutes planes, c'est-à-dire si le complété formel de $\mathcal{O}_{C,c}$ est isomorphe à $k[[x, y]]/(f(x, y))$ pour $f(x, y) \in (x, y) \subset k[[x, y]]$ quel que soit le point singulier c de C, alors Rego d'une part (cf. [24]) et Altmann, Iarrobino et Kleiman d'autre part (cf. [1]) ont montré que $\mathrm{Pic}(C)$ est dense dans $\overline{\mathrm{Pic}}(C)$ (ces auteurs ne considèrent que le cas où C est irréductible mais leur argument est général).

Supposons dorénavant que notre courbe C réduite, connexe et projective sur k a toutes ses singularités planes. Notons $C^{\mathrm{sing}} \subset C$ l'ensemble fini de ses singularités. On a un k-morphisme de champs algébriques

$$\prod_{c \in C^{\mathrm{sing}}} \bar{P}_{\widehat{\mathcal{O}}_{C,c}} \to \overline{\mathrm{Pic}}(C)$$

qui envoie $(M_c)_c$ sur le $\mathcal{O}_C$-Module cohérent obtenu en recollant $\mathcal{O}_{C-C^{\mathrm{sing}}}$ et les M_c le long de $(C - C^{\mathrm{sing}}) \cap \coprod_{c \in C^{\mathrm{sing}}} \mathrm{Spec}(\widehat{\mathcal{O}}_{C,c}) = \coprod_{c \in C^{\mathrm{sing}}} \mathrm{Spec}(\mathrm{Frac}(\widehat{\mathcal{O}}_{C,c}))$. Ce morphisme induit un morphisme de champs algébriques en groupes commutatifs

$$\prod_{c \in C^{\mathrm{sing}}} P_{\widehat{\mathcal{O}}_{C,c}} \to \mathrm{Pic}(C).$$

Proposition 11.2. *Le k-morphisme de champs algébriques déduit des morphismes précédents par passage au quotient*

$$\prod_{c \in C^{\mathrm{sing}}} [\bar{P}_{\widehat{\mathcal{O}}_{C,c}} / P_{\widehat{\mathcal{O}}_{C,c}}] \to [\overline{\mathrm{Pic}}(C)/\mathrm{Pic}(C)]$$

est un isomorphisme.

Compte-tenu de cette proposition et de la proposition 11.1 la conjecture de pureté de Goresky, Kottwitz et MacPherson 9.1 implique en particulier la conjecture suivante.

Conjecture 11.3. Soit C une courbe intègre et projective sur la clôture algébrique d'un corps fini. On suppose que toutes les singularités de C sont planes et unibranches. Alors la cohomologie ℓ-adique de $\overline{\mathrm{Pic}}(C)^0$ est pure.

Les propositions 11.1 et 11.2 permettent de donner une interprétation cohomologique des intégrales orbitales pour G en termes de $\overline{\mathrm{Pic}}(C)$ pour une courbe C convenable (cf. [21]). Un des gros avantages des champs de Picard compactifiés par rapport aux fibres de Springer affines est que toute déformation de C donne lieu à une déformation de $\overline{\mathrm{Pic}}(C)$.

La fibration de Hitchin fournit de manière naturelle du point de vue de la théorie des groupes une telle déformation (cf. [23]).

Changeons de notations. Soit maintenant C une courbe connexe, projective et lisse de genre $g \geq 2$ sur un corps k algébriquement clos et D un diviseur effectif de degré $\geq 2g-2$ sur C. On dispose du k-champ algébrique $\mathcal{M}$ des couples $(\mathcal{E}, \theta)$ où $\mathcal{E}$ est un fibré vectoriel de rang n sur C et $\theta\colon \mathcal{E} \to \mathcal{E}(D)$ est un endomorphisme tordu de $\mathcal{E}$. Soit $\mathcal{A}$ le k-espace vectoriel de dimension finie $\bigoplus_{i=1}^{n} H^0(X, \mathcal{O}_C(iD))$ vu comme un k-schéma affine. La fibration de Hitchin (cf. [10])

$$m\colon \mathcal{M} \to \mathcal{A}$$

est le morphisme qui envoie $(\mathcal{E}, \theta)$ sur le polynôme caractéristique de θ, c'est-à-dire défini par

$$m(\mathcal{E}, \theta) = (-\mathrm{tr}(\theta), \mathrm{tr}(\wedge^2\theta), \ldots, (-1)^n \mathrm{tr}(\wedge^n\theta))$$

Tout point $a \in \mathcal{A}$ définit un diviseur de Cartier C_a dans la surface réglée $\mathbb{V}(\mathcal{O}_C(-D))$, diviseur appelé par Hitchin la *courbe spectrale* en a, à savoir le diviseur d'équation

$$u^n + p^*a_1u^{n-1} + \cdots + p^*a_n = 0$$

où $p\colon \mathbb{V}(\mathcal{O}_C(-D)) \to C$ est la projection canonique et u est la section universelle de $p^*\mathcal{O}(-D)$. La restriction π_a de p à cette courbe C_a en fait un revêtement fini ramifié de C. Par construction $\pi_{a,*}\mathcal{O}_{C_a}$ est isomorphe à

$$\mathrm{Sym}_{\mathcal{O}_C}(\mathcal{O}_C(-D))/\mathcal{I}_a$$

où $\mathcal{I}_a$ est l'Idéal engendré par l'image de l'homomorphisme

$$\mathcal{O}_C(-nD) \to \bigoplus_{i=0}^{n} \mathcal{O}_C(-iD) \subset \mathrm{Sym}_{\mathcal{O}_C}(\mathcal{O}_C(-D))$$

de composantes $(a_n, a_{n-1}, \ldots, a_1, 1)$.

Supposons que C_a est réduite. On a alors un morphisme du champ algébrique $\overline{\mathrm{Pic}}(C_a)$ des $\mathcal{O}_{C_a}$-Modules cohérents sans torsion de rang 1 en tout point générique de C_a dans la fibre de la fibration de Hitchin $m^{-1}(a) = \mathcal{M}_a$ en a :

$$\overline{\mathrm{Pic}}(C_a) \to m^{-1}(a),\ \mathcal{F} \mapsto (\mathcal{E}, \theta)$$

où $\mathcal{E} = \pi_{a,*}\mathcal{F}$ et

$$\theta\colon \mathcal{O}_C(-D) \subset \mathrm{Sym}_{\mathcal{O}_C}(\mathcal{O}_C(-D))/\mathcal{I}_a = \pi_{a,*}\mathcal{O}_{C_a} \to \mathcal{E}nd_{\mathcal{O}_C}(\mathcal{E}).$$

Proposition 11.4 (Beauville, Narasimhan et Ramanan [4]). *Le morphisme de champs algébriques ci-dessus est un isomorphisme.*

Compte tenu des proposition 11.1 et 11.2, on a donc un lien entre les fibres de la fibration de Hitchin et fibres de Springer affines via les jacobiennes compactifiées. La fibration de Hitchin peut donc être vue comme une famille naturelle de (produits de) fibres de Springer affines. Elle joue un peu le rôle de la résolution simultanée de Grothendieck-Springer pour les fibres de Springer affines. C'est le point de départ de notre démonstration du théorème 8.2.

Remerciements. Je remercie Pierre-Henri Chaudouard et Ngô Bao Châu pour leur aide durant la préparation de cet exposé.

Equidistribution, L-functions and ergodic theory: on some problems of Yu. Linnik

Philippe Michel and Akshay Venkatesh*

Abstract. An old question of Linnik asks about the equidistribution of integral points on a large sphere. This question proved to be very rich: it is intimately linked to modular forms, to subconvex estimates for L-functions, and to dynamics of torus actions on homogeneous spaces. Indeed, Linnik gave a partial answer using ergodic methods, and his question was completely answered by Duke using harmonic analysis and modular forms. We survey the context of these ideas and their developments over the last decades.

Keywords. Automorphic L-functions, ergodic theory, equidistribution, subconvexity.

1. Linnik's problems

Given Q a homogeneous polynomial of degree m in n variables with integral coefficients, a classical problem in number theory is to understand the integral representations of an integer d by the polynomial Q, as $|d| \to +\infty$. Let $V_{Q,d}(\mathbb{Z}) = \{\boldsymbol{x} \in \mathbb{Z}^n, Q(\boldsymbol{x}) = d\}$ denote the set of such representations (possibly modulo some obvious symmetries). If $|V_{Q,d}(\mathbb{Z})| \to +\infty$ with d, it is natural to investigate the distribution of the discrete set $V_{Q,d}(\mathbb{Z})$ inside the affine variety "of level d"

$$V_{Q,d}(\mathbb{R}) = \{\boldsymbol{x} \in \mathbb{R}^n,\ Q(\boldsymbol{x}) = d\}.$$

In fact, one may rather consider the distribution, inside the variety of fixed level $V_{Q,\pm 1}(\mathbb{R})$, of the radial projection $|d|^{-1/m}.V_{Q,d}(\mathbb{Z})$ (here $\pm$ is the sign of d) and one would like to show that, as $|d| \to +\infty$, the set $|d|^{-1/m}.V_{Q,d}(\mathbb{Z})$ becomes equidistributed with respect to some natural measure $\mu_{Q,\pm 1}$ on $V_{Q,\pm 1}(\mathbb{R})$. Here, to take care of the case where $V_{Q,d}(\mathbb{Z})$ and $\mu_{Q,\pm 1}(V_{Q,\pm 1}(\mathbb{R}))$ are infinite, equidistribution w.r.t. $\mu_{Q,\pm 1}$ is defined by the following property: for any two sufficiently nice compact subsets $\Omega_1, \Omega_2 \subset V_{Q,\pm 1}(\mathbb{R})$ one has

$$\frac{\left||d|^{-1/m}.V_{Q,d}(\mathbb{Z}) \cap \Omega_1\right|}{\left||d|^{-1/m}.V_{Q,d}(\mathbb{Z}) \cap \Omega_2\right|} \longrightarrow \frac{\mu_{Q,\pm 1}(\Omega_1)}{\mu_{Q,\pm 1}(\Omega_2)} \quad \text{as } |d| \to +\infty. \tag{1.1}$$

Proceedings of the International Congress of Mathematicians, Madrid, Spain, 2006

The most general approach to this kind of problems is the circle method of Hardy–Littlewood. (Un)fortunately, that method is fundamentally limited to cases where the number of variables n is large compared with the degree m. To go further, one is led to make additional hypotheses on the varieties $V_{Q,d}$. It was anticipated by Linnik in the early 60's, and systematically suggested by Sarnak in the 90s [55], [56], [68], that for varieties which are homogeneous with respect to the action of some algebraic group $\boldsymbol{G}_{\mathbb{Q}}$, one should be able to take advantage of this action. Equidistribution problems on such homogeneous varieties are called (after Sarnak), equidistribution problems of Linnik's type.

By now, this expectation is largely confirmed by the resolution of wide classes of problems of Linnik's type ([10], [25], [30]–[32], [35], [57], [58], [65]); and the methods developed to deal with them rely heavily on powerful techniques from harmonic analysis (Langlands functoriality, quantitative equidistribution of Hecke points and approximations to the Ramanujan–Petersson conjecture) or from ergodic theory (especially Ratner's classification of measures invariant under unipotent subgroups), complemented by methods from number theory.

In this lecture we will not discuss that much the resolution of these important and general cases (for this we refer to [33], [72]); instead, we wish to focus on three, much older, examples of low dimension and degree ($m = 2$, $n = 3$) which were originally studied in the sixties by Linnik and his school. Our point in highlighting these examples is that the various methods developed to handle them are fairly different from the aforementioned ones which, in fact, may not apply or at least not directly.

The three problems correspond to taking Q to be a ternary quadratic form of signature $(3, 0)$ or $(1, 2)$. They are problems of Linnik's type with respect to the action of the orthogonal group $\boldsymbol{G} = \mathrm{SO}(Q)$ on $V_{Q,d}$.

The first problem is for the definite quadratic form $Q(A, B, C) = A^2 + B^2 + C^2$. For d an integer, $V_{Q,|d|}(\mathbb{Z})$ is the set of representations of $|d|$ as a sum of three squares

$$V_{Q,|d|}(\mathbb{Z}) = \{(a, b, c) \in \mathbb{Z}^3,\ a^2 + b^2 + c^2 = |d|\}$$

and $V_{Q,1}(\mathbb{R}) = S^2$ is the unit sphere. We denote by

$$\mathcal{G}_d = |d|^{-1/2}.V_{Q,|d|}(\mathbb{Z})$$

the radial projection of $V_{Q,|d|}(\mathbb{Z})$ on S^2:

Theorem 1 (Duke [17]). *For $d \to -\infty$, and $d \not\equiv 0, 1, 4 \pmod 8$ the set $\mathcal{G}_d$ is equidistributed on S^2 w.r.t. the Lebesgue measure μ_{S^2}.*

It will be useful to recall the "accidental" isomorphism of $\mathrm{SO}(Q)$ with $\boldsymbol{G} = \mathrm{PG}(\mathrm{B}^{(2,\infty)}) = \mathrm{B}^{\times}_{2,\infty}/Z(\mathrm{B}^{\times}_{2,\infty})$ where $\mathrm{B}^{(2,\infty)}$ is the algebra of the Hamilton quaternions. This arises from the identification of the quadratic space $(\mathbb{Q}^3, Q)$ with the trace-0 Hamilton quaternions endowed with the norm form $N(z) = z.\overline{z}$ via the map $(a, b, c) \to z = a.i + b.j + c.k$.

The second and third problems are relative to the indefinite quadratic form $Q(A, B, C) = B^2 - 4AC$, which is the discriminant of the binary quadratic forms $q_{A,B,C}(X, Y) = AX^2 + BXY + CY^2$. In that case, there is another "accidental" isomorphism of $\mathrm{SO}(Q)$ with PGL_2 via the map

$$(a, b, c) \to q_{a,b,c}(X, Y) = aX^2 + bXY + cY^2$$

which identifies $V_{Q,d}$ with the set $\mathcal{Q}_d$ of binary quadratic forms of discriminant d; PGL_2 acts on the latter by linear change of variables, twisted by inverse determinant. As $\mathrm{PGL}_2(\mathbb{Z})$ acts on $\mathcal{Q}_d(\mathbb{Z})$, one sees that, if $V_{Q,d}(\mathbb{Z}) = \mathcal{Q}_d(\mathbb{Z})$ is non empty (i.e. if $d \equiv 0, 1 \bmod 4$), it is infinite; so the proper way to define the equidistribution of $|d|^{-1/2}.V_{Q,d}(\mathbb{Z})$ inside $V_{Q,\pm 1}(\mathbb{R}) = \mathcal{Q}_{\pm 1}(\mathbb{R})$ is via (1.1). However, it is useful to formulate these problems in a slightly different (although equivalent) form which will be suitable for number theoretic applications. Let $\mathbb{H}^{\pm} = \mathbb{H}^+ \cup \mathbb{H}^- = \mathbb{C} - \mathbb{R} = \mathrm{PGL}_2(\mathbb{R})/\mathrm{SO}_2(\mathbb{R})$ denote the union of the upper and lower half-planes and $Y_0(1)$ denote the (non-compact) modular surface of full level i.e. $\mathrm{PGL}_2(\mathbb{Z})\backslash\mathbb{H}^{\pm} \simeq \mathrm{PSL}_2(\mathbb{Z})\backslash\mathbb{H}^+$.

As is well known, the quotient $\mathrm{PSL}_2(\mathbb{Z})\backslash\mathcal{Q}_d(\mathbb{Z})$ is finite, of cardinality some *class number* $h(d)$. For negative discriminants d, one associates to each $\mathrm{PSL}_2(\mathbb{Z})$-orbit $[q] \subset \mathcal{Q}_d(\mathbb{Z})$, the point $z_{[q]}$ in $Y_0(1)$ defined as the $\mathrm{PGL}_2(\mathbb{Z})$-orbit of the unique root of $q(X, 1)$ contained in $\mathbb{H}^+$. These points are called *Heegner points of discriminant*[1] d and we set

$$\mathcal{H}_d := \{z_{[q]},\ [q] \in \mathrm{PSL}_2(\mathbb{Z})\backslash\mathcal{Q}_d(\mathbb{Z})\} \subset Y_0(1).$$

An equivalent form to (1.1) for $Q(A, B, C) = B^2 - 4AC$ and $d \to -\infty$ is the following:

Theorem 2 (Duke [17]). *As $d \to -\infty$, $d \equiv 0, 1 \bmod 4$, the set $\mathcal{H}_d$ becomes equidistributed on $Y_0(1)$ w.r.t. the Poincaré measure $d\mu_P = \frac{3}{\pi}\frac{dxdy}{y^2}$.*

For positive discriminants d, one associates to each class of integral quadratic form $[q] \in \mathcal{Q}_d(\mathbb{Z})$ the positively oriented geodesic, $\gamma_{[q]}$, in $Y_0(1)$ which is the projection to $Y_0(1)$ of the geodesic line in $\mathbb{H}^+$ joining the two (real) roots of $q(X, 1)$. This is a closed geodesic – in fact, all closed geodesics on $Y_0(1)$ are of that form – whose length is essentially equal to the logarithm of the fundamental solution to Pell's equation $x^2 - dy^2 = 4$. We denote by

$$\Gamma_d := \{\gamma_{[q]},\ [q] \in \mathrm{PSL}_2(\mathbb{Z})\backslash\mathcal{Q}_d(\mathbb{Z})\}$$

the set of all geodesics of discriminant d.

Theorem 3 (Duke [17]). *As $d \to +\infty$, $d \equiv 0, 1 \bmod 4$, d not a perfect square, the set Γ_d becomes equidistributed on the unit tangent bundle of $Y_0(1)$, $S_1^*(Y_0(1))$, w.r.t. the Liouville measure $d\mu_L = \frac{3}{\pi}\frac{dxdy}{y^2}\frac{d\theta}{2\pi}$.*

[1] For simplicity, we will ignore non-primitivite forms.

These three problems (in their form (1.1)) were first proved by Linnik and by Skubenko by means of Linnik's *ergodic method*; we will return to this method in Section 6. The proof however is subject to an additional assumption which we call *Linnik's condition*, namely:

Theorem 4 (Linnik [54], [55], Skubenko [71]). *Let p be an arbitrary fixed prime, then the equidistribution statements of Theorems* 1, 2, 3 *hold for the subsequence of d such that p* is split *in the quadratic extension $K_d = \mathbb{Q}(\sqrt{d})$.*

We will see in Section 6 that Linnik's condition has a natural ergodic interpretation. It can be relaxed to the condition that for each d there is a prime $p = p(d) \leqslant |d|^{\frac{1}{10^{10}\log\log|d|}}$ which splits in $\mathbb{Q}(\sqrt{d})$. The latter condition is satisfied, for instance, by assuming that the L-functions of quadratic characters satisfying the Generalized Riemann Hypothesis (GRH). In particular, Linnik's condition (resp. the weaker one) is automatically fullfilled for subsequences of d such that K_d is a *fixed* quadratic field (resp. $\mathrm{disc}(K_d) = \exp\big(O\big(\frac{\log|d|}{\log\log|d|}\big)\big)$); however, in these cases, the proof of Theorems 1, 2, 3 is much simpler (see [11] for instance); so, as it is (from our perspective at least) the hardest case, we will limit ourselves to d's which are fundamental discriminants (i.e. $d = \mathrm{disc}(K_d)$).

Acknowledgements. The first author is scheduled to give a presentation based on this work in the ICM 2006. Since much of it is based on our joint work, we have decided to write this paper jointly. The results of Section 6 are all joint work with M. Einsiedler and E. Lindenstrauss and will also be discussed in their contribution to these proceedings [28].

It is our pleasure to thank Bill Duke, Henryk Iwaniec and Peter Sarnak for both their consistent encouragement and for many beautiful ideas which underlie the whole field. Peter Sarnak and Hee Oh carefully read an early draft and provided many helpful comments and corrections. We also would like to thank our collaborators Manfred Einsiedler and Elon Lindenstrauss, for patiently explaining ergodic ideas and methods to us.

2. Linnik's problems via harmonic analysis

Duke's unconditional solution of Linnik's problems is via harmonic analysis and in a sense, is very direct as it proceeds by verifying Weyl's equidistribution criterion. Let (X, μ) denote any of the probability spaces (S^2, μ_{S^2}), $(Y_0(1), \mu_P)$, $(S^1_*(Y_0(1)), \mu_L)$. For each case and for appropriate d, let μ_d denote the probability measure formed out of the respective sets $\mathcal{G}_d$, $\mathcal{H}_d$ or Γ_d: for instance for $X = S^2$,

$$\int_{S^2} \varphi \mu_d = \frac{1}{|\mathcal{G}_d|} \sum_{\substack{(a,b,c)\in\mathbb{Z}^3 \\ a^2+b^2+c^2=|d|}} \varphi\Big(\frac{a}{\sqrt{|d|}}, \frac{b}{\sqrt{|d|}}, \frac{c}{\sqrt{|d|}}\Big).$$

Showing that μ_d weak-$*$ converges to μ amounts to show that, for any φ ranging over a fixed orthogonal basis (made of continuous functions) of the L^2-space $L^2_0(X, \mu)$, the Weyl sum

$$W(\varphi, d) := \int_X \varphi \mu_d \quad \text{converges to 0 as } |d| \to +\infty. \tag{2.1}$$

In the context of Theorem 1 (resp. Theorem 2, resp. Theorem 3) such bases are taken to consist of non-constant harmonic polynomials (resp. Maass forms and Eisenstein series of weight 0, resp. Maass forms and Eisenstein series of non-negative, even, weight).

2.1. Duke's proof. The decay of the period integral $W(\varphi, d)$ is achieved by realizing it in terms of the d-th Fourier coefficient of a modular form of half-integral weight and level 4; this modular form – call it $\tilde{\varphi}$ – is obtained from φ through a theta correspondance.

In the case of Theorem 1, and when φ is a non-constant harmonic polynomial of degree r, this comes from the well known fact that the theta-series

$$\tilde{\varphi}(z) = \theta_\varphi(z) = \sum_{|d| \geqslant 1} \Big(\sum_{\substack{(a,b,c) \in \mathbb{Z}^3 \\ a^2+b^2+c^2 = |d|}} \varphi(a, b, c) \Big) e(|d|z)$$

is a modular form of weight $k = 3/2 + r$ for the modular group $\Gamma_0(4)$. This is a special case of a (theta) correspondance of Maass, which itself is now a special case of the theta correspondance for dual pairs; it associates to an automorphic form φ for an orthogonal group $\mathrm{SO}_{p,q}$ of signature (p, q), a Maass form $\tilde{\varphi}$ of weight $(q - p)/2$. Moreover, Maass provided a formula expressing the Fourier coefficients of $\tilde{\varphi}$ in terms of a certain integral of φ.

By the accidental isomorphisms recalled above, this provides a correspondance between automorphic forms either for $\mathrm{B}^\times_{2,\infty}$ or for PGL_2, and modular forms of half-integral weight. Under this correspondance, one has, for d a fundamental discriminant

$$W(\varphi, d) = c_{\varphi,d} \frac{\rho_{\tilde{\varphi}}(d)|d|^{-1/4}}{L(\chi_d, 1)} \tag{2.2}$$

where $c_{\varphi,d}$ is a constant depending on φ and mildly on d (i.e. $|d|^{-\varepsilon} \ll_{\varphi,\varepsilon} c_{\varphi,d} \ll_\varepsilon |d|^\varepsilon$ for any $\varepsilon > 0$), $\rho_{\tilde{\varphi}}(d)$ denotes the suitably normalized d-th fourier coefficient of $\tilde{\varphi}$ and χ_d is the quadratic character corresponding to K_d.

In particular, by Siegel's lower bound $L(\chi_d, 1) \gg_\varepsilon |d|^{-\varepsilon}$, (2.1) is a consequence of a bound of the form

$$\rho_{\tilde{\varphi}}(d) \ll |d|^{1/4-\delta} \tag{2.3}$$

for some absolute $\delta > 0$. The bound (2.3) is to be expected; indeed the half-integral weight analog of the Ramanujan–Petersson conjecture predicts that any $\delta < 1/4$ is admissible. This conjecture follows from the GRH, but, unlike its integral weight analogue, does not follow from the Weil conjectures.

The problem of bounding Fourier coefficient of modular forms can be approached through a Petersson–Kuznetzov type formula (due to Proskurin in the half-integral weight case): (un)fortunately the standard bound for the Salié sums occuring in the formula yield the above estimate only for $\delta < 0$. This "barricade" was eventually surmounted by Iwaniec (using an ingenious idea of averaging over the level, and obtaining the value $\delta = 1/28$, [41]) for $\tilde{\varphi}$ a holomorphic form of weight $\geqslant 5/2$ and by B. Duke for general forms by adapting Iwaniec's argument, and thus concluding the first fully unconditional proof of Theorems 1, 2, 3.

2.2. Equidistribution and subconvex bounds for L-functions. Shortly after Duke's proof, another approach emerged which turned out to be very fruitful, namely the connection between the decay of Weyl's sums (2.1) and the *subconvexity problem* for automorphic L-function (see Section 3).

2.2.1. Weyl's sums as period integrals: Waldspurger type formulae. It goes back to Gauss that the set of classes of quadratic forms $\mathrm{SL}_2(\mathbb{Z})\backslash\mathcal{Q}_d(\mathbb{Z})$ has the structure of a finite commutative group (the class group) $\mathrm{Cl}(d)$. In particular for the second problem ($d < 0$), $\mathcal{H}_d$ is a homogeneous space under the action of $\mathrm{Cl}(d)$ and the Weyl sums can be seen as period integrals for this action:

$$W(\varphi, d) = \int_{\mathrm{Cl}(d)} \varphi(\sigma.z_d)\, d\mu_{\mathrm{Haar}}(\sigma).$$

In a similar way, the Weyl's sums over $\mathcal{G}_d$ and Γ_d can be realized as orbital integrals for the action of some class group. The connection between such orbital integrals and L-functions follows from a formula basically due to Waldspurger. To describe it in greater detail it is useful and convenient to switch an adelic description of the Weyl's sums.

Let us recall recall that in the context of Theorem 1 with $Q(A, B, C) = A^2 + B^2 + C^2$ (resp. Theorems 2 and 3, with $Q(A, B, C) = B^2 - 4AC$) a solution $Q(a, b, c) = d$ gives rise to an embedding of the quadratic $\mathbb{Q}$-algebra K_d into the $\mathbb{Q}$-algebra $\mathrm{B}^{(2,\infty)}$ (resp. $M_{2,\mathbb{Q}}$) by sending $\sqrt{d}$ to $a.i + b.j + c.k$ (resp. $\left(\begin{smallmatrix} b & -2a \\ 2c & -b \end{smallmatrix}\right)$). This yields an embedding of $\mathbb{Q}$-algebraic groups, $\boldsymbol{T}_d := \mathrm{res}_{K/Q}\mathbb{G}_m/\mathbb{G}_m \hookrightarrow \boldsymbol{G}$, where $\boldsymbol{G} = \mathrm{PG}(\mathrm{B}^{(2,\infty)})$ (resp. $= \mathrm{PGL}_2$).

Let $\mathrm{K}_{f,\max}$ be a maximal compact subgroup of $\boldsymbol{G}(\boldsymbol{A}_f)$ in all three cases. In the context of Theorem 1 (resp. Theorem 2, resp. Theorem 3) take $\mathrm{K}_\infty = \boldsymbol{T}_d(\mathbb{R}) \cong \mathrm{SO}_2 \subset \boldsymbol{G}$ (resp. $\mathrm{K}_\infty = \boldsymbol{T}_d(\mathbb{R})$, resp. $\mathrm{K}_\infty = \{1\}$) and set $\mathrm{K} = \mathrm{K}_{f,\max}\mathrm{K}_\infty$; the quotient $\boldsymbol{G}(\mathbb{Q})\backslash\boldsymbol{G}(\boldsymbol{A}_\mathbb{Q})/\mathrm{K}$ then equals a quotient of S^2 by a finite group of rotations (resp. $Y_0(1)$, resp. the unit tangent bundle of $Y_0(1)$).

It transpires, with these identifications, the subsets

$$\mathcal{G}_d \subset S^2, \quad \mathcal{H}_d \subset Y_0(1), \quad \Gamma_d \subset S^1_*(Y_0(1))$$

may be uniformly described, after choosing a solution z_d, as a compact orbit of the adelic torus $\boldsymbol{T}_d$:

$$\boldsymbol{T}_d(\mathbb{Q})\backslash z_d.\boldsymbol{T}_d(\boldsymbol{A}_{\mathbb{Q}})/\mathrm{K}_{\boldsymbol{T}_d} \subset \boldsymbol{G}(\mathbb{Q})\backslash \boldsymbol{G}(\boldsymbol{A}_{\mathbb{Q}})/\mathrm{K}$$

where $\mathrm{K}_{\boldsymbol{T}_d} := \boldsymbol{T}_d(\boldsymbol{A}_{\mathbb{Q}}) \cap \mathrm{K}$. In this notation the Weyl sum is given as a *toric integral*

$$W(\varphi, d) = \int_{\boldsymbol{T}_d(\mathbb{Q})\backslash \boldsymbol{T}_d(\boldsymbol{A}_{\mathbb{Q}})/K_{\boldsymbol{T}_d}} \varphi(z_d.t)\, dt \tag{2.4}$$

when dt is the Haar measure on the toric quotient. A superficial advantage of this notation is that it allows for a uniform presentation of many equidistribution problems for "cycles" associated with quadratic orders in locally symmetric spaces associated to quaternion algebras. Indeed, as we shall see below, one can consider the above equidistribution problems while changing

- the group $\boldsymbol{G}$ to $\boldsymbol{G} = \mathrm{B}^\times/Z(\mathrm{B}^\times)$ for B any quaternion algebra over $\mathbb{Q}$;
- the compact $\mathrm{K}_{f,\max}$ to a compact subgroup $\mathrm{K}'_f \subset \mathrm{K}_{f,\max}$ (i.e. changing the level structure)
- the subgroup $\mathrm{K}_{\boldsymbol{T}_d}$ to a subgroup $\mathrm{K}'_{\boldsymbol{T}_d}$ (i.e. considering cycles associated to suborders $\mathcal{O}$ of the maximal order $\mathcal{O}_d$).
- the base field $\mathbb{Q}$ to a fixed totally real number field F.

When φ is a *new cuspform* (the L^2 normalized *new vector* in some automorphic representation π), Waldspurger's formula [76] relates $|W(\varphi, d)|^2$ (and correspondingly the square of the d-th Fourier coefficient $|\rho_{\tilde{\varphi}}(d)|^2$) to the central value of an automorphic L-function. In its original form, the formula was given up to some non-zero proportionality constant; as we are interested in the size $W(\varphi, d)$ a more precise expression is needed. Thanks to the work of many people ([12], [36], [37], [47], [50], [66], [78], [80], [81]) notably Gross, Zagier and Zhang such an expression is by now available in considerable generality. Under suitable hypotheses (which in the present cases are satisfied), it has the following form

$$|W(\varphi, d)|^2 = c_{\varphi,d} \frac{L(\pi, 1/2)L(\pi \times \chi_d, 1/2)}{L(\chi_d, 1)^2\sqrt{|d|}} \tag{2.5}$$

where π' is a GL_2-automorphic representation corresponding to π by the Jacquet–Langlands correspondance and $c_{\varphi,d} > 0$ is a constant which depends mildy on d.

The Waldspurger formula (2.5) is more powerful than (2.2) as it may be extended to a formula for more general toric integrals. Indeed, let χ be a character of the torus $\boldsymbol{T}_d(\mathbb{Q})\backslash \boldsymbol{T}_d(\boldsymbol{A}_{\mathbb{Q}}) = K_d^\times \boldsymbol{A}_{\mathbb{Q}}^\times \backslash \boldsymbol{A}_{K_d}^\times$ trivial on $\mathrm{K}_{\boldsymbol{T}_d}$. Under suitable compatibility assumptions between χ and φ and possibly under additional coprimality assumptions between the conductors of of π, χ, the relation (2.5) generalizes to

$$|W_\chi(\varphi, d)|^2 = c_{\varphi,d_\chi,\chi_\infty} \frac{L(\pi \times \pi_\chi, 1/2)}{L(\chi_d, 1)^2\sqrt{|d_\chi|}} \tag{2.6}$$

where $W_\chi(\varphi, d)$ is a *twisted toric integral* of the form

$$W_\chi(\varphi, d_\chi) = \int_{\boldsymbol{T}_d(\mathbb{Q})\backslash \boldsymbol{T}_d(\boldsymbol{A}_\mathbb{Q})} \chi(t)\varphi(z_{d_\chi}.t)\, dt,$$

π_χ is the GL_2-automorphic representation (of conductor d_χ) corresponding to χ by quadratic automorphic induction and $L(\pi \times \pi_\chi, s)$ is the Rankin–Selberg L-function of the pair (π, π_χ).

2.3. Subconvexity and (sparse) equidistribution. We see, from formula (2.5) and Siegel's lower bound that (2.1) follows from the bound

$$L(\pi \times \chi_d, 1/2) \ll_\pi |d|^{1/2-\delta} \tag{2.7}$$

for some absolute $\delta > 0$; subject to this bound, one obtains another proof of Linnik's equidistribution problems. More generally, we see from (2.6) that the twisted Weyl sums are decaying, i.e.

$$W_\chi(\varphi, d_\chi) \to 0 \quad \text{for } d_\chi \to +\infty, \tag{2.8}$$

as soon as

$$L(\pi \times \pi_\chi, 1/2) \ll |d_\chi|^{1/2-\delta}. \tag{2.9}$$

Both (2.7) and (2.9) are special cases of subconvex bounds for central values of automorphic L-functions and have been proven (see below).

One should note that the decay of the twisted toric integral is useful if one needs to perform *harmonic analysis along* the toric orbit $\boldsymbol{T}_d(\mathbb{Q})\backslash z_d.\boldsymbol{T}_d(\boldsymbol{A}_\mathbb{Q})/\mathrm{K}_{\boldsymbol{T}_d}$: this is particular the case when one needs equidistribution only for a stricly smaller suborbit of the full orbit, a problem we call a *sparse equidistribution problem*.

For instance one has:

Theorem 5 ([39]). *There is an absolute constant $0 < \eta < 1$ such that: for each fundamental discriminant $d < 0$, choose $z_{0,d} \in \mathcal{H}_d$ a Heegner point and choose G_d a subgroup of $\mathrm{Cl}(d)$ of size $|G_d| \geqslant |\mathrm{Cl}(d)|^\eta$ then the sequence of suborbits*

$$\mathcal{H}'_d := G_d.z_{0,d} = \{\sigma.z_{0,d},\ \sigma \in G_d\}$$

is equidistributed on $Y_0(1)$ w.r.t. μ_P.

One has also similar sparse equidistribution results for sufficiently large suborbits of $\mathcal{G}_d$ on the sphere and for suffciently large geodesic segments of Γ_d [60], [66]. Note however that the present method has fundamental limitations as one cannot take η too close to 0: even under the GRH, one would prove equidistribution only for $\eta > 1/2$. Nevertheless we would like to formulate the following

Conjecture 1 (Equidistribution of subgroups). Fix any $\eta > 0$ and for each fundamental discriminant $d < 0$, choose $z_{0,d} \in \mathcal{H}_d$ a Heegner point and choose G_d a subgroup of $\mathrm{Cl}(d)$ of size $|G_d| \geqslant |d|^\eta$. Then as $|d| \to +\infty$, the sequence of suborbits

$$\mathcal{H}'_d := G_d.z_{0,d} = \{\sigma.z_{0,d},\ \sigma \in G_d\}$$

is equidistributed on $Y_0(1)$ w.r.t. μ_P.

This conjecture is certainly difficult in general; however, we expect that, by ergodic methods like the ones described in Section 6, significant progress might be made, at least for subgroups G_d that satisfy suitable versions of Linnik's condition for some fixed prime p.

2.4. Equidistribution and non-vanishing of L-functions. Before continuing with the subconvexity problem, we would like to point out another interesting application. It combines subconvexity, equidistribution and the period relation (2.5) and applies them to the non-vanishing of L-functions.

Consider, for simplicity, the context of Theorem 2 (see also [62]): let φ be a Maass–Hecke eigenform of weight 0 and π be its associated automorphic representation. If one averages (2.5) over the characters of $\mathrm{Cl}(d)$, one obtains by orthogonality (here the constants $c_{\varphi,d_\chi,\chi_\infty}$ are equal to an absolute constant $c > 0$)

$$c\frac{\sqrt{d}}{|\mathrm{Cl}(d)|^2}\sum_{\chi\in\widehat{\mathrm{Cl}}(d)} L(\pi\times\pi_\chi, 1/2) = \int_{Y_0(1)} |\varphi|^2.\mu_d$$

and since by Theorem 2

$$\int_{Y_0(1)} |\varphi|^2.\mu_d \to \int_{Y_0(1)} |\varphi(z)|^2 d\mu_P(z) > 0 \quad \text{as } d \to -\infty$$

this shows that for some χ the central value $L(\pi\times\pi_\chi, 1/2)$ does not vanish. Moreover, by the subconvex bound (2.9), one obtains a quantitative form of non-vanishing

$$\left|\{\chi \in \widehat{\mathrm{Cl}}(d),\ L(\pi\times\pi_\chi, 1/2) \neq 0\}\right| \gg |d|^\eta \tag{2.10}$$

for some absolute $\eta > 0$.

Remark 2.1. When π corresponds to an Eisenstein series, stronger results where obtained before by Duke–Friedlander–Iwaniec [24] and Blomer [5]; although this it appears in a somewhat disguised (and more elaborate) form, the basic principle underlying the proof is the same.

By considering equidistribution relative to definite quaternion algebras, one can obtain similar non-vanishing results for central values $L(\pi\times\pi_\chi, 1/2)$ where π_∞ is in the discrete series and the sign of the functional equation of $L(\pi\times\pi_\chi, s)$ is $+1$. In particular when $\pi = \pi_E$ is the automorphic representation associated to an elliptic

curve $E/\mathbb{Q}$, such estimates provide a lower bound for the size of the "rank-0" part of the group $E(H_K)$ of points of E which are rational over the Hilbert class field of K as $d \to -\infty$.

An interesting problem is to adress the case where the sign of the functional equation is -1. In this case, $L(\pi \times \pi_\chi, 1/2) = 0$ and one considers instead the question of non-vanishing of the first derivative $L'(\pi \times \pi_\chi, 1/2)$. At least when π_∞ is in the holomorphic discrete series and π has trivial central character, the Gross–Zagier formula (and its extensions by Zhang) interprets $L'(\pi \times \pi_\chi, 1/2)$ as the "height" of some Heegner cycle above some modular (or Shimura) curve. This is not quite a period integral; however the height decomposes as a sum of local heights indexed by the places v of $\mathbb{Q}$. These local heights are either simple or can be interpreted as periods integrals over quadratic cycles associated with K which live over appropriate adelic quotients $\boldsymbol{G}^{(v)}(\mathbb{Q})\backslash\boldsymbol{G}^{(v)}(\boldsymbol{A})/\mathrm{K}_v$ where $\boldsymbol{G}^{(v)}$ is associated to a quaternion algebra $\mathrm{B}^{(v)}$ ramified at v.

It seem then plausible that one can compute the asymptotic of the average $\sum_\chi L'(\pi \times \pi_\chi, 1/2)$ by using the equidistribution property of quadratic cycles on these infinitely many quotients. One consequence of this would then be, for compatible E and K, a lower bound for the rank of $E(H_K)$:

$$\mathrm{rank}_{\mathbb{Z}}\, E(H_K) \gg |d|^\eta$$

for some $\eta > 0$ as $d \to -\infty$.

Remark 2.2. A few years ago, Vatsal and Cornut [16], [73], [74] used period relations and equidistribution in a similar way to obtain somewhat stronger non-vanishing results for Rankin–Selberg L-functions but associated to anti-cyclotomic[2] characters of a *fixed* imaginary quadratic field. Note that one of their main ingredient to obtain equidistribution came for ergodic theory and precisely from Ratner's theory.

3. The subconvexity problem

Although the subconvexity problem is a venerable topic in number theory – its study begins with Weyl's estimate $|\zeta(1/2 + it)| \ll_\varepsilon t^{1/6+\varepsilon}$ – there has been a renaissance of interest in it recently. This owes largely to the observation that a resolution of the subconvexity problem for automorphic L-functions on GL has many striking applications, as we have just seen to Linnik's equidistribution problems or to "Arithmetic Quantum Chaos." We refer to [44] for a discussion of all these questions in the broader context of the analytic theory of automorphic L-functions.

Let $\Pi = \Pi_\infty \otimes \bigotimes_p{}' \Pi_p$ some reasonable "automorphic object": by automorphic object we mean, for instance an automorphic representation or more generally an admissible representation constructed out of automorphic representations via the

[2]The case of cyclotomic characters was carried out even earlier by Rohrlich, by more direct methods.

formalism of L-groups (for instance the Rankin–Selberg convolution $\pi_1 \times \pi_2$ of two automorphic representations on some linear groups). To Π, one can usually associate a collection of local L-factors

$$L(\Pi_p, s) = \prod_{i=1}^{d} \left(1 - \frac{\alpha_{\Pi,i}(p)}{p^s}\right)^{-1}, \quad p \text{ prime}, \ L(\Pi_\infty, s) = \prod_{i=1}^{d} \Gamma_{\mathbb{R}}(s - \mu_{\Pi,i})$$

where $\Gamma_{\mathbb{R}}(s) = \pi^{-s/2}\Gamma(s/2)$ and $\{\alpha_{\Pi,i}(p)\}$, $\{\mu_{\Pi,i}\}$ are called the local numerical parameters of Π at p and at infinity; from these local datas one forms a global L-function

$$L(\Pi, s) = \sum_{n \geqslant 1} \frac{\lambda_\Pi(n)}{n^s} = \prod_p L(\Pi_p, s).$$

In favourable cases, one can show that $L(\Pi, s)$ has analytic continuation to $\mathbb{C}$ and satisfies a functional equation which we normalize into the form

$$q_\Pi^{s/2} L(\Pi_\infty, s) L(\Pi, s) = w_\Pi q_\Pi^{(1-s)/2} \overline{L(\Pi_\infty, 1 - \overline{s}) L(\Pi, 1 - \overline{s})},$$

where $|w_\Pi| = 1$ and $q_\Pi > 0$ is an integer called the conductor of Π. We recall (after Iwaniec–Sarnak [44]) that *the analytic conductor* of Π is the function of the complex variable s given by

$$C(\Pi, s) = q_\Pi \prod_{i=1}^{d} |s - \mu_{\Pi,i}|.$$

It is expected, and known in many cases, that the following *convexity bound* for the values of $L(\Pi, s)$ holds on the critical line $\Re es = 1/2$: for any $\varepsilon > 0$, one has

$$L(\Pi, s) \ll_{\varepsilon,d} C(\Pi, s)^{1/4+\varepsilon}.$$

This is known, in particular, when Π is an automorphic cuspidal representation of $\mathrm{GL}(n)$ over any number field, [63]. The Lindelöf conjecture, which is a consequence of the GRH, asserts that in fact $L(\Pi, s) \ll_{\varepsilon,d} C(\Pi, s)^{\varepsilon}$. In many applications, however, it is sufficient to improve the convexity bound.

The subconvexity problem consists in improving the exponent $1/4$ to $1/4 - \delta$ for some positive absolute δ. In fact, for most applications it is sufficient to improve that exponent only with respect to one of the three type of parameters s, q_Π or $\prod_{i=1}^{d}(1 + |\mu_{\Pi,i}|)$; these variants are called the s-aspect, the q-aspect (or *level*-aspect) and the ∞-aspect (or *eigenvalue*-aspect) respectively. See [34], [44] for an introduction to the subconvexity problem in this generality. During the last decade, there has been considerable progress on the subconvexity problem for L-functions associated to GL_1 and GL_2 automorphic forms. In this lecture, we mainly discuss the recent progress made on the q-aspect, although the other aspects are very interesting, both for applications and for conceptual reasons (see [6], [42], [46], [70]). In the level aspect, one has

Theorem 6. *Let F be a fixed number field and π_2 be a* fixed *cuspidal automorphic representation of $\mathrm{GL}_2(\boldsymbol{A}_F)$. Let χ_1, π_1 denote respectively a $\mathrm{GL}_1(\boldsymbol{A}_F)$-automorphic representation (i.e. a Grössencharacter), a $\mathrm{GL}_2(\boldsymbol{A}_F)$-automorphic representation and let $\mathfrak{q}_1$ denote either the conductor of χ_1 or π_1 and $q_1 = N_{F/\mathbb{Q}}(\mathfrak{q}_1)$. There exists an absolute constant $\delta > 0$ such that for $\Re es = 1/2$ one has*

$$L(\chi_1, s) \ll_s q_1^{1/4-\delta}, \tag{3.1}$$

$$L(\chi_1 \times \pi_2, s) \ll_{s,\pi_2,\chi_{1,\infty}} q_1^{1/2-\delta}, \tag{3.2}$$

$$L(\pi_1, s) \ll_{s,\pi_{1,\infty}} q_1^{1/4-\delta}, \tag{3.3}$$

$$L(\pi_1 \times \pi_2, s) \ll_{s,\pi_2,\pi_{1,\infty}} q_1^{1/2-\delta}. \tag{3.4}$$

Thus the subconvexity problem is solved in the q_1-aspect for all these L-functions.

• For $F = \mathbb{Q}$, the bound for Dirichlet L-functions (3.1) is due to Burgess (see also [15]). The bound for twisted L-function (3.2) is basically due to Duke–Friedlander–Iwaniec [19] (see also [7], [9] for the general bound over $\mathbb{Q}$ with a good subconvex exponent). The bound (3.3) is mainly to a series of works by Duke–Friedlander–Iwaniec: [20] for π_1 with trivial central character and [21], [22], [23] for the much harder case of a central character of conductor q_1; it has been recently completed for π_1 with arbitrary central character by Blomer, Harcos and the first author in [8]. The bound for Rankin–Selberg L-functions (3.4) for π having trivial central character is due to Kowalski, the first author and Vanderkam ([52]) by generalizing the methods of [20] and to Harcos and the first author for π_1 with an arbitrary central character [39], [60].

• In the case of a number field of higher degree, the first general subconvex result is due to Cogdell–Piatetski-Shapiro–Sarnak [13]: it consists of (3.2) when F is a totally real field and $\pi_{2,\infty}$ is in the holomorphic discrete series (i.e. corresponds to a holomorphic Hilbert modular form). Recently, the second author developed a new method and established, amongst other things, the bounds (3.1), (3.2), (3.3) and (3.4) for F an arbitrary number field, π_2 fixed but arbitrary and π_1 with a trivial central character [75]. Eventually the authors combined their respective methods from [60] and [75] to obtain (3.3) and (3.4) for π_1 with an arbitrary central character.

3.1. Amplification and the shifted convolution problem. Arguably, the most successful approach to subconvexity in the q-aspect is via the method of moments or more precisely via its variant, the *amplification method*. For the sake of completness we briefly recall the mechanism and refer to [34] and [43] for the philosophy underlying this method.

Given Π_1 and a (well choosen) family of automorphic objects $\mathcal{F} = \{\Pi\}$ containing Π_1, the amplification method builds on the possibility to obtain a bound for the amplified k-th moment of the $\{L(\Pi, s),\ \Pi \in \mathcal{F}\}$, $\Re es = 1/2$, of the form

$$\sum_{\Pi\in\mathcal{F}} |L(\Pi, s)|^k \Big| \sum_{\ell\leqslant L} \lambda_\Pi(\ell) a_\ell \Big|^2 \ll_\varepsilon |\mathcal{F}|^{1+\varepsilon} \sum_{\ell\leqslant L} |a_\ell|^2 \tag{3.5}$$

for any $\varepsilon > 0$, where the $(a_\ell)_{\ell \leqslant L}$ are *a priori* arbitrary complex coefficients and where L is some positive power of $|\mathcal{F}|$. Such a bound is expected if L is sufficiently small compared with $|\mathcal{F}|$, since the individual bound $|L(\Pi, s)|^k \ll_\varepsilon |\mathcal{F}|^\varepsilon$ would follow from the GRH and the estimate

$$\sum_{\Pi \in \mathcal{F}} \Big| \sum_{\ell \leqslant L} \lambda_\Pi(\ell) a_\ell \Big|^2 = |\mathcal{F}|(1 + o(1)) \sum_{\ell \leqslant L} |a_\ell|^2$$

should be a manisfestation of the *quasi-orthogonlity* of the $\{(\lambda_\Pi(\ell))_{\ell \leqslant L}\}_{\Pi \in \mathcal{F}}$ which is a frequently recurring theme in harmonic analysis. Assuming (3.5), one deduces a subconvex bound for $|L(\Pi_1, s)|^k$ by restricting (3.5) to one term and by choosing the coefficients $a_\ell = a_\ell(\Pi_1)$ appropriately.

All the subconvex bounds presented in Theorem 6 can be obtained by considering for $L(\Pi, s)$ an L-function of *Rankin–Selberg* type, i.e. an L-function either of the form $L(\chi_1 \times \pi_2, s)$ or of the form $L(\pi_1 \times \pi_2, s)$ with π_2 a fixed (not necessarily cuspidal) GL_2-automorphic representation. The families $\mathcal{F}$ considered are then essentially of the form $\{\chi \times \pi_2,\ q_\chi = q_1\}$ or $\{\pi \times \pi_2,\ q_\pi = q_1,\ \omega_\pi = \omega_{\pi_1}\}$ and the bound (3.5) is achieved for the second moment ($k = 2$). To analyze effectively the left-hand side of (3.5) one needs a manageable expression for $L(\Pi, s)$ for s on the critical line. The traditional method to do so is to apply an *approximate functional equation* technique which expresses $L(\Pi, s)$ essentially as a partial sum of the form

$$\Sigma(\Pi) := \sum_{n \geqslant 1} \frac{\lambda_\Pi(n)}{n^s} W\left(\frac{n}{\sqrt{q_\Pi}}\right)$$

with W a rapidly decreasing function (which depends on s and on Π_∞). In the context of Theorem 6, the second amplified moment (3.5) are then computed and transformed by spectral methods. These involve, in particular, the orthogonality relations for characters and the Kuznetsov–Petersson formula. These computations reduce the subconvex estimates to the problem of estimating non-trivially sums of the form

$$\Sigma_\pm(\varphi_2, \ell_1, \ell_2, h) := \sum_{\ell_1 m \pm \ell_2 n = h} \overline{\rho_{\varphi_2}(m)} \rho_{\varphi_2}(n) \mathcal{W}\left(\frac{m}{q}, \frac{n}{q}\right), \tag{3.6}$$

the trivial bound being $\ll_{\varphi_2} q^{1+o(1)}$; here $h = O(q)$ is a non-zero integer, $\rho_{\varphi_2}(n)$ denotes the n-th Fourier coefficient of some automorphic form φ_2 in the representation space of π_2, $\mathcal{W}(x, y)$ is a rapidly decreasing function and $\ell_1, \ell_2 \leqslant L$ are the parameters occuring as indices of the amplifier $(a_\ell)_{\ell \leqslant L}$. These sums are classical in analytic number theory and are called *shifted convolution sums*; the problem of estimating them non-trivially for various ranges of h, m, n is called a *shifted convolution problem*.[3]

[3]Historically, the shifted convolution problem already occured in the work of Kloosterman on the number of representations of an integer n by the quadratic form $a_1.x^2 + a_2.y^2 + a_3.z^2 + a_4.t^2$, and also in Ingham's work on the additive divisor problem. In Kloosterman's case φ_2 is a theta-series of weight 1, whereas in Ingham's case φ_2 is the standard non-holomorphic Eisenstein series.

3.2. Shifted convolutions via the circle method. In order to solve a shifted convolution problem, one needs an analytically manageable expression of the linear constraint $\ell_1 m \pm \ell_2 n = h$; one is to suitably decompose the integral

$$\delta_{\ell_1 m \pm \ell_2 n - h = 0} = \int_{\mathbb{R}/\mathbb{Z}} \exp(2\pi i (\ell_1 m \pm \ell_2 n - h)\alpha)\, d\alpha,$$

and there are several methods to achieve this; the first possibility in this context was Kloosterman's refinement of the circle method; other possibilities are the Δ-symbol method, used in [19] and [20] to prove some cases of (3.2) and (3.3) or Jutila's method of overleaping intervals which is particularly flexible [38], [45]. These methods provide an expression of the above integral into weighted sums of Ramanujan type sums of the form

$$\sum_{\substack{a \bmod c \\ (a,c)=1}} e\Big(\frac{(\ell_1 m \pm \ell_2 n - h).a}{c}\Big)$$

for c ranging over relatively small moduli. Such decomposition makes it possible to essentially "separate" the variable m from n and to reduce $\Sigma(\varphi_2, \ell_1, \ell_2, h)$ to sums over moduli c on additively twisted sums of Fourier coefficients

$$\sum_c \cdots \sum_{\substack{a \bmod c \\ (a,c)=1}} e\Big(\frac{-ha}{c}\Big)\Big(\sum_m \overline{\rho_{\varphi_2}(m)} e\Big(\frac{\ell_1 m a}{c}\Big) W\Big(\frac{m}{q}\Big)\Big)$$
$$\Big(\sum_n \rho_{\varphi_2}(n) e\Big(\pm\frac{\ell_2 n a}{c}\Big) W\Big(\frac{n}{q}\Big)\Big).$$

The independent m- and n-sums are then transformed via the Voronoï summation formula with the effect of replacing the test functions $W(\frac{\cdot}{q})$ by some Bessel transform and the additive shift $e\big(\pm\frac{\ell_2 a.}{c}\big)$ by $e\big(-\pm\frac{\bar{\ell}_2 \bar{a}.}{c}\big)$ where $\bar{a}$ denotes the multiplicative inverse of a mod c. After these transformations and after averaging over a mod c the sum $\Sigma_\pm(\varphi_2, \ell_1, \ell_2, h)$ takes essentially the following form (possibly up to a main term which occurs if φ_2 is an Eisenstein series [18])

$$MT_\pm(\varphi_2, \ell_1, \ell_2, h) \tag{3.7}$$
$$+ \sum_{c \equiv 0(\ell_1 \ell_2 q \pi_0)} \sum_{h'} \Big(\sum_{\mp \ell_1 n - \ell_2 m = h'} \alpha_m \overline{\rho_{\varphi_2}(m)} \beta_n \rho_{\varphi_2}(n) \Big) \mathrm{Kl}(-h, h'; c) \mathcal{V}(h, h'; c)$$

where $MT_\pm(\varphi_2, \ell_1, \ell_2, h)$ is non-zero only if φ_2 is an *Eisenstein series* (in which case it is a *main term* of size $\approx_{\ell_1, \ell_2, \varphi_2} q^{1+o(1)}$), α_m, β_n are smooth coefficients, $\mathrm{Kl}(-h, h'; c)$ is a Kloosterman sum and $\mathcal{V}$ is a smooth function. Eventually, Weil's bound for Kloosterman sums

$$\mathrm{Kl}(-h, h'; c) \ll (h, h', c)^{1/2} c^{1/2 + o(1))}$$

gives the formula

$$\Sigma_{\pm}(\varphi_2, \ell_1, \ell_2, h) = MT_{\pm}(\varphi_2, \ell_1, \ell_2, h) + O_{\varphi_2,\varepsilon}\big((\ell_1\ell_2)^A q^{3/4+\varepsilon}\big) \tag{3.8}$$

for some absolute constant A. Finally, from (3.8) one can deduce (3.2), (3.3), (3.4) when π has trivial central character although the derivation may be quite delicate if φ_2 is an Eisenstein series (cf. [20] and see also [51]).

3.3. Shifted convolutions and spectral theory. In [70], Sarnak, inspired by ideas of Selberg, developed a purely spectral approach to the shifted convolution sums (3.6) (previously some special cases have been treated by others, for instance by A. Good). This method, which at present has been entirely worked out when φ_2 is a classical holomorphic cuspform (say of weight $k \geqslant 2$ and level q_2), is based on the analytic properties of the Dirichlet series

$$D(\varphi_2, \ell_1, \ell_2, h, s) = \sum_{\substack{m,n\geqslant 1\\ \ell_1 m-\ell_2 n=h}} \frac{\overline{\rho_{\varphi_2}(m)}\rho_{\varphi_2}(n)}{(\ell_1 m+\ell_2 n)^s}\left(\frac{\sqrt{\ell_1\ell_2 mn}}{\ell_1 m+\ell_2 n}\right)^{k-1}.$$

Note that for $h = 0$ this series is essentially a Rankin–Selberg L-function. As in the Rankin–Selberg case, the analytic properties of D follows from an appropriate integral representation in the form of a triple product integral; however, for $h \neq 0$ one needs to replace the Eisenstein series by a Poincaré series. Precisely, one has $D(s) = (2\pi)^{s+k-1}(\ell_1\ell_2)^{1/2}\Gamma^{-1}(s+k-1)I(s)$ with

$$\begin{aligned} I(\varphi_2, \ell_1, \ell_2, h, s) &:= \langle (\ell_1 y)^{k/2}\varphi_2(\ell_1 z).(\ell_2 y)^{k/2}\overline{\varphi_2}(\ell_2 z),\, P_h(z,s)\rangle \\ &= \int_{\Gamma_0(q_2\ell_1\ell_2)\backslash\mathbb{H}} (\ell_1 y)^{k/2}\overline{\varphi_2}(\ell_1 z).(\ell_2 y)^{k/2}\varphi_2(\ell_2 z)P_h(z,s)\,\frac{dxdy}{y^2} \end{aligned}$$

where $P_h(z,s)$ is a non-holomorphic Poincaré series of weight 0. The analytic continuation for D follows from that of $P_h(.,s)$; in particular, from its spectral expansion one deduce that the latter is absolutely convergent for $\Re es > 1$ and has holomorphic continuation in the half-plane $\Re es > 1/2 + \theta$ where θ measures the quality of available results towards the Ramanujan–Petersson conjecture:

Hypothesis H_θ. For any cuspidal automorphic form π on $\mathrm{GL}_2(\mathbb{Q})\backslash\mathrm{GL}_2(\boldsymbol{A}_{\mathbb{Q}})$ with local Hecke parameters $\{\alpha_{\pi,i}(p),\ i = 1, 2\}$ for $p < \infty$ and $\{\mu_{\pi,i},\ i = 1, 2\}$ one has the bounds

$$\begin{aligned} |\alpha_{\pi,i}(p)| &\leqslant p^{\theta}, \quad i = 1, 2,\\ |\Re e\mu_{\pi,i}| &\leqslant \theta, \qquad i = 1, 2, \end{aligned}$$

provided π_p, π_∞ are unramified, respectively.

Remark 3.1. Hypothesis H_θ is known for $\theta > 3/26$ thanks to the works of Kim and Shahidi [48], [49].

A bound for $D(s)$ in a non-trivial domain is deduced from the spectral expansion of the inner product $I(s)$ over an suitable orthonormal basis of Maass forms, $\{\psi\}$ say, and of Eisenstein series of weight 0 and level $\ell_1\ell_2 q_0$: one has

$$\sum_{\psi}\langle((\ell_1 y)^{k/2}\varphi_2(\ell_1 z).(\ell_2 y)^{k/2}\overline{\varphi_2(\ell_2 z)},\ \psi\rangle\langle\psi, P_h(z,s)\rangle + \text{Eisenstein spectrum.} \quad (3.9)$$

For ψ in the cuspidal basis, let it_ψ denote the archimedean parameter $\mu_{\pi,1}$ of the representation π containing ψ; the second inner product $\langle\psi, P_h(z,s)\rangle$ equals the Fourier coefficient of ψ, $\overline{\rho_\psi(-h)}$ times a factor bounded by $(1+|t_\psi|)^B e^{\frac{\pi}{2}|t_\psi|}$. The Fourier coefficient $\overline{\rho_\psi(-h)}$ is bounded by $O(|h|^{\theta+o(1)})$ by Hypothesis H_θ at the non-archimedean places. The problem now, as was pointed out by Selberg, is to have a bound for the triple product integral $\langle(\ell_1 y)^{k/2}\varphi_2(\ell_1 z).(\ell_2 y)^{k/2}\overline{\varphi_2}(\ell_2 z),\ \psi\rangle$ which exhibits an exponential decay for the form $O((1+|t_\psi|)^C e^{-\frac{\pi}{2}|t_\psi|})$, so as to compensate the exponential growth of $\langle\psi, P_h(z,s)\rangle$. In this generality, this exponential decay property for triple product was achieved by Sarnak in [69]; later, a representation theoretic version of Sarnak's arguments as well as some improvements were given by Bernstein–Reznikov [2]. The final consequence of these bounds is the following estimate

$$\Sigma_-(\varphi_2, \ell_1, \ell_2, h) = O_{\varphi_2,\varepsilon}\big((\ell_1\ell_2)^A q^{1/2+\theta+\varepsilon}\big). \quad (3.10)$$

This approach is important for several reasons:

- It ties more closely the subconvexity problem for GL_2 L-functions – a problem whose origin lies in analytic number theory – to the Ramanujan–Petersson conjecture for $\mathrm{GL}_2(\boldsymbol{A}_{\mathbb{Q}})$; or, in other words, to the spectral gap property which is a classical problem in the harmonic analysis of groups;

- it gives an hint that automophic period integrals might be useful in the study of the subconvexity problem: this will be largely confirmed in Section 4.

- This approach is sufficiently smooth that it can be extended to number fields of higher degree: a few years ago, Cogdell–Piatetski-Shapiro–Sarnak used the amplification method in conjunction with this approach to obtain (3.2) when F is totally real and π_∞ is a holomorphic discrete series (see [13]).

Remark 3.2. The methods of sections 3.2 and 3.3 are closely related. This can be seen already by remarking that Weil's bound for Kloosterman sums yield the saving $q^{3/4+\varepsilon}$ in (3.8) which is precisely the saving following from Hypothesis $H_{1/4}$ in (3.10); moreover $H_{1/4}$ (a.k.a the Selberg–Gelbart–Jacquet bound) can be obtained by applying Weil's bound to the Kloosterman sums.One can push this coincidence further, by applying, in (3.7) the Kuznetzov–Petersson formula *backwards* in order to transform the sums of Kloosterman sums into sums of Fourier coefficients of Maass

forms:

$$(3.7) = \sum_{\psi}\sum_{h'}\Big(\sum_{\mp\ell_1 n-\ell_2 m=h'}\alpha_m\overline{\rho_{\varphi_2}(m)}\beta_n\rho_{\varphi_2}(n)\Big)\overline{\rho}_\psi(-h)\rho_\psi(h')\tilde{\mathcal{V}}(h,h',it_\psi)$$
$$+\text{ Discrete series Spectrum }+\text{ Eisenstein spectrum.}\quad(3.11)$$

Thus, we have realized the spectral expansion of the shifted convolution sum $\Sigma_\pm(\varphi_2,\ell_1,\ell_2,h)$ in a way similar to that obtained in (3.9); from there, we may use again the full force of spectral theory. This may look like a rather circuituous path to obtain the spectral expansion; this method however has some technical advantage over the method discussed in Section 3.3: it works even if φ_2 is a Maass form, without the need to find appropriate test vector or to obtain exponential decay for triple product integrals ! The spectral decomposition (3.11) will be very useful in the next section.

3.4. The case of a varying central character. The methods discussed so far are sufficient to establish (3.2), (3.3), (3.4) as long as the conductor of the central character, ω_1 say, of π_1 is significantly smaller than q_1. The case of a varying central character reveals new interesting features which we discuss here. To simplify, we consider the extremal (in a sense hardest) case where both conductors are equal $q_{\omega_1}=q_1=:q$.

3.4.1. Subconvexity via bilinear Kloosterman fractions. As usual for the subconvexity problem, the first result is due to Duke–Friedlander–Iwaniec for the case (3.3) [22], [23]. As pointed out above, the problem of bounding $L(\pi_1,s)$ for $\Re es=1/2$ may be formulated as the problem of bounding a Rankin–Selberg L-function

$$L(\pi_1\times\pi_2,s)=L(\pi_1,s)^2$$

where $\pi_2=1\boxplus 1$ is the representation corresponding to the the fully unramified Eisenstein series. Eventually, another approach was considered in [22], [23], which comes from the identity

$$|L(\pi_1,s)|^2=L(\pi_1\times\overline{\chi},1/2)L(\tilde{\pi}_1\times\chi,1/2)$$

where $\tilde{\pi}_1$ is the contragredient and $\chi=\omega_1|.|^{-it}$, $t=\Im ms$. The amplification method applied to the family $\{L(\pi\times\overline{\chi},1/2)L(\tilde{\pi}\times\chi,1/2),\ q_\pi=q_1:=q,\omega_\pi=\omega_1\}$ yields in practice to shifted convolution sums of the form ([22], [23])

$$\sum_{\ell_1 ad-\ell_2 bc=h}\overline{\chi}(a)\chi(c)\mathcal{W}\Big(\frac{a}{q^{1/2}},\frac{b}{q^{1/2}},\frac{c}{q^{1/2}},\frac{d}{q^{1/2}}\Big),$$

with $h\approx q$, $h\equiv 0(q)$. The later is essentially a truncated version of the shifted convolution sums associated to the Eisenstein series $E(1,\chi)$ of the representation $1\boxplus\chi$; the new feature by comparison with the previous shifted convolution problems

is that the coefficients $\rho_{E(1,\chi)}(n) = \sum_{bc=n} \chi(c)$ vary with q, which is essentially the range of the variables $m = ad$ and $n = bc$. Since χ has conductor q and a, c vary in ranges of size $\approx q^{1/2}$ one cannot really use the arithmetical structure of the weights $\overline{\chi}(a),\ \chi(c)$ so this shifted convolution problem is basically reduced to the non-trivial evaluation of a quite general sum:

$$\sum_{\ell_1 ad - \ell_2 bc = h} \alpha_a \gamma_c \mathcal{W}\Big(\frac{a}{q^{1/2}}, \frac{b}{q^{1/2}}, \frac{c}{q^{1/2}}, \frac{d}{q^{1/2}}\Big) = MT((\alpha_a), (\gamma_c), \ell_1, \ell_2, h) + O((\ell_1\ell_2)^A q^{1-\delta}) \tag{3.12}$$

for some $\delta > 0$ absolute and where $MT((\alpha_a), (\gamma_c), \ell_1, \ell_2, h)$ denotes a natural main term and with $(\alpha_a)_{a\sim q^{1/2}}$, $(\gamma_c)_{c\sim q^{1/2}}$ arbitrary complex numbers of modulus bounded by 1. Since the b variable is smooth, the condition $\ell_1 ad - \ell_2 bc = h$ is essentially equivalent to the congruence condition $\ell_1 ad \equiv h \bmod c\ell_2$. One can then analyze this congruence by Poisson summation applied on the remaining smooth variable d which yields sums of Kloosterman fractions of the shape

$$\sum_{\substack{a\sim A, c\sim C\\ (a,c)=1}} \alpha_a \gamma_c e\Big(h\frac{\bar{a}}{c}\Big), \quad \text{for } h \neq 0$$

and where the values of a, c, h and α_a, γ_c may be different from the previous ones. In [21] such sums are bounded non-trivially for any ranges A, C (the most crucial one being $A = C$).

A remarkable feature of this proof is that the bound is obtained from an application of the amplification method in a very unexpected direction, namely by amplifying the trivial (!) multiplicative characters $\chi_{0,a}$ of modulus a in the family of sums

$$\Big\{ \sum_{\substack{c\sim C\\ (a,c)=1}} \gamma_c \chi(c) e\Big(h\frac{\bar{a}}{c}\Big),\ \chi \bmod a,\ a \sim A\Big\}.$$

Remark 3.3. Note that (3.12) is more general than needed for (3.3) and may be used in other contexts (e.g. Bombieri–Vinogradov type results). On the other hand, in the subconvexity context, this method uses the special shape of Eisenstein series and does not seem to generalize to Rankin–Selberg L-functions.

3.4.2. Subconvexity of Rankin–Selberg L-functions via subconvexity for twisted L-functions. The case of Rankin–Selberg L-functions over $\mathbb{Q}$, $L(\pi_1 \times \pi_2, s)$ when π_2 is essentially fixed and π_1 has a central character ω_1 of large conductor was treated in [39], [60]. In the case of a varying central characters, subconvexity comes from an estimate for an average of shifted convolution sums of h of the form:

$$\sum_{0<|h|\ll q} \overline{\omega}(h) \Sigma_{\pm}(\varphi_2, \ell_1, \ell_2, h) \ll_{\varphi_2} (\ell_1\ell_2)^A q^{3/2-\delta} \tag{3.13}$$

for some $A, \delta > 0$ absolute. Observe however that this is stronger than just the shifted convolution problem on average over h. In particular even under the Ramanujan–Petersson conjecture (H_0), the individual bound (3.10) is "just" not sufficient: this means that one has to account for the averaging over the h variable.

This bound is achieved through the spectral decomposition of the shifted convolution sums (3.11): plugging this formula into the left-hand side of (3.13) one obtains a sum over the orthonormal basis $\{\psi\}$ of sums of the form

$$\sum_{0<|h|\ll q} \overline{\omega}(h)\rho_\psi(-h)$$

if ψ belong to the space V_τ of some automorphic representation, the later sums are partial sums associated to the twisted L-function $L(\tau \times \overline{\omega}, s)$. In that case, the subconvexity bound for twisted L-functions (3.2) is exactly sufficient to give (3.13).

Remark 3.4. Hence the subconvexity bound for an L-functions of degree 4 has been reduced to a collection of subconvex bounds for L-functions of automorphic forms of small level twisted by the original central character ω ! This surprising phenomenon is better explained via the approach described in the next section.

4. Subconvexity via periods of automorphic forms

4.1. The various perspectives on an L-function. From the perspective of analytic number theory, the definition of L-function might be "an analytic function sharing the key features of $\zeta(s)$: analytic continuation, functional equation, Euler product."

However, there are various "incarnations" of L-functions attached to automorphic forms; although equivalent, different features become apparent in different incarnations. For instance, one can define and study L-functions via constant terms of Eisenstein series (the Langlands-Shahidi method), via periods of automorphic forms (the theory of integral representations, which begins with the work of Hecke, or indeed already with Riemann), or via a Dirichlet series (which is often taken as their defining property).

Thus far in this article, we have discussed the subconvexity from the perspective of Dirichlet series. In particular, we have studied periods (e.g. (2.4)) by relating them to L-functions (via (2.2)) and then proving subconvexity for the latter. Relatively recently, the subconvexity question has also been succesfully approached via the "period" perspective by reversing this usual process: namely by deducing subconvexity from a geometric study of the periods. The first such result (in the eigenvalue aspect) was given by Bernstein-Reznikov [3], [4], and a little later a result in the level aspect was given by Venkatesh [75]. The two methods seem to be quite distinct. We shall discuss these briefly, and then discuss in more detail the joint work [61] of the authors, which also uses the period perspective.

These approaches are closely related to existing work, but in many cases the period perspective allows certain conceptual simplifications and it brings together harmonic analysis and ideas from dynamics. Such conceptual simplifications are particularly of value in passing from $\mathbb{Q}$ to a general number field; so far, with the exception of the result of Cogdell–Piatetski-Shapiro–Sarnak, all the results in Theorem 6 in the case $F \neq \mathbb{Q}$ are proven via the period approach.

On the other hand, it might be noted that a slight drawback to the period approach to subconvexity is that, especially for automorphic representations with complicated ramification, one must face the difficulty of choosing appropriate test vectors.

4.2. Triple product period and triple product L-function. At present, all known results towards the subconvexity of triple product L-functions $L(\pi_1 \times \pi_2 \times \pi_3, 1/2)$ arise from the "period" perspective.

The period of interest is

$$\int_{\mathrm{PGL}_2(\mathbb{Q})\backslash \mathrm{PGL}_2(\boldsymbol{A})} \varphi_1(g)\varphi_2(g)\varphi_3(g)\, dg$$

where $\varphi_i \in \pi_i$, and each π_i is an automorphic cuspidal representation of GL_2. It is expected that this period, and the variants when GL_2 is replaced by the multiplicative group of a quaternion algebra, is related to the central value of the triple product L-function $L(\pi_1 \times \pi_2 \times \pi_3, 1/2)$, see [40]. A precise relationship has been computed for the case of Maass forms at full level in [77]; indeed, the following formula is established:

$$\left| \int_{\mathrm{SL}_2(\mathbb{Z})\backslash \mathbb{H}} \varphi_1\varphi_2\varphi_3 d\mu \right|^2 = \frac{\Lambda(\varphi_1 \times \varphi_2 \times \varphi_3, 1/2)}{\Lambda(\wedge^2\varphi_1, 1)\Lambda(\wedge^2\varphi_2, 1)\Lambda(\wedge^2\varphi_3, 1)} \tag{4.1}$$

where Λ denotes the completed L-function and $d\mu$ is a suitable multiple of $\frac{dx\,dy}{y^2}$.

4.2.1. The eigenvalue aspect: the method of Bernstein–Reznikov. Let Γ be a (discrete) cocompact subgroup of $\mathrm{SL}_2(\mathbb{R})$, let $\mathbb{H}$ be the upper half-plane, let φ_1, φ_2 be fixed eigenfunctions of the Laplacian on $\Gamma\backslash\mathbb{H}$ and φ_λ an eigenfunction with eigenvalue $\lambda := 1/4+r^2$. In the paper [4], Bernstein and Reznikov establish the following bound:

$$r^2 e^{\pi r/2} \left| \int_{\Gamma\backslash\mathbb{H}} \varphi_1(z)\varphi_2(z)\varphi_\lambda(z)\, d\mu_z \right|^2 \ll_\varepsilon r^{5/3+\varepsilon}. \tag{4.2}$$

In fact the bound (4.2) remains valid if $\Gamma\backslash\mathbb{H}$ has only finite volume and $\varphi_1, \varphi_2, \varphi_\lambda$ are cusp forms. In particular, when $\Gamma = \mathrm{SL}_2(\mathbb{Z})$ and $\varphi_1, \varphi_2, \varphi_\lambda$ are Hecke–Maass forms associated to automorphic representations $\pi_1, \pi_2, \pi_\lambda$ respectively, the bound (4.2) translates, via (4.1), to the subconvex bound

$$L(\pi_1 \times \pi_2 \times \pi_\lambda, 1/2) \ll_{\varepsilon,\pi_1,\pi_2} r^{5/3+\varepsilon} \tag{4.3}$$

while the convexity bound for the left-hand side is $r^{2+\varepsilon}$.

Their method is based on the properties of the (local) real group $G = \mathrm{PGL}_2(\mathbb{R})$ and, in particular, on the fact that the space of G-invariant functionals on $\pi_1 \otimes \pi_2 \otimes \pi_\lambda$ is *at most* one dimensional. Hence the proof is purely local and by contrast to the method of [75], does not use either Hecke operators or the spectral gap.

4.2.2. The level aspect: the method of Venkatesh. Let F be a number field. Let π_2, π_3 be fixed automorphic cuspidal representations on $\mathrm{PGL}_2(\boldsymbol{A}_F)$ – say with coprime conductor – and let π_1 be a third automorphic cuspidal representation with conductor $\mathfrak{q}$, a prime ideal of F. In [75] it is established that

$$L(\pi_1 \times \pi_2 \times \pi_3, 1/2) \ll_{\pi_{1,\infty},\pi_2,\pi_3} \mathrm{N}(\mathfrak{q})^{1-\frac{1}{13}} \tag{4.4}$$

contingent on a suitable version of (4.1) when the level of one factor varies.[4] The convexity bound for the left-hand side is $\mathrm{N}(\mathfrak{q})^{1+\varepsilon}$.

Remark 4.1. In [75], a form of (4.4) is proved when π_2 and/or π_3 are Eisenstein series: in that case, (4.1) corresponds to simple computations in the Rankin–Selberg method and so is unconditional. In particular, this yields the bounds (3.3) and (3.4) for π_1 with trivial central character.

For reasons of space, we do not explain the details of the proof; in any case, this can also be approached by the method outlined in Section 4.3. It uses, in particular, quantitative results and ideas from ergodic theory, and the bound H_θ with $\theta < 1/4$, in the notation of Section 3.3.

4.3. Central character. In this section, we return to Section 3.4 and explain, via periods, the bound (3.4). In particular, this sheds light on the "reason" for the reduction to a lower rank subconvexity problem that was encountered in that section. The content of this section is carried out in detail in [61].

Let π_1, π_2 be automorphic cuspidal representations of $\mathrm{GL}_2(\boldsymbol{A}_F)$. Let ω be the central character of π_1. For simplicity, we restrict ourselves to the case where π_2, the "fixed" form, has level 1 and trivial central character; and where "all the ramification of π_1 comes from the central character," i.e. π_1 and ω have the same conductor $\mathfrak{q}$.

Let us first give a very approximate "philosophical" overview of the proof. There is an identity between mean values of L-functions of the following type:

$$\sum_{\pi_1} L(\pi_1 \times \pi_2, 1/2) \longleftrightarrow \sum_{\tau \text{ level } 1} L(\tau, 1/2) L(\tau \times \omega, 1/2) \tag{4.5}$$

where the left-hand summation is over π_1 of central character ω and conductor $\mathfrak{q}$, whereas the right-hand summation is over automorphic representations τ of trivial

[4] This has not appeared in the literature to our knowledge, except in the case where one of the π_j are Eisenstein; however, it should amount to a routine though very involved computation of p-adic integrals.

central character and level 1. It includes the trivial (one-dimensional) automorphic representation, which is in fact the dominant term and actually needs to be handled by regularization. [5]

By means of a suitable amplifier, one can restrict the left-hand summation to pick out a given π_1. When one does this, the necessary bounds on the right-hand side follow from two different inputs:

1. Subconvexity for $L(\tau \times \omega, 1/2)$ (in the aspect where ω varies), to handle the nontrivial τ.

2. A bound showing decay of matrix coefficients of p-adic groups, to handle the contribution of τ the trivial representation

4.3.1. The source of (4.5) via periods. Writing $Y_{\boldsymbol{A}} = \mathrm{PGL}_2(F)\backslash\mathrm{PGL}_2(\boldsymbol{A}_F)$, we note that the Rankin–Selberg L-function may be expressed as a period integral:

$$L(s, \pi_1 \times \pi_2) \sim \int_{Y_{\boldsymbol{A}}} \varphi_1(g)\varphi_2(g)E_s(g)\, dg$$

where $\varphi_i \in \pi_i$ are the respective newforms, and E_s is the Eisenstein series corresponding to the new vector of the automorphic representation $|\cdot|^s \boxplus \omega^{-1}|\cdot|^{-s}$. Here $\sim$ means that there is a suitable constant of proportionality, depending on the archimedean types of the representations.

Let $\mathcal{B}_{\omega,\mathfrak{q}}$ be an orthogonal basis for the space of forms on $\mathrm{GL}_2(F)\backslash\mathrm{GL}_2(\boldsymbol{A}_F)$ of level $\mathfrak{q}$ and central character ω; let $\mathcal{B}_{1,1}$ be an orthogonal basis for the space of forms on $Y_{\boldsymbol{A}}$ of full level and trivial central character. By spectral expansion, we have the following identity:

$$\begin{aligned}\sum_{\varphi_1 \in \mathcal{B}_{\omega,\mathfrak{q}}} \left|\int_{Y_{\boldsymbol{A}}} \varphi_1\varphi_2 E_s\right|^2 &= \int_{Y_{\boldsymbol{A}}} |\varphi_2 . E_s|^2 \\ &= \int_{Y_{\boldsymbol{A}}} |\varphi_2|^2\, |E_s|^2 = \sum_{\psi \in \mathcal{B}_{1,1}} \langle |E_s|^2, \psi\rangle \overline{\langle |\varphi_2|^2, \psi\rangle}.\end{aligned} \tag{4.6}$$

Here the ψ- summation is, *a priori*, over an orthonormal basis for $L^2(Y_{\boldsymbol{A}})$; however, the summand $\langle |\varphi_2|^2, \psi\rangle$ vanishes unless ψ is of level 1 and trivial central character. Note that the ψ-summation should, strictly, include a continuous contribution for the Eisenstein series, which also needs to be suitably regularized. This is not a trivial matter and occupies a good deal of [61]; we shall supress it for now.

In any case, if ψ belongs to the space of an automorphic representation τ, then the Rankin–Selberg method shows that $\langle |E_s|^2, \psi\rangle$ is a multiple of $L(\tau, 2s - 1/2)$ $L(\tau \times \omega, 1/2)$. Thus (4.6) basically yields (4.5)!

[5] Note that "morally", when τ is trivial, the L-function $L(\tau, s)L(\tau \times \omega, s) = \zeta(s+1/2)\zeta(s-1/2)L(\omega, s-1/2)$ $L(\omega, s + 1/2)$. Thus we obtain a pole at $s = 1/2$.

4.3.2. Amplification and the decay of matrix coefficients. We restrict to $s = 1/2$ for concreteness, although the method works for any s. The identity (4.6) does not suffice to obtain a nontrivial bound on $\int_{Y_A} \varphi_1\varphi_2 E_{1/2}$, for the left-hand summation is too large. To localize it, one introduces an amplifier. We phrase it adelically, but it should be made clear this is still the amplifier of Friedlander–Iwaniec.

For any function f on $\mathrm{GL}_2(F)\backslash\mathrm{GL}_2(\boldsymbol{A}_F)$ and any $g_0 \in \mathrm{GL}_2(\boldsymbol{A}_F)$, we write $f^{g_0}(g) = f(gg_0^{-1})$. Then one has the following tiny variant of (4.6), for $g_1, g_2 \in \mathrm{GL}_2(\boldsymbol{A}_F)$:

$$\begin{aligned}\sum_{\varphi_1\in\mathcal{B}_{\omega,\mathfrak{q}}} \left(\int_{Y_A} \varphi_1^{g_1^{-1}}\varphi_2 E_{1/2}\right)\overline{\left(\int_{Y_A} \varphi_1^{g_2^{-1}}\varphi_2 E_{1/2}\right)} \\ = \sum_{\psi\in L^2(Y_A)} \langle E_{1/2}^{g_1}\overline{E_{1/2}^{g_2}}, \psi\rangle\overline{\langle\overline{\varphi_2^{g_1}}\varphi_2^{g_2}, \psi\rangle}.\end{aligned} \tag{4.7}$$

This is again an identity of this shape (4.5), but with slightly more freedom due to the insertion of g_1, g_2. The left-hand (resp. right-hand) side is still proportional, by the Rankin–Selberg method, to $L(\pi_1 \times \pi_2, 1/2)$ (resp. $L(\tau, 1/2)L(\tau \times \omega, 1/2)$, if $\psi \in \tau$) but the constants of proportionality depend – in a precisely controllable way – on g_1, g_2. In effect, this allows one to introduce a "test function" $h(\pi_1)$ into the identity (4.5), thereby shortening the effective range of summation. It should be noted that in (4.7), by contrast with (4.5), the right hand ψ-summation is no longer over ψ of level 1; however, it involves only those ψ which are invariant by $\mathrm{PGL}_2(\hat{\mathbb{Z}}) \cap g_1^{-1}\mathrm{PGL}_2(\hat{\mathbb{Z}})g_1 \cap g_2^{-1}\mathrm{PGL}_2(\hat{\mathbb{Z}})g_2$, and in particular their level is bounded in a way that depends predictably on g_1, g_2.

A subconvex bound for $L(\pi_1 \times \pi_2, 1/2)$ follows from any method to get nontrivial bounds on the right-hand side of (4.7) for general g_1, g_2.

1. To deal with the case when ψ is perpendicular to the constants, we note that the terms $\langle E_{1/2}^{g_1}E_{1/2}^{g_2}, \psi\rangle$ are, by Rankin–Selberg, certain multiples of $L(\tau, 1/2)L(\tau \times \omega, 1/2)$ whenever $\psi \in \tau$, the space of an automorphic representation. We then apply subconvex bounds for $L(\tau \times \omega, 1/2)$, in the aspect when ω varies.
2. To deal with the case $\psi = \mathrm{Const}$, we note that the term $\langle \varphi_2^{g_1}\overline{\varphi_2^{g_2}}, \psi\rangle$ is, in that case, simply a multiple of the matrix coefficient $\langle \varphi_2^{g_1g_2^{-1}}, \varphi_2\rangle$. Thus it is bounded by bounds on the decay of matrix coefficients.

Obviously this description is dishonest, for the term $\langle |E_{1/2}|^2, \psi\rangle$ is not even convergent for $\psi = \mathrm{Const}$! However, this is a technical and not a conceptual difficulty: the only two analytic ingredients required are the two above.

4.3.3. Mysterious identities between families of L-functions. In a sense, the period identity (4.6) (or, approximately equivalent, the identity (4.5)) is the key point of

the above discussion; it explains immediately why one has the "reduction of degree" discussed in Section 3.4. This is another example of the phenomenon discussed in Section 4.1: the identity (4.5) is obvious from the "period" perspective, but not at all clear from the viewpoint of L-functions considered as Dirichlet series.

Another example of such a phenomenon – identities between *a priori* different families of L-functions – is Motohashi's beautiful formula [64] for the 4th moment of ζ. Roughly speaking, it relates integrals of $|\zeta(1/2+it)|^4$ to sums of $L(\varphi, 1/2)^3$, where φ varies over Maass forms. If φ is a suitably normalized Maass form on $\mathrm{SL}_2(\mathbb{Z})\backslash\mathbb{H}$, its completed L-function is given by the Hecke period $\Lambda(\varphi, 1/2+it) = \int_0^\infty \varphi(iy) y^{it} d^\times y$. Applying Plancherel's formula shows that $\frac{1}{2\pi}\int_{-\infty}^{\infty} |\Lambda(\varphi, 1/2+it)|^2 dt = \int_{y=0}^{\infty} |\varphi(iy)|^2 d^\times y$. Again, one can spectrally expand $|\varphi|^2$, yielding:

$$\begin{aligned}\frac{1}{2\pi}\int_{-\infty}^{\infty} |\Lambda(\varphi, 1/2+it)|^2\, dt &= \sum_{\psi} \frac{\langle |\varphi|^2, \psi\rangle}{\langle \psi, \psi\rangle} \int_0^\infty \psi(iy)\, d^\times y \\ &= \sum_{\psi} \frac{\langle |\varphi|^2, \psi\rangle}{\langle \psi, \psi\rangle} \Lambda(\psi, 1/2)\end{aligned} \tag{4.8}$$

where, again, the ψ-sum is over an orthogonal basis, suitably normalized, for $L^2(Y_0(1))$, and, again, we suppress the continuous spectrum; hence (4.8) expresses a relation between mean values of $L(\varphi, 1/2+it)$, where t varies, and the family of L-functions $L(\psi, 1/2)$, where ψ varies. Specializing (4.8) to the case of φ the Eisenstein series at the center of symmetry yields a formula "of Motohashi type." We emphasize that this argument has not been carried out rigorously to our knowledge and it would likely involve considerable technical difficulty (for the integrals diverge in the eisenstein case). Nevertheless, this approach may have value insofar as it offers some insight into the origin of such formulae. A. Reznikov has given a very general and elegant formalism [67] that encapsulates such identities as (4.5) and (4.8); one hopes that further analytic applications will stem from his formalism.

5. Applications

5.1. Subconvexity and functoriality. Via the functoriality principle of Langlands, it is now understood that the same L-function may be attached to automorphic forms on different groups. This gives rise to the possibility of studying the same L-function in different ways.

A recent instance where this kind of idea played a decisive role was the attempt to solve the subconvexity problem for the L-functions of the class group characters of a quadratic field K of large discriminant. In [24], the problem was solved but only under the assumption that K has sufficiently many small *split* primes (this would follow from GRH, but so far, has been established unconditionally only for special discriminants). This assumption, which was also encountered by the second author

in [75] in the context of periods and is closely related to Linnik's condition, is a fundamental and major unsolved issue that arises in many contexts, e.g. in work on the André–Oort conjecture [79]. A key observation of [23], is that, by functoriality, (in that case due to Hecke and Maass) a class group character L-function is the L-function of a Maass form of weight 0 or 1, with Laplace eigenvalue $1/4$. For these, as we have just seen, the subconvexity problem can be solved independently of any assumption.

In view of this example, we find it useful to spell out explicitly some direct consequences of the subconvex bounds of Theorem 6 and of functoriality.

Corollary 5.1. *Let F be a fixed number field and $\rho\colon \mathrm{Gal}(\bar{F}/F) \to \mathrm{GL}_2(\mathbb{C})$ be a modular Galois representation (for instance, if the image of ρ in $\mathrm{PGL}_2(\mathbb{C})$ is soluble). Let $\mathfrak{q}_\rho$ be the Artin conductor of ρ and let $L(\rho, s)$ be its Artin L-function, then for $\Re es = 1/2$*

$$L(\rho, s) \ll_{F,s} N_{F/\mathbb{Q}}(\mathfrak{q}_\rho)^{1/4-\delta}$$

for $\delta > 0$ some absolute constant.

Corollary 5.2. *Let F be a fixed number field and K be an extension of F of absolute discriminant $\mathrm{disc}(K/\mathbb{Q}) =: \Delta_K$ and let $\zeta_K(s)$ be the Dedekind zeta function of K; then, if K/F is abelian or cubic, one has for $\Re es = 1/2$*

$$\zeta_K(s) \ll_{F,s} |\Delta_K|^{1/4-\delta}$$

for $\delta > 0$ some absolute constant.

Corollary 5.3. *Let F be a fixed number field, π be a fixed $\mathrm{GL}_2(\boldsymbol{A}_F)$-automorphic cuspidal representation and let K be an extension of F of absolute discriminant $\mathrm{disc}(K/\mathbb{Q}) =: \Delta_K$. If K/F is abelian or cubic, we denote by π_K the base change lift of π from F to K (which exist by the works of Saito–Shintani–Langlands and Jacquet–Piatetski-Shapiro–Shalika). For $\Re es = 1/2$, one has*

$$L(\pi_K, s) \ll_{F,\pi,s} |\Delta_K|^{1/2-\delta}$$

for $\delta > 0$ some absolute constant.

5.2. Equidistribution on quaternionic varieties. We define a quaternionic variety as the locally homogeneous space given as an adelic quotient of the following form: for F a totally real number field, B a quaternion algebra over F, let $\boldsymbol{G}$ be the $\mathbb{Q}$-algebraic group $\mathrm{res}_{F/\mathbb{Q}}\mathrm{B}^\times/Z(\mathrm{B}^\times)$; one has

$$G(\mathbb{R}) \simeq \mathrm{PGL}_2(\mathbb{R})^{f'} \times \mathrm{SO}(3, \mathbb{R})^{f-f'}$$

where $f = \deg F$ and f' is the number of real place of F for which B splits. Let K_∞ be a compact subgroup of $\boldsymbol{G}(\mathbb{R})$ of the form

$$\mathrm{SO}(2, \mathbb{R})^{f'} \times \prod_{v=1}^{f-f'} \mathrm{K}_v$$

with $\mathrm{K}_v =$ either $\mathrm{SO}_2(\mathbb{R})$ or $\mathrm{SO}_3(\mathbb{R})$ and let X denote the quotient $\boldsymbol{G}(\mathbb{R})/\mathrm{K}_\infty$; finally let K_f be an open compact subgroup of $\boldsymbol{G}(\boldsymbol{A}_f)$ and $\mathrm{K} := \mathrm{K}_\infty.\mathrm{K}_f$.

The quaternionic variety $V_{\mathrm{K}}(\boldsymbol{G}, X)$ is defined as the quotient

$$V_{\mathrm{K}}(\boldsymbol{G}, X) := \boldsymbol{G}(\mathbb{Q})\backslash X \times \boldsymbol{G}(\boldsymbol{A}_f)/\mathrm{K}_f = \boldsymbol{G}(\mathbb{Q})\backslash \boldsymbol{G}(\boldsymbol{A}_{\mathbb{Q}})/\mathrm{K}.$$

It has the structure of a Riemannian manifold whose connected components are quotients, by a discrete subgroup of $\boldsymbol{G}(\mathbb{R})$, of the product of $(\mathbb{H}^{\pm})^{f'} \times (S^2)^{f''}$ for $f'' \leqslant f - f'$. The case of the sphere and of the modular surface correspond to the case $F = \mathbb{Q}$, B the algebra of 2×2 matrices $M_2(\mathbb{R})$ or the Hamilton quaternions $\mathrm{B}^{(2,\infty)}$.

Let K/F be a quadratic extension with an embedding into B, and let $\boldsymbol{T}$ denote the $\mathbb{Q}$-torus "$\mathrm{res}_{F/\mathbb{Q}} K^\times/F^\times$". As was pointed out in Section 2.2.1, there exists, in great generality, a precise relationship between

1. central values of some Rankin–Selberg L-function $L(\pi_\chi \times \pi_2, s)$ (for which the sign of the functional equation $w(\pi_\chi \times \pi_2)$ is $+1$); and
2. (the square of) twisted Weyl sums

$$\int_{\boldsymbol{T}(\mathbb{Q})\backslash \boldsymbol{T}(\boldsymbol{A}_{\mathbb{Q}})} \chi(t)\varphi_2(z.t)\, dt.$$

These Weyl sums describe the distribution properties of toric orbits, $\boldsymbol{T}(\mathbb{Q})\backslash z.\boldsymbol{T}(\boldsymbol{A}_{\mathbb{Q}})$ of cycles associated to (orders of) K inside $V_{\mathrm{K}}(\boldsymbol{G}, X)$.

The general scheme is that, in cases where these formula have been written out explicitly, the subconvex bound (3.2) (along possibly with hypothesis H_θ for some $\theta < 1/2$) yields at once the equidistribution of the *full* orbit and the subconvex bounds (3.4) yield the equidistribution of *big enough* suborbits of the toric orbit. We present below some sample results on these lines:

5.2.1. Hilbert's eleventh problem. When B is totally definite, $\mathrm{K}_\infty = \mathrm{SO}_2(\mathbb{R})^f$, $X = (S^2)^f$ is a product of spheres. In this case, the equidistribution of toric orbits (relative to a totally imaginary quadratic field) above can be interpreted in terms of the integral representations of a totally positive integer $d \in \mathcal{O}_F$ by a totally positive definite quadratic form q (more precisely $-q$ "is" the norm form $N_{B/F}(\mathbf{x})$ on the space of quaternions of trace 0). The following theorem of Cogdell–Piatetski-Shapiro–Sarnak combines the formula of [1] with (3.2) for π_2 holomorphic.

Theorem 7. *Let F be a totally real number field and q be an integral positive definite quadratic form over F; there is an absolute (ineffective) constant $N_{F,q} > 0$ such that if d is a squarefree totally positive integer with $N_{F/\mathbb{Q}}(d) > N_F$ then d is integraly represented by q iff d is everywhere locally integrally represented. Moreover, in the later case, the number, $r_q(d)$, of all such integral representation satisfies*

$$r_q(d) \gg_{q,F} N_{F/\mathbb{Q}}(d)^{1/2+o(1)} \quad \text{as } N_{F/\mathbb{Q}}(d) \to +\infty.$$

Remark 5.1. The question of the integral representability of d by some form in the genus of q was completely settled a long time ago by Siegel, in a quantitative way, through the Siegel mass formula. The present theorem (in a slightly more precise form) can then be interpreted by saying that the various representations d are *equidistributed* amongst the various genus classes of q; moreover it can be strengthened to an "equidistribution on ellipsoids" statement, cf. [26] for $F = \mathbb{Q}$.

5.2.2. CM points on quaternionic Shimura varieties. When B is indefinite at some real place and $\mathrm{K}_\infty = \mathrm{SO}_2(\mathbb{R})^{f'} \times \mathrm{SO}_3(\mathbb{R})^{f-f'}$ the quaternionic variety $V_{\mathrm{K}}(\boldsymbol{G}, X)$ is a Shimura variety, $\mathrm{Sh}_{\mathrm{K}_f}(\boldsymbol{G}, X)$ (a Hilbert modular variety of complex dimension f'). It has the structure of the complex points of an algebraic variety defined over some reflex field E/F.

In this setting, the generalization of the set of Heegner point is the so called set of "CM" points, $\mathcal{H}_{\mathfrak{d}}$, which is associated to a quadratic order $\mathcal{O}_{\mathfrak{d}}$ (say of discriminant $\mathfrak{d}$) of a (not necessarily fixed) totally imaginary K/F. In that case and under some natural local condition, the equidistribution of

$$\mathcal{H}_{\mathfrak{d}} = \boldsymbol{T}(\mathbb{Q})\backslash z_{\mathfrak{d}}.\boldsymbol{T}(\boldsymbol{A}_{\mathbb{Q}})/\boldsymbol{T}(\widehat{\mathcal{O}}_{\mathfrak{d}})$$

on $\mathrm{Sh}_{\mathrm{K}_f}(\boldsymbol{G}, X)$ as $|N_{F/\mathbb{Q}}(\mathfrak{d})| \to +\infty$ was established independently by Clozel–Ullmo, Cohen and Zhang [12], [14], [82] by using the subconvex bound (3.2) of the second author. For instance, one has

Theorem 8. *Suppose* $\mathrm{K}_f = \mathrm{K}_{f,\max}$ *is a maximal compact subgroup of* $\boldsymbol{G}(\boldsymbol{A}_F)$*, then for* $|N_{F/\mathbb{Q}}(\mathfrak{d})| \to +\infty$ *and* $\mathfrak{d}$ *coprime with* $\mathrm{disc}(F)$*, the set* $\mathcal{H}_{\mathfrak{d}}$ *becomes equidistributed on* $\mathrm{Sh}_{\mathrm{K}_f}(\boldsymbol{G}, X)$ *w.r.t. the hyperbolic measure.*

Similarly, as in Theorem 5, the bound (3.4) allows one to show the equidistribution of strict suborbits of $z_{\mathfrak{d}}$:

Theorem 9. *With the notations as above, there is an absolute constant* $0 < \eta < 1$ *such that, for any subtoric orbit* $\mathcal{H}'_{\mathfrak{d}} \subset \mathcal{H}_{\mathfrak{d}}$ *of size satisfying* $|\mathcal{H}'_{\mathfrak{d}}| \geqslant |\mathcal{H}_{\mathfrak{d}}|^{\eta}$*, then* $\mathcal{H}'_{\mathfrak{d}}$ *is equidistributed on* $\mathrm{Sh}_{\mathrm{K}_f}(\boldsymbol{G}, X)$ *as* $|N(\mathfrak{d})| \to +\infty$.

As was pointed out by Zhang [82], the possibility of considering strict suborbits of the full toric orbit has a nice arithmetic interpretation; the Galois orbits on CM points correspond to "subtoric orbits" of the type considered in Theorem 9.

6. Linnik's ergodic method: a modern perspective

As discussed, Linnik achieved partial results towards Theorems 1–3 by using some ingenious ideas which he collectively referred to as "the ergodic method." As Linnik pointed out (see, e.g., [57, Chapter XI, comments on Chapters IV–VI]) despite this name, this method remained rather *ad hoc* and did not fit into ergodic theory as it is

normally understood: that is to say, dynamics of a measure-preserving transformation. The joint work of the authors with M. Einsiedler and E. Lindenstrauss [29], remedies this, both putting Linnik's original work into a more standard ergodic context, and giving the first higher rank generalizations.

6.1. The source of dynamics. Although the relevance of dynamics to integral points on the sphere is not immediately apparent, it is not difficult to see from an adelic perspective. We have already mentioned in Section 2.2.1 that all three theorems (Theorems 1–3) may be considered as questions about the distribution of an orbit of an adelic torus $z_d.\boldsymbol{T}_d(\boldsymbol{A})$ inside $\boldsymbol{G}(\mathbb{Q})\backslash\boldsymbol{G}(\boldsymbol{A})$.

One can, therefore, hope to use results about the dynamics of a local torus $\boldsymbol{T}_d(\mathbb{Q}_v)$ acting on $\boldsymbol{G}(\mathbb{Q})\backslash\boldsymbol{G}(\boldsymbol{A})$ for some fixed place v. However, this is possible only if $\boldsymbol{T}_d(\mathbb{Q}_v)$ noncompact; for otherwise there is no dynamics of interest. This leads to Linnik's condition (cf. Theorem 4), because $\boldsymbol{T}_d(\mathbb{Q}_p)$ is noncompact precisely when $\mathbb{Q}(\sqrt{d})$ is split at p.

6.2. Linnik's method in the light of modern ergodic theory. Much of this joint work is based on the recent work of Einsiedler and Lindenstrauss on classification of invariant measures for toric actions, which is discussed in their contribution to these proceedings [28].

A central concept here is that of *entropy*; we briefly reprise the definition. We recall that if $\mathcal{P}$ is a partition of the probability space (X, ν), the entropy of $\mathcal{P}$ is defined as $h_\nu(\mathcal{P}) := \sum_{S\in\mathcal{P}} -\nu(S)\log\nu(S)$. If T is a measure-preserving transformation of (X, ν), then the measure entropy of T is defined as

$$h(T) = \sup_{\mathcal{P}} \lim_{n\to\infty} \frac{h_\nu(\mathcal{P} \vee T^{-1}\mathcal{P} \vee \cdots \vee T^{-(n-1)}\mathcal{P})}{n} \tag{6.1}$$

where the supremum is taken over all finite partitions of X.

Here are two results that illustrate the importance of this concept (we denote by Haar the G-invariant probability measure on a quotient space $\Gamma\backslash G$).

The first one is a specialization of the fact that on the unit tangent bundle of a surface of constant negative curvature, the Liouville measure is the unique measure of maximal entropy w.r.t. the action of the geodesic flow:

Fact 1. *Let μ on $\mathrm{SL}_2(\mathbb{Z})\backslash\mathrm{SL}_2(\mathbb{R})$ be invariant by the diagonal subgroup, and let a be a nontrivial diagonal matrix. Then $h_\mu(a) \leqslant h_{\mathrm{Haar}}(a)$, with equality if and only if $\mu = \mathrm{Haar}$.*

The second fact lies much deeper and is a result of Einsiedler, Katok and Lindenstrauss [27] which illustrate the phenomenon of *measure rigidity* for the action of tori of rank $\geqslant 2$:

Fact 2. *Let μ be a probability measure on $\mathrm{SL}_3(\mathbb{Z})\backslash\mathrm{SL}_3(\mathbb{R})$ invariant by the diagonal subgroup A and let $a \in A$ be nontrivial. If $h_\mu(a) > 0$ and μ is ergodic (w.r.t. A), then $\mu = \mathrm{Haar}$.*

The scheme of [29, I, II and III] is to treat Linnik problems by combining results of the above type – towards the classification of measures with positive entropy – with diophantine ideas that establish positive entropy. In the subsequent sections we discuss some applications of this general scheme; we have aimed for concreteness, but these methods are much more generally applicable.

6.3. Entropy and the "Linnik principle". In [29, II] we give a purely dynamical proof of Theorem 3. This proof is still based heavily on Linnik's ideas but it introduces considerable conceptual simplification using the notion of entropy discussed in the previous section, and uses in particular *Fact 1*.

We insist that our proof requires *no* splitting condition at some fixed prime p: the reason is that in the context of Theorem 3, the place $v = \infty$ splits in the real quadratic field $\mathbb{Q}(\sqrt{d})$ and so Linnik's condition is *satisfied*! Curiously this was apparently never remarked by Linnik and Skubenko who only used the action of a p-adic split torus.

Let $d > 0$ be a fundamental discriminant. The unit tangent bundle of $Y_0(1)$ is identified with $\mathrm{PGL}_2(\mathbb{Z})\backslash\mathrm{PGL}_2(\mathbb{R})$, and so the subset Γ_d described in Theorem 3 may be regarded as a subset $\Gamma_d \subset \mathrm{PGL}_2(\mathbb{Z})\backslash\mathrm{PGL}_2(\mathbb{R})$. Considered in this way, Γ_d is invariant by the subgroup

$$A = \left\{ a(t) = \begin{pmatrix} e^t & 0 \\ 0 & e^{-t} \end{pmatrix},\ t \in \mathbb{R} \right\}$$

of diagonal matrices with positive entries. It supports a natural A-invariant probability μ_d (the one which assigns the same mass to each connected component) and Theorem 3 asserts precisely that μ_d converge weakly to the $\mathrm{PGL}_2(\mathbb{R})$-invariant probability measure on $\mathrm{PGL}_2(\mathbb{Z})\backslash\mathrm{PGL}_2(\mathbb{R})$.

The dynamical proof uses Fact 1 together with a Diophantine computation to show that any weak limit of the μ_d has maximal entropy w.r.t. the action of $a(1)$. The Diophantine computation is a version of "Linnik's basic Lemma," [57, Theorem III.2.1] which in turn may be deduced from *Siegel's mass formula*.

6.4. A rank 3 version of Duke's theorem. A natural "rank 2" version of Theorem 3 is to consider the distribution properties of appropriate collections of compact *flats* inside the Riemannian manifold $\mathrm{PGL}_3(\mathbb{Z})\backslash\mathrm{PGL}_3(\mathbb{R})/\mathrm{PO}_3(\mathbb{R})$.

More generally, let D be a $\mathbb{R}$-split central simple algebra of rank 3 over $\mathbb{Q}$, i.e. $\dim_{\mathbb{Q}} \mathrm{D} = 9$, so that $\mathrm{D} \otimes_{\mathbb{Q}} \mathbb{R} = M_3(\mathbb{R})$. Let $\mathcal{O}_{\mathrm{D}}$ be a fixed maximal order in D. Let $\boldsymbol{G}$ be the algebraic group $\mathrm{PG}(\mathrm{D}) = \mathrm{D}^\times / Z(\mathrm{D})^\times$; we fix a maximal split torus $A = (\mathbb{R}^\times)^2$ inside $\boldsymbol{G}(\mathbb{R})$. Let U be the standard maximal compact subgroup $\prod_p \mathrm{PG}(\mathcal{O}_{\mathrm{D},p})$ of $\boldsymbol{G}(\boldsymbol{A}_f)$. We will assume, for simplicity, that the class number of $\mathcal{O}_{\mathrm{D}}$ is 1, i.e. that $\boldsymbol{G}(\boldsymbol{A}_f) = \boldsymbol{G}(\mathbb{Q}).U$.

Let $K \subset \mathrm{D}$ be a totally real cubic field, together with an isomorphism $\theta\colon K \otimes \mathbb{R} \to \mathbb{R}^3$. We assume for simplicity that $K \cap \mathcal{O}_{\mathrm{D}}$ is the maximal order $\mathcal{O}_K$ of K. This yields, in particular, an embedding of the torus $\boldsymbol{T}_K = \mathrm{res}_{K/\mathbb{Q}} K^\times / \mathbb{Q}^\times$

into the algebraic group PG(D). The choice of θ determines a unique $g_\theta \in \boldsymbol{G}(\mathbb{R})$ so that $g_\theta A g_\theta^{-1} = \boldsymbol{T}_K(\mathbb{R})$. Setting $U_T = \boldsymbol{T}_K(\boldsymbol{A}_f) \cap U$, we consider

$$\Gamma_K := (\boldsymbol{T}_K(\mathbb{Q})\backslash \boldsymbol{T}_K(\boldsymbol{A})/U_T) g_\theta \subset \boldsymbol{G}(\mathbb{Q})\backslash \boldsymbol{G}(\boldsymbol{A})/U \cong \mathcal{O}_{\mathrm{D}}^\times \backslash \mathrm{PGL}_3(\mathbb{R}).$$

This is a collection of compact A-orbits on $\mathcal{O}_{\mathrm{D}}^\times \backslash \mathrm{PGL}_3(\mathbb{R})$, which are indexed by $\mathbf{T}_K(\mathbb{Q})\backslash \mathbf{T}_K(\boldsymbol{A}_f)/U_T$ and the latter quotient is precisely the class group $\mathrm{Cl}(\mathcal{O}_K)$. Consequently, to any subset $S \subset \mathrm{Cl}(\mathcal{O}_K)$ of the class group, we may associate a collection $\Gamma_{K,S}$ of $|S|$ closed A-orbits on $\mathcal{O}_{\mathrm{D}}^\times \backslash \mathrm{PGL}_3(\mathbb{R})$. This set supports a natural A-invariant probability measure (which assigns the same mass to each of the constituent orbits); call this measure $\mu_{K,S}$. For $S = \mathrm{Cl}(\mathcal{O}_K)$ we write simply Γ_K and μ_K.

In [29, I and III] we investigate weak limits of such measures as $\mathrm{disc}(K) \to +\infty$. In the split case, we obtain equidistribution for the full packet of compact orbits which represents the 3-dimensional analog of Theorem 3:

Theorem 10. *Suppose* D *is split* (*i.e.* $\mathrm{D} = M_3(\mathbb{Q})$). *As* $\mathrm{disc}(K) \to \infty$, Γ_K *becomes equidistributed on* $\mathrm{PGL}_3(\mathbb{Z})\backslash \mathrm{PGL}_3(\mathbb{R})$ *with respect to the Haar measure.*

In the non-split case, we obtain a weak form of equidistribution but valid for rather small packets of compact orbits:

Theorem 11. *Suppose* D *is not* $\mathbb{Q}$*-split. Fix* $\delta < 1/2$. *There is a constant* $c = c(\delta) > 0$ *such that, if each set* $S \subset \mathrm{Cl}(\mathcal{O}_K)$ *satisfies* $\frac{|S|}{|\mathrm{Cl}(\mathcal{O}_K)|} \geqslant \mathrm{disc}(K)^{-\delta}$, *then any weak limit of* $\mu_{K,S}$ *contains a Haar component of size* $\geqslant c(\delta)$.

The proof of these results follows the general strategy outlined at the end of Section 6.2 and uses Fact 2 mentioned above as a key ingredient.

In the context of Theorem 10, the first point to verify (since $\mathrm{PGL}_3(\mathbb{Z})\backslash \mathrm{PGL}_3(\mathbb{R})$ is not compact) is that any weak limit of the μ_K, μ say, is a probability measure i.e. that there is no "escape of mass" to ∞. To circumvent this difficulty, we use a version of the harmonic analytic approach described in Section 2: from Mahler's compactness criterion, we build test functions which dominate the characteristic function of small neighborhoods of the cusp and we control escape of mass by bounding the corresponding Weyl sums. The test functions are in fact Eisenstein series (associated with the minimal parabolic of PGL_3) and the resulting Weyl sums can be expressed in terms of the Dedekind zeta function of K, ζ_K to which we apply Corollary 5.2 in the case $F = \mathbb{Q}$. More generally, a variant of this construction together with Corollary 5.2 enable us to bound from above the μ-mass of small neighborhoods of *any* point in $\mathrm{PGL}_3(\mathbb{Z})\backslash \mathrm{PGL}_3(\mathbb{R})$. This is sufficient to imply that *every* ergodic component of μ has positive entropy for some non-trivial $a \in A$. From this we conclude that $\mu = \mu_{\mathrm{Haar}}$ using Fact 2. It should be remarked that the very existence of such test functions is a special feature of the split case.

In the non-split case, there is no issue about possible escape of mass since $\mathcal{O}_{\mathrm{D}}^\times \backslash \mathrm{PGL}_3(\mathbb{R})$ is compact; on the other hand, simple test functions for which the Weyl sums could be evaluated and from which positive entropy could be deduced do

not seem to be available in the cocompact case; instead, we rely on a weaker version of Linnik's basic lemma – *Linnik's principle* – from which we deduce, at least, that a *positive proportion* of the ergodic components of μ have positive entropy; again we conclude by applying Fact 2 to these components. Although it does not achieve equidistribution, Theorem 11 nevertheless illustrates a major advantage of the ergodic approaches of [29] over harmonic-analysis methods: ergodic methods allow for nontrivial results even for *very small* torus orbits ("supersparse equidistribution"): indeed, any exponent $\delta < 1/2$ is admissible and since the size of the class group of $\mathcal{O}_K$ is at most $\mathrm{disc}(K)^{1/2+\varepsilon}$, this is as strong as could be hoped for. Distribution problems for *small* torus orbits arise naturally in several arithmetic questions: for instance we expect that measure rigidity results for actions of p-adic tori should allow for partial progress towards Zhang's measure-theoretic refinement of the André/Oort conjecture [82].

6.5. An application to Minkowski's Theorem. We first recall

Theorem (Minkowski). *Let K be a number field of degree d and maximal order $\mathcal{O}_K$; any ideal class for $\mathcal{O}_K$ possesses an integral representative $J \subset \mathcal{O}_K$ of norm $N(J) = O(\sqrt{\mathrm{disc}(K)})$ where the implicit constant depends only on d.*

We conjecture that this is not sharp for totally real number fields of degree $d \geqslant 3$:

Conjecture 2. Suppose $d \geqslant 3$ is fixed. Then any ideal class in a totally real number fields of degree d has an integral representative of norm $o(\sqrt{\mathrm{disc}(K)})$.

Let $m(K)$ denote the maximum, over ideal classes of $\mathcal{O}_K$, of the minimal norm of a representative. Conjecture 2 asserts that

$$\lim_{\mathrm{disc}(K)\to\infty} \frac{m(K)}{\mathrm{disc}(K)^{1/2}} = 0,$$

for K varying through totally real fields of fixed degree $d \geqslant 3$. It may be shown that for any $d \geqslant 2$ there exists a $c' > 0$ such that there is an infinite set of totally real fields of degree d for which $m(K) \geqslant c' \cdot \mathrm{disc}(K)^{1/2}(\log \mathrm{disc}(K))^{1-2d}$. Thus Minkowski's Theorem is rather close to sharp and in fact Conjecture 2 is unlikely to be true for $d = 2$. For $d \geqslant 3$ this conjecture can be seen as a result of the extra freedom that arises from having a group of units of rank $d - 1 \geqslant 2$, and is actually a consequence of a stronger conjecture formulated by Margulis [59].

We will call an ideal class of a field K δ-bad if it does not admit a representative of norm $< \delta \cdot \mathrm{disc}(K)^{1/2}$. Let $h_\delta(K)$ be the number of δ-bad ideal classes and let R_K denote the regulator of the field K. In [29, I] it is shown that:

Theorem 12. *Let $d \geqslant 3$, and let K denote a totally real number field of degree d. For all $\varepsilon, \delta > 0$ we have*

$$\sum_{\mathrm{disc}(K)<X} R_K h_\delta(K) \ll X^\varepsilon. \tag{6.2}$$

In particular:

1. *"Conjecture* 2 *is true for almost all fields": the number of fields K with discriminant $\leqslant X$ for which $m(K) \geqslant \delta \cdot \mathrm{disc}(K)^{1/2}$ is $O_{\varepsilon,\delta}(X^{\varepsilon})$, for any $\varepsilon, \delta > 0$.*

2. *"Conjecture* 2 *is true for all fields with large regulator": If $(K_i)_i$ is any sequence of fields for which $\liminf_i \frac{\log R_{K_i}}{\log \mathrm{disc}(K_i)} > 0$, then $m(K_i) = o(\mathrm{disc}(K_i)^{1/2})$.*

This is connected to the considerations of Section 6.4 in the following way. Consider the case $d = 3$; to a real cubic field K and suitable additional data we have associated a collection of compact A-orbits $\Gamma_K \subset \mathrm{PGL}_3(\mathbb{Z})\backslash\mathrm{PGL}_3(\mathbb{R})$, indexed by the class group of K. The key point is the following: the question of the minimal norm of a representative for a given ideal class is closely related to the question of how far the associated A-orbit penetrates into the "cusp" of the noncompact space $\mathrm{PGL}_3(\mathbb{Z})\backslash\mathrm{PGL}_3(\mathbb{R})$. This allows a geometric reformulation of Theorem 12 that is amenable to analysis by the methods of Section 6.4.

7. Ergodic theory vs. harmonic analysis

In this concluding section, we briefly compare dynamical methods and harmonic analysis.

Fundamentally, the most general type of problem we are considering is the following: let $\boldsymbol{H} \subset \boldsymbol{G}$ be a subgroup of a semisimple $\mathbb{Q}$-group $\boldsymbol{G}$; understand the "distribution" of $\boldsymbol{H}(\mathbb{Q})\backslash\boldsymbol{H}(\boldsymbol{A})$ inside $\boldsymbol{G}(\mathbb{Q})\backslash\boldsymbol{G}(\boldsymbol{A})$. Indeed such problems arise naturally in a large number of arithmetic questions. Two possible approaches to these questions are the following:

1. Ergodic. Here we choose a suitable finite set of places S and apply results constraining $\boldsymbol{H}(\mathbb{Q}_S)$-invariant measures on $\boldsymbol{G}(\mathbb{Q})\backslash\boldsymbol{G}(\boldsymbol{A})$.

2. Harmonic-analytic. Here we choose a suitable basis φ_i for functions on $\boldsymbol{G}(\mathbb{Q})\backslash\boldsymbol{G}(\boldsymbol{A})$ and compute the "periods"

$$\int_{\boldsymbol{H}(\mathbb{Q})\backslash\boldsymbol{H}(\boldsymbol{A})} \varphi_i, \tag{7.1}$$

   the main goal being to have "good" quantitative upper bound for (7.1)

Moreover, we note that there is considerable potential for interaction between the two approaches: in [29, I], harmonic analysis is used to control escape of mass issues, while in [75] quantitative ideas from ergodic theory are used to give estimates on periods like (7.1).

In any case, the following general principles tend to apply:

1. If $\boldsymbol{H}$ is "a large enough subgroup" of $\boldsymbol{G}$ (say if $\boldsymbol{H}$ acts with an open orbit on the flag variety of $\boldsymbol{G}$), the periods (7.1) will often have "arithmetic significance", i.e. are often interpretable in terms of quantities of arithmetic interest such as L-functions and one can at least *hope* for complete, quantitative results via harmonic analysis. Note that, in addition to "standard harmonic analysis," one should keep in mind the possibility of using an extra important trick: namely, of using *equalities between periods on different groups*. That is to say: often there will be another pair $(\boldsymbol{H}' \subset \boldsymbol{G}')$ with the property that, for each φ_i as above, one may associate functions φ_i' on $\boldsymbol{G}'(\mathbb{Q})\backslash\boldsymbol{G}'(\boldsymbol{A})$ so that

$$\int_{\boldsymbol{H}(\mathbb{Q})\backslash\boldsymbol{H}(\boldsymbol{A})} \varphi_j = \int_{\boldsymbol{H}'(\mathbb{Q})\backslash\boldsymbol{H}'(\boldsymbol{A})} \varphi_j'.$$

   The correspondence $\varphi \leftrightarrow \varphi'$ is usually related to functoriality. Thereby one can study the $\boldsymbol{H}$-periods on $\boldsymbol{G}$ by switching to $\boldsymbol{G}'$.

2. If $\boldsymbol{H}$ is not a torus, one often apply profitably Ratner's theorem in the ergodic approach and get strong, *although non-quantitative* results. We have not discussed any examples of this in the present article; a nice instance is [30].

3. If $\boldsymbol{H}$ is a torus, the emerging theory of measure rigidity for torus actions (see in particular [27], [28]) may offer a substitute for Ratner theory. This requires an extra input, positive entropy, and has two further disadvantages (compared to "Ratner theory") that might be noted:

   (a) At present there is no good general way to control, either escape of mass when $\boldsymbol{G}(\mathbb{Q})\backslash\boldsymbol{G}(\boldsymbol{A})$ is noncompact, or the related phenomenon of concentration on embedded subgroups.

   (b) One needs to have "Linnik's condition," i.e. a fixed set of places S such that $\boldsymbol{H}(\mathbb{Q}_v)$ is noncompact for $v \in S$.

Eventually, as a rough rule, the strength of ergodic theory is that it can handle orbits of very "small" subgroups – which at present seem far beyond the reach of traditional harmonic analysis– and its weakness is that it is not (yet) quantitative. On the other hand, the strength of harmonic analysis is that it imports all the rich internal structure of automorphic forms.

For instance, "why" is it that harmonic-analytic approaches to Theorem 1 have been able to avoid a Linnik-type condition? Our perspective to this question is that the Waldspurger formula (2.5) expresses a period over a non-split torus $\boldsymbol{T}_d$ in terms of the L-function $L(\pi, 1/2) \times L(\pi \times \chi_d, 1/2)$. But, by Hecke theory, the second L-function is expressible as a (χ_d-twisted) period of a form in π over a *split* torus in $\mathrm{GL}_2(\mathbb{Q})\backslash\mathrm{GL}_2(\boldsymbol{A}_{\mathbb{Q}})$! Thereby one has an *equality* between a period over a *nonsplit* torus $\boldsymbol{T}_d$ and a twisted period over a *split* torus $\boldsymbol{T}_{\mathrm{split}}$. This equality, which is an instance of functoriality, is part of the reason that one is able to sidestep the problem of small split primes that plagues any direct analysis of $\boldsymbol{T}_d$.

p-adic motivic cohomology in arithmetic

Wiesława Nizioł

Abstract. We will discuss recent progress by many people in the program of representing motivic cohomology with torsion coefficients of arithmetic schemes by various arithmetic p-adic cohomologies: étale, logarithmic de Rham–Witt, and syntomic. To illustrate possible applications in arithmetic geometry we will sketch proofs of the absolute purity conjecture in étale cohomology and comparison theorems of p-adic Hodge theory.

Mathematics Subject Classification (2000). Primary 14F42, 14F20, 11G25.

Keywords. motivic cohomology, K-theory, étale cohomology, crystalline cohomology, p-adic Hodge theory.

1. Introduction

In this report, we will survey results about the relationship between motivic cohomology and p-adic cohomologies of arithmetic schemes. We will concentrate on the stable ranges where the motivic cohomology with torsion coefficients tends to be represented by various cohomologies of arithmetic type. Much has happened in that subject in the last few years and a detailed survey can be found in [10]. For us motivic cohomology will mean Bloch higher Chow groups and its approximation – the gamma gradings of algebraic K-theory. They are defined using algebraic cycles and vector bundles, respectively, and are connected via an Atiyah–Hirzebruch spectral sequence. By inverting the Bott element or in some stable ranges motivic cohomology becomes isomorphic to its (étale) topological version. That is the content of the Beilinson–Lichtenbaum and Quillen–Lichtenbaum conjectures both of which follow (over fields) from the Bloch–Kato conjecture (now proved at least for mod 2 coefficients). Torsion étale motivic cohomology has a direct relationship with various arithmetic cohomologies: logarithmic de Rham–Witt (an arithmetic version of crystalline cohomology in positive characteristic), syntomic cohomology (an arithmetic version of crystalline cohomology in mixed characteristic), and arithmetic étale cohomology. As a result we can represent p-adic cohomology classes as algebraic cycle classes in a way reminiscent of the classical situation. This turns out to be – both conceptually and technically – a powerful tool. We present two applications: a proof of the absolute purity conjecture in étale cohomology and proofs of comparison theorems in p-adic Hodge theory.

of Mathematicians, Madrid, Spain, 2006

2. K-theory

2.1. Milnor K-theory. For a field k, the Milnor K-groups $K_*^M(k)$ are defined to be the quotient of the tensor algebra of the multiplicative group k^* of k by the ideal generated by the Steinberg relation $x \otimes (1-x)$ for $x \neq 0, 1$. This rather simple construction turns out to be a fundamental object in the subject.

If m is relatively prime to the characteristic of k, Kummer theory gives that $K_1^M(k)/m \simeq k^*/k^{*m} \xrightarrow{\sim} H^1(k_{\text{ét}}, \mu_m)$. Using cup product on Galois cohomology we get the Galois symbol map

$$K_n^M(k)/m \to H^n(k_{\text{ét}}, \mu_m^{\otimes n}).$$

Conjecture 2.1 (Bloch–Kato). The above symbol map is an isomorphism.

Voevodsky proved [40] the Bloch–Kato conjecture for m a power of 2 (Milnor conjecture) and has recently announced a proof for general m [41].

If $p > 0$ is equal to the characteristic of k, the Bloch–Kato conjecture could be interpreted as the theorem of Bloch–Gabber–Kato [3] giving an isomorphism

$$\operatorname{dlog}\colon K_n^M(k)/p^r \xrightarrow{\sim} H^0(k_{\text{ét}}, \nu_r^n),$$

where $\nu_r^n = W_r\Omega^n_{X,\log}$ is the logarithmic de Rham–Witt sheaf. It is a subsheaf of the de Rham–Witt sheaf $W_r\Omega_X^n$ generated locally for the étale topology by $\operatorname{dlog}\bar{x}_1 \wedge \cdots \wedge \operatorname{dlog}\bar{x}_n$, where $\bar{x} \in W_r\mathcal{O}_X$ are the Teichmüller lifts of units. It fits into the short exact sequence of pro-sheaves (F is the Frobenius)

$$0 \to \nu_\cdot^n \to W_\cdot\Omega_X^n \xrightarrow{F-1} W_\cdot\Omega_X^n \to 0.$$

2.2. Algebraic K-theory. For a noetherian scheme X, let $\mathcal{M}(X)$ and $\mathcal{P}(X)$ denote the categories of coherent and locally free sheaves on X, respectively. The higher algebraic K and K' groups of X are defined as homotopy groups of certain simplicial spaces associated to the above categories: $K_i(X) = \pi_i(\mathcal{K}(X))$, $K'_i(X) = \pi_i(\mathcal{K}'(X))$. For $i = 0$, $K_0(X)$ and $K'_0(X)$ are the Grothendieck groups of vector bundles and coherent sheaves, respectively. For a field k, the product structure on K-theory gives a natural homomorphism $K_n^M(k) \to K_n(k)$ that is an isomorphism for $n \leq 2$.

K-groups mod m, $K_i(X, \mathbb{Z}/m)$, are defined by taking homotopy groups with $\mathbb{Z}/m$ coefficients of the above spaces. They are related to $K_*(X)$ by a universal coefficient sequence. Exterior powers of vector bundles induce a descending filtration $F^*_\gamma K_*(X, \mathbb{Z}/m)$ (γ-filtration) and the graded pieces $\operatorname{gr}^*_\gamma K_*(X, \mathbb{Z}/m)$ can be considered an approximation to motivic cohomology groups.

Similarly, we get groups $K'_i(X, \mathbb{Z}/m)$. The natural homomorphism

$$K_i(X, \mathbb{Z}/m) \to K'_i(X, \mathbb{Z}/m)$$

is an isomorphism if X is regular ("Poincaré duality"), because every coherent sheaf has a finite resolution by locally free sheaves. For Z a closed subscheme of X with open complement U, there is a localization sequence in K'-theory

$$\to K'_{i+1}(U, \mathbb{Z}/m) \to K'_i(Z, \mathbb{Z}/m) \to K'_i(X, \mathbb{Z}/m) \to K'_i(U, \mathbb{Z}/m) \to$$

It is relatively easy to derive in this generality and (in arithmetic applications) it gives K-theory great technical advantage over other motivic cohomologies. The other important technical advantage is the ease with which one can define higher Chern classes into various cohomologies. To be able to follow Gillet's construction [17] all one really needs is that the cohomology of the classifying simplicial scheme BGL (and some of its variants) is the expected one.

Varying X, one can view $\mathcal{K}(X)$ as a presheaf of simplicial spaces. Let $\mathcal{K}/m$ denote the presheaf of corresponding spaces mod m. Assume that X is regular. Then the Mayer–Vietoris property of K-theory gives that $K_*(X, \mathbb{Z}/m) \simeq H^{-*}(X_{\mathrm{Zar}}, \mathcal{K}/m)$.

If m is invertible on X, under some additional technical assumptions on X, the étale K-theory of Dwyer–Friedlander [5] can be computed using presheaves $\mathcal{K}/m$: $K_j^{\text{ét}}(X, \mathbb{Z}/m) \simeq H^{-j}(X_{\text{ét}}, \mathcal{K}/m)$, for $j \geq 0$.

Conjecture 2.2 (Quillen–Lichtenbaum). The change of topology map

$$\rho_j \colon K_j(X, \mathbb{Z}/m) \to K_j^{\text{ét}}(X, \mathbb{Z}/m)$$

is an isomorphism for $j \geq \mathrm{cd}_m X_{\text{ét}}$ (the étale cohomological dimension of X).

Here and below we will review the current status of the Quillen–Lichtenbaum conjecture. Recall that Thomason [37] proved that the map ρ_j induces an isomorphism

$$\tilde{\rho}_j \colon K_j(X, \mathbb{Z}/m)[\beta_m^{-1}] \xrightarrow{\sim} K_j^{\text{ét}}(X, \mathbb{Z}/m),$$

where $K_j(X, \mathbb{Z}/m)[\beta_m^{-1}]$ denotes the j'th graded piece of the ring obtained by inverting the action of the Bott element β_m on $K_*(X, \mathbb{Z}/m)$. If $\mu_m \subset \Gamma(X, \mathcal{O}_X)$, then β_m is defined as an element in $K_2(X, \mathbb{Z}/m)$ canonically lifting a chosen primitive m'th root of unity in $K_1(X)$. A refined version of the proof of this theorem [38] allowed him to show that for a variety of schemes (not necessarily over an algebraically closed fields) the map ρ_j is surjective for j larger than (roughly) $N = (\dim X)^3$ and its kernel is annihilated by β_m^N. Over an algebraically closed field and for quasi-projective X we can do better: Walker shows [42] that in that case ρ_j is split surjective for $j \geq 2d$ and its kernel is annihilated by β_m^d, $d = \dim X$ (see also [12]).

Étale K-theory has a direct relationship to étale cohomology. Namely Gabber's rigidity and Suslin's computation of K-theory of algebraically closed fields imply that the sheaves of fundamental groups $\tilde{\pi}_i(\mathcal{K}/m)$ are isomorphic to $\mu_m^{\otimes i/2}$ for i even and are 0 for i odd. Then the local to global spectral sequence becomes

$$E_2^{p,q} = \begin{cases} H^p(X_{\text{ét}}, \mu_m^{q/2}) & \text{for } q \text{ even}, \\ 0 & \text{for } q \text{ odd} \end{cases} \quad \Rightarrow \quad K_{q-p}^{\text{ét}}(X, \mathbb{Z}/m).$$

Action of Adams operations shows that this spectral sequence degenerates at E_2 modulo torsion of a bounded order depending only on $\mathrm{cd}_m X_{\text{ét}}$. In particular, the Chern classes

$$c^{\text{ét}}_{i,j}\colon \operatorname{gr}^i_\gamma K^{\text{ét}}_j(X, \mathbb{Z}/m) \to H^{2i-j}(X_{\text{ét}}, \mu_m^{\otimes i})$$

are isomorphisms modulo small torsion.

If X is smooth over a perfect field of characteristic $p > 0$, Geisser–Levine [15] using motivic cohomology (see below) prove the isomorphism $\tilde{\pi}_n(\mathcal{K}/p^r) \simeq \nu^n_r$. Since ν^n_r vanishes for $n > \dim X$, the local to global spectral sequence

$$H^k(X, \tilde{\pi}_n(\mathcal{K}/p^r)) \Rightarrow K_{n-k}(X, \mathbb{Z}/p^r)$$

gives the important vanishing result: $K_n(X, \mathbb{Z}/p^r) = 0$ for $n > \dim X$.

2.3. Application: the absolute purity conjecture. The relationship between algebraic K-theory and étale cohomology just described was used by Thomason [36] and Gabber [13] to prove the absolute purity conjecture in étale cohomology. Thomason derived it (up to small torsion) from absolute purity in K-theory and Gabber – after some reductions – from vanishing results in K-theory.

Conjecture 2.3. Let $i\colon Y \hookrightarrow X$ be a closed immersion of noetherian, regular schemes of pure codimension d. Let n be an integer invertible on X. Then

$$\mathcal{H}^q_Y(X_{\text{ét}}, \mathbb{Z}/n) \simeq \begin{cases} 0 & \text{for } q \neq 2d, \\ \mathbb{Z}/n(-d) & \text{for } q = 2d. \end{cases}$$

Proof. Thomason's proof works (for example) for schemes of finite type over $\mathbb{Z}$ and m all of whose prime divisors are at least $\dim X+1$. Localization sequence immediately gives absolute purity in K-theory: one defines K-theory with support $K_Y(X)$ to be the homotopy fiber of the restriction $K(X) \to K(X \setminus Y)$ and by localization and Poincaré duality we get the isomorphism $K_{Y,*}(X) \simeq K_*(Y)$. Inverting the Bott element yields absolute cohomological purity in étale K-theory: $K^{\text{ét}}_{Y,*}(X) \simeq K^{\text{ét}}_*(Y)$. This can be now easily transferred to étale cohomology via the Atiyah–Hirzebruch spectral sequence. Namely, we have the sheafification of the Atiyah–Hirzebruch spectral sequence with support

$$E_2^{p,q} = \begin{cases} \mathcal{H}^p_Y(X_{\text{ét}}, \mu_m^{\otimes i}) & \text{for } q = 2i, \\ 0 & \text{for } q \neq 2i \end{cases}$$

strongly converging to the sheaf associated to $K^{\text{ét}}_{Y,q-p}(-, \mathbb{Z}/m) \simeq K^{\text{ét}}_{q-p}(-_Y, \mathbb{Z}/m)$. Evoking once more the Atiyah–Hirzebruch spectral sequence (this time on Y) one computes that this sheaf is periodic (of period two) and $\mathbb{Z}/m$ for $q = p$ and trivial for $q - p = 1$. Action of Adams operations shows that the above spectral sequence degenerates modulo a constant (depending on étale cohomological dimension of X) and that the same constant kills $E_\infty^{2j,2j}$ for $j \neq q$.

To prove absolute purity in general Gabber appeals to the Atiyah–Hirzebruch spectral sequence only in the situation where it does in fact degenerate. First, he defines a well-behaved global cycle class $c(Y) \in H^{2d}_Y(X_{\text{ét}}, \mu_m^{\otimes d})$ that allows him to reduce absolute purity to a punctual one: for a regular strict local ring $\mathcal{O}$ of dimension d with closed point $i_x\colon x \to \operatorname{Spec}\mathcal{O}$ the cycle class gives an isomorphism $cl(x)\colon \mu_{m,x} \simeq i_x^! \mu_m^{\otimes d}[2d]$. Induction now reduces it to a vanishing result: $H^p(\mathcal{O}[f^{-1}]_{\text{ét}}, \mu_m) = 0$ for $p \neq 0, 1$, where $f \in \mathfrak{m} \setminus \mathfrak{m}^2$ for the maximal ideal $\mathfrak{m} \subset \mathcal{O}$. Here he can assume $\mathcal{O}$ to be of arithmetic type.

Next, he considers the following Atiyah–Hirzebruch spectral sequence

$$E_2^{p,q} = \begin{cases} H^p(\mathcal{O}[f^{-1}]_{\text{ét}}, \mu_m^{q/2}) & \text{for } q \text{ even}, \\ 0 & \text{for } q \text{ odd} \end{cases} \quad \Rightarrow K^{\text{ét}}_{q-p}(\mathcal{O}[f^{-1}], \mathbb{Z}/m)$$

where the étale K-groups $K^{\text{ét}}_{q-p}(\mathcal{O}[f^{-1}], \mathbb{Z}/m)$ are equal to $K_0(\mathcal{O}[f^{-1}], \mathbb{Z}/m)(q/2)$ for q even and $K_1(\mathcal{O}[f^{-1}], \mathbb{Z}/m)((q-1)/2)$ for q odd. Inductively, using local affine Lefschetz and duality he gets vanishing of $H^p(\mathcal{O}[f^{-1}]_{\text{ét}}, \mu_m) = 0$ for $p \neq 0, 1, d-1, d$. That kills some colums in the above spectral sequence and the degeneration at E_2 follows. Now, vanishing of level 2 of the filtration on K-groups implies that $E_2^{p,q} = E_\infty^{p,q} = 0$ for $p \geq 2$ yielding $H^p(\mathcal{O}[f^{-1}]_{\text{ét}}, \mu_m) = 0$ for $p \neq 0, 1$, as wanted. □

3. Motivic cohomology

3.1. Motivic cohomology over a field. For a separated scheme X over a field, Bloch higher Chow groups [1] are the cohomology groups of a certain complex of abelian groups. To define this complex, denote by $\triangle^n$ the algebraic n-simplex $\operatorname{Spec}\mathbb{Z}[t_0, \ldots, t_n]/\big(\sum t_i - 1\big)$. Let $z^r(X, i)$ denote the free abelian group generated by irreducible codimension r subvarieties of $X \times \triangle^i$ meeting all faces properly. Let $z^r(X, *)$ be the chain complex thus defined with boundaries given by pullbacks of cycles along face maps. Denote by $H^i(X, \mathbb{Z}(r))$ the cohomology of the complex $\mathbb{Z}(r) := z^r(X, 2r - *)$ in degree i. The motivic cohomology with coefficients $\mathbb{Z}/m$ is the cohomology of the complex $\mathbb{Z}/m(r) = \mathbb{Z}(r) \otimes \mathbb{Z}/m$. It fits into the usual universal coefficient sequence.

Remark 3.1. There is another commonly used construction of motivic cohomology due to Suslin–Voevodsky [9]. It works well in characteristic zero but it is not well suited for studying mod p-phenomena in positive characteristic p.

Motivic cohomology groups are trivial for $i > 2n$ and $i > n + \dim X$ for dimension reasons. The Beilinson–Soulé conjecture (still open) postulates that they vanish for $i < 0$. We have $H^{2n}(X, \mathbb{Z}(n)) \simeq CH_n(X)$, the classical Chow group. For a field k, $H^i(k, \mathbb{Z}(n))$ are trivial for $i > n$ and agree with the Milnor group $K_n^M(k)$ for $i = n$. In particular, $H^n(k, \mathbb{Z}/m(n)) \simeq K_n^M(k)/m$.

For Z a closed subscheme of X of codimension c with open complement U, there is a localization sequence

$$\to H^{i-2c}(Z, \mathbb{Z}(n-c)) \to H^i(X, \mathbb{Z}(n)) \to H^i(U, \mathbb{Z}(n)) \to H^{i+1-2c}(Z, \mathbb{Z}(n-c)) \to$$

It is a difficult theorem to prove. It is also rather difficult in general to construct higher cycle classes $c_{i,n}\colon H^i(X, \mathbb{Z}(n)) \to H^i(X, n)$ into various bigraded cohomology theories relevant to arithmetic. The original method of Bloch [2] requires weak purity as well as homotopy property both of which fail for some commonly used p-adic cohomologies. In particular, we are still missing a definition of cycle classes into syntomic cohomology independent of the theory of p-adic periods.

It is even more difficult to show that the higher Chow groups and K'-theory are related by an Atiyah–Hirzebruch spectral sequence

$$E_2^{s,t} = H^{s-t}(X, \mathbb{Z}(-t)) \Rightarrow K'_{-s-t}(X). \tag{3.1}$$

This sequence was first constructed for fields by Bloch–Lichtenbaum [4], then generalized to quasi-projective varieties by Friedlander–Suslin [11], and finally to schemes of finite type by Levine [25],[23]. By different methods, it was also constructed by Grayson–Suslin [18], [34] and Levine [26]. If X is regular, the action of Adams operations shows that this sequence degenerates modulo small torsion and the resulting filtration differs from the γ-filtration by a small torsion. In particular, we get that

$$\mathrm{gr}^i_\gamma K_j(X) \otimes \mathbb{Q} \simeq H^{2i-j}(X, \mathbb{Q}(i)).$$

Varying X, one gets a sheaf $\mathbb{Z}(n) := z^n(-, 2n - *)$ in the étale topology. We have $\mathbb{Z}(0) \simeq \mathbb{Z}$ on a normal scheme and $\mathbb{Z}(1) \simeq \mathbb{G}_m[-1]$ on a smooth scheme. For a separated, noetherian scheme X of finite Krull dimension, the Mayer–Vietoris property yields the isomorphism $H^i(X, \mathbb{Z}(n)) \simeq H^i(X_{\mathrm{Zar}}, \mathbb{Z}(n))$. For X smooth, filtering $z^*(X, *)$ by codimension, we get the very useful Gersten resolution

$$0 \to \mathcal{H}^p(\mathbb{Z}(n)) \to \bigoplus_{x \in X^{(0)}} (i_x)_* H^p(k(x), \mathbb{Z}(n)) \to \bigoplus_{x \in X^{(1)}} (i_x)_* H^{p-1}(k(x), \mathbb{Z}(n-1)) \to$$

Here $X^{(s)}$ denotes the set of points in X of codimension s.

For X smooth and m invertible on X, rigidity in higher Chow groups and étale cohomology and the vanishing of $H^i(k_{\text{ét}}, \mathbb{Z}/m(n))$ for an algebraically closed field k [33] imply that $\mathbb{Z}/m(n)_{\text{ét}} \xrightarrow{\sim} \mu_m^{\otimes n}$. We get the isomorphism

$$c^{\text{ét}}_{i,n}\colon H^i(X_{\text{ét}}, \mathbb{Z}/m(n)) \xrightarrow{\sim} H^i(X_{\text{ét}}, \mu_m^{\otimes n}).$$

Conjecture 3.2 (Beilinson–Lichtenbaum). The canonical map

$$\rho_{i,n}\colon H^i(X_{\mathrm{Zar}}, \mathbb{Z}/m(n)) \to H^i(X_{\text{ét}}, \mathbb{Z}/m(n))$$

is an isomorphism for $i \leq n$.

It is clear that the Bloch–Kato conjecture is a special case of the above conjecture. What is not obvious is that it also implies it.

Theorem 3.3 (Suslin–Voevodsky [35], Geisser–Levine [16]). *The Bloch–Kato conjecture implies the Beilinson–Lichtenbaum conjecture.*

To prove this result via Gersten resolution one passes to the following statement for fields: the Bloch–Kato isomorphism $H^n(F, \mathbb{Z}/m(n)) \simeq K_n^M(F)/n \xrightarrow{\sim} H^n(F_{\text{ét}}, \mu_m^{\otimes n})$ for all fields F that are finitely generated over the base field implies that $\rho_{i,n}\colon H^i(F, \mathbb{Z}/m(n)) \to H^i(F_{\text{ét}}, \mathbb{Z}/m(n))$ is an isomorphism for all such F and $i \leq n$. This is proved by descending induction on the degree of cohomology by "bootstrapping" the Bloch–Kato isomorphism into relative cohomology of cubical complexes.

Unconditionally, we have two important results

Theorem 3.4 (Levine [24]). *If $\mu_m \in \Gamma(X, \mathcal{O}_X)$, inverting the Bott element $\beta_m \in H^0(X_{\text{Zar}}, \mathbb{Z}/m(1))$ gives an isomorphism*

$$\tilde{\rho}_{i,n}\colon H^i(X_{\text{Zar}}, \mathbb{Z}/m(n))[\beta_m^{-1}] \xrightarrow{\sim} H^i(X_{\text{ét}}, \mathbb{Z}/m(n)).$$

Theorem 3.5 (Suslin [33]). *The map $\rho_{i,n}$ is an isomorphism for X smooth over an algebraically closed field and $n \geq \dim X$.*

We can now use the Atiyah–Hirzebruch spectral sequence (3.1) and its étale analogue

$$E_2^{s,t} = H^{s-t}(X_{\text{ét}}, \mathbb{Z}/m(-t)) \Rightarrow K^{\text{ét}}_{-s-t}(X, \mathbb{Z}/m)$$

constructed by Levine to pass from motivic cohomology to K-theory and to conclude that

Theorem 3.6 (Levine [23]). *The Beilinson–Lichtenbaum conjecture implies the Quillen–Lichtenbaum conjecture.*

For X smooth over a perfect field of characteristic $p > 0$, Geisser–Levine [15] have shown that there is a quasi-isomorphism (in the Zariski and étale topology) $\mathbb{Z}/p^r(n) \xrightarrow{\sim} \nu_r^n[-n]$. They derive it from the fact that for any field k of characteristic p, $H^i(k, \mathbb{Z}/p^r(n)) = 0$ for $i \neq n$, which in turn they induce from the Bloch–Kato isomorphism $H^n(k, \mathbb{Z}/p^r(n)) \xleftarrow{\sim} K_n^M(k)/p^r \xrightarrow{\sim} \nu_r^n(k)$. As a result we get

$$H^{i+n}(X, \mathbb{Z}/p^r(n)) \simeq H^i(X_{\text{Zar}}, \nu_r^n), \quad H^{i+n}(X_{\text{ét}}, \mathbb{Z}/p^r(n)) \simeq H^i(X_{\text{ét}}, \nu_r^n).$$

The above implies that $\tilde{\pi}_n(\mathcal{K}/p^r) \simeq \nu_r^n$: via the Bloch–Lichtenbaum spectral sequence $H^{s-t}(k, \mathbb{Z}/p^r(-t)) \Rightarrow K_{-s-t}(k, \mathbb{Z}/p^r)$, the computation of $H^i(k, \mathbb{Z}/p^r(n))$ yields the isomorphism $K_n^M(k)/p^r \to K_n(k, \mathbb{Z}/p^r)$; having that it suffices now to evoke Gersten resolution.

3.2. Motivic cohomology over Dedekind domains. The construction of Bloch higher Chow groups and some of its basic properties (most notably the localization exact sequence and the Atiyah–Hirzebruch spectral sequence) as well as some computations of motivic sheaves can be extended to schemes of finite type over a Dedekind scheme ([25], [23], [14]). Here is an example. Let X be a smooth scheme over a complete discrete valuation ring V of mixed characteristic $(0, p)$ with a perfect residue field k. Denote by $i: Y \hookrightarrow X$ and $j: U \hookrightarrow X$ the special and generic fibers, respectively. We will sketch how assuming the Bloch–Kato conjecture mod p we get a quasi-isomorphism [14]

$$i^*\mathbb{Z}/p^n(r)_{\text{ét}} \to S_n(r) \quad \text{for } r < p-1.$$

Here $S_n(r)$ is the syntomic complex of Fontaine–Messing [8] (philosophically) defined as the mapping cone of the map $Ru_*J^{[r]}_{X_n/W_n(k)} \overset{1-\phi^r}{\to} Ru_*\mathcal{O}_{X_n/W_n(k)}$, where $W(k)$ is the ring of Witt vectors of k, $\mathcal{O}_{X_n/W_n(k)}$ is the crystalline structure sheaf, $J_{X_n/W_n(k)} = \ker(\mathcal{O}_{X_n/W_n(k)}) \to \mathcal{O}_{X_n})$, $u: X_n/W_n(k)_{\text{cr,ét}} \to X_{n,\text{ét}}$ is the natural projection, and $\phi^r = \phi/p^r$ is the divided Frobenius. We always get the long exact sequence

$$\to H^i(X_n, S_n(r)) \to H^i_{\text{cr}}(X_n/W_n(k), J^{[r]}) \xrightarrow{1-\phi^r} H^i_{\text{cr}}(X_n/W_n(k)) \to$$

By the theory of p-adic periods [21] we have the distinguished triangle

$$\to S_n(r) \to \tau_{\le n} i^* Rj_*\mu_{p^n}^{\otimes r} \to \nu_n^{r-1}[-r] \to$$

This triangle can be seen as a realization of the "localization" sequence for the étale motivic sheaves: we apply the above computations of motivic sheaves over fields and a purity result $\mathbb{Z}(r-1)_{\text{ét}}[-2] \xrightarrow{\sim} \tau_{\le r+1} Ri^!\mathbb{Z}(r)_{\text{ét}}$ (contingent on the Beilinson–Lichtenbaum conjecture mod p) to the localization sequence and get the distinguished triangle

$$\to i^*\mathbb{Z}/p^n(r)_{\text{ét}} \to \tau_{\le r} i^* Rj_*\mu_{p^n}^{\otimes r} \to \nu_n^{r-1}[-r] \to .$$

Comparing the above two triangles, we get that the cycle class map $i^*\mathbb{Z}/p^n(r)_{\text{ét}} \to S_n(r)$ is a quasi-isomorphism inducing a cycle map (an isomorphism for X proper)

$$c^{\text{syn}}_{i,r}: H^i(X_{\text{ét}}, \mathbb{Z}/p^n(r)) \to H^i(X, S_n(r)), \quad r < p-1.$$

4. Application: p-adic Hodge theory

In p-adic Hodge theory we attempt to understand p-adic Galois representations coming from the étale cohomology of varieties over p-adic fields via the de Rham cohomology of these varieties. The maps relating étale and de Rham cohomology groups are called p-adic period morphisms. Just as in the classical case, we would like to see them as integration of differential forms. Motivic cohomology allows us to do that [30], [31]. We will sketch briefly how.

Remark 4.1. The main comparison theorems of p-adic Hodge theory were proved earlier by two different methods: by Fontaine–Messing–Kato [8], [20], Kato [19], and Tsuji [39] via a study of p-adic nearby cycles and by Faltings [6], [7] using the theory of almost étale extensions.

4.1. The good reduction case. Let k be a perfect field of positive characteristic p, $W(k)$ the corresponding ring of Witt vectors and K its field of fractions. Let $\overline{K}$ be an algebraic closure of K and let $\mathrm{Gal}(\overline{K}/K)$ denote its Galois group. Let X be a smooth proper scheme over $V = W(k)$ of relative dimension d. We have a functor which carries the crystalline cohomology groups of X with all their structures into representations of $\mathrm{Gal}(\overline{K}/K)$. For $p-2 \geq r \geq i$, set

$$\boldsymbol{L}(H^i_{\mathrm{cr}}(X_n/V_n)\{-r\}) := (F^0(H^i_{\mathrm{cr}}(X_n/V_n)\{-r\} \otimes B^+_{\mathrm{cr},n}))^{1=\phi^0}.$$

Here $B^+_{\mathrm{cr},n} = H^*_{\mathrm{cr}}(\mathrm{Spec}(\overline{V}_n)/W_n(k))$ is one of Fontaine's rings of periods. It is equipped with a decreasing filtration $F^i B^+_{\mathrm{cr},n}$, Frobenius, and an action of the group $\mathrm{Gal}(\overline{K}/K)$. The crystalline cohomology groups $H^i_{\mathrm{cr}}(X_n/V_n) \simeq H^i_{dR}(X_n/V_n)$ have a natural Hodge filtration and ϕ^0 comes from the tensor of divided Frobeniuses $\phi^j = \phi/p^j$. The twist $\{-r\}$ refers to twisting the Hodge filtration and the Frobenius.

Conjecture 4.2 (Crystalline conjecture). For p large enough, there exists a canonical Galois equivariant period isomorphism

$$\alpha_{\mathrm{cr}} \colon H^i(X_{\overline{K}}, \mu_n^{\otimes r}) \xrightarrow{\sim} \boldsymbol{L}(H^i_{\mathrm{cr}}(X_n/V_n)\{-r\}).$$

The proof using K-theory we sketch here works for $r \geq 2d$, $p-2 \geq 2r+d$ (or rationally with no restriction on p and the degree of the finite extension $V/W(k)$).

Since $B^+_{\mathrm{cr},n} \simeq H^*_{\mathrm{cr}}(\overline{V}_n/V_n)$, by the Künneth formula $H^*_{\mathrm{cr}}(X_n/V_n) \otimes B^+_{\mathrm{cr}} \simeq H^*_{\mathrm{cr}}(X_{\overline{V},n}/V_n)$, where $\overline{V}$ is the integral closure of V in $\overline{K}$. The defining property of syntomic cohomology yields a natural map (in fact an isomorphism)

$$H^i(X_{\overline{V}}, S_n(r)) \to \boldsymbol{L}(H^i_{\mathrm{cr}}(X_n/V_n)\{-r\}).$$

It follows that to prove the conjecture, by a standard argument, it suffices to construct a Galois equivariant map

$$\alpha_{i,r} \colon H^i(X_{\overline{K}}, \mu_{p^n}^{\otimes r}) \to H^i(X_{\overline{V}}, S_n(r))$$

compatible with Poincaré duality and some cycle classes. To construct this map as

an integration we will use the following diagram

$$\begin{array}{ccc}
F^r_\gamma/F^{r+1}_\gamma K_{2r-i}(X_{\overline{V}},\mathbb{Z}/p^n) & \xrightarrow[j^*]{\sim} & F^r_\gamma/F^{r+1}_\gamma K_{2r-i}(X_{\overline{K}},\mathbb{Z}/p^n) \\
\downarrow{\scriptstyle \rho_{2r-i}} & & \downarrow{\scriptstyle \rho_{2r-i}} \\
F^r_\gamma/F^{r+1}_\gamma K^{\text{ét}}_{2r-i}(X_{\overline{V}},\mathbb{Z}/p^n) & \xrightarrow[j^*]{} & F^r_\gamma/F^{r+1}_\gamma K^{\text{ét}}_{2r-i}(X_{\overline{K}},\mathbb{Z}/p^n) \\
\downarrow{\scriptstyle c^{\text{syn}}_{r,2r-i}} & & \downarrow{\scriptstyle c^{\text{ét}}_{r,2r-i}} \\
H^i(X_{\overline{V}},S_n(r)) & \xleftarrow[\alpha_{i,r}]{} & H^i(X_{\overline{K}},\mu^{\otimes r}_{p^n}).
\end{array}$$

The right-hand side allows us to represent étale classes by higher algebraic cycle classes on $X_{\overline{K}}$. Those can be lifted (via j^*) to the integral model $X_{\overline{V}}$ and we can integrate differential forms along them to get the period map $\alpha_{i,r}$. Specifically, by Quillen–Lichtenbaum conjecture or by Suslin the map ρ_{2r-i} is an isomorphism for $2r-i \geq \operatorname{cd}_p X_{\text{ét}} = 2d$. The degeneration of the étale Atiyah–Hirzebruch spectral sequence gives that $c^{\text{ét}}_{r,2r-i}$ is an isomorphism modulo small torsion. Also the restriction j^* is an isomorphism: since the scheme $X_{\overline{V}}$ is smooth we can pass to K'-theory; by localization, the kernel and cokernel of j^* is controlled by mod p^n K'-groups of special fibers and those can be killed by totally ramified extensions of V of degree p^n. For p and r as above, we define the map $\alpha_{i,r}$ to make this diagram commute.

Corollary 4.3. *For $r \geq d + i/2$, $p-2 \geq r + d/2$, there exists a unique period map $\alpha_{i,r}\colon H^i(X_{\overline{K}},\mu^{\otimes r}_{p^n}) \to H^i(X_{\overline{V}},S_n(r))$ compatible with the étale and syntomic higher Chern classes from K-theory mod p^n of $X_{\overline{K}}$ and $X_{\overline{V}}$.*

Based on [29], [28] we expect all the existing constructions of the period maps to be compatible with higher Chern classes hence equal.

Assume that we are able to define syntomic higher cycle maps without using p-adic periods. Then a construction of the period map $\alpha_{i,r}$ as an integral can be done in a more precise way by the following diagram.

$$\begin{array}{ccc}
H^i(X_{\overline{V}},\mathbb{Z}/p^n(r)) & \xrightarrow[j^*]{\sim} & H^i(X_{\overline{K}},\mathbb{Z}/p^n(r)) \\
\downarrow{\scriptstyle \rho_{i,r}} & & \downarrow{\scriptstyle \rho_{i,r}} \\
H^i(X_{\overline{V},\text{ét}},\mathbb{Z}/p^n(r)) & \xrightarrow{j^*} & H^i(X_{\overline{K},\text{ét}},\mathbb{Z}/p^n(r)) \\
\downarrow{\scriptstyle c^{\text{syn}}_{i,r}} & & \downarrow{\scriptstyle c^{\text{ét}}_{i,r}} \\
H^i(X_{\overline{V}},S_n(r)) & \xleftarrow[\alpha_{i,r}]{} & H^i(X_{\overline{K}},\mu^{\otimes r}_{p^n})
\end{array} \tag{4.1}$$

Arguing as above, we see that the restriction map j^* is an isomorphism. The map $\rho_{i,r}$ on the right is an isomorphism for $r \geq i$ by the Beilinson–Lichtenbaum conjecture or for $r \geq d$ by Suslin. That gives the definition of $\alpha_{i,r}$ in these two cases and a proof

of the Crystalline conjecture for all i and $2d \leq r \leq p-2$. Notice that then all the maps in the above diagram are isomorphisms.

Remark 4.4. Our period map $\alpha_{i,r}$ goes in the opposite direction than the period maps constructed by other methods. This implies that one can simply use Poincaré duality to prove that the map is an isomorphism. Rationally that works well but integrally it doubles the lower bound on p.

4.2. The semistable reduction case. Let now K be a complete discrete valuation field of mixed characteristic $(0, p)$ with ring of integers V and a perfect residue field k. Let $X^\times$ be a fine and saturated log-smooth proper $V^\times$-scheme, where V is equipped with the log-structure associated to the closed point, such that the generic fiber X_K is smooth over K and the special fiber $X_0^\times$ is of Cartier type. A standard example would be a scheme X with simple semistable reduction.

Conjecture 4.5 (Semistable conjecture). There exists a natural period isomorphism

$$\alpha_{st}\colon H^*(X_{\overline{K}}, \mathbb{Q}_p) \otimes_{\mathbb{Q}_p} B_{\mathrm{st}} \simeq H^*_{\mathrm{cr}}(X_0^\times / W(k)^0) \otimes_{W(k)} B_{\mathrm{st}}$$

preservings Galois action, monodromy, filtration and Frobenius.

Here the period ring B_{st} is equipped with Galois action, Frobenius and monodromy operators. It maps naturally into another ring of periods B_{dR}, which is equipped with a decreasing filtration. The log-crystalline cohomology groups $H^*_{\mathrm{cr}}(X^\times / W(k)^0)[1/p]$ (analogues of limit Hodge structures) are also equipped with Frobenius and monodromy operators. There is also a canonical isomorphism $K \otimes_{W(k)} H^*_{\mathrm{cr}}(X_0^\times / W(k)^0) \simeq H^*_{dR}(X_K/K)$ via which Hodge filtration induces a descending filtration on these groups. The period isomorphism and its base change to B_{dR} should preserve all these structures. As a corollary, one gets that the étale cohomology as a Galois representation can be recovered from the log-crystalline cohomology

$$H^*(X_{\overline{K}}, \mathbb{Q}_p) \simeq (H^*_{\mathrm{cr}}(X_0^\times / W(k)^0) \otimes_{W(k)} B_{\mathrm{st}})^{N=0,\phi=1} \cap F^0(B_{dR} \otimes_K H^*_{dR}(X_K/K)).$$

In the above formula the kernel of the monodromy was computed by Kato to be $\mathbb{Q} \otimes \operatorname{proj\,lim}_n H^*_{\mathrm{cr}}(X^\times_{\overline{V},n} / W_n(k))$. If we now take into account both Frobenius and the filtration, we can pass to log-syntomic cohomology and we see that to prove the conjecture it suffices to construct a Galois equivariant family of maps

$$\alpha^n_{i,r}\colon H^i(X_{\overline{K}}, \mu_{p^n}^{\otimes r}) \to H^i_{\mathrm{cr}}(X^\times_{\overline{V}}, S_n(r)),$$

at least for r large enough, that is compatible with Poincaré duality and the trace map.

The main problem with trying to carry over our motivic proof of the Crystalline conjecture to this setting is that the integral model $X_{\overline{V}}$ is in general singular. It becomes then very difficult to control the kernel and cokernel of the restriction map j^*. However the singularities are rather mild (they are of toric type) and we find [32]

that every model $X^{\times}_{V'}$, for a finite extension V'/V, can be desingularized by a log-blow-up $Y^{\times} \to X^{\times}_{V'}$. Since we are blowing up only strata this desingularization does not change the log-syntomic cohomology. Obviously it does not change the étale cohomology either, so to define the maps $\alpha^n_{i,r}$ we can work with the regular models $Y^{\times}$. We have the usual "integration" diagram

$$\begin{array}{ccc} F^r_\gamma/F^{r+1}_\gamma K_{2r-i}(Y, \mathbb{Z}/p^n) & \xrightarrow{j^*} & F^r_\gamma/F^{r+1}_\gamma K_{2r-i}(Y_K, \mathbb{Z}/p^n) \\ \downarrow{\scriptstyle c^{\mathrm{syn}}_{r,2r-i}\rho_{2r-i}} & & \downarrow{\scriptstyle c^{\text{ét}}_{r,2r-i}\rho_{2r-i}} \\ H^i(Y^{\times}, S_n(r)) & \xleftarrow[\alpha^n_{i,r}]{} & H^i(Y_K, \mu_{p^n}(r)). \end{array}$$

The right-hand side of the diagram behaves like before. The restriction j^* is an isomorphism for $2r - i > \dim X_K + 1$ because by the localization sequence its kernel and cokernel are controlled by $K'_j(Y_k, \mathbb{Z}/p^n)$, which vanishes for $j > \dim X_K$ by Geisser–Levine. Hence we can integrate differential forms against higher cycles (on the integral model Y) to get the period maps $\alpha^n_{i,r}$. Again as a corollary we get a uniqueness statement for semistable period maps.

Remark 4.6. Notice that the above vanishing result of Geisser–Levine and the resulting bijectivity of the restriction map j^* are entirely p-adic phenomena. The analogous statements mod l are false. This is in contrast with the good reduction case where j^* is an isomorphism mod l as well.

Question 4.7. Is it possible to define log-motivic complexes and cohomology that would specialize to log-syntomic cohomology? More precisely, one would like to have a log-analogue of the motivic diagram (4.1) for a semistable scheme $X^{\times}$ (with logs everywhere in the left column). For that we need a good definition of log-motivic complexes $\mathbb{Z}/p^n(r)^{\times}$ and log-syntomic cycle classes

$$c^{\mathrm{syn}}_{i,r} \colon H^i(X^{\times}, \mathbb{Z}/p^n(r)^{\times}) \to H^i(X^{\times}, S_n(r))$$

(isomorphisms for X proper and $i \leq r < p - 1$). We would expect the restriction map

$$j^* \colon H^i(X^{\times}, \mathbb{Z}/p^n(r)^{\times}) \to H^i(X_K, \mathbb{Z}/p^n(r))$$

to be an isomorphism.

This question is closely related to that of the existence of limit motivic cohomology (see the recent work of Marc Levine [27] on that subject in the case of schemes over a field).

Acknowledgments. I would like to thank Thomas Geisser and Marc Levine for helpful comments.

Vanishing of L-functions and ranks of Selmer groups

Christopher Skinner and Eric Urban*

Abstract. This paper connects the vanishing at the central critical value of the L-functions of certain polarized regular motives with the positivity of the rank of the associated p-adic (Bloch–Kato) Selmer groups. For the motives studied it is shown that vanishing of the L-value implies positivity of the rank of the Selmer group. It is further shown that if the order of vanishing is positive and even then the Selmer group has rank at least two. The proofs make extensive use of families of p-adic modular forms. Additionally, the proofs assume the existence of Galois representations associated to holomorphic eigenforms on unitary groups over an imaginary quadratic field.

Keywords. p-adic modular forms, Galois representations, Selmer groups, L-functions.

Introduction

This paper aims to connect the order of vanishing of the L-functions of certain (motivic p-adic) Galois representations with the ranks of their associated Selmer groups. This connection, really an assertion of equality, is part of the general Bloch–Kato conjectures (cf. [BK] and [FP]), but its origins are in the 'class number formula' for number fields – part of which is the assertion that the order of vanishing at $s = 0$ of the Dedekind zeta-function $\zeta_K(s)$ of a number field K equals the rank of the group of units of K – and the celebrated conjecture of Birch and Swinnterton-Dyer – which asserts that the order of vanishing at $s = 1$ of the L-function $L(E, s)$ of an elliptic curve over a number field K equals the rank of the Mordell–Weil group $E(K)$. In both of these instances the equality can be restated in terms of ranks of Selmer groups (in the case of elliptic curves this requires finiteness of the (p-primary part of the) Tate–Shafarevich group of the curve).

In this paper we work in the context of a polarized regular (pure motivic) Galois representation $R\colon G_{\mathcal{K}} \to \mathrm{GL}_d(L)$ of the absolute Galois group $G_{\mathcal{K}}$ of an imaginary quadratic field $\mathcal{K}$ defined over a p-adic field L; we fix a prime p that splits in $\mathcal{K}$. The polarization condition is an isomorphism

$$R^\vee(1) \cong R^c$$

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

of the arithmetic dual of R with the conjugate of R by the non-trivial automorphism c of $\mathcal{K}$. The (motivic and) regular condition is that R is Hodge–Tate at the primes above p and that the Hodge–Tate weights are regular. We further restrict to the case where the Hodge–Tate weights of R do not include 0 or -1. Unfortunately, this excludes the case of elliptic curves. The L-functions $L(R, s)$ of such Galois representations, defined using geometric Frobenius elements (throughout we adopt geometric conventions), are expected to have meromorphic continuations to all of $\mathbb{C}$ and to satisfy the functional equation

$$L(R, s) = \varepsilon(R, s)L(R^\vee(1), 1 - s).$$

The value $s = 0$ is a critical value of $L(R, s)$, and the connection between orders of vanishing and ranks of Selmer groups is the following.

Conjecture. $\mathrm{ord}_{s=0}L(R, s) = \mathrm{rank}_L H^1_f(\mathcal{K}, R^\vee(1))$.

Here $H^1_f(\mathcal{K}, R^\vee(1)) \subseteq H^1(\mathcal{K}, R^\vee(1))$ is the Bloch–Kato Selmer group. This is defined by imposing local conditions at all primes. At primes not dividing p the classes are required to be unramified, while at primes v dividing p they are required to be crystalline: their image in $H^1(I_v, R^\vee(1) \otimes B_{\mathrm{cris}})$ is zero, where B_{cris} is Fontaine's ring of p-adic periods.

The Galois representations we consider are expected to be automorphic in the sense that for a given R there should exist a unitary group $U(V)$ in d-variables, an automorphic representation π of $U(V)$ with infinity-type a holomorphic discrete series, and an algebraic idele class character χ of $\mathcal{K}$ satisfying $\chi|^\times_{\boldsymbol{A}_\mathbb{Q}} = |\cdot|^{2\kappa'}_{\boldsymbol{A}_\mathbb{Q}}$ such that $L(R, s) = L(\pi, \chi^{-1}, s + \kappa' + 1/2)$, where the right-hand side is a twist of the standard L-function of π. Such an identification is generally the only known strategy for proving the conjectured analytic properties of $L(R, s)$. So we start by assuming that given π and χ, the corresponding R exists. In general this is only known for unitary groups in 3 or fewer variables (see [BR92]) or under certain local hypotheses on π (see [HL04]) (these conditions certainly do not hold in all the cases we consider). We further assume that π and χ are unramified at primes above p. We then prove two theorems – Theorems 4.3.1 and Theorems 5.1.1 – in the direction of the above conjecture. We emphasize that their proofs require the existence of Galois representations associated to certain cuspidal representations of unitary groups; this existence is made precise in Conjecture 4.1.1. The first of these theorems is the following.

Theorem A. *If* $L(\pi, \chi^{-1}, \kappa' + 1/2) = L(R, 0) = 0$ *then* $\mathrm{rank}\, H^1_f(\mathcal{K}, R^\vee(1)) \geq 1$.

We include a few remarks about this theorem.

(i) In earlier work [SU02], [SU06] we proved a result similar to Theorem A: if F is a holomorphic modular form of even weight $2k$ and trivial nebentypus and ordinary for p and if $\mathrm{ord}_{s=k}L(F, s)$ is odd then the rank of the corresponding p-adic Selmer group $H^1_f(\mathbb{Q}, V_F(k))$ is positive (V_F is the p-adic Galois representation associated

to F). The positivity of the rank in the case of even order vanishing – at least if F is unramified at p – will follow from our forth-coming work [SU-MC] on the Iwasawa main conjecture for modular forms[1]. For prior results in the same vein (by Gross and Zagier, Greenberg, Nekovář, Bellaïche,…) the interested reader should consult the introduction to [SU06].

(ii) When π is just an idele class character, so R is one-dimensional, Theorem A is unconditional. Since no hypothesis is imposed on the epsilon factor $\varepsilon(R, 0)$, Theorem A in this case generalizes the complex multiplication case of [SU02], [SU06], where $\varepsilon(R, 0) = -1$ is required (the $\varepsilon(R, 0) = -1$ case is also the main result of [BC04]; our proof of Theorem A provides an alternate proof of this case).

(iii) Suppose F is a holomorphic modular form of even weight $2k > 2$, trivial nebentypus, and level prime to p. One consequence of Theorem A is that if $L(F, k) = 0$, then the rank of $H^1_f(\mathcal{K}, V_F(k))$ is positive. Choosing $\mathcal{K}$ so that the twist $F_{\mathcal{K}}$ of F by the character of $\mathcal{K}$ is such that $L(F_{\mathcal{K}}, k) \neq 0$ and appealing to a result of Kato [Ka04] that asserts $H^1_f(\mathbb{Q}, V_{F_{\mathcal{K}}}(k)) = 0$ in this case, we can then conclude that $H^1_f(\mathbb{Q}, V_F(k))$ has positive rank. This provides another proof of the results from remark (i) as well as an extension of them to the non-ordinary case.

(iv) The authors of [BC04] have announced a result in the spirit of Theorem A but with a number of additional hypotheses, including $\varepsilon(R, 0) = -1$ and certain of the Arthur conjectures.

Our proof of Theorem A follows along the same lines as the proof of the main result in [SU02], [SU06]. As explained in §1, the vanishing of the L-function at $s = 0$ implies the existence of a holomorphic Eisenstein series on a larger unitary group. This is analogous to the situation in *loc. cit.* where odd-order vanishing implies the existence of a special cuspform on a larger group, there a symplectic group of genus 2. In §§2 and 3 we construct a p-adic deformation of this Eisenstein series, a p-adic family of automorphic representations containing the Eisenstein representation. The generic member of this family is cuspidal. The Galois representations associated to these cuspidal representations (whose existence is one of our primary hypotheses) are generically irreducible. Putting all this together, we construct an irreducible family of Galois representations that specializes at one point to the reducible Galois representation $1 \oplus \varepsilon_p \oplus R$ (the Galois representation of the Eisenstein series). By a now standard argument, we then deduce the existence of a non-trivial $G_{\mathcal{K}}$-extension $0 \to L(1) \to E \to R \to 0$. Using a result of Kisin [Ki] we are able to deduce that this extension lies in $H^1_f(\mathcal{K}, R^\vee(1))$.

In the last section of this paper we extend Theorem A to a higher-rank case (under the same hypotheses on χ and π).

Theorem B. *If* $\mathrm{ord}_{s=0} L(\pi, \chi^{-1}, s + \kappa' + 1/2) = \mathrm{ord}_{s=0} L(R, s)$ *is even and positive, then* $\mathrm{rank}\, H^1(\mathcal{K}, R^\vee(1)) \geq 2$.

The proof of Theorem B relies on that of Theorem A. The hypothesis that $L(R, s)$

[1] This work includes a local hypothesis on the modular form F and its associated mod p Galois representation.

vanishes to even order at $s = 0$ means that $\varepsilon(R, 0) = 1$. And so the epsilon factor of the primitive L-function of the Eisenstein series constructed in the proof of Theorem A is equal to -1. This is then true of all the cuspidal representations in the p-adic family from the proof of that theorem. In particular, their L-functions satisfy the hypothesis of Theorem A. So running through the proof of that theorem for these cuspidal representations, one deduces the existence of a p-adic family of generically irreducible Galois representations which specializes at one point to the representation $L^2 \oplus L(1)^2 \oplus R$. And then from this we deduce the existence of a subspace of rank 2 in the Selmer group.

The proofs of Theorems A and B rely crucially on the theory of p-adic families of automorphic representations, especially as developed in [KL] and in [U06].

The authors thank Laurent Berger and Mark Kisin for some useful conversations.

Standard notation. Throughout this paper p is a fixed prime. Let $\overline{\mathbb{Q}}$ and $\overline{\mathbb{Q}}_p$ be, respectively, algebraic closures of $\mathbb{Q}$ and $\mathbb{Q}_p$ and let $\mathbb{C}$ be the field of complex numbers. We fix embeddings $\iota_\infty : \overline{\mathbb{Q}} \hookrightarrow \mathbb{C}$ and $\iota_p : \overline{\mathbb{Q}} \hookrightarrow \overline{\mathbb{Q}}_p$. Throughout we implicitly view $\overline{\mathbb{Q}}$ as a subfield of $\mathbb{C}$ and $\overline{\mathbb{Q}}_p$ via the embeddings ι_∞ and ι_p. Let $\mathbb{C}_p$ be the completion of $\overline{\mathbb{Q}}_p$ with respect to its p-adic metric. We fix an identification $\mathbb{C}_p \cong \mathbb{C}$ compatible with the embeddings ι_p and ι_∞.

We fix $\mathcal{K} \subset \overline{\mathbb{Q}}$ an imaginary quadratic field. We denote by c the complex conjugation of $\mathbb{C}$ (and hence of $\mathcal{K}$). We assume that p splits in $\mathcal{K}$: $p = \wp\wp^c$ with $\wp$ the prime ideal of $\mathcal{K}$ induced by ι_p. We write ϖ for an uniformizer of $\wp$.

1. Eisenstein series and vanishing of L-functions

1.1. Unitary groups. Let θ be a totally imaginary element in $\mathcal{K}$ such that $-i\theta > 0$ and let $\Delta = \theta\bar{\theta}$ (a positive rational number). In Sections 2–5 we will assume that $\mathrm{ord}_p(\Delta) = 0$. Given integers $b \geq a \geq 0$, $a + b = d > 0$, we let

$$T_{a,b} = \begin{pmatrix} & & 1_b \\ & \theta^{-1} & \\ -1_b & & \end{pmatrix} \in \mathrm{GL}_d(\mathcal{K}).$$

We let $G_{a,b}$ be the unitary group associated to this (skew-Hermitian) matrix: for any $\mathbb{Q}$-algebra R

$$G_{a,b}(R) = \{g \in \mathrm{GL}_d(\mathcal{K} \otimes R) \ : g T_{a,b} {}^t\bar{g} = T_{a,b}\}.$$

Then $G_{a,b}(\mathbb{R})$ is a real unitary group of signature (a, b). The unbounded symmetric domain associated to this group is

$$\mathcal{D}_{a,b} = \Big\{ \begin{bmatrix} z \\ u \\ 1_a \end{bmatrix} \in \mathrm{M}_{d\times a}(\mathbb{C}) \ : \ z \in \mathrm{M}_{a\times a}(\mathbb{C}),\ u \in \mathrm{M}_{(b-a)\times a}(\mathbb{C}), \\ \theta^{-1}(z - z^*) - u^*u > 0 \Big\}.$$

The action of $G_{a,b}(\mathbb{R})$ on $\mathcal{D}_{a,b}$ is defined as follows: for $g \in G_{a,b}(\mathbb{R})$ and $x \in \mathcal{D}_{a,b}$

$$g(x) = g \cdot x \cdot t^{-1}, \quad g.x = \begin{bmatrix} r \\ s \\ t \end{bmatrix}, \ r, t \in \mathrm{M}_{a\times a}(\mathbb{C}),$$

where . denotes the usual matrix multiplication. Let

$$x_0 = \begin{bmatrix} i \\ 0 \\ 1 \end{bmatrix} \in \mathcal{D}_{a,b}.$$

The stabilizer of x_0 in $G_{a,b}(\mathbb{R})$ is a maximal compact, which we denote $K_{a,b}$. This is the group of $\mathbb{R}$-points of an $\mathbb{R}$-group that we also denote by $K_{a,b}$. The map $g \mapsto g(x_0)$ is a real analytic isomorphism of $G_{a,b}(\mathbb{R})/K_{a,b}$ with $\mathcal{D}_{a,b}$. We will often write an element g of $G_{a,b}$ or $\mathrm{M}_{d\times d}$ in block form: $g = (g_{ij})_{1\le i,j\ge 3}$ with $g_{11}, g_{33} \in \mathrm{M}_{a\times a}$. We let $B_{a,b}$ be the $\mathbb{Q}$-rational Borel of $G_{a,b}$ defined by requiring $g_{21} = g_{31} = g_{32} = 0$ and g_{33} to be upper-triangular (so g_{11} is lower-triangular).

Let

$$c = c_{a,b} = 2^{-1/2} \begin{pmatrix} 1_a & & -i1_a \\ & \sqrt{|\theta|}1_{b-a} & \\ -i1_a & & 1_a \end{pmatrix} \in \mathrm{GL}_d(\mathbb{C}).$$

Then $cT_{a,b}{}^t\bar{c} = i/2\mathrm{diag}(1_a, -1_b)$, so $k \mapsto ckc^{-1}$ identifies $K_{a,b}$ with the $\mathbb{R}$-group $U(a) \times U(b)$ (embedded diagonally in $\mathrm{GL}_d(\mathbb{C})$). Let $H_{a,b}$ be the Cartan subgroup of $K_{a,b}$ that is identified with the group of diagonal matrices in $U(a) \times U(b)$. Let $J_{a,b}\colon G_{a,b}(\mathbb{R}) \times \mathcal{D}_{a,b} \to K_{a,b}(\mathbb{C})$ be the canonical automorphy factor: if $k \in K_{a,b}$ then $J_{a,b}(k, x_0) = k$, and

$$cJ_{a,b}\Big(\begin{pmatrix} a_{11} & a_{12} & a_{13} \\ & a_{22} & a_{23} \\ & & a_{33} \end{pmatrix}, x_0\Big)c^{-1} = \big(a_{11}, \begin{pmatrix} a_{22} & a_{23} \\ & a_{33} \end{pmatrix}\big).$$

These properties, together with the usual cocycle condition, completely determine $J_{a,b}$.

We also fix for each prime ℓ a maximal compact $K_{a,b,\ell} \subset G_{a,b}(\mathbb{Q}_\ell)$, and let $K_{a,b,f} = \prod K_{a,b,\ell}$.

Let $a' = a+1$, $b' = b+1$. Let $P_{a,b}$ be stabilizer in $G_{a',b'}$ of the line $\{(0, \dots, 0, x) \in \mathcal{K}^{d+2} : x \in \mathcal{K}\}$. Then $P_{a,b}$ is a standard, maximal $\mathbb{Q}$-parabolic of $G_{a',b'}$ with standard Levi subgroup $L_{a,b}$ isomorphic to $G_{a,b} \times \mathrm{Res}_{\mathcal{K}/\mathbb{Q}}\boldsymbol{G}_m$: a pair $(g, t) \in G_{a,b} \times \mathrm{Res}_{\mathcal{K}/\mathbb{Q}}\boldsymbol{G}_m$ is identified with

$$m(g,t) = \begin{pmatrix} g_{11} & & g_{12} & g_{13} \\ & \bar{t}^{-1} & & \\ g_{21} & & g_{22} & g_{23} \\ g_{31} & & g_{32} & g_{33} \end{pmatrix}_{t} \in G_{a',b'}.$$

We write $N_{a,b}$ for the unipotent radical of $P_{a,b}$. The map $r_{a,b} : \mathcal{D}_{a',b'} \to \mathcal{D}_{a,b}$ given by

$$r_{a,b}\Big(\begin{bmatrix} z \\ u \\ 1_{a'} \end{bmatrix}\Big) = \begin{bmatrix} z' \\ u' \\ 1_a \end{bmatrix},$$

$$z = (z_{ij})_{1\le i,j\le a+1}, \quad z' = (z_{ij})_{1\le i,j\le a},$$

$$u = (u_{i,j}), \quad u' = (u_{i,j})_{j\le a},$$

is $P_{a,b}(\mathbb{R})$-equivariant in the sense that if $p = m(g,t)n \in P_{a,b}(\mathbb{R}) = L_{a,b}(\mathbb{R})N_{a,b}(\mathbb{R})$ then $r_{a,b}(p(x)) = g(r_{a,b}(x))$.

The algebraic characters of $G_{a,b}$ correspond to d-tuples of integers $(c_d, \dots, c_{b+1}; c_1, \dots, c_b)$ in the usual way. The irreducible algebraic representations of $K_{a,b}$ are then classified by those d-tuples satisfying $c_1 \geq c_2 \geq \cdots \geq c_b$ and $c_{b+1} \geq c_{b+2} \geq c_d$. Such d-tuples also classify the L-packets of discrete series representations of $G_{a,b}(\mathbb{R})$. The holomorphic discrete series correspond to those d-tuples such that $c_b - c_{b+1} \geq d$. Given such a d-tuple τ, we write π_τ^H for the corresponding holomorphic discrete series.

When a and b are fixed or their exact values unimportant, we write G for $G_{a,b}$ and H for $G_{a',b'}$. In our remaining notation we drop the subscript 'a, b' and replace the subscript 'a', b'' with a superscript $'$.

1.2. *L*-functions. Let π be an automorphic representation of G and χ an idele class character of $\boldsymbol{A}_{\mathcal{K}}^\times$. We write $L(\pi, \chi, s)$ for the standard L-function associated to π and χ: if $\mathrm{BC}(\pi)$ is the formal base change of π to $\mathrm{GL}(d)_{/\mathcal{K}}$ then $L(\pi, \chi, s) = L(\mathrm{BC}(\pi), \chi, s)$. If S is a finite set of places of $\mathbb{Q}$ then the superscript 'S' on $L^S(\pi, \chi, s)$ will, as usual, mean that the Euler factors at the places in S have been omitted. If $d > 1$ and π is cuspidal and not endoscopic or CAP, then $\mathrm{BC}(\pi)$ is expected to be cuspidal, hence the L-functions $L^S(\pi, \chi, s)$ are expected to satisfy the following:

$$L^S(\pi, \chi, s) \text{ is holomorphic on all of } \mathbb{C} \tag{1.2.1}$$

and

$$\text{if } \pi \text{ and } \chi \text{ are unitary, then } L^S(\pi, \chi, s) \neq 0 \text{ for } \mathrm{Re}(s) \geq 1. \tag{1.2.2}$$

Remark 1.2.1. That $\mathrm{BC}(\pi)$ is cuspidal as expected is known in certain cases: (1) if $d = 2, 3$ or (2) if π_v is supercuspidal for some finite place v.

1.3. Eisenstein series. Given a cuspidal automorphic representation π of G with underlying space V_π and an idele class character χ of $\boldsymbol{A}_{\mathcal{K}}^\times$, we let $\rho = \rho_{\pi,\chi}$ be the representation of $P(\boldsymbol{A})$ on V_π defined by $\rho(m(g,t)n)v = \chi(t)\pi(g)v$, $m(g,t) \in M(\boldsymbol{A})$, $n \in N(\boldsymbol{A})$. Let $I(\rho)$ be the space of smooth, K'-finite functions $f : H(\boldsymbol{A}) \to V_\pi^{\mathrm{sm}}$ such that $f(pg) = \rho(p)f(g)$. We assume that V_π has been identified with a cuspidal subspace of $L^2(G(\mathbb{Q})\backslash G(\boldsymbol{A}))$, so the smooth vectors V_π^{sm} are smooth functions and the smooth, K-finite vectors $V_\pi^{\mathrm{sm,fin}}$ are cuspforms. Then evaluation at the identity converts $f \in I(\rho)$ into a $\mathbb{C}$-valued function on $H(\boldsymbol{A})$; we often write $f(x)$ for $f(x)(1)$. Bearing this in mind, given $f \in I(\rho)$ and a complex number s we consider the Eisenstein series

$$E(f; s, g) = \sum_{\gamma \in P(\mathbb{Q})\backslash H(\mathbb{Q})} f(\gamma g)\delta(\gamma g)^{s+1/2},$$

where δ is the usual modulus function for P: $\delta(m(g,t)) = |t\bar{t}|_{\boldsymbol{A}}^{-(d+1)}$. If $\mathrm{Re}(s)$ is sufficiently large (if π and χ are unitary and π is tempered then $\mathrm{Re}(s) > 1/2$ suffices)

then this series converges absolutely and uniformly for s and g in compact sets and so is holomorphic in s and defines an automorphic form on $H(\boldsymbol{A})$. The general theory of Eisenstein series provides a meromorphic continuation of $E(f; s, g)$ to all of $\mathbb{C}$.

1.4. Holomorphy and vanishing of L-functions. Suppose that $\pi = \otimes\pi_v$ is such that $\pi_\infty = \pi_\tau^H$ for some d-tuple $\tau = (c_d, \ldots, c_{b+1}; c_1, \ldots, c_b)$. We identify τ with the corresponding algebraic representation of K and write V_τ for the complex points of the underlying module (so V_τ is a finite-dimensional complex vector space and τ defines an action of $K(\mathbb{C})$ on V_τ). Then $(V_{\pi_\infty}^{\mathrm{sm,fin}} \otimes V_\tau)^K$ is one-dimensional. Let φ_∞ be a non-zero generator of this space. Let $\varphi_f \in \otimes_{\ell\neq\infty} V_{\pi_\ell}^{\mathrm{sm}}$ and let $\varphi = \varphi_\infty \otimes \varphi_f \in V_\pi^{\mathrm{sm,fin}} \otimes V_\tau$. We convert φ into something more classical as follows. We write $\tau(g, x)$ for $\tau(J(g, x))$ and set

$$F(Z) = \tau(g, x_0)\varphi(gx), \quad g \in G(\mathbb{R}),\ g(x_0) = Z \in \mathcal{D}_G.$$

This is a holomorphic function of Z, and if $U \subseteq G(\boldsymbol{A}_f)$ is an open compact such that $\varphi(gk) = \varphi(g)$ for all $k \in U$ then F satisfies

$$F(\gamma(Z)) = \tau(\gamma, Z)F(Z), \quad \gamma \in \Gamma = G(\mathbb{Q}) \cap U.$$

Let $\chi = \otimes\chi_v$ be an idele class character of $\boldsymbol{A}_{\mathcal{K}}^\times$ such that $\chi_\infty = z^n\bar{z}^m$ with $n + m$ having the same parity as d. Let $\kappa, \kappa' \in \frac{1}{2}\mathbb{Z}$ be defined by $2\kappa = n - m$ and $2\kappa' = n + m$ and assume κ satisfies

$$c_b \geq \kappa + d/2 + 1, \quad \kappa - d/2 - 1 \geq c_{b+1}. \tag{1.4.1}$$

Let ξ be the $d+2$-tuple $\xi = (c_d, \ldots, c_{b+1}, \kappa - d/2 - 1; c_1, \ldots, c_b, \kappa + d/2 + 1)$. As in the case of τ, we identify ξ with the corresponding algebraic representation of K' and write V_ξ for the complex points of the underlying module. The representation τ appears with multiplicity one in the restriction of ξ to K, the latter viewed as a subgroup of K' via $k \mapsto m(k, 1)$; the other irreducible representations appearing in this restriction have highest weight dominated by τ. We fix a K-equivariant inclusion of V_τ into V_ξ (explicitly, if v and w are respective highest weight vectors of these representations then $v \mapsto w$ determines such an inclusion). Then $(V_\pi^{\mathrm{sm,fin}} \otimes V_\xi)^K = (V_\pi^{\mathrm{sm,fin}} \otimes V_\tau)^K$ since τ is the minimal K-type in π_∞.

There are compatible factorizations $\rho = \otimes\rho_v$ and $I(\rho) = \otimes I(\rho_v)$, with $\rho_v = \rho_{\pi_v, \chi_v}$ and $I(\rho_v)$ defined similarly to ρ and $I(\rho)$. Let $\rho_f = \otimes_{v\neq\infty}\rho_v$ and $I(\rho_f) = \otimes_{v\neq\infty} I(\rho_v)$. A straight-forward application of Frobenius reciprocity shows that $(I(\rho_\infty) \otimes V_\xi)^{K'}$ is one-dimensional. Let Φ_∞ be a generator of this space. Let $\Phi_f \in I(\rho_f)$ and let $\Phi = \Phi_\infty \otimes \Phi_f \in (I(\rho) \otimes V_\xi)^{K_{H,\infty}}$. For $h \in H(\boldsymbol{A}_f)$, $\Phi(h) \in (V_\pi^{\mathrm{sm,fin}} \otimes V_\xi)^{K_{G,\infty}} = (V_\pi^{\mathrm{sm,fin}} \otimes V_\tau)^{K_{G,\infty}}$. Let $\varphi_h = \Phi(h)$. Then $\varphi_h = \varphi_\infty \otimes \varphi_{h,f}$.

We relate Φ to something more classical as we did φ (and hence each φ_h). For $g \in H(\mathbb{R})$ and $Z \in \mathcal{D}'$ we let $\xi(g, Z) = \xi(J'(g, Z))$. For $h \in H(\boldsymbol{A}_f)$ and $s \in \mathbb{C}$ we

then set

$$\mathcal{F}_h(s, Z) = \xi(g, x_0)\Phi(gh)\delta(g)^{s+1/2}, \quad g \in H(\mathbb{R}), g(x_0) = Z \in \mathcal{D}'.$$

If $U \subseteq H(\boldsymbol{A}_f)$ is an open compact such that $\Phi_f(gkh) = \Phi_f(gh)$ for all $k \in U$, then $\mathcal{F}_h$ satisfies

$$\mathcal{F}_h(s, p(Z)) = \xi(p, Z)\mathcal{F}_h(s, Z), \quad p \in P(\mathbb{Q}) \cap U.$$

It follows from the definition of $\mathcal{F}_h(s, Z)$ that if $p = m(g, t)n \in P(\mathbb{R})$ is such that $p(x_0) = Z$ (such a p always exists since $H(\mathbb{R}) = P(\mathbb{R})K_H$), then

$$\mathcal{F}_h(s, Z) = (t\bar{t})^{1/2+\kappa'-s(d+1)}F_h(r(Z)),$$

where F_h is the function on $\mathcal{D}$ associated to $\varphi_h = \Phi(h) \in (V_\pi^{\mathrm{sm,fin}} \otimes V_\xi)^K$ as above. In particular, if

$$s_0 = (1/2 + \kappa')/(d + 1)$$

then $\mathcal{F}_h(s_0, Z)$ is visibly holomorphic as a function on $\mathcal{D}'$.

Let $v_1, \ldots, v_n$ be a basis for V_ξ and write $\Phi_\infty = \sum \Phi_{\infty,i} \otimes v_i$ with $\Phi_{\infty,i} \in I(\rho_\infty)$. Put $\Phi_i = \Phi_{\infty,i} \otimes \Phi_f$ and $E(\Phi; s, g) = \sum E(\Phi_i; s, g) \otimes v_i$ and

$$E(\mathcal{F}_h; s, Z) = \xi(g, x_0)E(\Phi; s, gh), \quad g \in H(\mathbb{R}),\ g(x_0) = Z.$$

This last is a V_ξ-valued Eisenstein series on $\mathcal{D}'$. It is holomorphic at $s \in \mathbb{C}$ if $E(\Phi; s, g)$ (so if each $E(\Phi_i; s, g)$ is).

Proposition 1.4.1. *Suppose π is the twist of a tempered representation and suppose* (1.2.1) *and* (1.2.2) *hold.*

(i) *The series $E(\mathcal{F}_h; s, Z)$ is holomorphic as a function of s at $s = s_0$.*

(ii) *If $\chi|_{\boldsymbol{A}_\mathbb{Q}^\times} \neq |\cdot|_{\boldsymbol{A}}^{2\kappa'}$ or if $L(\pi, \chi^{-1}, 1/2+\kappa') = 0$ then $E(\mathcal{F}_h; Z) = E(\mathcal{F}_h; s_0, Z)$ is holomorphic as a function of Z.*

Remark 1.4.2. An important observation is that no hypotheses have been imposed on the section Φ_f. In practice we will assume π and χ to be unramified at p and take the p-component of Φ_f to be a certain 'p-stabilization' of the spherical vector, chosen to be amenable to methods of p-adic deformations of modular forms. At the primes different from p we will generally take Φ_f to be as unramified as possible.

Proof. We briefly indicate a proof of Proposition 1.4.1. Parts (i) and (ii) both follow from analyzing the constant terms of the Eisenstein series $E(\Phi_i; s, g)$ and $E(\Phi; s, g)$. First we note that since π is cuspidal and P is maximal, the constant term along a standard parabolic other than P or G is zero. The constant term of $E(\Phi_i; s, g)$ along P can be expressed in terms of the image of Φ_i under a certain intertwining operator, as we now recall.

Implicit in the factorization $V_\pi = \otimes V_{\pi_v}$ is the choice of a new vector $\phi_v \in V_{\pi_v}^{K_v}$ at each v at which π_v is unramified. If π_v and χ_v are both unramified then we let $\Phi_v^{\mathrm{sph}} \in I(\rho_v)^{K_v'}$ be the generator such that $\Phi_v^{\mathrm{sph}}(1) = \phi_v$. The factorization $I(\rho) = \otimes I(\rho_v)$ is with respect to the Φ_v^{sph}'s.

Let $\rho^\vee$ and $I(\rho^\vee)$ be defined as ρ and $I(\rho)$ were but with χ replaced by $\chi^\vee = (\chi^c)^{-1}$, and let $\rho_v^\vee$ and $I(\rho_v^\vee)$, v a place of $\mathbb{Q}$, be similarly defined. If π_v and χ_v (and hence $\chi_v^\vee$) are unramified at v, then we let $\Phi_v^{\vee,\mathrm{sph}} \in I(\rho_v^\vee)^{K_v'}$ be such that $\Phi_v^{\vee,\mathrm{sph}}(1) = \phi_v$. We let $\Phi_\infty^\vee \in (I(\rho_\infty^\vee) \otimes V_\xi)^{K'}$ be a non-zero generator and write $\Phi_\infty^\vee = \sum \Phi_{\infty,i}^\vee \otimes v_i$.

For $\phi \in I(\rho)$ or $I(\rho^\vee)$ and $s \in \mathbb{C}$ we let $\phi_s = \phi\delta^{s+1/2}$. The constant term of $E(\Phi_i; s, g)$ along P is $\Phi_{i,s} + M(s, \Phi_i)_{-s}$ where $M(s, -)\colon I(\rho) \to I(\rho^\vee)$ is the usual intertwining operator associated to P; this is meromorphic as a function of s and for $\mathrm{Re}(s)$ sufficiently large it is defined by the integral

$$M(s, \varphi)_{-s}(g) = \int_{N(\boldsymbol{A})} \varphi_s(wng)dn, \quad w = \begin{pmatrix} 1_a & & \\ & & 1 \\ & 1_b & \\ -1 & & \end{pmatrix} \in H(\mathbb{Q}). \tag{1.4.1}$$

We let $M_v(s, -)\colon I(\rho_v) \to I(\rho_v^\vee)$ be the usual local intertwining operator associated to P; for $\mathrm{Re}(s)$ sufficiently large, but independent of v, these are given by the local versions of the integral (1.4.1). If $\varphi = \otimes\varphi_v$ we then have $M(s, \varphi) = \otimes M_v(s, \varphi_v)$, provided the right-hand side converges. For us, the important properties of the $M_v(s, -)$'s are

(a) if π_v and χ_v are unramified then

$$M_v(s, \Phi_v^{\mathrm{sph}}) = \frac{L(\pi_v, \chi_v^{-1}, (d+1)s)L(\chi_v', (2d+2)s)}{L(\pi_v, \chi_v^{-1}, (d+1)s+1)L(\chi_v', (2d+2)s+1)}\Phi_v^{\vee,\mathrm{sph}},$$

where $\chi_v' = \chi_v^{-1}|_{\mathbb{Q}_v^\times}$;

(b) for a finite place v, $M_v(s, -)$ is holomorphic at $s = s_0$;

(c) $\sum M_\infty(s, \Phi_{\infty,i}) \otimes v_i = c(s)\Phi_\infty^\vee$, where $c(s)$ is a meromorphic function with a simple zero at $s = s_0$.

Part (a), of course, is a well-known computation. Part (b) follows from [Sh] and the hypothesis that π is a twist of a tempered representation. Part (c) is a relatively straight-forward computation.

Suppose $\Phi_f = \otimes\Phi_\ell$; we may assume this without loss of generality since any Φ_f is a linear combination of such. Let S be the set of primes ℓ such that π_ℓ or χ_ℓ is ramified or $\Phi_\ell \neq \Phi_\ell^{\mathrm{sph}}$. From (a) and (c) above it follows that for $\mathrm{Re}(s)$ sufficiently large we then have

$$M(s, \Phi_i) = \frac{c(s)L^S(\pi, \chi^{-1}, (d+1)s)L^S(\chi', (2d+2)s)}{L^S(\pi, \chi^{-1}, (d+1)s+1)L^S(\chi', (2d+2)s+1)} \cdot \Phi_{\infty,i}^\vee \otimes_{\ell\notin S} \Phi_\ell^{\mathrm{sph}} \otimes_{\ell\in S} M_\ell(s, \Phi_\ell).$$

Note that $\chi' = \chi^{-1}|_{\boldsymbol{A}_{\mathbb{Q}}^\times}$ is an idele class character of $\boldsymbol{A}_{\mathbb{Q}}^\times$ with infinity type $z^{-2\kappa'}$. Thus $L^S(\chi', (2d+2)s)$ is holomorphic at $s = s_0$ unless $\chi' = |\cdot|_{\boldsymbol{A}}^{-2\kappa'}$ in which case the L-function has a simple pole at $s = s_0$. It also follows that $L^S(\chi', (2d+2)s+1)$ is holomorphic and non-zero at $s = s_0$. In particular, $c(s)L^S(\chi', (2d+2)s)/L^S(\chi', (2d+2)s+1)$ is holomorphic at $s = s_0$ and non-zero only if $\chi' = |\cdot|_{\boldsymbol{A}}^{-2\kappa'}$. It follows from (1.2.1) and (1.2.2) that $L^S(\pi, \chi^{-1}, (d+1)s)/L^S(\pi, \chi^{-1}, (d+1)s+1)$ is holomorphic at $s = s_0$ and zero if and only if $L^S(\pi, \chi^{-1}, 1/2+\kappa') = 0$. Putting all this together with (b) above we find that

(d) $M(s, \Phi_i)$ is holomorphic at $s = s_0$;

(e) $M(s, \Phi_i) = 0$ if $\chi' \neq |\cdot|_{\boldsymbol{A}}^{-2\kappa'}$ or if $L(\pi, \chi^{-1}, 1/2+\kappa') = 0$.

The general theory of Eisenstein series implies that $E(\Phi_i; s, g)$ is holomorphic at $s = s_0$ if its constant terms are. Thus (d) above implies the holomorphy of $E(\Phi_i; s, g)$, and hence of each $E(\mathcal{F}_h; s, Z)$, at $s = s_0$, proving part (i) of the proposition. It also follows from the general theory of Eisenstein series that $E(\mathcal{F}_h; s_0, Z)$ is holomorphic as a function of Z if its constant terms are. This is equivalent to the holomorphy of the functions

$$Z \mapsto \xi(g, x_0)\left(\Phi_s(gx) + M(s, \Phi)_{-s}(gx)\right), \quad g \in H(\mathbb{R}),\ g(x_0) = Z,\ x \in H(\boldsymbol{A}_f),$$

where $M(s, \Phi) = \sum M(s, \Phi_i) \otimes v_i$. If $\chi' \neq |\cdot|_{\boldsymbol{A}}^{-2\kappa'}$ or $L(\pi, \chi^{-1}, 1/2+\kappa') = 0$, it follows from (e) above that this function equals $\mathcal{F}_x(s_0, Z)$ at $s = s_0$ and so is holomorphic. This proves part (ii) of the proposition. □

2. *p*-adic deformations of automorphic representations

It is impossible to list here all the contributors to this area. However, we want to emphasize that the important recent developments grew from the seminal ideas of Hida, Coleman, Mazur and Stevens. For our application, we rely mostly on an approach that has been stressed in [U06]: instead of constructing a space interpolating spaces of automorphic forms, one directly studies the p-adic properties of the 'trace' distribution. This approach is analogous to Wiles' introduction of pseudo-representations for the study of deformations of Galois representations.

2.1. Hecke operators. In this paper we take a Hecke operator to be a compactly supported smooth $\mathbb{Q}$-valued function on $G(\boldsymbol{A}_f)$. We fix a Haar measure on $G(\boldsymbol{A}_f)$ such that the maximal compact K_f has volume 1. If (π, V_π) is a smooth representation, then the action of a Hecke operator on V_π is defined using this Haar measure.

We need to restrict attention to Hecke operators of specific types at the prime p. To describe these we first fix an isomorphism $G(\mathbb{Q}_p) \cong \mathrm{GL}_d(\mathcal{K}_\wp) = \mathrm{GL}_d(\mathbb{Q}_p)$ so that $g = (g_{ij}) \in G(\mathbb{Q}_p)$ is identified with $g' = (g'_{ij}) \in \mathrm{GL}_d(\mathcal{K}_\wp)$ with $g'_{11} = {}^t g_{11}$ and

$g'_{33} = g_{33}$ and so that $B(\mathbb{Q}_p)$ is identified with a standard parabolic of $\mathrm{GL}_d(\mathbb{Q}_p)$ (i.e., contains the subgroup of upper-triangular matrices). We assume that the maximal compact $K_p \subset G(\mathbb{Q}_p)$ is identified with $\mathrm{GL}_d(\mathbb{Z}_p)$.

For each positive integer m we let $I_m \subset \mathrm{GL}_d(\mathbb{Z}_p)$ be the subgroup of matrices that are upper-triangular modulo p^m. Let $t = (t_1, \ldots, t_d)$ be a decreasing sequence of n integers. We denote by u_t the characteristic function on $\mathrm{GL}_d(\mathbb{Q}_p)$ of the double class $I_m.\mathrm{diag}(p^{t_1}, \ldots, p^{t_n}).I_m$. The u_t's generate a commutative algebra[2] via the convolution product. We denote this algebra by $\mathcal{U}_p$.

Let S be a set of finite primes containing p and the primes at which G is ramified. We let $K^S = \prod_{\ell \notin S} K_\ell \subset G(\boldsymbol{A}_f^S)$, a maximal compact open subgroup, and we put

$$\mathcal{R}_{S,p} := \mathcal{C}_c^\infty(K^S \backslash G(\boldsymbol{A}_f^S)/K^S), \mathbb{Z}) \otimes \mathcal{U}_p.$$

This Hecke operator acts naturally on any $V_\pi^{I_n.K^S}$.

2.2. *p*-stabilizations and normalizations. Let (π, V_π) be an automorphic representation such that $V_\pi^{K^S.I_n} \neq 0$ and $\pi_\infty \cong \pi_\tau^H$ with τ a d-tuple as in §1.1. There is a natural action of $R_{S,p}$ on the subspace $V_\pi^{K^S.I_n}$. The choice of an eigenspace is called a p-stabilization of π. Given an eigenspace, we write λ_π for the corresponding character of $R_{S,p}$. Of course, the choice of a p-stabilization is purely local at p: it depends only on the choice of an eigenvector for $\mathcal{U}_p$ in $\pi_p^{I_m}$.

For any $\tau = (c_d, \ldots, c_{b+1}; c_1, \ldots, c_b)$ as in §1.1, the associated normalized weight is $w_\tau := (c_1 - a, \ldots, c_b - a, c_{b+1} + b, \ldots, c_d + b)$; this defines a dominant weight of the diagonal torus of $\mathrm{GL}_d(\mathbb{Q}_p)$ since $c_b - c_{b+1} \geq d$. For the purpose of p-adic variation we normalize the character λ_π, setting $\lambda_\pi^\dagger(f) = \lambda_\pi(f)$ for any $f \in \mathcal{C}_c^\infty(K_m^S \backslash G(\boldsymbol{A}_f^S)/K_m^S), \mathbb{Z})$ and

$$\lambda_\pi^\dagger(u_t) := \frac{\lambda_\pi(u_t)}{w_\tau(t)}$$

for any $u_t \in \mathcal{U}_p$. It can be checked (cf. [Hi04]) that this normalization preserves the p-integrality of the eigenvalues.

Given a p-stabilization of π, we let I_π be the distribution defined by

$$\mathcal{C}_c^\infty(G(\boldsymbol{A}_f^p), \mathbb{Z}) \otimes \mathcal{U}_p \ni f \otimes u_t \mapsto I_\pi(f) := \mathrm{tr}(\pi(f))\lambda_\pi(u_t),$$

and we define the normalized distribution $I_\pi^\dagger$ by replacing λ_π with $\lambda_\pi^\dagger$. We call $I_\pi^\dagger$ a p-stabilized distribution associated to π. Note that $I_\pi^\dagger|_{\mathcal{R}_{S,p}} = \lambda_\pi^\dagger$.

Let $T_d \subset \mathrm{GL}_d$ be the diagonal torus and $B_d \subset \mathrm{GL}_d$ the Borel subgroup of upper-triangular matrices. Assume that $\pi_p = I(\chi) := \mathrm{Ind}_{B_d(\mathbb{Q}_p)}^{\mathrm{GL}_d(\mathbb{Q}_p)} \chi$ with χ an unramified character of $T_d(\mathbb{Q}_p)$. Let $I = I_1$. The choice of a p-stabilization is given by the choice

[2] It is easily checked that this algebra is independent of m.

of an eigenvector for $\mathcal{U}_p$ in $I(\chi)^I$. For each element of the Weyl group $W(G,T)$, there exists such an eigenvector $v_{\chi,w} \in I(\chi)^I$ with the property that

$$u_t.v_{\chi,w} = \chi^w\rho(t)\cdot v_{\chi,w},$$

where $\rho = \left(\frac{d-1}{2}, \frac{d-3}{2}, \ldots, \frac{1-d}{2}\right)$ is half the sum of the positive roots. The choice of a p-stabilization is therefore equivalent to an ordering of the Langlands parameters of the spherical representation $I(\chi)$. If $(\alpha_1, \ldots, \alpha_d)$ is the corresponding ordering, then we have

$$\lambda_\pi(u_t) = \prod_{i=1}^{d} \alpha_i^{t_i}.$$

In general, if π_p is spherical but associated to a non-unitary character χ, it may not equal the full induction of χ, in which case some orderings of the Langlands parameters do not have a corresponding p-stabilizations (see [SU02] for an example in the symplectic case).

A p-stabilization has *finite slope* if there is a d-tuple $s(\lambda_\pi^\dagger) = (s_1, \ldots, s_n) \in \mathbb{Q}^n$ such that

$$v_p(\lambda_\pi^\dagger(u_t)) = -\sum_{k=1}^{d} t_k.s_k, \quad t = \mathrm{diag}(t_1, \ldots, t_d).$$

Such a d-tuple is necessarily unique and called the slope of the p-stabilization. The integrality of the normalization implies that $s(\lambda_\pi^\dagger)$ belongs to the positive obtuse cone (in more automorphic terms this means that the Newton polygon lies above the Hodge polygon), and it can be easily checked that $s_1 + \cdots + s_d = 0$ (i.e., the Newton and Hodge polygon meet at their beginning and end) by considering the action of the center. If $s(\lambda_\pi^\dagger) = (0, \ldots, 0)$ then the p-stabilization is said to be ordinary. In general, the slope is said to be non-critical if $s_{i+1} - s_i < c_{i+1} - c_i + 2$ for all $i = 1, \ldots, d-1$. Otherwise, it is said to be critical. Note that the non-critical conditions define an alcove of the obtuse cone.

2.3. Families. We consider $\mathfrak{X}_{/\mathbb{Q}_p}$, the rigid analytic variety over $\mathbb{Q}_p$ such that

$$\mathfrak{X}(L) = \mathrm{Hom}_{\mathrm{cont}}(T(\mathbb{Z}_p), L^\times)$$

for any finite extension L of $\mathbb{Q}_p$. A point (or p-adic weight) $w \in \mathfrak{X}(L)$ is called arithmetic if the restriction of w to some open subgroup of $T(\mathbb{Z}_p)$ is algebraic and dominant. The corresponding algebraic character is then denoted $w^{\mathrm{alg}} = (a_1, \ldots, a_d)$ and we write $\mathfrak{X}(\overline{\mathbb{Q}}_p)^{\mathrm{alg}}$ for the subset of arithmetic weights. We sometimes write $\mathfrak{X}^d$ instead of $\mathfrak{X}$, d being the dimension of $\mathfrak{X}$, to emphasize the dimension of $\mathfrak{X}$.

For any rigid space $\mathfrak{U}$ we denote by $A(\mathfrak{U})$ the ring of analytic function on $\mathfrak{U}$. For our purposes a p-adic family of automorphic forms is a character

$$\lambda\colon\ \mathcal{R}_{S,p} \to A(\mathfrak{U}),$$

where $\mathfrak{U}$ is an irreducible rigid space over $\mathfrak{X}$ of positive dimension with projection map denoted w and such that there is a Zariski dense set of points $\Sigma \subset \mathfrak{U}(\overline{\mathbb{Q}}_p)^{\mathrm{alg}} := \{y \in \mathfrak{U}(\overline{\mathbb{Q}}_p) \mid \mathrm{w}(y) \in \mathfrak{X}^{\mathrm{alg}}(\overline{\mathbb{Q}}_p)\}$ with the property that for any $y \in \Sigma$ the compositum λ_y of λ with the evalutation map[3] at y is a normalized p-stabilization $\lambda_\pi^\dagger$ of an automorphic representation π of normalized weight $\mathrm{w}(y)^{\mathrm{alg}}$.

Definition 2.3.1 (strong form). A p-adic family of automorphic representations is a linear functional

$$I: \ \mathcal{C}_c^\infty(G(\boldsymbol{A}_S), \mathbb{Z}_p) \otimes \mathcal{R}_{S,p} \to A(\mathfrak{U})$$

such that $\lambda_I := I|_{\mathcal{R}_{S,p}}$ is a p-adic family in the weak sense and such that for all $y \in \Sigma$ as above, the compositum I_y of I with the evalutation map at y is the p-stabilized distribution $I_\pi^\dagger$ of an automorphic representation π of normalized weight $\mathrm{w}(y)^{\mathrm{alg}}$.

Note that these definitions, and hence all subsequent discussion, are relative to some fixed set S of primes containing the prime p.

A fundamental question in the area is whether an individual p-stabilization $I_\pi^\dagger$ is a member of a p-adic family. A positive answer to this question has been given by Hida in the ordinary case. Using the techniques of [Hi04], it can be shown that any ordinary p-adic *almost cuspidal*[4] eigenform is the member of a (strong) p-adic family of almost cuspidal eigenforms of dimension d. We say that an holomorphic modular form for $G_{a,b}$ is almost cuspidal if its constant terms along the parabolic subgroup $P_{a-1,b-1}$ are cuspidal. Using the techniques of [SU06], this can be generalized to forms with slope s satisfying $s_b = s_{b+1}$ (i.e., the semi-ordinary case, which means that $I_\pi^\dagger(u_0)$ is a p-adic unit where u_0 is the operator corresponding to the trace of the relative Frobenius [5] on the Shimura variety associated to $G_{a,b}$ in characteristic p. Note also that the following theorem is a special case of the results of [U06].

Theorem 2.3.2. *If I_0 is a non-critical cuspidal finite slope distribution of regular arithmetic weight w_0, then there exists $\mathfrak{U} \xrightarrow{\mathrm{w}} \mathfrak{X}$ of dimension d, $y_0 \in \mathfrak{U}(\overline{\mathbb{Q}}_p)$, and a p-adic $\mathfrak{U}$-family I such that*

$$I_{y_0} = I_0 + I_1 + \cdots + I_s$$

with $I_1, \ldots, I_s$ irreducible character distributions of $C_c^\infty(\boldsymbol{A}_S) \otimes \mathcal{R}_{S,p}$ such that

$$I_i|_{\mathcal{R}_{S,p}} = I_0|_{\mathcal{R}_{S,p}} \quad \textit{for all } i = 1, \ldots, s.$$

We expect that a similar result must be true for general *overconvergent* modular forms. Using techniques from Kisin–Lai [KL], it is possible to construct such a deformation provided one only requires it to be of dimension one. We will use this technique for critical Eisenstein series.

[3] The map $A(\mathfrak{U}) \to \overline{\mathbb{Q}}_p$ given by $f \mapsto f(y)$.

[4] This terminology is non-standard.

[5] It corresponds to the d-tuple $(\underbrace{1, \ldots, 1}_{b}, \underbrace{p, \ldots, p}_{a})$.

3. Deformations of Eisenstein series

We keep to the notation of Sections 1 and 2. Recall that we have groups $G = G_{a,b}$ and $H = G_{a',b'}$ and $L = G \times \mathrm{Res}_{\mathcal{K}/\mathbb{Q}}\boldsymbol{G}_m$ a standard Levi subgroup of a parabolic P of H. In this section, we will consider specific p-adic families for the groups G and H. Keeping with our practice from Section 1, we will add a superscript $'$ when the notion is relative to H. For instance, I'_m means an Iwahori subgroup of $H(\mathbb{Q}_p)$.

3.1. Critical Eisenstein series. We now fix a cuspidal tempered representation π of $G(\boldsymbol{A})$ and an idele class character χ of $\boldsymbol{A}_{\mathcal{K}}^{\times}$ as in §1.4. We will assume that

$$\chi^{1+c} = |\cdot|_{\boldsymbol{A}_{\mathcal{K}}}^{2\kappa'} \tag{3.1.1}$$

and that the assumptions of Proposition 1.4.1 are satisfied along with

$$L(\pi, \chi^{-1}, \kappa' + 1/2) = 0. \tag{3.1.2}$$

To simplify matters, we will also assume that π and χ are unramified at primes above p. We let S be the set comprising the primes of ramification of π, χ, and G (and hence also of H) together with p. Let $m > 0$ be an integer. Then $\pi_p^{I_m} \neq 0$, and we choose $v_0 \in \pi_p^{I_m}$ a p-stabilization of π_p. We consider the section $\Phi_p^{\mathrm{crit}} \in I(\rho_p)$ defined for all $h \in H(\mathbb{Q}_p)$ by

$$\Phi_p^{\mathrm{crit}}(h) = \begin{cases} \chi(t)\pi_p(g).v_0 & \text{if } h = n.m(g,t)wk_0 \in P(\mathbb{Q}_p)wI'_m, \\ 0 & \text{otherwise.} \end{cases} \tag{3.1.3}$$

Here w is the Weyl element from (1.4.1).

For $s \in \mathbb{C}$ let $I(\rho_v, s) = \{\varphi_s = \varphi\delta^{s+1/2} \ ; \ \varphi \in I(\rho_v)\}$. The following lemma follows from a direct computation.

Lemma 3.1.1. *For each $s \in \mathbb{C}$ the section $\Phi_{p,s}^{\mathrm{crit}} = \Phi_p^{\mathrm{crit}}\delta^{s+1/2} \in I(\rho_p, s)$ is an eigenvector for the action of $\mathcal{U}'_p$. Moreover, if $(\alpha_1, \ldots, \alpha_d)$ is the ordering of Langlands parameters specifying the chosen p-stabilization v_0 of π_p then the ordering associated to $\Phi_{p,s_0}^{\mathrm{crit}}$ is given by*

$$(\alpha_1, \ldots, \alpha_b, \chi(\varpi)p^{\kappa'}, \chi(\varpi)p^{\kappa'+1}, \alpha_{b+1}, \ldots, \alpha_d),$$

and if the slope of v_0 is $(s_1, \ldots, s_d)$ then the slope of $\Phi_{p,s_0}^{\mathrm{crit}}$ is

$$(s_1, \ldots, s_b, 1, -1, s_{b+1}, \ldots, s_d).$$

In particular, it is critical[6].

[6] In contrast, the semi-ordinary p-stabilization obtained by taking $\Phi_p^{\mathrm{ord}} := M(\Phi_p^{\mathrm{crit},\vee}, -s_0)$, where $\Phi_p^{\mathrm{crit},\vee} \in I(\rho_p^{\vee})$ is defined analogously to Φ_p^{crit}, has slope $(s_1, \ldots, s_b, 0, 0, s_{b+1}, \ldots, s_d)$.

We consider the space V_0 generated by the Eisenstein series $E(\mathcal{F}_h; s_0, Z)$ associated to the sections $\Phi = \Phi_{\infty,i} \otimes \Phi_p^{\mathrm{crit}} \otimes \Phi^{p,\infty}$ with $\Phi^{p,\infty} = \otimes_{v \neq p,\infty} \Phi_v$ and $\Phi_v = \Phi_v^{\mathrm{sph}}$ if $v \notin S$. We let $V_1 \subset V_0$ be the subspace of Eisenstein series as above with the extra condition that $M(\Phi_v, s_0) = 0$ for all $v \in S \backslash \{p\}$ and let $E^{\mathrm{cr}}(\pi, \chi) := V_0/V_1$. This last space, a quotient of a space of almost cuspidal holomorphic automorphic forms for H of weight $\xi = (c_d, \ldots, c_{b+1}, \kappa - d/2 - 1; c_1, \ldots, c_b, \kappa + d/2 + 1)$, is acted on by $\mathcal{R}_{S,p} \otimes C_c^\infty(H(\boldsymbol{A}_S), \mathbb{Z}_p)$ and decomposes as

$$E^{\mathrm{cr}}(\pi, \chi) = \bigotimes_{v \in S \backslash \{p\}} \mathcal{L}(\pi_v, \chi_v, s_0)$$

with $\mathcal{L}(\pi_v, \chi_v, s_0)$ the Langlands quotient of $I(\rho_v, s_0)$. We denote by $I_{E^{\mathrm{cr}}(\pi,\chi)}$ the corresponding distribution of $\mathcal{R}_{S,p} \otimes C_c^\infty(H(\boldsymbol{A}_S), \mathbb{Z}_p)$.

For any finite place v of $\mathcal{K}$ and any representation Π_v of $\mathrm{GL}_n(\mathcal{K}_v)$, we denote by $\mathrm{rec}(\Pi_v)$ the n-dimensional representation of the Weil–Deligne group associated to Π_v by the local Langlands correspondence as established by Harris–Taylor [HT01]. Then we have

$$\mathrm{rec}(\mathrm{BC}(\mathcal{L}(\pi_v, \chi_v, s_0))) = \mathrm{rec}(\mathrm{BC}(\pi)_v) \oplus \chi_v \circ \mathrm{Art}_{\mathcal{K}_v}^{-1} \oplus \varepsilon^{-1}\chi_v \circ \mathrm{Art}_{\mathcal{K}_v}^{-1}$$

where $\mathrm{Art}_{\mathcal{K}_v}$ stands for the Artin reciprocity map sending a uniformizer to a geometric Frobenius and where ε denotes the cyclotomic character.

3.2. p-adic deformations. Let $\mathfrak{X}^{d+2}/\mathbb{Q}_p$ be the weight space for H. For any $w_0 = (c_1, \ldots, c_{d+2}) \in \mathfrak{X}^{d+2}$, we put

$$\mathfrak{X}_{w_0}^{d+2} = \{w = (e_1, \ldots, e_{d+2}) \in \mathfrak{X}^{d+2} \mid e_i - e_{i+1} = c_i - c_{i+1} \text{ for all } i \neq b+1\}.$$

This is clearly a two-dimensional closed subspace of $\mathfrak{X}^{d+2}$.

Theorem 3.2.1. *Suppose that* $w_0 = w_\xi = (c_1 - a - 1, \ldots, c_b - a - 1, \kappa + (b-a)/2, \kappa + (b-a)/2, c_{b+1} + b + 1, \ldots, c_d + b + 1)$. *There exist an affinoid* $\mathfrak{U}$ *sitting over* $\mathfrak{X}_{w_0}^{d+2}$, *a point* $y_0 \in \mathfrak{U}(\overline{\mathbb{Q}}_p)$ *over* w_0, *and a two-dimensional family* $I : C_c^\infty(H(\boldsymbol{A}_S), \mathbb{Z}_p) \otimes \mathcal{R}_{S,p} \to A(\mathfrak{U})$ *such that*

$$I_{y_0} = I_{E^{\mathrm{cr}}(\pi,\chi)} + I_1 + \cdots + I_s$$

with the I_i*'s irreducible characters distributions satisfying*

$$I_i|_{\mathcal{R}_{S,p}} = I_{E^{\mathrm{cr}}(\pi,\chi)}|_{\mathcal{R}_{S,p}} \quad \textit{for all } i = 1, \ldots, s.$$

If $\pi_\infty = \pi_\tau^H$ *with* τ *regular, then this family extends to a* $d+2$*-dimensional family over* $\mathfrak{X}^{d+2}$.

Proof. We give just an idea of how this theorem is proved. The details will appear elsewhere. The proof does not require one to start from an Eisenstein series. The

techniques one uses to prove the first point of this theorem are similar to those used by Coleman, Kisin–Lai, and Kassaei. The deformations are constructed by studying the compact action of u_0 on the space of overconvergent modular forms for H obtained by multiplying one of the original critical Eisenstein series by powers of a characteristic zero lifting of powers of the Hasse invariant[7]. This requires that we first establish the rationality of (scalar multiples of) our critical Eisenstein series. The proof then employs the theory of the canonical subgroup as developed by various authors (Abbes–Mokrane, Kisin–Lai, Conrad). This provides a one-variable family. To obtain a two-variable family, one twists the one-variable family by anticyclotomic characters of p-power conductor. To prove the second point, one shows that the constructed curve sits in the eigenvarieties associated to H in [U06]. The regularity condition on τ should not be necessary in this special case. In general, however, it might be necessary to make sure that the 'classical' systems of Hecke eigenvalues occurring in the one variable family contribute only to the middle cohomology of the Shimura variety for H. □

The next lemma helps describe the restrictions $I|_{C_c^\infty(H(\mathbb{Q}_v))}$, $v \in S\backslash\{p\}$. Its proof will appear elsewhere.

Lemma 3.2.2. *Let π_0 be a unitary irreducible representation of $G(\mathbb{Q}_v)$ and χ_0 a unitary character of $\mathcal{K}_v^\times$. Let $J : C_c^\infty(H(\mathbb{Q}_v)) \to A(\mathfrak{U})$ be an analytic $\mathfrak{U}$-family of local character distributions such that*

$$J_{x_0}(f) = \mathrm{tr}(\mathcal{L}(\pi_0, \chi_0, s_0)(f)) + I_1(f) + \cdots + I_s(f)$$

where $I_1, \ldots, I_s$ are irreducible character distributions of $H(\mathbb{Q}_v)$. Assume J is generically irreducible. Then one of the two following cases holds:

(i) *There exist an analytic $\mathfrak{U}$-family of representations π of $G(\mathbb{Q}_v)$ and an analytic $\mathfrak{U}$-family of characters χ of $\mathcal{K}_v$ such that $J_x(f) = \mathrm{tr}(L(\pi_x, \chi_x, s_0)(f))$ for all $x \in \mathfrak{U}(\overline{\mathbb{Q}}_p)$.*

(ii) *The place v is split. There exist an analytic $\mathfrak{U}$-family of representations π of $\mathrm{GL}_d(\mathbb{Q}_v)$ and two analytic $\mathfrak{U}$-families of characters μ and ν of $\mathbb{Q}_v$ with $\mu \neq \nu|\cdot|_v^{\pm 1}$ such that $J_x^H(f) = \mathrm{tr}((\mu_x \times \pi_x \times \nu_x)(f))$ for a Zariski dense set of points $x \in \mathfrak{U}(\overline{\mathbb{Q}}_p)$ where $\mu_x \times \pi_x \times \nu_x$ is the irreducible induction $\mathrm{Ind}_{\boldsymbol{G}_m \times \mathrm{GL}_d \times \boldsymbol{G}_m}^{\mathrm{GL}_{d+2}} \mu_x \otimes \pi_x \otimes \nu_x$.*

4. Galois representations and applications to Selmer groups

4.1. Galois representations for automorphic representations. We begin with notation for the local theory.

[7] This is possible thanks to the theory of the arithmetic toroidal compactification of the Shimura variety associated to H by K. Fujiwara [Fu]

Let w be a finite place of $\mathcal{K}$ and $G_{\mathcal{K}_w}$ the absolute Galois group of the completion of $\mathcal{K}$ at w. We denote by $\mathrm{Frob}_w \in G_{\mathcal{K}_w}$ a geometric Frobenius element, $I_{\mathcal{K}_w} \subset G_{\mathcal{K}_w}$ the inertia subgroup, and $W_{\mathcal{K}_w} \subset G_{\mathcal{K}_w}$ the Weil subgroup.

Assume first that the residual characteristic of w is not p. To any finite-dimensional representation $R\colon G_{\mathcal{K}_w} \to \mathrm{GL}_n(\overline{\mathbb{Q}}_p)$, one associates a Weil–Deligne representation $\mathrm{WD}(R) = (r, N)$ where $r\colon W_{\mathcal{K}_w} \to \mathrm{GL}_n(\overline{\mathbb{Q}}_p)$ is a representation and $N \in M_n(\overline{\mathbb{Q}}_p)$ is such that

$$R(\mathrm{Frob}_w^m \sigma) = r(\mathrm{Frob}_w^m \sigma) exp(t(\sigma)N)$$

where $t\colon I_{\mathcal{K}_w} \to \mathbb{Z}_p$ is defined by $\sigma(\sqrt[p^f]{\varpi_w}) = \zeta_{p^f}^{t(\sigma)} \cdot \sqrt[p^f]{\varpi_w}$ for a fixed choice of a compatible system $\{\zeta_{p^f}\}$ of p-power roots of unity and a uniformizer ϖ_w of $\mathcal{K}_w$. It is well-known that (r, N) is uniquely defined up to isomorphism.

If the residual characteristic of w is equal to p, one generally uses Fontaine's rings to study the p-adic representations of $G_{\mathcal{K}_w}$. If V is such a representation, one defines $D_?(V) = (V \otimes_{\mathbb{Q}_p} B_?)^{G_{\mathcal{K}_w}}$ with $? = \mathrm{dR}$, cris or st, where B_{dR}, B_{cris} and B_{st} are the usual rings of p-adic periods introduced by Fontaine. We write $D^i_{\mathrm{dR}}(V)$ for the i-th step of the Hodge filtration of $D_{\mathrm{dR}}(V)$. We adopt the geometric conventions for the Frobenius and the Hodge–Tate weights (so the Hodge–Tate weights of V are the jumps of the Hodge filtration of $D_{\mathrm{dR}}(V)$).

In both the local and global cases, we denote by ε_p the p-adic cyclotomic character and we write $V(n)$ for the n-th Tate twist of a Galois representation V.

Let now $\pi = \pi_f \otimes \pi_\infty$ be an automorphic representation of $G(\boldsymbol{A})$ such that $\pi_\infty = \pi_\tau^H$ for some $\tau = (c_d, \ldots, c_{b+1}; c_1, \ldots, c_b)$. Let $\boldsymbol{\kappa}_\tau = (\kappa_1, \ldots, \kappa_d)$ be the strictly increasing sequence of integers defined by

$$\kappa_{d-i+1} := c_i + d - i + \delta_i \quad \text{for all } i = 1, \ldots, d,$$

where $\delta_i = -a$ if $i \leq b$ and $\delta_i = b$ if $i \geq b+1$. Let S_π be the set of finite places of $\mathcal{K}$ above primes of ramification of π. The following conjecture[8] is expected to result from the stabilization of the trace formula for unitary groups.

Conjecture 4.1.1. There exists a finite extension L of $\overline{\mathbb{Q}}_p$ and a Galois representation

$$R_p(\pi)\colon G_{\mathcal{K}} \longrightarrow \mathrm{GL}_d(L)$$

satisfying the following properties:

1. $R_p(\pi)^\vee(1-d) \cong R_p(\pi)^c$.
2. $R_p(\pi)$ is unramified outside $S_\pi \cup \{\wp, \bar{\wp}\}$.
3. For each finite place w of $\mathcal{K}$ of residue characteristic prime to p, we have

$$\mathrm{WD}(R_p(\pi)|_{W_{K_w}}) \cong \mathrm{rec}(\mathrm{BC}(\pi)_w^\vee \otimes |\det|^{\frac{1-d}{2}})$$

[8] This conjecture is a theorem for unitary groups appearing in the works of Kottwitz, Clozel, Harris–Taylor, Yoshida-Taylor [HT01, TY06]

where rec is the reciprocity map given by the Local Langlands correspondence of Harris–Taylor [HT01] (using our identification of $\mathbb{C}_p$ with $\mathbb{C}$).

4. $R_p(\pi)|_{G_{\mathcal{K}_\wp}}$ is Hodge–Tate with Hodge–Tate weight given by $\boldsymbol{\kappa}_\tau$.

5. If π_p is unramified, then the eigenvalues of the Frobenius endomorphism of $D_{\mathrm{cris}}(R_p(\pi))$ are given by the Langlands parameters of π_p (again using the identification of $\mathbb{C}_p$ with $\mathbb{C}$).

Let χ_p be the Galois character of $G_{\mathcal{K}}$ associated to an idele class character χ as in §1.4 (i.e., such that $\chi_p(\mathrm{Frob}_w) = \chi(\varpi_w)$ if χ is unramified at w). We see in particular that (3) implies that

$$L^{\{p\}}(R_p(\pi) \otimes \chi_p, s) = L^{\{p\}}\left(\pi^\vee, \chi, s + \frac{1-d}{2}\right) \tag{4.1.1}$$

where $L^{\{p\}}$ means we have omitted the Euler factor at p and the L-function for the Galois representation is defined using the geometric Frobenius elements. Moreover, if χ also satisfies (3.1.1) then (4.1.1) implies

$$L^{\{p\}}(R_p(\pi) \otimes \chi_p, s) = L^{\{p\}}\left(\pi, \chi^{-1}, s + 2\kappa' + \frac{1-d}{2}\right). \tag{4.1.2}$$

4.2. Families of Galois representations. Let $\mathfrak{U}$ be a smooth connected affinoid variety defined over a p-adic field, and let G_F be the absolute Galois group of a number or ℓ-adic field F (ℓ may be equal to p). We call a pseudo-representation $T\colon G_F \to A^0(\mathfrak{U})$ an analytic family of Galois representations over $\mathfrak{U}$. For any reduced affinoid subdomain $\mathfrak{Z} \subset \mathfrak{U}$, we denote by $R^T_{\mathfrak{Z}}$ the semi-simple Galois representation (defined up to isomorphism) over a finite extension of the fraction ring $F(\mathfrak{Z})$ of $\mathfrak{Z}$ whose trace is the pseudo-representation $G_F \to A^0(\mathfrak{U}) \to A^0(\mathfrak{Z})$. We say that T is n-dimensional if $R^T_{\mathfrak{Z}}$ is. If $\mathcal{L}$ is a G_F-stable lattice of $R^T_{\mathfrak{U}}$ and $y \in \mathfrak{U}(\overline{\mathbb{Q}}_p)$, then we denote by $R^{\mathcal{L}}_y$ the representation on the specialization $\mathcal{L} \otimes_{A_0(\mathfrak{U})} A(\mathfrak{U})/I_y$, where I_y is the ideal of analytic function on $\mathfrak{U}$ vanishing at y.

Assume F is a p-adic field. Let T be a family of representations of G_F of dimension d over an affinoid $\mathfrak{U}$. We denote by $\kappa_1, \ldots, \kappa_d \in A(\mathfrak{U})$ the Hodge–Tate–Sen weights of T. Let r be the dimension of the affinoid $\mathfrak{U}$. The family T is said to be of finite slope[9] if there exist

(i) $\varphi_1, \ldots, \varphi_d \in A^0(\mathfrak{U})$,

(ii) $\Sigma \subset \mathfrak{U}(\overline{\mathbb{Q}}_p)$,

(iii) a subset of $\{1, \ldots, d\}$ of r positive integers $i_1 \leq \cdots \leq i_r$,

such that

[9]This is "trianguline" in the terminology of Colmez.

(a) for all $y \in \Sigma$, we have the inequalities $\kappa_1(y) \leq \cdots \leq \kappa_d(y)$,

(b1) for all $i \notin \{i_1, \ldots, i_r\}$, $y \mapsto \kappa_{i+1}(y) - \kappa_i(y)$ is constant on $\mathfrak{U}$,

(b2) for all positive real numbers C, the subset Σ_C of points $y \in \Sigma$ such that $\kappa_{i_j}(y) - \kappa_{i_{j+1}}(y) > C$ for all $i = 1, \ldots, r$ is Zariski dense.

(c) for all $y \in \Sigma$, R_y^T is crystalline, and the eigenvalues of Frobenius on $D_{\mathrm{cris}}(R_y^T)$ are given by $\varphi_1(y)p^{\kappa_1(y)}, \ldots, \varphi_d(y)p^{\kappa_d(y)}$

Let $y_0 \in \mathfrak{U}(L)$ such that $(\kappa_1(y_0), \ldots, \kappa_d(y_0))$ is an increasing sequence of integers. According to a terminology of B. Mazur [M00], we say that T is a finite slope deformation of R_{y_0} of refinement $(\varphi_1(y_0)p^{k_1(y_0)}, \ldots, \varphi_d(y_0)p^{k_d(y_0)})$ and Hodge–Tate variation $(i_1, i_2 - i_1, \ldots, d - i_r)$.

Of course, there is a close link between p-stabilization and refinement. More precisely, we have the following easy lemma.

Lemma 4.2.1. *Assume Conjecture* 4.1.1. *Let π be a cuspidal representation which is tempered and unramified at p and of weight τ (i.e., $\pi_\infty = \pi_\tau^H$). Let $\mathfrak{U}$ be an affinoid sitting over $\mathfrak{X}$ and let I be a p-adic deformation of π with p-stabilization given by $(\alpha_1, \ldots, \alpha_d)$. Then there exists a p-adic deformation T_I over $\mathfrak{U}$ of $R_p(\pi)$ such that the restriction of T_I to $G_{\mathcal{K}_\wp}$ is a finite slope deformation of $\rho_\pi|_{G_{\mathcal{K}_\wp}}$ of refinement $(\varphi_1 p^{\kappa_1}, \ldots, \varphi_d p^{\kappa_d})$ with*

$$\varphi_i = \alpha_{d-i+1}^{-1} \cdot p^{-\kappa_i + (d-1)/2} \quad \text{for all } i = 1, \ldots, d, \tag{4.2.1}$$

where $\boldsymbol{\kappa}_\tau = (\kappa_1, \ldots, \kappa_d)$.

Proof. The existence of T_I follows from the theory of pseudo-representations. The asserted properties of the restriction of T_I to $G_{\mathcal{K}_\wp}$ follows from parts (4) and (5) of the Conjecture 4.1.1. The details are left to the reader. □

We recall the following useful result of Kisin.

Proposition 4.2.2. *Let $T : G_F \to A^0(\mathfrak{U})$ be a finite slope family as above. Let $\mathcal{L}$ be any G_F-stable free $A(\mathfrak{U})$-lattice of $R_{\mathfrak{U}}^T$. Let F_0 be the maximal unramified subfield of F. After shrinking $\mathfrak{U}$ around some fixed $y_0 \in \mathfrak{U}(\overline{\mathbb{Q}}_p)$, the following holds:*

(i) *Let $1 \leq i \leq i_1$ be an integer. If $y \in \mathfrak{U}(\overline{\mathbb{Q}}_p)$ is such that $\kappa_i(y) \in \mathbb{Z}$, then*

$$\mathrm{rank}_{L \otimes K_0} D_{\mathrm{cris}}(R_y^{\mathcal{L}})^{\phi = \varphi_i(y)p^{\kappa_i(y)}} \geq 1,$$

where $L = A(\mathfrak{U})/I_y$. Furthermore, there exists an integer N independent of y such that

$$D_{\mathrm{cris}}(R_y^{\mathcal{L}})^{\phi = \varphi_i(y)p^{\kappa_i(y)}} \hookrightarrow (R_y^{\mathcal{L}} \otimes B_{\mathrm{dR}}/t^{\kappa_i(y)+N} B_{\mathrm{dR}}^+)^{G_K}$$

for all $y \in \mathfrak{U}(\overline{\mathbb{Q}}_p)$.

(ii) *Let* $Q_y(X) := \prod_{i=1}^{i_1}(X - \varphi_i(y)p^{\kappa_i(y)})$. *For any* y *such that* $\kappa_1(y) \in \mathbb{Z}$,

$$\mathrm{rank}_{L\otimes F_0} D_{\mathrm{cris}}(R_y^{\mathcal{L}})^{Q_y(\phi)=0} \geq i_1,$$

where $L = A(\mathfrak{U})/I_y$. *Furthermore, there exists an integer* N *independent of* y *such that*

$$D_{\mathrm{cris}}(R_y^{\mathcal{L}})^{Q_y(\phi)=0} \hookrightarrow (R_y^{\mathcal{L}} \otimes B_{\mathrm{dR}}/t^{\kappa_i(y)+N} B_{\mathrm{dR}}^+)^{G_K}$$

for all $y \in \mathfrak{U}(\overline{\mathbb{Q}}_p)$.

Proof. The first part of the proposition, and hence the second part when $Q_y(X)$ has only simple roots, is a direct consequence of Corollary 5.3 of [Ki]. When $Q_y(X)$ has multiple roots a simple generalization of the argument of [Ki] does the job. We can also as suggested to us by M. Kisin apply (i) to the case $\mathfrak{V} := Sp(A(\mathfrak{U})[X]/(Q(X))$ at least when $Q(X)$ has only generic simple roots. □

We deduce from this proposition a few interesting consequences that we will use to construct elements in Selmer groups.

Lemma 4.2.3. *Let* T *be a finite slope* $\mathfrak{U}$*-family of representations of* G_F *as in Proposition* 4.2.2, *and let* $y \in \mathfrak{U}(L)$ *be such that* $R_y^T := L(1)^f \oplus L^e \oplus V^{ss}$ *for* V *a de Rham representation of* G_F. *We assume that*

(i) 1 *is a root of* $Q_y(X)$ *of order* e,

(ii) $D_{\mathrm{cris}}(V)^{\phi=1} = 0$.

Let $\mathcal{L}$ *be a free lattice such that we have an exact sequence*

$$0 \to V \to R_y^{\mathcal{L}} \to W \to 0,$$

then

(a) *any non trivial extension of* L *by* $L(1)$ *appearing as a subquotient of* W *is crystalline;*

(b) *if* E *is the inverse image of* W^{G_F} *by the projection map from* $R_y^{\mathcal{L}}$ *to* W, *then* E *is an extension of* W^{G_F} *by* V, *the class* $[E]$ *of which is contained in* $H_f^1(K, \mathrm{Hom}(W^{G_F}, V))$.

Proof. Since $D_{\mathrm{cris}}(W/W^{G_F})^{\phi=1}$ and $D_{\mathrm{cris}}(E)^{\phi=1}$ have rank at most $e - \dim W^{G_F}$ and $\dim W^{G_F}$, respectively, by hypothesis (ii), and since the rank of $D_{\mathrm{cris}}(R_y^{\mathcal{L}})^{\phi=1}$ is e by hypothesis (i) and Proposition 4.2.2, we deduce that the respective ranks of $D_{\mathrm{cris}}(W/W^{G_K})^{\phi=1}$ and $D_{\mathrm{cris}}(E)^{\phi=1}$ equal $e - \dim W^{G_K}$ and $\dim W^{G_K}$. From $D_{\mathrm{cris}}(V)^{\phi=1} = 0$ and $D_{\mathrm{cris}}(E)^{\phi=1}$ being of rank $\dim W^{G_K}$, we deduce the surjectivity in the following short exact sequence:

$$0 \to D_{\mathrm{cris}}(V) \to D_{\mathrm{cris}}(E) \to D_{\mathrm{cris}}(W^{G_K}) \to 0.$$

Exactness of this sequence means, by definition, that $[E] \in H^1_f(K, \mathrm{Hom}(W^{G_K}, V))$ and (b) is proved. The proof of (a) follows similarly using $\mathrm{rank} D_{\mathrm{cris}}(W/W^{G_K})^{\phi=1} = e - \dim W^{G_K}$. The details are left to the reader. □

The following lemma will be used in the last section of this paper.

Lemma 4.2.4. *Let K be a p-adic field and let R_0 be a de Rham representation of G_K over a finite extension L of $\mathbb{Q}_p$. Let $\mathfrak{U}$ be an affinoid and $T: G_K \to A(\mathfrak{U})$ a finite slope deformation of the character representation $T_0 = 1 + \mathrm{tr}(R_0)$ of refinement $\varphi_1, \ldots, \varphi_{n+1}$ and Hodge–Tate weight variation $(i_1, i_2 - i_1, \ldots, n + 1 - i_r)$ Let $\mathcal{L}$ be a free G_K-stable $A(\mathfrak{U})$-lattice. We assume the following hypotheses are satisfied.*

(i) $\varphi_i \neq 1$ *if* $i \leq i_1$.

(ii) *There exists* $y \in \mathfrak{U}(L)$ *such that* $T_y = T_0$ *and* $k_i(y) > 0$ *for* $i > i_1$.

(iii) *The representation* $R^{\mathcal{L}}_{\mathfrak{U}}$ *is an extension of the form*

$$0 \to A(\mathfrak{U}) \to R^{\mathcal{L}}_{\mathfrak{U}} \to S_{\mathfrak{U}} \to 0$$

with trivial action of G_K *on* $A(\mathfrak{U})$.

Then the rank over $L \otimes K$ *of* $\mathrm{gr}^0 D_{\mathrm{dR}}(R^{\mathcal{L}}_y) = (R^{\mathcal{L}}_y \otimes \mathbb{C}_p)^{G_K}$ *is one more than the rank of* $\mathrm{gr}^0 D_{\mathrm{dR}}(R_0)$.

Proof. We have to prove that the Sen operator determining the action of a finite index subgroup of G_K on $R^{\mathcal{L}}_y \otimes \mathbb{C}_p$ has the eigenvalue 0 with multiplicity $1 + h_0$ with $h_0 := \mathrm{rank}\ \mathrm{gr}^0 D_{\mathrm{dR}}(R_0)$. Equivalently, we need to show that the order of vanishing at 0 of the minimal polynomial of the Sen operator of $R^{\mathcal{L}}_y$ is one. By hypothesis (ii), it is easy to see that it is therefore sufficient to show the same statement for $R^{\mathcal{L}}_z$ for any z sufficiently closed to y and such that

(a) $k_i(z) = k_i(y)$ if $i \leq i_1$,

(b) $k_i(z) > C$ if $i > i_1$,

where C is any arbitrary large constant (we know that we can approach y by such points by the axioms of a finite slope deformation). We now prove the result for z satisfying (a) and (b).

After (if necessary) replacing $\mathfrak{U}$ by a sufficiently small neighborhood of y, we know by Proposition 4.2.2 that

$$D_{\mathrm{cris}}(R^{\mathcal{L}}_z)^{Q_z(\phi)=0} \otimes K \hookrightarrow (R^{\mathcal{L}}_z \otimes B_{\mathrm{dR}}/t^{k_{i_1}(z)+N} B^+_{\mathrm{dR}})^{G_K}.$$

If $C > N + k_{i_1}(y)$, we therefore have that if z satisfies (a) and (b) then the image of $D_{\mathrm{cris}}(R^{\mathcal{L}}_z)^{Q_z(\phi)=0} \otimes K \cap D^0_{\mathrm{dR}}(R^{\mathcal{L}}_z)$ in $\mathrm{gr}^0(D_{\mathrm{dR}}(R^{\mathcal{L}}_z))$ is of rank h_0. On the other hand, by our hypothesis (iii), we have an exact sequence

$$0 \to L \to R^{\mathcal{L}}_z \to S_z \to 0$$

and therefore $\mathrm{gr}^0(D_{\mathrm{dR}}(R_z^{\mathcal{L}}))$ contains also the non trivial image of $D_{\mathrm{cris}}(L)$ on which the action of ϕ is given by the eigenvalue 1. By hypothesis (i) we may assume that $Q_z(1) \neq 0$ for z sufficiently close to y and therefore the images of $D_{\mathrm{cris}}(L)$ and $D_{\mathrm{cris}}(R_z^{\mathcal{L}})^{Q_z(\phi)=0} \otimes K \cap D^0_{\mathrm{dR}}(R_z^{\mathcal{L}})$ in $\mathrm{gr}^0(D_{\mathrm{dR}}(R_z^{\mathcal{L}}))$ are disjoint and hence $\mathrm{gr}^0(D_{\mathrm{dR}}(R_z^{\mathcal{L}}))$ has rank $1 + h_0$. □

4.3. Deformations of some reducible Galois representations and Selmer groups. Let χ and π be as in §§1.4 and 3.1. Let S be a finite set of places of $\mathcal{K}$ containing $\wp, \wp^c$ and the primes of ramification of $\mathrm{BC}(\pi)$ and χ. Assuming $L(\pi, \chi^{-1}, \kappa' + 1/2) = 0$, we have constructed in §§1 and 3 an Eisenstein representation $E^{\mathrm{cr}}(\pi, \chi)$ whose S-primitive L-function is given by

$$L^S(E^{\mathrm{cr}}(\pi, \chi), s) = L^S(\pi, s)L^S(\chi, s - \kappa' - 1/2)L^S((\chi^c)^{-1}, s + \kappa' + 1/2).$$

Therefore the Galois representation associated to our Eisenstein representation is:

$$R_p(\pi)(-1) \oplus \chi_p^{-1}\varepsilon^{1+\kappa'-d/2} \oplus \chi_p^c\varepsilon^{\kappa'-d/2}.$$

Assume now that χ satisfies (3.1.1). We consider the Galois representation

$$R := R_p(\pi) \otimes \chi_p\varepsilon^{d/2-\kappa'}.$$

It satisfies

$$R^c \cong R^\vee(1) \tag{4.3.1}$$

and we therefore have the functional equation

$$L(R, -s) = \varepsilon(R, s)L(R, s),$$

and $s = 0$ is the central value for $L(R, s)$. By (4.1.2), $L^S(R, 0) = L^S(\pi, \chi^{-1}, \kappa' + 1/2)$. Note that the conditions on the weights of χ and π at the beginning of Section 1.4 imply that R does not have the Hodge–Tate weights 0 and -1. It can be seen that any (automorphic) irreducible Galois representation of $G_{\mathcal{K}}$ with regular Hodge–Tate weights having no Hodge–Tate weights equal to 0 and -1 and satisfying the condition (4.3.1) should be obtained in this way. Although it is not necessary, we will assume that R is irreducible.

The following result is suggested by the Bloch–Kato conjectures.

Theorem 4.3.1. *Assume Conjecture* 4.1.1 *for unitary groups in $d + 2$ variables. Assume π is tempered and that π and χ are unramified at primes above p. Assume also that $R_p(\pi)$ is irreducible. Then, if $L(R, 0) = 0$, we have*

$$\mathrm{rank}\ H^1_f(\mathcal{K}, R^\vee(1)) \geq 1.$$

Here $H^1_f(\mathcal{K}, R^\vee(1))$ is the Bloch–Kato Selmer group associated to the p-adic representation $R^\vee(1)$; for a definition see [BK] or [FP].

Proof. The proof of this theorem runs along the same lines as that of Theorem 4.1.4 in [SU06].

We first choose a non-critical p-stabilization $(\alpha_1, \dots, \alpha_d)$ of π and denote by $(\varphi_1, \dots, \varphi_d)$ the corresponding refinement of $R_p(\pi)$ (given by (4.2.1)). Recall that we write τ for the weight of π_∞ and ξ for the weight of the Eisenstein series. Since we assume the existence of Galois representations for cuspidal representations of the unitary group $G_{a+1,b+1}$, by Theorem 3.2.1 there exists a two-dimensional affinoid subdomain $\mathfrak{U}$ sitting over a closed subspace of $\mathfrak{X}^{d+2}_{w_\xi}$, a point $y_0 \in \mathfrak{U}(\overline{\mathbb{Q}}_p)$ over $w_0 = w_\xi$, and a $\mathfrak{U}$-family T of Galois representations such that the specialization of T at y_0 is the pseudo-representation associated to $R_p(\pi)(-1) \oplus \chi_p^{-1}\varepsilon^{\kappa'-d/2} \oplus \chi_p^{-1}\varepsilon^{\kappa'-d/2-1}$ and such that the restriction of T to $G_{\mathcal{K}_\wp}$ is of refinement

$$(p\varphi_1, \dots, p\varphi_a, \chi(\varpi)^{-1}p^{d/2-\kappa'+1}, \chi(\varpi)^{-1}p^{d/2-\kappa'}, p\varphi_{a+1}, \dots, p\varphi_d)$$

and Hodge–Tate variation $(a+1, b+1)$ (i.e. $r = 1$ and $i_1 = a+1$). Furthermore, from Lemma 3.2.2 and property (3) of the Conjecture 4.1.1, for all finite places w of $\mathcal{K}$ prime to p,

$$R^T_{\mathfrak{U}}|_{G_{\mathcal{K}_w}} \cong \mu_1 \oplus R_w \oplus \mu_2 \tag{4.3.1}$$

where μ_1, μ_2 are two $A(\mathfrak{U})$-valued characters of $G_{\mathcal{K}_w}$ specializing to $\chi_p^{-1}\varepsilon^{\kappa'-d/2}|_{G_{\mathcal{K}_w}}$ and $\chi_p^{-1}\varepsilon^{\kappa'-d/2+1}|_{G_{\mathcal{K}_w}}$ at the point y and R_w is a d-dimensional representation specializing to $R_p(\pi)|_{G_{\mathcal{K}_w}}$ at y.

We consider the normalized deformation $\tilde{R}_{\mathfrak{U}} := R^T_{\mathfrak{U}} \otimes \chi_p\varepsilon_p^{d/2-\kappa'+1}$. We have $\tilde{R}^\vee_{\mathfrak{U}}(1) = \tilde{R}^c_{\mathfrak{U}}$, and the semi-simplified specialization of $\tilde{R}_{\mathfrak{U}}$ at $y \in \mathfrak{U}(L)$ is given by $\tilde{R}_{\mathfrak{U},y} = L \oplus L(1) \oplus R$. The restriction of $\tilde{R}_{\mathfrak{U}}$ to $G_{\mathcal{K}_\wp}$ is a deformation of $\tilde{R}_{\mathfrak{U},y}|_{G_{\mathcal{K}_\wp}}$ of refinement $(\beta_1, \dots, \beta_a, 1, p^{-1}, \beta_{a+1}, \dots, \beta_d)$ with $\beta_i = \varphi_i\chi(\varpi)p^{\kappa'-d/2}$ and of Hodge variation $(a+1, b+1)$. We deduce from this that the restriction of $\tilde{R}_{\mathfrak{U}}$ to the decomposition subgroup $G_{\mathcal{K}_{\wp^c}}$ is a deformation of $\tilde{R}_{\mathfrak{U},y}|_{G_{\mathcal{K}_{\wp^c}}}$ of refinement $(p^{-1}\beta_d^{-1}, \dots, p^{-1}\beta_{a+1}^{-1}, 1, p^{-1}, p^{-1}\beta_a^{-1}, \dots, p^{-1}\beta_1^{-1})$ and of Hodge variation $(b+1, a+1)$.

We claim that $\mathrm{tr}(\tilde{R}^{ss}_{\mathfrak{U}})$ is not of the form $T' + T''$ where T' and T'' are two pseudo-representations. Were this the case, then they would have to satisfy $T'_y(g) = 1+\varepsilon_p(g)$ and $T''(g) = \mathrm{tr}(R(g))$ for all $g \in G_{\mathcal{K}}$. Assume this is so, and let us show we get a contradiction. First we show that the restriction to $G_{\mathcal{K}_\wp}$ of the representation R' associated to T' would be irreducible. By Proposition 4.2.2 the specialization of R' at any arithmetic point y' such that $s = \kappa_{b+2}(y') - \kappa_{b+1}(y') > 1$ would be a crystalline representation of Hodge–Tate weights $(0, s)$ and slopes $(1, s-1)$ and is therefore irreducible. The same statement holds for the restriction to $G_{\mathcal{K}_{\wp^c}}$. Moreover, the restriction of R' to $G_{\mathcal{K}_w}$ for $w \nmid p$ is a split sum of two characters by (4.3.1). Then exactly as in [SU06, Thms 4.2.7 or 4.3.4] we would deduce that there is an non-trivial extension class in $H^1_f(\mathcal{K}, \overline{\mathbb{Q}}_p(1))$; but we know that this group is trivial since the rank of the units in $\mathcal{K}$ is 0.

From the above discussion we deduce that $\tilde{R}_{\mathfrak{U}}$ is irreducible. Let $g \in G_{\mathcal{K}}$ be such that one of the eigenvalues, say α_0, of $\tilde{R}(g)$ is distinct from 1 and $\varepsilon_p(g)$ and choose α in some finite normal extension $A(\mathfrak{V})$ of $A(\mathfrak{U})$ such that $\alpha(z) = \alpha_0$ for some $z \in \mathfrak{V}(\overline{\mathbb{Q}}_p)$ above y. We take v in the representation space of $\tilde{R}'_{\mathfrak{V}} := \tilde{R}'_{\mathfrak{U}} \otimes_{A(\mathfrak{U})} A(\mathfrak{V})$ such that $g.v = \alpha.v$. We then consider the $A(\mathfrak{V})$-lattice $\mathcal{L}$ of $\tilde{R}'_{\mathfrak{V}}$ generated by $g.v$ over $A(\mathfrak{V})$ as g runs through $G_{\mathcal{K}}$. After possibly shrinking $\mathfrak{V}$ around z, we can assume $\mathcal{L}$ is free. By construction, $\mathcal{L}_z$ has a unique irreducible quotient, and this quotient is isomorphic to R. We therefore have an exact sequence of $G_{\mathcal{K}}$-representations

$$0 \to W \to R_z^{\mathcal{L}} \to R \to 0$$

with $W^{ss} \cong L \oplus L(1)$, L being the residue field of z. We first note that by (4.3.1) the restriction of W to $G_{\mathcal{K}_w}$, $w \nmid p$, is split. Moreover, we know by the application of Proposition 4.2.2 that $D_{\mathrm{cris}}(R_z^{\mathcal{L}})^{\phi=1}$ is non zero. Since 1 is not a root of Frobenius for R since $L(\mathrm{BC}(\pi)_w, \chi_w, 1/2)^{-1} \neq 0$ at $w|p$ by [JS, sect. 2.5], we deduce $D_{\mathrm{cris}}(W|_{G_{\mathcal{K}_w}})^{\phi=1}$ has rank 1 for all $w|p$. This shows that W is not a non-trivial extension of L by $L(1)$ since this extension would belong to $H^1_f(\mathcal{K}, L(1)) = 0$ (same argument as in [SU06, 4.3.4]).

Therefore L_z contains the trivial representation L and we can take $E := \mathcal{L}_z/L$. This gives a non-trivial extension:

$$0 \to R^\vee(1) \to E^\vee(1) \to L \to 0.$$

It follows from lemma 4.2.3, that $\mathrm{Res}_{\mathcal{K}_w}([E^\vee(1)]) \in H^1_f(\mathcal{K}_w, R^\vee(1))$ for $w|p$. Note that we again use the fact that 1 is not a root of the Frobenius for $R^\vee(1) \cong R^c$ as this is an hypothesis of the quoted lemma. If $w \nmid p$, $\mathrm{Res}_{\mathcal{K}_w}([E^\vee(1)]) \in H^1_f(\mathcal{K}_w, R^\vee(1))$ follows from (4.3.1). This ends the proof of the theorem. □

5. Higher order vanishing and higher rank Selmer groups

5.1. Higher order of vanishing. In this section, we assume, as in Theorem 4.3.1, that

$$L(\pi, \chi^{-1}, 1/2 + \kappa') = L(R, 0) = 0.$$

Since we are assuming (4.3.1), the primitive L-function of the Eisenstein representation $E^{\mathrm{cr}}(\pi, \chi)$ twisted by χ^{-1} is

$$L(E^{\mathrm{cr}}(\pi, \chi), \chi^{-1}, s) = L(\pi, \chi^{-1}, s)\zeta_{\mathcal{K}}(s - \kappa' - 1/2)\zeta_{\mathcal{K}}(s - \kappa' + 1/2).$$

Therefore the order of vanishing of $L^S(E^{\mathrm{cr}}(\pi, \chi), \chi^{-1}, s)$ at $s = s_0 = \kappa' + 1/2$ is one less than the order of vanishing of $L(\pi, \chi^{-1}, s)$ at $s = s_0$, because $\zeta_{\mathcal{K}}(0) \neq 0$ and $\zeta_{\mathcal{F}}(s)$ has a simple pole at $s = 1$. This remark is the starting point of a method of constructing a higher rank subspace in the Selmer group $H^1_f(\mathcal{K}, R^\vee(1))$ when such

a space is predicted by the Bloch–Kato conjecture (i.e., when $L(R, s)$ vanishes to higher order at $s = 0$). In this final section of this paper, we deal with the case of even order vanishing. More precisely, we will sketch a proof of the following theorem.

Theorem 5.1.1. *Let π and χ as in Theorem* 4.3.1. *We assume Conjecture* 4.1.1 *for $G_{a+2,b+2}$. If $L(R, s)$ vanishes to even order at $s = 0$, then*

$$\text{rank } H^1_f(\mathcal{K}, R^\vee(1)) \geq 2.$$

5.2. Sketch of proof. Since $L(R, s)$ vanishes to even order at $s = 0$, $\varepsilon(\pi, \chi^{-1}, 1/2+\kappa') = \varepsilon(R, 0) = 1$. This implies, by the remark at the beginning of this section, that

$$\varepsilon(R \oplus \varepsilon_p \oplus 1) = -\varepsilon(R, 0) = -1. \tag{5.2.1}$$

Let $\mathfrak{U}$ above $\mathfrak{X}^{d+2}$ and Σ be as in Theorem 3.2.1 and let $\tilde{R}_{\mathfrak{U}}$ be as in the proof of Theorem 4.3.1. By (5.2.1), for each $z \in \mathfrak{U}(\overline{\mathbb{Q}}_p)$, $\varepsilon(\tilde{R}_z, 0) = -1$. In particular, for each arithmetic point $z \in \Sigma^{\text{reg}}$, the subset of elements $z \in \Sigma$ with $\mathrm{w}(z) = (w_1, \ldots, w_{d+2})$ satisfying the regularity condition $w_{b+1} \geq \kappa + (b-a)/2 + 1$ and $w_{b+2} \leq \kappa + (b-a)/2 + 1$ (the analog of (1.4.1) with d replaced by $d+2$), we have $L(\pi(z), \chi^{-1}, 1/2+\kappa') = 0$ where $\pi(z)$ is the (holomorphic) cuspidal automorphic representation of $G_{a+1,b+1}(\boldsymbol{A})$ associated to z. We can therefore apply Proposition 1.4.1 and Theorem 3.2.1 with $\pi(z)$ and $G_{a+1,b+1}$ in place of π and $G_{a,b}$ and then repeat the argument of Theorem 4.3.1. Let ξ_z the weight of the Eisenstein series representation $E^{\text{cr}}(\pi(z), \chi)$. For each $z \in \Sigma$, there exists $\mathfrak{U}_z$ above $\mathfrak{X}^{d+4}_{w_{\xi_z}}$, a point $y_z \in \mathfrak{U}_z(\overline{\mathbb{Q}}_p)$ over w_{ξ_z}, and a pseudo-representation $T_z \colon G_{\mathcal{K}} \to A(\mathfrak{U}_z)$ as in the proof of Theorem 4.3.1.

Let w_1 be the arithmetic weight of $\mathfrak{X}^{d+4}$ defined by $w_1 := (c_1 - a - 2, \ldots, c_b - a - 2, \kappa + \frac{b-a}{2} - 1, \kappa + \frac{b-a}{2}, \kappa + \frac{b-a}{2}, \kappa + \frac{b-a}{2} + 1, c_{b+1} + b + 2, \ldots, c_d + b + 2)$. Let $\mathfrak{Y} \subset \mathfrak{X}^{d+4}$ be the set of weight $w = (e_1, \ldots, e_{d+4})$ such that $e_i = e_{i+1}$ for $i \neq b+1, b+2, b+3, d+4$. This is a 4-dimensional subspace of $\mathfrak{X}^{d+4}$. One can show there exists a 4-dimensional affinoid $\mathfrak{V}$ sitting over $\mathfrak{Y}_{w_1} := w_1 + \mathfrak{Y}$, containing $\mathfrak{U}_z$ for each $z \in \Sigma^{\text{reg}}$, and admitting a $\mathfrak{V}$-family of automorphic representations interpolating the $\mathfrak{U}_z$-families. In other words, the $\mathfrak{U}_z$-families fit together into a 4-dimensional family.

Let $S \colon G_{\mathcal{K}} \to A(\mathfrak{V})$ be the Galois deformation associated to the above $\mathfrak{V}$-family. It is a deformation of

$$\begin{aligned} S_{y_1} = \mathrm{tr}(R_p(\pi)(-2)) &+ \chi_p^{-1}\varepsilon_p^{\kappa'-d/2-1} + \chi_p^{-1}\varepsilon_p^{\kappa'-d/2-1} \\ &+ \chi_p^{-1}\varepsilon_p^{\kappa'-d/2-2} + \chi_p^{-1}\varepsilon_p^{\kappa'-d/2-2}. \end{aligned}$$

for some point $y_1 \in \mathfrak{V}(L)$ sitting over w_1. We consider the normalization defined by $\tilde{\tilde{R}}_{\mathfrak{V}} := R^S_{\mathfrak{V}} \otimes \chi_p \varepsilon_p^{d/2-\kappa'+2}$. Then, $\tilde{\tilde{R}}_{\mathfrak{V}}$ is a deformation of $\mathrm{tr}(R) + 1 + 1 + \varepsilon_p + \varepsilon_p$.

It is also a deformation of $\mathrm{tr}(R_z) + 1 + \varepsilon_p$ for all $z \in \Sigma^{\mathrm{reg}}$ where we have written $R_z := R_p(\pi(z)) \otimes \chi_p \varepsilon_p^{d/2-\kappa'+1}$. From the construction, it follows also that $\tilde{\tilde{R}}_{\mathfrak{V}}|_{G_{\mathcal{K}_\wp}}$ is a finite slope deformation of refinement $(\beta_1, \ldots, \beta_a, 1, 1, p^{-1}, p^{-1}, \beta_{a+1}, \ldots, \beta_d)$ and Hodge variation type $(a+1, 1, 1, b+1)$, and similarly for the restriction of $\tilde{\tilde{R}}_{\mathfrak{V}}$ to $G_{\mathcal{K}_{\wp^c}}$.

As in Theorem 4.3.1, we consider a lattice $\mathcal{L} \subset \tilde{\tilde{R}}_{\mathfrak{V}}$ such that the specialization $R_{y_1}^{\mathcal{L}}$ has a unique quotient isomorphic to R. In particular, this implies that $R_z^{\mathcal{L}}$ has a unique quotient isomorphic to R_z. Moreover, from the proof of Theorem 4.3.1 applied to $\pi(z)$, we see that $R_z^{\mathcal{L}}$ contains the trivial representation as a unique subrepresentation and has a quotient defining an extension E_z whose class belongs to $H_f^1(\mathcal{K}, R_z^\vee(1))$. In what follows, we will assume for simplicity that $\mathcal{L}$ is free although this might not be the case in general. However, it would not be difficult – although a bit cumbersome – to put ourselves in such a situation with a 'localization' argument similar to the one used in [SU06, §4.3.2].

Let $\mathfrak{U} := \mathfrak{V} \times_{\mathfrak{Y}_{w_1}} \mathfrak{X}_{w_1}^{d+4}$. This is the Zariski closure of Σ^{reg}. It follows from the discussion above that $R_{\mathfrak{V}}^{\mathcal{L}} \otimes A(\mathfrak{U})$ contains the trivial representation and that the quotient $\tilde{E}$ by the latter is an extension

$$0 \to A(\mathfrak{U}).\varepsilon_p \to \tilde{E} \to \tilde{R} \to 0$$

where $\tilde{R}$ is the deformation of $\mathrm{tr}(R) + 1 + \varepsilon_p$ having a unique quotient isomorphic to R that appeared in the proof of Theorem 4.3.1. Then the restriction of $\tilde{E}$ to $G_{\mathcal{K}_\wp}$ is a finite slope deformation of refinement $(\beta_1, \ldots, \beta_a, 1, p^{-1}, p^{-1}, \beta_{a+1}, \ldots, \beta_d)$ and Hodge variation type $(a+1, b+2)$, and similarly for the restriction of $\tilde{E}$ to $G_{\mathcal{K}_{\wp^c}}$.

We now study the specialization $\tilde{E}_{y_1}$. It has a unique quotient isomorphic to R and has semi-simplification $L \oplus L(1) \oplus L(1) \oplus R$. We first remark that the trivial representation has to be a subrepresentation of $\tilde{E}_{y_1}$, for otherwise the latter would contain a non-trivial extension of L by $L(1)$. This extension would be unramified outside p and crystalline at p by another application of Proposition 4.2.2 and therefore would give a non-trivial element in $H_f^1(\mathcal{K}, L(1))$.

Quotienting $\tilde{E}_{y_1}$ by this trivial representation, we get an extension E_1. We will now prove that E_1 contains $L(1) \oplus L(1)$. Otherwise, it will contain a non-trivial extension of $L(1)$ by $L(1)$. It is easy to see that this extension would be unramified outside p. It would also be Hodge–Tate by Lemma 4.2.4 applied to $E_1 \otimes L(-1)$ with $R_0 = R(-1) \oplus L$. Such a non-trivial extension does not exist.

We deduce that $E_1^\vee(1)$ is an extension of the form

$$0 \to R^\vee(1) \to E_1^\vee(1) \xrightarrow{f} V \to 0$$

with V a L-vector space of dimension 2 with trivial action of Galois. We deduce that we have an exact sequence

$$0 \to H^0(\mathcal{K}, R^\vee(1)) \to H^0(\mathcal{K}, E_1^\vee(1)) \to V \xrightarrow{\delta} H^1(\mathcal{K}, R^\vee(1).$$

We have $H^0(\mathcal{K}, E_1^\vee(1)) = 0$, for otherwise $E_1^\vee(1)$ contains the trivial representation, but $R^\vee(1)$ is the only subrepresentation of $E^\vee(1)$ since R is the only quotient of E_1 and $R^\vee(1) \cong R^c$ does not contain the trivial representation by hypothesis. Thus δ is injective. We can show that its image is contained in $H_f^1(\mathcal{K}, R^\vee(1))$ using Lemma 4.2.3 just as we proved this for the class $[E^\vee(1)]$ in the proof of Theorem 4.3.1. Since V is of dimension 2, this proves the theorem. □

Special values of L-functions modulo p

Vinayak Vatsal

Abstract. This article surveys the various known results on non-vanishing of special values of L-functions in p-adic families, with an emphasis on the rigidity theorems that underlie the proof in each case.

Mathematics Subject Classification (2000). Primary 14G10; Secondary 37A45.

Keywords. L-functions, ergodic theory.

1. Introduction

The original intent of this article was to survey the results of the author on the nonvanishing of p-adic families of anticyclotomic twists of modular L-functions of GL_2, and in particular, the introduction of Ratner's theorems in ergodic theory to this domain. However, in preparing the article, it soon became evident that the use of Ratner's theorem is an instance of an apparently general phenomenon – namely, that every result thus far known (to the author, at least) about non-vanishing modulo p of L-functions in p-adic families seems to ultimately rely on some kind of ergodic principle about the closure of certain group action orbits, of which Ratner's theorem is a sophisticated example. Since the particular subject of anticyclotomic twists has been amply described elsewhere (notably in the introduction to [7]), the present article will focus instead on surveying the general issue of nonvanishing of p-adic families of twists in variety of different settings, with the goal of exposing the common theme of rigidity which seems to underpin the whole subject. This approach may perhaps be interesting to a wider audience, and in any case may have historical legitimacy since it is the observation that orbit closures of group actions played a key role in the classical theorems of Ferrero and Washington that led the author to introduce ergodic theory in the more general setting.

1.1. Non-vanishing of twists in general. Let $\zeta(s) = \sum_{n\geq 1} n^{-s}$ denote the Riemann zeta function. This series is convergent when the real part of s is greater than 1, and admits a meromorphic continuation to $s \in \mathbb{C}$, with a simple pole at $s = 1$. Furthermore, $\zeta(s)$ satisfies the functional equation

$$\pi^{-s/2}\Gamma(s/2)\zeta(s) = \pi^{-(1-s)/2}\Gamma((1-s)/2)\zeta(1-s), \tag{1}$$

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

It follows trivially from this functional equation that $\zeta(k) = 0$ whenever k is a negative even integer. On the other hand, it was known to Euler that the value of $\zeta(k)$ is rational when k is negative and *odd*. For instance, the well-known formulae $\zeta(2) = \sum_n 1/n^2 = \pi^2/6$ and $\zeta(4) = \sum 1/n^4 = \pi^4/90$, together with the functional equation, show that

$$\zeta(-1) = -1/12 \quad \text{and} \quad \zeta(-3) = 1/60.$$

More generally, it can be shown that if k is a positive integer, then

$$\zeta(1-2k) = -B_k/k$$

where B_k is the Bernoulli number defined by the Taylor expansion

$$\frac{t}{e^t - 1} = \sum_{k=0}^{\infty} B_k \frac{t^k}{k!}.$$

The Bernoulli numbers B_k are closely related to the arithmetic of the cyclotomic fields $\mathbb{Q}(\zeta_p)$, where $\zeta_p = e^{2\pi i/p}$. In fact, one has the following

Theorem 1.1 (Kummer). *Let p denote an odd prime number. Then the class number of the cyclotomic field $\mathbb{Q}(\zeta_p)$ is divisible by p if and only if p divides the numerator of some B_k, for $k = 2, 4, 6, \ldots, p-3$.*

More generally, let $N > 2$ denote an integer, and let $\chi : (\mathbb{Z}/N\mathbb{Z})^\times \to \mathbb{C}^\times$ denote a primitive Dirichlet character modulo N. Then it can be shown that if $n \geq 1$ is an integer, then

$$L(1-n, \chi) = -B_{n,\chi}/n \tag{2}$$

where the twisted Bernoulli number $B_{n,\chi}$ is the algebraic number defined by the formula

$$\sum_{a=1}^{N} \frac{\chi(a) t e^{at}}{e^{Nt} - 1} = \sum B_{n,\chi} \frac{t^n}{n!}. \tag{3}$$

Furthermore, the class number formula, due to Dirichlet, relates the quantities $B_{1,\chi}$ with the class number of certain cyclotomic fields. For instance, suppose that $\chi = \chi_p$ is the quadratic residue character associated to the imaginary quadratic field $\mathbb{Q}(\sqrt{-p})$, where $p > 3$ is a prime . Then one can show that the class number $h(\mathbb{Q}(\sqrt{-p}))$ is given by

$$h(\mathbb{Q}(\sqrt{-p})) = \frac{\sqrt{p}}{\pi} \cdot L(1, \chi).$$

In this article, we will consider the general issue of determining whether some fixed prime p divides the special values of L-functions as above. In view of the class number formulae, this gives information on whether or not certain class numbers are divisible by p. For any given character, this is of course a hopeless problem, so one is naturally led to pose the following question: Suppose that S is a family of Dirichlet characters, and that n is a positive integer. Then how often is the number $L(1-n, \chi)$ divisible by a fixed prime $\mathfrak{p}$ of $\overline{\mathbb{Q}}$?

Example 1.2. Suppose that $S = S_{\text{quad}}$ is the family of quadratic characters associated to imaginary quadratic fields. Then Gauss showed that the 2-primary subgroup of the class group of $\mathbb{Q}(\sqrt{-D})$ has order 2^{g-1}, where g is the number of distinct primes dividing the discriminant of $\mathbb{Q}(\sqrt{-D})$. In particular, $h(\mathbb{Q}(\sqrt{-D}))$ is even unless D is a prime congruent to 1 mod 4.

What about other primes? If $p = 3$, Davenport and Heilbronn showed that $h(\mathbb{Q}(\sqrt{-D}))$ is prime to 3 for a positive proportion of D. For $p > 3$ it is known that there are infinitely many D with $(h(\sqrt{-D}), p) = 1$, and also infinitely many D with $(h(\sqrt{-D}), p) = p$.

Example 1.3. Recent work of Bhargava shows that at least 75% of totally real cubic fields and 50% of complex cubic fields have odd class number. For more in this direction, we refer to [2].

The examples cited above give information on the p-divisibility of various class numbers, and in view of the class number formulae, may be translated into statements about L-functions. However, it is to be noted that the *proofs* of these results are based essentially on the study of homogeneous forms of various degree, and make no reference to the L-functions as such. In the rest of this paper, we will restrict our attention to examples where one can study the L-functions directly. Specifically, we will consider the divisibility by a prime ℓ of L-functions varying in certain p-adic families. Here ℓ may or may not be the same as p.

2. p-adic families

2.1. Cyclotomic Dirichlet characters and the work of Ferrero–Washington

Example 2.1. Thus, for a different kind of example, we now take $S = S_{p\text{-cyc}}$ to denote the set of Dirichlet characters of conductor p^n, for $n \geq 0$. Such characters are in bijective correspondence with characters of the group $\text{Gal}(\mathbb{Q}(\mu_{p^\infty})/\mathbb{Q})$, where $\mathbb{Q}(\mu_{p^\infty})$ is the field obtained by adjoining to $\mathbb{Q}$ all p-power roots of unity. Thus $\mathbb{Q}(\mu_{p^\infty})$ is the union of the fields $K_n = \mathbb{Q}(\zeta_{p^n})$, where ζ_{p^n} is a primitive p^n-th root of unity. Let $h(K_n)$ denote the class number of K_n. Then one can ask how often $h(K_n)$ is divisible by a fixed prime ℓ. It turns out that the behavior depends basically on whether or not $\ell = p$.

We consider first the case that $\ell = p$. In this case, it was shown by Iwasawa that if p^{e_n} denotes the exact power of $\ell = p$ dividing the class number $h(K_n)$, then there exist integers λ, μ, and ν, such that

$$e_n = \lambda n + \mu p^n + \nu.$$

for all n sufficiently large. Iwasawa conjectured further that in fact $\mu = 0$, so that e_n is a linear function of n, which is constant if and only if $\lambda = 0$. On the other hand, experimental evidence suggests that $\text{ord}_\ell(h(K_n))$ is bounded if $\ell \neq p$. Both these phenomena were confirmed by Ferrero and Washington.

Theorem 2.2 (Ferrero–Washington). *Suppose that p is a prime number. Then the invariant μ vanishes, so we have $e_n = \lambda n + \nu$, for sufficiently large n. If $\ell \neq p$ is a fixed prime, then* $\mathrm{ord}_\ell(h(K_n))$ *is bounded as n tends towards infinity.*

We now want to make some remarks about the proof of the Ferrero–Washington theorems, since this will be the first appearance in the subject of ideas from ergodic theory.

As we have remarked above, the first step in Ferrero–Washington is to express the class numbers in terms of L-values. In view of the formula (2), the problem becomes one of determining the divisibility properties of the numbers $B_{n,\chi}$ defined in (3). In the original papers [11] and [36], the authors use an ingenious formula (apparently due to Iwasawa) which expresses the numbers $B_{n,\chi}$ in terms of the p-adic digits of certain p-adic numbers related to the $p-1$-st roots of unity. The calculation is somewhat involved, and we will not reproduce it here. But the central point may be succinctly described: to obtain the properties stated in Theorem 2.2, one needs to show that the digits of certain r-tuples of p-adic numbers behave like independent random variables.

To state this precisely, recall that $\beta \in \mathbb{Z}_p$ is called *normal* if the digits in the p-adic expansion of β contain every random string of length k with asymptotic frequency p^{-k}. It is not hard to see that β is normal in this sense if and only if the sequence of numbers $x_n(\beta) = p^{-n}s_n(\beta)$ is uniformly distributed mod 1, where $s_n(\beta)$ denotes the unique integer in the range $[0, p^n - 1]$ such that $s_n(\beta) \equiv \beta \pmod{p^n}$.

Now the main lemma in Ferrero–Washington may be stated as follows:

Lemma 2.2.1 ([11]). *Suppose that $\gamma_1, \gamma_2, \ldots, \gamma_r \in \mathbb{Z}_p$ are linearly independent over $\mathbb{Q}$. Then for almost all $\beta \in \mathbb{Z}_p$ the sequence of vectors*

$$X_n(\beta) = (x_n(\beta\gamma_1), \ldots, x_n(\beta\gamma_r)) \in [0, 1)^r$$

is uniformly distributed mod 1.

In practice, the numbers $\gamma_1, \ldots, \gamma_r$ are taken to be a maximal set of linearly independent $p-1$-st roots of unity. The connection with ergodic theory comes by analogy with the classical result of Kronecker:

Theorem 2.3 (Kronecker). *Suppose that $\gamma_1, \ldots, \gamma_r$ are real numbers, linearly independent over $\mathbb{Q}$. Then the image of the* 1*-parameter group $(t\gamma_1, \ldots, t\gamma_r)$ for $t \in \mathbb{R}$ is dense in the torus $\mathbb{R}^r/\mathbb{Z}^r$. More generally, for arbitrary γ_i, the closure of the group $(t\gamma_1, \ldots, t\gamma_r)$ is a subtorus of rank equal to the $\mathbb{Q}$-rank of the vector space spanned by the γ_i over $\mathbb{Q}$.*

Another view of the Ferrero–Washington theorems was given by Sinnott in [31] and [32], where it was observed that one can relate the Bernoulli numbers to the derivatives of certain rational functions. (This was already known to Euler.) Letting $\mathbb{F}_p$ denote the finite field with p elements, and letting $\mathbb{F}((T-1))$ denote the field of Laurent expansions in the variable $T-1$, the key lemma takes the following form:

Lemma 2.3.1 (Sinnott). *Suppose that $\gamma_1, \gamma_2, \ldots, \gamma_r \in \mathbb{Z}_p$ are linearly independent over $\mathbb{Q}$. Then the power series $T^{\gamma_1}, T^{\gamma_2}, \ldots, T^{\gamma_r}$ are algebraically independent in $\mathbb{F}_p((T-1))$.*

Here we understand that $T^a = \sum_{n=0}^{\infty} \binom{a}{n}(T-1)^n$ for any $a \in \mathbb{Z}_p$, where $\binom{a}{n} = a \cdot (a-1)\ldots(a-n+1)$.

Remark 2.4. We would like to point out here that the main ingredient in the proof of Sinnott's lemma is quite elementary and amounts to an application of Artin's theorem on the linear independence of characters. In particular, the use of explicit ergodic theory is completely absent. However, the statement that the T^{γ_i} are algebraically independent may be rephrased as stating that the ring $\mathbb{F}_p[T^{\gamma_1}, \ldots, T^{\gamma_r}] \subset \mathbb{F}_p[[T-1]]$ is isomorphic to a polynomial ring in r variables. Since $\mathbb{F}_p[[T-1]]$ is complete along the ideal $(T-1)$, and Specf$(\mathbb{F}_p[[T-1]])$ is a formal torus, this statement is formally analogous to Kronecker's theorem above in the sense that the image of the 1-parameter formal torus is Zariski dense in the r-dimensional variety Spec$(\mathbb{F}_p[T^{\gamma_1}, \ldots, T^{\gamma_r}])$.

2.2. CM L-functions. In this section we discuss the case of Hecke L-series associated to imaginary quadratic and more general CM fields. Thus let F denote a totally real field, and let M/F denote a totally imaginary quadratic extension of F. Let $\lambda\colon M^\times \backslash \boldsymbol{A}_M^\times \to \mathbb{C}$ denote an arithmetic idele class character of M. Let λ_∞ denote the restriction of λ to $(M \otimes \mathbb{R})^\times$ and write

$$\lambda_\infty(x) = \prod_\sigma \sigma(x)^{\kappa_\sigma}$$

where the product is taken over all embeddings $\sigma\colon M \to \mathbb{C}$. The formal sum $\kappa = \sum \kappa_\sigma \cdot \sigma$ is called the infinity type of λ. Let $\mathfrak{f}$ denote the conductor of λ, so that $\mathfrak{f}$ is the largest ideal of the ring of integers $\mathcal{O}_M$ with the property that $\lambda(x) = 1$ for all $x \in \mathcal{O}_M \otimes \hat{\mathbb{Z}}$ such that $x \equiv 1 \pmod{\mathfrak{f}}$.

Now let $L(s, \lambda)$ denote the L-function associated to the idele class character λ. It is well-known that the values $L(0, \lambda)$ are critical in the sense of Deligne [9], under some suitable condition on the infinity type of λ (see [8] for the case $F = \mathbb{Q}$, or [30] in general). In other words, there exists a period Ω_λ associated to λ such that the number

$$L^{\mathrm{alg}}(0, \lambda) = \frac{L(0, \lambda)}{\Omega_\lambda}$$

is an algebraic number. If we fix embeddings i_∞ and i_p of $\overline{\mathbb{Q}}$ in to $\mathbb{C}$ and $\mathbb{C}_p$ respectively, we may regard the complex number $L^{\mathrm{alg}}(0, \lambda)$ as being an element of $\mathbb{C}_p$, via the map $i_p \circ i_\infty^{-1}$. Furthermore, if one normalizes the period Ω_λ in some canonical way, one can even show that the number L^{alg} is p-adically integral in $\mathbb{C}_p$, and one can then ask whether these numbers are p-adic units, as λ varies over the members of some family. This problem was first studied by Gillard [13], [14], and Schneps [29], in the case of $F = \mathbb{Q}$ using a generalization of Sinnott's method, and the connection

between the L-values and explicit elliptic units. Further results in the case $F = \mathbb{Q}$ were given by Finis in [12]. Recently the subject was taken up by Hida in a series of deep papers (see [19], [20], for example) which treat the subject in great generality. For a sample of Hida's results, we restrict ourselves to a (relatively) simple statement. But to state even this, we need to introduce some notation. Here we follow [20].

Let X denote a finite set of embeddings $M \to \mathbb{C}$ of cardinality $[F : \mathbb{Q}]$, such that $X \cap cX = \emptyset$, where cX denotes the set $\{c\sigma,\ \sigma \in X\}$, and c denotes complex conjugation. We say that X is a p-ordinary CM-type of M if the set $\{i_p \circ i_\infty^{-1} \circ \sigma\}_{\sigma \in X}$ consists of $[F : \mathbb{Q}]$ distinct p-adic places of M. Then we consider a character λ as above whose infinity type is given by

$$k \sum_{\sigma \in X} \sigma + \kappa(1 - c)$$

where $\kappa = \sum_{\sigma \in X} \kappa_\sigma \sigma$ with $\kappa_\sigma \geq 0$ for $\sigma \in X$, and $0 < k \in \mathbb{Z}$. Then to define the transcendental factor Ω_λ, we can proceed as follows. Pick an abelian variety A of CM type such that $A(\mathbb{C}) \cong \mathbb{C}^{[F:\mathbb{Q}]}/\mathfrak{a}$, where the product is indexed by the $[F : \mathbb{Q}]$ places in X, and the fractional ideal $\mathfrak{a} \subset \mathcal{O}_M$ is embedded diagonally via the corresponding places of X. Let $R \subset \overline{\mathbb{Q}}$ denote the Witt ring of $\mathcal{O}_M$, with respect to the place induced by i_p. Then A can be defined over R, and we can pick a Néron differential ω on A such that ω generates $\Omega_{A/W}$ over R. Picking an isomorphism $\phi\colon A(\mathbb{C}) \cong \mathbb{C}^{[F:\mathbb{Q}]}/\mathfrak{a}$, we define a vector $\Omega_\infty \in \mathbb{C}^{[F:\mathbb{Q}]}$ via $\phi^*\big(\prod(du_\sigma)\big) = \Omega_\infty \omega$. Here u_σ is the standard complex variable on the copy of $\mathbb{C}$ indexed by σ. Writing the components of Ω_∞ as Ω_σ for $\sigma \in X$, we have that $\Omega_\sigma \neq 0$, and

$$L^{\mathrm{alg}}(0, \lambda) = \frac{\prod_{\sigma \in X} \pi^{\kappa_\sigma} \Gamma(k + \kappa_\sigma) L(0, \lambda)}{\prod_{\sigma \in X} \Omega_\sigma^{k+2\kappa_\sigma}} \in R \tag{4}$$

Then the problem is to study p-divisibility properties of the numbers $L^{\mathrm{alg}}(0, \lambda)$ as defined above, as λ varies over some prescribed set. Recall therefore that the character $\chi\colon \boldsymbol{A}_M^\times \to \mathbb{C}^\times$ is called anticyclotomic if $\chi \circ \tau = \chi^{-1}$, where τ is the nontrivial automorphism of M/F. Then we let λ denote a fixed Hecke character, and consider the values $L^{\mathrm{alg}}(0, \lambda\chi)$, as χ varies over the set of anticyclotomic characters of M of conductor $\mathfrak{l}^n$, for some fixed prime $\mathfrak{l}$ of K with residue characteristic $\ell \neq p$, and an integer n. The principal result in this direction is due to Hida. To state the theorem, let us write $L_{\mathfrak{l}}^{\mathrm{alg}}(0, \lambda\chi) = L^{\mathrm{alg}}(0, \lambda\chi) \cdot (1 - \lambda\chi(\mathfrak{l}))$ for the algebraic part of the $\mathfrak{l}$-imprimitive L-function.

Theorem 2.5 ([20], Theorem 1.1). *Suppose that $p > 2$ is an unramified prime in $M/\mathbb{Q}$ and that (M, X) is a p-ordinary CM type. Fix a character λ of conductor 1 with infinity type $k \sum_{\sigma \in X} \sigma + \kappa(1 - c)$ as above. Then we have*

$$|L^{\mathrm{alg}}(0, \lambda\chi)|_p = 1$$

for almost all anticyclotomic characters of $\mathfrak{l}$-power conductor, unless the following three conditions are satisfied simultaneously:

1. *M/F is unramified at all finite places,*

2. *the Artin symbol $\left(\frac{M/F}{\mathfrak{c}}\right)$ has the value -1, for the polarization ideal $\mathfrak{c}$ of A, and*

3. *for all ideals $\mathfrak{a}$ prime to p, we have $\lambda N(\mathfrak{a}) \equiv \left(\frac{M/F}{\mathfrak{c}}\right) \pmod{\mathfrak{m}}$.*

If all these conditions are satisfied simultaneously, then $|L^{\mathrm{alg}}(0, \lambda\chi)|_p < 1$ for all χ.

Here we understand that 'almost all' means 'a Zariski dense subset' in general, and 'all but finitely many' if $F_{\mathfrak{l}}$ has dimension 1 over $\mathbb{Q}_p$.

The proof of this theorem is long and intricate, and we will not discuss it here, except to remark that the proof is a generalization of Sinnott's method mentioned above. Essentially, one has to relate the values of the L-function to the values of certain Hilbert modular Eisenstein series at CM points, and prove a basic result on the linear independence of certain of these series in characteristic p. For our purposes, it will suffice to observe that key ingredient is a rigidity theorem of C.-L. Chai, which enables one to prove that under some condition, schemes fixed by torus actions tend to be rather big. For comparison with the results from ergodic theory that were cited above, we state a precise theorem, as follows.

Suppose that k is an algebraically closed field of characteristic $p > 0$ and let X be a finite dimensional smooth formal p-divisible group over k. Let $E_{\mathbb{Z}_p} = \mathrm{End}(X)$ and set $E = E_{\mathbb{Z}_p} \otimes_{\mathbb{Z}_p} \mathbb{Q}_p$. Then E is a finite dimensional vector space over $\mathbb{Q}_p$. We let $\boldsymbol{E}$ denote the linear algebraic group over $\mathbb{Q}_p$ such that $\boldsymbol{E}(R) = (E \otimes_{\mathbb{Q}_p} R)^{\times}$ for any commutative $\mathbb{Q}_p$-algebra R.

If G is any connected algebraic group over $\mathbb{Q}_p$, and $\rho\colon G \to \boldsymbol{E}$ is a homomorphism of algebraic groups, then we may regard ρ as a linear representation of G on the vector space E via the canonical map $\boldsymbol{E} \subset \mathrm{Aut}(E)$. Then Chai has proven the following striking result. (The notation is as above.)

Theorem 2.6 (Chai). *Suppose that the trivial representation is not a subquotient of the representation ρ of G on E. Suppose also that Z is a reduced and irreducible closed formal subscheme of X which is closed under the action of an open subgroup of $G(\mathbb{Z}_p)$. Then Z is closed under the group law of X and is a p-divisible subgroup scheme of X.*

2.3. Anticyclotomic L-functions. Finally, we treat the applications of ergodic theory to anticyclotomic L-functions associated to Hilbert modular forms over totally real fields.

To describe the results, let F denote a totally real field, and let K/F denote an imaginary quadratic extension. Let π denote a cuspidal automorphic representation of $\mathrm{GL}_2(F)$. We assume throughout that the data of π and K are *non-exceptional*, meaning that the representations π and $\pi \otimes \eta$ are distinct, where η denotes the quadratic character associated to the extension K/F.

Let $\chi : \boldsymbol{A}_K^\times / K^\times \to \mathbb{C}$ be a quasi-character of K, and write $L(\pi, \chi, s)$ for the Rankin–Selberg L-function associated to π and $\pi(\chi)$. Here $\pi(\chi)$ denotes the automorphic representation of GL_2 attached to χ. (For the definitions, we refer the reader to [22] and [21].) Then this L-function, which is first defined as a product of Euler factors over all places of F, may be shown to have a meromorphic extension to $\mathbb{C}$ with functional equation

$$L(\pi, \chi, s) = \varepsilon(\pi, \chi, s) L(\tilde{\pi}, \chi^{-1}, 1 - s)$$

where $\tilde{\pi}$ is the contragredient of π and $\varepsilon(\pi, \chi, s)$ is the ε-factor.

Let $\omega : \boldsymbol{A}_F^\times / F^\times \to \mathbb{C}^\times$ be the central quasi-character of π. We will make the following assumption on the quasi-characters ω and χ:

$$\chi \cdot \omega = 1 \quad \text{on } \boldsymbol{A}_F^\times \subset \boldsymbol{A}_K^\times. \tag{5}$$

This assumption implies that $L(\pi, \chi, s)$ is entire and equal to $L(\tilde{\pi}, \chi^{-1}, s)$. Thus the functional equation of $L(\pi, \chi, s)$ may be restated as

$$L(\pi, \chi, s) = \varepsilon(\pi, \chi, s) L(\pi, \chi, 1 - s)$$

and the parity of the order of vanishing of $L(\pi, \chi, s)$ at $s = 1/2$ is determined by the value of

$$\varepsilon(\pi, \chi) \stackrel{\text{def}}{=} \varepsilon(\pi, \chi, 1/2) \in \{\pm 1\}.$$

Following [6] and [7], we say that the pair (π, χ) is *even* or *odd*, depending upon whether $\varepsilon(\pi, \chi)$ is $+1$ or -1. According to the conjectures introduced by Mazur in[24], it is expected that the order of vanishing of $L(\pi, \chi, s)$ at $s = 1/2$ should 'usually' be minimal, meaning that either $L(\pi, \chi, 1/2)$ or $L'(\pi, \chi, 1/2)$ should be nonzero, depending upon whether (π, χ) is even or odd.

Results of this kind were first proven by Rohrlich [28], for the case where $F = \mathbb{Q}$, and π and K are *exceptional* in the sense that $\pi \cong \pi \otimes \eta$, using results from transcendence theory, notably p-adic cases of Roth's theorems. However, nothing was known for non-exceptional π and K until the introduction of ergodic theory in [33] and [34], which treated the case of $F = \mathbb{Q}$. The ideas from ergodic theory were quickly assimilated and extended in [5], and the generalization to the case of general F was given in [6] and [7].

To proceed, we need to introduce some notation. Thus let $\mathfrak{n}$ denote the conductor of the representation π. Let $\mathfrak{p}$ denote a fixed prime of F, and let χ denote a ring class character of $\mathfrak{p}$-power conductor. Here we recall that the quasi-character χ of K is called a ring class character, or an anticyclotomic character, if the restriction of χ to $\boldsymbol{A}_F^\times$ is everywhere unramified. Then we propose to study the order of vanishing of $L(\pi, \chi, s)$ at $s = 1/2$ as χ varies over the set $S = S_{\mathfrak{p}}^{\text{anticyc}}$ of ring class characters of $\mathfrak{p}$-power conductor.

In view of equation (5), it makes sense to require that the central character ω of π is everywhere unramified. We assume also that π corresponds to a Hilbert modular

form of parallel weight $(2, \ldots, 2)$ and that the discriminant $\mathfrak{D}$ of K/F is relatively prime to the prime-to-$\mathfrak{p}$ part $\mathfrak{n}'$ of $\mathfrak{n}$. Under these conditions, it may be shown that for all $n \gg 0$, and all χ of conductor $\mathfrak{p}^n$, the root number $\varepsilon(\pi, \chi)$ is given by the formula

$$\varepsilon(\pi, \chi) = (-1)^{\#S} \tag{6}$$

where S denotes the set of real places of F, together with those finite primes of F which do not divide $\mathfrak{p}$, are inert in K, and divide $\mathfrak{n}$ to an odd power. In particular, the root number $\varepsilon = \varepsilon(\pi, \chi) = \pm 1$ depends only on π and K and $\mathfrak{p}$, once the conductor of χ is sufficiently divisible. Thus one expects the order of vanishing of $L(\pi, \chi, 1/2)$ to be equal to either 0 or 1, for 'generic' χ, depending only on the sign of ε. That this is indeed the case was confirmed by the main results in [6] and [7], and we refer the reader to the introduction of [6] for a very detailed discussion.

In the present paper, we will focus on the non-vanishing of $L(\pi, \chi, 1/2)$ modulo a prime of $\overline{\mathbb{Q}}$. The basic results in this direction were given in [34], for the case $F = \mathbb{Q}$, and we now proceed to state them.

Thus, let us assume that $F = \mathbb{Q}$. Let $N = \mathfrak{n}$ denote the level of π, let $D = \mathfrak{D}$ denote the discriminant of the imaginary quadratic field $K = \mathbb{Q}(\sqrt{D})$, and let $p = \mathfrak{p}$ denote a rational prime. We assume further that the numbers N, D, p are pairwise co-prime. We let f denote the primitive form of level N associated to π; since the central character ω of π is unramified and $\mathbb{Q}$ has class number 1, we see that f is a primitive form on the group $\Gamma_0(N)$. We assume further that we are in the even case, so that there are an even number of places in S. We let $\Omega_\pi = \Omega_f$ denote the canonical integral period for f, as defined by Hida in [18]. Then the number

$$L^{\mathrm{alg}}(\pi, \chi) = \frac{L(\pi, \chi, 1/2)}{\Omega_\pi} \cdot C_\chi$$

is an algebraic integer. Here $C_\chi = Dp^{2n}$, where p^n denotes the conductor of χ. Let λ denote a fixed prime of $\overline{\mathbb{Q}}$, and consider the λ-adic absolute value $|L^{\mathrm{alg}}(\pi, \chi)|_\lambda$. We want to study the general question of how $|L^{\mathrm{alg}}(\pi, \chi)|_\lambda$ varies as a function of χ, and the result depends on whether or not λ has residue characteristic p. In either case, let us define two constants C_{csp} and C_{Eis} associated to π, as in [34], Section 2.4.[1]

Then one has the following result:

Theorem 2.7 ([34]). *Suppose that λ has residue characteristic $\ell \neq p$. Then we have*

$$|L^{\mathrm{alg}}(\pi, \chi)|_\lambda = |C_{\mathrm{csp}}^2 C_{\mathrm{Eis}}|_\lambda$$

for all but finitely many λ of conductor p^n.

Actually, the theorem above was stated in [34] under some mild assumptions on ℓ, but these restrictions are easily removed, for example with the improved formalism

[1] The definition of these constants is rather technical, and we prefer not to reproduce it. The significance of these numbers, in particular the relationship to congruences, is elucidated in the paper [25].

introduced in [7], or by a slightly more detailed analysis of the original proof. We remark here that the numbers C_{csp} and C_{Eis} are *not* necessarily λ-adic units.

As for the case where λ has residue characteristic p, the result is in the same vein, provided one assumes that the local component π_p is ordinary at λ, in the sense that the Hecke eigenvalue $a_p(\pi)$ is a λ-adic unit.

Theorem 2.8 ([34]). *Suppose that λ has residue characteristic $\ell = p$ and that π_p is ordinary at λ. Then we have*

$$\lim_{\chi} |L^{\mathrm{alg}}(\pi, \chi)|_\lambda = |C_{\mathrm{csp}}^2 C_{\mathrm{Eis}}|_\lambda,$$

where the limit is taken over characters χ of conductor p^n, as $n \to \infty$.

Remark 2.9. In view of recent results in the Iwasawa theory of elliptic curves, our results on L-functions may be formulated in terms of the growths of certain Selmer groups, which are generalizations of the Iwasawa ideal class groups occurring in our discussion of the Ferrero–Washington theorem above. For more details, we refer the reader to [1] and [25]. We remark also that our results above have not yet been extended to general F, but it seems likely that such generalizations would follow without difficulty from the techniques of [7].

Remark 2.10. We point out also that there are results analogous to those above in the case that the sign in the functional equation is -1. However, in these cases, one is dealing with derivatives of L-functions, and there is no general notion of what it means for a derivative of an L-function to be nonzero modulo p. In the case at hand one has an *ad hoc* definition in terms of p-divisibility of certain Heegner points arising from the Gross–Zagier formula for derivatives, and it is this kind of result that is proven. For details we refer the reader to [34] and [5].

In keeping with the general theme of this article, we wish now to elaborate on the role of ergodic theorems in the proofs of our results. A detailed description of the strategy may be found in the introductions to [33] and [7], and we will not cut and paste from those articles here. For the present, we simply note that the starting point comes from the formulae of Gross, Zagier, and Zhang, which relate the values of the L-functions in question to the heights of certain special points on quaternion algebras. (See [17], [15], and [37] for the theorems, which were then reframed in the article [16]. A more elementary perspective may be found in [35].) In view of these special value formulae, the essential point in proving that the L-values are non-zero modulo p boils down to showing that certain vectors whose components are formed by the special points and their conjugates, are uniformly distributed in the appropriate sense on certain Shimura varieties. The necessary uniform distribution is then deduced by applying deep theorems in ergodic theory due to M. Ratner [27].[2]

[2] In [6] and [7], appeals were made to results of Margulis and Tomanov [23], since these results were formulated in a manner convenient for our applications there. The author has since been informed by Ratner that the results we quoted from [23] can in fact be deduced from those given earlier in [26].

The reduction of our number theoretic results to Ratner's theorem has been amply documented elsewhere, so we will just state some of Ratner's key results, in a manner that we hope will make clear the analogy with the results of Ferrero–Washington, Sinnott, and Chai. It is perhaps germane to remark here that the introduction of Ratner's theorem in [33] was inspired by direct analogy with the use of Kronecker's theorem by Ferrero and Washington.

Thus let G denote the p-adic Lie group $\mathrm{SL}_2(\mathbb{Q}_p)$, and let $\Gamma_i \subset G$, $i = 1, 2$ denote discrete and cocompact subgroups. We say that Γ_1 and Γ_2 are commensurable if $\Gamma_1 \cap \Gamma_2$ has finite index in Γ_1 and Γ_2. Then the following remarkable result is a very simple consequence of the main results in [27]:

Theorem 2.11 (Ratner). *The set* $\Gamma_1 \cdot \Gamma_2 = \{\gamma_1 \cdot \gamma_2,\ \gamma_1 \in \Gamma_1,\ \gamma_2 \in \Gamma_2\}$ *is dense in* G *if and only if the subgroups* Γ_1 *and* Γ_2 *are not commensurable.*

Remark 2.12. Note that it is obvious that the product $\Gamma_1 \cdot \Gamma_2$ cannot be dense if Γ_1 and Γ_2 are commensurable. But the reverse implication is extremely deep, and seems to admit no elementary proof.

Remark 2.13. For an analogy, let G denote the additive group $\mathbb{R}$ of real numbers, and let X_i, $i = 1, 2$ denote discrete subgroups of G. Then each X_i is abstractly isomorphic to the additive group of $\mathbb{Z}$. If x_i is a generator of X_i, then the groups X_i are commensurable if and only if the x_i are linearly dependent over $\mathbb{Q}$. In this case the product $X_1 \cdot X_2$ is discrete in G. On the other hand, Kronecker's theorem implies that the product $X_1 \cdot X_2$ is dense if the x_i are independent over $\mathbb{Q}$, which is to say, if the groups X_i fail to be commensurable. Thus Ratner's theorem above is a p-adic and non-abelian analogue of Kronecker's theorem.

Actually, one requires a slightly more refined theorem for the applications to number theory. As above, write G for the p-adic Lie group $\mathrm{SL}_2(\mathbb{Q}_p)$. Let r denote a positive integer, and for each i with $1 \leq i \leq r$, we let Γ_i denote a discrete and cocompact subgroup of G. Then

$$\Gamma = \prod_{i=1}^{r} \Gamma_i \subset \prod_{i=1}^{r} G$$

is a discrete and cocompact subgroup of the product G^r of r copies of G. We may then formulate the following result:

Theorem 2.14 (Ratner). *Suppose that the groups* Γ_i *are pairwise non-commensurable. Then the image of the diagonal* $\Delta(G) = \{(g, \ldots, g),\ g \in G\} \subset G^r$ *has dense image in the quotient* $\Gamma \backslash G^r$.

Finally, we give a rigidity result which implies the two above as special cases.

Theorem 2.15 (Ratner). *Let* G *denote a* p*-adic Lie group, and let* $\Gamma \subset G$ *be such that* $\Gamma \backslash G$ *has finite volume with respect to the unique* G*-invariant measure. Let* $U \subset G$

denote any subgroup generated by 1*-parameter subgroups, namely, by the image of* (*additive*) *homomorphisms* $u_i : \mathbb{Q}_p \to G$. *Then the closure* $\overline{U}$ *of the orbit of* U *in* $\Gamma\backslash G$ *is homogeneous, in the sense that there exists a subgroup* H *of* G *such that the orbit of* H *is closed in* $\Gamma\backslash G$ *and* $\overline{U}$ *coincides with the orbit of* H.

Remark 2.16. We would like to point out here that for the purposes of the results in [5] and some of the results in [7] (namely, the indefinite case), one can get by with yet another kind of rigidity principle, namely certain cases of the André–Oort conjecture. For more on this subject, we refer the reader to [5]. For the relationship with Chai's theorem, see [3]. Further discussion of this and related topics may be found in [10] and [4].

To conclude, we would hope that the analogy between the theorems of Kronecker, Sinnott, Chai, and Ratner is now evident. Namely, in every case, we are asserting that the closure of rather small group orbits, (the diagonal, in Ratner's case, or a 1-parameter group in Kronecker's theorem) is forced, by rigidity, to be rather big. In the Ferrero–Washington and anticyclotomic cases, the orbit of a small group inside an r-dimensional object turns out to be dense, and in every case, including the theorem of Chai, the key statement is a rigidity principle of the form that the closures of the relevant orbits coincide with the orbits of subgroups. Is there a general ergodic or rigidity principle that accounts for all of these results? We hope that the answer is affirmative, but at present we seem to be far from finding it.

Higher-dimensional analogues of stable curves

Valery Alexeev

Abstract. The Minimal Model Program offers natural higher-dimensional analogues of stable n-pointed curves and maps: stable pairs consisting of a projective variety X of dimension ≥ 2 and a divisor B, that should satisfy a few simple conditions, and stable maps $f\colon (X, B) \to Y$. Although MMP remains conjectural in higher dimensions, in several important situations the moduli spaces of stable pairs, generalizing those of Deligne–Mumford, Knudsen and Kontsevich, can be constructed more directly, and in considerable generality. We review these constructions, with particular attention paid to varieties with group action, and list some open problems.

Mathematics Subject Classification (2000). Primary 14J10; Secondary 14E30, 14L30.

Keywords. Moduli spaces, stable pairs, Minimal Model Program.

Introduction

Stable curves were introduced by Deligne and Mumford in [19] and proved to be extremely useful, with diverse applications in many fields of mathematics and in physics. Stable maps from n-pointed curves to varieties were used by Kontsevich to define Gromov–Witten invariants. The study of the moduli spaces of stable curves and maps is a thriving field.

Stable surfaces, the two-dimensional analogues of stable curves, were introduced by Kollár and Shepherd-Barron in [39]. It was consequently realized [4], [3] that this definition can be extended to higher-dimensional varieties and, moreover, to pairs (X, B), consisting of a projective variety X of dimension ≥ 2 and a divisor B, and to stable maps $f\colon (X, B) \to Y$. One arrives at this definition by mimicking the construction of stable one-parameter limits of curves in the higher-dimensional case, and replacing contractions of (-1)- and (-2)-curves by the methods of the Minimal Model Program.

Stable pairs provide an apparently very general, nearly universal way to compactify moduli spaces of smooth or mildly singular varieties and pairs. There are, however, two complications. First, as of this writing, the Minimal Model Program in arbitrary dimensions is still conjectural. Secondly, even in the case of surfaces the resulting moduli spaces turn out to be very complicated, and numerical computations similar to the curve case seem to be out of reach.

The situation can be improved in both respects by looking at some particularly nice classes of varieties, such as abelian varieties and other varieties with group action:

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

toric, spherical, and also at varieties and pairs closely related to them, for example the hyperplane arrangements.

In all of these cases the Minimal Model Program can be used for guessing the correct answer, but the actual constructions of the moduli spaces can be made without it, by exploiting symmetries of the situation. At the same time, the resulting moduli spaces come equipped with rich combinatorial structures, typically with stratifications labeled by various polytopal tilings.

The aim of this paper is to review the basic constructions and several of the examples mentioned above. My understanding of the subject was shaped over the years by discussions with (in the chronological order) J. Kollár, S. Mori, I. Nakamura, K. Hulek, Ch. Birkenhake, M. Brion, B. Hassett, A. Knutson, and many other people whom I am unable to list here. I am indebted to them all.

1. Definition of stable pairs and maps

To define varieties and pairs, we work over an algebraically closed field k of arbitrary characteristic. All *varieties* will be assumed to be connected and reduced but not necessarily irreducible. A *polarized variety* is a projective variety X with an ample invertible sheaf L.

Definition 1.1. Let X be a projective variety, B_j, $i = 1, \dots, n$, be effective Weil divisors on X, possibly reducible, and b_j be some rational numbers with $0 < b_j \leq 1$. The pair $(X, B = \sum b_j B_j)$ (resp. a map $f\colon (X, B) \to Y$) is called *stable* if the following two conditions are satisfied:

1. *on singularities:* the pair (X, B) is semi log canonical, and
2. *numerical:* the divisor $K_X + B$ is ample (resp. f-ample).

Both parts require an explanation.

Definition 1.2. Assume that X is a *normal* variety. Then X has a canonical Weil divisor K_X defined up to linear equivalence. The pair (X, B) is called *log canonical* if

1. $K_X + B$ is $\mathbb{Q}$-Cartier, i.e. some positive multiple is a Cartier divisor, and
2. for every proper birational morphism $\pi\colon X' \to X$ with normal X', in the natural formula

$$K_{X'} + \pi_*^{-1} B = \pi^*(K_X + B) + \sum a_i E_i$$

one has $a_i \geq -1$. Here, E_i are the irreducible exceptional divisors of π, and the pullback π^* is defined by extending $\mathbb{Q}$-linearly the pullback on Cartier divisors. $\pi_*^{-1} B$ is the strict preimage of B.

If $\operatorname{char} k = 0$ then X has a resolution of singularities $\pi\colon X' \to X$ such that $\operatorname{Supp}(\pi_*^{-1} B) \cup E_i$ is a normal crossing divisor; then it is sufficient to check the condition $a_i \geq -1$ for this morphism π only.

The definition for semi log canonical surface singularities X originated in [39]. The following definition, equivalent to [39] in the surface case, and extending it to higher-dimensional varieties and pairs, is from [3].

Definition 1.3. A pair (X, B) is called *semi log canonical* if

1. X satisfies Serre's condition S2, in particular, equidimensional,
2. X has at worst double normal crossing singularities in codimension one, and no divisor B_j contains any component of this double locus,
3. some multiple of the Weil $\mathbb{Q}$-divisor $K_X + B$, well defined thanks to the previous condition, is $\mathbb{Q}$-Cartier, and
4. denoting by $\nu : X^\nu \to X$ the normalization, the pair $(X^\nu,\ (\text{double locus}) + \nu^{-1}B)$ is log canonical.

Example 1.4. Assume that X is a curve. Then (X, B) is semi log canonical iff X is at worst nodal, B_j do not contain any nodes, and for every $P \in X$ one has $\operatorname{mult}_P B = \sum b_j \operatorname{mult}_P B_j \leq 1$. A map $f\colon (X, B) \to Y$ is stable if, in addition to this condition on singularities, the divisor $K_X + B$ has positive degree on every irreducible component of X collapsed by f.

Hence, for $b_j = 1$, $\deg B_j = 1$, and $Y =$ a point (i.e. in the absolute case) these are precisely the Deligne–Mumford–Knudsen stable n-pointed curves [19], [33], [32]. With the same assumptions on B but Y arbitrary, these are Kontsevich's stable maps. Hassett [27] considered the absolute case with $0 < b \leq 1$, $\deg B_j = 1$, for which he constructed a smooth Deligne–Mumford stack with a projective moduli space.

The motivation for the definition of stable pairs is that they appear as natural limits of one-parameter families of smooth varieties and pairs $(X, B) \to S$, as will be developed in Section 2. In higher dimensions, there is an additional complication: if the total divisor B is not $\mathbb{Q}$-Cartier then the central fiber B_0 may have an embedded component, so no longer be an ordinary divisor. There are several ways to fix this:

1. Pairs with floating coefficients b_j. We will say that a pair
$$\Bigl(X,\ B = \sum b_j B_j + \sum (b_k + \varepsilon_k) B_k\Bigr)$$
(resp. a map) is stable if, in addition, the divisors B_k in the second group are $\mathbb{Q}$-Cartier and for all $0 < \varepsilon_k \ll 1$, the pair $\bigl(X, \sum b_j B_j + \sum (b_k + \varepsilon_k) B_k\bigr)$ is stable.
2. Pairs with coefficients b_j outside of a "bad" subset of $[0, 1]$. Again, the idea here is the same as in (1), to avoid the values b_j for which the total divisors B_j may be not $\mathbb{Q}$-Cartier.
3. Working with subschemes $B_j \subset X$ instead of simply divisors.
4. Working with finite morphisms $B_j \to X$, where B_j are (reduced) varieties of dimension $\dim B_j = \dim X - 1$, rather than with embedded divisors.

2. Minimal Model Program construction

The true motivation for the introduction of stable pairs is that they inevitably appear as limits of one-parameter families of smooth varieties and pairs, when one tries to follow the classical construction in the case of curves. This is explained by the following statement, which however is conditional: it depends on the validity of the log Minimal Model Program in dimension $\dim X + 1$ (so, currently problematic for pairs (X, B) with $\dim X \geq 3$) and on Inversion of Adjunction in an appropriate sense, as explained in the sketch of the proof below. The argument also requires $\operatorname{char} k = 0$ or X to be a curve for the resolution of singularities and semistable reduction.

This statement appeared in [39] in the case of surfaces with $B = 0$, where it is not conjectural and in [3] in the more general case (see also [26]).

By a one-parameter family of stable maps we will understand a morphism $f\colon (X, B) \to Y \times S$, where $(S, 0)$ is a germ of a nonsingular curve, such that $\pi = p_2 \circ f\colon X \to S$ and $\pi|_{B_j}\colon B_j \to S$ are flat, and every geometric fiber $f_{\bar{s}}\colon (X_{\bar{s}}, B_{\bar{s}}) \to Y$ is a stable map. We will denote $S \setminus 0$ by U.

The definition of a family over an arbitrary scheme S is similar but requires care, especially if S is not reduced. We will discuss it in the next section.

Theorem 2.1 (Properness of the functor of stable maps). *Every punctured family $f_U\colon (X_U, B_U) \to Y \times U$, of stable pairs has at most one extension to a family of stable pairs over S. Moreover, such an extension does exist after a finite base change $(S', 0) \to (S, 0)$.*

Sketch of the proof. We assume that fibers X_s for $s \neq 0$ are normal, for simplicity. Denote an extension by $f\colon (X, B) \to Y \times S$. Inversion of Adjunction of Shokurov–Kollár (see, e.g. [35], 17.3) says that the central fiber (X_0, B_0) is semi log canonical iff the pair $(X, B + X_0)$ is log canonical.

Now suppose that we have an extension. Then $(X, B + X_0)$ has log canonical singularities and $K_X + B + X_0$ is f-ample. Hence, $(X, B + X_0)$ is *the log canonical model* of $(\widetilde{X}, \widetilde{B} + \widetilde{X}_{0,\mathrm{red}})$ over $Y \times S$ for any resolution of singularities $(\widetilde{X}, \widetilde{B})$ of any extension of f_U. Existence of the log canonical model is the main result of the log Minimal Model Program, and its uniqueness is a basic and easy fact, see, e.g. [38].

In the opposite direction, pick some extension family. Take a resolution of singularities, which introduces some exceptional divisors E_i. Apply the Semistable Reduction Theorem to this resolution. The result is that after a ramified base change $(S', 0) \to (S, 0)$ we now have an extended family $\tilde{f}'\colon (\widetilde{X}', \widetilde{B}')$ such that $\widetilde{X}'$ is smooth, the central fiber $\widetilde{X}'_0$ is a reduced normal crossing divisor, and, moreover, $\widetilde{X}'_0 \cup \operatorname{Supp} \widetilde{B}' \cup \widetilde{E}'_i$ is a normal crossing divisor.

It follows that the pair $(\widetilde{X}', \widetilde{B}' + \widetilde{X}'_0 + \sum \widetilde{E}'_i)$ has log canonical singularities and is relatively of general type over $Y \times S'$. Now let $f'\colon (X', B' + X'_0) \to Y \times S'$ be its log canonical model, guaranteed by the log Minimal Model Program. The divisor $K_{X'} + B' + X'_0$ is f'-ample. Inversion of Adjunction – applied in the opposite direction

now – guarantees that the central fiber (X'_0, B'_0) has semi log canonical singularities. Finally, since (X_U, B_U) has log canonical singularities, outside the central fiber the log canonical model of $(\widetilde{X}'_U, \widetilde{B}'_U + \sum \widetilde{E}'_{i,U})$ coincides with $(X_U, B_U) \times_U U'$. So we obtained the desired extension. □

3. Surfaces

The situation with the moduli spaces of surfaces is as follows. The broad outline has been understood for a long time, see [39], [34], [4], but answers to several thorny technical questions have been published only recently. With these technical questions resolved, for any fixed projective scheme Y one can construct the moduli space of stable maps $f\colon (X, B) \to Y$ with B empty or reduced (i.e. with all $b_j = 1$), as a projective scheme. For the arbitrary coefficients b_j, one faces the difficulties with subschemes B_j acquiring embedded components (an example due to Hassett shows that this really happens), and the technical details of the solution are yet to be published. We now give a brief overview.

Definition of the moduli functor. We choose a triple of positive rational numbers $C = (C_1, C_2, C_3)$ and a positive integer N. We also fix a very ample sheaf $\mathcal{O}_Y(1)$ on Y. Then the basic moduli functor $M_{C,N}$ associates to every Noetherian scheme S over a base scheme the set $M_{C,N}(S)$ of maps $f\colon (X, B) \to Y \times S$ with the following properties:

1. X and B_j are flat schemes over S.
2. The double dual $\mathcal{L}_N(X/S) = \left(\omega_{X/S}^{\otimes N} \otimes \mathcal{O}_X(NB)\right)^{**}$ is an invertible sheaf on X, relatively ample over $Y \times S$.
3. For every geometric fiber, $(K_{X_s} + B_s)^2 = C_1$, $(K_{X_s} + B_s)H_s = C_2$, and $H_s^2 = C_3$, where $\mathcal{O}_X(H) = f^*\mathcal{O}_Y(1)$.

Kollár suggested a different moduli functor, of families for which the formation of the sheaves $\mathcal{L}_N(X/S)$ commutes with arbitrary base changes $S' \to S$, i.e.

$$\mathcal{L}_N(X \times_S S'/S') = \phi^*\mathcal{L}_N(X/S)$$

for *all* sheaves $\mathcal{L}_N$ for which NB is integral (e.g., all $N \in \mathbb{Z}$ if B is reduced).

Boundedness. Boundedness means that for any stable map over an algebraically closed field, with fixed invariants C_1, C_2, C_3, there exists N such that the sheaf $L_N = \mathcal{O}_X(N(K_X + B))$ is invertible. Then it is easy to prove that for a fixed multiple M of N the sheaf L_M is very ample with trivial higher cohomologies.

For surface pairs with fixed b_j boundedness was proved in [2], see also [14] for a somewhat simpler, and effective version. For the stable maps it was proved in [4].

(We also note that Karu [30] proved boundedness for *smoothable* stable varieties of dimension d assuming Minimal Model program in dimension $d+1$.)

Local closedness. This means that for every family of pairs $f\colon (X, B) \to Y \times S$, with fibers not assumed to be stable pairs, there exists a locally closed subscheme $U \to S$ with the following universal property: For every $S' \to S$, the pullback family represents an element of $M_N(S')$ if and only if $S' \to S$ factors though U. An important case of this statement from which the general case follows, was established in [28].

Construction of the moduli space. Let $f\colon (X, B) \to Y \times S$ be a family of stable maps over S. By boundedness, for some fixed multiple M of N, the sheaf $\pi_*\mathcal{L}_M$ is locally free, so it can be trivialized on an open cover $S = \cup S_i$. With such trivializations chosen, the graphs of the maps $f_i = f|_{S_i}$ are closed subschemes of $\mathbb{P}^n \times Y$, and so represent a collection of S_i-points of the Hilbert scheme $\mathrm{Hilb}_{\mathbb{P}^n \times Y, p}$, for an easily computable Hilbert polynomial p. For a different choice of trivializations, the points differ by the action of $\mathrm{PGL}_{n+1}(S_i)$.

By local closedness, there exist a locally closed subscheme $U \to \mathrm{Hilb}_{\mathbb{P}^n \times Y, p(x)}$ such that the above S_i-points of the Hilbert scheme are S_i-points of U. Vice versa, every morphism $S \to U$ gives a family of stable maps over S.

It follows that the moduli functor is the quotient functor U/PGL_{n+1}. The separatedness of the moduli functor implies that the PGL_{n+1}-action is proper. Then the quotient exists as an algebraic space by applying either [36] or [31]. It is a proper algebraic space because the moduli functor is proper.

Projectivity of the moduli space. Kollár [34] provided a general method for proving projectivity of complete moduli spaces. It applies in this situation with minor modifications. In particular, the moduli space is a scheme.

We note that the quasiprojectivity of the open part corresponding to arbitrary-dimensional polarized varieties with canonical singularities was proved by Viehweg [48] by using methods of Geometric Invariant Theory.

A floating coefficient version. Hacking [22] constructed a moduli space for the stable pairs $(\mathbb{P}^2, (3/d+\varepsilon)B)$, where B is a plane curve of degree d, and their degenerations.

Other special surfaces. Other papers treating special cases include [1], [25], [47].

4. Toric and spherical varieties

In terms of Definition 1.1, this case corresponds to the pairs $(X, \Delta + \varepsilon B)$, with a floating coefficient. The following very easy statement is the main bridge connecting the log Minimal Model Program and stable pairs with the combinatorics of toric varieties.

We fix a multiplicative torus $T = \mathbb{G}_m^r$. Below, *toric variety* means a normal variety with T-action and an open T-orbit; no special point is chosen (as opposed to a torus embedding).

Lemma 4.1 ([3]). *Let X be a projective toric variety, Δ be the complement of the main T-orbit, and B be an effective $\mathbb{Q}$-Cartier divisor. Then the pair (X, Δ) has log canonical singularities, and the pair $(X, \Delta + \varepsilon B)$ with effective divisor B and $0 < \varepsilon \ll 1$ is stable iff B is an ample Cartier divisor which does not contain any T-orbits.*

Proof. For any toric variety one has $K_X + \Delta = 0$. In particular, we can apply this to X and to a toric resolution of singularities $\pi : \widetilde{X} \to X$. The divisor $\widetilde{\Delta}$, the union of $\pi_*^{-1}\Delta$ and the exceptional divisors E_i, is a normal crossing divisor. But then the formula $K_{\widetilde{X}} + \widetilde{\Delta} = 0 = \pi^*(K_X + \Delta)$ says that the discrepancies a_i in the formula $K_{\widetilde{X}} + \pi_*^{-1}\Delta = \pi^*(K_X + \Delta) + \sum a_i E_i$ all equal -1.

For the pair $(X, \Delta + \varepsilon B)$ to be stable, B must be $\mathbb{Q}$-Cartier and ample, since $K_X + \Delta + \varepsilon B = \varepsilon B$. By continuity of discrepancies of $(X, \Delta + \varepsilon B)$ in ε, we see that the latter pair is log canonical iff $\pi^* B$ does not contain any irreducible components of $\widetilde{\Delta}$, i.e. the closures of proper T-orbits on $\widetilde{X}$. Equivalently, B should not contain any T-orbits. Finally, any effective Weil divisor not containing a T-orbit is Cartier. □

Definition 4.2. Let X be a variety with T-action, and $B \subset X$ be an effective Cartier divisor. The variety X, resp. the pair (X, B) is called a *stable toric variety* (resp. *stable toric pair*) if the following three conditions are satisfied:

1. *on singularities:* X is seminormal (resp. and B does not contain any T-orbits),
2. *on group action:* isotropy groups T_x are subtori (so connected and reduced), and there are only finitely many orbits,
3. *numerical:* (resp. the divisor B is ample).

A *family of stable toric pairs* is a proper flat morphism $f : (X, B) \to S$, where X is a scheme endowed with an action of $T_S := T \times S$, with a relative Cartier divisor B, so that every geometric fiber is a stable toric pair. We will denote the invertible sheaf $\mathcal{O}_X(B)$ by L.

A polarized T-variety (X, L) is *linearized* if X is projective, and the sheaf L is provided with a T-linearization.

We see that a pair (X, B) with a toric variety X is a stable toric pair iff the pair $(X, \Delta + \varepsilon B)$ is a stable pair in the sense of Definition 1.1. We also note that the boundary Δ is determined by the group action, and so can be omitted.

One proves rather easily that a linearized stable toric variety is a union of (normal) polarized toric varieties (X_i, L_i) which, as it is well known [44], correspond to lattice polytopes Q_i. In this way, one obtains a *complex of polytopes* $\mathcal{Q} = (Q_i)$, and X is

glued from the varieties X_i combinatorially in the same way as the topological space $|\mathcal{Q}|$ is glued from Q_i. The complex $\mathcal{Q}$ comes with a *reference map* $\rho\colon |\mathcal{Q}| \to M_{\mathbb{R}}$, where M is the character group of T, identifying each cell Q_i with a lattice polytope. The pair $(|\mathcal{Q}|, \rho)$ is called the *type* of a stable toric variety.

A section $s \in H^0(X, L)$ with $B = (s)$ gives a collection of sections

$$s_i = \sum s_{i,m} e^m \in H^0(X_i, L_i) = \bigoplus\nolimits_{m \in Q \cap M} k e^m.$$

For each polytope Q_i this gives a subset $C_i = \{m \mid s_{i,m} \neq 0\}$ and, since B does not contain any T-orbits, one must have $\operatorname{Conv} C_i = Q_i$. This defines a *complex of marked polytopes* $(\mathcal{Q}, \mathcal{C})$.

4.3. All stable toric varieties X (resp. pairs (X, B)), are classified, up to an isomorphism, by the following data:

1. A complex of polytopes $\mathcal{Q}$ with a reference map $\rho\colon |\mathcal{Q}| \to M_{\mathbb{R}}$ (resp. a complex of marked polytopes $(\mathcal{Q}, \mathcal{C})$ with a reference map).

2. An element of a certain cohomology group which we briefly describe.

For each polytope $Q_i \in \mathcal{Q}$, let $\widetilde{M}_i \subset \widetilde{M} = \mathbb{Z} \times M$ be the saturated sublattice of $\widetilde{M}$ generated by $(1, Q_i)$, and let $\widetilde{T}_i = \operatorname{Hom}(\widetilde{M}_i, \mathbb{G}_m)$ be the corresponding torus. The collection of stalks $\{\widetilde{T}_i\}$ defines the sheaf $\underline{\widetilde{T}}$ on the complex $\mathcal{Q}$. Then the set of isomorphism classes of polarized stable toric varieties is simply $H^1(\mathcal{Q}, \underline{\widetilde{T}})$, and each of them has automorphism group $H^0(\mathcal{Q}, \underline{\widetilde{T}})$.

Similarly, one defines the sheaf $\underline{\widehat{C}} = \operatorname{Hom}(\mathcal{C}, \mathbb{G}_m)$ with the stalks $\operatorname{Hom}(C_i, \mathbb{G}_m)$ in which the sections s_i live. The natural sheaf homomorphism $\underline{\widetilde{T}} \to \underline{\widehat{C}}$ gives a homomorphism of cochain complexes $\phi\colon C^*(\underline{\widetilde{T}}) \to C^*(\underline{\widehat{C}})$. Then the first cohomology of the cone complex $\operatorname{Cone}(\phi)$ is the set of isomorphism classes of stable toric pairs of type $(\mathcal{Q}, \mathcal{C})$, and the zero cohomology gives the automorphism groups of the pairs. These automorphism groups are finite.

The following lemma also goes back to [3].

Lemma 4.4. *Suppose that the topological space $|\mathcal{Q}|$ is homeomorphic to a manifold with boundary. Let (X, B) be a stable toric pair in the sense of Definition* 4.2. *Let Δ be the reduced divisor corresponding to the boundary of $|\mathcal{Q}|$. Then the pair $(X, \Delta + \varepsilon B)$ is stable in the sense of Definition* 1.1.

Proof. One proves that with the above assumption on $|\mathcal{Q}|$ the variety X is Cohen–Macaulay, a fortiori, satisfies S2, and has only simple crossings in codimension 1 (each component of the double locus corresponds to a codimension-1 polytope in $\mathcal{Q}$ which is a face of two maximal-dimensional polytopes). The normalization of $(X, \Delta + \varepsilon B)$ with the double locus added is the disjoint union of toric pairs $(X_i, \Delta_i + \varepsilon B_i)$, which are log canonical by Lemma 4.1. Hence, $(X, \Delta + \varepsilon B)$ is semi log canonical. Moreover,

$$\nu^*(K_X + \Delta + \varepsilon B)\,|_{X_i} = K_{X_i} + \Delta_i + \varepsilon B_i,$$

so the divisor $K_X + \Delta + \varepsilon B$ is ample. □

We would like to mention the following essential facts: Higher cohomology groups of positive powers L^d vanish. The moduli functor of stable toric pairs is proper, i.e. every one-parameter family has at most one limit, and the limit always exists after a finite base change $(S', 0) \to (S, 0)$. The limit of a family of pairs of type $\mathcal{Q}$ corresponds to a complex $\mathcal{Q}'$ such that $|\mathcal{Q}'| = |\mathcal{Q}|$, and $\mathcal{Q}'$ is obtained from $\mathcal{Q}$ by a *convex* subdivision.

Recall that a subdivision of a single polytope Q is *convex* if it is the projection of the lower envelope of several points $\big(m, h(m)\big)$ where m are some points with $\mathrm{Conv}(m) = Q$, and $h\colon \{m\} \to \mathbb{R}$ is an arbitrary function, called *height function*. This was generalized in [6] to convex subdivisions of a polytopal complex $\mathcal{Q}$ by requiring that the height functions of two polytopes Q_1, Q_2 differ by a linear function on $Q_1 \cap Q_2$.

The stable toric variety X is *multiplicity-free* if the reference map $\rho\colon |\mathcal{Q}| \to M_{\mathbb{R}}$ is injective. We will restrict ourselves to this case for the rest of this section.

Theorem 4.5 ([6]). *The functor of stable toric pairs has a coarse moduli space M over $\mathbb{Z}$. It is a disjoint union of subschemes $M_{|\mathcal{Q}|}$, each of them projective. Each moduli space $M_{|\mathcal{Q}|}$ has a natural stratification with strata corresponding to subdivisions of $|\mathcal{Q}|$ into lattice polytopes.*

When $|\mathcal{Q}| = Q$ is a polytope, the moduli space M_Q contains an open subset U_Q which is the moduli space of pairs (X, B) with a toric variety X. The closure of U_Q is an irreducible component of M_Q. The strata in this closure correspond to convex subdivisions of Q, and the normalization of $\overline{U}_Q$ coincides with the toric variety for the secondary polytope of $(Q, Q \cap M)$.

Rather than relying on the methods of the Minimal Model Program, the proof is rather direct. To each family $(T_S \curvearrowright X, B) \to S$ we can associate the graded algebra $R(X/S, L) = \bigoplus_{d \geq 0} \pi_* L^d$, multigraded by M due to the T_S-action, and multiplicity-free by the assumptions on the fibers, with a section s, an equation of B. Then the moduli of stable toric pairs is equivalent to the moduli of algebras (R, s) with a section, and the latter is rather straightforward.

We note that the faces of the secondary polytope of $(Q, Q \cap M)$ (see [20] for the definition) are in bijection with the convex subdivisions of Q.

For some polytopes Q the moduli space M_Q does indeed have several irreducible components. The extra components always appear when there exists a non-convex subdivision of Q into lattice polytopes.

Another situation where the extra components are guaranteed is when the stratum for a particular convex subdivision has higher dimension in M_Q than it does in the toric variety for the secondary polytope. Both can be computed effectively: the latter is the codimension of the corresponding cone in the normal fan of the secondary polytope, and for M_Q it is the dimension of the cohomology group describing the gluing, as in 4.3.

On the other hand, the following dual point of view turns out to be very important.

Definition 4.6. Let Y be a projective scheme. A *variety over* $\boldsymbol{Y}$ is a reduced, but possibly reducible, projective variety X together with a finite morphism $f\colon X \to Y$. A *family of varieties over* $\boldsymbol{Y}$ is a finite morphism $f\colon X \to Y \times S$ such that $X \to S$ is flat, and every geometric fiber is a variety over Y, as above.

If G is an algebraic group acting linearly on $Y \subset \mathbb{P}^n$, then a G-variety (resp. family) over Y is a morphism $f\colon X \to Y$ as before which, in addition, is G-equivariant.

Lemma 4.7. *Families of stable toric pairs of type $|\mathcal{Q}|$ are in a natural bijective correspondence with families of stable toric varieties over $\mathbb{P}^n$ with the homogeneous coordinates x^m, $m \in M \cap |\mathcal{Q}|$, on which T acts with the characters m.*

Proof. Indeed, the data for both the morphism to $\mathbb{P}^n$ and the divisor B not containing any T-orbits is the same: working locally over $S = \operatorname{Spec} A$, it is a collection $(c_m \in A)$ such that $c_m(s) \neq 0$ for every *vertex* m of a polytope Q_i corresponding to the fiber X_s. □

Remark 4.8. We note that there exists another moduli space closely related to our moduli space M of stable toric varieties: it is the toric Hilbert scheme $\operatorname{Hilb}^T_{\mathbb{P}^n}$ [46], [24] parameterizing *subschemes* $X \subset \mathbb{P}^n$ corresponding to the multiplicity-free multigraded algebras. So, geometrically what we have done is the following: we replaced *closed subschemes* of Y by *reduced* varieties X with a *finite morphism to* Y.

Indeed, this is a general situation, and in [13] such a universal substitute for the Hilbert scheme is constructed in general, without the multiplicity-free assumption (or group action). Reduced varieties with a finite morphism to a scheme Y are called *branchvarieties of* $\boldsymbol{Y}$, to contrast with subvarieties or subschemes of Y.

Over a field of characteristic zero, the above picture can be generalized to stable spherical varieties over Y. Recall that if G is a connected reductive group then a G-variety X is called *spherical* if it is normal and a Borel subgroup of G has an open orbit. One motivation for considering spherical varieties is the following important finiteness property: a G-variety is spherical iff any G-variety birationally isomorphic to it has only finitely many G-orbits.

A polarized G-linearized variety (X, L) is spherical iff it is normal and the algebra $R(X, L) = \bigoplus_{d\geq 0} H^0(X, L^d)$ is multiplicity free, i.e. when it is written as a direct sum over the irreducible representations $V_{d,\lambda}$ of the group $\widetilde{G} = \mathbb{G}_m \times G$, each multiplicity is 1 or 0.

One important difference between the toric and spherical cases is that the spherical varieties are *not* completely classified. For any homogeneous spherical variety G/H, its normal G-embeddings correspond to colored fans. However, the homogeneous spherical varieties G/H are currently only classified in types A and D, [41], [17].

For a polarized spherical variety (X, L) one can define its moment polytope [18] which, when working over $\mathbb{C}$, coincides with the moment polytope of X as a Hamiltonian variety. Which polytopes may appear as moment polytopes is not known.

However, it is known that the set of moment polytopes contained in any bounded set is finite [11], [12]. Together with the boundedness results of [13], this implies that the set of moment polytopes of polarized stable spherical varieties (X, L) with a fixed Hilbert polynomial is finite.

Definition 4.9. A *stable spherical variety over* a G-variety $\boldsymbol{Y} \subset \mathbb{P}^n$ is a G-variety over Y such that the G-module $R(X, L)$, $L = f^*\mathcal{O}_Y(1)$ is multiplicity-free,

Similarly, a *family of stable spherical varieties over* $\boldsymbol{Y}$ is a proper family of G-varieties $f\colon G_S \curvearrowright X \to Y \times S$ over Y such that, denoting $L = f^*\mathcal{O}_{Y\times S}(1)$, one has

$$R(X/S, L) = \bigoplus_{d\geq 0} \pi_*(X, L^d) = \bigoplus_\lambda V_{d,\lambda} \otimes F_{d,\lambda},$$

where $V_{d,\lambda}$ are the irreducible $(\mathbb{G}_m \times G)$-representations and $F_{d,\lambda}$ are locally free sheaves of rank 1 or 0.

There is an equivalent more geometric definition in terms of gluing from spherical varieties. However, as was noted above, the structure of the "building blocks", i.e. ordinary spherical varieties, is a little mysterious.

Theorem 4.10 ([12]). *The functor of stable spherical pairs over Y has a coarse moduli space M_Y over $\mathbb{Q}$. It is a disjoint union of projective schemes.*

As in the toric case, one can define a *stable spherical pair* (X, B). However, when G is not a torus, this turns out to be a very special case of stable maps. The analogue of Lemma 4.7 in the spherical case is the following:

Lemma 4.11 ([12], Prop.3.3.2). *Families of stable spherical pairs of type $|\mathcal{Q}|$ are in a natural bijective correspondence with families of stable spherical varieties over $\mathbb{P}\big(\oplus \operatorname{End}(V_m)\big)$, where m go over the weights in $|\mathcal{Q}|$.*

One important case where all stable spherical varieties are completely classified is the case of *stable reductive varieties* [9], [10]. Each polarized stable reductive variety corresponds to a complex $\mathcal{Q} = (Q_i)$ of lattice polytopes in $\Lambda_{\mathbb{R}}$, where Λ is the weight lattice of G, and the complex $\mathcal{Q}$ is required to be invariant under the action of Weyl group. Limits of one-parameter degenerations again correspond to convex subdivisions.

5. Abelian varieties

In terms of Definition 1.1, this case corresponds to the pairs $(X, \varepsilon B)$, with a floating coefficient. Here, X is an abelian variety, or more accurately an abelian torsor (i.e. no origin is fixed) or a similar "stable" variety, and B is a theta divisor. But again, Minimal Model Program is not used, and the constructions and proofs of [6] are more direct, using the symmetries of the situation.

A fundamental insight from the Minimal Model Program is that we should be working with abelian torsors with divisors ($B \subset X$) instead of abelian varieties ($0 \in X$), because the former fit into the general settings of Definition 1.1 and the basic construction of Section 2, and the latter do not. The bridge is the following

Lemma 5.1 ([6]). *There is a natural bijective correspondence between principally polarized abelian schemes $(A, \lambda\colon A \to A^t) \to S$ and flat families of abelian torsors $(A \curvearrowright X, B) \to S$ such that B is an effective relative Cartier divisor defining a principal polarization on each geometric fiber.*

For example, if $C \to S$ is a smooth family of curves then $(\mathrm{Pic}^0_{C/S}, \lambda)$ is the principally polarized abelian scheme, and $(\mathrm{Pic}^0_{C/S} \curvearrowright \mathrm{Pic}^{g-1}_{C/S} \supset \Theta_{g-1})$ is the family of abelian torsors. The two families are usually not isomorphic, unless $C \to S$ has a section.

Recall that a *semiabelian variety* is a group variety G which is an extension

$$1 \to T \to G \to A \to 0$$

of an abelian variety by a multiplicative torus. Let $g = \dim G = r + a = \dim T + \dim A$. We will denote the lattice of characters of T by $M_0 \simeq \mathbb{Z}^r$ and reserve $M \simeq \mathbb{Z}^g$ for a certain lattice of which M_0 will be a quotient.

Generalizing directly Definition 4.2, we give the following:

Definition 5.2. Let X be a variety with an action of a semiabelian variety G, and $B \subset X$ be an effective Cartier divisor. The variety X, resp. the pair (X, B) is called a *stable quasiabelian variety* (resp. *stable quasiabelian pair*) if the following three conditions are satisfied:

1. *on singularities:* X is seminormal (resp. and B does not contain any G-orbits),
2. *on group action:* isotropy groups G_x are subtori, and
3. *numerical:* (resp. the divisor B is ample).

A proper flat morphism $f : (G \curvearrowright X, B) \to S$ is called a *family of stable quasiabelian pairs*; here G is a semiabelian group scheme over S, X is a scheme endowed with an action $G \times_S X \to X$, with a relative Cartier divisor B, so that every geometric fiber is a stable quasiabelian pair.

The essential difference with the case of stable toric varieties is that the group variety G may vary, and in particular the torus part T may change its rank.

Intuitively (and this actually works when working over $\mathbb{C}$) a polarized abelian variety should be thought of as a stable toric variety for a *constant* torus that, in terms of the data 4.3, corresponds to a topological space $|\mathcal{Q}| = \mathbb{R}^g/\mathbb{Z}^g$ and an element of a cohomology group describing the gluing, as in 4.3.2; however, the Čech cohomology should be replaced by the group cohomology. A general polarized stable quasiabelian variety should be thought of as a similar quotient of a bigger stable toric variety for a constant torus by a lattice.

Remark 5.3. Namikawa [43] defined SQAVs, or "stable quasiabelian varieties" not intrinsically but as certain limits of abelian varieties. They are different from our varieties in several respects. In particular, some of Namikawa's varieties are not reduced, and it is not clear if they vary in flat families. The above definition also includes varieties which are not limits of abelian varieties.

The varieties of Definition 5.2 were called stable semiabelic varieties in [6]. Since this was a somewhat awkward name, I am reverting to the old name.

A stable quasiabelian pair is *linearized* if the sheaf $L = \mathcal{O}_X(B)$ is provided with a T-linearization (*not* G-linearization!) The first step is to classify the linearized varieties, which is quite easy:

Theorem 5.4. *A linearized stable quasiabelian variety* $(G \curvearrowright X, L)$ *is equivalent to the following data:*

1. (*toric part*) *a linearized stable toric variety* (X_0, L_0) *for* T*, and*
2. (*abelian part*) *a polarized abelian torsor* (X_1, L_1) *for* A.

The variety X *is isomorphic to the twisted product*

$$X = X_0 \times^T G = (X_0 \times G)/T, \quad T \text{ acting by } (t, t^{-1})$$

and there is a locally trivial fibration $X \to X_1$ *with fibers isomorphic to* X_0*. Each closed orbit of* $G \curvearrowright X$ *with the restriction of* L *is isomorphic to the pair* (X_1, L_1).

5.5. Hence, the linearized stable quasiabelian varieties (X, L) (resp. pairs (X, B)) over a field $k = \bar{k}$ are easy to classify, and are described by the following data:

1. A complex of polytopes $\mathcal{Q}_0$ with a reference map $\tilde{\rho}_0 \colon |\mathcal{Q}_0| \to M_{0,\mathbb{R}}$.
2. A polarized abelian torsor (X_1, L_1), which is equivalent to a polarized abelian variety $(A, \lambda \colon A \to A^t)$.
3. A semiabelian variety G, which is equivalent to a homomorphism $c \colon M_0 \to A^t$.
4. A certain cohomology group, very similar to the one in 4.3, describing the gluing. The only difference is that in this case the sheaves, instead of tori, have coefficients in certain $\mathbb{G}_m$-torsors.

The topological space $|\mathcal{Q}_0|$ has dimension $\dim X_0 \leq \dim T = r$, the toric rank of G. The analogy with stable toric varieties becomes even stronger when we associate to (X, L) a *cell* complex $\mathcal{Q}$ of dimension $\dim X$. This is done as follows:

The kernel of the polarization map $\lambda \colon A \to A^t$ has order d^2, where d is the degree of polarization, and comes with a skew-symmetric bilinear form. If $\operatorname{char} k \nmid d$, it can be written as $\ker \lambda = H \times \operatorname{Hom}(H, \mathbb{G}_m)$ for a unique finite abelian group H of rank $\leq \dim A$. Write H as a quotient M_1/Γ_1, where $M_1 = \mathbb{Z}^a$ and Γ_1 is a subgroup of finite index.

The cell complex $\mathcal{Q}_1$ we associate to the abelian torsor (X_1, L_1) consists of one cell $M_{1,\mathbb{R}}/\Gamma_1 \simeq \mathbb{R}^a/\mathbb{Z}^a$, a real torus of dimension a. Let $M = M_0 \times M_1$ and $\Gamma = \Gamma_1$. Then the cell complex associated to the linearized pair (X, L) is $\mathcal{Q} = \mathcal{Q}_0 \times \mathcal{Q}_1$. It comes with a reference map $\rho\colon |\mathcal{Q}| \to M_{\mathbb{R}}/\Gamma_1 \simeq \mathbb{R}^g/\mathbb{Z}^a$.

It turns out, however, that if $(T \curvearrowright X, B)$ is a degeneration of abelian varieties with $T \neq 1$, the invertible sheaf L is *never* linearized. On the other hand, there exists an infinite *algebraic* cover $f\colon \widetilde{X} \to X$ such that the pullback $\widetilde{L} = f^*L$ is linearized in a canonical way:

Theorem 5.6 ([6]). *Let G be a semiabelian group scheme over a connected scheme S, and assume that G is a global extension $1 \to T \to G \to A \to 0$ of an abelian scheme A by a split torus T. Then a family of stable quasiabelian pairs $(G \curvearrowright X, B) \to S$ is equivalent to a family of* linearized *stable quasiabelian pairs $(G \curvearrowright \widetilde{X}, \widetilde{B}) \to S$ whose fibers are only* locally of finite type*, with a compatible* free in Zariski topology *action of $M_0 = \mathbb{Z}^r$ so that $(X, B) = (\widetilde{X}, \widetilde{B})/M_0$.*

Moreover, there exists a subgroup $\Gamma_0 \simeq \mathbb{Z}^{r'}$, $r' \leq r$, of M_0 such that $\widetilde{X}$ is a disjoint union of $[M_0 : \Gamma_0]$ copies of a connected scheme $\widetilde{X}'$, and $(X, B) = (\widetilde{X}', \widetilde{B}')/\Gamma_0$.

A polarized toric variety (X, L) provides a trivial case of this theorem: in this case $\Gamma_0 = 0$, and X is the disjoint union of $M_0 \simeq \mathbb{Z}^r$ copies of X, one for each possible T-linearization of the sheaf L.

A less trivial, but equally familiar example is the rational nodal curve, which is a quotient $\widetilde{X}/\mathbb{Z}$ of an infinite chain of $\mathbb{P}^1$s by $M_0 \simeq \mathbb{Z}$. Mumford [42] constructed a number of degenerations of abelian varieties which are such infinite quotients. So the above statement may be considered to be a precise inverse of Mumford's construction.

The scheme $\widetilde{X}'$ can be written in the form $\widetilde{X}_0 \times^T G$, where $\widetilde{X}_0$ is a linearized scheme locally of finite type. Then locally $\widetilde{X}_0$ is isomorphic to a linearized stable toric variety. This defines a locally finite complex of polytopes $\widetilde{\mathcal{Q}}_0$ with a reference map $\tilde{\rho}_0\colon |\widetilde{\mathcal{Q}}_0| \to M_{0,\mathbb{R}}$. Moreover, $\widetilde{\mathcal{Q}}_0$ has a Γ_0-action with only finitely many orbits, and $\tilde{\rho}_0$ is Γ_0-invariant. This can be summed up by saying that each stable quasiabelian pair defines a finite complex of polytopes $\rho_0\colon \mathcal{Q}_0 = \widetilde{\mathcal{Q}}_0/\Gamma_0 \to M_{0,\mathbb{R}}/\Gamma_0 \simeq \mathbb{R}^r/\mathbb{Z}^{r'}$.

Again, we can add to this the abelian part, and obtain a complex of dimension $\dim X$. As above, the abelian part gives a one-cell complex $\mathcal{Q}_1 = M_{1,\mathbb{R}}/\Gamma_1 \simeq \mathbb{R}^a/\mathbb{Z}^a$. We set $\mathcal{Q} = \mathcal{Q}_0 \times \mathcal{Q}_1$, $M = M_0 \times M_1$, and $\Gamma = \Gamma_0 \times \Gamma_1$. Then $\mathcal{Q}$ is a finite cell complex, and it comes with a reference map $\rho\colon |\mathcal{Q}| \to M_{\mathbb{R}}/\Gamma \simeq \mathbb{R}^g/\mathbb{Z}^{a+r'}$.

The topological space $\rho\colon |\mathcal{Q}| \to M_{\mathbb{R}}/\Gamma$ together with the reference map is the *type of a stable quasiabelian variety* (X, L), resp. of a pair (X, B). We say that the type is *injective* if the reference map ρ is injective. In this case it can be shown that the type is constant in connected families, and so we can talk about moduli spaces $M_{|\mathcal{Q}|}$.

5.7. The classification of isomorphism classes in the stable toric case 4.3 and linearized stable semiabelian case 5.5 can be translated to this most general case almost verbatim.

The most important of the moduli spaces $M_{|\mathcal{Q}|}$ are the ones containing abelian torsors of degree d, defining a polarization $\lambda\colon A \to A^t$ with $\ker\lambda \simeq H \times \mathrm{Hom}(H, \mathbb{G}_m)$. In this case, the type is a real torus $M_{\mathbb{R}}/\Gamma \simeq \mathbb{R}^g/\mathbb{Z}^g$, where $\Gamma \subset M$ is a sublattice with $M/\Gamma \simeq H$. One observes that this *real torus with a lattice structure* is an analogue of a lattice polytope Q in the stable toric case.

A cell subdivision of $|\mathcal{Q}|$ in this case is the same as a Γ-periodic subdivision of $M_{\mathbb{R}}$ which is a pullback of a Γ_0-periodic subdivision of $M_{0,\mathbb{R}}$ into lattice polytopes with vertices in M_0.

One proves that the moduli functor of stable quasiabelian pairs of injective type is proper, and that one-parameter degenerations correspond to suitably understood convex subdivisions of $|\mathcal{Q}|$.

A Γ-periodic subdivision of $M_{\mathbb{R}}$ is *convex* if it is the projection of the lower envelope of the points $(m, h(m))$, where m goes over $M \simeq \mathbb{Z}^g$, and $h\colon M \to \mathbb{R}$ is a function of the form

$$h(m) = (\text{positive semidefinite quadratic form}) + r(m \bmod \Gamma),$$

where $r\colon M/\Gamma \to \mathbb{R}$ is a function defined on the finite set of residues.

In particular, the principally polarized case corresponds to $\Gamma = M = \mathbb{Z}^g$. The convex subdivisions of $\mathbb{R}^g/\mathbb{Z}^g$ in this case are the classical *Delaunay decompositions*, that appeared in [50]. A detailed combinatorial description of one-parameter degenerations of principally polarized abelian varieties from the present point of view, in which Delaunay decompositions naturally appear, was given in [15].

By analogy, when $\Gamma \subset M$ is a sublattice of finite index, we call the convex subdivisions of $M_{\mathbb{R}}/\Gamma$ *semi-Delaunay decompositions*.

We will denote the moduli spaces appearing in this case by $\overline{\mathrm{AP}}_{g,H}$, resp. $\overline{\mathrm{AP}}_g$ in the principally polarized case; AP stands for *abelian pairs*.

Theorem 5.8. *For each of the types $|\mathcal{Q}| = M_{\mathbb{R}}/\Gamma \simeq \mathbb{R}^g/\mathbb{Z}^g$, $|M/\Gamma| = d$, the functor of stable quasiabelian pairs of type $|\mathcal{Q}|$ over $\mathbb{Z}[1/d]$ has a coarse moduli space $\overline{\mathrm{AP}}_{g,H}$, a proper algebraic space over $\mathbb{Z}[1/d]$. The moduli space $\overline{\mathrm{AP}}_{g,H}$ has a natural stratification with strata corresponding to subdivisions of $|\mathcal{Q}|$ modulo symmetries of (M, Γ).*

The moduli space $\overline{\mathrm{AP}}_{g,H}$ contains an open subset $U_{|\mathcal{Q}|}$ of dimension $\frac{g(g+1)}{2} + d - 1$ which is the moduli space of abelian torsors (X, B) defining a polarization of degree d. The closure of $U_{|\mathcal{Q}|}$ is an irreducible component of $\overline{\mathrm{AP}}_{g,H}$. The strata in this closure correspond to semi-Delaunay subdivisions.

In particular, one has the following:

Theorem 5.9. *For $|\mathcal{Q}| = M_{\mathbb{R}}/M \simeq \mathbb{R}^g/\mathbb{Z}^g$, the functor of stable quasiabelian pairs of type $|\mathcal{Q}|$ has a coarse moduli space $\overline{\mathrm{AP}}_g$, a proper algebraic space over $\mathbb{Z}$. The moduli space $\overline{\mathrm{AP}}_g$ has a natural stratification with strata corresponding to $\mathbb{Z}^g$-periodic subdivisions of $\mathbb{R}^g$, pullbacks of $\mathbb{Z}^r$-periodic subdivisions of $\mathbb{R}^r$ into lattice polytopes with the set of vertices equal to the lattice $\mathbb{Z}^r$ of periods, modulo* $\mathrm{GL}(g, \mathbb{Z})$.

The moduli space $\overline{\mathrm{AP}}_g$ contains an open subset which is the moduli space A_g of principally polarized abelian varieties. The closure of A_g is an irreducible component of $\overline{\mathrm{AP}}_g$. The strata in this closure correspond to Delaunay subdivisions, and the normalization of $\bar{A}_g$ coincides with the toroidal compactification $\bar{A}_g^{\mathrm{vor}}$ for the second Voronoi fan. This toroidal compactification is projective.

The proof of the theorems exploits the connection with the toric case in the following way. Although the toric rank in a family of stable quasiabelian varieties may change, in an infinitesimal family it does not. Hence, Theorem 5.6 together with the toric methods give the deformation and obstruction theory for the moduli functor. The moduli spaces then can be constructed by using Artin's method [16].

The (locally closed) cones of the second Voronoi fan consist of positive semidefinite quadratic forms that define the same Delaunay decomposition. Thus, we see that this fan, introduced by Voronoi in [50], is the precise infinite periodic analogue of (the normal fan of) the secondary polytope, and predates it by about 80 years.

Starting with $g = 4$, the moduli spaces $\overline{\mathrm{AP}}_g$ do indeed have several irreducible components (as do the moduli spaces of stable toric varieties). The extra components always appear when there exists a non-Delaunay $\mathbb{Z}^r$-periodic subdivision of $\mathbb{R}^r$ into lattice polytopes with vertices in the same $\mathbb{Z}^r$, with $r \leq g$.

Another situation where the extra components are guaranteed is when the stratum for a particular Delaunay decomposition has higher dimension in $\overline{\mathrm{AP}}_g$ than it does in $\bar{A}_g^{\mathrm{vor}}$. Both can be computed effectively: for the Voronoi compactification it is the codimension of a cone in the 2nd Voronoi fan, and for $\overline{\mathrm{AP}}_g$ it is the dimension of the cohomology group describing the gluing, as in 4.3, 5.5, 5.7. See [5] for more on this.

One important construction involving moduli spaces of abelian varieties is the Torelli map $M_g \to A_g$ which associates to a smooth curve C of genus g its Jacobian, a principally polarized abelian variety $(A, \lambda\colon A \to A^t)$ of dimension g. Combinatorially, it was understood by Mumford (see [43]) that the Torelli map can be extended to a morphism from the Deligne–Mumford compactification $\bar{M}_g$ to $\bar{A}_g^{\mathrm{vor}}$, and this was the original motivation for considering the second Voronoi fan in [43].

The moduli interpretation of the extended morphism $\bar{M}_g \to \overline{\mathrm{AP}}_g$ was given in [7]. To a nonsingular curve C, it associates the pair $(\mathrm{Pic}^0 C \curvearrowright \mathrm{Pic}^{g-1} C, \Theta)$, and to a stable curve, the stable quasiabelian pair $(\mathrm{Pic}^0 C \curvearrowright \mathrm{Jac}_{g-1} C, \Theta)$, where $\mathrm{Jac}_{g-1} C$ is the moduli stable of semistable rank 1 sheaves on C of degree $g-1$, and Θ is the divisor corresponding to sheaves with sections.

The $\mathbb{Z}^g$-periodic cell decompositions corresponding to the image of $\bar{M}_g$ have a simple description. First of all, they are not arbitrary but are given by subdividing $\mathbb{R}^r$ (and by pullback, $\mathbb{R}^g$) by systems of parallel hyperplanes $\{l_i(m) = n \in \mathbb{Z}\}$. The condition that the set of vertices of the polytopes in $\mathbb{R}^r$ cut out by the hyperplanes is the same lattice of periods $\mathbb{Z}^r$ is equivalent to the condition that $\{l_i \in M_0^\vee\}$ is a *unimodular system of vectors*, i.e. every $(r \times r)$-minor is 0, 1 or -1. Another name used for unimodular systems of vectors is *regular matroid*, see [45].

In these terms, the answer to "combinatorial Schottky" or "tropical Schottky" problem is the following: the strata in the image of $\overline{M}_g$ correspond to special matroids that are called *cographic*. If $\mathcal{G}$ is a graph then its cographic subdivision is the $H_1(\mathcal{G}, \mathbb{Z})$-periodic subdivision of $H_1(\mathcal{G}, \mathbb{R})$ obtained by intersecting H_1 with $C_1(\mathcal{G}, \mathbb{R})$ divided into standard Euclidean cubes.

This theory was extended to the degenerations of Prym varieties in [8], [49], and many non-cographic matroids appear there. For example, using the above theory Gwena [21] described some of the degenerations of intermediate Jacobians of cubic 3-folds, including a particular one that corresponds to a very symmetric regular matroid R_{10} which is neither cographic, nor graphic.

In conclusion, we would like to mention one other important motivation from the Minimal Model Program for looking at stable abelian pairs: by a theorem of Kollár [37], if A is a principally polarized variety then the pair (A, Θ) has log canonical singularities.

6. Grassmannians

In Section 4 we defined stable toric (and spherical) varieties over a projective G-scheme $Y \subset \mathbb{P}^n$. The corresponding moduli spaces $M_{Y,Q}$ are projective. What does one get by looking at some particular varieties Y? One nice case that has many connections with other fields is the case when $Y \subset \mathbb{P}^n$ is a grassmannian with its Plücker embedding and the group is the multiplicative torus.

Let $E = E_1 \oplus \cdots \oplus E_n$ be a linear space with the coordinate-wise action by the torus $T = \mathbb{G}_m^n$ with character group $M = \mathbb{Z}^n$. (Dimensions of E_i are arbitrary.) Let r be a positive integer, and

$$i : Y = \mathrm{Gr}(r, E) \hookrightarrow \mathbb{P}(\Lambda^r E)$$

be the grassmannian variety of r-dimensional subspaces of E with its Plücker embedding.

For each collection of 2^n nonnegative integers $\underline{d} = (d_I \mid I \subset \{1, \ldots, n\})$, the *thin Schubert cell* is defined to be the locally closed subscheme of $\mathrm{Gr}(r, E)$

$$\mathrm{Gr}_{\underline{d}} = \left\{ V \subset E \mid \mathrm{rank}(V \cap \textstyle\bigoplus_{i \in I} E_i) = d_I \right\}.$$

(Some of these may be empty; one necessary condition for non-emptiness is the inequality $d_{I \cap J} + d_{I \cup J} \geq d_I + d_J$ for all I, J.) There is a subtorus $T_{\underline{d}}$ acting trivially on $\mathrm{Gr}_{\underline{d}}$, and the quotient torus $(T / T_{\underline{d}})$ acts freely.

A *generalized matroid polytope* is a polytope in $\mathbb{R}^n$ defined by the inequalities

$$Q_{\underline{d}} = \left\{ 0 \leq x_i \leq \dim E_i,\ \textstyle\sum_{i=1}^n x_i = r \text{ and } \sum_{i \in I} x_i \geq d_I \text{ for all } I \right\}.$$

The classical *matroid polytopes* are a special case, when all $\dim E_i = 1$.

In [40], Lafforgue constructed certain compactifications of the quotients of thin Schubert cells

$$\mathrm{Gr}_{\underline{d}}/T = \mathrm{Gr}_{\underline{d}}/(T/T_{\underline{d}}).$$

These compactifications have important applications in Langlands program, and they include compactifications of the homogeneous spaces $\mathrm{PGL}_r^{n-1}/\mathrm{PGL}_r$ equivariant with respect to the action by PGL_r (this is the case of all $\dim E_i = r$ and $d_I = 0$ for all $I \neq \{1, \dots, n\}$).

As shown in [12], the main irreducible components of the moduli spaces $M_{\mathrm{Gr}(r,E),Q_{\underline{d}}}$ of stable toric varieties over $\mathrm{Gr}(r, E)$, as in Section 4, coincide with the Lafforgue's compactifications, at least up to normalization.

The connection is as follows. For each point $p \in \mathrm{Gr}_{\underline{d}}$, the normalization of the closure of the orbit $T \cdot p$ defines a T-toric variety $X \to \mathrm{Gr}(r, E)$ for the polytope $Q_{\underline{d}}$. This gives a canonical identification of $\mathrm{Gr}_{\underline{d}}/T$ with an open subset U of the moduli space $M_{\mathrm{Gr}(r,E),Q_{\underline{d}}}$. Since the latter is projective, this gives a moduli compactification of $\mathrm{Gr}_{\underline{d}}/T$.

A case of particular interest is when all $\dim E_i = 1$ and Q is the moment polytope of a generic point $p \in \mathrm{Gr}(r, n)$. In this case $Q_{\underline{d}} = \Delta(r, n)$, a *hypersimplex*. This case was considered by Kapranov in [29] who constructed a compactification he called the Chow quotient, by using the Chow variety.

The moduli space $M = M_{\mathrm{Gr}(r,n),\Delta(2,n)}$ in this case can be interpreted as a compactified moduli space of hyperplane arrangements. This interpretation, with a somewhat folk status, was recorded by Hacking–Keel–Tevelev in [23], along with many new results about this moduli space. We note that the latter paper uses the toric Hilbert scheme, rather than stable toric varieties over Y. But in this case the two points of view coincide, because matroid polytopes, as was observed in [23], are unimodular (by which we mean that the monoid of integral points in the cone over Q is generated by the integral points of Q). As a consequence, stable toric varieties over $\mathrm{Gr}(r, n)$ are actually T-invariant *subschemes* of $\mathrm{Gr}(r, n)$.

We now review this interpretation. Let $p \in \mathrm{Gr}^0(r, n)$ be a generic point, and $X = \overline{T \cdot p}$ be the orbit closure, isomorphic to a (normal) toric variety for the polytope $\Delta(r, n)$. Then $X \to \mathrm{Gr}(r, n)$ can be equivalently interpreted as any of the following:

1. a point in $\mathrm{Gr}^0(r, n)/T$,
2. a point of an open subset $U = U_{\mathrm{Gr}(r,n),\Delta(r,n)}$ of $M_{\mathrm{Gr}(r,n),\Delta(r,n)}$,
3. a point of an open subset U of the toric Hilbert scheme of $\mathrm{Gr}(r, n)$.

Now pick a generic point $e \in \mathbb{A}^n$ and consider the closed subvariety Y_e of X corresponding to the r-dimensional subspaces that contain e. This is Kapranov's *visible contour*. It is easy to see that:

1. For generic e, e' the varieties Y_e and $Y_{e'}$ are isomorphic since they differ by T-action. So we could as well associate one variety Y with each X, up to an isomorphism.

2. As the line $\mathbb{A}^1_e$ changes, the disjoint subvarieties Y_e cover an open subset V of X, so they are fibers of a proper fibration $V \to T/\mathbb{G}_m$. In particular, the singularities of $(Y_e, \Delta \cap Y_e)$ are no worse than singularities of (X, Δ), where Δ is the complement of the dense torus orbit in X.

3. In fact, each Y is isomorphic to $\mathbb{P}^{r-1}$, and $Y \cap \Delta = B_1 \cup B_2 \cup \cdots \cup B_n$ is the union of n hyperplanes in $\mathbb{P}^{r-1}$ in general position. The divisors B_i correspond to the n coordinate hyperplanes in $E = (\mathbb{A}^1)^n$.

4. By the Gelfand–MacPherson correspondence, the T-orbits of $\mathrm{Gr}^0(r, n)$ are in a natural bijection with PGL_r-orbits of n hyperplanes in $\mathbb{P}^{r-1}$ that are in general position, i.e. with isomorphism classes of labeled hyperplane arrangements $(\mathbb{P}^{r-1}, B_1 + \cdots + B_n)$. So, $U = U_{\mathrm{Gr}(r,n),\Delta(r,n)}$ is the moduli space of the general-position hyperplane arrangements.

Now look at any *stable* toric variety $X \to \mathrm{Gr}(r, n)$ of type $|\mathcal{Q}| = \Delta(r, n)$ and at a corresponding subvariety Y_e. Then the properties (1) and (2) above still hold. In particular, each Y is a generic section of X, and the singularities of $(Y, B_1 + \cdots + B_n = Y \cap \Delta)$ are no worse than the singularities of the pair (X, Δ). But by Lemma 4.4 the latter are semi log canonical. This implies that each pair $(Y, B_1 + \cdots + B_n)$ is stable in the sense of Definition 1.1.

Question 6.1. Can the moduli spaces $M_{Y,Q}$ in the case when Y is a partial flag variety, for example a variety of two-step flags, be interpreted as the moduli space of stable maps?

We also note that [7] provides an interpretation of the morphism

$$M_{\mathrm{Gr}(r,n),\Delta(r,n)} \to M_{\mathbb{P}(\Lambda^e E),\Delta(r,n)}$$

as a toric analogue of the extended Torelli map $\overline{M}_g \to \bar{A}_g$.

7. Higher Gromov–Witten theory

One of the exciting new frontiers for the moduli of stable pairs is the "higher-dimensional" Gromov–Witten theory, obtained by replacing the n-pointed stable curves $(X, B_1 + \cdots + B_n) \to Y$ by stable pairs with $\dim X \geq 2$. We list several questions in this direction.

Question 7.1. One way to define "higher" Gromov–Witten-invariants is to use evaluations at the intersections points $\bigcap_{j\in J} B_j$ with $|J| = \dim X$. Can a "generalized" quantum cohomology ring be defined using these evaluations? And is it a richer structure than simply an associative ring?

Question 7.2. Is there a more nontrivial definition, using evaluations at divisors rather than at points?

Question 7.3. Do the moduli spaces of weighted n-pointed curves, constructed by Hassett [27] lead to new ways to compute ordinary Gromov–Witten-invariants and descendants? When one varies the weights b_j and the moduli space $\overline{M}_{0,n}^{(b_j)}(\beta, Y)$ changes, is there a nice "wall-crossing" formula?

Question 7.4. The formula for the intersection products of ψ-classes on $\overline{M}_{0,n}$ is particularly easy (these are just the multinomial coefficients). What is the generalization of this formula for the compactified moduli space of hyperplane arrangements? Can it be obtained by using the toric degeneration of $\mathrm{Gr}(r, n)$ to a Gelfand–Tsetlin toric variety Z and thus degenerating $M_{\mathrm{Gr}(r,n),Q}$ to $M_{Z,Q}$?

Evaluation maps, slopes, and algebraicity criteria

Jean-Benoît Bost

Abstract. We discuss criteria for the algebraicity of a formal subscheme $\hat{V}$ in the completion $\hat{X}_P$ at some rational point P of an algebraic variety X over some field K. In particular we consider the case where K is a function field or a number field, and we discuss applications concerning the algebraicity of leaves of algebraic foliations, algebraic groups, absolute Tate cycles, and the rationality of germs of formal functions on a curve over a number field.

Mathematics Subject Classification (2000). 11G35, 11Jxx, 14G40, 14B20, 14F30, 14L15, 37F75.

Keywords. Arakelov geometry, algebraic foliations, algebraic groups, algebraicity and rationality criteria, capacity, Diophantine approximation and slopes.

1. Introduction

This article presents a survey of the *arithmetic algebraicity criteria* and their applications that have been developed in [12], [13], and in the subsequent joint work with Chambert-Loir [14].

The proofs of these criteria rely on what might be called the *method of slopes*, that is inspired by the classical techniques of auxiliary polynomials in Diophantine approximation, but is formulated in a geometric framework. In this approach, when investigating a projective algebraic variety X equipped with some ample line bundle L defined over a number field K, and some zero-dimensional subschemes Σ_i of X, the basic objects of interest are the *evaluation maps*

$$\eta_{D,i} : \Gamma(X, L^{\otimes D}) \longrightarrow \Gamma(\Sigma_i, L^{\otimes D})$$

which map global sections of $L^{\otimes D}$ to their restrictions to Σ_i. Typically, when X is the compactification of an algebraic group G, the Σ_i's may be some sets of multiples of some rational points of G, or some thickenings of such subsets. In the situation we shall deal with in this paper, the Σ_i's will be the successive infinitesimal neighbourhoods of some point P of $X(K)$ in a formal subscheme $\hat{V}$ of the formal completion $\hat{X}_P$.

The geometry of the Σ_i's in X turns out to be reflected by the injectivity properties of these evaluation maps – this is the contents of the so-called zero lemmas when X is some compactified algebraic group, and, in the setting of this paper, of the algebraicity criterion in Proposition 2.1 below. This geometry is finally related to the arithmetic properties of the data X, L, and Σ_i through the *slopes inequalities* satisfied by the

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

K-linear maps $\eta_{D,i}$. Indeed, after the choice of auxiliary data (such as integral models for X, L, and the Σ_i's, and hermitian metrics on $X(\mathbb{C})$ and $L_{\mathbb{C}}$), the source and range of $\eta_{D,i}$ appear as the underlying K-vector spaces attached to some hermitian vector bundles over $\mathrm{Spec}\,\mathcal{O}_K$. To them, elementary Arakelov geometry attaches arithmetic invariants, such as the *height* of $\eta_{D,i}$ and the *Arakelov degree* and the *slopes* of these hermitian vector bundles. The slope inequality for $\eta_{D,i}$ asserts that, when for instance $\eta_{D,i}$ is injective, the maximal slope of its source is bounded from above by the sum of its height and of the maximal slope of its range.

The approach to proving Diophantine statements by the consideration of evaluation maps and of the associated slope estimates has been introduced in a Bourbaki report [10], devoted to the work by Masser and Wüstholz on periods and minimal abelian subvarieties of abelian varieties over number fields [35]. The flexibility of this new geometric approach allowed the author to combine the original arguments in [35], phrased in terms of classical theta functions, with the "modern" theory of abelian schemes (including deep results due to Néron, Mumford, and Moret-Bailly), and to establish variants of the original work of Masser and Wüstholz where constants occuring in various estimates are explicitly bounded.

These effective versions of the "period theorem" of Masser and Wüstholz and of the consequent "isogeny estimates" have been recently improved by Viada ([43], [42]), by means of the same techniques. The combination of the method of slopes and of the modern theory of abelian schemes has also been used by Gaudron ([26]) to derive effective estimates on linear forms in logarithms on abelian varieties.

The results in the present article have been inspired by the work of D. and G. Chudnovsky [19], [18], and by the generalization of the results in [19] to abelian varieties by Graftieaux in [27] and [28], who also used the above combination of techniques. However, in the formulation and the proofs of the results discussed below, the flexibility of the method of slopes has not been exploited to derive Diophantine statements on abelian varieties involving *explicit* estimates, but instead to establish results valid in some *general geometric* setting by means of relatively non-technical arguments, at the expense of explicitness.

Another illustration of the flexibility of the method of slopes, in a spirit similar to this paper, is provided by the recent work by Gasbarri [25], who used this method to derive generalizations of transcendance theorems *à la* Schneider–Lang–Bombieri in general geometric situations and to clarify their relations with higher dimensional Nevanlinna theory.

In this article, we shall focus on these geometric aspects, instead of going into the details of the arguments of Arakelov geometry involved in proofs. For those, we refer to the original papers [12], [13], and [14] and to Chambert-Loir's Bourbaki report [16], which also discusses the link between slopes inequalities and more traditional techniques, such as Siegel's lemma and the interpolation determinants of Laurent [33].

To emphasize the geometric content of our approach, we shall first explain how the methods of auxiliary polynomials, in the guise of the study of the maps $\eta_{D,i}$ above, provides a simple algebraicity criterion for formal germs in an arbitrary projective

variety over a field K (section 2). Then, assuming that K is the function field $k(C)$ of some projective curve over some field k, we shall derive some geometric analogues of the results presented in the later sections. The proofs of these analogues will demonstrate how inequalities between slopes – of vector bundles over the curve C in this geometric setting – may be used to establish that, under suitable positivity conditions, the hypotheses of our previous algebraicity criterion are fulfilled (Section 3). Albeit technically simpler in the function field case, these arguments will give some insight into the proof of the arithmetic algebraicity criteria stated in Sections 6 and 7.

Besides, we shall illustrate these arithmetic criteria by applications to the algebraicity of leaves of *algebraic foliation*. Here, by an algebraic foliation over some base field K, we mean a smooth algebraic variety X over K, equipped with some sub-vector bundle F of the tangent bundle T_X, that is involutive (*i.e.*, whose sheaf of sections is closed under Lie bracket). When K is a field of characteristic $p > 0$, the sheaf of sections of T_X is equipped with the operation of p-th power, and it makes sense to require the sheaf of section of F to be closed under this operation. When K is a field of characteristic zero, for any point P in $X(K)$, one may consider the formal leaf of the foliation (X, F) through P, namely the unique smooth formal subscheme $\hat{V}$ of dimension rk F in the completion $\hat{X}_P$ whose formal tangent bundle coincides with the restriction of F.

When K is a number field with ring of integers $\mathcal{O}_K$, we may introduce some smooth model $\mathcal{X}$ of X over an open subscheme S of Spec $\mathcal{O}_K$ such that F extends to a sub-vector bundle $\mathcal{F}$ of $T_{\mathcal{X}/S}$, and consider the following condition, which we shall call the *Grothendieck–Katz condition*:

For almost every maximal ideal $\mathfrak{p}$ *in* Spec $\mathcal{O}_K$, *of residue characteristic* p, *the involutive subbundle* $\mathcal{F}_{\mathbb{F}_p}$ *of* $T_{\mathcal{X}_{\mathbb{F}_p}}$ *is stable under* p*-th power.*

It is easily seen to be satisfied when the foliation (X, F) is algebraically integrable[1]. The *generalized conjecture of Grothendieck–Katz* asserts that the converse holds. It was initially stated for linear differential systems by Katz [31] who attributes it to Grothendieck. The general formulation of the conjecture is due to Ekedahl, Shepherd-Barron, and Taylor [24]. Its investigation has been one of the main motivations behind the algebraicity results presented in this survey (see in particular, Section 6 and Theorems 6.1 and 6.2 below) which may also be considered as extensions of the earlier works of Chudnovsky ([18]) and André ([2], Chapter VIII, and [4], Section 5) on the original conjecture of Grothendieck–Katz.

For lack of space, we do not attempt to give any complete historical account of the origins of the algebraization techniques discussed below. Let us however indicate that these techniques – based on the consideration of maps sending global sections of ample line bundles to their restrictions to thickened points – goes back at least to the paper of Poincaré [37], where he presented an overview of his main results concerning abelian functions (see especially its Section II). Besides, the original proof of Chow's

[1] This means, by definition, that for any field extension Ω of K, the formal leaf through any point of $X(\Omega)$ of the algebraic foliation (X_Ω, F_Ω) is itself algebraic.

theorem relies on a criterion somewhat in the spirit of Proposition 2.1 below (see [17], Theorem IV). One might also refer to the article of Siegel [40] for historical comments on the proofs of algebraization statements in the framework of analytic geometry during the "pre-GAGA" era.

Algebraicity criteria in a geometric setting involving positivity conditions in the spirit of Theorem 3.1 below may also be deduced from classical results by Andreotti and Grauert on fields of meromorphic functions ([6], [5]) and by Hironaka, Matsumura, and Hartshorne on fields of formal meromorphic functions ([30], [29]); see [12], Section 3.3, and [9].

We refer to the monograph [7] for additional references concerning these techniques of formal geometry and their applications to extension and connectedness problems in projective geometry over a field. Many of these applications may be expected to have arithmetic counterparts which would extend the results in this article.

Conventions. The following notation and terminology are used throughout the article.

By an *algebraic scheme* over some field k, we mean a separated scheme of finite type over k. Integral algebraic schemes X over k will be called *algebraic varieties* over k.

Let G be an algebraic group over a field K of characteristic 0. Its Lie algebra Lie G is the fiber at the unit element $e \in G(K)$ of the tangent bundle T_G, and may be identified with the K-vector space of the left-invariant regular sections of T_G over G. The Lie bracket on Lie G is, by definition, the restriction of the Lie bracket on vector fields in $\Gamma(G, T_G)$. A Lie subalgebra $\boldsymbol{h}$, defined over K, of Lie G is called an *algebraic Lie subalgebra* when it is the Lie algebra of some algebraic subgroup H in G. When this holds, the subgroup H may be supposed connected, and then is unique and defined over any field of definition of G and $\boldsymbol{h}$.

If K is a number field, its ring of integers will be denoted $\mathcal{O}_K$. For any non-zero prime ideal $\boldsymbol{p}$ of $\mathcal{O}_K$, we let $N\boldsymbol{p} := |\mathcal{O}_K/\boldsymbol{p}|$ its norm, $K_{\boldsymbol{p}}$ (resp. $\mathcal{O}_{\boldsymbol{p}}$) the $\boldsymbol{p}$-adic completion of K (resp. of $\mathcal{O}_K$), and $|\ |_{\boldsymbol{p}}$ the $\boldsymbol{p}$-adic absolute value on $K_{\boldsymbol{p}}$ normalized in such a way that, for any uniformizing element ϖ of $\mathcal{O}_{\boldsymbol{p}}$, $|\varpi|_{\boldsymbol{p}} = N\boldsymbol{p}^{-1}$. We shall also denote K_v the completion of K at some place v (possibly archimedean).

2. Algebraic formal germs and auxiliary polynomials

Let X be an algebraic scheme over a field K, P a point of $X(K)$, $\hat{X}_P$ the formal completion of X at P, and $\hat{V} \hookrightarrow \hat{X}_P$ a smooth formal subscheme. Such a $\hat{V}$ will also be called a *smooth formal germ of subvariety* through P in X. For any non-negative integer i, we shall denote V_i the i-th infinitesimal neighborhood of P in $\hat{V}$. Thus,

$$V_0 = \{P\} \subset V_1 \subset V_2 \subset \cdots$$

and

$$\hat{V} = \varinjlim V_i.$$

We may consider the Zariski closure of $\hat{V}$ in X, namely, the smallest closed subscheme Z of X such that $\hat{Z}_P$ contain $\hat{V}$. Observe that it is a subvariety of X containing P: the ideal in $\mathcal{O}_{X,P}$ defining its germ at P is the intersection of $\mathcal{O}_{X,P}$ and of the ideal in its completion $\hat{\mathcal{O}}_{X,P} = \mathcal{O}_{\hat{X}_P}$ that defines $\hat{V}$, hence is prime. Moreover, since $\hat{Z}_P$ contains $\hat{V}$, the dimension of Z is at least equal to the dimension of $\hat{V}$.

The formal germ $\hat{V}$ is called *algebraic* when these two dimensions are equal. Indeed, using the compatibility properties of completion and normalization, one easily checks that this condition is equivalent to each of the following ones, which could have been used as alternative definitions:

(i) There exists a closed subvariety Z of X such that P belongs to $Z(K)$ and $\hat{V}$ is a branch of Z through P (*i.e.*, a component of the completion $\hat{Z}_P$).

(ii) There exist an integral algebraic scheme Y over K, a point 0 of $Y(K)$ and a K-morphism $f\colon Y \to X$ which maps 0 to P, such that the induced morphism on formal completions

$$\hat{f}_0\colon \hat{Y}_0 \longrightarrow \hat{X}_P$$

factorizes through $\hat{V} \hookrightarrow \hat{X}_P$ and defines a formal isomorphism from $\hat{Y}_0$ to $\hat{V}$.

Let us moreover assume that X *is projective* over K. We may choose an ample line bundle L on X, and introduce the following K-vector spaces and K-linear maps, for any non-negative integers D and i:

$$E_D := \Gamma(X, L^{\otimes D}),$$

$$\begin{aligned} \eta_D\colon E_D &\longrightarrow \Gamma(\hat{V}, L^{\otimes D}) \\ s &\longmapsto s_{|\hat{V}}, \end{aligned}$$

$$\begin{aligned} \eta_D^i\colon E_D &\longrightarrow \Gamma(V_i, L^{\otimes D}) \\ s &\longmapsto s_{|V_i}, \end{aligned}$$

and[2]

$$E_D^i := \{s \in E_D \mid s_{V_{i-1}} = 0\} = \ker \eta_D^{i-1}.$$

Observe that there is a canonical isomorphism $\Gamma(\hat{V}, L^{\otimes D}) \simeq \varprojlim_i \Gamma(V_i, L^{\otimes D})$, by means of which the map η_D gets identified with $\varprojlim_i \eta_D^i$.

The subspaces E_D^i define a decreasing filtration of E_D:

$$E_D = E_D^0 \supset E_D^1 \supset \cdots \supset E_D^i \supset E_D^{i+1} \supset \cdots.$$

Since the K-vector space E_D is finite dimensional, this filtration is stationary, and the very definition of Z as the Zariski closure of $\hat{V}$ shows that, if $\mathcal{I}_Z$ denotes its ideal sheaf in $\mathcal{O}_X$, we have

$$\bigcap_{i \geq 0} E_D^i = \ker \eta_D = \Gamma(X, \mathcal{I}_Z.L^{\otimes D}). \tag{2.1}$$

[2] In this definition, when $i = 0$, we let $V_{-1} = \emptyset$ and $\eta_D^{-1} = 0$.

Finally, if $T_{\hat{V}}$ denotes the tangent space of $\hat{V}$, then, for any non-negative integer i, the kernel of the restriction map from $\Gamma(V_i, L^{\otimes D})$ to $\Gamma(V_{i-1}, L^{\otimes D})$ may be identified with $S^i \check{T}_{\hat{V}} \otimes L_P^D$, and the restriction of the evaluation map η_D^i to E_D^i defines a K-linear map:

$$\gamma_D^i \colon E_D^i \longrightarrow S^i \check{T}_{\hat{V}} \otimes L_P^{\otimes D}.$$

Roughly speaking, it is the map which sends a section of $L^{\otimes D}$ vanishing up to order i at P along $\hat{V}$ to the $(i+1)$-th "Taylor coefficient" of its restriction to $\hat{V}$. By construction,

$$\ker \gamma_D^i = E_D^{i+1}. \tag{2.2}$$

The following proposition shows how the algebraicity of $\hat{V}$ and the asymptotic behaviour of the ranks of the subquotients E_D^i/E_D^{i+1} are related. It may be considered as a geometric version of the techniques of "auxiliary polynomials" used in the theory of Diophantine approximation: in our setting, the elements of the space $E_D := \Gamma(X, L^{\otimes D})$ play the role of auxiliary polynomials of degree D.

Proposition 2.1. *The following three conditions are equivalent:*

(i) *the formal germ $\hat{V}$ is algebraic;*

(ii) *there exists $c > 0$ such that, for any $(D, i) \in \mathbb{N}^2$ satisfying $i > cD$, the map γ_D^i vanishes;*

(iii) *the ratio*

$$\frac{\sum_{i\geq 0}(i/D)\mathrm{rk}\,(E_D^i/E_D^{i+1})}{\sum_{i\geq 0}\mathrm{rk}\,(E_D^i/E_D^{i+1})} \tag{2.3}$$

does not *admit the limit $+\infty$ when D goes to infinity.*

Condition (ii) may be also expressed by saying that, for every positive integer D the filtration $(E_D^i)_{i\geq 0}$ becomes stationary – or equivalently that η_D vanishes on E_D^i – when $i > cD$.

The implication (i) $\Rightarrow$ (ii) is a straightforward consequence of the basic theory of ample line bundles and their Seshadri constants (see for instance [34], Chapter 5, notably Proposition 5.1.9). The implication (ii) $\Rightarrow$ (iii) is clear. We sketch the proof of (ii) $\Rightarrow$ (i) below. The one of the implication (iii) $\Rightarrow$ (i) – which constitutes the algebraicity criterion we shall use in the sequel – is similar, but slightly more elaborate; see [13], Section 2.2, for more details.

Let us assume that condition (ii) holds, and let d denote the dimension of $\hat{V}$, which we may assume positive. Then, for any non-negative integers D and i, the quotient vector space $E_D^i/E_D^{i+1} = E_D^i/\ker \gamma_D^i \simeq \mathrm{im}\,\gamma_D^i$ has rank at most $\mathrm{rk}\,(S^i \check{T}_{\hat{V}} \otimes L_P^D) = \binom{d+i-1}{i}$ and vanishes if $i > cD$. This implies that

$$\mathrm{rk}\left(E_D/\bigcap_{i\geq 0} E_D^i\right) = \sum_{i\geq 0}\mathrm{rk}\,(E_D^i/E_D^{i+1}) \leq \sum_{i=0}^{[cD]}\binom{d+i-1}{i}.$$

Moreover the last sum is equivalent to $\frac{c^d}{d!}D^d$ when D goes to infinity.

Besides, according to (2.1),

$$E_D \Big/ \bigcap_{i\geq 0} E_D^i = \Gamma(X, L^{\otimes D}) / \Gamma(X, \mathfrak{I}_Z . L^{\otimes D}).$$

For D large enough, this space may be identified with $\Gamma(Z, L^{\otimes D})$ and its rank is equivalent to $\frac{\deg_L Z}{(\dim Z)!} D^{\dim Z}$ when D goes to infinity.

This shows that $\dim Z$ is at most d, and therefore is equal to d. This establishes condition (i), and completes the proof of (ii) $\Rightarrow$ (i).

3. An algebraicity criterion for smooth formal germs in varieties over function fields

Let C be a smooth projective, geometrically connected curve over some field k and let $K := k(C)$ be the associated function field.

Recall that, if E is a vector bundle of positive rank on C, its *slope* is defined as the quotient of its degree by its rank

$$\mu(E) := \frac{\deg E}{\operatorname{rk} E},$$

and its *maximal slope* $\mu_{\max}(E)$ is the maximum of the slopes $\mu(F)$ of sub-vector bundles of positive rank in E. Observe that, if L is any line bundle on C,

$$\mu_{\max}(E \otimes L) = \mu_{\max}(E) + \deg L.$$

Moreover, if E_1 and E_2 are vector bundles over C with E_2 of positive rank, and if there exists some (generically) injective morphism of vector bundles $\varphi\colon E_1 \to E_2$, then the following slope inequality holds:

$$\deg E_1 \leq \operatorname{rk} E_1 . \mu_{\max}(E_2). \tag{3.1}$$

Finally, recall that a vector bundle E over C is ample iff it has positive rank and there exists $c > 0$ such that, for any non-negative integer i,

$$\mu_{\max}(S^i \check{E}) \leq -c.i.$$

Let X be an algebraic scheme over K, P a point in $X(K)$, and $\hat{V} \subset \hat{X}_P$ a smooth formal germ of subvariety through P in X.

After possibly shrinking X, we may assume that it is quasi-projective and choose a quasi-projective model[3] $\pi : \mathcal{X} \longrightarrow C$ such that P extends to a section $\mathcal{P}$ of π.

[3] namely, a quasi-projective k-variety $\mathcal{X}$, equipped with a flat k-morphism $\pi : \mathcal{X} \to C$ and an isomorphism of its generic fiber $\mathcal{X}_K$ with X.

Theorem 3.1 ([13], Theorem 2.5). *With the above notation, assume that the following two conditions are satisfied:*

(i) *the formal subscheme $\hat{V}$ in $\hat{X}_P$ extends to a formal subscheme $\hat{\mathcal{V}}$ of $\hat{\mathcal{X}}_{\mathcal{P}}$ that is smooth over C;*

(ii) *the normal bundle $N_{\mathcal{P}}\hat{\mathcal{V}}$ of $\hat{\mathcal{V}}$ along $\mathcal{P}$ is ample.*

Then $\hat{V}$ is algebraic.

This algebraicity criterion may be seen as a "geometric model", concerning functions fields, of the arithmetic algebraicity criterion in Theorem 6.1 below, devoted to formal germs in varieties over number fields.

Our proof of Theorem 3.1 will rely on the implication (iii) $\Rightarrow$ (i) in Proposition 2.1. Indeed there exists a projective compactification of $\mathcal{X}$ to which the morphism π extends. Therefore we may assume that $\mathcal{X}$ is projective, and choose some ample line bundle $\mathcal{L}$ on $\mathcal{X}$. Let $L := \mathcal{L}_K$ be its restriction to X, and let E_D, E_D^i, η_D^i, and γ_D^i be as in the previous section. We are going to show that, when conditions (i) and (ii) in Theorem 3.1 are satisfied, the ratio (2.3) stays bounded when D goes to infinity.

To achieve this, let us consider the direct images $\mathcal{E}_D := \pi_*\mathcal{L}^{\otimes D}$ and $\pi_{|\mathcal{V}_i *}\mathcal{L}^{\otimes D}$, where $\mathcal{V}_i$ denotes the i-th infinitesimal neighbourhood of $\mathcal{P}$ in $\mathcal{V}$. These are torsion free coherent sheaves – or equivalently vector bundles – on C, which at the generic point Spec K of C coincide with the K-vector spaces E_D and $\Gamma(V_i, L^{\otimes D})$. Moreover, every restriction map $\eta_D^i \colon E_D \longrightarrow \Gamma(V_i, L^{\otimes D})$ extends to a morphism of vector bundles:

$$\begin{aligned} \overline{\eta}_D^i \colon \mathcal{E}_D &\longrightarrow \pi_{|\mathcal{V}_i *}\mathcal{L}^{\otimes D} \\ s &\longmapsto s_{|\mathcal{V}_i}. \end{aligned}$$

The filtration $(E_D^i)_{i\geq 0}$ of E_D also extends to the filtration of $\mathcal{E}_D$ by the sub-vector bundles $\mathcal{E}_D^i := \ker \overline{\eta}_D^{i-1}$. Finally, the kernel of the restriction map from $\pi_{|\mathcal{V}_i *}\mathcal{L}^{\otimes D}$ to $\pi_{|\mathcal{V}_{i-1} *}\mathcal{L}^{\otimes D}$ may be identified with $S^i(\check{N}_{\mathcal{P}}\hat{\mathcal{V}}) \otimes \mathcal{P}^*\mathcal{L}^{\otimes D}$ and the restriction of the evaluation map $\overline{\eta}_D^i$ to $\mathcal{E}_D^i$ defines a morphism of vector bundles $\overline{\gamma}_D^i \colon \mathcal{E}_D^i \to S^i(\check{N}_{\mathcal{P}}\hat{\mathcal{V}}) \otimes \mathcal{P}^*\mathcal{L}^{\otimes D}$, which coincides with γ_D^i at the generic point of C. The kernel of $\overline{\gamma}_D^i$ is $\mathcal{E}_D^{i+1}$ and therefore $\overline{\gamma}_D^i$ factorizes through a (generically) injective morphism of vector bundles $\tilde{\gamma}_D^i \colon \mathcal{E}_D^i/\mathcal{E}_D^{i+1} \to S^i(\check{N}_{\mathcal{P}}\hat{\mathcal{V}}) \otimes \mathcal{P}^*\mathcal{L}^{\otimes D}$.

The ampleness of $N_{\mathcal{P}}\hat{\mathcal{V}}$ and the slope inequality (3.1) applied to the morphisms $\tilde{\gamma}_D^i$ now show that, for some $c > 0$ independent of i and D, we have:

$$\deg(\mathcal{E}_D^i/\mathcal{E}_D^{i+1}) \leq \mathrm{rk}\,(E_D^i/E_D^{i+1})(-c.i + D.\deg \mathcal{P}^*\mathcal{L}).$$

Besides, since $\mathcal{L}$ is ample, the sheaf $\mathcal{E}_D$ is generated by its global sections for D large enough, and consequently:

$$\deg\Big(\mathcal{E}_D \Big/ \bigcap_{i\geq 0} \mathcal{E}_D^i\Big) \geq 0.$$

Moreover we may write:

$$\deg\left(\mathcal{E}_D\Big/\bigcap_{i\geq 0}\mathcal{E}_D^i\right)=\sum_{i\geq 0}\deg\left(\mathcal{E}_D^i/\mathcal{E}_D^{i+1}\right).$$

When D is large enough, the above three inequalities establish that

$$c.\sum_{i\geq 0}(i/D)\,\mathrm{rk}\,(E_D^i/E_D^{i+1})\leq \deg \mathcal{P}^*\mathcal{L}.\sum_{i\geq 0}\mathrm{rk}\,(E_D^i/E_D^{i+1}),$$

and finally that the ratio (2.3) is at most $(\deg \mathcal{P}^*\mathcal{L})/c$.

The following application of Theorem 3.1 illustrates how the algebraicity criteria contained in Proposition 2.1 and Theorem 3.1 lead to non-trivial geometric consequences in spite of the elementary nature of their proof (see also [9], [20], and [32] for applications of similar techniques to algebraic and rationally connected leaves of algebraic foliations).

Theorem 3.2 ([13], Theorem 2.6). *Let C be a smooth projective, geometrically connected curve over a field k of characteristic zero, $K := k(C)$ its function field, and $\pi : \mathcal{G} \to C$ a smooth group scheme over C. Let $G := \mathcal{G}_K$ be its generic fiber, and* Lie $\mathcal{G}$ *its Lie algebra*[4].

If the sub-vector bundle of Lie $\mathcal{G}$ *defined by some Lie subalgebra (over K) $\boldsymbol{h}$ of* Lie G *is ample, then it is an algebraic Lie subalgebra. More specifically, there exists a unipotent linear K-algebraic subgroup H in G such that $\boldsymbol{h} =$* Lie H.

In the classical analogy between function fields and number fields, this statement may be considered as a counterpart of Diophantine results concerning algebraic groups over number fields such as Theorem 6.3 below.

Observe also that, if G is a semi-abelian variety over K (hence does not admit any non-trivial unipotent algebraic subgroup), Theorem 3.2 asserts the semi-negativity of Lie $\mathcal{G}$. When $\mathcal{G}$ is an abelian scheme over C, this also follows from a classical curvature argument due to Griffiths.

Under the hypotheses of Theorem 3.2, to establish the existence of an algebraic subgroup H of G such that $\boldsymbol{h} =$ Lie H, one applies Theorem 3.1 in the situation where X is G, P is the unit element e of $G(K)$, and $\hat{V}$ is the "formal exponential" of the Lie subalgebra $\boldsymbol{h}$, namely, the formal subgroup of $\hat{G}_e$ such that $T_P\hat{V} = \boldsymbol{h}$. Its Zariski closure provides the sought for algebraic subgroup.

When the Lie bracket vanishes on $\boldsymbol{h}$, one may consider the vector group $\mathrm{Vect}(\boldsymbol{h})$ defined by $\boldsymbol{h}$ and the product $G' := \mathrm{Vect}(\boldsymbol{h})\times G$. The graph of the injection $\boldsymbol{h} \hookrightarrow$ Lie G is an algebraic Lie subalgebra of Lie G', and is the Lie algebra of the graph of an isomorphism $\mathrm{Vect}(\boldsymbol{h}) \simeq H \hookrightarrow G$.

[4]It is defined as the restriction along the zero section of π of the relative tangent bundle T_π. It is a vector bundle over C, equipped with a $\mathcal{O}_C$-bilinear Lie bracket, which coincides at the generic point Spec K of C with the Lie bracket of the Lie algebra Lie $G \simeq (\text{Lie } \mathcal{G})_K$ of the K-algebraic group G.

In general, one establishes that H is linear and unipotent by a similar argument, after having deduced that $\boldsymbol{h}$ is nilpotent from analyzing the compatibility of the Lie bracket on $\boldsymbol{h}$ with the Harder–Narasimhan filtration of the associated sub-vector bundle in Lie $\mathcal{G}$.

4. Sizes of formal subschemes over p-adic and global fields

This section and the next one are devoted to preliminaries needed for stating our arithmetic algebraicity criteria in Sections 6 and 7.

We first describe some constructions introduced in [12], Section 3, and further developed in [13], Section 4.1, and [14], Section 2. We refer to these papers for details and proofs.

Let k be a p-adic field (*i.e.*, a finite extension of $\mathbb{Q}_p$), $\mathcal{O}$ its subring of integers (*i.e.*, the integral closure of $\mathbb{Z}_p$ in k), $|\ |\colon k \to \mathbb{R}_+$ its absolute value, and $\mathbb{F}$ its residue field[5].

4.1. Groups of formal and analytic automorphisms. If $g := \sum_{I \in \mathbb{N}^d} a_I X^I$ is a formal power series in $k[[X_1, \ldots, X_d]]$ and if $r \in \mathbb{R}_+^*$, we define

$$\|g\|_r := \sup_I |a_I| r^{|I|} \in \mathbb{R}_+ \cup \{+\infty\}.$$

The "norm" $\|g\|_r$ is finite iff the series g is convergent and bounded on the open ball of radius r in $\overline{k}^d$.

Let $\hat{\mathbb{A}}_k^d$ be the formal completion at the origin of the d-dimensional affine space over k. Its group $\mathrm{Aut}\,\hat{\mathbb{A}}_k^d$ of automorphisms may be identified with the space of d-tuples $f = (f_i)_{1 \leq i \leq d}$ of formal series $f_i \in k[[x_1, \ldots, x_d]]$ such that $f(0) = 0$ and $Df(0) := \left(\frac{\partial f_i}{\partial x_j}(0)\right)_{1 \leq i,j \leq d}$ belongs to $\mathrm{GL}_n(k)$.

We shall consider the following subgroups of $\mathrm{Aut}\,\hat{\mathbb{A}}_k^d$:

- the subgroup G_{for} formed by the formal automorphisms f such that $Df(0)$ belongs to $\mathrm{GL}_n(\mathcal{O})$;
- the subgroup G_ω formed by the elements $f := (f_i)_{1 \leq i \leq d}$ of G_{for} such that the series f_i have positive radii of convergence;
- for any $r \in \mathbb{R}_+^*$, the subgroup $G_\omega(r)$ of G_ω formed by the elements $f := (f_i)_{1 \leq i \leq d}$ of G_{for} such that the series f_i satisfy the bounds $\|f_i\|_r \leq r$.

The group $G_\omega(r)$ may be seen as the group of analytic automorphisms, defined over k and preserving the origin, of the open d-dimensional ball of radius r. Moreover

[5] Actually we might assume more generally that k is any field equipped with a complete non-Archimedean absolute value $|\ |\colon k \to \mathbb{R}_+$ and let $\mathcal{O} := \{t \in k \mid |t| \leq 1\}$ be its valuation ring.

we have:

$$r' > r > 0 \Longrightarrow G_\omega(r') \subset G_\omega(r) \quad \text{and} \quad \bigcup_{r>0} G_\omega(r) = G_\omega.$$

4.2. The size $S_{\mathcal{X}}(\hat{V})$ of a formal germ $\hat{V}$. The filtration $(G_\omega(r))_{r>0}$ of the group G_ω may be used to attach a number $S_{\mathcal{X}}(\hat{V})$ in $[0, 1]$ to any smooth formal germ $\hat{V}$ in an algebraic variety X over k, depending on the choice of some model $\mathcal{X}$ of X over $\mathcal{O}$. This number shall provide some quantitative measure of the analyticity of $\hat{V}$.

Let $\hat{V}$ be a formal subscheme of $\hat{\mathbb{A}}^d_k$. For any φ in Aut $\hat{\mathbb{A}}^d_k$, we may consider its inverse image $\varphi^*(\hat{V})$, which also is a formal subscheme of $\hat{\mathbb{A}}^d_k$. Observe that $\hat{V}$ is a smooth formal scheme of dimension v iff there exists φ in Aut $\hat{\mathbb{A}}^d_k$ such that $\varphi^*(\hat{V})$ is the formal subscheme $\hat{\mathbb{A}}^v_k \times \{0\}$ of $\hat{\mathbb{A}}^d_k$. Moreover, when this holds, φ may be chosen in G_{for}.

Similarly, the formal germ $\hat{V}$ is *analytic and smooth* – namely, it is the formal scheme attached to some germ at 0 of smooth analytic subspace of dimension v of the d-dimensional affine space over k – iff there exists φ in G_ω such that $\varphi^*(\hat{V})$ is the formal subscheme $\hat{\mathbb{A}}^v_k \times \{0\}$ of $\hat{\mathbb{A}}^d_k$.

These observations lead us to introduce the *size of a smooth formal subscheme* $\hat{V}$ of dimension v of $\hat{\mathbb{A}}^d_k$, defined as the supremum $S(\hat{V})$ in $[0, 1]$ of the real numbers $r \in]0, 1]$ for which there exists φ in $G_\omega(r)$ such that $\varphi^*(\hat{V})$ is the formal subscheme $\hat{\mathbb{A}}^v_k \times \{0\}$ of $\hat{\mathbb{A}}^d_k$.

More generally, if $\mathcal{X}$ is an $\mathcal{O}$-scheme of finite type equipped with a section $\mathcal{P} \in \mathcal{X}(\mathcal{O})$ and if $\hat{V}$ is a smooth formal subscheme of the formal completion $\hat{X}_P$ of $X := \mathcal{X}_k$ at $P := \mathcal{P}_k$, then the *size* $S_{\mathcal{X}}(\hat{V})$ *of* $\hat{V}$ *with respect to the model* $\mathcal{X}$ of X will be defined as the size of $i(\hat{V})$, where $i\colon U \hookrightarrow \mathbb{A}^d_{\mathcal{O}}$ is an embedding of some open neighbourhood U in $\mathcal{X}$ of the section $\mathcal{P}$ into an affine space of large enough dimension d, which additionally maps $\mathcal{P}$ to the origin $0 \in \mathbb{A}^d_{\mathcal{O}}(\mathcal{O})$.

This definition is independent of the choices of U, d, and i, and extends the previous one. Actually it satisfies the following invariance properties:

I1. If $\mathcal{X}$ is a subscheme of a scheme $\mathcal{X}'$ over $\mathcal{O}$, then $S_{\mathcal{X}'}(\hat{V}) = S_{\mathcal{X}}(\hat{V})$.

I2. If $\mathcal{X}$, X, $\mathcal{P}$, $\hat{V}$ and $\mathcal{X}'$, X', $\mathcal{P}'$, $\hat{V}'$ are as above, and if there exists an $\mathcal{O}$-morphism $\phi\colon \mathcal{X} \to \mathcal{X}'$ mapping $\mathcal{P}$ to $\mathcal{P}'$, étale along $\mathcal{P}$, such that the formal isomorphism $\hat{\phi}_k\colon \hat{X}_P \xrightarrow{\sim} \hat{X}'_{P'}$ maps isomorphically $\hat{V}$ onto $\hat{V}'$, then $S_{\mathcal{X}'}(\hat{V}') = S_{\mathcal{X}}(\hat{V})$.

Besides, the size $S_{\mathcal{X}}(\hat{V})$ is invariant by extension of the p-adic base field k (*cf.* [14]).

Finally observe that, with the same notation as above, the size $S_{\mathcal{X}}(\hat{V})$ is positive iff $\hat{V}$ is analytic. Moreover, if $\hat{V}$ extends to a formal subscheme $\hat{\mathcal{V}}$ of the formal completion of $\mathcal{X}$ along $\mathcal{P}$ which is smooth along $\mathcal{P}$, then $S_{\mathcal{X}}(\hat{V}) = 1$.

4.3. Size of formal leaves of algebraic foliations. It is possible to establish lower bounds on the sizes of formal germs of solutions of algebraic ordinary differential equations. These bounds will allow us to apply our arithmetic algebraicity criteria below to the solutions of algebraic differential equations – or more generally, to leaves of algebraic foliations – defined over number fields.

Proposition 4.1. *Let $\mathcal{X}$ be a smooth scheme over* Spec $\mathcal{O}$*, $\mathcal{P}$ a section in $\mathcal{X}(\mathcal{O})$, and $\mathcal{F}$ a sub-vector bundle of rank f in $T_{\mathcal{X}/\mathcal{O}}$. Let us assume that the subbundle $F := \mathcal{F}_k$ of the tangent bundle T_X of the smooth k-variety $X := \mathcal{X}_k$ is involutive, and let $\hat{V}$ be the formal germ of leave of this involutive bundle through $P := \mathcal{P}_k$.*

1) *The size of $\hat{V}$ with respect to $\mathcal{X}$ satisfies the lower bound:*

$$S_{\mathcal{X}}(\hat{V}) \geq |\pi| := |p|^{\frac{1}{p-1}}. \tag{4.1}$$

2) *If moreover k is absolutely unramified and if the reduction $\mathcal{F}_{\mathbb{F}} \hookrightarrow T_{\mathcal{X}_{\mathbb{F}}}$ of $\mathcal{F}$ to the closed fiber $\mathcal{X}_{\mathbb{F}}$ of $\mathcal{X}$ is closed under p-th power, then*

$$S_{\mathcal{X}}(\hat{V}) \geq |p|^{\frac{1}{p(p-1)}}. \tag{4.2}$$

This is proved in [12], Proposition 3.9, and [13], Proposition 4.1, by first reducing the construction of $\hat{V}$ to the one of the formal flow $\psi_{(t_1,\dots,t_f)}$ of suitably chosen commuting sections $v_1, \dots, v_f$ of F. Then one studies the analyticity properties of this flow by expanding the map $\psi^*_{(t_1,\dots,t_f)}$ (defined by $\psi_{(t_1,\dots,t_f)}$ acting on functions) *à la* Cauchy:

$$\psi^*_{(t_1,\dots,t_f)} = \exp\Big(\sum_{1\leq i\leq f} t_i.v_i\Big) := \sum_{(i_1,\dots,i_f)\in\mathbb{N}^f} \frac{t_1^{i_1}\dots t_f^{i_f}}{i_1!\dots i_f!} D_1^{i_1}\circ\dots\circ D_f^{i_f},$$

where $D_1, \dots, D_f$ denote the derivations of the sheaf of regular functions on X defined by $v_1, \dots, v_f$.

4.4. A-germs. Consider an algebraic variety X over some number field K, P a point in $X(K)$, and $\hat{V}$ a smooth formal subscheme in $\hat{X}_P$.

Let N be a positive integer and $(\mathcal{X}, \mathcal{P})$ a model of (X, P) over $\mathcal{O}_K[1/N]$. For any maximal ideal $\boldsymbol{p}$ in $\mathcal{O}_K$ not dividing N, by base change we get a smooth formal germ $\hat{V}_{K_{\boldsymbol{p}}}$ through $P_{K_{\boldsymbol{p}}}$ in the algebraic variety $X_{K_{\boldsymbol{p}}}$ over the p-adic field $K_{\boldsymbol{p}}$, and a model $(\mathcal{X}_{\mathcal{O}_{\boldsymbol{p}}}, \mathcal{P}_{\mathcal{O}_{\boldsymbol{p}}})$ over $\mathcal{O}_{\boldsymbol{p}}$ of the pair $(X_{K_{\boldsymbol{p}}}, P_{K_{\boldsymbol{p}}})$. Consequently, for any such $\boldsymbol{p}$, the size $S_{\mathcal{X}_{\mathcal{O}_{\boldsymbol{p}}}}(\hat{V}_{K_{\boldsymbol{p}}})$ is a well-defined element in $[0, 1]$.

We shall say that the formal germ $\hat{V}$ in X is *A-analytic*, or is an *A-germ*, when the following two conditions are satisfied:

1. *for any place v of K, the formal germ $\hat{V}_{K_v}$ is K_v-analytic*[6];

[6] or equivalently, if for any maximal ideal $\boldsymbol{p}$ of $\mathcal{O}_K$, the formal germ $\hat{V}_{K_{\boldsymbol{p}}}$ is $K_{\boldsymbol{p}}$-analytic in $X_{K_{\boldsymbol{p}}}$, and for any complex embedding $\sigma : K \hookrightarrow \mathbb{C}$, $\hat{V}_\sigma$ is $\mathbb{C}$-analytic in X_σ.

2. *the infinite product* $\prod_{\mathfrak{p}\nmid N} S_{\mathcal{X}_{\mathcal{O}_\mathfrak{p}}}(\hat{V}_{K_\mathfrak{p}})$ *is positive*, or equivalently,

$$\sum_{\mathfrak{p}\nmid N} \log S_{\mathcal{X}_{\mathcal{O}_\mathfrak{p}}}(\hat{V}_{K_\mathfrak{p}})^{-1} < +\infty.$$

This pair of conditions does not depend on the choices of the integer N and the model $(\mathcal{X}, \mathcal{P})$. Moreover, it is invariant under extension of the base field[7].

Recall that, if X is a variety over a number field K and P is some smooth point in $X(K)$, then the G-functions at the point P of X are the elements f in the completion $\mathcal{O}_{\hat{X}_P}$ of $\mathcal{O}_{X,P}$ defined by similar conditions: the analyticity at every place of K, and the positivity of the infinite product as in Condition 2 above, where $S_{\mathcal{X}_{\mathcal{O}_\mathfrak{p}}}(\hat{V}_{K_\mathfrak{p}})$ is replaced by $\min(1, R_\mathfrak{p})$, $R_\mathfrak{p}$ denoting the $\mathfrak{p}$-adic radius of convergence of f expressed in some fixed system of local coordinates on X at P (see for instance [2] and [22] for details and references).

It is straightforward that, if the graph $\mathrm{Gr}\, f$ of some f in $\mathcal{O}_{\hat{X}_P}$ – this graph is a smooth formal germ through $P' := (P, f(P))$ in $X' := X \times \mathbb{A}^1$ – is A-analytic, then f is a G-function. Let us emphasize that the converse does *not* hold[8].

Observe also that an algebraic smooth formal germ is always A-analytic. Even more, if $\hat{V}$ is an algebraic smooth formal germ in $\hat{X}_P$, where as above X denotes an algebraic variety over some number field K and P a point in $X(K)$, and if N is a positive integer and $(\mathcal{X}, \mathcal{P})$ some model of (X, P) over $\mathrm{Spec}\, \mathcal{O}_K[1/N]$, then almost all the sizes $S_{\mathcal{X}_{\mathcal{O}_\mathfrak{p}}}(\hat{V}_{K_\mathfrak{p}})$ are equal to one. Indeed, after "shrinking" $\mathrm{Spec}\, \mathcal{O}_K[1/N]$ to $\mathrm{Spec}\, \mathcal{O}_K[1/N']$, with N' a suitable multiple of N, the formal scheme $\hat{V}$ extends to a formal subscheme $\hat{\mathcal{V}}$ of the formal completion of $\mathcal{X}$ along $\mathcal{P}$ which is smooth along $\mathcal{P}$. (In substance, this observation goes back to the last memoir of Eisenstein [23], which may be considered as the starting point of the arithmetic theory of differential equations.)

Finally, observe that Proposition 4.1 admits the following straightforward consequence:

Corollary 4.2. *If X is a smooth algebraic variety over some number field K and if F is an involutive subbundle of T_X that satisfies the Grothendieck–Katz condition* (*see Introduction*)*, then the formal germ of leave of the so-defined algebraic foliation through any point P in $X(K)$ is A-analytic.*

[7] Namely, with the above notation, for any finite degree extension L of K, the formal germ $\hat{V}_L$ through P_L in the algebraic variety X_L over the number field L is A-analytic iff $\hat{V}$ is.

[8] For instance, the series $\log(1+x) := \sum_{n=1}^{+\infty} x^n/n \in \mathbb{Q}[[x]]$ defines a G-function at the point 0 in $\mathbb{A}^1_\mathbb{Q}$. However, its graph coincides with the transpose of the graph of the series $\exp y - 1 := \sum_{n=1}^{+\infty} y^n/n!$, which is not a G-function, and consequently is not an A-germ.

5. Condition L and canonical semi-norms

5.1. Consistent sequences of norms. Let k be a local field, X a projective scheme over k, and L a line bundle over X.

We may consider the following natural constructions of sequences of norms on the spaces of sections $\Gamma(X, L^{\otimes n})$:

1. When k is a p-adic field, with ring of integer $\mathcal{O}$, we may choose a pair $(\mathcal{X}, \mathcal{L})$, where $\mathcal{X}$ is a projective flat model of X over $\mathcal{O}$, and $\mathcal{L}$ a line bundle over $\mathcal{X}$ extending L. Then, for any integer n, the $\mathcal{O}$-module $\Gamma(\mathcal{X}, \mathcal{L}^{\otimes n})$ is (torsion-)free of finite rank and may be identified with an $\mathcal{O}$-lattice in the k-vector space $\Gamma(X, L^{\otimes n})$, and consequently defines a norm on the latter – namely, the norm $\| \, . \, \|_n$ such that a section $s \in \Gamma(X, L^{\otimes n})$ satisfies $\|s\|_n \leq 1$ iff s extends to a section of $\mathcal{L}^{\otimes n}$ over $\mathcal{X}$.

2. When $k = \mathbb{C}$ and X is reduced, we may consider any continuous norm $\| \, . \, \|_L$ on the $\mathbb{C}$-analytic line bundle L_{an} defined by L on the compact and reduced complex analytic space $X(\mathbb{C})$. Then, for any integer n, the space of algebraic regular sections $\Gamma(X, L^{\otimes n})$ may be identified with a subspace of the space of continuous sections of $L_{\mathrm{an}}^{\otimes n}$ over $X(\mathbb{C})$. Thus it is endowed with the restriction of the L^∞-norm, defined by:

$$\|s\|_{\mathrm{L}^\infty, n} := \sup_{x \in X(\mathbb{C})} \|s(x)\|_{L^{\otimes n}} \quad \text{for any } s \in \Gamma(X, L^{\otimes n}), \tag{5.1}$$

where $\| \, . \, \|_{L^{\otimes n}}$ denotes the continuous norm on $L_{\mathrm{an}}^{\otimes n}$ deduced from $\| \, . \, \|_L$ by taking the n-th tensor power.

This construction admits a variant where, instead of the sup-norms (5.1), one considers the L^p-norms defined by using some "Lebesgue measure" (*cf.* [12], 4.1.3, and [38], Théorème 3.10).

3. When $k = \mathbb{R}$ and X is reduced, the previous constructions define complex norms on the complex vector spaces

$$\Gamma(X, L^{\otimes n}) \otimes_{\mathbb{R}} \mathbb{C} \simeq \Gamma(X_{\mathbb{C}}, L_{\mathbb{C}}^{\otimes n})$$

and, by restriction, real norms on the real vector spaces $\Gamma(X, L^{\otimes n})$.

For any given k, X, and L as above, we shall say that two sequences $(\| \, . \, \|_n)_{n \in \mathbb{N}}$ and $(\| \, . \, \|'_n)_{n \in \mathbb{N}}$ of norms on the finite k-dimensional vector spaces $(\Gamma(X, L^{\otimes n}))_{n \in \mathbb{N}}$ are *equivalent* when, for some positive constant C and any positive integer n,

$$C^{-n} \, \| \, . \, \|'_n \leq \| \, . \, \|_n \leq C^n \, \| \, . \, \|'_n \, .$$

One easily checks that the previous constructions provide sequences of norms $(\| \, . \, \|_n)_{n \in \mathbb{N}}$ on the spaces $(\Gamma(X, L^{\otimes n}))_{n \in \mathbb{N}}$ which are all equivalent. A sequence of norms on these spaces equivalent to one (or, equivalently, to any) of the sequences thus constructed will be called *consistent*. This notion immediately extends to sequences $(\| \, . \, \|_n)_{n \geq n_0}$ of norms on the spaces $\Gamma(X, L^{\otimes n})$ defined for n large enough.

When the line bundle L is ample, consistent sequences of norms are provided by additional constructions. Indeed we have:

Proposition 5.1. *Let k be a local field, X a projective scheme over k, and L an* ample *line bundle over X. Let moreover Y be a closed subscheme of X, and assume X and Y reduced when k is archimedean.*

For any consistent sequence of norms $(\|\,.\,\|_n)_{n\in\mathbb{N}}$ on $(\Gamma(X, L^{\otimes n}))_{n\in\mathbb{N}}$, the quotient norms $(\|\,.\,\|'_n)_{n\in\mathbb{N}}$ on the spaces $(\Gamma(Y, L_{|Y}^{\otimes n}))_{n\geq n_0}$, deduced from the norms $\|\,.\,\|_n$ by means of the restriction maps $\Gamma(X, L^{\otimes n}) \longrightarrow \Gamma(Y, L_{|Y}^{\otimes n})$ – which are surjective for $n \geq n_0$ large enough since L is ample – *constitute a consistent sequence.*

When k is archimedean, this is proved in [13], Appendix, by introducing a positive metric on L, as a consequence of Grauert's finiteness theorem for pseudo-convex domains applied to the unit disk bundle of $\check{L}$ (see also [38]). When k is a p-adic field with ring of integers $\mathcal{O}$, Proposition 5.1 follows from the basic properties of ample line bundles over projective $\mathcal{O}$-schemes.

Let E be a finite dimensional vector space over the local field k, equipped with some norm, supposed to be euclidean or hermitian in the archimedean case. This norm induces similar norms on the tensor powers $E^{\otimes n}$, $n \in \mathbb{N}$, hence – by taking the quotient norms – on the symmetric powers $S^n E$. If X is the projective space $\mathbb{P}(E) := \operatorname{Proj} \operatorname{Sym}^{\cdot}(E)$ and L the line bundle $\mathcal{O}(1)$, then the canonical isomorphisms $S^n E \simeq \Gamma(X, L^{\otimes n})$ allow one to see these norms as a sequence of norms on $(\Gamma(X, L^{\otimes n}))_{n\in\mathbb{N}}$. One easily checks that this sequence is consistent[9].

For any closed subvariety Y in $\mathbb{P}(E)$ and any $n \in \mathbb{N}$, we may consider the commutative diagram of k-linear maps:

$$\begin{array}{ccccc} S^n E & \xrightarrow{\sim} & S^n \Gamma(\mathbb{P}(E), \mathcal{O}(1)) & \xrightarrow{\sim} & \Gamma(\mathbb{P}(E), \mathcal{O}(n)) \\ & & \downarrow & & \downarrow{\scriptstyle \alpha_n} \\ & & S^n \Gamma(Y, \mathcal{O}(1)) & \xrightarrow{\beta_n} & \Gamma(Y, \mathcal{O}(n)) \end{array}$$

where the vertical maps are the obvious restriction morphisms. The maps α_n, and consequently β_n, are surjective if n is large enough.

Together with Proposition 5.1, these observations yield the following corollary:

Corollary 5.2. *Let k, E and Y a closed subscheme[10] of $\mathbb{P}(E)$ be as above. Let us choose a norm on E (resp. on $\Gamma(Y, \mathcal{O}(1))$) and let us equip $S^n E$ (resp. $S^n \Gamma(Y, \mathcal{O}(1))$) with the induced norm, for any $n \in \mathbb{N}$.*

Then the sequence of quotient norms on $\Gamma(Y, \mathcal{O}(n))$ defined, when n is large enough, by means of the surjective morphisms $\alpha_n \colon S^n E \longrightarrow \Gamma(Y, \mathcal{O}(n))$ (resp. by $\beta_n \colon S^n \Gamma(Y, \mathcal{O}(1)) \longrightarrow \Gamma(Y, \mathcal{O}(n))$) is consistent.

5.2. Conditions L and $\mathbf{L}_v$. Let k be a local field, and X a projective integral scheme over k, equipped with an ample line bundle L. Moreover let $\hat{V} \hookrightarrow \hat{X}_P$ be a smooth

[9] This is straightforward in the p-adic case. When k is archimedean, this follows for instance from [15], Lemma 4.3.6.

[10] reduced if k is archimedean.

formal germ in X through a point $P \in X(k)$, and consider its tangent space $T_P\hat{V}$, the fiber L_P of L at P, and the evaluation maps

$$\gamma_D^i : \Gamma(X, \mathcal{I}_{V_{i-1}} \otimes L^{\otimes D}) \longrightarrow S^i \check{T}_{\hat{V}} \otimes L_P^{\otimes D} \tag{5.2}$$

introduced in Section 2.

Let us choose a consistent sequence of norms $(\| \, . \, \|_n)_{n\in\mathbb{N}}$ on the k-vector spaces $(\Gamma(X, L^{\otimes n}))_{n\in\mathbb{N}}$, and arbitrary norms $\| \, . \, \|_{T_P\hat{V}}$ on $T_P\hat{V}$ and $\| \, . \, \|_{L_P}$ on L_P. Then we may consider the operator norms $\|\gamma_D^i\|$ of the maps (5.2) and their logarithms $\log \|\gamma_D^i\|$ in $[-\infty, +\infty[$.

We shall say that $\hat{V}$ *satisfies condition* L when

$$\lim_{i/D\to+\infty} \frac{1}{i} \log \|\gamma_D^i\| = -\infty. \tag{5.3}$$

Clearly this condition does not depend on the above choices of norms. It is also invariant by extension of the local field k, and is easily seen not to depend on the choice of the ample line bundle L. Proposition 5.1 also implies that it is invariant under "reembedding" of X into some larger projective variety.

Moreover condition L is birationally invariant in the following sense: if $X' \dashrightarrow X$ is a birational map between projective varieties over k that define an isomorphism $f : U' \xrightarrow{\sim} U$ between non-empty open subvarieties in X' and X, and if P belongs to $U(k)$, then a smooth formal germ $\hat{V}$ through P in X satisfies L iff the smooth formal germ $f^*\hat{V}$ through $P' := f_{|U'}^{-1}(P)$ in X' does. (See [13], 3.2, when k is archimedean and $\dim \hat{V} = 1$; the general case is similar.)

As a consequence, condition L makes sense for a smooth formal germ $\hat{V} \hookrightarrow \hat{X}_P$ through a k-rational point in a general algebraic variety X over k – namely, if U is any quasi-projective open neighbourhood of P in X and if $\tilde{X}$ is a projective completion of U, we shall say that $\hat{V}$ satisfies L when $\hat{V}$ seen as a formal subscheme of $\tilde{X}$ satisfies it. Again, this condition is invariant under extension of k and reembedding of X.

Finally, if K is a number field and v a place of K, we shall say that a smooth formal subscheme $\hat{V} \hookrightarrow \hat{X}_P$ through a rational point P in a variety X over K satisfies *condition* L_v when the formal subscheme $\hat{V}_{K_v}$ through P in X_{K_v}, deduced from $\hat{V}$ by extension of scalars from K to the completion K_v of K at v, satisfies condition L over the local field K_v.

5.3. Condition L over $\mathbb{C}$ and Liouville complex manifolds. A connected complex manifold M is said to satisfy the *Liouville property*, or to be a *Liouville complex manifold,* when every bounded plurisubharmonic function on M is constant. In particular, the connected Riemann surfaces satisfying the Liouville property are precisely the ones which are "parabolic" in the sense of Myrberg, or equivalently, have "null-boundary" in the sense of R. Nevanlinna.

The following observations are straightforward consequences of the basic properties of plurisubharmonic functions and algebraic varieties:

1. Let $\pi : M \longrightarrow N$ be a surjective analytic map between connected complex manifolds. If M is Liouville, then N is Liouville. Conversely, when π has smooth connected fibers, if N and the fibers of π are Liouville, then M also is Liouville.
2. The complement of any closed pluripolar subset (for instance, a lower dimensional analytic subset) in a Liouville complex manifold is again Liouville.
3. Any compact connected complex manifold is Liouville.
4. The manifold of complex points of any smooth connected complex algebraic variety is Liouville.
5. Any connected complex Lie group is a Liouville complex manifold.

Over archimedean local fields, the property L may be checked in various significant cases by means of the following criterion:

Proposition 5.3 ([12], Proposition 4.12)). *Let X be a complex algebraic variety, P a point in $X(\mathbb{C})$, and $\hat{V} \hookrightarrow \hat{X}_P$ a smooth formal germ through P.*

Let us assume that there exist a connected complex manifold M, a point O in M, and a $\mathbb{C}$-analytic map $\varphi : M \longrightarrow X(\mathbb{C})$ sending O to P that induces an isomorphism of formal germs

$$\hat{\varphi}_O : \hat{M}_O \xrightarrow{\sim} \hat{V}. \tag{5.4}$$

If furthermore M is Liouville, then $\hat{V}$ satisfies L.

5.4. Germs of analytic curves in algebraic varieties over local fields and canonical semi-norms. In this paragraph, we return to the notation of the beginning of 5.2, and we assume that the smooth formal germ $\hat{V}$ is *one-dimensional* and *k-analytic*. Then, by means of the evaluation maps γ_D^i (see (5.2)) and their operator norms, as in the definition of condition L by (5.3), we may define some *canonical semi-norm* $\| \, . \, \|_{P,\hat{V}}^{\mathrm{can}}$ on the k-line $T_P\hat{V}$ as follows. We consider

$$\rho := \limsup_{i/D \to +\infty} \frac{1}{i} \log \left\| \gamma_D^i \right\|.$$

A straightforward application of Cauchy's inequalities shows that it belongs to $[-\infty, +\infty[$, and therefore by setting

$$\| \, . \, \|_{P,\hat{V}}^{\mathrm{can}} := e^{\rho} \| \, . \, \|_{T_P\hat{V}},$$

we define a semi-norm on $T_P\hat{V}$.

For a given projective variety X containing $\hat{V}$, one easily checks that it depends neither on the auxiliary choices of norms, nor on the ample line bundle L. Actually, like condition L, the canonical semi-norm $\| \, . \, \|_{P,\hat{V}}^{\mathrm{can}}$ is invariant under "reembedding" of X in some larger projective variety, and by birational isomorphisms which are isomorphisms in some neighbourhood of P ([13], 3.2–3.3, and [14]). Consequently,

the canonical semi-norm on $T_P\hat{V}$ may be defined for any smooth analytic germ of curve $\hat{V} \hookrightarrow \hat{X}_P$ through a rational point in an algebraic scheme over k.

In the p-adic case, Cauchy's inequalities lead actually to the following upper bound on the canonical semi-norm in terms of the size relative to some model:

Lemma 5.4. *Let k be a p-adic field, $\mathcal{O}$ its ring of integers, and $\mathcal{X}$ a separated scheme of finite type over $\mathcal{O}$ equipped with a section P. Let $\hat{V}$ be a smooth formal subscheme of the formal completion $\hat{X}_{P_k}$ of $X := \mathcal{X}_k$ at P_k. If $\hat{V}$ is one-dimensional and analytic, and if $\|\,.\,\|^{\mathcal{X}}_{T_P\hat{V}}$ denotes the p-adic norm on the k-line $T_P\hat{V}$ defined by the integral model $\mathcal{X}$*[11]*, then we have:*

$$\|\,.\,\|^{\mathrm{can}}_{P,\hat{V}} \leq S_{\mathcal{X}}(\hat{V})^{-1}.\,\|\,.\,\|^{\mathcal{X}}_{T_P\hat{V}}\,.$$

Finally observe that the construction of $\|\,.\,\|^{\mathrm{can}}_{P,\hat{V}}$ is compatible with (finite degree) extensions of the local field k.

5.5. Canonical semi-norms and capacity. Recall that, if M is a Riemann surface, O a point of M, and Ω an open neighbourhood of O that is relatively compact in M and has a non-empty sufficiently regular boundary[12], we may consider the *Green function of O in Ω*, namely the continuous function $g_{O,\Omega}\colon \overline{\Omega} \setminus \{O\} \to \mathbb{R}_+$ which vanishes on the boundary of Ω, is harmonic on $\Omega \setminus \{O\}$, and possesses a logarithmic singularity at O. In other words, if z denotes some holomorphic coordinates on some open neighbourhood U of O, we have

$$g_{O,\Omega} = \log|z - z(O)|^{-1} + h \quad \text{on } U \setminus \{O\},$$

where h is a harmonic function on U. From the value of h at O, one defines the *capacitary norm* $\|\,.\,\|^{\mathrm{cap}}_{O,\Omega}$ on the complex line $T_O M = \mathbb{C}\frac{\partial}{\partial z}_{|O}$ by

$$\|\frac{\partial}{\partial z}_{|O}\|^{\mathrm{cap}}_{O,\Omega} := e^{-h(O)} = \lim_{Q \to O} \frac{e^{-g_{O\Omega}(Q)}}{|z(Q) - z(O)|}. \tag{5.5}$$

Proposition 5.5 ([13], Proposition 3.6). *With the above notation, if $f\colon \Omega \to X$ is a holomorphic map with value in some complex algebraic variety X, and if C denotes some germ of smooth analytic curve through $P := f(O)$ in X such that f maps the germ of Ω at O to C, then, for any v in $T_O M$,*

$$\|Df(O)v\|^{\mathrm{can}}_{P,C} \leq \|v\|^{\mathrm{cap}}_{O,\Omega}.$$

[11] By definition, the unit disk in $\check{T}_P\hat{V}$ equipped with the norm dual to $\|\,.\,\|^{\mathcal{X}}_{T_P\hat{V}}$ is the $\mathcal{O}$-lattice image of the composite map $P^*\Omega^1_{\mathcal{X}/\mathcal{O}} \to \Omega^1_{X/k|P_k} \twoheadrightarrow \check{T}_P\hat{V}$.

[12] say, a domain with differentiable non-empty boundary, or in other terms, the interior of some connected 2-dimensional submanifold with non-empty boundary. See also [11], especially A.8, for weaker conditions.

The construction of the Green function $g_{P,\Omega}$ admits analogues over p-adic curves, developed in particular by Rumely [39] and Thuillier [41] (see also [14] for a more "algebraic" approach relying on formal geometry). This Green function makes sense for instance when M is a smooth projective geometrically connected algebraic curve over some p-adic field k, O is some point in $M(k)$, and Ω is defined as the complement of some non-empty affinoid subspace of X that does not contain P. It has a logarithmic singularity at O and the equation (5.5) still makes sense and defines the capacitary norm as a p-adic norm on the k-line $T_O M$. Moreover Proposition 5.5 still holds with k instead of $\mathbb{C}$ as a base field, and "rigid analytic" instead of "holomorphic" (*cf.* [14], Sections 6 and 7).

6. An algebraicity criterion for smooth formal germs in varieties over number fields

6.1. An algebraization theorem. The following theorem provides sufficient conditions of algebraicity for a formal subscheme of the formal completion $\hat{X}_P$ of some algebraic variety X over a number field K at a rational point $P \in X(K)$.

Theorem 6.1. *Let X be an algebraic variety over a number field K, P a point in $X(K)$, and $\hat{V}$ a smooth formal subscheme of the completion $\hat{X}_P$ of X at P.*

If $\hat{V}$ is A-analytic and satisfies condition L_v for some place v of K, then $\hat{V}$ is algebraic.

This theorem is proved by using the algebraicity criterion (iii) $\Rightarrow$ (i) in Proposition 2.1. Validity of condition (iii) is derived by means of slope inequalities, involving now heights of K-linear maps and arithmetic slopes attached to hermitian vector bundles over $\operatorname{Spec} \mathcal{O}_K$, in the spirit of the proof of Theorem 3.1. See [12], Section 4 when the place v is archimedean; the general case is similar.

6.2. Algebraic leaves of algebraic foliations over number fields. Combined with Corollary 4.2 and Proposition 5.3, Theorem 6.1 admits the following consequence:

Theorem 6.2 ([12], Theorem 2.1). *Let X be a smooth algebraic variety over a number field K equipped with an involutive subbundle F, and let P be point in $X(K)$. If* (i) *the algebraic foliation (X, F) satisfies the Grothendieck–Katz condition, and* (ii) *for some field embedding $\sigma_0 \colon K \hookrightarrow \mathbb{C}$, the analytic leaf through P of the complex analytic foliation $(X(\mathbb{C}), F_{\mathbb{C}})$ is Liouville, then the leaf of (X, F) through P is algebraic.*

6.3. Algebraic Lie subalgebras of algebraic groups over number fields. Let G be an algebraic group over a number field K. For any sufficiently divisible integer N, there exists a model $\mathcal{G}$ of G, *i.e.*, a smooth quasi-projective group scheme over $S := \operatorname{Spec} \mathcal{O}_K[1/N]$ whose generic fiber $\mathcal{G}_K$ coincides with G. The restriction to the zero-section of $\mathcal{G}$ of the relative tangent bundle $T_{\mathcal{G}/S}$ defines the Lie algebra $\operatorname{Lie} \mathcal{G}$ of $\mathcal{G}$:

it is a finitely generated projective module and a Lie algebra over $\mathcal{O}_K[1/N]$, and the K-Lie algebra $(\mathrm{Lie}\,\mathcal{G})_K$ is canonically isomorphic to $\mathrm{Lie}\,G$.

Moreover, for every maximal ideal $\boldsymbol{p}$ of $\mathcal{O}_K[1/N]$ with residue field $\mathbb{F}_{\boldsymbol{p}}$ of characteristic p, the $\mathbb{F}_{\boldsymbol{p}}$-Lie algebra $(\mathrm{Lie}\,\mathcal{G})_{\mathbb{F}_{\boldsymbol{p}}}$ is canonically isomorphic to the Lie algebra of the smooth algebraic group $\mathcal{G}_{\mathbb{F}_{\boldsymbol{p}}}$ over the finite field $\mathbb{F}_{\boldsymbol{p}}$, and is therefore endowed with a p-th power map, given by the restriction of the p-th power map on global sections of $T_{\mathcal{G}_{\mathbb{F}_{\boldsymbol{p}}}}$ to the left-invariant ones.

For translation invariant foliations on G, Theorem 6.2 takes the following form which proves a conjecture of Ekedahl, Shepherd-Barron, and Taylor ([24]):

Theorem 6.3 ([12], Theorem 2.3). *For any Lie subalgebra* $\boldsymbol{h}$ *of* $\mathrm{Lie}\,G$ (*defined over* K)*, the following two conditions are equivalent:*

(i) *For almost every maximal ideal* $\boldsymbol{p}$ *of* $\mathcal{O}_K[1/N]$*, the* $\mathbb{F}_{\boldsymbol{p}}$*-Lie subalgebra* $(\boldsymbol{h} \cap \mathrm{Lie}\,\mathcal{G})_{\mathbb{F}_{\boldsymbol{p}}}$ *of* $\mathrm{Lie}\,\mathcal{G}_{\mathbb{F}_{\boldsymbol{p}}}$ *is closed under* p*-th powers.*

(ii) $\boldsymbol{h}$ *is an algebraic Lie subalgebra of* $\mathrm{Lie}\,G$.

6.4. Ogus conjecture on absolute Tate cycles in abelian varieties. Theorem 6.3 may be extended to the case where the field K is any extension of finite type of $\mathbb{Q}$, in the spirit of the original formulation of the Grothendieck–Katz conjecture [31]. In this section, we discuss some consequence of this generalization.

Let K be a field of characteristic zero, extension of finite type of $\mathbb{Q}$, and let X be a proper and smooth scheme over K. We can find models of X and K which are smooth over $\mathrm{Spec}\,\mathbb{Z}$ – namely an integral affine scheme $S = \mathrm{Spec}\,R$ smooth over $\mathrm{Spec}\,\mathbb{Z}$ such that K is the function field $\kappa(S)$ of S, and a proper and smooth scheme $\mathcal{X}$ over S such that $X = \mathcal{X}_K$. After possibly shrinking S, we can also assume that the Hodge cohomology groups $H^q(\mathcal{X}, \Omega^p_{\mathcal{X}/S})$ are flat R-modules. This implies that the formation of the (relative) Hodge and de Rham cohomology groups of $\mathcal{X}$ is compatible with any base change $S' \to S$ and the degeneracy of the "Hodge to de Rham" spectral sequence.

Let k be a perfect field of characteristic $p > 0$, W its ring of Witt vectors, $\overline{\sigma}$ a point in $S(k)$, and σ a lift of $\overline{\sigma}$ in $S(W)$. The crystalline cohomology groups $H^i_{\mathrm{cris}}(\mathcal{X}_{\overline{\sigma}}/W)$ are W-modules attached to the k-scheme $\mathcal{X}_{\overline{\sigma}}$. By functoriality, the absolute Frobenius endomorphism of $\mathcal{X}_{\overline{\sigma}}$ induces a Frobenius-linear endomorphism Φ of the W-module $H^i_{\mathrm{cris}}(\mathcal{X}_{\overline{\sigma}}/W)$. Besides, the comparison theorem of Berthelot ([8]) provides a canonical isomorphism from this W-module onto the de Rham cohomology $H^i_{\mathrm{dR}}(\mathcal{X}_\sigma/W) \simeq H^i_{\mathrm{dR}}(\mathcal{X}/R) \otimes_\sigma W$. Consequently, Φ defines a semi-linear endomorphism Φ_σ of the W-module $H^i_{\mathrm{dR}}(\mathcal{X}/R) \otimes_\sigma W$.

Let r be an integer in $\{0, \ldots, \dim X\}$. Following the terminology of Ogus in [36], a class ξ in the algebraic de Rham cohomology group $H^{2r}_{\mathrm{dR}}(\mathcal{X}/S)$ over R is said to be *absolutely Tate* iff, for any p, k, and σ as above[13], the equality

$$\Phi_\sigma(\xi) = p^r \xi$$

[13] Actually, one might consider only some "limited" classes of fields k and points $\overline{\sigma}$ in $\mathcal{X}(k)$ – for instance, closed points, or geometric generic points of the fibres of $S \to \mathrm{Spec}\,\mathbb{Z}$ – which still define the same condition.

holds in $H^{2r}_{\mathrm{dR}}(\mathcal{X}/S)\otimes_\sigma W$. More generally a class ξ in $H^{2r}_{\mathrm{dR}}(X/K)$ is said to be absolutely Tate if, after possibly replacing S by some non-empty affine open subscheme, it is absolutely Tate in $H^{2r}_{\mathrm{dR}}(\mathcal{X}/S)$.

For instance, any algebraic class, namely any class in the image of the "cycle class" map $Z^r(X)_{\mathbb{Q}} \longrightarrow H^{2r}_{\mathrm{dR}}(X/K)$, is absolutely Tate. Ogus ([36], Section 2) conjectured that the converse holds, that is:

O(X, r): *every absolutely Tate class in* $H^{2r}_{\mathrm{dR}}(X/K)$ *is algebraic.*

As a consequence of the aforementioned generalization[14] of Theorem 6.3 to algebraic groups over K, we can prove:

Theorem 6.4. *For any field extension K of finite type of $\mathbb{Q}$, the conjecture* O(X, r) *holds when X is an abelian variety over K and $r = 1$.*

See also [3], Section 7.4, for a discussion of an essentially equivalent theorem, which characterizes the K-linear maps between the first de Rham cohomology groups of abelian varieties over a number field K induced by morphisms of K-varieties, up to isogeny, as the ones compatible with (almost all) the crystalline Frobenius maps[15].

The derivation of Theorem 6.4 relies on the identification of the Lie algebra of the universal vector extension of the dual abelian variety $\hat{X}$ with the de Rham cohomology group $H^1_{\mathrm{dR}}(X/K)$, and on the fact that the p-th power map on the reduction of this Lie algebra at some closed point $\boldsymbol{p}$ in S of residue characteristic p coincides with the reduction modulo p of the crystalline Frobenius at $\boldsymbol{p}$.

7. An algebraicity criterion for smooth formal curves in varieties over number fields

7.1. Normed and semi-normed lines over number fields. We define a *normed line*

$$\bar{L} := (L_K, (\|\,.\,\|_{\boldsymbol{p}}), (\|\,.\,\|_\sigma))$$

over a number field K as the data of a rank one K-vector space L_K, of a family $(\|\,.\,\|_{\boldsymbol{p}})$ of $\boldsymbol{p}$-adic norms on the $K_{\boldsymbol{p}}$-lines $L_K\otimes_K K_{\boldsymbol{p}}$ indexed by the non-zero prime ideals $\boldsymbol{p}$ of $\mathcal{O}_K$, and of a family $(\|\,.\,\|_\sigma)$ of hermitian norms on the complex lines $L_K\otimes_{K,\sigma}\mathbb{C}$, indexed by the fields embeddings $\sigma\colon K\hookrightarrow\mathbb{C}$. Moreover the family $(\|\,.\,\|_\sigma)$ is required to be stable under complex conjugation[16].

[14] This generalization concerns an algebraic group G over K, and a smooth group scheme $\mathcal{G}$ extending it over S; in condition (i) in Theorem 6.3, one now requires the p-closure condition to hold for every closed point $\boldsymbol{p}$ in some non-empty open subscheme of S over which $\boldsymbol{h}$ extends as a subvector bundle of Lie $\mathcal{G}$. Its proof relies on the fact that a complex manifold is Liouville when it may be fibered over a complex algebraic variety with fibers some complex Lie groups.

[15] The author became aware of Ogus conjecture in the above formulation while reading a preliminary version of Y. André's beautiful survey on motives [3], and realized that, when K is a number field, X an abelian variety, and $r = 1$, it would be a consequence of Theorem 6.3. Actually, in [36], Section 2, Ogus formulates more general conjectures, stated in terms of the conjugate filtration on $H^*_{\mathrm{dR}}(X/K)$ and its reductions, and asks explicitly about the validity of O(X, r) only when K is a number field.

We shall say that a normed K-line is *summable* if for some (or equivalently, for any) non-zero element l of L_K, the family of real numbers $(\log \|l\|_{\boldsymbol{p}})_{\boldsymbol{p}}$ is summable. Then we may define its *Arakelov degree* as the real number

$$\widehat{\deg}\, \bar{L} := \sum_{\boldsymbol{p}} \log \|l\|_{\boldsymbol{p}}^{-1} + \sum_{\sigma} \log \|l\|_{\sigma}^{-1}. \tag{7.1}$$

Indeed, by the product formula, the right-hand side of (7.1) does not depend on the choice of l.

Observe that hermitian line bundles over $\operatorname{Spec} \mathcal{O}_K$, as usually defined in Arakelov geometry, provide examples of normed lines over K: if $\bar{\mathcal{L}} = (\mathcal{L}, (\|\,.\,\|_{\sigma})_{\sigma\colon K \hookrightarrow \mathbb{C}})$ is such an hermitian line bundle – so $\mathcal{L}$ is a projective $\mathcal{O}_K$-module of rank 1, and $(\|\,.\,\|_{\sigma})_{\sigma\colon K \hookrightarrow \mathbb{C}})$ is a family, invariant under complex conjugation, of norms on the complex lines $\mathcal{L}_{\sigma} := \mathcal{L} \otimes_{\sigma\colon \mathcal{O}_K \to \mathbb{C}} \mathbb{C}$ – the corresponding normed K-line is $\mathcal{L}_K$ equipped with the p-adic norms defined by the $\mathcal{O}_{\boldsymbol{p}}$-lattices $\mathcal{L} \otimes_{\mathcal{O}_K} \mathcal{O}_{\boldsymbol{p}}$ in $\mathcal{L} \otimes_{\mathcal{O}_K} K_{\boldsymbol{p}} \simeq L \otimes_K K_{\boldsymbol{p}}$ and with the hermitian norms $(\|\,.\,\|_{\sigma})$. The so-defined normed lines are summable, and their Arakelov degree, as defined by (7.1), coincide with the usual Arakelov degree of hermitian line bundles.

It is convenient to extend the definitions of normed lines and Arakelov degree as follows: we shall define a *semi-normed K-line* $\bar{L}$ as a K-vector space L_K of rank one, equipped with families of *semi-norms* $(\|\,.\,\|_{\boldsymbol{p}})$ and $(\|\,.\,\|_{\sigma})$, where the latter is assumed to be stable under complex conjugation. In other words, we allow some of the $\|\,.\,\|_{\boldsymbol{p}}$ or $\|\,.\,\|_{\sigma}$ to vanish.

We shall say that the Arakelov degree of a semi-normed K-line $\bar{L}$ is *well-defined* if, for some (or equivalently, for any), non-zero element l of L_K, the family of real numbers $(\log^+ \|l\|_{\boldsymbol{p}})_{\boldsymbol{p}}$ is summable. Then we may again define its Arakelov degree by means of (7.1), where we follow the usual convention $\log 0^{-1} = +\infty$. It is an element of $]-\infty, +\infty]$.

7.2. Arithmetic positivity and algebraicity of A-germs of curves. The following algebraicity criterion is a refined version of Theorem 6.1, concerning formal germs of curves:

Theorem 7.1 ([14]). *Let X be an algebraic variety over a number field K, P a point in $X(K)$, and $\hat{V}$ a smooth formal subscheme of dimension* 1 *in the completion $\hat{X}_P$ of X at P.*

Assume that the following two conditions are satisfied:

(i) *$\hat{V}$ is A-analytic;*

(ii) *the semi-normed K-line*

$$\overline{T}_P \hat{V}^{\mathrm{can}} := (T_P \hat{V}, (\|\,.\,\|^{\mathrm{can}}_{P, \hat{V}_{K_{\boldsymbol{p}}}}), (\|\,.\,\|^{\mathrm{can}}_{P, \hat{V}_{\sigma}})),$$

[16] The data of these families of norms is equivalent to the data of a family $(\|\,.\,\|_v)_v$, indexed by the set of all places v of K, of v-adic norms on the rank one vector spaces $L_v := L_K \otimes_K K_v$ over the v-adic completions K_v of K.

defined by endowing $T_P\hat{V}$ with its canonical semi-norm at every place of K, satisfies

$$\widehat{\deg}\,\overline{T}_P\hat{V}^{\mathrm{can}} > 0. \tag{7.2}$$

Then $\hat{V}$ is algebraic.

Observe that, as a consequence of Lemma 5.4, the Arakelov degree of $\overline{T}_P\hat{V}^{\mathrm{can}}$ is well defined in $]-\infty,+\infty]$ when Condition (i) is satisfied. Moreover it takes the value $+\infty$ if there exists some place v of K such that Condition L_v is satisfied.

7.3. A rationality criterion for formal germs of functions on algebraic curves over number fields. Let K be a number field, $\mathcal{C}$ a regular projective arithmetic surface over $\operatorname{Spec}\mathcal{O}_K$ whose generic fiber $C := \mathcal{X}_K$ is geometrically connected, P a point in $X(K)$, and $\mathcal{P}$ in $\mathcal{X}(\mathcal{O}_K)$ extending P.

Let F be a finite set of closed points in $\operatorname{Spec}\mathcal{O}_K$ and, for any $\boldsymbol{p}$ in F, let $\Omega_{\boldsymbol{p}}$ be the complement in the rigid curve $X_{K_{\boldsymbol{p}}}$ of some affinoid not containing $P_{K_{\boldsymbol{p}}}$. Moreover, for any embedding $\sigma\colon K \to \mathbb{C}$, let Ω_σ be an open neighbourhood of P_σ in the Riemann surface $C_\sigma(\mathbb{C})$, which for simplicity we suppose to be domains with differentiable non-empty boundaries. We shall assume that the data of the Ω_σ's are compatible with complex conjugation, namely, that for any embedding σ, $\Omega_{\bar{\sigma}}$ is the complex conjugate of Ω_σ.

Let finally $\overline{T}_P^{\mathrm{cap}}C := (T_PC, (\|\,.\,\|_{\boldsymbol{p}}), (\|\,.\,\|_\sigma))$ be the semi-normed line over K defined by the tangent line T_C of C at P, equipped with the $\boldsymbol{p}$-adic norm $\|\,.\,\|_{\boldsymbol{p}} := \|\,.\,\|^{\mathrm{cap}}_{P_{K_{\boldsymbol{p}}},\Omega_{\boldsymbol{p}}}$ if $\boldsymbol{p}$ belongs to F, and otherwise with the $\boldsymbol{p}$-adic norm deduced from the integral structure on $N_{\mathcal{P}}\mathcal{X}$ (through the isomorphism $T_PC\otimes_K K_{\boldsymbol{p}} \simeq N_{\mathcal{P}}\mathcal{X}\otimes_{\mathcal{O}_K} K_{\boldsymbol{p}}$). Its Arakelov degree is clearly defined.

The following theorem extends the classical rationality criteria of Borel–Dwork and Polya–Bertrandias (*cf.* [21] and [1], Chapter 5); one recovers them in the special case $C = \mathbb{P}^1_K$.

Theorem 7.2 ([14]). *With the above notation, let $\varphi \in \hat{\mathcal{O}}_{C,P}$ be a formal germ of function on C at P, and assume that the following conditions are satisfied:*

(i) *for any $\boldsymbol{p}$ in F (resp. any embedding $\sigma\colon k \hookrightarrow \mathbb{C}$), after the base change $K \hookrightarrow K_{\boldsymbol{p}}$ (resp. σ), φ extends to a rigid meromorphic function on $\Omega_{\boldsymbol{p}}$ (resp. to a meromorphic function on Ω_σ);*

(ii) *the formal function φ extends to a formal rational function on the completion $\hat{\mathcal{X}}_{\mathcal{P}}$ over* $\operatorname{Spec}\mathcal{O}_K \setminus F$*;*

(iii) $\widehat{\deg}\,\overline{T}_P^{\mathrm{cap}}C > 0$.

Then φ is rational, i.e.*, is an element of the local ring $\mathcal{O}_{X,P} \subset \hat{\mathcal{O}}_{X,P}$.*

To establish Theorem 7.2, we consider the graph of φ. It is a formal germ of curve through the point $(P,\varphi(P))$ in the algebraic variety $X := C\times\mathbb{P}^1_K$ over K. From

Theorem 7.1, Proposition 5.5, and its p-adic analogue, we derive that this graph is algebraic. Finally, we show that it is the germ of graph of some rational function on C by applying a generalization of the connectedness theorems in [11], Section 4.

Derived categories of coherent sheaves

Tom Bridgeland

Abstract. We discuss derived categories of coherent sheaves on algebraic varieties. We focus on the case of non-singular Calabi–Yau varieties and consider two unsolved problems: proving that birational varieties have equivalent derived categories, and computing the group of derived autoequivalences. We also introduce the space of stability conditions on a triangulated category and explain its relevance to these two problems.

Mathematics Subject Classification (2000). 18E30, 14J32.

Keywords. Derived categories, coherent sheaves.

1. Introduction

In the usual approach to the study of algebraic varieties one focuses directly on geometric properties of the varieties in question. Thus one considers embedded curves, hyperplane sections, branched covers and so on. A more algebraic approach is to study the varieties indirectly via their (derived) categories of coherent sheaves. This second approach has been taken up by an increasing number of researchers in the last few years. We can perhaps identify three reasons for this new emphasis on categorical methods.

Firstly, algebraic geometers have been attempting to understand string theory. The conformal field theory associated to a variety in string theory contains a huge amount of non-trivial information. However this information seems to be packaged in a categorical way rather than in directly geometric terms. This perhaps first became clear in Kontsevich's famous homological mirror symmetry conjecture [31]. Building on Kontsevich's work, it is now understood that the derived category of coherent sheaves appears in string theory as the category of branes in a topological twist of the sigma model. This means that many dualities in string theory can be described mathematically as equivalences of derived categories.

A second motivation for studying varieties via their sheaves is that this approach is expected to generalise more easily to non-commutative varieties. Although the definition of such objects is not yet clear, there are many interesting examples. In general non-commutative objects have no points in the usual sense, so that direct geometrical methods do not apply. Nonetheless one can hope that the (derived) category of coherent sheaves is well-defined and has similar properties to the corresponding object in the commutative case.

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

A third reason is that recent results leave the impression that categorical methods enable one to obtain a truer description of certain varieties than current geometric techniques allow. For example many equivalences relating the derived categories of pairs of varieties are now known to exist. Any such equivalence points to a close relationship between the two varieties in question, and these relationships are often impossible to describe by other methods. Similarly, some varieties have been found to have interesting groups of derived autoequivalences, implying the existence of symmetries associated to the variety that are not visible in the geometry. It will be interesting to see whether a more geometric framework for these phenomena emerges over the next few years.

Despite a lot of recent work our understanding of derived categories of coherent sheaves is still quite primitive. To illustrate this we shall focus in this paper on two easily stated problems, both of which have been around since Bondal and Orlov's pioneering work in the nineties [5], and both of which remain largely unsolved. Of course the choice of these problems is very much a matter of personal taste. Other survey articles are available by Bondal and Orlov [7], by Hille and van den Bergh [19] and by Rouquier [45].

Of the many important contributions not discussed in detail here, we must at least mention Kuznetsov's beautiful work on semi-orthogonal decompositions for Fano varieties. As well as specific results on Fano threefolds, Kuznetsov has obtained a general theory of homological projective duality with many applications to derived categories of varieties of interest in classical algebraic geometry. The theory also leads to some extremely interesting derived equivalences between non-commutative varieties. For more details we refer the reader to the original papers [32], [33], [34], [35].

Acknowledgements. I am very grateful to Antony Maciocia for teaching me about derived categories in the first place, and to Alastair King, Miles Reid and Richard Thomas for explaining many things since then. The material in Section 5 has benefited from discussions with Yukinobu Toda. The author is supported by a Royal Society University Research Fellowship.

Notation. We write $\mathrm{D}(X) := \mathrm{D}^b \operatorname{Coh}(X)$ for the bounded derived category of coherent sheaves on a variety X. All varieties are assumed to be over the complex numbers.

2. Some basic problems

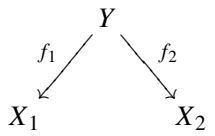
In this section we describe the basic problems we shall focus on and review some of the known results relating to them.

2.1. The following conjecture was first made by Bondal and Orlov [5].

Conjecture 2.1 (Bondal, Orlov). If X_1 and X_2 are birational smooth projective Calabi–Yau varieties of dimension n then there is an equivalence of categories $\mathrm{D}(X_1) \cong \mathrm{D}(X_2)$.

So far this is only known to hold in dimension $n = 3$. We shall describe the proof in this case in Section 3 below. There are also some local results available in all dimensions.

Theorem 2.2 (Bondal, Orlov [5]). *Suppose that X_1 and X_2 are related by a standard flop, so that there is a diagram*

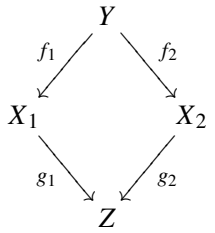


with f_i being the blow-up of a smooth subvariety $E_i \cong \mathbb{P}^d \subset X_i$ with normal bundle $\mathcal{O}(-1)^{d+1}$. Then the functor

$$\mathbf{R}f_{2,*} \circ \mathbf{L}f_1^* \colon \mathrm{D}(X_1) \to \mathrm{D}(X_2)$$

is an equivalence.

Theorem 2.3 (Kawamata [26], Namikawa [39]). *Suppose that X_1 and X_2 are related by a Mukai flop, so that there is a diagram*



with f_i being the blow-up of a smooth subvariety $E_i \cong \mathbb{P}^d \subset X_i$ with normal bundle equal to the cotangent bundle $\Omega^1(\mathbb{P}^d)$, and g_i the contraction of E_i to a point. Let $p_i \colon X_1 \times_Z X_2 \to X_i$ be the projection of the fibre product onto its factors. Then the functor

$$\mathbf{R}p_{2,*} \circ \mathbf{L}p_1^* \colon \mathrm{D}(X_1) \to \mathrm{D}(X_2)$$

is an equivalence, whilst in general the functor $\mathbf{R}f_{2,*} \circ \mathbf{L}f_1^*$ is not.

A result of Wierzba and Wisniewski [51] states that birationally equivalent complex symplectic fourfolds are related by a finite chain of Mukai flops, so Theorem 2.3 gives

Corollary 2.4. *Conjecture* 2.1 *holds when X_1 and X_2 are complex symplectic fourfolds.*

Kawamata and Namikawa have also studied certain stratified Mukai flops [29], [40]. In these cases neither a common resolution nor the fibre product give rise to an equivalence, although equivalences do nonetheless exist. Thus we see that the first problem faced in attempting to prove Conjecture 2.1 is writing down a candidate equivalence.

2.2. A famous variant of Conjecture 2.1 is the derived McKay correspondence, first stated by Reid [43], [44].

Conjecture 2.5. Let $G \subset \mathrm{SL}(n, \mathbb{C})$ be a finite subgroup. Let $\mathrm{D}_G(\mathbb{C}^n)$ denote the bounded derived category of the category of G-equivariant coherent sheaves on $\mathbb{C}^n$. Suppose $Y \to \mathbb{C}^n/G$ is a crepant resolution of singularities. Then there is an equivalence of categories $\mathrm{D}(Y) \cong \mathrm{D}_G(\mathbb{C}^n)$.

It seems certain that any method which proves Conjecture 2.1 will also apply to this case. On the other hand the McKay correspondence lends itself to more algebraic methods of attack.

Conjecture 2.5 is known to hold in dimension $n = 3$ due to work of Bridgeland, King and Reid [10] together with the results of [11]. In this case the quotient variety $\mathbb{C}^3/G$ always has a crepant resolution, a distinguished choice being given by Nakamura's G-Hilbert scheme. This scheme is perhaps best thought of as a moduli space of representations of the skew group algebra $\mathbb{C}[x, y, z] * G$ that are stable with respect to a certain choice of stability condition. Craw and Ishii [16] showed how to obtain other resolutions by varying the stability condition.

The conjecture has recently been shown to hold in two other situations, although the methods of proof are very different from that employed in the dimension three case. Firstly, Bezrukavnikov and Kaledin [4] used characteristic p methods and deformation quantization to deal with symplectic group quotients.

Theorem 2.6 (Bezrukavnikov, Kaledin [4]). *Conjecture* 2.5 *holds when G preserves a complex symplectic form on $\mathbb{C}^n$.*

Secondly, a special case of Kawamata's work [27] on the effect of toroidal flips and flops on derived categories is the following result.

Theorem 2.7 (Kawamata [28]). *Conjecture* 2.5 *holds when G is abelian.*

Note that in this case all resolutions are toric. Kawamata's proof uses the toric minimal model programme together with explicit computations of Hom spaces.

2.3. The second problem we wish to focus on is even easier to state, namely

Problem 2.8. *Compute the group of autoequivalences of the derived category of a smooth projective Calabi–Yau variety X.*

If X is any smooth projective variety there are certain standard autoequivalences of $\mathrm{D}(X)$, namely the automorphisms of X itself, twists by elements of $\mathrm{Pic}(X)$, and the shift functor [1]. Bondal and Orlov [5], [6] showed that if X has ample canonical or anticanonical bundle, then these standard equivalences generate $\mathrm{Aut}\,\mathrm{D}(X)$. Thus the group $\mathrm{Aut}\,\mathrm{D}(X)$ is not so interesting. In fact $\mathrm{Aut}\,\mathrm{D}(X)$ seems to be most interesting when X is Calabi–Yau, so we shall concentrate on this case.

Certain types of objects are known to define autoequivalences. The most well-known are spherical objects.

Theorem 2.9 (Seidel, Thomas [46]). *Let X be a smooth projective Calabi–Yau of dimension n and let $S \in \mathrm{D}(X)$ be a spherical object, which is to say an object satisfying*

$$\mathrm{Hom}^k_{\mathrm{D}(X)}(S, S) = \begin{cases} \mathbb{C} & \text{if } k = 0 \text{ or } n, \\ 0 & \text{otherwise.} \end{cases}$$

Then there is an autoequivalence $\Phi_S \in \mathrm{Aut}(\mathrm{D}(X))$ such that for any object $E \in \mathrm{D}(X)$ there is an exact triangle

$$\mathrm{Hom}_{\mathrm{D}(X)}(S, E) \otimes S \longrightarrow E \longrightarrow \Phi_S(E).$$

Horja [20] generalised the construction of Seidel and Thomas to define new autoequivalences. Szendrői [47] showed how certain configurations of surfaces in Calabi–Yau threefolds lead to interesting groups of autoequivalences. More recently, Huybrechts and Thomas [21] have studied projective space objects, which also give rise to autoequivalences.

Problem 2.8 is already non-trivial when X is an elliptic curve. Since X can be identified with its dual abelian variety $\mathrm{Pic}^0(X)$ in the dimension one case, the original Fourier transform of Mukai [37] defines an autoequivalence $\mathcal{F} \in \mathrm{Aut}\,\mathrm{D}(X)$. This enables one to prove

Theorem 2.10. *The group $\mathrm{Aut}\,\mathrm{D}(X)$ is generated by the standard autoequivalences together with $\mathcal{F}$. There is an exact sequence*

$$1 \longrightarrow \mathbb{Z} \times (\mathrm{Aut}(X) \ltimes \mathrm{Pic}^0(X)) \longrightarrow \mathrm{Aut}\,\mathrm{D}(X) \xrightarrow{f} \mathrm{SL}(2, \mathbb{Z}) \longrightarrow 1.$$

where the factor of $\mathbb{Z}$ is generated by the double shift [2]*, and the map f is defined by*

$$\begin{pmatrix} \mathrm{rank}(\Phi(E)) \\ \deg(\Phi(E)) \end{pmatrix} = f(\Phi) \begin{pmatrix} \mathrm{rank}(E) \\ \deg(E) \end{pmatrix}$$

for all $E \in \mathrm{D}(X)$.

If L is a degree one line bundle on X then, neglecting shifts, the autoequivalences $- \otimes L$ and $\mathcal{F}$ generate a subgroup of $\mathrm{Aut}\,\mathrm{D}(X)$ isomorphic to $\mathrm{SL}(2, \mathbb{Z})$. This $\mathrm{SL}(2, \mathbb{Z})$ action discovered by Mukai was perhaps an early pointer to homological mirror symmetry.

Theorem 2.10 was generalised by Orlov [42] who calculated the group $\mathrm{Aut}\,\mathrm{D}(X)$ for all abelian varieties X. The group of derived autoequivalences of the minimal resolution of a Kleinian singularity was studied in [23]. But beyond these results not much is known. We shall consider the case when X is a K3 surface in Section 6.

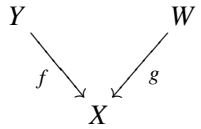
3. Threefold flops

In this section we shall be concerned with the following result.

Theorem 3.1. *Conjecture* 2.1 *holds when X_1 and X_2 have dimension three.*

Of course in dimensions two or less, birational Calabi–Yau varieties are isomorphic. We start by giving a bare outline of the original proof of Theorem 3.1 and then return to make some further remarks on each step. Full details of the proof can be found in [11]. A more direct proof has since been found by Kawamata [26] using results of Van den Bergh [50]. Nonetheless, the original proof is worth describing since it gives a moduli-theoretic interpretation of threefold flops which is interesting in its own right.

Sketch of proof. The first step is to apply the minimal model programme in the shape of a result of Kawamata [24] (a simpler proof is given in Kollár [30]) which says that any birational transform between smooth projective threefolds that preserves the canonical class can be split into a finite sequence of flops. Thus we can reduce to the case where we have a flopping diagram



Here Y and W are smooth and projective, X has Gorenstein terminal singularities, and f and g are crepant birational maps contracting only finitely many rational curves.

The second step is to define a full subcategory $\mathrm{Per}(Y/X) \subset \mathrm{D}(Y)$ consisting of objects $E \in \mathrm{D}(Y)$ satisfying the following three conditions

(a) $H^i(E) = 0$ unless $i = 0$ or -1,

(b) $\mathbf{R}^1 f_*\, H^0(E) = 0$ and $\mathbf{R}^0 f_*\, H^{-1}(E) = 0$,

(c) $\mathrm{Hom}_Y(H^0(E), C) = 0$ for any sheaf C on Y satisfying $\mathbf{R} f_*(C) = 0$.

In fact $\mathrm{Per}(Y/X)$ is the heart of a bounded t-structure on $\mathrm{D}(Y)$ and hence is abelian. We call the objects of $\mathrm{Per}(Y/X)$ perverse coherent sheaves.

Define a perverse point sheaf on Y to be an object of $\mathrm{Per}(Y/X)$ which has the same Chern classes as the structure sheaf of a point $y \in Y$, and which is a quotient

of $\mathcal{O}_Y$ in $\mathrm{Per}(Y/X)$. The third step is to show that there is a fine moduli space M for perverse point sheaves on Y. Since perverse point sheaves are not sheaves in general, but complexes of sheaves with nontrivial cohomology in more than one place, the usual moduli space techniques do not apply. In fact we can side-step this issue as follows.

By definition each perverse point sheaf E fits into a short exact sequence

$$0 \longrightarrow F \longrightarrow \mathcal{O}_Y \longrightarrow E \longrightarrow 0$$

in $\mathrm{Per}(Y/X)$. Taking the long exact sequence in cohomology shows that F is actually a sheaf, although not necessarily torsion-free. One can construct a fine moduli space M for the objects F using a standard GIT argument, and since the Es and Fs determine one another this space is also a fine moduli space for perverse point sheaves.

The moduli space M has a natural map to X since it is easily shown that if E is a perverse point sheaf on Y then $\mathbf{R}f_*(E)$ is the structure sheaf of a point of X. The fourth step is to show that M is smooth and that the universal family $\mathcal{P}$ on $M \times Y$ induces a Fourier–Mukai equivalence $\Phi\colon \mathrm{D}(M) \to \mathrm{D}(Y)$. This involves an application of the famous new intersection theorem. Once one has this it is easy to see that M with its natural map to X is the flop of $Y \to X$ and hence can be identified with W.

Finally, we should note that Chen [15, Prop. 4.2] was able to show that the universal family $\mathcal{P}$ is isomorphic to the object $\mathcal{O}_{W\times_X Y}$. Thus the resulting functor Φ is of the same form used in Bondal and Orlov's result Theorem 2.2. Later Kawamata [26] was able to show directly that this functor gives an equivalence. □

Example 3.2. To understand why the moduli of perverse point sheaves gives the flop consider the simplest example when $f\colon Y \to X$ is the contraction of a non-singular rational curve C with normal bundle $\mathcal{O}_C(-1) \oplus \mathcal{O}_C(-1)$.

Structure sheaves of points $y \in Y$ are objects of the category $\mathrm{Per}(Y/X)$ for all $y \in Y$. However, if $y \in C$ then the nonzero map $\mathcal{O}_C(-1) \to \mathcal{O}_y$ means that $\mathcal{O}_y$ is not an object of $\mathrm{Per}(Y/X)$, so that $\mathcal{O}_y$ is not a quotient of $\mathcal{O}_Y$ in $\mathrm{Per}(Y/X)$ and hence is not a perverse point sheaf. In fact for $y \in C$, the sheaf $\mathcal{O}_y$ fits into the exact sequence

$$0 \longrightarrow \mathcal{O}_C(-1) \longrightarrow \mathcal{O}_C \longrightarrow \mathcal{O}_y \longrightarrow 0. \tag{1}$$

Now $\mathcal{O}_C$ is a perverse sheaf, but $\mathcal{O}_C(-1)$ is not, so that the triangle in $\mathrm{D}(Y)$ arising from (1) does not define an exact sequence in $\mathrm{Per}(Y/X)$. However the complex obtained by shifting $\mathcal{O}_C(-1)$ to the left by one place *is* a perverse sheaf, so there is an exact sequence of perverse sheaves

$$0 \longrightarrow \mathcal{O}_C \longrightarrow \mathcal{O}_y \longrightarrow \mathcal{O}_C(-1)[1] \longrightarrow 0 \tag{2}$$

which could be thought of as destabilizing $\mathcal{O}_y$.

Flipping the extension of perverse sheaves (2) gives objects of $\mathrm{Per}(Y/X)$ fitting into an exact sequence of perverse sheaves

$$0 \longrightarrow \mathcal{O}_C(-1)[1] \longrightarrow E \longrightarrow \mathcal{O}_C \longrightarrow 0. \tag{3}$$

It is easy to see that these objects E are perverse point sheaves. Note that they are not sheaves, indeed any such object has two nonzero cohomology sheaves $H^{-1}(E) = \mathcal{O}_C(-1)$ and $H^0(E) = \mathcal{O}_C$. Roughly speaking, the space W is obtained from X by replacing the rational curve C parameterising extensions (2) by another rational curve C' parameterising extensions (3).

We now make some further remarks on the proof with an eye to generalising the method to higher dimensions, although, as we shall see, the prospects for doing this do not seem particularly good.

It is clear that the key step in the proof is the introduction of the category $\mathrm{Per}(Y/X)$. There are two possible ways to arrive at this definition as we shall now explain. Unfortunately neither of them seems to generalise directly to higher dimensional situations.

Construction 1. The first approach is to use the theory of tilting in abelian categories as developed by Happel, Reiten and Smalø [18]. This is an abstraction of the notion of tilting of algebras due to Brenner and Butler [9]. In fact in our situation the full subcategory

$$\mathcal{F} = \{E \in \mathrm{Coh}(Y) : f_*(E) = 0\}$$

is the torsion-free subcategory of a torsion pair on $\mathrm{Coh}(Y)$. The corresponding torsion subcategory consists of objects $E \in \mathrm{Coh}(Y)$ for which $\mathbf{R}^1 f_*(E) = 0$ and $\mathrm{Hom}_Y(E, C) = 0$ for any sheaf C on Y satisfying $\mathbf{R} f_*(C) = 0$. Tilting with respect to this torsion pair gives the t-structure on $\mathrm{D}(Y)$ whose heart is $\mathrm{Per}(Y/X)$.

Construction 2. Van den Bergh [50] found another characterisation of $\mathrm{Per}(Y/X)$ involving sheaves of non-commutative algebras. He first introduced a particular locally-free sheaf P on Y and considered the coherent sheaf of algebras $\mathcal{A} = \mathbf{R} f_* \mathcal{E}\mathrm{nd}_{\mathcal{O}_Y}(P)$ on X. Then he showed that there is an equivalence

$$\mathbf{R} f_* \mathcal{H}\mathrm{om}_{\mathcal{O}_Y}(P, -) \colon \mathrm{D}(Y) \longrightarrow \mathrm{D}(\mathcal{A}),$$

where $\mathrm{D}(\mathcal{A})$ is the bounded derived category of the abelian category $\mathrm{Coh}(\mathcal{A})$ of coherent sheaves of $\mathcal{A}$-modules on X. Pulling back the standard t-structure on $\mathrm{D}(\mathcal{A})$ gives the t-structure on $\mathrm{D}(Y)$ whose heart is $\mathrm{Per}(Y/X)$. In particular the above derived equivalence restricts to give an equivalence of abelian subcategories $\mathrm{Per}(Y/X) \to \mathrm{Coh}(\mathcal{A})$.

The third step in the proof of Theorem 3.1 was to construct a fine moduli space for perverse point sheaves. The trick we used in dimension three will not work in higher dimensions. Instead one must construct the moduli space directly. Recent results of Inaba [22] and Toen and Vaquie [49] construct spaces parameterising very general classes of objects of derived categories. For applications we need a more geometric approach. We first need to understand what it means for an object of a triangulated category to be stable. The general notion of a stability condition introduced in the next section sheds some light on this. After that we need to construct good moduli spaces of stable objects, where good might mean for example that the moduli space

is a projective scheme. We refer to Abramovich and Polishchuk [1] for some recent progress in this direction.

The final step in the proof of Theorem 3.1 was very much dependent on the dimension three assumption. The estimates needed to apply the intersection theorem just do not work in higher dimensions. In fact, in dimension four and higher, one can obtain singular varieties by flopping non-singular ones, so we cannot expect to prove that the relevant moduli space is smooth. Derived categories of singular varieties are still poorly understood at present, a point to which we shall return in the last section.

4. Stability conditions

The notion of a stability condition was introduced in [12] as a way to understand Douglas' work on π-stability for D-branes in string theory [17]. Here we wish to emphasise the purely mathematical aspects of this definition.

In the context of the present article stability conditions are relevant for three reasons. Firstly, the choice of a stability condition picks out classes of stable objects for which one can hope to form well-behaved moduli spaces. Secondly the space of all stability conditions Stab(D) allows one to bring geometric methods to bear on the problem of understanding t-structures on D. Finally, the space Stab(D) provides a complex manifold on which the group Aut(D) naturally acts.

In this section D is a fixed triangulated category. We shall assume that D is essentially small, i.e. equivalent to a category whose objects form a set. The Grothendieck group of D is denoted $K(\mathrm{D})$. For details on the results of this section see [12].

4.1. The definition of a stability condition is as follows.

Definition 4.1. A stability condition $\sigma = (Z, \mathcal{P})$ on D consists of a group homomorphism $Z\colon K(\mathrm{D}) \to \mathbb{C}$ called the central charge, and full additive subcategories $\mathcal{P}(\phi) \subset \mathrm{D}$ for each $\phi \in \mathbf{R}$, satisfying the following axioms:

(a) if $E \in \mathcal{P}(\phi)$ then $Z(E) = m(E)\exp(i\pi\phi)$ for some $m(E) \in \mathbf{R}_{>0}$,

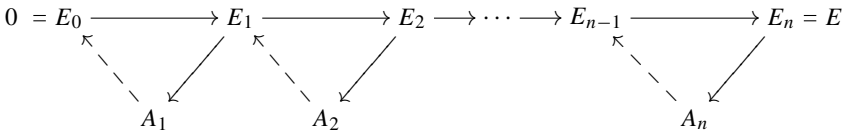
(b) for all $\phi \in \mathbf{R}$, $\mathcal{P}(\phi + 1) = \mathcal{P}(\phi)[1]$,

(c) if $\phi_1 > \phi_2$ and $A_j \in \mathcal{P}(\phi_j)$ then $\mathrm{Hom}_{\mathrm{D}}(A_1, A_2) = 0$,

(d) for each nonzero object $E \in \mathrm{D}$ there is a finite sequence of real numbers

$$\phi_1 > \phi_2 > \cdots > \phi_n$$

and a collection of triangles



with $A_j \in \mathcal{P}(\phi_j)$ for all j.

Given a stability condition $\sigma = (Z, \mathcal{P})$ as in the definition, each subcategory $\mathcal{P}(\phi)$ is abelian. The nonzero objects of $\mathcal{P}(\phi)$ are said to be semistable of phase ϕ in σ, and the simple objects of $\mathcal{P}(\phi)$ are said to be stable. It follows from the other axioms that the decomposition of an object $0 \neq E \in \mathrm{D}$ given by axiom (d) is uniquely defined up to isomorphism. Write $\phi^+_\sigma(E) = \phi_1$ and $\phi^-_\sigma(E) = \phi_n$. The mass of E is defined to be the positive real number $m_\sigma(E) = \sum_i |Z(A_i)|$.

For any interval $I \subset \mathbb{R}$, define $\mathcal{P}(I)$ to be the extension-closed subcategory of D generated by the subcategories $\mathcal{P}(\phi)$ for $\phi \in I$. Thus, for example, the full subcategory $\mathcal{P}((a, b))$ consists of the zero objects of D together with those objects $0 \neq E \in \mathrm{D}$ which satisfy $a < \phi^-_\sigma(E) \leqslant \phi^+_\sigma(E) < b$. A stability condition is called locally finite if there is some $\varepsilon > 0$ such that each quasi-abelian category $\mathcal{P}((\phi - \varepsilon, \phi + \varepsilon))$ is of finite length.

4.2. If $\sigma = (Z, \mathcal{P})$ is a stability condition on D, one can check that the full subcategory $\mathcal{A} = \mathcal{P}((0, 1])$ is the heart of a bounded t-structure on D. We call it the heart of σ. The stability condition σ can easily be reconstructed from its heart $\mathcal{A}$ together with the central charge map Z. Since this will be important in Section 5 we spell it out in a little more detail.

Define a stability function on an abelian category $\mathcal{A}$ to be a group homomorphism $Z\colon K(\mathcal{A}) \to \mathbb{C}$ such that

$$0 \neq E \in \mathcal{A} \implies Z(E) \in \mathbf{R}_{>0} \exp(i\pi\phi(E)) \text{ with } 0 < \phi(E) \leqslant 1.$$

The real number $\phi(E) \in (0, 1]$ is called the phase of the object E.

A nonzero object $E \in \mathcal{A}$ is said to be semistable with respect to Z if every subobject $0 \neq A \subset E$ satisfies $\phi(A) \leqslant \phi(E)$. The stability function Z is said to have the Harder–Narasimhan property if every nonzero object $E \in \mathcal{A}$ has a finite filtration

$$0 = E_0 \subset E_1 \subset \cdots \subset E_{n-1} \subset E_n = E$$

whose factors $F_j = E_j/E_{j-1}$ are semistable objects of $\mathcal{A}$ with

$$\phi(F_1) > \phi(F_2) > \cdots > \phi(F_n).$$

Given a stability condition on D, the central charge defines a stability function on its heart $\mathcal{A} = \mathcal{P}((0, 1]) \subset \mathrm{D}$, and the decompositions of axiom (d) give Harder–Narasimhan filtrations. Conversely, given a bounded t-structure on D together with a stability function Z on its heart $\mathcal{A} \subset \mathrm{D}$, we can define subcategories $\mathcal{P}(\phi) \subset \mathcal{A} \subset \mathrm{D}$ to be the semistable objects in $\mathcal{A}$ of phase ϕ for each $\phi \in (0, 1]$. Axiom (b) then fixes $\mathcal{P}(\phi)$ for all $\phi \in \mathbf{R}$. Thus we have

Proposition 4.2. *To give a stability condition on* D *is equivalent to giving a bounded t-structure on* D *and a stability function on its heart with the Harder–Narasimhan property.*

4.3. The set Stab(D) of locally-finite stability conditions on D has a natural topology induced by the metric

$$d(\sigma_1,\sigma_2)=\sup_{0\neq E\in \mathrm{D}}\left\{|\phi^-_{\sigma_2}(E)-\phi^-_{\sigma_1}(E)|,\,|\phi^+_{\sigma_2}(E)-\phi^+_{\sigma_1}(E)|,\,\left|\log\frac{m_{\sigma_2}(E)}{m_{\sigma_1}(E)}\right|\right\}\in[0,\infty].$$

The following result was proved in [11]. Its slogan is that deformations of the central charge lift uniquely to deformations of the stability condition.

Theorem 4.3. *For each connected component* $\Sigma\subset \mathrm{Stab}(\mathrm{D})$ *there is a linear subspace* $V(\Sigma)\subset \mathrm{Hom}_{\mathbb{Z}}(K(\mathrm{D}),\mathbb{Z})$ *with a well-defined linear topology and a local homeomorphism* $\mathcal{Z}\colon \Sigma\to V(\Sigma)$ *which maps a stability condition* $(Z,\mathcal{P})$ *to its central charge* Z.

If X is a smooth projective variety we write $\mathrm{Stab}(X)$ for the set of locally-finite stability conditions on $\mathrm{D}(X)$ for which the central charge Z factors via the Chern character map $\mathrm{ch}\colon K(X)\to H^*(X,\mathbb{Q})$. Theorem 4.3 immediately implies that $\mathrm{Stab}(X)$ is a finite-dimensional complex manifold. By Proposition 4.2, the points of $\mathrm{Stab}(X)$ parameterise bounded t-structures on $\mathrm{D}(X)$, together with the extra data of the map Z.

So far the manifolds $\mathrm{Stab}(X)$ have only been computed for varieties X of dimension one [36], [41]. The case of K3 and abelian surfaces was studied in [13]; we shall return to the K3 case in Section 6. Various non-compact examples have also been considered (see e.g. [14], [48]).

5. Stability conditions and threefold flops

Let $f\colon Y\to X$ be a small, crepant birational map of threefolds with Y smooth. Thus X has terminal Gorenstein singularities and f contracts a finite number of rational curves C, each satisfying $K_Y\cdot C=0$. The aim of this section is to show how the category of perverse sheaves defined in Section 3 arises naturally by considering stability conditions on Y. We shall go into more detail than we have in previous sections, since the results provide an excellent example of how stability conditions can be used to relate the derived category to geometry. For full proofs the reader can consult Toda's paper [48]. The string theory point of view on the same material is described in [2].

5.1. Define $\mathrm{D}(Y/X)$ to be the full subcategory of $\mathrm{D}(Y)$ consisting of objects supported on (a fat neighbourhood of) the exceptional locus of f. Since $\mathrm{D}(Y/X)$ only depends on a formal neighbourhood of the singular locus of X we may as well assume that X is the spectrum of a complete local ring.

One can easily show that there is an isomorphism of abelian groups

$$K(\mathrm{D}(Y/X))\cong N_1(Y/X)\oplus\mathbb{Z}.$$

It will be convenient to consider the codimension one slice of the full space $\mathrm{Stab}(\mathrm{D}(Y/X))$ consisting of stability conditions satisfying the additional condition that $Z(\mathcal{O}_y) = -1$, where $\mathcal{O}_y$ is the structure sheaf of a point $y \in Y$. We shall denote it simply by $\mathrm{Stab}(Y/X)$. Since the dual of $N_1(Y/X)$ is naturally $N^1(Y/X)$, the central charge $Z\colon K(\mathrm{D}(Y/X)) \to \mathbb{C}$ of a stability condition in $\mathrm{Stab}(Y/X)$ is defined by an element $\beta + i\omega$ of the vector space $N^1(Y/X) \otimes \mathbb{C}$. Explicitly the correspondence is given by

$$Z(E) = (\beta + i\omega) \cdot \mathrm{ch}_2(E) - \mathrm{ch}_3(E). \qquad (\dagger)$$

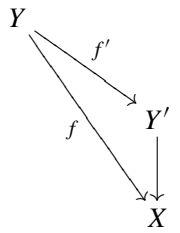
The map $\mathcal{Z}$ of Theorem 4.3 now becomes a map

$$\mathcal{Z}\colon \mathrm{Stab}(Y/X) \longrightarrow N^1(X/Y) \otimes \mathbb{C}.$$

The standard t-structure on $\mathrm{D}(Y)$ induces a bounded t-structure on $\mathrm{D}(Y/X)$ whose heart $\mathrm{Coh}(Y/X) = \mathrm{Coh}(Y) \cap \mathrm{D}(Y/X)$ is the subcategory of $\mathrm{Coh}(Y)$ consisting of sheaves supported on the exceptional locus. A simple application of Proposition 4.2 gives

Proposition 5.1. *A stability function for the t-structure with heart* $\mathrm{Coh}(Y/X) \subset \mathrm{D}(Y/X)$ *is given by* (†) *with* $\beta, \omega \in N^1(Y/X) \otimes \mathbf{R}$ *such that* $\omega \in \mathrm{Amp}(Y/X)$ *lies in the ample cone. This stability function has the Harder–Narasimhan property. Thus there is a region in* $U(Y/X) \subset \mathrm{Stab}(Y/X)$ *isomorphic to the complexified ample cone of* Y/X.

5.2. Suppose now that $\sigma = (Z, \mathcal{P})$ is a stability condition in the boundary of the region $U(Y/X)$. Then Z is given by the formula above for some $\beta, \omega \in N^1(Y/X) \otimes \mathbf{R}$ with ω an f-nef divisor which is not ample. There is a unique birational map $f'\colon Y \to Y'$ factoring $f\colon Y \to X$ such that $\omega = (f')^*(\omega')$ with ω' an ample $\mathbf{R}$-divisor on Y'.



The map f' is also crepant and contracts precisely those irreducible rational curves $C \subset Y$ satisfying $\omega \cdot C = 0$.

Let C be a rational curve contracted by f'. Note that for all stability conditions in $U(Y/X)$, the objects $\mathcal{O}_C(k)$ are stable, since their only proper quotients in $\mathrm{Coh}(Y/X)$ are skyscraper sheaves. It follows that these objects are at least semistable in σ, and hence $Z(\mathcal{O}_C(k)) \neq 0$. Since $\omega \cdot C = 0$ we must have $\beta \cdot C \notin \mathbb{Z}$.

The map Z defined by (†) no longer defines a stability function for $\mathrm{Coh}(Y/X)$ because if C is contracted by f' and $k \ll 0$ then $Z(\mathcal{O}_C(k))$ lies on the positive real axis. Thus the heart of the stability condition σ cannot be $\mathrm{Coh}(Y/X) \subset \mathrm{D}(Y/X)$.

Instead, consider the perverse t-structure on $\mathrm{D}(Y)$ induced by the contraction f' and restrict it to $\mathrm{D}(Y/X)$ to give a bounded t-structure whose heart $\mathrm{Per}(Y/Y') \cap \mathrm{D}(Y/X)$ we shall also denote $\mathrm{Per}(Y/Y')$. One can then show that providing $0 < \beta \cdot C < 1$ for all irreducible curves C with $\omega \cdot C = 0$ then the heart of σ is indeed equal to $\mathrm{Per}(Y/Y')$.

Suppose for a moment that σ lies on a codimension one face of the boundary of $U(Y/X)$, by which we mean that $\mathrm{Pic}(Y/Y') = \mathbb{Z}$. Note that $\mathrm{Pic}(Y/X)$ acts on $\mathrm{Stab}(Y/X)$ and on the region $U(Y/X)$. Thus twisting by a line bundle we can always assume that the condition $0 < \beta \cdot C < 1$ holds.

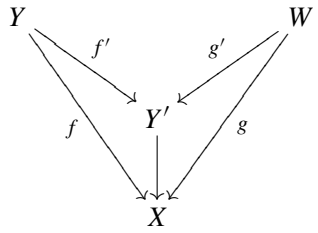
Conversely, considering the definition of $\mathrm{Per}(Y/Y')$ as a tilt, one can show that if the above condition on β and ω holds then the map Z defined by (†) gives a stability function on $\mathrm{Per}(Y/Y')$, and this is easily checked to satisfy the Harder–Narasimhan property. These arguments give

Proposition 5.2. *Let $f' \colon Y \to Y'$ be a birational map factoring $f \colon Y \to X$. A stability function for the t-structure with heart* $\mathrm{Per}(Y/Y')$ *is given by* (†) *for classes $\beta, \omega \in N^1(Y/X) \otimes \mathbf{R}$ such that $\omega = (f')^*(\omega')$ for some $\omega' \in \mathrm{Amp}(Y'/X)$ and $0 < \beta \cdot C < 1$ for all curves C contracted by f'. The resulting stability conditions lie in the boundary of the region $U(Y/X)$. Conversely, any stability condition lying on a codimension one face of the boundary of $U(Y/X)$ is of this form up to a twist by a line bundle.*

The key point we wish to emphasize is that the perverse t-structure arises naturally by passing to the boundary of the region $U(Y/X)$.

5.3. Consider now an open neighbourhood of a point σ lying in the boundary of $U(Y/X)$. This region will contain stability conditions with central charges Z defined by (†) with ω lying in the ample cone of a different birational model of $f \colon Y \to X$. It can be shown that all these stability conditions can be obtained by pulling back stability conditions of the form given in Proposition 5.1 by derived equivalences.

For example, suppose $g \colon W \to X$ is obtained from f by taking the flop of a contraction $f' \colon Y \to Y'$ factoring f with $\mathrm{Pic}(Y/Y') \cong \mathbb{Z}^{\oplus d}$.



Such a map f' defines a codimension d face of the ample cone $\mathrm{Amp}(Y/X)$. Let $\Phi \colon \mathrm{D}(Y) \longrightarrow \mathrm{D}(W)$ be the equivalence with kernel $\mathcal{O}_{Y \times_{Y'} W}$ on $Y \times W$. Then Φ

induces an isomorphism fitting into a diagram

$$\begin{array}{ccc} \mathrm{Stab}(Y/X) & \xrightarrow{\quad\Phi\quad} & \mathrm{Stab}(W/X) \\ {\scriptstyle\mathcal{Z}}\downarrow & & \downarrow{\scriptstyle\mathcal{Z}} \\ N^1(Y/X)\otimes\mathbb{C} & \xrightarrow{(g^{-1}\circ f)_*} & N^1(W/X)\otimes\mathbb{C} \end{array}$$

where the isomorphism $N^1(Y/X) \to N^1(W/X)$ is induced by the codimension one isomorphism $g^{-1} \circ f \colon Y \dashrightarrow W$. One can show that the closure of the inverse image $\Phi^{-1}(U(W/X))$ intersects the closure of $U(Y/X)$ along a real codimension d component of the boundary.

It is well known that the general hyperplane section of X is a Kleinian ADE surface singularity. Furthermore the abelian group $N_1(Y/X)$ can be identified with the root lattice of the corresponding simple Lie algebra. Let $\Lambda \subset N_1(Y/X)$ be the set of roots.

Theorem 5.3 (Toda, [48]). *The map*

$$\mathcal{Z}\colon\ \mathrm{Stab}(Y/X) \longrightarrow N^1(Y/X)\otimes\mathbb{C}$$

restricted to the connected component of $\mathrm{Stab}(Y/X)$ *containing* $U(Y/X)$ *is a covering map of the hyperplane complement*

$$\{\beta + i\omega \in N^1(Y/X)\otimes\mathbb{C} : \beta + i\omega \cdot C \notin \mathbb{Z} \text{ for all } C \in \Lambda\}.$$

For each smooth birational model $W \to X$ *and each Fourier–Mukai equivalence*

$$\Phi\colon\ \mathrm{D}(Y) \longrightarrow \mathrm{D}(W)$$

over X *there is a region* $\Phi^{-1}(U(W/X)) \subset \mathrm{Stab}(Y/X)$ *isomorphic to the complexified ample cone of* W/X. *The closures of these regions cover a connected component of* $\mathrm{Stab}(Y/X)$, *and any two of the regions are either disjoint or equal.*

6. Stability conditions on K3 surfaces

Suppose that X is an algebraic K3 surface over $\mathbb{C}$. In this section we consider stability conditions on $\mathrm{D}(X)$ and explain how they may help to determine the group of autoequivalences $\mathrm{Aut}\,\mathrm{D}(X)$. Full details can be found in [13].

6.1. Following Mukai [38], one introduces the extended cohomology lattice of X by using the formula

$$\big((r_1, D_1, s_1), (r_2, D_2, s_2)\big) = D_1 \cdot D_2 - r_1 s_2 - r_2 s_1$$

to define a symmetric bilinear form on the cohomology ring

$$H^*(X,\mathbb{Z}) = H^0(X,\mathbb{Z}) \oplus H^2(X,\mathbb{Z}) \oplus H^4(X,\mathbb{Z}).$$

The resulting lattice $H^*(X, \mathbb{Z})$ is even and non-degenerate and has signature $(4, 20)$. Let $H^{2,0}(X) \subset H^2(X, \mathbb{C})$ denote the one-dimensional complex subspace spanned by the class of a nonzero holomorphic two-form Ω on X. An isometry

$$\varphi\colon H^*(X, \mathbb{Z}) \to H^*(X, \mathbb{Z})$$

is called a Hodge isometry if $\varphi \otimes \mathbb{C}$ preserves this subspace. The group of Hodge isometries of $H^*(X, \mathbb{Z})$ will be denoted $\operatorname{Aut} H^*(X, \mathbb{Z})$.

The Mukai vector of an object $E \in \mathrm{D}(X)$ is the element of the sublattice

$$\mathcal{N}(X) = \mathbb{Z} \oplus \mathrm{NS}(X) \oplus \mathbb{Z} = H^*(X, \mathbb{Z}) \cap \Omega^\perp \subset H^*(X, \mathbb{C})$$

defined by the formula

$$v(E) = (r(E), c_1(E), s(E)) = \mathrm{ch}(E)\sqrt{\mathrm{Td}(X)} \in H^*(X, \mathbb{Z}),$$

where $\mathrm{ch}(E)$ is the Chern character of E and $s(E) = \mathrm{ch}_2(E) + r(E)$. The Mukai bilinear form makes $\mathcal{N}(X)$ into an even lattice of signature $(2, \rho)$, where $1 \leqslant \rho \leqslant 20$ is the Picard number of X. The Riemann–Roch theorem shows that this form is the negative of the Euler form, that is, for any pair of objects E and F of $\mathrm{D}(X)$

$$\chi(E, F) = \sum_i (-1)^i \dim_{\mathbb{C}} \operatorname{Hom}^i_X(E, F) = -(v(E), v(F)).$$

A result of Orlov [42], extending work of Mukai [38], shows that every exact autoequivalence of $\mathrm{D}(X)$ induces a Hodge isometry of the lattice $H^*(X, \mathbb{Z})$. Thus there is a group homomorphism

$$\varpi\colon \operatorname{Aut} \mathrm{D}(X) \longrightarrow \operatorname{Aut} H^*(X, \mathbb{Z}).$$

The kernel of this homomorphism will be denoted $\operatorname{Aut}^0 \mathrm{D}(X)$.

For any point $\sigma = (Z, \mathcal{P}) \in \mathrm{Stab}(X)$ the central charge $Z(E)$ depends only on the Chern character of E and hence can be written in the form

$$Z(E) = (\mho, v(E))$$

for some vector $\mho \in \mathcal{N}(X) \otimes \mathbb{C}$. Thus the map $\mathcal{Z}$ of Theorem 4.3 becomes a map

$$\mathcal{Z}\colon \mathrm{Stab}(X) \to \mathcal{N}(X) \otimes \mathbb{C}$$

sending a stability condition to the corresponding vector $\mho \in \mathcal{N}(X) \otimes \mathbb{C}$.

Define an open subset

$$\mathcal{P}^{\pm}(X) \subset \mathcal{N}(X) \otimes \mathbb{C}$$

consisting of those vectors which span positive definite two-planes in $\mathcal{N}(X) \otimes \mathbf{R}$. This space has two connected components that are exchanged by complex conjugation. Let $\mathcal{P}^+(X)$ denote the component containing vectors of the form $\exp(i\omega) = (1, i\omega, -\omega^2/2)$ for ample divisor classes $\omega \in \mathrm{NS}(X) \otimes \mathbf{R}$. Set

$$\Delta(X) = \{\delta \in \mathcal{N}(X) : (\delta, \delta) = -2\}$$

and for each $\delta \in \Delta(X)$ let

$$\delta^{\perp} = \{\mho \in \mathcal{N}(X) \otimes \mathbb{C} : (\mho, \delta) = 0\} \subset \mathcal{N}(X) \otimes \mathbb{C}$$

be the corresponding complex hyperplane. The following result was proved in [13].

Theorem 6.1. *There is a connected component $\Sigma(X) \subset \mathrm{Stab}(X)$ that is mapped by $\mathcal{Z}$ onto the open subset*

$$\mathcal{P}_0^+(X) = \mathcal{P}^+(X) \setminus \bigcup_{\delta \in \Delta(X)} \delta^{\perp} \subset \mathcal{N}(X) \otimes \mathbb{C}.$$

Moreover, the induced map $\mathcal{Z}\colon \Sigma(X) \to \mathcal{P}_0^+(X)$ is a regular covering map and the subgroup of $\mathrm{Aut}^0 \mathrm{D}(X)$ which preserves the connected component $\Sigma(X)$ acts freely on $\Sigma(X)$ and is the group of deck transformations of $\mathcal{Z}$.

Unfortunately, Theorem 6.1 is not enough to determine the group $\mathrm{Aut}\,\mathrm{D}(X)$. Nonetheless it provides a hope to solve this problem by studying the geometry of $\mathrm{Stab}(X)$. The obvious thing to conjecture is as follows.

Conjecture 6.2. The action of $\mathrm{Aut}\,\mathrm{D}(X)$ on $\mathrm{Stab}(X)$ preserves the connected component $\Sigma(X)$. Moreover $\Sigma(X)$ is simply-connected.

This conjecture would imply that there is a short exact sequence of groups

$$1 \longrightarrow \pi_1 \mathcal{P}_0^+(X) \longrightarrow \mathrm{Aut}\,\mathrm{D}(X) \xrightarrow{\varpi} \mathrm{Aut}^+ H^*(X, \mathbb{Z}) \longrightarrow 1$$

where

$$\mathrm{Aut}^+ H^*(X, \mathbb{Z}) \subset \mathrm{Aut}\, H^*(X, \mathbb{Z})$$

is the index 2 subgroup consisting of elements which do not exchange the two components of $\mathcal{P}^{\pm}(X)$.

As a final remark in this section note that Borcherds' work on modular forms [8] allows one to write down product expansions for holomorphic functions on $\mathrm{Stab}(X)$ that are invariant under the group $\mathrm{Aut}\,\mathrm{D}(X)$. It would be interesting to connect these formulae with counting invariants for stable objects in $\mathrm{D}(X)$.

7. Derived categories and the minimal model programme

In this section we briefly mention some further recent work on birational geometry and derived categories of coherent sheaves and give some references.

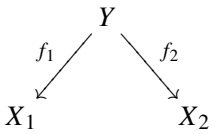
7.1. Conjecture 2.1 is the simplest version of a much more general set of conjectures about derived categories and birational geometry. The basic idea, due to Bondal and Orlov, is that each of the operations in the minimal model programme should induce fully faithful embeddings of derived categories. Thus for example, if $f\colon Y \to X$

is a birational map of smooth projective varieties, then $\mathbf{R}f_*(\mathcal{O}_Y) = \mathcal{O}_X$, and the projection formula implies that the functor

$$\mathbf{L}f^*\colon \mathrm{D}(X) \longrightarrow \mathrm{D}(Y)$$

is full and faithful. Much more generally Bondal and Orlov conjectured

Conjecture 7.1 (Bondal, Orlov). Suppose



are birational maps of smooth projective varieties. Suppose the divisor

$$K_{X_2/X_1} = f_2^*(K_{X_2}) - f_1^*(K_{X_1})$$

is effective. Then there is a fully faithful functor $F\colon \mathrm{D}(X_1) \hookrightarrow \mathrm{D}(X_2)$. If $K_{X_2/X_1} = 0$ then F is an equivalence.

One might well imagine that a proof of Conjecture 2.1 would also apply to this much more general situation. See [26], [27] for more details on this conjecture.

One of the main problems with studying the effect of the minimal model programme on derived categories is the presence of singularities. Considering varieties with mild singularities is essential for the minimal model programme in dimension at least three. But many of the techniques that have been developed to understand derived categories rely on smoothness.

The situation in dimension three is rather special since there is an explicit list of local models for terminal singularities. Each is a finite quotient of a hypersurface singularity. The hypersurface singularity can be thought of as a special fibre of a smooth fourfold, which allows one to get around the bad behaviour of derived categories of singular varieties. In this way Chen [15] was able to extend Theorem 3.1 so as to allow Gorenstein terminal singularities.

It is easy to see that if some version of Conjecture 7.1 is to hold, then for certain singular varieties the derived category must be modified in some way. Thus for example there exist flops and flips which take one from a smooth variety to a singular one. But there can never be a fully faithful embedding $\mathrm{D}(Y_1) \hookrightarrow \mathrm{D}(Y_2)$ if Y_1 is singular and Y_2 smooth because of the following straightforward consequence of Serre's theorem on regularity of local rings.

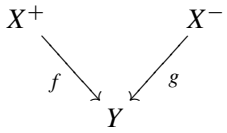
Proposition 7.2. *Let Y be a projective variety and $\mathrm{D}(Y)$ its bounded derived category of coherent sheaves. Then Y is smooth if and only if*

$$\dim_{\mathbb{C}} \bigoplus_{i\in\mathbb{Z}} \mathrm{Hom}^i_{\mathrm{D}(Y)}(A, B[i]) < \infty$$

for all objects A and B of $\mathrm{D}(Y)$.

At the moment this problem of how to modify the derived category for singular varieties is the biggest obstacle to progress in this area.

If a variety has only quotient singularities it is clear that one should consider the derived category of coherent sheaves on the corresponding stack. Kawamata explained this using the example of the Francia flip [25]. This is a threefold flip



in which X^- is smooth but X^+ has an isolated quotient singularity. By the argument above there cannot be an embedding $\mathrm{D}(X^+) \hookrightarrow \mathrm{D}(X^-)$. On the other hand there is an embedding $\mathrm{D}(\mathcal{X}^+) \hookrightarrow \mathrm{D}(X^-)$, where $\mathcal{X}^+ \to X^+$ is the Deligne–Mumford stack associated to the quotient singularity. In the same way, Chen's result on Gorenstein threefold flops extends to arbitrary terminal threefolds so long as one considers the derived categories of the corresponding stacks [26].

Kawamata has extended Conjecture 7.1 to a statement involving log varieties with quotient singularities. In an impressive piece of work [27] he was able to prove his conjecture under the additional assumption that the birational maps f_i were toroidal. Roughly speaking this means that they are locally defined by toric data. The derived McKay correspondence for abelian groups (Theorem 2.7) follows as a special case of this result.

Finally, Kawamata was able [28] to use his result together with the log minimal model programme for toric varieties to solve a long-standing problem: the existence of a full exceptional collection on any toric variety. For more on these state of the art developments we refer the reader to [27], [28].

Invariants of singularities of pairs

Lawrence Ein and Mircea Mustaţă*

Abstract. Let X be a smooth complex variety and Y be a closed subvariety of X, or more generally, a closed subscheme of X. We are interested in invariants attached to the singularities of the pair (X, Y). We discuss various methods to construct such invariants, coming from the theory of multiplier ideals, D-modules, the geometry of the space of arcs and characteristic p techniques. We present several applications of these invariants to algebra, higher dimensional birational geometry and to singularities.

Mathematics Subject Classification (2000). 14J17, 14J40, 14E05, 14E30.

Keywords. Singularities, birational maps.

1. Introduction

Let X be a smooth complex variety of dimension n and Y be a closed subvariety of X (or more generally, a closed subscheme of X). We are interested in studying the singularities of the pair (X, Y). The general setup is to assume only that X is normal and $\mathbb{Q}$-Gorenstein, as in [32]. However, several of the approaches we will discuss become particularly transparent if we assume, as we do, the smoothness of the ambient variety. The following are some examples of pairs.

Examples 1.1. (i) Let $X = \mathbb{C}^n$ and let Y be a hypersurface defined by an equation $f(x_1, \ldots, x_n) = 0$. For instance f can be the Fermat hypersurface $x_1^m + x_2^m + \cdots + x_n^m = 0$, which has an isolated singularity of multiplicity m at the origin.

(ii) If X is a smooth projective variety and L is a line bundle on X, then we take Y to be the base locus of the complete linear system $|L|$, i.e. $Y = \bigcap_{D \in |L|} D$.

(iii) Let X be a smooth affine variety with coordinate ring R. If $I \subseteq R$ is an ideal, then we take Y to be the closed subscheme defined by I.

In what follows we present various invariants attached to such pairs and we discuss some of their applications. Our main point is that the same invariants that play an important role in higher dimensional algebraic geometry arise also in several other approaches to singularities.

of Mathematicians, Madrid, Spain, 2006

2. Multiplier ideals

Multiplier ideals were first introduced by J. Kohn for solving certain partial differential equations. Siu and Nadel introduced them to complex geometry. We discuss below these ideals in the context of algebraic geometry.

Let X be a smooth complex affine variety and Y be a closed subscheme of X. Suppose that the ideal of Y is generated by $f_1, \ldots, f_m$, and let λ be a positive real number. We define the multiplier ideal of (X, Y) of coefficient λ as follows:

$$\mathcal{J}(X, \lambda \cdot Y) = \left\{ g \in \mathcal{O}_X \mid \frac{|g|^2}{\left(\sum_{i=1}^m |f_i|^2\right)^{\lambda}} \text{ is locally integrable} \right\}.$$

Example 2.1. Let $X = \mathbb{C}^n$ and let Y be the closed subscheme of X defined by $f = x_1^{a_1} \ldots x_n^{a_n}$. Then

$$\mathcal{J}(X, \lambda \cdot Y) = (x_1^{\lfloor \lambda a_1 \rfloor} \ldots x_n^{\lfloor \lambda a_n \rfloor}),$$

where $\lfloor \alpha \rfloor$ denotes the integer part of α. Equivalently, if H_i is the divisor defined by $x_i = 0$, then g is in $\mathcal{J}(X, \lambda \cdot Y)$ if and only if

$$\operatorname{ord}_{H_i} g \geq \lfloor \lambda a_i \rfloor,$$

for $i = 1, \ldots, n$.

We can use a log resolution of singularities and the above example to give in general a more geometric description of the multiplier ideals of (X, Y). By Hironaka's Theorem there is a log resolution of singularities of the pair (X, Y), i.e. a proper birational morphism

$$\mu \colon X' \longrightarrow X$$

with the following properties. The variety X' is smooth, $\mu^{-1}(Y)$ is a divisor, and the union of $\mu^{-1}(Y)$ and the exceptional locus of μ has simple normal crossings. The relative canonical divisor $K_{X'/X}$ is locally defined by the determinant of the Jacobian $J(\mu)$ of μ, hence it is supported on the exceptional locus of μ. We write $\mu^{-1}(Y) = \sum_{i=1}^N a_i E_i$ and $K_{X'/X} = \sum_{i=1}^N k_i E_i$, where the E_i are distinct smooth irreducible divisors in X' such that $\sum_{i=1}^N E_i$ has only simple normal crossing singularities.

Suppose that $x_1, \ldots, x_n$ are local coordinates in X and $y_1, y_2, \ldots, y_n$ are local coordinates for an open set in X'. Note that

$$\mu^* dx_1 \ldots dx_n d\bar{x}_1 \ldots d\bar{x}_n = |\det(J(\mu)|^2 dy_1 \ldots dy_n d\bar{y}_1 \ldots d\bar{y}_n. \tag{1}$$

The local integrability of a function g on X can be expressed as a local integrability condition on X' via the change of variable formula. This reduces us to a monomial situation, similar to that in Example 2.1. On deduces that $g \in \mathcal{J}(X, \lambda \cdot Y)$ if and only if

$$\operatorname{ord}_{E_i} g \geq \lfloor \lambda a_i \rfloor - k_i$$

for every i. Equivalently, if we put $\lfloor \lambda \mu^{-1}(Y) \rfloor = \sum_i \lfloor \lambda a_i E_i \rfloor$, then

$$\mathcal{J}(X, \lambda \cdot Y) = \mu_* \mathcal{O}_{X'}(K_{X'/X} - \lfloor \lambda \mu^{-1}(Y) \rfloor). \tag{2}$$

We refer to [34] for details.

Note that because of the original definition, it follows that this expression for $\mathcal{J}(X, \lambda \cdot Y)$ is independent of the choice of a resolution of singularities. On the other hand, the formula (2) applies also when X is non necessarily affine. Note also that this formula implies that if $\lambda_1 \geq \lambda_2$, then

$$\mathcal{J}(X, \lambda_1 \cdot Y) \subseteq \mathcal{J}(X, \lambda_2 \cdot Y).$$

If λ is small enough, then $\lambda a_i < k_i + 1$ for $i = 1, \ldots, N$. This implies that

$$\operatorname{ord}_{E_i} 1 \geq \lfloor \lambda a_i \rfloor - k_i,$$

hence $\mathcal{J}(X, \lambda \cdot Y) = \mathcal{O}_X$. This leads us to the definition of the log canonical threshold of the pair (X, Y): this is the smallest λ such that $\mathcal{J}(X, \lambda \cdot Y) \neq \mathcal{O}_X$, i.e.

$$c = \operatorname{lc}(X, Y) = \min_i \left\{ \frac{k_i + 1}{a_i} \right\}.$$

We may regard $\frac{1}{c}$ as a refined version of multiplicity. In general a singularity with a smaller log canonical threshold tends to be more complex.

The first appearance of the log canonical threshold was in the work of Arnold, Gusein-Zade and Varchenko (see [2] and [48]), in connection with the behavior of certain integrals over vanishing cycles. In the last decade this invariant has enjoyed renewed interest due to its applications to birational geometry. The following is probably the most interesting open problem about log canonical thresholds.

Conjecture 2.2 (Shokurov). For every n, the set

$$\{\operatorname{lc}(X, Y) \mid \dim(X) = n, Y \subset X\}$$

satisfies the Ascending Chain Condition: it contains no strictly increasing sequences.

We can consider also higher jumping numbers. In general, we say that λ is a jumping number of (X, Y), if

$$\mathcal{J}(X, \lambda \cdot Y) \subsetneq \mathcal{J}(X, (\lambda - \varepsilon) \cdot Y)$$

for all $\varepsilon > 0$. If λa_i is not an integer, then $\lfloor \lambda a_i \rfloor = \lfloor (\lambda - \varepsilon) a_i \rfloor$ for sufficiently small positive ε. We see that a necessary condition for λ to be a jumping number is that λa_i is an integer for some i. In particular, if λ is a jumping number, then it is rational and has a bounded denominator.

The following theorem gives a periodicity property of the jumping numbers.

Theorem 2.3. (i) *If $Y = D$ is a hypersurface in X, then*

$$\mathcal{J}(X, \lambda \cdot D) \cdot \mathcal{O}_X(-D) = \mathcal{J}(X, (\lambda + 1) \cdot D).$$

(ii) (Ein and Lazarsfeld [16]) *For every Y defined by the ideal I_Y, if $\lambda \geq \dim X - 1$, then*

$$\mathcal{J}(X, \lambda \cdot Y) \cdot I_Y = \mathcal{J}(X, (\lambda + 1) \cdot Y).$$

Corollary 2.4. *If $\lambda > \dim X - 1$, then λ is a jumping number for (X, Y) if and only if so is $(\lambda + 1)$.*

We conclude that the set of jumping numbers of the pair (X, Y) is a discrete subset of $\mathbb{Q}$ and it is eventually periodic with period one.

Example 2.5. If Y is a smooth subvariety of X of codimension e, then the set of jumping numbers of the pair (X, Y) is $\{e, e + 1, \dots\}$. In particular $\mathrm{lc}(X, Y) = e$.

Example 2.6. (Howald) Let $X = \mathbb{C}^n$ and let Y be the closed subscheme defined by a monomial ideal $\mathfrak{a}$. If $a = (a_1, a_2, \dots, a_n) \in \mathbb{N}^n$, we denote the monomial $x_1^{a_1} \dots x_n^{a_n}$ by x^a. Consider the Newton polyhedron $P_{\mathfrak{a}}$ associated with $\mathfrak{a}$: this is the convex hull of those $a \in \mathbb{N}^n$ such that $x^a \in \mathfrak{a}$. Using toric geometry Howald showed in [27] that

$$\mathcal{J}(X, \lambda \cdot Y) = (x^a \mid a + e \in \mathrm{Int}(\lambda \cdot P_{\mathfrak{a}})),$$

where $e = (1, \dots, 1)$. In particular, the log canonical threshold c of (X, Y) is characterized by the fact $c \cdot e$ lies on the boundary of $P_{\mathfrak{a}}$.

For example, suppose that $\mathfrak{a}$ is the ideal $(x_1^{a_1}, \dots, x_n^{a_n})$. In this case, the boundary of $P_{\mathfrak{a}}$ is

$$\Big\{u = (u_1, \dots, u_n) \in \mathbb{R}_+^n \mid \textstyle\sum_{i=1}^n \frac{u_i}{a_i} = 1\Big\}.$$

Therefore $\mathrm{lc}(X, Y) = \sum_i \frac{1}{a_i}$.

Example 2.7. Suppose that $X = \mathbb{C}^2$ and Y is the plane cuspidal curve defined by $x^3 + y^5 = 0$. Then the set of jumping numbers for Y is periodic with period 1. The jumping numbers in $(0, 1]$ are $\big\{\frac{8}{15}, \frac{11}{15}, \frac{13}{15}, \frac{14}{15}, 1\big\}$.

One reason that multiplier ideals have been very powerful in studying questions in higher dimensional algebraic geometry is that they appear naturally in a Kodaira type vanishing theorem. The following statement is the algebraic version of a result due to Nadel. In our context, it can be deduced from the Kawamata–Viehweg Vanishing Theorem (see [34]).

Theorem 2.8. *Let X be a smooth projective variety and Y a closed subscheme of X defined by the ideal I_Y. If A is a line bundle such that $I_Y \otimes A$ is globally generated, and if L is a line bundle such that $L - A$ is big and nef, then for every $i > 0$*

$$H^i(X, \mathcal{O}_X(K_X + L) \otimes \mathcal{J}(X, Y)) = 0.$$

3. Applications of multiplier ideals

One of the most important applications of multiplier ideals is the following theorem of Siu (see [44] and [45]) on the deformation invariance of plurigenera.

Theorem 3.1. *Let $f : X \longrightarrow T$ be a smooth projective morphism of relative dimension n between two smooth irreducible varieties. If we denote by X_t the fiber $f^{-1}(t)$ for each $t \in T$, then for every fixed $m > 0$, the dimension of the cohomology group $H^0(X_t, (\Omega^n_{X_t})^{\otimes m})$ is independent of t.*

The techniques involved in the proof of this theorem have been recently applied by Siu, Hacon and McKernan to study one of the outstanding problems in higher dimensional algebraic geometry, the finite generation of the canonical ring (see, for example, [23]).

In a different direction, there are applications of multiplier ideals to singularities of theta divisors on abelian varieties. Let (X, Θ) be a principally polarized abelian variety, that is, Θ is an ample divisor on an abelian variety X such that $\dim H^0(X, \mathcal{O}_X(\Theta)) = 1$. The following result is due to Ein and Lazarsfeld [17].

Theorem 3.2. *Let (X, Θ) be a principally polarized abelian variety. If Θ is irreducible, then Θ has at most rational singularities.*

Corollary 3.3. *Let (X, Θ) be a principally polarized abelian variety of dimension g, with Θ irreducible. If*

$$\Sigma_k(\Theta) = \{x \in X \mid \mathrm{mult}_x(\Theta) \geq k\},$$

then for every $k \geq 2$ we have $\mathrm{codim}(\Sigma_k(\Theta), X) \geq k+1$. In particular, Θ is a normal variety and $\mathrm{mult}_x(\Theta) \leq g - 1$ for every singular point x on Θ.

Remark 3.4. The fact that Θ is normal was first conjectured by Arbarello, De Concini and Beauville. When X is the Jacobian of a curve, the fact that Θ has only rational singularities was proved by Kempf. Note also that in this case, a classical theorem of Riemann expresses the multiplicity of Θ at a point in term of the dimension of the corresponding linear system on the curve. It was Kollár who first observed in [31] that one can use vanishing theorems to study the singularities of the theta divisor: he showed that for every principally polarized abelian variety (X, Θ), we have $\mathrm{lc}(X, \Theta) = 1$. Theorem 3.2 above is a strengthening of Kollár's result.

Multiplier ideals have been applied in several other directions: to Fujita's problem on adjoint linear systems [3], to Effective Nullstellensatz [16], to Effective Artin–Rees Theorem [20]. Building on work of Tsuji, recently Hacon and McKernan and independently, Takayama have used multiplier ideals to prove a very interesting result on boundedness of pluricanonical maps for varieties of general type (see [24] and [47]). We end this section with an application to commutative algebra due to Ein, Lazarsfeld and Smith [19].

Let X be a smooth n-dimensional variety and $Y \subseteq X$ defined by the reduced sheaf of ideals $\mathfrak{a}$. The m^{th} symbolic power of $\mathfrak{a}$ is the sheaf $\mathfrak{a}^{(m)}$ of functions on X that vanish with multiplicity at least m at the generic point of every irreducible component of Y. If Y is smooth, then the symbolic powers of $\mathfrak{a}$ agree with the usual powers, but in general they are very different.

Theorem 3.5. *If X is a smooth n-dimensional variety and if $\mathfrak{a}$ is a reduced sheaf of ideals, then $\mathfrak{a}^{(mn)} \subseteq \mathfrak{a}^m$ for every m.*

4. Bounds on log canonical thresholds and birational rigidity

In this section we compare the log canonical threshold with the classical Samuel multiplicity. We give then an application of the inequality between these two invariants to a classical question on birational rigidity. Let X be a smooth complex variety and $x \in X$ a point. Denote by R the local ring of X at x, and by $\mathfrak{m}$ its maximal ideal. The following result was proved by de Fernex, Ein and Mustaţă in [10].

Theorem 4.1. *Let $\mathfrak{a}$ be an ideal in R that defines a subscheme Y supported at x. Let c be the log canonical threshold of (X, Y), $l(R/\mathfrak{a})$ be the length of $R/\mathfrak{a}$ and $e(\mathfrak{a})$ be the Samuel multiplicity of R along $\mathfrak{a}$. If $n = \dim R$, then we have the following inequalities.*

(i) $l(R/\mathfrak{a}) \geq \frac{n^n}{n! \cdot c^n}$.

(ii) $e(\mathfrak{a}) \geq \frac{n^n}{c^n}$. *Furthermore, this is an equality if and only if the integral closure of $\mathfrak{a}$ is equal to $\mathfrak{m}^k$ for some k.*

The first assertion in (ii) above can be easily deduced from (i). The proof of (i) proceeds by reduction to the monomial case, via a Gröbner deformation. When $\mathfrak{a}$ is monomial, the inequality follows by a combinatorial argument from the explicit description of the invariants.

Example 4.2. Suppose that $\mathfrak{a} = (x_1^{a_1}, \ldots, x_n^{a_n})$. In this case $e(\mathfrak{a}) = \prod_{i=1}^n a_i$ and $\mathrm{lc}(\mathfrak{a}) = \sum_{i=1}^n \frac{1}{a_i}$. The inequality in Theorem 4.1(ii) becomes

$$\prod_{i=1}^n a_i \geq \frac{n^n}{\left(\sum_{i=1}^n \frac{1}{a_i}\right)^n}.$$

This is equivalent to

$$\left(\frac{1}{n}\sum_{i=1}^n \frac{1}{a_i}\right)^n \geq \prod_{i=1}^n \frac{1}{a_i},$$

which is just the classical inequality between the arithmetic and the geometric mean.

Remark 4.3. When X is a surface, the inequality in (ii) above was first proved by Corti [9].

Theorem 4.1 is used in [11] to study the behavior of the log canonical threshold under a generic projection. More generally, one proves the following

Theorem 4.4. *Let $f : X \longrightarrow Y$ be a smooth proper morphism of relative dimension k between two smooth complex varieties. If V is a locally complete intersection of codimension k in X such that $f|_V$ is finite, then*

$$\mathrm{lc}(Y,\, f_*(V)) \leq \frac{\mathrm{lc}(X,\, V)^k}{k^k}.$$

Using Theorem 4.4 and some beautiful geometric ideas of Pukhlikov [42], one gives in [11] a simple uniform proof for the following result.

Theorem 4.5. *If X is a smooth hypersurface of degree N in $\mathbb{CP}^N$, with $4 \leq N \leq 12$, then X is birationally superrigid. In particular, every birational automorphism of X is biregular.*

Remark 4.6. Consider the group $\mathrm{Aut}_{\mathbb{C}}(\mathbb{C}(X))$, the automorphism group of the field of rational functions of X. This is naturally isomorphic to $\mathrm{Bir}_{\mathbb{C}}(X)$, the group of birational automorphisms of X. If X is birationally superrigid, then $\mathrm{Bir}_{\mathbb{C}}(X) \simeq \mathrm{Aut}_{\mathbb{C}}(X)$, the automorphism group of X. When X is a hypersurface of degree N in $\mathbb{P}^N$, X has no nonzero vector fields and therefore $\mathrm{Aut}_{\mathbb{C}}(X)$ is a finite group. This shows that X is not a rational variety: if $\mathbb{C}(X)$ is purely transcendental, then $\mathrm{Aut}_{\mathbb{C}}(X)$ will contain a subgroup isomorphic to the general linear group GL_n.

Remark 4.7. When $N = 4$, it is a classical theorem of Iskovskikh and Manin that X is birationally rigid [28]. They used this to show that the function field of a suitable quartic threefold provides a counterexample to the classical Lüroth problem: $\mathbb{C}(X)$ is a $\mathbb{C}$-subfield of the purely transcendental field $\mathbb{C}(x_1, x_2, x_3)$ but $\mathbb{C}(X)$ is not purely transcendental. For $N = 5$, Theorem 4.5 is a result of Pukhlikov [40]. The cases $N = 6$, 7 and 8 were first proved by Cheltsov [8]. We mention also that Pukhlikov [41] has shown that a generic hypersurface of degree N in $\mathbb{P}^N$ is superrigid for every $N \geq 4$.

5. Bernstein–Sato polynomials

Let $f \in \mathbb{C}[x_1, x_2, \ldots, x_n]$ be a nonzero polynomial. We denote by A_n the Weyl algebra of differential operators on $\mathbb{A}^n$, that is

$$A_n = \mathbb{C}[x_1, \ldots, x_n, \partial_{x_1}, \ldots, \partial_{x_n}].$$

Let s be another variable and consider the following functional equation:

$$b(s) f^s = P(s, x, \partial_x) \bullet f^{s+1}, \tag{3}$$

where $b(s) \in \mathbb{C}[s]$ and $P \in A_n[s]$. Here f^s is considered a formal symbol, and the action $\bullet$ of P is defined via $\partial_{x_i} \bullet f^s = sf^{-1}\frac{\partial f}{\partial x_i} f^s$. On the other hand, if we let $s = m$ for an integer m, then (3) has the obvious meaning.

It is easy to see that the set of polynomials $b(s)$ for which there is P satisfying (3) is an ideal in the polynomial ring $\mathbb{C}[s]$. It was proved by Bernstein in [4] using the theory of holonomic D-modules that this ideal is nonzero. Its monic generator is denoted by $b_f(s)$ and is called the Bernstein–Sato polynomial of f. It is an interesting and subtle invariant of the singularities of the hypersurface defined by f.

Examples 5.1. (1) Making $s = 1$ in (3) we see that $b_f(-1)f^{-1}$ lies in $\mathbb{C}[x_1, \ldots, x_n]$. If f is nonconstant, it follows that -1 is a root of b_f.

(2) If $f = x$, then $b_f(s) = (s + 1)$. Indeed, we have

$$(s + 1)f^s = \partial_x \bullet f^{s+1}.$$

More generally, if f defines a nonsingular hypersurface, then $b_f(s) = (s + 1)$.

(3) If $f = x_1^2 + \cdots + x_n^2$, then $b_f(s) = (s + 1)\left(s + \frac{n}{2}\right)$ and

$$b_f(s)f^s = \frac{1}{4}(\partial_{x_1}^2 + \cdots + \partial_{x_n}^2) \bullet f^{s+1}.$$

(4) If $f = x^2 + y^3$, then $b_f(s) = \left(s + \frac{5}{6}\right)(s + 1)\left(s + \frac{7}{6}\right)$ and

$$b_f(s)f^s = \left(\frac{1}{27}\partial_y^3 + \frac{1}{6}y\partial_x^2\partial_y + \frac{1}{8}x\partial_x^3 + \frac{3}{8}\partial_x^2\right) \bullet f^{s+1}.$$

Computing Bernstein–Sato polynomials in general is quite subtle (see [49]). On the other hand, there has been a lot of recent progress in algorithmic computation using Gröbner bases in the Weyl algebra (see [43]).

We describe now the connection between the roots of the Bernstein–Sato polynomial of f and the jumping numbers of the hypersurface Y defined in $\mathbb{A}^n$ by f. An important theorem of Kashiwara [30] asserts that all the roots of $b_f(s)$ are negative rational numbers. Building on Kashiwara's work, Lichtin made this more explicit in [35], describing a connection between the roots of $b_f(s)$ and a log resolution of the pair $(\mathbb{A}^n, Y)$. This says that if $\mu\colon X' \to \mathbb{A}^n$ is a log resolution of (X, Y), then every root of $b_f(s)$ is of the form $-\frac{k_i+m}{a_i}$ for some i and some positive integer m (we use the notation introduced in §2). In particular, we see that every root of $b_f(s)$ is rational, and no larger than $-\mathrm{lc}(\mathbb{A}^n, Y)$. However, we stress that unlike in the case of multiplier ideals, there is no explicit description of the Bernstein–Sato polynomial in terms of a log resolution.

On the other hand, the following result of Ein, Lazarsfeld, Smith and Varolin [20] shows that in a suitable range, all jumping numbers give roots of the Bernstein–Sato polynomial.

Theorem 5.2. *If $\lambda \in (0, 1]$ is a jumping number of $(\mathbb{A}^n, Y)$, then $-\lambda$ is a root of the Bernstein–Sato polynomial $b_f(s)$.*

The proof of this theorem uses the functional equation (3) and integration by parts. The case when $\lambda = \mathrm{lc}(\mathbb{A}^n, Y)$ was proved by Kollár in [32]. Note that in conjunction with the above mentioned result of Lichtin, this gives the following

Corollary 5.3. *The largest root of $b_f(s)$ is $-\mathrm{lc}(\mathbb{A}^n, Y)$.*

A different point of view on the connection between multiplier ideals and Bernstein–Sato polynomials was given by Budur and Saito. In fact, they show how to recover the multiplier ideals from a filtration that appears in D-module theory, the V-filtration. We present now their result.

Let t be a new variable, and let A_{n+1} denote the Weyl algebra corresponding to the affine space $\mathbb{A}^{n+1}$, with coordinates $x_1, \ldots, x_n, t$. We consider the module B_f that is the first local cohomology module of $\mathbb{A}^{n+1}$ along the embedding of $\mathbb{A}^n$ as the graph of f, i.e.

$$B_f = \mathbb{C}[x_1, \ldots, x_n, t]_{f-t}/\mathbb{C}[x_1, \ldots, x_n, t].$$

Let δ be the class of $\frac{1}{f-t}$ in B_f (δ is the "delta-function associated to the graph of f").

Note that B_f has a natural structure of left module over A_{n+1}. Since $\partial_t^m \delta$ is the class of $\frac{m!}{(f-t)^{m+1}}$ in B_f, we see that B_f is free over $\mathbb{C}[x_1, \ldots, x_n]$, with basis given by $\{\partial_t^j \delta \mid j \geq 0\}$.

The V-filtration is a decreasing filtration on B_f by left A_n-submodules V^α indexed by $\alpha \in \mathbb{Q}$, with the following properties:

(i) $\bigcup_\alpha V^\alpha = B_f$.

(ii) The filtration is semicontinuous and discrete in the following sense: there is a positive integer ℓ such that for every integer m and every $\alpha \in \left(\frac{m-1}{\ell}, \frac{m}{\ell}\right]$ we have $V^\alpha = V^{m/\ell}$.

(iii) We have $t \cdot V^\alpha \subseteq V^{\alpha+1}$ for every α, with equality if $\alpha > 0$.

(iv) We have $\partial_t \cdot V^\alpha \subseteq V^{\alpha-1}$ for every α.

(v) For every α, if we put $V^{>\alpha} := \cup_{\beta>\alpha} V^\beta$, then $(\partial_t t - \alpha)$ is nilpotent on $V^\alpha/V^{>\alpha}$.

The key property is (v) above. One can think of the V-filtration as an attempt to diagonalize the operator $\partial_t t$ on B_f. It is not hard to show that if a filtration as above exists, then it is unique. Malgrange [36] proved the existence of the V-filtration using the existence of the Bernstein–Sato polynomial and the rationality of its roots. To explain the role played by $b_f(s)$ in the construction of the V-filtration, we mention that the equation (3) in the definition of b_f is equivalent with the following equality in B_f:

$$b(-\partial_t t) \cdot \delta = P(-\partial_t t, x, \partial_x) \cdot t\delta. \tag{4}$$

The following result of Budur and Saito [5] shows that the multiplier ideals can be obtained as a piece of the V-filtration. We consider $\mathbb{C}[x_1, \ldots, x_n]$ embedded in B_f by $h \to h\delta$.

Theorem 5.4. *If Y is the hypersurface defined by f, then for every $\lambda > 0$ we have $\mathcal{J}(\mathbb{A}^n, \lambda \cdot Y) = V^{\lambda+\varepsilon} \cap \mathbb{C}[x_1, \ldots, x_n]$, where $0 < \varepsilon \ll 1$.*

The assertion in Theorem 5.2 can be deduced from this statement. The proof of Theorem 5.4 involves two steps. First, one describes the V-filtration in the case when f defines a divisor with simple normal crossings: $f = x_1^{a_1} \ldots x_n^{a_n}$. In this case, let us put $\mathcal{J}'(\mathbb{A}^n, \alpha \cdot Y) := \mathcal{J}(\mathbb{A}^n, (\alpha - \varepsilon) \cdot Y)$ for $0 < \varepsilon \ll 1$ (with the convention $\mathcal{J}'(\mathbb{A}^n, \alpha \cdot Y) = \mathbb{C}[x_1, \ldots, x_n]$ if $\alpha \leq 0$). If we take V^α to be generated over A_n by $\mathcal{J}'(\mathbb{A}^n, (\alpha + j) \cdot Y)\partial_t^j \delta$, where j varies over the nonnegative integers, then one can check that these V^α satisfy the properties in the definition of the V-filtration. In particular, this easily implies the statement of Theorem 5.4 in this case. The hard part of the proof uses Saito's theory of mixed Hodge modules to deduce the general case of the theorem by relating the V-filtrations of f and of a log resolution.

We mention that Kashiwara constructed in [29] a V-filtration associated to several polynomials. Budur, Mustaţă and Saito used this in [7] to introduce and study the Bernstein–Sato polynomial associated to a subscheme not necessarily of codimension one, and to generalize Theorems 5.2 and 5.4 to this setting.

6. Spaces of arcs and contact loci

Let X be a smooth n-dimensional complex variety. Given $m \geq 0$, we denote by

$$X_m = \mathrm{Hom}(\mathrm{Spec}\, \mathbb{C}[t]/(t^{m+1}), X)$$

the space of m^{th} order jets on X. This carries a natural scheme structure. Similarly we define the space of formal arcs on X as

$$X_\infty = \mathrm{Hom}(\mathrm{Spec}\, \mathbb{C}[[t]], X).$$

These constructions are functorial, hence to every morphism $\mu\colon X' \to X$ we associate corresponding morphisms μ_m and μ_∞. Thanks to the work of Kontsevich, Denef, Loeser and others on motivic integration, in recent years these spaces have been very useful in constructing invariants of singular algebraic varieties. In what follows we describe some applications of these spaces to the study of singularities.

We have natural projection maps induced by truncation $X_{m+1} \to X_m$. Since X is smooth, this is locally trivial in the Zariski topology, with fiber $\mathbb{A}^n$. We similarly have projection maps $X_\infty \to X_m$. A subset C of X_∞ is called a *cylinder* if it is the inverse image of a constructible set S in some X_m. Moreover, C is called locally closed (closed, irreducible) if S is so. If C is a closed cylinder that is the inverse image of $S \subset X_m$, its codimension in X_∞ is equal to the codimension of S in X_m.

Consider a nonzero ideal sheaf $\mathfrak{a} \subseteq \mathcal{O}_X$ defining a subscheme $Y \subset X$. Given a finite jet or an arc γ on X, the order of vanishing of $\mathfrak{a}$ – or the order of contact of the

corresponding scheme Y – along γ is defined in the natural way. Specifically, pulling $\mathfrak{a}$ back via γ yields an ideal (t^e) in $\mathbb{C}[t]/(t^{m+1})$ or $\mathbb{C}[[t]]$, and one sets

$$\mathrm{ord}_\gamma(\mathfrak{a}) = \mathrm{ord}_\gamma(Y) = e.$$

(Take $\mathrm{ord}_\gamma(\mathfrak{a}) = m+1$ when $\mathfrak{a}$ pulls back to the zero ideal in $\mathbb{C}[t]/(t^{m+1})$ and $\mathrm{ord}_\gamma(\mathfrak{a}) = \infty$ when it pulls back to the zero ideal in $\mathbb{C}[[t]]$.) For a fixed integer $p \geq 0$, we define the *contact locus*

$$\mathrm{Cont}^p(Y) = \mathrm{Cont}^p(\mathfrak{a}) =_{\mathrm{def}} \{\gamma \in X_\infty \mid \mathrm{ord}_\gamma(\mathfrak{a}) = p\}.$$

Note that this is a locally closed cylinder: for $m \geq p$, it is the inverse image of

$$\mathrm{Cont}^p(Y)_m = \mathrm{Cont}^p(\mathfrak{a})_m =_{\mathrm{def}} \{\gamma \in X_m \mid \mathrm{ord}_\gamma(\mathfrak{a}) = p\}, \tag{5}$$

which is locally closed in X_m. A subset of X_∞ is called an *irreducible closed contact subvariety* if it is the closure of an irreducible component of $\mathrm{Cont}^p(Y)$ for some p and Y.

Suppose now that W is an arbitrary irreducible closed cylinder in X_∞. We can naturally associate a valuation of the function field of X to W as follows. If f is a nonzero rational function of X, we put

$$\mathrm{val}_W(f) = \mathrm{ord}_\gamma(f) \quad \text{for a general } \gamma \in W.$$

This valuation is not identically zero if and only if W does not dominate X.

If $\mu\colon X' \longrightarrow X$ is a proper birational morphism, with X' smooth, and if E is an irreducible divisor on X', then we define a valuation by

$$\mathrm{val}_E(f) = \text{ the vanishing order of } f \circ \mu \text{ along } E.$$

A valuation on the function field of X is called a *divisorial valuation* (with center on X) if it is of the form $m \cdot \mathrm{val}_E$ for some positive integer m and some divisor E as above.

A key invariant associated to a divisorial valuation v is its *log discrepancy*. If E is a divisor as above, we put $k_E = \mathrm{val}_E(\det(J(\mu))$, where $J(\mu)$ is the Jacobian matrix of μ. Equivalently, k_E is the coefficient of E in the relative canonical divisor $K_{X'/X}$. Note that k_E depends only on val_E (it does not depend on the model X'). Given an arbitrary divisorial valuation $m \cdot \mathrm{val}_E$, we define its log discrepancy as $m(k_E + 1)$.

Consider a divisor E on X' as above. If $C_m(E)$ is the closure of $\mu_\infty(\mathrm{Cont}^m(E))$, then it is not hard to see that $C_m(E)$ is an irreducible closed contact subvariety of X_∞ such that $\mathrm{val}_{C_m(E)} = m \cdot \mathrm{val}_E$. The following result of Ein, Lazarsfeld and Mustaţă [18] describes in general the connection between cylinders and divisorial valuations.

Theorem 6.1. *Let X be a smooth variety.*

(i) *If W is an irreducible, closed cylinder in X_∞ that does not dominate X, then the valuation* val_W *is divisorial.*

(ii) *For every divisorial valuation* $m \cdot \mathrm{val}_E$*, there is a unique maximal irreducible closed cylinder* W *such that* $\mathrm{val}_W = m \cdot \mathrm{val}_E$*: this is* $W = C_m(E)$.

(iii) *The map that sends* $m \cdot \mathrm{val}_E$ *to* $C_m(E)$ *gives a bijection between divisorial valuations of* $\mathbb{C}(X)$ *with center on* X *and the set of irreducible closed contact subvarieties of* X_∞.

The applicability of this result to the study of singularities is due to the following description of log discrepancy of a divisorial valuation in terms of the codimension of a certain set of arcs.

Theorem 6.2. *Given a divisorial valuation* $v = m \cdot \mathrm{val}_E$ *with center on* X*, if* $C_m(E)$ *is its associated irreducible closed contact subvariety in* X_∞*, then the log discrepancy of* v *is equal to* $\mathrm{codim}(C_m(E), X_\infty)$.

Combining the statements of the above theorems, we deduce a lower bound for the codimension of an arbitrary cylinder in terms of the log discrepancy of the corresponding divisor.

Corollary 6.3. *If* W *is a closed, irreducible cylinder in* X_∞ *that does not dominate* X*, then* $\mathrm{codim}(W, X_\infty)$ *is bounded below by the log discrepancy of* val_W.

Remark 6.4. The above two theorems also hold for singular varieties after some minor modifications using Nash's blow-up and Mather's canonical class.

The key ingredient in the proof of the above theorems is the following result due to Kontsevich, Denef and Loeser (see [14]. It constitutes the geometric content of the so-called Change of Variable Theorem in motivic integration. Suppose that $\mu\colon X' \longrightarrow X$ is a proper, birational morphism of smooth varieties and let $K_{X'/X}$ be the relative canonical divisor.

Theorem 6.5. *Given integers* $e \geq 0$ *and* $m \geq e$*, consider the contact locus*

$$\mathrm{Cont}^e(K_{X'/X})_m = \{\gamma' \in X'_m \mid \mathrm{ord}_{\gamma'}(K_{X'/X}) = e\}.$$

If $m \geq 2e$*, then* $\mathrm{Cont}^e(K_{X'/X})_m$ *is a union of fibres of* $\mu_m\colon X'_m \longrightarrow X_m$*, each of which is isomorphic to an affine space* $\mathbb{A}^e$*. Moreover, if*

$$\gamma', \gamma'' \in \mathrm{Cont}^e(K_{X'/X})_m$$

lie in the same fibre of μ_m*, then they have the same image in* X'_{m-e}.

As an application of Theorems 6.1 and 6.2, one gives in [18] a simple proof of the following result of Mustaţă [37] describing the log canonical threshold in terms of the geometry of the space of jets.

Theorem 6.6. *Let* X *be a smooth complex variety and* Y *be a closed subscheme of* X *defined by the nonzero ideal sheaf* I_Y*. Let* X_m *and* Y_m *be the spaces of* m^{th} *order jets of* X *and* Y*, respectively. If* $c = \mathrm{lc}(X, Y)$*, then*

(i) *For every m we have* $\operatorname{codim}(Y_m, X_m) \geq c \cdot (m+1)$. *More generally, if $W \subset X_\infty$ is an irreducible closed cylinder that does not dominate X, then* $\operatorname{codim}(W, X_\infty) \geq c \cdot \operatorname{val}_W(I_Y)$.

(ii) *If m is sufficiently divisible, then* $\operatorname{codim}(Y_m, X_m) = c \cdot (m+1)$.

(iii) *We have* $c = \lim_{m\to\infty} \frac{\operatorname{codim}(Y_m, X_m)}{m+1}$.

The above results relating divisorial valuations with the space of arcs can be used to study more subtle invariants of singularities of pairs. Let Y be a closed subscheme of the smooth variety X, and let λ be a positive real number. We associate a numerical invariant to the pair $(X, \lambda \cdot Y)$ and to an arbitrary nonempty closed subset $B \subseteq X$, as follows.

Consider a divisorial valuation of the form val_E with center $c_X(E)$ in X (the center is the image of E in X). The *log discrepancy* of the pair $(X, \lambda \cdot Y)$ along E is

$$a(E, X, \lambda \cdot Y) = k_E + 1 - \lambda \cdot \operatorname{val}_E(I_Y),$$

where I_Y is the ideal of Y in X. Note that if $Y = \emptyset$, we recover the log discrepancy of val_E. The idea is to measure the singularities of the pair $(X, \lambda \cdot Y)$ using the log discrepancies along divisors with center contained in B.

Definition 6.7. Let $B \subset X$ be a nonempty closed subset. The minimal log discrepancy of $(X, \lambda \cdot Y)$ over B is defined by

$$\operatorname{mld}(B; X, \lambda \cdot Y) := \inf_{c_X(E) \subseteq B} \{a(E; X, \lambda \cdot Y)\}. \tag{6}$$

Remark 6.8. One can show that $\operatorname{mld}(B; X, \lambda \cdot Y)$ is either $-\infty$ or a nonnegative real number. In fact, $\operatorname{mld}(B; X, \lambda \cdot Y) \neq -\infty$ if and only if there is an open neighborhood U of B such that $\operatorname{lc}(U, U \cap Y) \geq \lambda$. An important fact about minimal log discrepancies is that they can be computed using a log resolution of $(X, B \cup Y)$, see [1].

The following theorem of Ein, Mustaţă and Yasuda [22] gives a description of minimal log-discrepancies in term of the geometry of the space of arcs.

Theorem 6.9. *Let B be a nonempty, proper closed subset of X, and let $\pi : X_\infty \longrightarrow X$ be the projection map. For every proper closed subscheme Y of X and for every λ and $\tau \in \mathbb{R}_+$ we have* $\operatorname{mld}(B; X, \lambda \cdot Y) \geq \tau$ *if and only if for every irreducible closed cylinder $W \subseteq \pi^{-1}(B)$ we have*

$$\operatorname{codim}(W, X_\infty) \geq \lambda \cdot \operatorname{val}_W(I_Y) + \tau.$$

The above theorem can be applied to study the behavior of singularities of pairs under restriction to a divisor. This is useful whenever one wants to do induction on dimension. Suppose that D is a smooth divisor on X. We want to relate the singularities of $(X, \lambda \cdot Y)$ with those of $(D, \lambda \cdot Y|_D)$. The adjunction formula suggests that the precise relation should be between $(X, D + \lambda \cdot Y)$ and $(D, \lambda \cdot Y|_D)$. The precise formula is the content of the following theorem from [22].

Theorem 6.10. *Let D be a smooth divisor on the smooth variety X and let B be a nonempty proper closed subset of D. If Y is a closed subscheme of X such that $D \not\subseteq Y$, and if $\lambda \in \mathbb{R}_+$, then*

$$\mathrm{mld}(B; X, D + \lambda \cdot Y) = \mathrm{mld}(B; D, \lambda \cdot Y|_D).$$

Remark 6.11. The notion of minimal log discrepancy plays an important role in the Minimal Model Program. It can be defined under weak assumptions on the singularities of X: one requires only that X is normal and $\mathbb{Q}$-Gorenstein. Kollár and Shokurov have conjectured the statement of Theorem 6.10 with the assumption that X and D are only normal and $\mathbb{Q}$-Gorenstein. It is easy to see that the inequality "$\leq$" holds in general, and the opposite inequality is known as Inversion of Adjunction (see [32] and [33] for a discussion of this conjecture and related topics). Theorem 6.10 has been generalized in [21] to the case when both X and D are normal locally complete intersections.

The interpretation of minimal log discrepancies in terms of spaces of arcs gives also the following semicontinuity statement. This was conjectured for an arbitrary (normal and $\mathbb{Q}$-Gorenstein) variety X by Ambro and Shokurov, see [1]. The statement below, due to Ein, Mustaţă and Yasuda [22] has been generalized to the case of a normal locally complete intersection variety in [21].

Theorem 6.12. *If X is a smooth variety and if Y is a closed subscheme of X, then for every $\lambda \in \mathbb{R}_+$, the function on X defined by $x \to \mathrm{mld}(x; X, \lambda \cdot Y)$ is lower semicontinuous.*

We end with a result that translates properties of the minimal log discrepancy over the singular locus of a locally complete intersection variety into geometric properties of its spaces of jets.

Theorem 6.13. *Let X be a normal locally complete intersection variety of dimension n.*

(i) *X_m has pure dimension $n(m+1)$ for every m (and in this case X_m is also a locally complete intersection) if and only if* $\mathrm{mld}(X_{\mathrm{sing}}; X, \emptyset) \geq 0$ (*this says that X has* log canonical singularities).

(ii) *X_m is irreducible for every m (and in this case it is also reduced) if and only if* $\mathrm{mld}(X_{\mathrm{sing}}; X, \emptyset) \geq 1$ (*this says that X canonical singularities*).

(iii) *X_m is normal for every m if and only if* $\mathrm{mld}(X_{\mathrm{sing}}; X, \emptyset) > 1$ (*this says that X has* terminal singularities).

(iv) *In general, we have* $\mathrm{codim}((X_m)_{\mathrm{sing}}, X_m) \geq \mathrm{mld}(X_{\mathrm{sing}}; X, \emptyset)$ *for every m.*

Remark 6.14. The description in (ii) above was first proved in [38]. Note that since X is in particular Gorenstein, it is known that X has canonical singularities if and only

if it has rational singularities. All the statements in the above theorem were obtained in [22] and [21] combining the description of minimal log discrepancies in terms of spaces of arcs and Inversion of Adjunction.

7. Invariants in positive characteristic

Several invariants have been recently introduced in positive characteristic using the Frobenius morphism, invariants whose behavior is formally very similar to the ones we have discussed in characteristic zero. Moreover, there are interesting results and conjectures involving the comparison between the two sets of invariants via reduction mod p.

As in the case of singularities of pairs (X, Y) in characteristic zero, one can develop the theory under very mild assumptions on the ambient variety X (in fact, the positive characteristic theory does not even need the assumption that X is $\mathbb{Q}$-Gorenstein). For this one needs to use the full power of the theory of tight closure of Hochster and Huneke [26]. However, the definitions become particularly transparent if we assume X nonsingular. Therefore, in accord with the setup in the previous sections, we will make this assumption. The theory we present here is due to Hara and Yoshida [25] building on previous work of Hara, Smith, Takagi and Watanabe.

We work in the local setting with a regular local ring $(R, \mathfrak{m}, k)$ of characteristic $p > 0$. Let $n = \dim(R)$ and let E be the top local cohomology module of R, $E = H^n_{\mathfrak{m}}(R)$. If $x_1, \ldots, x_n$ generate $\mathfrak{m}$, then

$$E \simeq R_{x_1 \ldots x_n} \Big/ \sum_{i=1}^{n} R_{x_1 \ldots \widehat{x_i} \ldots x_n}. \tag{7}$$

The Frobenius morphism on R induces a Frobenius morphism F_E on E that via the isomorphism (7) takes the class of $u/(x_1 \ldots x_n)^d$ to the class of $u^p/(x_1 \ldots x_n)^{pd}$.

We want to study the singularities of the pair (X, Y), where $X = \operatorname{Spec}(R)$ and Y is defined by a nonzero ideal $\mathfrak{a}$. For every $r \geq 0$ and every $e \geq 1$, we put

$$Z_{r,e} := \ker(\mathfrak{a}^r F_E^e) = \{w \in E \mid h F_E^e(w) = 0 \text{ for all } h \in \mathfrak{a}^r\}.$$

Given a nonnegative real number λ, the *test ideal* of the pair $(X, \lambda \cdot Y)$ is

$$\tau(X, \lambda \cdot Y) := \operatorname{Ann}_R\Big(\bigcap_{e \geq 1} Z_{\lceil \lambda p^e \rceil, e}\Big).$$

Here $\lceil \alpha \rceil$ denotes the smallest integer that is $\geq \alpha$.

As Hara and Yoshida show in [25], the test ideals $\tau(X, \lambda \cdot Y)$ enjoy formal properties similar to those of the multiplier ideals $\mathcal{J}(X, \lambda \cdot Y)$ in characteristic zero. In particular, we can consider the jumping numbers for the test ideals: these are the λ such that $\tau(X, \lambda \cdot Y) \subsetneq \tau(X, (\lambda - \varepsilon) \cdot Y)$ for every positive ε.

The set of jumping numbers for the test ideals are also eventually periodic with period one. However, two basic properties that for multiplier ideals follow simply from the description in terms of a log resolution are not known for test ideals: it is not known whether every jumping number for the test ideals is rational, and whether in every bounded interval there are only finitely many such jumping numbers. We want to stress that the problem does *not* come from the fact that we do not know, in general, whether such resolutions exist. Even when we have such resolutions, the invariants in characteristic p do not depend simply on the numerical data of the resolution (see Example 7.4 below for the case of the cusp).

There is a more direct description of the set of jumping numbers given by Mustaţă, Takagi and Watanabe in [39]. Suppose that J is a proper ideal of R containing $\mathfrak{a}$ in its radical. For every $e \geq 1$, define $\nu^J(p^e)$ to be the largest r such that $\mathfrak{a}^r$ is not contained in the e^{th} Frobenius power of J

$$J^{[p^e]} := (u^{p^e} \mid u \in J).$$

It is easy to see that $\nu^J(p^e)/p^e \leq \nu^J(p^{e+1})/p^{e+1}$, and the *F-threshold* of $\mathfrak{a}$ with respect to J is defined by

$$c^J(\mathfrak{a}) := \sup_e \frac{\nu^J(p^e)}{p^e}.$$

It is shown in [39] that the set of F-thresholds of $\mathfrak{a}$ (with respect to various J) is precisely the set of jumping numbers for the test ideals of (X, Y). Note that the smallest F-threshold is obtained for $J = \mathfrak{m}$: this is an analogue of the log canonical threshold that was introduced and studied by Takagi and Watanabe in [46].

There are several interesting results and questions relating the invariants in characteristic zero and those obtained via reduction mod p. To keep the notation simple we will work in the following setup. Suppose that $\mathfrak{a}$ is an ideal in $A[x_1, \ldots, x_n]$, where A is the localization of $\mathbb{Z}$ at some integer. Let Y be the subscheme of $X = \mathbb{A}^n_A$ defined by $\mathfrak{a}$. If p is a prime that is large enough, then by reducing mod p and localizing at $(x_1, \ldots, x_n)$ we get a closed subscheme Y_p in $X_p = \operatorname{Spec} \mathbb{F}_p[x_1, \ldots, x_n]_{(x_1,\ldots,x_n)}$ defined by the ideal $\mathfrak{a}_p$.

The multiplier ideals of the pair (X, Y) (more precisely, of its extension to $\mathbb{C}$) can be computed by a log resolution defined over $\mathbb{Q}$. After suitably localizing A we may assume that the multiplier ideals are defined over A, too. The following results relate the reduction mod p of the multiplier ideals with the test ideals. They are due to Hara and Yoshida [25], based on previous work of Hara, Smith, Takagi and Watanabe.

Theorem 7.1. *With the above notation, if $p \gg 0$, then for every λ we have*

$$\tau(X_p, \lambda \cdot Y_p) \subseteq \mathcal{J}(X, \lambda \cdot Y)_p.$$

Note that since our primes are large enough, the log resolution over $\mathbb{Q}$ induces by reduction mod p log resolutions for (X_p, Y_p). The proof of Theorem 7.1 is based on the use of local duality for the reduction mod p of the log resolution. The proof of the

next result is more involved, using the approach of Deligne and Illusie to the positive characteristic proof of the Kodaira Vanishing Theorem.

Theorem 7.2. *With the above notation, for every λ and for every $p \gg 0$ (depending on λ) we have*

$$\tau(X_p, \lambda \cdot Y_p) = \mathcal{J}(X, \lambda \cdot Y)_p.$$

Remark 7.3. We reinterpret the above statements in terms of jumping numbers. For simplicity, we restrict ourselves to the smallest such number: given $\mathfrak{a}$ as above and $p \gg 0$, we want to compare the log canonical threshold c of the pair (X, Y) in some small neighborhood of the origin, with the F-pure threshold $c_p = c^{\mathfrak{m}}(\mathfrak{a}_p)$. Theorem 7.1 implies that for all $p \gg 0$ we have $c \geq c_p$, while Theorem 7.2 implies that $\lim_{p\to\infty} c_p = c$.

Example 7.4. Let $\mathfrak{a}$ be generated by $f = x^2 + y^3$, whose log canonical threshold is $\frac{5}{6}$. Let $p > 3$ be a prime. One can show that if $p \equiv 1 \pmod 3$, then the largest r such that f^r does not lie in (x^{p^e}, y^{p^e}) is given by $\nu(p^e) = \frac{5}{6}(p^e - 1)$ for every $e \geq 1$, so that $c_p = \frac{5}{6}$. On the other hand, if $p \equiv 2 \pmod 3$, then $\nu(p) = \frac{5p-7}{6}$, while $\nu(p^e) = \frac{5p^e - p^{e-1} - 6}{6}$ for $e \geq 2$. Therefore in this case $c_p = \frac{5}{6} - \frac{1}{6p}$.

Conjecture 7.5. For every ideal $\mathfrak{a}$ in $A[x_1, \ldots, x_n]$ there are infinitely many primes p for which the F-pure threshold c_p is equal to the log canonical threshold c.

For a discussion of this conjecture we refer to [39]. We end by mentioning a connection between the positive characteristic invariants and the Bernstein–Sato polynomial. Suppose that $f \in A[x_1, \ldots, x_n]$ is as above. We know that the Bernstein–Sato polynomial $b_f(s)$ has rational roots, and in fact, one can show that one can find an equation (3) as in the definition of $b_f(s)$ with P having rational coefficients. Therefore, after suitably localizing A, we may assume that both b_f and P have coefficients in A and that (3) holds over A. It follows that if p is a large enough prime, we get a similar equation over $\mathbb{F}_p$.

Consider now an ideal J in the ring $\mathbb{F}_p[x_1, \ldots, x_n]_{(x_1,\ldots,x_n)}$, such that f_p lies in the radical of J. Let us apply (3) with $s = \nu^J(p^e)$, the largest integer such that f_p^r is not in $J^{[p^e]}$. Since the ideal $J^{[p^e]}$ is a module over the ring $\mathbb{F}_p[x, \partial_x]$, we deduce that $b_f(\nu^J(p^e)) \equiv 0 \pmod p$. Therefore the functions ν^J give roots of $b_f \bmod p$. Sometimes one can use this observation to find actual roots of b_f.

Example 7.6. Let $f = x^2 + y^3$. We have described in Example 7.4 the function $\nu = \nu^J$ when J is the maximal ideal. If $p \equiv 1 \pmod 3$, then $\nu(p^e) = \frac{5}{6}(p^e - 1)$. The above discussion implies that p divides $b_f(-5/6)$. Since there are infinitely many such primes, we deduce that $-\frac{5}{6}$ is a root of b_f. Similarly, if $p \equiv 2 \pmod 3$, then it follows from the formula for $\nu(p)$ that $-\frac{7}{6}$ is a root of b_f, and from the formula for $\nu(p^e)$, with $e \geq 2$ that -1 is a root of b_f. Therefore we have obtained all roots of the Bernstein–Sato polynomial of f by this method.

A similar picture can be seen in other examples, though at the moment there is no general result in this direction. In [6] this approach was used to describe all the roots of the Bernstein–Sato polynomial of a monomial ideal. It would be very interesting to find a more conceptual framework that would explain the connection between the Bernstein polynomial and the invariants in positive characteristic.

Acknowledgements. We would like to express a special thanks to Rob Lazarsfeld. Many results in this paper were joint work with him. Moreover, we have benefited from many inspiring discussions.

Rational curves and rational points

Tom Graber*

Abstract. We survey some recent results proving the existence of rational points over one dimensional function fields and finite fields on varieties containing many rational curves. We also consider conjectural extensions of these theorems to higher dimensional function fields.

Mathematics Subject Classification (2000). 14G05.

Keywords. Rationally connected varieties, rational points.

1. Introduction

In the past five years there has been substantial progress giving geometric interpretations and generalizations of classical theorems about C_1 fields. In this lecture I would like to focus on some results about the existence of rational points on certain classes of varieties over function fields of curves and over finite fields. The geometry of rational curves play a central role in this work.

Recent results of de Jong and Starr give hope that in the future we will see a similar development for function fields of higher dimensional varieties, although so far we do not have even a precise conjectural formulation. The program that they and others have proposed raises many interesting questions, most of which are still relatively unexplored.

It is a pleasure to thank my collaborators from whom I learned most of what I know about this material: Joe Harris, Barry Mazur, and Jason Starr, to whom I am particularly grateful for helpful comments on this lecture.

2. Classical results

All the results and conjectures that I want to consider have their origins in two theorems proven in the 1930s which guarantee that over certain fields, hypersurfaces of low degree in projective space possess rational points. To make this precise, we make a definition.

*The author is grateful to the Institut des Hautes Études Scientifiques for hospitality during the writing of this paper.

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

Definition 2.1. A field K is said to be C_1 if every homogeneous polynomial $f \in K[x_0, \ldots, x_n]$ has a nontrivial zero provided that $\deg(f) \leq n$.

The first two known classes of C_1 fields were provided by the following two well-known theorems.

Theorem 2.2 (Tsen). *If k is an algebraically closed field and C is an irreducible curve over k with function field K, then K is a C_1 field.*

Theorem 2.3 (Chevalley). *Finite fields are C_1.*

There are two natural ways to search for generalizations of these results: we can try to extend the class of fields considered, or extend the class of varieties. There are substantial generalizations in both directions. We will start by considering the second question, namely, for which types of varieties can we guarantee that they will possess points over finite fields or over one dimensional function fields? At the expense of making less than optimal statements, we will always restrict our attention to smooth projective varieties. In this context, there are many natural generalizations of the class of hypersurfaces above. The two most obvious ones for an algebraic geometer before 1992 were the following.

Remark 2.4. If X is a smooth hypersurface in $\mathbb{P}^n$ of degree d, then the following conditions are equivalent.

- $d \leq n$.
- X is Fano, that is, the canonical line bundle K_X has ample dual.
- $h^i(X, \mathcal{O}_X) = 0$ for all $i > 0$.

These naturally gives rise to four questions, do Tsen's or Chevalley's theorems generalize to either of these classes of varieties? The answer to one of these questions has been known for some time.

Theorem 2.5 (Katz). *If X is a projective variety over $\mathbb{F}_q$ such that $h^i(X, \mathcal{O}_X) = 0$ for all $i > 0$, then X has an $\mathbb{F}_q$-point.*

The other three have all been (nearly) settled in the new millennium, in large part due to a fundamental shift in viewpoint coming from a third geometric condition – *rational connectivity* – which is also equivalent for smooth hypersurfaces to the inequality $d \leq n$.

3. Rationally connected varieties

The basic theory of rational connectivity was developed independently by Campana [C] and Kollar, Miyaoka, and Mori [KMM]. We will give a quick review of some of the main points. Throughout, we work over a ground field k. To simplify our

discussion we will restrict our attention to smooth projective varieties, and we will take k to be an uncountable algebraically closed field. A careful reader will notice that this last hypothesis will not be satisfied in many of the applications we refer to later. To avoid this, one must either make more careful definitions, or first base change to such a field. For a good treatment of the foundations of the theory of rationally connected varieties, we refer to [K] or [D].

Given a projective variety X, by a *rational curve* in X, we mean the image of a morphism $f\colon \mathbb{P}^1 \to X$.

Definition 3.1. A smooth projective variety X is *rationally connected* (RC) if two general points of X can be connected by a rational curve.

If $k = \mathbb{C}$ this notion is equivalent to many other conditions guaranteeing the existence of an abundance of rational curves in X. Since these other conditions can fail to be equivalent to rational connectedness over other fields (or for singular varieties), they have their own names.

Definition 3.2. X is *rationally chain connected* (RCC) if any two points of X can be joined by a chain of rational curves.

Definition 3.3. X is *separably rationally connected* (SRC) if there exists a morphism $f\colon \mathbb{P}^1 \to X$ such that $f^*(TX)$ is an ample vector bundle.

While this last definition appears quite different from the previous two, it is straightforward to verify that such a morphism deforms so freely that it guarantees the existence of a rational curve through two general points. Combining this with the elementary fact that every irreducible component of a degeneration of a rational curve is rational, we obtain the implications

$$\text{SRC} \implies \text{RC} \implies \text{RCC}.$$

In characteristic zero, by more delicate arguments, one can reverse these implications. The equivalence of these notions is quite convenient, because it is easy to see that the property of being rationally chain connected is closed in families, while that of being separably rationally connected is open. As a result, we find that in characteristic zero, rational connectivity is a deformation invariant property. This is one reason why the notion is particularly well suited to the classification theory of higher dimensional varieties.

The following beautiful theorem, which even over the complex numbers can be proven at this time only by making use of results in characteristic p, was established in [C] and [KMM].

Theorem 3.4. *Fano varieties are rationally chain connected.*

As a result, one can try to address questions about Fano varieties by studying the geometry of rational curves. Indeed, rational connectivity seems to be a more useful notion for questions about the existence of rational points.

4. Rational points on rationally connected varieties

For both finite fields and function fields, the study of rational points often takes as its starting point a more geometric interpretation of the notion of rational point. The very different methods used in the two cases reflect the difference in this geometric interpretation. We will start with the case of function fields.

If we let K be the function field of a smooth curve C defined over an algebraically closed field k, then given a projective variety X_K over K, we can always find a C model for X_K. That is, we can find a projective variety X over k together with a morphism $\pi : X \to C$ such that the base change to Spec K is X_K. A rational point of X_K then corresponds exactly to a section of π. Thus the geometry of rational points over K is intimately connected to the geometry of curves in higher dimensional varieties. From this point of view, then, the notion of rational connectivity is particularly appealing, since it is also directly connected with the same type of geometric objects. Moreover, it is not difficult to see that the variety X_K is geometrically rationally connected if and only if a general fiber of the morphism π is rationally connected.

Thus, the following theorem, which is proven in characteristic zero in [GHS] and in positive characteristic in [dJS] is a natural generalization of Tsen's theorem.

Theorem 4.1. *If C is a smooth curve over an algebraically closed field, and $\pi : X \to C$ is a proper morphism whose general fiber is separably rationally connected, then π admits a section.*

Combining with Theorem 3.4 we get a partial answer to one of the questions raised in Section 2.

Corollary 4.2. *If K is the function field of a curve defined over an algebraically closed field of characteristic zero, then every Fano variety over K has a rational point.*

To my knowledge the analogous question in positive characteristic remains open, since Fano varieties are not known to be separably rationally connected.

The proof of Theorem 4.1 is based on the geometry of Kontsevich's space of stable maps, $\overline{M}_g(X)$. This space, which compactifies the space of smooth curves in X by allowing them to degenerate to morphisms from nodal curves, was introduced into mathematics in order to study ideas coming from string theory. It is extremely useful in this context, however, because it has two advantages over the traditional compactifications of the space of curves in X. Its deformation theory is extremely simple and it has an obvious functorial property – given a morphism of varieties $\pi : X \to Y$, we get an induced morphism $\overline{M}(\pi) : \overline{M}_g(X) \to \overline{M}_g(Y)$. In the setting of Theorem 4.1, the point is that via degeneration methods, one can produce a curve B in X such that B corresponds to a smooth point of $\overline{M}_g(X)$ at which the differential of $\overline{M}(\pi)$ is surjective. As this last statement involves only the tangent spaces to the moduli spaces, it can be verified using elementary deformation theory, but nonetheless

it is very powerful, since it guarantees that $\overline{M}(\pi)$ dominates at least one irreducible component of $\overline{M}_g(C)$. Thus, the proof is completed by finding a suitable degeneration of a morphism of curves, which can be done by elementary techniques.

In [GHMS], by making a careful study of the maps $\overline{M}(\pi)$ for general morphisms of varieties π it is shown that in a certain sense the property of rational connectivity is universal for the problem of finding rational points over function fields of curves. In other words, we cannot really hope to find a larger class of varieties which will always possess a point over function fields than the class given by Theorem 4.1.

In particular, there exist varieties X over $K(C)$ such that $h^i(X, \mathcal{O}_X) = 0$ for all $i > 0$ but without a rational point. We remark that while the methods of [GHMS] prove the existence of such a variety, they are not effective and give little insight into how to actually write one down. In [Laf] G. Lafon produces an explicit Enriques surface over $\mathbb{Q}(t)$ with no rational point even over $\mathbb{C}((t))$.

Turning our attention to finite fields, the theory has a rather different flavor. The geometric interpretation of an $\mathbb{F}_q$-point of a variety X is that it is a fixed point of the action of the Frobenius morphism. This point of view is very useful in connection with cohomological conditions, since one can use Lefschetz type theorems that relate fixed points to cohomological data. In particular, Theorem 2.5 was proven by establishing the analogue for the Frobenius morphism of the holomorphic Lefschetz fixed point theorem – that the number of points of a smooth projective variety over $\mathbb{F}_q$ is congruent modulo p to the alternating sum of the traces of Frobenius on the cohomology groups $H^i(X, \mathcal{O}_X)$. Since the trace of Frobenius on H^0 is obviously 1 the existence result follows immediately, as well as the sharper statement that the number of $\mathbb{F}_q$-points on X is congruent to 1 modulo p.

In [E], H. Esnault shows how it is possible to relate rational curves to this circle of ideas. She observes that an immediate consequence of rational chain connectivity is that the Chow group of zero cycles is $\mathbb{Z}$. A method introduced by Bloch (cf. [B]) can then be used to control the eigenvalues of the action of Frobenius on the étale (or crystalline) cohomology of X. This is done by thinking of the diagonal $\Delta \subset X \times X$ as a zero cycle in $X_{K(X)}$ and using the triviality of the Chow group to move it via rational equivalence to $[\{p\} \times X] \cup \Gamma$ where Γ is a cycle whose projection to the second factor is not dominant. Interpreting this as the decomposition of the identity map on the cohomology of X into the projection onto H^0 plus the projection onto the rest, together with formal (but deep) properties of étale cohomology then yield that the eigenvalues of the action of Frobenius on $H^i_{et}(X, \mathbb{Q}_l)$ are divisible by q for all $i > 0$. Now using the Lefschetz–Verdier trace formula, she concludes the following theorem.

Theorem 4.3. *If X is a smooth projective variety over $\mathbb{F}_q$ with $Ch_0(X \times \overline{K(X)}) = \mathbb{Z}$, then X has a rational point.*

This has as immediate corollaries:

Corollary 4.4. *Every smooth, projective, rationally chain connected variety over a finite field has a rational point.*

Corollary 4.5. *Fano varieties over finite fields have rational points.*

As before, one actually gets a sharper statement – the number of rational points is congruent to 1 mod q.

5. Higher rational connectivity

We would now like to consider some more speculative material about the existence of points on varieties over more complicated fields. We will describe (in very rough terms) a program of de Jong and Starr, and following them, we will consider here only fields of the form $K(X)$ for X a complex variety. We encourage the reader to consider analogous questions over other classes of fields, where it is easy to make similar speculations.

Long before any of the work described here, Serge Lang gave an entirely different generalization of Tsen's theorem. Following him, we first generalize the definition of C_1.

Definition 5.1. A field K is called C_r if every homogeneous polynomial f in $K[x_0, \ldots, x_n]$ has a nontrivial zero provided $d^r \leq n$.

Then Lang proves the following theorem.

Theorem 5.2. *If X is a variety of dimension r over an algebraically closed field, then the function field $K(X)$ is C_r.*

It is natural to ask whether there is a common generalization of Theorem 4.1 and Theorem 5.2. In other words, can we single out a class of abstract varieties which generalizes the class of degree d hypersurfaces in $\mathbb{P}^n$ with $d^r \leq n$ such that they will always have a rational point over function fields of dimension r? So far there are few positive results, but there is an analogy which is extremely tantalizing and which takes as its starting point the observation that rational connectivity is just the usual topological notion of path connectedness with the interval replaced by $\mathbb{P}^1$. If we systematically translate between topology and algebraic geometry using fiber bundle as the analogue of family and the interval as the analogue of $\mathbb{P}^1$, then Theorem 4.1 translates into the elementary topological fact that over a one dimensional manifold, any fiber bundle with connected fiber admits a section.

This topological fact has a straightforward generalization to higher dimensional bases. Namely, if $\phi\colon X \to M$ is a fibration with M an r-dimensional manifold and fiber F such that $\pi_i(F) = 0$ for all $i < r$, then ϕ admits a section. This suggests the hope that we could try to define some notion of higher rational connectedness and prove a theorem that r-rationally connected varieties over r dimensional function fields have rational points.

Unfortunately, such a theorem cannot hold. Certainly any generalization of the class of low degree hypersurfaces will include projective space itself (the case $d = 1$.)

It is well known, however, that over higher dimensional bases, there are families all of whose fibers are isomorphic to $\mathbb{P}^n$ but which do not admit a section. The obstruction to the existence of a section lies in the Brauer group of the base of the family. While this might dash one's hope, de Jong and Starr have taken the optimistic view that at least in dimension 2, the Brauer group might be the only obstruction.

In particular, the Brauer class associated to a family of projective spaces admits a generalization to this situation. Given a morphism $\phi\colon X \to B$, one gets a sequence

$$\mathrm{Pic}(X_K) \to \mathrm{Pic}(X_{\overline{K}})^G \to \mathrm{Br}(K).$$

If X has a K-point, the rightmost map in this sequence vanishes, thus the nonvanishing of this map is an obstruction to the existence of a K-point. We will refer to this as the Brauer obstruction. We remark that this obstruction will always vanish for the projection to B of a hypersurface of dimension at least 3 in $\mathbb{P}^n \times B$. Now we can state the

Metaconjecture. There exists a notion of rationally simply connected such that for any morphism $\pi\colon X \to B$ with B a complex surface and with rationally simply connected general fiber, ϕ admits a rational section if and only if the Brauer obstruction vanishes. Moreover, for smooth hypersurfaces, this notion should agree with the condition that $d^2 \leq n$.

There is a natural guess for how to go about formulating what it means for a variety X to be rationally simply connected. For a topological space, simple connectivity means that the space of loops is path connected, or equivalently that the space of paths between any two fixed points is path connected. By again replacing paths with rational curves, we would arrive at a provisional definition that the space of rational curves joining two general points of X should be rationally connected. Unfortunately, this is impossible, since the space of rational curves joining two points will not even be connected – a rational curve has a discrete invariant, its homology class, which is invariant under deformation. The most we can ask for is for the space of rational curves *of fixed topological type* joining two general points to be rationally connected. Finally, it seems more reasonable to ask for this only in sufficiently positive homology classes since rational connectedness itself is really only a condition on the high degree curves. There are various possible meanings of "sufficiently positive" and the optimal choice is not clear. At least if $\mathrm{Pic}(X) = \mathbb{Z}$ (which will be the case for smooth hypersurfaces), the condition is unambiguous.

Unfortunately, this does not seem to be enough, since de Jong and Starr are able to prove that smooth hypersurfaces of degree d in $\mathbb{P}^n$ satisfy this constraint provided that $d^2 \leq n + 1$ which in this case is too good of a theorem, since Lang's result is sharp. To repair this, they propose that there is an additional condition which might be seen as an analogue of the condition appearing in the definition of separable rational connectivity, namely the existence of a curve in the space of curves satisfying certain positivity properties. This condition is satisfied for hypersurfaces of the desired degree range. We refer the reader to their preprints for the precise conditions they use.

They also propose a strategy for establishing that families of such varieties over surfaces possess a rational section provided that the Brauer obstruction vanishes. To date, they are able to carry out this program only under extremely restrictive hypotheses, which in particular rule out almost all families of hypersurfaces of degree greater than 2. Nonetheless, the work they have done lends tremendous credibility to the belief that there should be theorems in this direction, providing a geometric explanation for (at least the $r = 2$ case of) Lang's theorem. Moreover, their existing results apply to families of Grassmannians and give a new proof of de Jong's period-index theorem.

At this point, one might be inclined to believe that we would at least have a reasonably clear idea of how to generalize this type of conjecture to higher rational connectivity, but there are further issues to confront in order to do this. Since rational connectivity is a property depending only on the birational equivalence class of a variety, in defining rationally simply connected, we did not have to choose a particular compactification of the space of rational curves joining two general points. However, under any definition currently considered, the property of being rationally simply connected is not invariant under birational modification (and should not be), so to generalize these ideas to higher dimension, one needs either to fix a choice of compactification or find a different framework in which to discuss these questions. This direction is wide open and seems likely to provide interesting – and difficult – questions for some time to come.

Rigidity of rational homogeneous spaces

Jun-Muk Hwang

Abstract. Rigidity questions on rational homogeneous spaces arise naturally as higher dimensional generalizations of Riemann's uniformization theorem in one complex variable. We will give an overview of some results obtained in this area by the study of minimal rational curves and geometric structures defined by the their tangent directions.

Mathematics Subject Classification (2000). Primary 14J45; Secondary 32M10, 32G05.

Keywords. Uniformization, rational homogeneous space, minimal rational curves.

1. Introduction

Riemann's uniformization theorem in one complex variable says that the three basic Riemann surfaces, namely, the Riemann sphere $\mathbb{P}_1$, the complex plane $\mathbb{C}$ and the unit disc Δ, exhaust all simply connected Riemann surfaces. Finding an analog of this result in higher dimensions has been one of the main themes of research in complex geometry. A number of approaches from different view-points have been developed for this. Our approach here is to regard Riemann's uniformization theorem as a characterization of the three basic Riemann surfaces. From this approach, the uniformization problem in several complex variables is to find suitable conditions which characterize some basic classes of complex manifolds generalizing the three basic Riemann surfaces. The most natural higher-dimensional analogs of the three basic Riemann surfaces are Hermitian symmetric spaces. Thus the uniformization problem in several complex variables leads to the study of rigidity of Hermitian symmetric spaces.

A nice survey of results on the rigidity of Hermitian symmetric spaces obtained up to early 1990s was given in Siu's article 'Uniformization in Several Complex Variables' [28]. As one can see in [28], the methods employed are quite different depending on whether the Hermitian symmetric spaces are of compact type, of Euclidean type, or of non-compact type. The methods used for compact type have close connection with algebraic geometry, while those for Euclidean or non-compact types are closer to differential geometry. Since we have little expertise for the cases of Euclidean type or non-compact type, we will restrict our discussion to the case of compact type. From the view-point of algebraic geometry, it is more natural to consider a larger class of complex manifolds, the rational homogeneous spaces, which include Hermitian symmetric spaces of compact type. We will discuss rigidity problems of

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

rational homogeneous spaces, especially those related to the problems considered in Siu's survey. Our aim is to report the progress on these problems made after 1990.

As explained in Siu's survey, there are two approaches to the uniformization in several complex variables, one via topological conditions and the other via curvature conditions. The approach by topological conditions asks under what additional condition a complex manifold diffeomorphic to a rational homogeneous space is biholomorphic to it. The natural additional condition one can consider is the Kähler condition, the Moishezon condition or the deformation condition. Regarding the first two conditions, little new development was made after [28]. On the other hand, there has been much progress under the deformation condition. This development will be discussed in Section 3. The approach by curvature conditions is to characterize rational homogeneous spaces as manifolds with positive curvature in a suitable sense. There are various ways to impose curvature conditions, but all reasonable assumptions contain the positivity of the anti-canonical bundle. Complex manifolds with positive anti-canonical bundles are called Fano manifolds. Rational homogeneous spaces are just homogeneous Fano manifolds. Thus the question is to characterize homogeneous spaces among Fano manifolds by certain curvature properties of the tangent bundle. Typical examples are the Hartshorne conjecture, the Frankel conjecture and the generalized Frankel conjecture whose solutions by Mori [26], Siu-Yau [29], and Mok [23] were surveyed in [28]. In Section 4, we will discuss the Campana–Peternell conjecture, which generalizes these three results in the context of rational homogeneous spaces.

The results we will discuss on the rigidity problem both under the deformation condition and under the curvature condition depend on the study of minimal rational curves of Fano manifolds. This study originated from Mori's solution of the Hartshorne conjecture [26] which concerns the projective space. To handle problems on general rational homogeneous spaces other than the projective space, it is important to study the tangent directions of minimal rational curves, more precisely, the variety of minimal rational tangents (see Section 2 for definition). We will start with a discussion of this concept and related matters, before we discuss specific rigidity problems in Section 3 and Section 4. The methods of the variety of minimal rational tangents in the study of Fano manifolds have many aspects and applications other than those related to rigidity problems of rational homogeneous spaces. Here we will concentrate only on those aspects directly related to rational homogeneous spaces. For the other aspects, we refer the reader to [11], [14] and [18].

Some comments on the notation. For a vector space V, its projectivization $\mathbb{P}V$ is the set of 1-dimensional subspaces of V. For a complex manifold X and $x \in X$, the holomorphic tangent space of X at x will be denoted by $T_x(X)$ and the holomorphic tangent bundle of X will be denoted by $T(X)$.

Acknowledgment. I would like to thank Ngaiming Mok for valuable comments.

2. Geometric structures arising from minimal rational curves

To handle the rigidity questions, we need to show that a given complex manifold with certain additional conditions is a rational homogeneous space. Thus a common problem in these questions is how to recognize rational homogeneous spaces. Since we are interested in algebro-geometric conditions, we should be able to recognize them in terms of algebro-geometric data. Some special cases, like the projective spaces or the hyperquadrics, can be handled by the properties of certain linear systems. However such approaches are hard to generalize to other rational homogeneous spaces.

To get a hint on this problem, we should look at previous results in uniformization problems concerning rational homogeneous spaces more general than projective spaces or hyperquadrics. Very few results of this type are known. In Siu's survey [28], we found only one result of this type, namely, Mok's solution [23] of the generalized Frankel conjecture, which we will discuss again in Section 4. In Mok's work, after a deformation of the metric by the heat equation, one is given a compact complex manifold X with a Kähler metric g of positive Ricci curvature and of nonnegative holomorphic bisectional curvature, and one has to show that X is a symmetric space. For this, Mok constructed a distinguished subvariety $\mathcal{C}$ of the projectivized tangent bundle $\mathbb{P}T(X)$ which is a proper subvariety unless X is a projective space, and showed that $\mathcal{C}$ is invariant under the holonomy action of the Riemannian metric g. This implies that X is symmetric by Berger's theorem on Riemannian holonomy.

How should we formulate an algebro-geometric analog of Mok's argument? Luckily, Mok's construction of the distinguished subvariety $\mathcal{C} \subset \mathbb{P}T(X)$ is essentially algebraic. His construction can be generalized to arbitrary Fano manifolds as follows.

Let X be a Fano manifold. By Mori [26] X is covered by rational curves. Let us fix an irreducible component $\mathcal{K}$ of the space of rational curves whose members sweep out an open subset of X and have minimal degree with respect to the anticanonical bundle. Members of $\mathcal{K}$ are called minimal rational curves. Whenever we mention minimal rational curves below, we tacitly assume that a choice of $\mathcal{K}$ is made. For a general point $x \in X$, let $\mathcal{K}_x$ be the normalization of the subvariety of $\mathcal{K}$ parametrizing members of $\mathcal{K}$ passing through x. In [26], it is proved that $\mathcal{K}_x$ is a projective manifold. [20] showed that each member of $\mathcal{K}_x$ is immersed at x. Thus there exists a morphism

$$\tau_x : \mathcal{K}_x \longrightarrow \mathbb{P}T_x(X),$$

called the tangent morphism, assigning to each curve its tangent direction at x. Its image $\tau_x(\mathcal{K}_x)$ is called the variety of minimal rational tangents at x and denoted by $\mathcal{C}_x$. Let $\mathcal{C}$ be the closure of the union of $\{\mathcal{C}_x,\ \text{general } x \in X\}$ in $\mathbb{P}T(X)$. $\mathcal{C}$ is called the variety of minimal rational tangents. The variety $\mathcal{C}$ constructed in [23] on a Fano manifold X with nonnegative holomorphic bisectional curvature coincides with the variety of minimal rational tangents on X. It is helpful to look at some examples.

Example 1. Let X be the complex projective space $\mathbb{P}_n$. Minimal rational curves on X are just lines on the projective space. For any point $x \in X$ and any tangent direction

$\alpha \in \mathbb{P}T_x(X)$, there exists a line through x in the direction of α. Thus $\mathcal{C}_x = \mathbb{P}T_x(X)$ and $\mathcal{C} = \mathbb{P}T(X)$.

Example 2. Let X be the n-dimensional hyperquadric $\boldsymbol{Q}_n$ in $\mathbb{P}_{n+1}$. Minimal rational curves on X are just lines of $\mathbb{P}_{n+1}$ which lie on $\boldsymbol{Q}_n$. For a given point $x \in X$, the tangent directions to lines through x lying on $\boldsymbol{Q}_n$ defines a hyperquadric $\mathcal{C}_x \cong \boldsymbol{Q}_{n-2}$ in the projective space $\mathbb{P}T_x(X) \cong \mathbb{P}_{n-1}$.

Example 3. Let X be the Grassmannian $\mathbb{G}(u, v)$ of u-dimensional subspaces of a $(u + v)$-dimensional complex vector space V. There are two universal quotient bundles $\mathcal{U}$ of rank u and $\mathcal{V}$ of rank v such that $T(X) \cong \mathcal{U} \otimes \mathcal{V}$. There is a natural embedding of X into $\mathbb{P}\Lambda^u V$ called the Plücker embedding. Minimal rational curves on X are just lines of $\mathbb{P}\Lambda^u V$ lying on X. It is easy to check that for each $x \in X$, the variety of minimal rational tangents at x, $\mathcal{C}_x \subset \mathbb{P}T_x(X)$, is isomorphic to the set of pure tensors in $\mathbb{P}T_x(X) \cong \mathbb{P}(\mathcal{U}_x \otimes \mathcal{V}_x)$. In other words, $\mathcal{C}_x$ is isomorphic to the Segre embedding of $\mathbb{P}_{u-1} \times \mathbb{P}_{v-1}$.

Now we confront the second part of Mok's argument, which is more subtle: how to use the variety of minimal rational tangents to characterize rational homogeneous spaces. What should be the algebro-geometric analog of Riemannian holonomy and Berger's theorem? Since it is hard to answer this directly, let us approach from a more general setting. Riemannian holonomy is one special part of the general theory of geometric structures in differential geometry. In a broad sense, we can say that a geometric structure is given on a manifold X, if some extra conditions are imposed on the tangent bundle $T(X)$ or its associated fiber bundles. The existence of a distinguished subvariety $\mathcal{C}$ of the projectivized tangent bundle $\mathbb{P}T(X)$ of a complex manifold X can be regarded as a geometric structure on X. For example, the hyperquadric in Example 2 has the structure given by the hypersurface $\mathcal{C} \subset \mathbb{P}T(X)$ which defines a nondegenerate quadratic form on $T_x(X)$ up to a scalar. Such a structure is called a conformal structure. The Grassmannian in Example 3 has the variety of minimal rational tangents isomorphic to the Segre embedding. Such a geometric structure has been studied by differential geometers in connection with twistor theory.

Now that we have a geometric structure arising from minimal rational curves on any Fano manifold, how can we use them to characterize rational homogeneous spaces? A natural approach is by the equivalence problem for such geometric structures, which is the basic problem of E. Cartan's approach to differential geometry. The equivalence problem for the geometric structure is usually a local question. One may wonder whether such a local differential geometric study will be useful in dealing with problems formulated in algebraic geometry. More precisely, let us assume that there exists an analytic open subset $U \subset X$ such that the structure $\mathcal{C}|_U$ is equivalent to that of an analytic open subset of a rational homogeneous space S. What algebro-geometric consequence would this give? For example, can we say that X is biholomorphic to S? The answer is plainly no. A counterexample can be given just by setting X to be the blow-up of S along a subvariety. This example is certainly

uninteresting. There are a number of ways to avoid these inessential problems. One simple way is just to restrict our discussion to complex manifolds of second Betti number 1. This may look like an over-simplification, but there is still a lot to say even under this restriction. From now on let us assume that our complex manifolds have $b_2 = 1$. In this case, we have the following result which shows that the approach via local equivalence of geometric structures is promising.

Theorem 2.1. *Let X be a Fano manifold of $b_2 = 1$ and $\mathcal{C} \subset \mathbb{P}T(X)$ be the variety of minimal rational tangents associated to a family of minimal rational curves. Let S be a rational homogeneous space of $b_2 = 1$ different from $\mathbb{P}_n$ and $\mathcal{C}' \subset \mathbb{P}T(S)$ be the variety of minimal rational tangents. Suppose there exist connected analytic open sets $U \subset X$ and $U' \subset S$ with a biholomorphic map $\varphi\colon U \to U'$ such that its differential $d\varphi\colon \mathbb{P}T(U) \to \mathbb{P}T(U')$ sends $\mathcal{C}|_U$ onto $\mathcal{C}'|_{U'}$. Then φ can be extended to a biholomorphic map $X \cong S$.*

This is a special case of [15], where a similar result was proved for a large class of Fano manifolds including rational homogeneous spaces. The main idea of proof in [15] is the extension of the biholomorphic map φ outside U by an analytic continuation 'along the minimal rational curves'. This extension is possible over the whole manifold X because X is rationally connected by minimal rational curves from $b_2 = 1$. One difficulty of the problem is to prove the univalence of the analytic continuation, where the simply connectedness of X is used crucially.

By Theorem 2.1, the problem of recognizing rational homogeneous spaces of $b_2 = 1$ is reduced to the local equivalence question for the geometric structure defined by the variety of minimal rational tangents. So the question is how to show the existence of the local equivalence map φ. One necessary condition is that for each general point $x \in X$, the variety of minimal rational tangents $\mathcal{C}_x \subset \mathbb{P}T_x(X)$ must be isomorphic to the variety of minimal rational tangents $\mathcal{C}'_s \subset \mathbb{P}T_s(S)$ at a base point $s \in S$. In fact, it is expected that this is a sufficient condition:

Conjecture 2.2. Let S be a rational homogeneous space of $b_2 = 1$ and $\mathcal{C}'_s \subset \mathbb{P}T_s(S)$ be the variety of minimal rational tangents at a base point $s \in S$. Let X be a Fano manifold of $b_2 = 1$ and $\mathcal{C}_x \subset \mathbb{P}T_x(X)$ be the variety of minimal rational tangents at a general point $x \in X$ associated to a family of minimal rational curves. Suppose that $\mathcal{C}'_s \subset \mathbb{P}T_s(S)$ and $\mathcal{C}_x \subset \mathbb{P}T_x(X)$ are isomorphic as projective subvarieties. Then X is biholomorphic to S.

This conjecture is known to be true for a number of cases. When S is the projective space, it follows from the following result proved in [4]:

Theorem 2.3. *Let X be a Fano manifold whose variety of minimal rational tangents at a general point is the whole $\mathbb{P}T_x(X)$. Then X is the projective space.*

The proof in [4] is by a careful study of the singularity of minimal rational curves. When S is the hyperquadric of dimension ≥ 3, Conjecture 2.2 follows from Miyaoka's result [22]. In fact, Miyaoka proved the following stronger result.

Theorem 2.4. *Let X be a Fano manifold of $b_2 = 1$ whose variety of minimal rational tangents at a general point x is a hypersurface in $\mathbb{P}T_x(X)$. Then X is the hyperquadric.*

One special feature of Miyaoka's proof is that it requires a study of rational curves which are not minimal. It would be very interesting if one can prove Theorem 2.4 using only minimal rational curves. Conjecture 2.2 for hyperquadrics can be proved using only minimal rational curves as we will see shortly.

Methods used in [4] or [22] for projective spaces and hyperquadrics are rather special, unrelated to ideas of E. Cartan's equivalence problems. These methods cannot be applied to other rational homogeneous spaces to solve Conjecture 2.2. For general rational homogeneous spaces, the most promising approach seems to be via the techniques used in the equivalence problem for the geometric structure. The assumption in Conjecture 2.2 means that a geometric structure modelled on that of S is given on a Zariski open subset of X. By Theorem 2.1, the question is whether this structure is isomorphic to the standard one on S. There is a procedure in Cartan's theory to solve such problems. When a geometric structure is given, Cartan's procedure gives certain curvature tensors on some principal bundle whose vanishing will guarantee that the structure is locally isomorphic to the flat model of the given geometric structure. In fact, certain geometric structures modelled on rational homogeneous spaces have been studied in differential geometry ever since Cartan and the curvature tensors have been computed (e.g. [7], [30]). However, the model geometric structures on rational homogeneous spaces studied in these works do not necessarily agree with our geometric structure arising from the variety of minimal rational tangents. Recall that for each rational homogeneous space S of $b_2 = 1$, there is an associated simple root of the Lie algebra of automorphisms of S. When the rational homogeneous space S is associated to a long simple root, the two geometric structures coincide, as proved in [16]. These include Hermitian symmetric spaces and homogeneous contact manifolds, the latter meaning rational homogeneous spaces of $b_2 = 1$ where the isotropy representation on the tangent space has an irreducible subspace of codimension 1.

Thus at least for S associated to a long simple root, we have certain computational tools to check the validity of Conjecture 2.2: there are certain curvature tensors defined on the Zariski open subset of X at each point of which the variety of minimal rational tangents is isomorphic to the variety of minimal rational tangents at a point of S and the main problem is to show the vanishing of these curvature tensors. In some cases, these curvature tensors vanish for a purely local algebraic reason as proved in [31]. But in many cases, including the cases of Hermitian symmetric spaces and homogeneous contact manifolds, proving the vanishing of these curvature tensors requires a delicate geometric argument using minimal rational curves. One approach is to proceed in the following two steps. The first step is to prove the vanishing of the curvature assuming that the geometric structure modelled on S is defined on the whole X, in other words, that $\mathcal{C}_x$ is isomorphic to $\mathcal{C}'_s$ for each $x \in X$. Under this assumption, one studies the behavior of the curvature tensor along minimal rational curves to conclude the vanishing. This has been done for Hermitian symmetric spaces

in [12] and for homogeneous contact manifolds in [8]. The second step is to prove that the geometric structure modelled on S which is defined on a Zariski open subset of X extends to the whole X. This extension can be proved by looking at the local projective geometric invariants of the variety of minimal rational tangents $\mathcal{C}_x$ as x varies along a minimal rational curve, an idea introduced in [24]. In this manner, Conjecture 2.2 is proved for Hermitian symmetric spaces and homogeneous contact manifolds in [25]. It may be possible to extend these arguments further to prove Conjecture 2.2 when the rational homogeneous space is associated to a long simple root. However, Conjecture 2.2 for S associated to a short simple root looks much harder, and remains a challenge for future research.

Now that we know Conjecture 2.2 can be proved in many cases, how can we use this in the rigidity problems? The main question is how to get the assumption in Conjecture 2.2 from the conditions imposed on X in various rigidity questions. This depends on the individual rigidity problem and is often a difficult problem. We will see two examples below.

3. Deformation rigidity of rational homogeneous spaces

It is expected that the following generalization of Conjecture 3.5 in [28] holds. We will call it the deformation rigidity problem for rational homogeneous spaces.

Conjecture 3.1. Let $\pi : M \to \Delta$ be a smooth family of Fano manifolds such that the fiber M_t for each $t \neq 0$ is biholomorphic to a rational homogeneous space S. Then the central fiber M_0 is also biholomorphic to S.

More precisely speaking, this is the global deformation rigidity problem. It is well-known that the local deformation rigidity of rational homogeneous spaces follows from the vanishing $H^1(S, T(S)) = 0$, which is a consequence of Borel–Weil–Bott theorem.

Note that the Fano condition is necessary. In fact, the rational homogeneous space $S = \mathbb{P}_1 \times \mathbb{P}_1$ can be deformed to a non-Fano Hirzebruch surface. In this example, the automorphism group of S is not simple. One can also give examples whose automorphism groups are simple. For example, $S = \mathbb{P}T(\mathbb{P}_{2m+1})$ can be deformed to a non-Fano manifold of the form $\mathbb{P}(D \oplus L)$ where D is the null-correlation bundle and L is a line bundle on the odd-dimensional projective space $\mathbb{P}_{2m+1}$. In all these examples, $b_2(S) > 1$.

When $b_2(S) = 1$, the Fano condition is equivalent to the assumption that the central fiber is Kähler. In this case, it is expected that the following stronger rigidity holds.

Conjecture 3.2. Let $\pi : M \to \Delta$ be a smooth family of compact complex manifolds such that the fiber M_t for each $t \neq 0$ is biholomorphic to a rational homogeneous space S of $b_2 = 1$. Then the central fiber M_0 is also biholomorphic to S.

This is a generalization of Conjecture 3.4 in [28]. Conjecture 3.2 is proved for the projective space in [27] and for the hyperquadric in [9]. In these works, the main problem is to prove the existence of certain rational curves on M_0, which can play the role of minimal rational curves of Fano manifolds. Thus the nature of the problem is quite different from what we have discussed in Section 2. At the moment, it looks very hard to generalize the methods of [9] and [27] to other homogeneous spaces. For the other cases, the weaker conjecture, Conjecture 3.1, is already very interesting.

Regarding Conjecture 3.1, little work has been done when $b_2(S) > 1$. Conjecture 3.1 when $b_2(S) = 1$ has been proved in a series of works [10], [13] [16], [17], [19]. For the rest of the section, we will sketch the main ideas in this proof.

Taking the approach to rigidity problems discussed in Section 2, we see that one central problem is the following. Let $x \in M_0$ be a general point. Is the variety of minimal rational tangents at x, $\mathcal{C}_x \subset \mathbb{P}T_x(M_0)$, isomorphic to that of S?

To handle this question, we proceed as follows. Let us take a section $\{x_t, t \in \Delta\}$ of π such that $x_0 = x$. We compare the family of tangent morphisms

$$\tau_{x_t} \colon \mathcal{K}_{x_t} \to \mathcal{C}_{x_t} \subset \mathbb{P}T_{x_t}(M_t)$$

with the model

$$\tau_s \colon \mathcal{K}_s \to \mathcal{C}_s \subset \mathbb{P}T_s(S).$$

By the assumption τ_{x_t} is isomorphic to τ_s when $t \neq 0$. In particular, $\{\mathcal{K}_{x_t}, t \in \Delta\}$ is a smooth family of projective manifolds such that $\mathcal{K}_{x_t}$ is biholomorphic to $\mathcal{K}_s$ for $t \neq 0$. The first question to ask is whether $\mathcal{K}_{x_0}$ is biholomorphic to $\mathcal{K}_s$. This itself is a deformation rigidity problem. For many cases of S, $\mathcal{K}_s$ itself is a rational homogeneous space. In general, $\mathcal{K}_s$ is a variety very close to a rational homogeneous space. This indicates the possibility of using an induction on the dimension to solve Conjecture 3.1. Indeed, using additional information coming from the fact that $\mathcal{K}_{x_0}$ is the space of minimal rational curves through x_0, we can carry out this induction argument to show that $\mathcal{K}_{x_0}$ is biholomorphic to $\mathcal{K}_s$.

Now the problem is reduced to the study of the linear system defining τ_{x_t}. For the model S, τ_s is defined by a complete linear system when we view it as a morphism into the linear span of $\mathcal{C}_s$. Thus to show that τ_{x_0} is isomorphic to τ_s, it suffices to show that the linear span of $\mathcal{C}_{x_0}$ has the same dimension as that of $\mathcal{C}_s$. This leads to the study of the linear span of the variety of minimal rational tangents.

To crystalize the essential idea here, it is better to deal with a general Fano manifold X of $b_2 = 1$. Assume that we have a choice of the variety of minimal rational tangents $\mathcal{C} \subset \mathbb{P}T(X)$ such that for a general $x \in X$, $\mathcal{C}_x$ is irreducible. Let $D_x \subset T_x(X)$ be the linear span of $\mathcal{C}_x$. As x varies, D_x defines a Pfaffian system D on a Zariski open set of X. From the topological restriction $b_2(X) = 1$, one can show that D cannot be integrable. An essential property of D, which is one of the key points of [13], is that the Frobenius bracket at a general point

$$[\,,\,] \colon \Lambda^2 D_x \to T_x(X)/D_x$$

annihilates planes in D_x corresponding to tangent lines to the variety of minimal rational tangents $\mathcal{C}_x$. This follows from deformation theoretic properties of minimal rational curves.

Applying this general property of D to the variety of minimal rational tangents on M_0, one can show that if the linear span of $\mathcal{C}_{x_0}$ has dimension different from that of $\mathcal{C}_s$, then the Pfaffian system generated by $\mathcal{C}_{x_0}$ must be integrable, a contradiction to $b_2(M_0) = 1$. Thus we conclude that τ_{x_0} is isomorphic to τ_s.

From the discussion in Section 2, this already shows Conjecture 3.1 for Hermitian symmetric spaces and homogeneous contact manifolds. Also, when S is associated to a long simple root, we know, from Section 2, that there are some curvature tensors defined in a neighborhood of x_0 whose vanishing will guarantee that M_0 is biholomorphic to S. Since M_t has the same geometric structure modelled on S, the curvature tensor at x_0 is just the limit of the curvature tensor at x_t. As M_t, $t \neq 0$, is biholomorphic to S, the curvature tensor at x_t, $t \neq 0$, vanishes. By the continuity, the curvature tensor also vanishes at x_0. This completes the proof of Conjecture 3.1 when S is associated to a long simple root.

When S is associated to a short root, this argument does not work. In a sense, the difficulty lies in local differential geometry: the geometric structure given by the variety of minimal rational tangents has only part of the information needed for the geometric structure modelled on S studied by differential geometers. Thus we have only a 'crude' geometric structure, and in terms of this crude structure, S is not quite flat. One can still hope that there are certain structure constants involved and the constancy of the structure constants for $t \neq 0$ would imply that they remain unchanged at $t = 0$. Unfortunately, this idea can be worked out only in one special case [17].

For the final handling of Conjecture 3.1 for S associated to a short root, we do not deal with the equivalence problem directly. But instead we use the variety of minimal rational tangents to control the automorphism group of M_0. In a sense, instead of showing directly that the geometric structure defined by the variety of minimal rational tangents on M_0 is locally equivalent to that of S, we study the local automorphisms of the geometric structure to show that the group of automorphisms of M_0 is isomorphic to that of S. This suffices to conclude that M_0 is biholomorphic to S, in the setting of the deformation problem.

The study of the local automorphisms of a geometric structure leads to the theory of prolongations of linear Lie algebras (cf. [3], [21]). This theory is essentially algebraic and many works have been done in the context of the theory of filtered Lie algebras. Unfortunately, many results in this area requires that the linear Lie algebra involved is reductive, while the linear Lie algebra of the infinitesimal automorphisms of the variety of minimal rational tangents of a rational homogeneous space associated to a short root is not reductive. Thus from the view-point of Lie algebras, the variety of minimal rational tangents $\mathcal{C}_s$ is not really a nice object. But from the view-point of projective algebraic geometry, $\mathcal{C}_s$ is very nice: it is smooth and linearly normal, among other things. This motivates us to develop the theory of prolongations of linear

automorphisms of such nice projective varieties, using projective geometry instead of Lie algebra. In this theory, one makes use of the rich results on projective geometry such as [32] to replace the computational tool of semi-simple Lie algebras. This theory is developed in [19] to the extent needed for the proof of Conjecture 3.1 for S of $b_2 = 1$. As a byproduct, one can give new geometric proofs of many results on prolongations of reductive linear Lie algebras, too.

Readers must have noticed that our proof of Conjecture 3.1 for $b_2(S) = 1$ is not very uniform. A proof of Conjecture 2.2, or a further development of the prolongation theory of [19] would give a more uniform proof of Conjecture 3.1.

Conjecture 3.1 for the case of $b_2(S) > 1$ is wide open, except for some special cases. To attack this general situation, we would need to develop the theory of the variety of minimal rational tangents for Fano manifolds with $b_2 > 1$. Fano manifolds with $b_2 > 1$ admit non-trivial Mori contractions, which are crucial in understanding their geometry. Thus the geometry of the variety of minimal rational tangents has to be combined with Mori theory. This will be an interesting direction for future research.

4. The Campana–Peternell conjecture

The generalized Frankel conjecture which was proved by Mok in [23] states that a Fano manifold with a Kähler metric with nonnegative holomorphic bisectional curvature is a Hermitian symmetric space of compact type. In [1], Campana and Peternell proposed an algebraic generalization of this. Here we will discuss the following slightly stronger form of their conjecture:

Conjecture 4.1. A Fano manifold X is homogeneous if all rational curves on X are free.

A rational curve $\nu\colon \mathbb{P}_1 \to X$ is free if $\nu^*T(X)$ is a semi-positive vector bundle. There are many reasons to believe that Conjecture 4.1 is one of the central problems of the uniformization theory in several complex variables. In [5], it is proved that Conjecture 4.1 would give a complete description of Kähler manifolds with semi-positive curvature in a most reasonable sense.

One can check that Conjecture 4.1 is true for $\dim X \leq 3$ from the classification of Fano threefolds (cf. [1], [33]). However, in higher dimensions, very few results on Conjecture 4.1 are known. In the rest of the paper we will give a proof of the following which illustrates how the variety of minimal rational tangents can be used in rigidity problems.

Theorem 4.2. *Conjecture* 4.1 *is true in dimension* 4.

The proof uses the works of [2], [4], [22] and [24]. First of all, using Mori theory, [2] showed that Theorem 4.2 is true for Fano 4-folds with $b_2 > 1$. Thus we may

assume that $b_2(X) = 1$. Pick a family of minimal rational curves on X and consider the variety of minimal rational tangents $\mathcal{C}_x$ at a general point $x \in X$. Suppose $\dim \mathcal{C}_x = 3$. Then $X = \mathbb{P}_4$ by Theorem 2.3. Suppose $\dim \mathcal{C}_x = 2$. Then $X = \boldsymbol{Q}_3$ by Theorem 2.4. If $\dim \mathcal{C}_x = 0$, the freeness of all minimal rational curves implies $\mathcal{C}$ is an etale cover of X. Since a Fano manifold is simply connected, this shows that $\mathcal{C}$ is biholomorphic to X by the natural projection. This will give a regular foliation of X by minimal rational curves, a contradiction to $b_2(X) = 1$. Thus we are left with the case of $\dim \mathcal{C}_x = 1$. To handle this case, we use the following result of Mok from [24].

Theorem 4.3. *Let X be a Fano manifold with $b_2(X) = 1$. Assume that all rational curves on X are free and $\dim \mathcal{C}_x = 1$ for a general point $x \in X$. Assume in addition that $b_4(X) = 1$. Then X is homogeneous.*

Let us give a brief sketch of Mok's proof. By the freeness of rational curves, the space $\mathcal{K}$ of minimal rational curves is a projective manifold and the associated universal family morphisms $\rho\colon \mathcal{U} \to \mathcal{K}$, $\mu\colon \mathcal{U} \to X$ are smooth morphisms whose fibers are curves. By definition, ρ is a $\mathbb{P}_1$-bundle. If the fibers of μ have genus ≥ 1, μ must be a trivial fiber bundle over minimal rational curves on X. This contradicts some basic geometric feature of the morphism μ. Thus μ is a $\mathbb{P}_1$-bundle and the variety of minimal rational tangents at each $x \in X$ is a rational curve. The key point of [24] is to show that this rational curve $\mathcal{C}_x \subset \mathbb{P}T_x(X)$ has degree $d \leq 3$. Using this bound, one can see that the geometric structure defined by $\mathcal{C}$ is isomorphic to the one modelled on $\mathbb{P}_2$, $\boldsymbol{Q}_3$, or the 5-dimensional homogeneous contact manifold. Thus by the discussion in Section 2, X must be the model.

To get the bound on the degree d of $\mathcal{C}_x \subset \mathbb{P}T_x(X)$, Mok observed that there exists a stable vector bundle of rank 2 on $\mathcal{K}$ whose projectivization is $\rho\colon \mathcal{U} \to \mathcal{K}$. The crucial part of Mok's work is to show that the Chern number inequality for this stable bundle on $\mathcal{K}$ gives the bound $d \leq 3$. The additional assumption $b_4(X) = 1$ was used in this step. $b_4(X) = 1$ implies $b_4(\mathcal{K}) = 1$, which makes it possible to translate the Chern number inequality to the inequality $d \leq 3$.

In order to use Theorem 4.3 to complete the proof of Theorem 4.2, it suffices to show that the additional assumption $b_4(X) = 1$ in Theorem 4.3 can be removed. Since this part has not appeared in print, we will give full details.

First recall from [6] that the i-th Chow group $A_i(Z)$ of a variety Z is the abelian group of algebraic cycles of dimension i on Z modulo the rational equivalence. The i-th rational Chow group $A_i(Z)_{\mathbb{Q}}$ is the tensor product of $A_i(Z)$ with $\mathbb{Q}$. As mentioned above, the condition $b_4(X) = 1$ in the proof of Theorem 4.3 was used to get $b_4(\mathcal{K}) = 1$, which was necessary for the Chern class computation to get $d \leq 3$. Since Chern classes can be defined as algebraic cycles, it suffices to have $A_2(\mathcal{K})_{\mathbb{Q}} \cong \mathbb{Q}$ to conclude $d \leq 3$.

To prove $A_2(\mathcal{K})_{\mathbb{Q}} \cong \mathbb{Q}$ in the setting of Theorem 4.3 (without the assumption $b_4(X) = 1$), we use the double $\mathbb{P}_1$-bundle structure on $\mathcal{U}$ given by ρ and μ. We define, inductively, a sequence of smooth irreducible projective varieties Z_i, $i = 1, 2, 3 \ldots$,

of dimension i together with a morphism $\nu_i : Z_{i+1} \to Z_i$ and a morphism $\eta_i : Z_i \to \mathcal{U}$ as follows. Fix a general point $x \in X$. Let $Z_1 := \mu^{-1}(x)$ and $\eta_1 : Z_1 \to \mathcal{U}$ be the natural injection. Let Z_2 be the $\mathbb{P}_1$-bundle on Z_1 obtained as the pull-back of ρ by the morphism $\rho \circ \eta_1 : Z_1 \to \mathcal{K}$. Denote the bundle map $Z_2 \to Z_1$ by ν_1 and the natural map $Z_2 \to \mathcal{U}$ by η_2. Note that ν_1 has a natural section defined by η_1. Now let Z_3 be the $\mathbb{P}_1$-bundle over Z_2 obtained as the pull-back of μ by the morphism $\mu \circ \eta_2$. Denote the bundle map by $\nu_2 : Z_3 \to Z_2$ and the natural map $Z_3 \to \mathcal{U}$ by η_3. Then ν_2 has a natural section defined by η_2. Continuing in this manner, we define Z_{i+1} to be the $\mathbb{P}_1$-bundle over Z_i obtained as the pull-back of ρ or μ by $\rho \circ \eta_i$ or $\mu \circ \eta_i$ depending on whether i is odd or even. Denote the bundle map by $\nu_i : Z_{i+1} \to Z_i$ and the natural map to $\mathcal{U}$ by η_{i+1}. Then ν_i has a section defined by η_i.

Now we will apply the following lemma which is a simple consequence of Theorem 3.3 in [6].

Lemma 4.4. *Let $p : Z' \to Z$ be a $\mathbb{P}_1$-bundle with a section $\sigma : Z \to Z'$. Then any $\beta \in A_k(Z')$ is of the form $\beta = \sigma_*\alpha + p^*\gamma$ for some $\alpha \in A_k(Z)$ and $\gamma \in A_{k-1}(Z)$.*

Note that since X, $\mathcal{K}$ and Z_i are all rationally connected, $A_0(X)_{\mathbb{Q}} \cong A_0(\mathcal{K})_{\mathbb{Q}} \cong A_0(Z_i)_{\mathbb{Q}} \cong \mathbb{Q}$. Repeatedly applying Lemma 4.4, we see that $A_1(Z_i)$ is generated by curves which are sent by η_i to either a ρ-fiber or a μ-fiber in $\mathcal{U}$. Similarly, $A_2(Z_i)$ is generated by surfaces whose images in $\mathcal{U}$ under η_i are either a curve or surfaces of the form $\mu^{-1}(\mu(C))$ for some ρ-fiber C or $\rho^{-1}(\rho(C'))$ for some μ-fiber C'. It follows that the rank of the image of the push-forward

$$(\rho \circ \eta_i)_* : A_2(Z_i)_{\mathbb{Q}} \to A_2(\mathcal{K})_{\mathbb{Q}}$$

is ≤ 1. From $b_2(X) = 1$, there exists some ℓ such that $\eta_\ell : Z_\ell \to \mathcal{U}$ is surjective. Recall that when $\psi : Z \to Y$ is a proper surjective morphism of algebraic varieties, the induced push-forward map $\psi_* : A_i(Z)_{\mathbb{Q}} \to A_i(Y)_{\mathbb{Q}}$ is surjective. Thus

$$(\rho \circ \eta_\ell)_* : A_2(Z_\ell)_{\mathbb{Q}} \to A_2(\mathcal{K})_{\mathbb{Q}}$$

is surjective. It follows that $A_2(\mathcal{K})_{\mathbb{Q}} \cong \mathbb{Q}$. This finishes the proof of Theorem 4.2.

Geometry of multiple zeta values

Tomohide Terasoma

Abstract. Many relations are known between multiple zeta values $\zeta(k_1, \dots, k_n)$. A relation coming from the associator condition for the Drinfeld associator, the generating function of multiple zeta values, is a geometric relation. By the theory of mixed motives, we can control the dimension of the rational linear hull of multiple zeta values. The harmonic shuffle relation also comes from geometry, and more strongly, this is implied by the associator relation.

Mathematics Subject Classification (2000). Primary 14C30; Secondary 14F42.

Keywords. Multiple zeta value, mixed motif.

1. Introduction

Let $k_1, \dots, k_n \geq 1$ be integers such that $k_n \geq 2$. We define a multiple zeta value $\zeta(k_1, \dots, k_n)$ by

$$\zeta(k_1, \dots, k_n) = \sum_{0<m_1<m_2<\cdots<m_n} \frac{1}{m_1^{k_1} \cdots m_n^{k_n}}.$$

We define the weight w of the index $(k_1, \dots, k_n)$ by $w = k_1 + \cdots + k_n$. Many relations between multiple zeta values are known for a long time; for example,

$$\zeta(2) \cdot \zeta(2) = 4\zeta(1,3) + 2\zeta(2,2), \quad \zeta(3) = \zeta(1,2), \quad \zeta(4) = 4\zeta(1,3).$$

The first one is a quadratic relation and the second and the third ones are linear relations between multiple zeta values. Several systematic methods are known to produce a series of relations for multiple zeta values: iterated integral shuffle relation, duality relation, harmonic shuffle relation, and so on. The iterated integral relation and the duality relation are a part of the associator relation, which is closely related to the Grothendieck–Teichmüller group. These relations produce many linear relations between multiple zeta values. What is very interesting is that all the known rational relations preserve the weights introduced above. So it is natural to expect that all $\mathbb{Q}$-relations come from geometry.

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

2. Iterated integral expression

A multiple zeta value has an iterated integral expression, which enables us to study multiple zeta values from a geometric point of view. Let $\omega_1, \dots, \omega_n$ be one-forms on a manifold X and let $\gamma\colon [0,1] \to X$ be a path starting from a point a and ending with a point b. An iterated integral is defined by

$$\int_\gamma \omega_1\omega_2\cdots\omega_n = \int_{0<t_n<t_{n-1}<\cdots<t_1<1} \mathrm{pr}_1^*\,\omega_1 \wedge \mathrm{pr}_2^*\,\omega_2 \wedge \cdots \wedge \mathrm{pr}_n^*\,\omega_n,$$

where $\mathrm{pr}_i\colon [0,1]^n \to [0,1]$ is the i-th projection. A multiple zeta value is expressed as

$$\zeta(k_1,\dots,k_n) = \int_{[0,1]} \left(\frac{dx}{x}\right)^{k_n-1} \frac{dx}{1-x} \cdots \left(\frac{dx}{x}\right)^{k_1-1} \frac{dx}{1-x}.$$

To control many relations it is convenient to consider the "generating function" of multiple zeta values which is called the Drinfeld associator ([Dr]). Let $A = \mathbb{C}\langle\langle e_0, e_1\rangle\rangle$ be the non-commutative formal power series ring generated by e_0 and e_1 over $\mathbb{C}$ and $\omega = \frac{e_0 dx}{x} + \frac{e_1 dx}{x-1}$ an A-valued one-form. The Drinfeld associator Φ is defined by

$$\Phi = \Phi(e_0, e_1) = \lim_{t\to 0} t^{-e_1}\left[\exp\int_t^{1-t}\omega\right]t^{e_0},$$

where $\exp\int_a^b \omega = 1 + \sum_{i=1}^\infty \int_a^b \underbrace{\omega\cdots\omega}_{i\text{-times}}$. The multiple zeta value $(-1)^n\zeta(k_1,\dots,k_n)$ appears as the coefficient of $e_0^{k_n-1}e_1\cdots e_0^{k_1-1}e_1$.

3. Period of fundamental group of $\mathbb{P}^1 - \{0, 1, \infty\}$

The Drinfeld associator Φ describes the period of the fundamental group of $\mathcal{M}_{0,4} = \mathbb{P}^1 - \{0,1,\infty\}$ for tangential base points introduced by Deligne [De]. Let $|\mathcal{M}_{0,4}| = \{\vec{01}, \vec{10}, \dots\}$ be a set of tangential points of $\mathcal{M}_{0,4}$ and p, q be elements of $|\mathcal{M}_{0,4}|$. The comparison isomorphism

$$\mathrm{comp}\colon \mathbb{Q}[\pi_1(\mathbb{P}^1 - \{0,1,\infty\}, p, q)]\hat{} \otimes \mathbb{C} \simeq \mathbb{Q}\langle\langle e_0, e_1\rangle\rangle \otimes \mathbb{C} \tag{1}$$

defines a mixed Hodge structure on $\mathbb{Q}[\pi_1(\mathbb{P}^1 - \{0,1,\infty\}, p, q)]\hat{}$. The Drinfeld associator is equal to the image of $[0,1]$ under the comparison homomorphism. The Drinfeld associator satisfies the associator relations arising from the compatibility condition for homomorphisms of mixed Hodge structures. In general, the associator relations can be formulated via the compatibility condition for isomorphisms between topological and de Rham fundamental groups. To interpret an associator as a functorial isomorphism we introduce the fundamental category (Fund) and the notion of algebroids.

Definition 3.1. Let K be a field. A K-algebroid $\mathcal{U} = \{\mathcal{U}_{ab}\}_{ab}$ over a set B consists of

(1) a family of K-vector spaces $\{\mathcal{U}_{ab}\}_{ab}$ indexed by $a, b \in B$, and
(2) a family of homomorphisms

$$\mathcal{U}_{bc} \otimes \mathcal{U}_{ab} \to \mathcal{U}_{ac},$$

which is associative.

We assume the following properties:

(1) For $a \in B$ the associative ring $\mathcal{U}_{aa}$ has a unit.
(2) The vector space $\mathcal{U}_{ab}$ is a free left $\mathcal{U}_{bb}$-module of rank one and a free right $\mathcal{U}_{aa}$-module of rank one.
(3) The natural homomorphism

$$\mathcal{U}_{bc} \otimes_{\mathcal{U}_{bb}} \mathcal{U}_{ab} \to \mathcal{U}_{ac}$$

is an isomorphism.

We can define the notion of K-Hopf algebroids similarly. For a $\mathbb{Q}$-algebraic variety, by attaching a completion of the $\mathbb{Q}$-linear hull of Betti and de Rham fundamental groupoids, we get two functors

$$\mathcal{U}^{\mathrm{B}}, \mathcal{U}^{\mathrm{DR}} \colon (\mathrm{Var}/\mathbb{Q}) \to (\text{Hopf-alg}/\mathbb{Q})$$

from the category $(\mathrm{Var}/\mathbb{Q})$ of $\mathbb{Q}$-algebraic varieties to the category $(\text{Hopf-alg}/\mathbb{Q})$ of $\mathbb{Q}$-Hopf algebroids. The comparison map obtained by Hodge theory gives a functorial isomorphism of these two functors over $\mathbb{C}$.

The object of the fundamental category (Fund) consists of four spaces $\mathcal{M}_{0,4}$, $\mathcal{M}_{0,5}$, $\overline{\mathcal{M}_{0,4}} - \{0, \infty\}$ and the punctured disc Δ^*, with tangential points. Morphisms are generated by

(1) inclusions $\Delta^* \to \mathcal{M}_{0,4}$ around points 0, 1 or ∞,
(2) "infinitesimal inclusions" $\mathcal{M}_{0,4} \to \mathcal{M}_{0,5}$, and
(3) natural inclusion $\mathcal{M}_{0,4} \to \overline{\mathcal{M}_{0,4}} - \{0, \infty\}$.

We can define two functors of Betti and de Rham fundamental algebroids over a set of tangential points $\mathcal{U}^{\mathrm{B}}(?) = \mathbb{Q}[\pi_1^{\mathrm{B}}(?)]\hat{}$ and $\mathcal{U}^{\mathrm{DR}}(?) = \mathbb{Q}[\pi_1^{\mathrm{DR}}(?)]\hat{}$: $(\mathrm{Fund}) \to (\text{Hopf-alg}/\mathbb{Q})$. The set of functorial isomorphisms from $\mathcal{U}^{\mathrm{B}} \otimes \mathbb{C}$ to $\mathcal{U}^{\mathrm{DR}} \otimes \mathbb{C}$ is denoted by $\mathrm{Isom}(\mathcal{U}^{\mathrm{B}} \otimes \mathbb{C}, \mathcal{U}^{\mathrm{DR}} \otimes \mathbb{C})$.

Definition 3.2 (Associator). (1) Let ρ and e be the canonical generators of $\pi_1(\Delta^*, +)$ and the dual of $\frac{dx}{x}$ in $\mathcal{U}^{\mathrm{DR}}(\Delta^*)$. Here $+$ denotes a tangential point of Δ^* defined by the local coordinate x. For an element $\varphi \in \mathrm{Isom}(\mathcal{U}^{\mathrm{B}} \otimes \mathbb{C}, \mathcal{U}^{\mathrm{DR}} \otimes \mathbb{C})$ we define $\lambda(\varphi) \in \mathbb{C}^\times$ by $\lambda(\varphi) = \varphi(\log(\rho))/e$. Thus we have a map

$$\lambda \colon \mathrm{Isom}(\mathcal{U}^{\mathrm{B}} \otimes \mathbb{C}, \mathcal{U}^{\mathrm{DR}} \otimes \mathbb{C}) \to \mathbb{C}^\times.$$

(2) We define the set of associator Ass as the inverse image

$$\lambda^{-1}(2\pi i) \subset \mathrm{Isom}(\mathcal{U}^{\mathrm{B}} \otimes \mathbb{C}, \mathcal{U}^{\mathrm{B}} \otimes \mathbb{C})$$

of $2\pi i$ under the map λ.

Remark 3.3. The functorial isomorphism φ is determined by the element $\Phi = \varphi([0,1]) \in \mathcal{U}^{\mathrm{DR}}(\mathcal{M}_{0,4}) = \mathbb{C}\langle\langle e_0, e_1\rangle\rangle$. The condition for an element Φ to be able to be continued to a functorial isomorphism is nothing but the classical condition for associators (see [Dr]). By this correspondence, the Drinfeld associator corresponds to the classical comparison map. This has been communicated to the author by M. Matsumoto.

Definition 3.4 (Grothendieck–Teichmüller group). (1) Let X be an algebraic variety over $\mathbb{Q}$. The $\mathbb{Q}_l$ completion of the etale fundamental groupoid of a variety $X \otimes \overline{\mathbb{Q}}$ is denoted by $\pi_1^l(X \otimes \overline{\mathbb{Q}})$. The completion of the $\mathbb{Q}_l$-linear hull of $\pi_1^l(X \otimes \overline{\mathbb{Q}})$ is denoted by $\mathcal{U}^l(X)$. If X is one of $\Delta^* = \mathrm{Spec}(\mathbb{Q}[\![x]\!])$, $\mathcal{M}_{0,4}$ or $\mathcal{M}_{0,5}$, we can similarly define similar tangential base points (see [I]). The Hopf algebroid $\mathcal{U}^l(X)$ gives a functor $\mathcal{U}^l$: (Fund) $\to$ (Hopf-alg/$\mathbb{Q}_l$).

(2) Let $* = \mathrm{B}, \mathrm{DR}$ or l. The group $\mathrm{GT}_* = \mathrm{Aut}(\mathcal{U}^*)$ of functorial automorphisms of $\mathcal{U}^*$ is called the $*$-Grothendieck–Teichmüller group. The groups GT_{B}, $\mathrm{GT}_{\mathrm{DR}}$ and GT_l are pro-algebraic groups over $\mathbb{Q}$, $\mathbb{Q}$ and $\mathbb{Q}_l$, respectively. For an element of $\varphi \in \mathrm{Aut}(\mathcal{U}^*)$, by attaching $\varphi(\Delta^*) \in \mathrm{Aut}_{\text{Hopf-alg}}(\mathcal{U}^*(\Delta^*))$, we have a homomorphism of pro-algebraic groups:

$$\lambda\colon\ \mathrm{GT}_* = \mathrm{Aut}(\mathcal{U}^*) \to \boldsymbol{G}_m,$$

where $\boldsymbol{G}_m$ is the multiplicative group. The kernel of $\lambda\colon\ \mathrm{GT}_* \to \boldsymbol{G}_m$ is denoted by $\mathrm{GT}_*^{(1)}$. It is a pro-nilpotent algebraic group.

(3) By the action of $\mathrm{Gal}(\overline{\mathbb{Q}}/\mathbb{Q})$ we have a natural homomorphism $\mathrm{Gal}(\overline{\mathbb{Q}}/\mathbb{Q}) \to \mathrm{GT}_l$.

4. Mixed Tate motives and Grothendieck–Teichmüller group

Following Levine, Voevodsky, Hanamura ([L]) we can define an abelian category $\mathrm{MTM}_{\mathbb{Q}}$ of mixed Tate motives over $\mathbb{Q}$. Goncharov ([G]) defined a full subcategory $\mathrm{MTM}_{\mathbb{Z}}$ of mixed Tate motives over $\mathbb{Z}$. By the classical comparison map (1), $\mathcal{U}^{\mathrm{B+DR}}(\mathbb{P}^1 - \{0,1,\infty\})_{\vec{01},\vec{10}}$ becomes a mixed Hodge structure of mixed Tate type. This mixed Hodge structure is obtained by the nearby fiber (= the limit of mixed Hodge structure) at $\vec{01}, \vec{10}$ of the variation of mixed Hodge structure $\mathcal{U}(\mathbb{P}^1 - \{0,1,\infty\})_{ab}$ of two variables a, b. It is natural to expect that the near by fiber of a family of mixed motives is also a mixed motif, which is not well formulated up to now. In fact, for Hodge realization, a limit of a mixed Hodge structure depends on "the tangential structure", i.e. the choice of a branch of "$\log(t)$". But in our setting, we are very happy to have the following.

Theorem 4.1 (Deligne–Goncharov [DG], Terasoma [T]). *There exists an object* $\mathcal{U}^M(\mathbb{P}^1 - \{0, 1, \infty\})^{\rightarrow\ \rightarrow}_{01,10}$ *in* $\mathrm{MTM}_{\mathbb{Z}}$ *whose Hodge realization is isomorphic to* $\mathcal{U}^{\mathrm{B+DR}}(\mathbb{P}^1 - \{0, 1, \infty\})^{\rightarrow\ \rightarrow}_{01,10}$.

We state a consequence of the above theorem in the language of Tannakian category. Let $H^{\mathrm{DR}}\colon \mathrm{MTM}_{\mathbb{Z}} \to (\mathrm{Vec}_{\mathbb{Q}})$ be the de Rham realization functor, let $\pi_1(\mathrm{MTM}_{\mathbb{Z}}, H^{\mathrm{DR}})$ be the Tannaka fundamental group (see [DM]) of $\mathrm{MTM}_{\mathbb{Z}}$ for the fiber functor H^{DR} and let $\lambda\colon \pi_1(\mathrm{MTM}_{\mathbb{Z}}, H^{\mathrm{DR}}) \to \boldsymbol{G}_m$ be the homomorphism obtained by the functor attaching the associated graded module for weight filtration. The kernel of λ is denoted by $\pi_1(\mathrm{MTM}_{\mathbb{Z}}, H^{\mathrm{DR}})^{(1)}$. Let $\mathcal{U}(\pi_1(\mathrm{MTM}_{\mathbb{Z}}, H^{\mathrm{DR}}))$ be the completion of the $\mathbb{Q}$-linear hull of $\pi_1(\mathrm{MTM}_{\mathbb{Z}}, H^{\mathrm{DR}})$. An object in $\mathrm{MTM}_{\mathbb{Z}}$ corresponding to the representation $\mathcal{U}(\pi_1(\mathrm{MTM}_{\mathbb{Z}}, H^{\mathrm{DR}}))$ of $\pi_1(\mathrm{MTM}_{\mathbb{Z}}, H^{\mathrm{DR}})$ is denoted by $\mathcal{U}^M(\pi_1(\mathrm{MTM}_{\mathbb{Z}}))$. By the above theorem and the definition of Tannaka fundamental group, $H^{\mathrm{DR}}\mathcal{U}^M(\mathbb{P}^1 - \{0, 1, \infty\})^{\rightarrow\ \rightarrow}_{01,10})$ becomes a (homogeneous) $\mathcal{U}(\pi_1(\mathrm{MTM}_{\mathbb{Z}}, H^{\mathrm{DR}}))$-module. Therefore the periods of $\mathcal{U}^M(\mathbb{P}^1 - \{0, 1, \infty\})$ are controlled by those of $\mathcal{U}^M(\pi_1(\mathrm{MTM}_{\mathbb{Z}}))$. Taking into account the real structures we have the following corollary.

Corollary 4.2 (Conjectured by Zagier, ([G], [T])). *Let* L_n *be the* $\mathbb{Q}$*-vector space generated by multiple zeta values of weight* n*. Then we have* $\dim_{\mathbb{Q}} L_n \leq d_n$*, where* d_n *is defined by the generating function* $\sum_{i=0}^{\infty} d_n t^n = \frac{1}{1-t^2-t^3}$.

Either

(1) by comparing $\mathrm{Gal}(\overline{\mathbb{Q}}/\mathbb{Q})$ and $\pi_1(\mathrm{MTM}_{\mathbb{Z}}, H^l)$ via the homomorphism $\mathrm{Gal}(\overline{\mathbb{Q}}/\mathbb{Q}) \to \pi_1(\mathrm{MTM}_{\mathbb{Z}}, H^l)$ by using Hain–Matsumoto's result, or

(2) by using the infinitesimal embedding $\mathcal{U}^M(\mathcal{M}_{0,4}) \to \mathcal{U}^M(\mathcal{M}_{0,5})$ of mixed Tate motives according to Deligne–Goncharov,

we have a homomorphism of pro-algebraic groups

$$\mathrm{Rep}\colon \pi_1(\mathrm{MTM}_{\mathbb{Z}}, H^{\mathrm{B}}) \to \mathrm{GT}_{\mathrm{B}}$$

which is compatible with the weight homomorphisms λ. The Deligne–Ihara conjecture asserts

Conjecture 4.3 (Deligne–Ihara). The homomorphism Rep is an isomorphism.

Remark 4.4. The injectivity of Rep is equivalent to the following statement:

Any mixed Tate motif over $\mathbb{Z}$ is generated by $\mathcal{U}^M(\mathbb{P}^1 - \{0, 1, \infty\})^{\rightarrow\ \rightarrow}_{01,10}$.

As a consequence the injectivity of Rep implies that periods of any mixed Tate motif over $\mathbb{Z}$ are $\mathbb{Q}$-linear combinations of multiple zeta values.

Note that $\mathcal{U}(\pi_1(\mathrm{MTM}_{\mathbb{Z}}, H^{\mathrm{B}})^{(1)})$ is known to be a free Lie algebra generated by $c_3, c_5, c_7, \ldots$ ([DG]), and the description of GT_{B} is combinatorial. Therefore the above conjecture is (in principle) a combinatorial question. It is answered in the positive up to a quite high degree.

5. Harmonic shuffle relation

In this section we introduce the harmonic shuffle relation according to Hoffman [H] and its regularized version by Ihara–Kaneko–Zagier and Racinet ([IKZ], [R]). The rearrangement of the product of two multiple zeta values expressed by infinite series leads to a $\mathbb{Z}$-linear combination of multiple zeta values: for example, we have

$$\zeta(2)\zeta(2) = \sum_{0<n} \frac{1}{n^2} \cdot \sum_{0<m} \frac{1}{m^2} = \sum_{0<n} \frac{1}{n^4} + 2 \sum_{0<n<m} \frac{1}{n^2 m^2} = \zeta(4) + 2\zeta(2,2).$$

A relation of this type is called harmonic shuffle relation. Using the technique of regularization we also consider a relation of this type for non-convergent sums. As a consequence Racinet and Ihara–Kaneko–Zagier obtained a wider class of relations, the so-called "regularized harmonic shuffle relation". We briefly recall the formulation by Racinet of the regularized harmonic shuffle relation. We have the following approximation of the partial summation

$$\begin{aligned} \zeta_N(k_1, \dots, k_n) &= \sum_{0<m_1<m_2<\cdots<m_n<N} \frac{1}{m_1^{k_1} \dots m_n^{k_n}} \\ &= P_{k_1,\dots,k_n}(\log N + \gamma) + O(N^{-\epsilon}) \end{aligned} \tag{2}$$

by a real coefficient polynomial $P_{k_1,\dots,k_n}(T)$. Using Boutet de Monvel–Zagier's theorem, the generating series of $P_{k_1,\dots,k_n}(T)$ can be computed from the Drinfeld associator. By rearranging the partial summation up to N and using the asymptotic expression (2), the product $P_{k_1,\dots,k_n}(T)P_{k'_1,\dots,k'_{n'}}(T)$ becomes a $\mathbb{Z}$-linear combination of polynomials of the form $P_{k''_1,\dots,k''_{n''}}(T)$. In order to formulate the result it is convenient to introduce a new coproduct, the harmonic coproduct. Let W be a subalgebra $\mathbb{C} \oplus \mathbb{C}\langle\langle e_0, e_1\rangle\rangle e_1$ of $\mathbb{C}\langle\langle e_0, e_1\rangle\rangle$. This algebra is isomorphic to a weighted completion $\mathbb{C}\langle\langle y_1, y_2 \dots\rangle\rangle$ of the free algebra generated by $y_1 = -e_1$, $y_2 = -e_0e_1, \dots$, $y_i = -e_0^{i-1}e_1, \dots$. We define a harmonic coproduct $\Delta_*\colon W \to W \otimes W$ by an algebra homomorphism given by

$$\Delta_*(y_n) = \sum_{i=0}^{n} y_i \otimes y_{n-i},$$

with $y_0 = 1$. Let $\Phi_{\mathrm{DR}} = 1 + \varphi_0 e_0 + \varphi_1 e_1$ be the Drinfeld associator and set $\Phi_{\mathrm{DR},Y} = 1 + \varphi_1 e_1 \in W$. Then there is a unique formal power series $\Gamma_{\mathrm{DR}}(s) \in 1 + s^2\mathbb{C}[\![s]\!]$ such that

$$\Phi^{\mathrm{ab}}_{\mathrm{DR},Y}(e_0, e_1) = \frac{\Gamma_{\mathrm{DR}}(-e_0)\Gamma_{\mathrm{DR}}(-e_1)}{\Gamma_{\mathrm{DR}}(-e_0 - e_1)},$$

where $\Phi^{\mathrm{ab}}_{\mathrm{DR},Y}$ is the image of $\Phi_{\mathrm{DR},Y}$ in the abelianization $\mathbb{C}[\![e_0, e_1]\!]$. We define the modified Y-series $\Phi^{\mathrm{mod}}_{\mathrm{DR},Y}$ by $\Phi^{\mathrm{mod}}_{\mathrm{DR},Y} = \Gamma_{\mathrm{DR}}(y_1)^{-1}\Phi_{\mathrm{DR},Y} \in W$.

Theorem 5.1 (Racinet [R], Ihara–Kaneko–Zagier [IKZ] in a different formalism). *With the above notation, we have*

$$\Delta_*(\Phi_{\mathrm{DR},Y}^{\mathrm{mod}}) = \Phi_{\mathrm{DR},Y}^{\mathrm{mod}} \otimes \Phi_{\mathrm{DR},Y}^{\mathrm{mod}}.$$

In other words, $\Phi_{\mathrm{DR},Y}^{\mathrm{mod}}$ *is a group-like element under the harmonic coproduct.*

6. Fake Hodge realization and harmonic shuffle relation

As is shown in Sections 3 and 5, the origin of the harmonic shuffle relation comes from the rearrangement of partial series, and that of the associator relation comes essentially from the functoriality for infinitesimal inclusions from $\mathcal{M}_{0,4}$ into $\mathcal{M}_{0,5}$. Though two origins are quite different, we can show that the associator relation implies the harmonic shuffle relation. The contents of this section is a result of collaboration with P. Deligne.

For an associator $\Phi = 1+\varphi_0 e_0+\varphi_1 e_1$ set $\Phi_Y = 1+\varphi_1 e_1 = \Phi_Y(y_1, y_2, \dots) \in W$.

Theorem 6.1 (Deligne–Terasoma). (1) *Let* Φ_Y^{ab} *be the image of* Φ_Y *in the abelianization* $\mathbb{C}[\![e_0, e_1]\!]$. *Then there exists a unique element* $\Gamma_\Phi(s)$ *in* $1 + s^2\mathbb{C}[\![s]\!]$ *such that*

$$\Phi_Y^{\mathrm{ab}}(e_0, e_1) = \frac{\Gamma_\Phi(-e_0)\Gamma_\Phi(-e_1)}{\Gamma_\Phi(-e_0 - e_1)}.$$

(2) *Using* Γ_Φ *obtained in* (1) *we define*

$$\Phi_Y^{\mathrm{mod}}(y_1, y_2, \dots) := \Gamma_\Phi(y_1)^{-1}\Phi_Y(y_1, y_2, \dots) \in W.$$

Then we have

$$\Delta_*(\Phi_Y^{\mathrm{mod}}) = \Phi_Y^{\mathrm{mod}} \otimes \Phi_Y^{\mathrm{mod}}.$$

The proof of the above theorem is divided into two parts.

6.1. Fake Hodge realization attached to an associator. By Definition 3.2 an associator defines Hopf algebroid objects $\mathcal{U}(\mathcal{M}_{0,4})$ and $\mathcal{U}(\mathcal{M}_{0,5})$ in the category

$$\begin{aligned}\mathcal{M} &= \mathrm{Vec}_{\mathbb{Q}} \times_{\mathrm{Vec}_{\mathbb{C}}} \mathrm{Vec}_{\mathbb{Q}} \\ &= \{(V^{\mathrm{B}}, V^{\mathrm{DR}}, \varphi) \mid V^{\mathrm{B}} \text{ and } V^{\mathrm{DR}} \text{ are } \mathbb{Q}\text{-vector spaces, } \varphi\colon V^{\mathrm{B}} \otimes \mathbb{C} \xrightarrow{\simeq} V^{\mathrm{DR}} \otimes \mathbb{C} \\ &\qquad\qquad \text{is an isomorphism of } \mathbb{C} \text{ vector spaces}\}.\end{aligned}$$

The i-th projection induces a homomorphism $\mathrm{pr}_i\colon \mathcal{U}(\mathcal{M}_{0,5}) \to \mathcal{U}(\mathcal{M}_{0,4})$ of Hopf algebroids in $\mathcal{M}$. For an algebroid $\mathcal{U}$ in $\mathcal{M}$, we can introduce a notion of "$\mathcal{U}$-modules" in the category $\mathcal{M}$. For a $\mathcal{U}(\mathcal{M}_{0,5})$-module M we can define a $\mathcal{U}(\mathcal{M}_{0,4})$-module $R^j \mathrm{pr}_i M$ by using cohomological technology. Note that an isomorphism

$$R^j \mathrm{pr}_i M^{\mathrm{B}} \otimes \mathbb{C} \xrightarrow{\simeq} R^j \mathrm{pr}_i M^{\mathrm{DR}} \otimes \mathbb{C}$$

is encoded in the object $R^j \operatorname{pr}_i M$, which can be computed from the associator chosen first. This isomorphism is called a fake comparison map associated to an associator. We can also define the notion of "perverse" sheaf, and so on. These modules are equipped with a mixed Hodge structure which is different from the natural one. They are called a fake Hodge realization.

6.2. Multiplicative convolution. Following Deligne we introduce a geometric interpretation of harmonic shuffle relation. Let $\mathcal{A}$ be the category of topological perverse sheaves on $\overline{\mathcal{M}_{0,4}} - \{0, \infty\} \simeq \boldsymbol{G}_m$ smooth outside of $\{1\}$ with a nilpotent monodromy. We introduce an equivalence relation on $\mathcal{A}$ as follows. A morphism $\mathcal{F}_1 \to \mathcal{F}_2$ in $\mathcal{A}$ is equivalent if the induced homomorphism of vanishing cycles is an isomorphism. The quotient category under this equivalence relation is denoted by $\bar{\mathcal{A}}$. Then $\bar{\mathcal{A}}$ is again an abelian category and we can show that this abelian category is equivalent to the category of W^{B} modules, where

$$W^{\mathrm{B}} = \mathcal{U}^{\mathrm{B}}_{\substack{\to \\ 10,10}} \log \rho_1 \oplus \mathbb{Q},$$

ρ_1 being the canonical generator of local monodromy around $\{1\}$. For two perverse sheaves $\mathcal{F}_1$ and $\mathcal{F}_2$, we can define a biadditive functor $*\colon \mathcal{A} \times \mathcal{A} \to \mathcal{A}$ by the multiplicative convolution

$$\mathcal{F}_1 * \mathcal{F}_2 = {}^p\mathcal{H}^1 \mathbb{R} \operatorname{pr}_{5*}(\operatorname{pr}_1^*(\mathcal{F}_1) \otimes \operatorname{pr}_2^*(\mathcal{F}_2)).$$

The equivalence class of the above convolution $\mathcal{F}_1 * \mathcal{F}_2$ depends only on the equivalence class of $\mathcal{F}_1$ and $\mathcal{F}_2$ and, as a consequence, the convolution induces a biadditive functor $*\colon \bar{\mathcal{A}} \times \bar{\mathcal{A}} \to \bar{\mathcal{A}}$. The corresponding ring homomorphism $W^{\mathrm{B}} \to W^{\mathrm{B}} \otimes W^{\mathrm{B}}$ is denoted by Δ_*. This picture can be filled into the $\mathcal{M} = \mathrm{Vec}_{\mathbb{Q}} \times_{\mathrm{Vec}_{\mathbb{C}}} \mathrm{Vec}_{\mathbb{Q}}$ world with a comparison isomorphism attached to an associator Φ. By the computation of the cohomology of algebroids we can show that the de Rham realization $\Delta_*\colon W^{\mathrm{DR}} \to W^{\mathrm{DR}} \otimes W^{\mathrm{DR}}$ is equal to the harmonic coproduct. By using the fake comparison isomorphism we have the theorem.

Geometry over nonclosed fields

Yuri Tschinkel

Abstract. I discuss some arithmetic aspects of higher-dimensional algebraic geometry. I focus on varieties with many rational points and on connections with classification theory and the minimal model program.

Mathematics Subject Classification (2000). Primary 14G05; Secondary 14G40.

Keywords. Rational and integral points, heights, rational curves, rational connectedness.

1. Introduction

Let k be a field, X an algebraic variety over k and $X(k)$ the set of k-rational points on X. Broadly speaking, arithmetic geometry is concerned with the set $X(k)$, but usually with additional structure, coming from the Zariski topology on X or the Galois group of k. Questions of arithmetic nature arise even in classical algebraic geometry over $\mathbb{C}$ – a rational section of a fibration $X \to B$ is a rational point of the generic fiber, considered as a variety over the function field $\mathbb{C}(B)$ of the base. Of particular importance are "small" ground fields k, such as finite fields $\mathbb{F}_p$ or the rational numbers $\mathbb{Q}$, as they are closest to the theory of diophantine equations, with its wealth of challenging problems.

The geometric approach to diophantine equations is inspired by the analogy "numbers – functions" going back at least to Riemann, Dedekind, Kronecker, Weber, Hensel, Weil, and many others. More concretely, one expects close relationships between global geometric properties of X, considered as an algebraic variety over "large" fields such as $\mathbb{C}$, and arithmetic properties. Sometimes one may need to stabilize the arithmetic situation by passing to finite or even infinite extensions of k, or by excluding exceptional subsets.

This area of arithmetic and geometry is dominated by the following themes:

- Existence of rational points. In dimension one this includes the work of Mazur and Merel on torsion points on elliptic curves, conjectures of Birch and Swinnerton-Dyer, Wiles' work on Fermat's conjecture, the theorems of Gross–Zagier, Kolyvagin and their generalizations. In higher dimensions, the attention is on the Brauer–Manin obstruction to the Hasse principle and weak approximation, its uniqueness and effective computation (see [54]).

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

- Density of rational points in various topologies, e.g., Zariski density or density in analytic topologies (see [51], [39]).
- Heights. This covers questions of bounding heights of points on higher genus curves (effective Mordell), finding lower bounds for heights of rational and algebraic points, Manin's conjecture about asymptotics of rational points of bounded height and its refinements (see [13], [55]).

The field is evolving rapidly, opening new directions of research and raising many concrete and interesting questions. In this survey I focus on varieties with many rational points and discuss connections with classification theory and the minimal model program in algebraic geometry.

Acknowledgments. I am deeply grateful to my teachers, friends and collaborators for sharing their ideas and insights, which over the years shaped my understanding of the subject: V. Batyrev, F. Bogomolov, A. Chambert-Loir, J. Franke, J. Harris, B. Hassett, J. Kollár, A. Kresch, Y. Manin, B. Mazur, E. Peyre, J. Shalika, M. Strauch, R. Takloo-Bighash.

2. Classification schemes

In this section we work over $\mathbb{C}$. Smooth projective algebraic varieties X can be classified by their topological and algebraic invariants: fundamental group $\pi_1(X)$, Brauer group $\mathrm{Br}(X)$, or a property of the canonical line bundle K_X:

$$\kappa(X) := \limsup_{n\to\infty} \log(h^0(X, nK_X))/\log(n) \in \{-\infty, 0, 1, \dots, \dim(X)\},$$

the Kodaira dimension. Alternatively, there are several geometric notions reflecting how close X is to a projective space $\mathbb{P}^n$: rationality, unirationality, uniruledness or rational connectedness, resp. chain-connectedness. Sometimes, X is realized by particularly simple equations, e.g., as a complete intersection in projective or weighted projective space. In this case, one could also classify by the degree $\deg(X)$ in this embedding. Sometimes, there is a distinguished polarization: (multiples of) the canonical, resp. the anticanonical line bundle; in the first case, $\kappa(X) = \dim(X)$, and one speaks of varieties of *general type*, and in the second, of *Fano* varieties. For historical reasons, Fano surfaces are called Del Pezzo surfaces. All other varieties are called varieties of *intermediate type*; an important subclass are varieties with trivial canonical class, e.g., abelian varieties and Calabi–Yau varieties.

The only Fano variety in dimension 1 is $\mathbb{P}^1$. Curves of general type are curves of genus ≥ 2. Smooth Del Pezzo surfaces divide into following types: $\mathbb{P}^2$, $\mathbb{P}^1 \times \mathbb{P}^1$, and blowups of $\mathbb{P}^2$ in ≤ 8 points in general position. In each dimension, there are only finitely many families of Fano varieties [49], [19].

The notions above are intertwined in many ways. For example, a smooth hypersurface $X \subset \mathbb{P}^n$ is Fano if $\deg(X) < n + 1$, and of general type if $\deg(X) > n + 1$,

so that we generally think of Fano varieties as being varieties of *small* degree, and geometrically not "too far" from $\mathbb{P}^n$. A Fano variety is rationally connected. If X is rationally connected, then it has trivial $\pi_1(X)$. If X is smooth and rational then $\mathrm{Br}(X)$ is trivial. A rationally connected X is rational, provided $\dim(X) \leq 2$, but not necessarily if $\dim(X) = 3$, etc. There are conjectured criteria linking algebraic and geometric properties, e.g., X is uniruled if and only if $\kappa(X) = -\infty$. A fundamental result is the following:

Theorem 2.1 (Graber–Harris–Starr [36]). *Let $\pi : X \to B$ be a morphism from a smooth projective variety to a smooth projective curve. Assume that the generic fiber is a rationally connected variety. Then π has a section.*

For applications, one needs to better understand the class of varieties of intermediate type. As a consequence of Theorem 2.1 and [49], [19], we know that every X admits an *MRC quotient*, a rational map $\pi_r : X \to Y = R(X)$ with rationally connected fibers and base not uniruled. If Y is not a point, this is followed by another fibration $Y \to Z$, with $\dim(Z) = \kappa(Y)$ and generic fiber of Kodaira dimension zero. However, Z is not necessarily of general type, and the construction may have to be iterated.

An alternative classification scheme has been proposed by Campana. A variety X is *special* if there are no (birational) dominant maps $\pi : X \to Y$, where Y is a smooth variety of $\dim(Y) \geq 1$ and of *orbi*-general type, with *orbi*-canonical class computed taking into account *multiplicities* of singular fibers of π. The class of special varieties includes rationally connected varieties and varieties of Kodaira dimension zero. Every X admits (birationally) a fibration $\pi_c : X \to Y = C(X)$ onto its *core* (or *le cœur*), with *special* generic fiber and base of orbi-general type [20]. For examples of simply connected X which do not admit birational maps onto varieties of general type of $\dim \geq 1$, but have a nontrivial core $C(X)$, see [10].

3. Potential density

One says that rational points on an algebraic variety X over a field k are *potentially dense* if there exists a finite extension k'/k such that $X(k')$ is Zariski dense in X. This birational property holds for projective spaces and abelian varieties and thus for varieties dominated by these, e.g., unirational varieties or Kummer varieties. It is preserved under étale covers of proper varieties. An important problem is to find necessary and sufficient geometric conditions for potential density of rational points. An extremal statement, almost an "axiom", is the following generalization of Mordell's conjecture to higher dimensions.

Conjecture 3.1 (Bombieri–Lang). Let X be a variety of general type over a number field k. Then $X(k)$ is contained in a proper subvariety, i.e., rational points on X are not potentially dense.

The outstanding result is Faltings' proof of this conjecture for subvarieties of abelian varieties [32], and in particular, curves of genus ≥ 2. Conjecture 3.1 has surprising consequences for *uniform* bounds for the number of rational points on curves of higher genus: it implies that there is a constant $c(k, \mathsf{g})$ such that for every curve C of genus $\mathsf{g} \geq 2$ over k one has $\#C(k) \leq c(k, \mathsf{g})$ [22].

In the opposite case of Fano varieties it is expected that their arithmetic properties are not too far from those of the projective space:

Conjecture 3.2 ([38]). Let X be a Fano variety over a number field k. Then rational points on X are potentially dense.

Conjecture 3.2 holds in dimension ≤ 2, for smooth quartic hypersurfaces of dimension ≥ 3 and for smooth hypersurfaces of degree 6 in the weighted projective space $\mathbb{P}(1, 1, 1, 2, 3)$ [38], [8]. There remains only one family of smooth Fano threefolds for which this question is open:

Problem 3.3. Let $X \to \mathbb{P}^3$ be a double cover ramified in a smooth surface S of degree 6. Show that rational points on X are potentially dense.

For singular S this has been resolved in [25].

The above conjectures are subsumed in

Conjecture 3.4 (Campana [20]). Let X be a smooth projective variety over a number field k. Rational points on X are potentially dense if and only if X is special.

An interesting subclass of special varieties to consider is the class of Calabi–Yau varieties, e.g., K3 surfaces and their higher-dimensional analogs – holomorphic symplectic varieties. Potential density holds for Enriques surfaces, elliptic K3 surfaces and K3 surfaces with infinite automorphism groups [9]; symmetric products of arbitrary K3 surfaces have been treated in [40]. Potential density holds *a posteriori* for varieties dominated by these.

Problem 3.5. Let X be a K3 surface over a number field, with geometric Picard number one. Show that rational points on X are potentially dense.

It would also be worthwhile to find nontrivial examples of three-dimensional Calabi–Yau varieties over number fields with dense sets of rational points.

The proofs of potential density rely on either automorphisms or on fibration structures, with fibers abelian varieties. It would be interesting to involve endomorphisms and to study orbits of the corresponding dynamical systems, in the spirit of [21]. Examples of quite nontrivial endomorphisms on certain holomorphic symplectic fourfolds are given in [67].

4. Points of bounded height

Assuming that rational points are Zariski dense one may seek some quantitative understanding of their distribution. A natural approach to this proceeds via the theory of heights. Let X be a projective algebraic variety over a number field k and $\mathcal{L} = (L, \|\cdot\|)$ an adelically metrized very ample line bundle on X (i.e., L is equipped with a family of v-adic norms, for each place v of k, which at almost all places are induced from a fixed global integral model, see [55]). Let

$$H_{\mathcal{L}}\colon X(k) \to \mathbb{R}_{>0}$$

be the associated height function, $X^\circ \subset X$ a subvariety of X and

$$\mathcal{N}(X^\circ, \mathcal{L}, B) := \#\{x \in X^\circ(k) \mid H_{\mathcal{L}}(x) \le B\} < \infty, \tag{1}$$

the counting function. The goal is to investigate its asymptotic behavior as $B \to \infty$, in terms of the pair $(X^\circ, \mathcal{L})$.

For example, let $X \subset \mathbb{P}^n$ be a hypersurface given by $f(\boldsymbol{x}) = 0$, where f is a homogeneous form in the variables $\boldsymbol{x} = (x_0, \dots, x_n)$ of degree d with coefficients in $\mathbb{Z}$. It is Fano for $n \ge d$. A counting function over $\mathbb{Q}$ is defined as

$$\mathcal{N}(X, \mathcal{O}(1), B) := \#\big\{\boldsymbol{x} \in (\mathbb{Z}^{n+1}_{\text{prim}} \setminus 0)/\pm,\ f(\boldsymbol{x}) = 0, \max_j |x_j| \le B\big\},$$

where $\mathbb{Z}^{n+1}_{\text{prim}}$ is the set of primitive vectors. The counting problem is to understand the asymptotic of this function as $B \to \infty$. The classical circle method solves this problem when the hypersurface X is smooth, the number of variables $n+1 \gg 2^d$ and if there exist solutions to $f(\boldsymbol{x}) = 0$ in all completions of $\mathbb{Q}$. Strong uniform bounds for points on hypersurfaces were recently established in [18], [46], [60]; these papers use in a crucial way the case of curves considered in [58], [14].

Problem 4.1. Let $X \subset \mathbb{P}^n$ be a smooth hypersurface of degree $d \le n$, over $\mathbb{Q}$. Show that there exists a Zariski open subset $X^\circ \subset X$ such that

$$\mathcal{N}(X^\circ, \mathcal{O}(1), B) = O(B^{n+1-d+\varepsilon}),$$

for all $\varepsilon > 0$. This is open already for $d = n = 3$.

In general, it is also difficult to produce rational points, even numerically. Interesting examples of varieties with *a priori* dense sets of rational points arise from group actions. More precisely, let G/k be a linear algebraic group, e.g., the Heisenberg group, the additive group $\mathbb{G}_a^d$ or the algebraic torus $\mathbb{G}_m^d$. Let

$$\rho\colon \mathsf{G} \to \mathrm{PGL}_{n+1} \tag{2}$$

be a representation over k. Fixing a point $\boldsymbol{x} \in \mathbb{P}^n(k)$, we can consider the *flow* $\rho(\mathsf{G})\cdot\boldsymbol{x}$ and count

$$\#\{\gamma \in \mathsf{G}(k) \mid H_{\mathcal{O}(1)}(\rho(\gamma)\cdot x) \le B\},$$

respectively, k-points in G/H, when the stabilizer H is nontrivial.

The asymptotic will depend on the group, the representation, the initial point $\boldsymbol{x}$, and the choice of the height. The difficulty is that already for $\mathsf{G} = \mathbb{G}_a^2$ there is no reasonable classification of possible representations ρ. This necessitates a change of language, from representation-theoretic to algebro-geometric: Let X be the Zariski closure of $\rho(\mathsf{G}) \cdot \boldsymbol{x} \subset \mathbb{P}^n$. Then X is

- an equivariant compactification of $X^\circ := \mathsf{G}/\mathsf{H}$,
- with a G-linearized very ample line bundle L,
- which is equipped with an adelic metrization $\mathscr{L} = (L, \|\cdot\|)$.

Then the counting problem is as in (1). Using equivariant resolution of singularities we can now reduce the counting problem to the case when X is smooth, and the boundary $X \setminus X^\circ$ is a divisor with normal crossings.

Over number fields, in available examples arising from group actions, such as flag varieties [33], toric varieties [4], horospherical varieties [66], equivariant compactification of $\mathbb{G}_a^n$ [23], De Concini–Procesi equivariant compactifications of semi-simple groups of adjoint type [64], [34], bi-equivariant compactifications of unipotent groups [63], the *algebraic-geometric* picture is as follows:

- the Picard group $\mathrm{Pic}(X)$ is a torsion free $\mathbb{Z}$-module,
- the (closed) cone of effective divisors $\Lambda_{\mathrm{eff}}(X) \subset \mathrm{Pic}(X)\otimes_{\mathbb{R}}$ is finitely generated,
- $-K_X$ is contained in the interior of $\Lambda_{\mathrm{eff}}(X)$.

The arithmetic picture, reflected in asymptotic formulas for the counting function (1), is described in terms of the geometric invariants as follows:

$$\mathscr{N}(X^\circ(k), \mathscr{L}, B) = c(\mathscr{L}) B^{a(L)} \log(B)^{b(L)-1}(1 + o(1)), \quad B \to \infty, \tag{3}$$

where

- $a(L) := \inf\{a \mid aL + K_X \in \Lambda_{\mathrm{eff}}(X)\}$,
- $b(L)$ is the maximal codimension of the face of $\Lambda_{\mathrm{eff}}(X)$ containing the class $a(L)L + K_X$.

In particular, $a(-K_X) = 1$ and $b(-K_X)$ is the rank of the Picard group of X, over k. The constant $c(\mathscr{L})$ depends on the choice of an adelic metrization, which determines the height. It was defined for $L = -K_X$ in [52] and in general in [5]:

$$c(-\mathcal{K}_X) := \alpha(X)\beta(X)\tau(\mathcal{K}_X) \tag{4}$$

where

- $\alpha(X)$ is the volume of certain polytope (intersection of the dual cone to $\Lambda_{\text{eff}}(X)$ with the affine hyperplane $\langle -K_X, \cdot \rangle = 1$),
- $\beta(X) = |\text{Br}(X)/\text{Br}(k)| = |H^1(\Gamma, \text{Pic}(\bar{X}))|$, is the order of the nontrivial part of the Brauer group,
- $\tau(-\mathcal{K}_X)$ is a Tamagawa type number.

For general polarizations, $c(\mathcal{L}) = \sum'_{y \in Y(k)} c(\mathcal{L}_y)$, where $X \to Y$ is a certain fibration arising in Fujita's version of the minimal model program; the summation is over a possibly infinite subset of the set of rational points on the base and $c(\mathcal{L}_y)$ are constants similar to (4).

Some of the above results have been extended to function fields $\mathbb{F}_q(B)$, where B is a curve over a finite field $\mathbb{F}_q$ [57], [16]. Over these fields, the constant $c(-\mathcal{K}_X)$ differs by an additional integral factor, $\neq 1$ already for some toric varieties [16].

Tamagawa numbers occurring here are natural generalizations of those in the theory of algebraic groups. An adelic metrization of K_X gives rise to v-adic measures ω_v on v-adic analytic manifolds $X(k_v)$. A regularized global measure $\omega_{\mathcal{K}}$ on the adeles $X(\mathbb{A}_k)$ is given by

$$\omega_{\mathcal{K}} := \text{L}^*_{\mathsf{S}}(1, \text{Pic}(X))|\text{disc}(k)|^{-\dim(X)/2} \prod_v \lambda_v^{-1} \omega_v, \tag{5}$$

where S is a finite set of valuations of k, including the archimedean ones, $\text{disc}(k)$ is the discriminant of k, the regularizing factors

$$\lambda_v := \begin{cases} \text{L}_v(1, \text{Pic}(X)) & v \notin \mathsf{S}, \\ 1 & v \in \mathsf{S}, \end{cases}$$

and

$$\text{L}^*_{\mathsf{S}}(1, \text{Pic}(X)) := \lim_{s \to 1} (s-1)^r \text{L}_{\mathsf{S}}(s, \text{Pic}(X))$$

is the leading coefficient at the pole of the partial Artin L-function associated to the Galois representation on the module $\text{Pic}(\bar{X})$. Then

$$\tau(-\mathcal{K}_X) := \int_{\overline{X(k)} \subset X(\mathbb{A}_k)} \omega_{\mathcal{K}}, \tag{6}$$

an integral over the closure of rational points in the adeles, in the direct product topology.

The proofs of these asymptotics use a combination of techniques from arithmetic geometry and analysis. A useful tool is the *height zeta function* defined by the series

$$\mathcal{Z}(X^\circ, \mathcal{L}, s) = \sum_{x \in X^\circ(k)} H_{\mathcal{L}}(x)^{-s}.$$

Tauberian theorems relate the asymptotic behavior of the counting function to analytic properties of the height zeta function. Analytic properties of $\mathcal{Z}$ are investigated via harmonic analysis on adelic groups or ergodic theory.

Problem 4.2. Prove Formula (3) for general equivariant compactifications of unipotent and solvable groups.

An alternative approach to asymptotics uses universal torsors. The essence of the method consists in the lifting of the counting problem for rational points on X to a counting problem for integral points on an auxiliary variety of higher dimension. This method has been used to reprove asymptotic results on toric varieties [60]. It has also been successfully applied to nonhomogeneous varieties, such as $\bar{\mathcal{M}}_{0,5}$ [17] and certain singular cubic surfaces [47], [26].

In the simplest case of a projective space, this can be explained by the familiar

$$\mathbb{Z}^{n+1}_{\mathrm{prim}} \setminus 0/\pm \xrightarrow{\mathbb{G}_m} \mathbb{P}^n(\mathbb{Q}),$$

certain integral points on the torsor $\mathbb{A}^{n+1} \setminus 0$, modulo units, are in bijection with rational points on the projective space. In general, the study of universal torsors leads to interesting algebraic problems, involving ideas from geometric invariant theory and toric geometry [2], [59], [42].

Problem 4.3. Compute equations of universal torsors for singular Del Pezzo surfaces in degrees $1, \dots, 4$.

The initial conjecture of Batyrev–Manin was that Formula (3) should hold for *all* Fano varieties, after enlarging the ground field, and restricting to appropriate Zariski open subsets X°. It is necessary to allow finite field extensions, since a Fano variety may not have any rational points over the ground field (e.g., a nonsplit conic). The restriction to Zariski open subsets is also necessary since the variety X may contain *accumulating* subvarieties, and the asymptotic of rational points on them can violate the conjecture (e.g, lines on a cubic surface). The Batyrev–Manin conjecture had to be adjusted, already in dimension 3, after the realization that certain fibrations may lead to differing $b(L)$ [3], [5]. The results mentioned above are convincing evidence, that the Batyrev–Manin conjecture and its refinement by Peyre should hold for Del Pezzo surfaces and for equivariant compactifications of all linear algebraic groups and their homogeneous spaces. A first step would be

Problem 4.4. Prove Formula (3) for singular Del Pezzo surfaces whose universal torsor is a hypersurface.

Problem 4.5. Prove Formula (3) for general spherical varieties over number fields.

5. Integral points

Let k be a number field, X a smooth projective algebraic variety over k and $D \subset X$ a divisor with strict normal crossings. In this log-geometric setup, it is the ampleness

of $(K_X + D)$, resp. $-(K_X + D)$, which characterizes the opposites in the classification picture. We need a theory of log-uniruledness, log-rational connectivity, and classification results and notions comparable to those in Section 2. e.g., log-special varieties etc. Like for rational points, one is interested in the distribution of integral points in Zariski topology and with respect to heights.

Choose models $\mathcal{X}$, $\mathcal{D}$ of X, D over the ring of integers $\mathfrak{o}_k$ of k. A rational point $x \in X(k)$ gives rise to a section $\pi_x \colon \mathrm{Spec}(\mathfrak{o}_k) \to \mathcal{X}$ of the structure morphism. Choose a finite set of places S of $\mathfrak{o}_k$. A $(\mathcal{D}, \mathsf{S})$-integral point is a section π_x such that for all $v \notin \mathsf{S}$ one has

$$\pi_{x,v} \cap \mathcal{D}_v = \emptyset,$$

i.e., π_x avoids $\mathcal{D}$ over $\mathrm{Spec}(\mathfrak{o}_k) \setminus \mathsf{S}$. We say that D-integral points on X are potentially dense, if there exists a finite extension k'/k, a finite set of places S' of $\mathfrak{o}_{k'}$, models $\mathcal{X}'$, $\mathcal{D}'$ of X, D over S' such that $(\mathcal{D}', \mathsf{S}')$-integral points in $X(k')$ are Zariski dense.

Conjecture 5.1 (Vojta). Assume that $K_X + D$ is ample. Then $(\mathcal{D}, \mathsf{S})$-integral points are contained in a proper subvariety, i.e., integral points are not potentially dense.

In analogy with Conjecture 3.2 we can formulate

Conjecture 5.2. Assume that $-(K_X + D)$ is ample. Then D-integral points on X are potentially dense.

An instance of what is expected in intermediate cases is the following "puncturing" conjecture, which could serve as a guiding principle:

Conjecture 5.3 ([41]). Let (X, Z) be a pair consisting of a smooth projective variety X and a smooth irreducible subvariety $Z \subset X$ of codimension ≥ 2, defined over a number field k. Let $\tilde{X} := \mathrm{Bl}_Z(X)$ be the blowup of X with center in Z, and D the exceptional divisor. Assume that rational points on X are potentially dense. Then D-integral points on $\tilde{X}$ are potentially dense.

Problem 5.4. Let X be an abelian variety of dimension ≥ 2 and Z a point. Prove potential density of D-integral points on the blowup $\tilde{X}$, where D is the exceptional divisor.

This holds if X is a product of at least two abelian varieties [41]. For numerical evidence in dimension 2, see [48].

Problem 5.5. Let X be a surface and $D \subset X$ a reduced effective Weil divisor such that the pair (X, D) has log-terminal singularities and $(K_X + D)$ is trivial. Show that D-integral points on X are potentially dense.

A special case, for $D = \emptyset$ and X smooth, is stated in Problem 3.5. Another open case arises for X a smooth Del Pezzo surface, and D a singular anticanonical curve.

When $X = \mathbb{P}^2$ this problem has been treated in [65] and [6]. Cubic surfaces X and smooth D have been considered in [7], this has been extended to smooth Del Pezzo surfaces X and smooth D in [41].

Assume now that $-(K_X + D)$ is ample and that $(\mathcal{D}, \mathsf{S})$-integral points are Zariski dense. Like in the case of rational points, group actions give a rich supply of quasi-projective projective varieties with many integral points. For example, replacing the projective representation ρ in (2) by a representation of an algebraic group G into GL_n and fixing $\mathbb{Z}$-structures leads to the study of points in $\mathsf{G}(\mathbb{Z})$, or integral points on the corresponding homogeneous spaces [27], [29], [30], [15].

For a Zariski open $X^\circ \subset X$, let

$$\mathcal{N}(X^\circ, -(\mathcal{K}_X + \mathcal{D}), B) := \#\{x \mid H_{-(\mathcal{K}_X+\mathcal{D})}(x) \le B\}$$

be the counting function on the set of $(\mathcal{D}, \mathsf{S})$-integral points in $X^\circ(k)$.

Our goal is a geometric interpretation of asymptotic formulas, similar to the one in Section 4 (see [24] for more details). Available asymptotics, proved via ergodic theory or harmonic analysis, are of the shape

$$\mathcal{N}(X^\circ, -(\mathcal{K}_X + \mathcal{D}), B) \sim c_{\mathsf{S}} B \log(B)^{b_S - 1}, \tag{7}$$

where

- $b_{\mathsf{S}} = \mathrm{rk}\ \mathrm{Pic}(X \setminus D) + \sum_{v \in \mathsf{S} \cup \mathsf{S}_\infty} r_v$;
- $r_v = \dim \mathrm{Cl}(\mathcal{D}_v)$, the dimension of the Clemens polytope associated to the set of boundary components of the reduction of $\mathcal{D}$ modulo v (vertices correspond to irreducible components, faces of codimension one to pairs of intersecting components, etc.);
- c_{S} is a constant similar to the one in (3), it involves a Tamagawa volume of the adeles outside S of $X \setminus D$ as in (6), with respect to the restriction of the Tamagawa measure from (5), and for each $v \in \mathsf{S} \cup \mathsf{S}_\infty$ and $\sigma \in \mathrm{Cl}_{\max}(\mathcal{D}_v)$, the Tamagawa volume of the closed subvariety $Z_{\sigma,v} \subset X(k_v)$, the intersection of corresponding components from σ. Here $\mathrm{Cl}_{\max}(\mathcal{D}_v)$ is the set of faces of the Clemens polytope of maximal dimension, and the Tamagawa measure on $Z_{\sigma,v}$ is obtained by adjunction.

Problem 5.6. Prove (7) for $X = \mathbb{P}^n$, $D \subset X$ a smooth hypersurface of low degree, defined by a form $f \in \mathbb{Z}[x_0, \dots, x_n]$, and S a finite set of primes of good reduction for D.

6. Arithmetic over function fields of curves

Here we work over $k = \mathbb{C}(B)$, where B is a smooth projective curve. Let X be a smooth projective variety over k and $\pi\colon \mathcal{X} \to B$ a model of X over B. Points in $X(k)$ correspond to sections of π, i.e., to certain curves in $\mathcal{X}$. A reformulation of Theorem 2.1 is

Theorem 6.1 ([36]). *Let X be a rationally connected variety over $k = \mathbb{C}(B)$. Then $X(k) \neq \emptyset$.*

One corollary of Theorem 2.1 is the proof of potential density, Conjecture 3.2, for rationally connected varieties over $k = \mathbb{C}(B)$. More precisely, after choosing finitely many smooth fibers and a point in each of these fibers one can find a section passing through these points [50]. This can be strengthened: after choosing finite *jets* (reductions of local analytic sections) in finitely many smooth fibers one can find a section which reduces to these jets [43]. It would be important to extend this property, called *weak approximation*, to singular fibers. Careful analysis of desingularizations of compound du Val singularities should yield a solution to

Problem 6.2. Prove weak approximation for cubic surfaces over function fields of curves.

Another step beyond what can be currently proved over number fields, are examples of K3 surfaces, and more generally, Calabi–Yau varieties, of geometric Picard number one with Zariski dense sets of rational points in [45].

Problem 6.3. Prove potential density of rational points for all K3 surfaces over $k = \mathbb{C}(B)$.

There are analogous questions for log-Fano varieties. For example,

Problem 6.4. Prove potential density of integral points on log-Fano varieties (Conjecture 5.2) over function fields of curves.

One of the main advantages of the field $k = \mathbb{C}(B)$ is that curves often deform. This opens the door for a systematic application of deformation theory, the theory of moduli spaces of stable curves and maps etc. The proofs of properties like potential density or weak approximation proceed by finding and smoothing special chains of rational curves (*combs* and *combs with broken teeth*).

An alternative approach to potential density, based on endomorphisms from [67], leads to examples of holomorphic symplectic fourfolds X over $\mathbb{C}(x)$ with geometric Picard number one and dense rational points [1].

7. Geometry over finite fields

In some aspects, finite fields are similar to function fields of curves. For example, an analog of Theorem 6.1 is:

Theorem 7.1 ([31]). *Let X be a smooth projective rationally connected variety over a finite field $k = \mathbb{F}_q$. Then $X(k) \neq \emptyset$.*

On the other hand, the classification schemes as outlined in Section 2 have to be adjusted. In particular, the relation between the ampleness of the canonical, resp. anticanonical, line bundle and rational connectedness is much less clear. For example, in positive characteristic, there exist unirational, and thus rationally connected, varieties of general type. But over finite fields $k = \mathbb{F}_q$, and their closures $\bar{k}$, there are also examples of surfaces X of general type which are not uniruled, have a nontrivial Brauer group, nontrivial fundamental group, and still have the property that on some dense Zariski open subset $X^\circ \subset X$, every finite set of $\bar{k}$-points lies a geometrically irreducible rational curve in X, defined over k. Moreover, every Kummer K3 surface over a finite field has this rather strong rational connectedness property [11], [12].

Problem 7.2. Let X be an elliptic K3 surface over a sufficiently large finite field. Show that X is rationally connected (in the above sense).

Algebraic Morse theory and the weak factorization theorem

Jarosław Włodarczyk*

Abstract. We develop a Morse-like theory for complex algebraic varieties. In this theory a Morse function is replaced by a $\mathbb{C}^*$-action. The critical points of the Morse function correspond to connected fixed point components. "Passing through the fixed points" induces some simple birational transformations called blow-ups, blow-downs and flips which are analogous to spherical modifications.

In classical Morse theory by means of a Morse function we can decompose the manifold into elementary pieces – "handles". In algebraic Morse theory we decompose a birational map between two smooth complex algebraic varieties into a sequence of blow-ups and blow-downs with smooth centers.

Mathematics Subject Classification (2000). Primary 14E05.

Keywords. Birational maps, blow-ups, $\mathbb{C}^*$-actions, toric varieties.

1. Introduction

We shall work over an algebraically closed field K of characteristic zero. We denote by K^* the multiplicative group of K.

In this paper we outline our proof of the following theorem:

Theorem 1.1 (The Weak Factorization Theorem). 1. *Let $f : X \dashrightarrow Y$ be a birational map of smooth complete varieties over a field of characteristic zero, which is an isomorphism over an open set U. Then f can be factored as*

$$X = X_0 \overset{f_0}{\dashrightarrow} X_1 \overset{f_1}{\dashrightarrow} \cdots \overset{f_{n-1}}{\dashrightarrow} X_n = Y,$$

where each X_i is a smooth complete variety and f_i is a blow-up or blow-down at a smooth center which is an isomorphism over U.

2. *Moreover, if $X \setminus U$ and $Y \setminus U$ are divisors with simple normal crossings, then each $D_i := X_i \setminus U$ is a divisor with simple normal crossings and f_i is a blow-up or blow-down at a smooth center which has normal crossings with components of D_i.*

3. *There is an index $1 \leq r \leq n$ such that for all $i \leq r$ the induced birational map $X_i \overset{f_0}{\dashrightarrow} X$ is a projective morphism and for all $r \leq i \leq n$ the map $X_i \overset{f_0}{\dashrightarrow} Y$ is projective morphism.*

*The author was supported in part by NSF grant DMS-0500659 and Polish KBN grant GR-1784.

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

4. *The above factorization commutes with any automorphisms ϕ_X of X, and ϕ_Y of Y such that $f \circ \phi_X = \phi_Y \circ f$.*

The theorem was proven in [38] and in [3] in a more general version. The above formulation essentially reflects the statement of the theorem in [3].

The weak factorization theorem extends a theorem of Zariski, which states that any birational map between two smooth complete surfaces can be factored into a succession of blow-ups at points followed by a succession of blow-downs at points. A stronger version of the above theorem, called the strong factorization conjecture, remains open.

Conjecture 1.2 (Strong Factorization Conjecture). Any birational map $f\colon X \dashrightarrow Y$ of smooth complete varieties can be factored into a succession of blow-ups at smooth centers followed by a succession of blow-downs at smooth centers.

Note that both statements are equivalent in dimension 2. One can find the formulation of the relevant conjectures in many papers. Hironaka [17] formulated the strong factorization conjecture. The weak factorization problem was stated by Miyake and Oda [30]. The toric versions of the strong and weak factorizations were also conjectured by Miyake and Oda [30] and are called the strong and weak Oda conjectures. The 3-dimensional toric version of the weak form was established by Danilov [12] (see also Ewald [14]). The weak toric conjecture in arbitrary dimensions was proved in [36] and later independently by Morelli [27], who also claimed to have a proof of the strong factorization conjecture (see also Morelli [28]). Morelli's proof of the weak Oda conjecture was completed, revised and generalized to the toroidal case by Abramovich, Matsuki and Rashid in [4]. A gap in Morelli's proof of the strong Oda conjecture, which went unnoticed in [4], was later found by K. Karu.

The local version of the strong factorization problem was posed by Abhyankar in dimension 2 and by Christensen in general; Christensen has solved it for 3-dimensional toric varieties [8]. The local version of the weak factorization problem (in characteristic 0) was solved by Cutkosky [9], who also showed that Oda's strong conjecture implies the local version of the strong conjecture for proper birational morphisms [10] and proved the local strong factorization conjecture in dimension 3 ([10]) via Christensen's theorem. Finally Karu generalized Christensen's result to any dimension and completed the argument for the local strong factorization ([22]).

The proofs in [38] and [3] are both build upon the idea of cobordism which was developed in [37] and was inspired by Morelli's theory of polyhedral cobordisms [27]. The main idea of [37] is to construct a space with a K^*-action for a given birational map. The space called a birational cobordism resembles the idea of Morse cobordism and determines a decomposition of the birational map into elementary transformations (see Remark 2.6). This gives a factorization into a sequence of weighted blow-ups and blow-downs. One can view the birational maps determined by cobordisms also in terms of VGIT developed in papers of Thaddeus ([34]) and Dolgachev–Hu ([13]). As shown in [37] the weighted blow-ups which occur in the factorization have

locally a natural toric and combinatorial description which is crucial for their further regularization.

The two existing methods of regularizing centers of this factorization are π-desingularization of cobordisms as in [38] and local torification of the action as in [3].

The present proof is essentially the same as in [38]. Instead of working in full generality and developing the suitable language for toroidal varieties we focus on applying the general ideas to a particular construction of a smooth cobordism. The reader can find also a more general and extended version of this proof in [39]. The π-desingularization is a desingularization of geometric quotients of a K^*-action. This can be done locally and the procedure can be globalized in the functorial and even canonical way. The π-desingularization makes all the intermediate varieties (which are geometric quotients) smooth, and also the connecting blow-ups have smooth centers.

The proof of Abramovich, Karu, Matsuki and the author [3] relies on a subtle analysis of differences between locally toric and toroidal structures defined by the action of K^*. The Abramovich–de Jong idea of torification is roughly speaking to construct the ideal sheaves whose blow-ups (or principalizations) introduce the structure of toroidal varieties in neighborhoods of fixed points of the action. This allows one to pass from birational maps between intermediate varieties in the neighborhood of fixed points to birational toroidal maps. The latter can be factored into a sequence of smooth blow-ups by using the same combinatorial methods as for toric varieties. Combining all the local factorizations together we get a global factorization.

For simplicity we restrict our considerations to projective varieties. We will not discuss here compatibility with divisors and functorial properties.

2. Birational cobordisms

2.1. Definition of a birational cobordism. Recall some basic definitions from Mumford's GIT theory.

Definition 2.1. Let K^* act on X. By a *good quotient* we mean a variety $Y = X//K^*$ together with a morphism $\pi\colon X \to Y$ which is constant on G-orbits such that for any affine open subset $U \subset Y$ the inverse image $\pi^{-1}(U)$ is affine and $\pi^*\colon O_Y(U) \to O_X(\pi^{-1}(U))^{K^*}$ is an isomorphism. If additionally for any closed point $y \in Y$ its inverse limit $\pi^{-1}(x)$ is a single orbit we call $Y := X/K^*$ together with $\pi\colon X \to Y$ a *geometric quotient*.

Remark 2.2. A geometric quotient is a space of orbits while a good quotient is a space of equivalence classes of orbits generated by the relation that two orbits are equivalent if their closures intersect.

Definition 2.3. Let K^* act on X. We say that $\lim_{t\to 0} tx$ exists (respectively $\lim_{t\to\infty} tx$ exists) if the morphism $K^* \to X$ given by $t \mapsto tx$ extends to $K^* \subset \mathbb{A}^1 \to X$ (or respectively $K^* \subset \mathbb{P}^1 \setminus \{0\} \to X$).

Definition 2.4 ([37]). Let X_1 and X_2 be two birationally equivalent normal varieties. A *birational cobordism* or simply a *cobordism* $B := B(X_1, X_2)$ between them is a normal variety B with an algebraic action of K^* such that the sets

$$B_- := \{x \in B \mid \lim_{t\to 0} tx \text{ does not exist}$$

and

$$B_+ := \{x \in B \mid \lim_{t\to \infty} tx \text{ does not exist}\}$$

are nonempty and open and there exist geometric quotients B_-/K^* and B_+/K^* such that $B_+/K^* \simeq X_1$ and $B_-/K^* \simeq X_2$ and the birational map $X_1 \dashrightarrow X_2$ is given by the above isomorphisms and the open embeddings of $B_+ \cap B_-/K^*$ into B_+/K^* and B_-/K^* respectively.

Remark 2.5. An analogous notion of cobordism of fans of toric varieties was introduced by Morelli in [27].

Remark 2.6. The above definition can also be considered as an analog of the notion of cobordism in Morse theory. Let W be a cobordism in Morse theory of two differentiable manifolds X and X' and $f\colon W \to [a, b] \subset \mathbb{R}$ be a Morse function such that $f^{-1}(a) = X$ and $f^{-1}(b) = X'$. Then X and X' have open neighborhoods $X \subseteq V \subseteq W$ and $X' \subseteq V' \subseteq W'$ such that $V \simeq X \times [a, a + \varepsilon)$ and $V' \simeq X' \times (b - \varepsilon, b]$ for which $f_{|V}\colon V \simeq X \times [a, a + \varepsilon) \to [a, b]$ and $f_{|V'}\colon V' \simeq X' \times (b - \varepsilon, b] \to [a, b]$ are the natural projections on the second coordinate. Let $W' := W \cup_V X \times (-\infty, a + \varepsilon) \cup_{V'} X' \times (b - \varepsilon, +\infty)$. One can easily see that W' is isomorphic to $W \setminus X \setminus X' = \{x \in W \mid a < f(x) < b\}$. Let $f'\colon W' \to \mathbb{R}$ be the map defined by glueing the function f and the natural projection on the second coordinate. Then $\operatorname{grad}(f')$ defines an action on W' of a 1-parameter group $T \simeq \mathbb{R} \simeq \mathbb{R}^*_{>0}$ of diffeomorphisms. The last group isomorphism is given by the exponential.

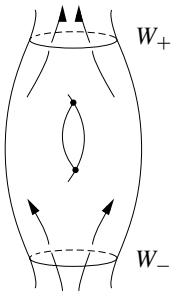

Figure 1. Cobordism in Morse theory.

Then one can see that $W'_- := \{x \in W' \mid \lim_{t\to 0} tx \text{ does not exist}\}$ and $W'_+ := \{x \in W' \mid \lim_{t\to\infty} tx \text{ does not exist}\}$ are open and X and X' can be considered as

quotients of these sets by T. The critical points of the Morse function are T-fixed points. "Passing through the fixed points" of the action induces a simple birational transformation similar to spherical modification in Morse theory (see Example 2.7).

Example 2.7. Let K^* act on $B := \mathbb{A}_K^{l+m+r}$ by

$$t(x_1, \dots, x_l, y_1, \dots, y_m, z_1, \dots, z_r) \\ = (t^{a_1} \cdot x_1, \dots, t^{a_l} \cdot x_l, t^{-b_1} \cdot y_1, \dots, t^{-b_m} \cdot y_m, z_1, \dots, z_r),$$

where $a_1, \dots, a_l, b_1, \dots, b_m > 0$. Set $\bar{x} = (x_1, \dots, x_l)$, $\bar{y} = (y_1, \dots, y_m)$, $\bar{z} = (z_1, \dots, z_r)$. Then

$$B_- = \{p = (\bar{x}, \bar{y}, \bar{z}) \in \mathbb{A}_K^{l+m+r} \mid \bar{y} \neq 0\},$$
$$B_+ = \{p = (\bar{x}, \bar{y}, \bar{z}) \in \mathbb{A}_K^{l+m+r} \mid \bar{x} \neq 0\}.$$

Case 1. $a_i = b_i = 1$, $r = 0$ (Atiyah, Reid). One can easily see that $B//K^*$ is the affine cone over the Segre embedding $\mathbb{P}^{l-1} \times \mathbb{P}^{m-1} \to \mathbb{P}^{l \cdot m - 1}$, and B_+/K^* and B_-/K^* are smooth.

The relevant birational map $\phi\colon B_-/K^* \dashrightarrow B_+/K^*$ is a flip for $l, m \geq 2$ replacing $\mathbb{P}^{l-1} \subset B_-/K^*$ with $\mathbb{P}^{m-1} \subset B_+/K^*$. For $l = 1$, $m \geq 2$, ϕ is a blow-down, and for $l \geq 2$, $m = 1$ it is a blow-up. If $l = m = 1$ then ϕ is the identity. One can show that $\phi\colon B_-/K^* \dashrightarrow B_+/K^*$ factors into the blow-up of $\mathbb{P}^{l-1} \subset B_-/K^*$ followed by the blow-down of $\mathbb{P}^{m-1} \subset B_+/K^*$.

Case 2. General case. For $l = 1$, $m \geq 2$, ϕ is a toric blow-up whose exceptional fibers are weighted projective spaces. For $l \geq 2$, $m = 1$, ϕ is a toric blow-down. If $l = m = 1$ then ϕ is the identity. The birational map $\phi\colon B_-/K^* \dashrightarrow B_+/K^*$ factors into a weighted blow-up and a weighted blow-down.

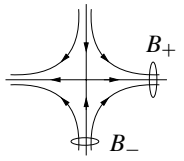

Figure 2. Affine Cobordism.

Remark 2.8. In Morse theory we have an analogous situation. In cobordisms with one critical point we replace S^{l-1} by S^{m-1}.

2.2. Fixed points of the action. Let X be a variety with an action of K^*. Denote by X^{K^*} the set of fixed points of the action and by $\mathcal{C}(X^{K^*})$ the set of its irreducible fixed components. For any $F \in \mathcal{C}(X^{K^*})$ set

$$F^+(X) = F^+ = \{x \in X \mid \lim_{t \to 0} tx \in F\}, \quad F^-(X) = F^- = \{x \in X \mid \lim_{t \to \infty} tx \in F\}.$$

Example 2.9. In Example 2.7,

$$F = \{p \in B \mid \bar{x} = \bar{y} = 0\}, \quad F^- = \{p \in B \mid \bar{x} = 0\}, \quad F^+ = \{p \in B \mid \bar{y} = 0\}.$$

Lemma 2.10. *If F is the fixed point set of an affine variety U then F, F^+ and F^- are closed in U. Moreover the ideals $I_{F^+}, I_{F^-} \subset K[V]$ are generated by all semiinvariant functions with positive (respectively negative) weights.*

Proof. Embed U equivariantly into affine space $\mathbb{A}^n$ with linear action and use the example above. □

2.3. Existence of a smooth birational cobordism

Proposition 2.11. *Let $\phi\colon X \dashrightarrow Y$ be a birational map between smooth projective varieties. Then ϕ factors as $X \leftarrow Z \to Y$, where $Z \to X$ and $Z \to Y$ are birational morphisms from a smooth projective variety Z.*

Proof. Let $\Gamma(X, Y) \subset X \times Y$ be the graph of ϕ and Z be its canonical resolution of singularities [17]. □

It suffices to construct the cobordism and factorization for the projective morphism $Y \to X$.

Proposition 2.12 ([37]). *Let $\varphi\colon Y \to X$ be a birational morphism of smooth projective varieties with the exceptional divisor D. Let $U \subset X, Y$ be an open subset where φ is an isomorphism. There exists a smooth projective variety $\overline{B}$ with a K^*-action, which contains fixed point components isomorphic to X and Y such that*

- *$B = B(X, Y) := \overline{B} \setminus (X \cup Y)$ is a cobordism between X and Y;*
- *$U \times K^* \subset B_- \cap B_+ \subset B$;*
- *there are K^*-equivariant isomorphisms $X^- \simeq X \times (\mathbb{P}^1 \setminus \{0\})$ and $Y^+ \simeq \mathcal{O}_Y(D)$;*
- *$X^- \setminus X = B_+$ and $Y^+ \setminus Y = B_-$*

In further considerations we shall refer to $\overline{B}$ as a *compactified cobordism.*

Proof. We follow here the Abramovich construction of cobordism. Let $\mathcal{I} \subset \mathcal{O}_X$ be a sheaf of ideals such that $Y = \mathrm{Bl}_{\mathcal{I}} X$ is obtained from X by blowing up of $\mathcal{I}$. Let z denote the standard coordinate on $\mathbb{P}^1$ and let $\mathcal{I}_0$ be the ideal of the point $z = 0$ on $\mathbb{P}^1$. Set $W := X \times \mathbb{P}^1$ and denote by $\pi_1\colon W \to X, \pi_2\colon W \to \mathbb{P}^1$ the standard projections. Then $\mathcal{J} := \pi_1^*(\mathcal{I}) + \pi_2^*(\mathcal{I}_0)$ is an ideal supported on $X \times \{0\}$. Set $W' := \mathrm{Bl}_{\mathcal{J}} W$. The proper transform of $X \times \{0\}$ is isomorphic to Y and we identify it with Y. Let us describe Y locally. Let $f_1, \ldots, f_k$ generate the ideal $\mathcal{I}$ on some open affine set $U \subset X$. Then after the blow-up $Y \to X$ at $\mathcal{I}$ the inverse image of U is a union of open charts $U_i \subset Y$, where

$$K[U_i] = K[U][f_1/f_i, \ldots, f_k/f_i].$$

Now the functions $f_1, \ldots, f_k, z$ generate the ideal $\mathcal{J}$ on $U \times \mathbb{A}^1 \subset W$. After the blow-up $W' \to W$ at $\mathcal{J}$, the inverse image of $U \times \mathbb{A}^1$ is a union of open charts $V_i \supset Y$, where

$$K[V_i] = K[U][f_1/f_i, \ldots, f_k/f_i, z/f_i] = K[U_i][z/f_i]$$

and the relevant V_z which does not intersect Y. Then $V_i = U_i^+ \simeq U_i \times \mathbb{A}^1$ where $z' := z/f_i$ is the standard coordinate on $\mathbb{A}^1$. The action of K^* on the factor U is trivial while on $\mathbb{A}^1$ it is standard given by $t(z') = tz$. Thus the open subset $Y^+ = \bigcup U_i^+ = \bigcup V_i \subset W'$ is a line bundle over Y with the standard action of K^*. On the other hand the neighborhood $X^- := X \times (\mathbb{P}^1 \setminus \{0\})$ of $X \subset W$ remains unchanged after the blow-up of $\mathcal{J}$. We identify X with $X \times \{\infty\}$. We define $\bar{B}$ to be the canonical desingularization of W. Then $B := \bar{B} \setminus X \setminus Y$. We get $B_-/K^* = (Y^+ \setminus Y)/K^* = Y$, while $B_+/K^* = (X^+ \setminus X)/K^* = X$. □

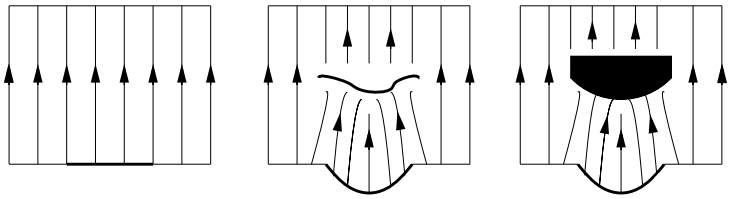

Figure 3. Compactified cobordism.

Remark 2.13. The Abramovich construction can be considered as a generalization of the Fulton–Macpherson construction of the deformation to the normal cone. If we let $\mathcal{I} = \mathcal{I}_C$ be the ideal sheaf of the smooth center then the relevant blow-up is already smooth. On the other hand this is a particular case of the very first example in [37] of a cobordism which is a K^*-equivariant completion of the space

$$L(Y, D; X, 0) := O_Y(D) \cup_{U \times K^*} X \times (\mathbb{P}^1 \setminus \{0\}).$$

Another variant of our construction is given by Hu and Keel in [21].

2.4. Collapsibility

Definition 2.14 ([37]). Let X be a cobordism or any variety with a K^*-action.

1. We say that $F \in \mathcal{C}(X^{K^*})$ is an *immediate predecessor* of $F' \in \mathcal{C}(X^{K^*})$ if there exists a nonfixed point x such that $\lim_{t\to 0} tx \in F$ and $\lim_{t\to\infty} tx \in F'$.

2. We say that F *precedes* F' and write $F < F'$ if there exists a sequence of connected fixed point set components $F_0 = F, F_1, \ldots, F_l = F'$ such that F_{i-1} is an immediate predecessor of F_i (see [5]).

3. We call a cobordism (or a variety with a K^*-action) *collapsible* (see also Morelli [27]) if the relation $<$ on its set of connected components of the fixed point set is an order. (Here an order is just required to be transitive.)

Definition 2.15 ([3], [37]). A function $\chi\colon \mathcal{C}(X^{K^*}) \to \mathbb{Z}$ is *strictly increasing* if $\chi(F) < \chi(F')$ whenever $F < F'$.

2.5. Existence of a strictly increasing function for $\mathbb{P}^k$ and $\bar{B}$. The space $\mathbb{P}^k = \mathbb{P}(\mathbb{A}^{k+1})$ splits according to the weights as

$$\mathbb{P}^k = \mathbb{P}(\mathbb{A}^{k+1}) = \mathbb{P}(\mathbb{A}_{a_1} \oplus \cdots \oplus \mathbb{A}_{a_r})$$

where K^* acts on $\mathbb{A}_{a_i}$ with the weight a_i. Assume that $a_1 < \cdots < a_r$. Let $\bar{x}_{a_i} = [x_{i,1}, \ldots, x_{i,r_i}]$ be the coordinates on $\mathbb{A}_{a_i}$. The action of K^* is given by

$$t[\bar{x}_{a_1}, \ldots, \bar{x}_{a_r}] = [t^{a_1}\bar{x}_{a_1}, \ldots, t^{a_r}\bar{x}_{a_r}].$$

It follows that the fixed point components of $(\mathbb{P}^k)^{K^*}$ are $\mathbb{P}(\mathbb{A}_{a_i})$. We define a strictly increasing function $\chi_{\mathbb{P}}\colon \mathcal{C}(\mathbb{P}^{K^*}) \to \mathbb{Z}$ by

$$\chi_{\mathbb{P}}(\mathbb{P}(\mathbb{A}_{a_i})) = a_i.$$

We see that for $\bar{x} = [\bar{x}_{a_0}, \ldots, \bar{x}_{a_r}]$, $\lim_{t\to 0} tx \in \mathbb{P}(\mathbb{A}_{a_{\min}})$, $\lim_{t\to\infty} tx \in \mathbb{P}(\mathbb{A}_{a_{\max}})$, where

$$a_{\max} = \max\{a \mid \bar{x}_a \neq 0\}, \quad a_{\min} = \min\{a \mid \bar{x}_a \neq 0\}.$$

Then $\mathbb{P}(\mathbb{A}_{a_i}) < \mathbb{P}(\mathbb{A}_{a_j})$ iff $a_i < a_j$.

By the Sumihiro theorem ([33]), we embed $\bar{B}$ equivariantly into a projective space $\mathbb{P}^k$. Then every fixed point component F in $\mathcal{C}(\bar{B}^{K^*})$ is contained in $\mathbb{P}(\mathbb{A}_a) \in \mathcal{C}((\mathbb{P}^k)^{K^*})$ and we put $\chi_B(F) = \chi_{\mathbb{P}}(\mathbb{P}(\mathbb{A}_a)) = a_i$. The function $\chi_{\mathbb{P}}$ is strictly increasing on $\mathcal{C}((\mathbb{P}^k)^{K^*})$ and the function χ_B is strictly increasing on $\mathcal{C}(\bar{B}^{K^*})$. This implies

Lemma 2.16. *A compactified cobordism $\bar{B}$ is collapsible.*

2.6. Decomposition of a birational cobordism

Definition 2.17 ([3], [37]). A cobordism B is *elementary* if any $F \neq F' \in \mathcal{C}(B^{K^*})$ are incomparable with respect to $>$.

The function χ_F defines a decomposition of $\mathcal{C}(B^{K^*})$ into elementary cobordisms

$$B_{a_i} := B \setminus \Big(\bigcup_{\chi_B(F)<a_i} F^- \cup \bigcup_{\chi_B(F)>a_i} F^+ \Big),$$

where $a_1 < \cdots < a_r$ are the values of χ_B. This yields

Lemma 2.18. 1. $(B_{a_1})_- = B_-$, $(B_{a_r})_+ = B_+$.

2. $(B_{a_{i+1}})_- = (B_{a_i})_+ = B \setminus \big(\bigcup_{\chi_B(F)\le a_i} F^- \cup \bigcup_{\chi_B(F)\ge a_{i+1}} F^+\big)$.

3. $\chi(F) = a_i$ *for any* $F \in \mathcal{C}(B_{a_i})$.

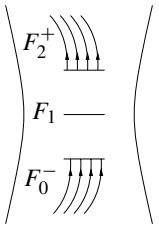

Figure 4. Elementary birational cobordism.

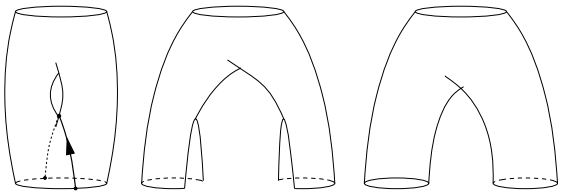

Figure 5. "Handle"-elementary cobordism in Morse Theory.

2.7. Decomposition of $\mathbb{P}^k$. Set $\mathbb{A}_{\geq a_i} := \mathbb{A}_{a_i} \oplus \cdots \oplus \mathbb{A}_{a_r}$, $\mathbb{A}_{>a_i} := \mathbb{A}_{a_{i+1}} \oplus \cdots \oplus \mathbb{A}_{a_r}$, and define $\mathbb{A}_{<a_i}$, $\mathbb{A}_{\leq a_i}$ analogously.

Lemma 2.19. $\mathbb{P}(\mathbb{A}_{a_i})^+ = \mathbb{P}(\mathbb{A}_{\geq a_i})$ *and* $\mathbb{P}(\mathbb{A}_{a_i})^- = \mathbb{P}(\mathbb{A}_{\leq a_i})$.

Lemma 2.20. *Set* $\mathbb{P}_{a_i} := \mathbb{P}^k \setminus \big(\bigcup_{\chi_{\mathbb{P}}(F)<a_i} F^- \cup \bigcup_{\chi_{\mathbb{P}}(F)>a_i} F^+\big)$. *Then*

$$\mathbb{P}_{a_i} = \mathbb{P}^k \setminus \mathbb{P}(\mathbb{A}_{>a_i}) \setminus \mathbb{P}(\mathbb{A}_{<a_i}), \quad (\mathbb{P}_{a_i})_+ = \mathbb{P}^k \setminus \mathbb{P}(\mathbb{A}_{\geq a_i}) \setminus \mathbb{P}(\mathbb{A}_{<a_i})$$
$$(\mathbb{P}_{a_i})_- = \mathbb{P}^k \setminus \mathbb{P}(\mathbb{A}_{>a_i}) \setminus \mathbb{P}(\mathbb{A}_{\leq a_i}).$$

Lemma 2.21. $B_{a_i} = \overline{B} \cap \mathbb{P}_{a_i}$, $(B_{a_i})_- = \overline{B} \cap (\mathbb{P}_{a_i})_-$, $(B_{a_i})_+ = \overline{B} \cap (\mathbb{P}_{a_i})_+$.

2.8. GIT and existence of quotients for $\mathbb{P}^k$. The sets $\mathbb{P}_{a_i}$ can be interpreted in terms of Mumford's GIT theory. Any lifting of the action of K^* on $\mathbb{P}^k = \mathbb{P}(\mathbb{A}^{k+1})$ to $\mathbb{A}^{k+1}$ is called a *linearization*. Consider the twisted action on $\mathbb{A}^{k+1}$,

$$t_r(x) = t^{-r} \cdot t(x).$$

The twisting does not change the action on $\mathbb{P}(\mathbb{A}^{k+1})$ and defines different linearizations. If we compose the action with a group monomorphism $t \mapsto t^k$ the weights of the new action $t^k(x)$ will be multiplied by k. The good and geometric quotients for $t(x)$ and $t^k(x)$ are the same. Keeping this in mind it is convenient to allow linearizations with rational weights.

Definition 2.22. A point $x \in \mathbb{P}^k$ is *semistable* with respect to t_r, written $x \in (\mathbb{P}^k, t_r)^{\mathrm{ss}}$, if there exists an invariant section $s \in \Gamma(\mathcal{O}_{\mathbb{P}^{k+1}}(n)^{t_r})$, for some $n \in \mathbb{N}$ such that $s(x) \neq 0$.

Lemma 2.23 ([3]). $\mathbb{P}_{a_i} = (\mathbb{P}^k, t_{a_i})^{\mathrm{ss}}$, $(\mathbb{P}_{a_i})_- = (\mathbb{P}^k, t_{a_i-\frac{1}{2}})^{\mathrm{ss}}$, $(\mathbb{P}_{a_i})_+ = (\mathbb{P}^k, t_{a_i+\frac{1}{2}})^{\mathrm{ss}}$.

Proof. $x \in \mathbb{P}_{a_i}$ iff either $\bar{x}_{a_i} \neq 0$ or $\bar{x}_{a_{j_1}} \neq 0$ and $\bar{x}_{a_{j_2}} \neq 0$ for $a_{j_1} < r = a_i < a_{j_2}$. In both situations we find a nonzero t_r-invariant section $s_i = x_i$ or $s_{j_1 j_2} = x_{j_1}^{b_1} x_{j_2}^{b_2}$ for suitable coprime b_1 and b_2.

$x \in (\mathbb{P}_{a_i})_-$ iff $\bar{x}_{a_{j_1}} \neq 0$ and $\bar{x}_{a_{j_2}} \neq 0$ for $a_{j_1} < a_i \leq a_{j_2}$ (or equivalently $a_{j_1} < r = a_i - 1/2 < a_{j_2}$). As before there is a nonzero t_r-invariant section $x_{j_1}^{b_1} x_{j_2}^{b_2}$ for suitable coprime b_1 and b_2. □

It follows from GIT theory that $(\mathbb{P}^k, t^r)^{\mathrm{ss}} /\!/ K^*$ exists and it is a projective variety. By Lemma 2.21 and the above we get

Corollary 2.24. *There exist quotients $\pi_{a_i} \colon B_{a_i} \to B_{a_i} /\!/ K^*$ and $\pi_{a_i-} = B_{a_i-} \to (B_{a_i})_-/K^*$, $\pi_{a_i+} = (B_{a_i})_+ \to (B_{a_i})_+/K^*$.*

2.9. Local description

Proposition 2.25 ([37]). *Let B_a be a smooth elementary cobordism. Then for any $x \in F_0$ there exists an invariant neighborhood V_x of x and a K^*-equivariant étale morphism (i.e. locally analytic isomorphism) $\phi \colon V_x \to \mathrm{Tan}_x$, where $\mathrm{Tan}_x \simeq \mathbb{A}_K^n$ is the tangent space with the induced linear K^*-action, such that in the diagram*

$$\begin{array}{ccccccc}
(B_a)_-/K^* & \supset & V_x /\!/ K^* \times_{\mathrm{Tan}_x /\!/ K^*} \mathrm{Tan}_{x-}/K^* & \simeq & V_{x-}/K^* & \to & \mathrm{Tan}_{x-}/K^* \\
\downarrow & & & & \downarrow & & \downarrow \\
B_a /\!/ K^* & & \supset & & V_x /\!/ K^* & \to & \mathrm{Tan}_x /\!/ K^* \\
\uparrow & & & & \uparrow & & \uparrow \\
(B_a)_+/K^* & \supset & V_x /\!/ K^* \times_{\mathrm{Tan}_x /\!/ K^*} \mathrm{Tan}_{x+}/K^* & \simeq & V_{x+}/K^* & \to & \mathrm{Tan}_{x+}/K^*
\end{array}$$

the vertical arrows are defined by open embeddings and the horizontal morphisms are defined by ϕ and are étale.

Proof. By taking local semiinvariant parameters at the point $x \in F_0$ one can construct an equivariant morphism $\phi \colon U_x \to \mathrm{Tan}_x \simeq \mathbb{A}_K^n$ from some open affine invariant neighborhood U_x such that ϕ is étale at x. By Luna's Lemma (see [Lu], Lemme 3 (Lemme Fondamental)) there exists an invariant affine neighborhood $V_x \subseteq U_x$ of the point x such that $\phi_{|V_x}$ is étale, the induced map $\phi_{|V_x /\!/ K^*} \colon V_x /\!/ K^* \to \mathrm{Tan}_x /\!/ K^*$ is étale and $V_x \simeq V_x /\!/ K^* \times_{\mathrm{Tan}_x /\!/ K^*} \mathrm{Tan}_x$. This defines the isomorphisms $V_x /\!/ K^* \times_{\mathrm{Tan}_x /\!/ K^*} \mathrm{Tan}_{x-}/K^* \simeq V_{x-}/K^*$. Note that $(B_a)_- = B_a \setminus \bigcup F^+_{F \in \mathcal{C}(B^{K^*})}$ and $V_x \cap F^+ = (V_x \cap F)^+$. (Both sets are closed and irreducible.) Thus $(V_x)_- = V_x \cap (B_a)_-$ and we get the horizontal inclusions. □

Proposition 2.26 ([37]). *There is a factorization of the morphism $\phi \colon Y \to X$ given by $Y = (B_{a_1})_-/K^* \dashrightarrow (B_{a_1})_+/K^* = (B_{a_2})_-/K^* \dashrightarrow \cdots \dashrightarrow (B_{a_{k-1}})_+/K^* = (B_{a_k})_-/K^* \dashrightarrow (B_{a_k})_+/K^* = X$.*

Remark 2.27. The birational maps $(B_a)_-/K^* \dashrightarrow (B_a)_+/K^*$ are locally described by Example 2.7. Both spaces have cyclic singularities and differ by the composite of a weighted blow-up and a weighted blow-down. To achieve the factorization we need to desingularize quotients as in for instance case 1 of the example. It is hopeless to modify weights by birational modification of smooth varieties. Instead we want to view Example 2.7 from the perspective of toric varieties.

3. Toric varieties

3.1. Fans and toric varieties. Let $N \simeq \mathbb{Z}^k$ be a lattice contained in the vector space $N^{\mathbb{Q}} := N \otimes \mathbb{Q} \supset N$.

Definition 3.1 ([11], [31]). By a *fan* Σ in $N^{\mathbb{Q}}$ we mean a finite collection of finitely generated strictly convex cones σ in $N^{\mathbb{Q}}$ such that

- any face of a cone in Σ belongs to Σ,
- any two cones of Σ intersect in a common face.

If σ is a face of σ' we shall write $\sigma \preceq \sigma'$.

We say that a cone σ in $N^{\mathbb{Q}}$ is *regular* if it is generated by a part of a basis of the lattice $e_1, \ldots, e_k \in N$, written $\sigma = \langle e_1, \ldots, e_k \rangle$. A cone σ is *simplicial* if it is generated over $\mathbb{Q}$ by linearly independent integral vectors $v_1, \ldots, v_k$, written $\sigma = \langle v_1, \ldots, v_k \rangle$

Definition 3.2. Let Σ be a fan and $\tau \in \Sigma$. The *star* of the cone τ and the *closed star* of τ are defined as follows:

$$\mathrm{Star}(\tau, \Sigma) := \{\sigma \in \Sigma \mid \tau \preceq \sigma\},$$

$$\overline{\mathrm{Star}}(\tau, \Sigma) := \{\sigma \in \Sigma \mid \sigma' \preceq \sigma \text{ for some } \sigma' \in \mathrm{Star}(\tau, \Sigma)\}.$$

To a fan Σ there is associated a toric variety $X_\Sigma \supset T$, i.e. a normal variety on which a torus T acts effectively with an open dense orbit (see [23], [12], [31], [15]). To each cone $\sigma \in \Sigma$ corresponds an open affine invariant subset X_σ and its unique closed orbit O_σ. The orbits in the closure of the orbit O_σ correspond to the cones of $\mathrm{Star}(\sigma, \Sigma)$. In particular, $\tau \preceq \sigma$ iff $\overline{O}_\tau \supset O_\sigma$.

The fan Σ is *nonsingular* (resp. *simplicial*) if all its cones are nonsingular (resp. simplicial). Nonsingular fans correspond to nonsingular varieties.

Denote by

$$M := \mathrm{Hom}_{\mathrm{alg.gr.}}(T, K^*)$$

the lattice of group homomorphisms to K^*, i.e. characters of T. The dual lattice $\mathrm{Hom}_{\mathrm{alg.gr.}}(K^*, T)$ of 1-parameter subgroups of T can be identified with the lattice N. Then the vector space $M^{\mathbb{Q}} := M \otimes \mathbb{Q}$ is dual to $N^{\mathbb{Q}} = N \otimes \mathbb{Q}$.

The elements $F \in M = N^*$ are functionals on N and integral functionals on $N^{\mathbb{Q}}$. For any $\sigma \subset N^{\mathbb{Q}}$ we denote by

$$\sigma^\vee := \{F \in M \mid F(v) \geq 0 \text{ for any } v \in \sigma\}$$

the set of integral vectors of the dual cone to σ. Then the ring of regular functions $K[X_\sigma]$ is $K[\sigma^\vee]$.

We call a vector $v \in N$ *primitive* if it generates the sublattice $\mathbb{Q}_{\geq 0} v \cap N$. Primitive vectors correspond to 1-parameter monomorphisms.

For any $\sigma \subset N^{\mathbb{Q}}$ set

$$\sigma^\perp := \{m \in M \mid (v, m) = 0 \text{ for any } v \in \sigma\}.$$

The latter set represents all invertible characters on X_σ. All noninvertible characters are in $\sigma^\vee \setminus \sigma^\perp$ and vanish on O_σ. The ring of regular functions on $O_\sigma \subset X_\sigma$ can be written as $K[O_\sigma] = K[\sigma^\perp] \subset K[\sigma^\vee]$.

3.2. Star subdivisions and blow-ups

Definition 3.3 ([23], [31], [12], [15]). A *birational toric morphism* or simply a *toric morphism* of toric varieties $X_\Sigma \to X_{\Sigma'}$ is a morphism identical on $T \subset X_\Sigma, X_{\Sigma'}$.

By the *support* of a fan Σ we mean the union of all its faces, $|\Sigma| = \bigcup_{\sigma \in \Sigma} \sigma$.

Definition 3.4 ([23], [31], [12], [15]). A *subdivision* of a fan Σ is a fan Δ such that $|\Delta| = |\Sigma|$ and any cone $\sigma \in \Sigma$ is a union of cones $\delta \in \Delta$.

Definition 3.5. Let Σ be a fan and ϱ be a ray passing in the relative interior of $\tau \in \Sigma$. Then the *star subdivision* $\varrho \cdot \Sigma$ of Σ with respect to ϱ is defined to be

$$\varrho \cdot \Sigma = (\Sigma \setminus \mathrm{Star}(\tau, \Sigma)) \cup \{\varrho + \sigma \mid \sigma \in \overline{\mathrm{Star}}(\tau, \Sigma) \setminus \mathrm{Star}(\tau, \Sigma)\}.$$

If Σ is nonsingular, i.e. all its cones are nonsingular, $\tau = \langle v_1, \ldots, v_l \rangle$ and $\varrho = \langle v_1 + \cdots + v_l \rangle$ then we call the star subdivision $\varrho \cdot \Sigma$ *nonsingular*.

Proposition 3.6 ([23], [12], [31], [15]). *Let X_Σ be a toric variety. There is a* 1-1 *correspondence between subdivisions of the fan Σ and proper toric morphisms $X_{\Sigma'} \to X_\Sigma$.*

Remark 3.7. Nonsingular star subdivisions from 3.5 correspond to blow-ups of smooth varieties at closures of orbits ([31], [15]). Arbitrary star subdivisions correspond to blow-ups of some ideals associated to valuations (see Lemma 5.20).

4. Polyhedral cobordisms of Morelli

4.1. Preliminaries. By $N^{\mathbb{Q}+}$ we shall denote a vector space $N^{\mathbb{Q}+} \approx \mathbb{Q}^k$ containing a lattice $N^+ \simeq \mathbb{Z}^k$, together with a primitive vector $v_0 \in N^+$ and the canonical projection

$$\pi : N^{\mathbb{Q}+} \to N^{\mathbb{Q}} \simeq N^{\mathbb{Q}+}/\mathbb{Q} \cdot v_0.$$

Definition 4.1 ([27]). A cone $\sigma \subset N^{\mathbb{Q}+}$ is *π-strictly convex* if $\pi(\sigma)$ is strictly convex (contains no line). A fan Σ is π-strictly convex if it consists of π-strictly convex cones.

In the following all the cones in $N^{\mathbb{Q}+}$ are assumed to be π-strictly convex and simplicial. The π-strictly convex cones σ in $N^{\mathbb{Q}+}$ split into two categories.

Definition 4.2. A cone $\sigma \subset N^{\mathbb{Q}+}$ is called *independent* if the restriction of π to σ is a linear isomorphism (equivalently $v_0 \notin \operatorname{span}(\sigma)$). A cone $\sigma \subset N^{\mathbb{Q}+}$ is called *dependent* if the restriction of π to σ is a lattice submersion which is not an isomorphism (equivalently $v_0 \in \operatorname{span}(\sigma)$).

A dependent cone is called a *circuit* if all its proper faces are independent.

Lemma 4.3. *Any dependent cone σ contains a unique circuit δ.*

4.2. K^*-actions and $N^{\mathbb{Q}+}$. The vector $v_0 = (a_1, \dots, a_k) \in N^{\mathbb{Q}+}$ defines a 1-parameter subgroup $t^{v_0} := t_1^{a_1} \dots t_k^{a_k}$ acting on T and all toric varieties $X \supset T$. Denote by M^+ the lattice dual to N^+. Then the lattice $N := N^+/\mathbb{Z} \cdot v_0$ is dual to the lattice $M := \{a \in M^+ \mid (a, v_0) = 0\}$ of all the characters invariant with respect to the group action. The natural projection of cones $\pi : \sigma \to \sigma^\Gamma$ defines the good quotient morphism

$$X_\sigma = \operatorname{Spec} K[\sigma^\vee] \to X_\sigma // K^* = \operatorname{Spec} K[\sigma^\vee \cap M] = \operatorname{Spec} K[(\sigma^\Gamma)^\vee] = X_{\sigma^\Gamma}.$$

Lemma 4.4. *A cone σ is independent iff the geometric quotient $X_\sigma \to X_\sigma/K^*$ exists or alternatively if X_σ contains no fixed points. The cone σ is dependent if O_σ is a fixed point set.*

Proof. Note that the set $X_\sigma^{K^*}$ is closed and if it is nonempty then it contains O_σ. Then a point $p \in O_\sigma$ is fixed, i.e. $t^{v_0} p = p$, iff for all functionals $F \in \sigma^\perp$ (i.e. $x^F(p) \neq 0$) we have $x^F(p) = x^F(t^{v_0} p) = t^{F(v_0)} x^F(p)$.

Then for all $F \in \sigma^\perp \subset \operatorname{span}(\sigma)^\perp$ we have $F(v_0) = 0$ so $v_0 \in \operatorname{span}(\sigma)$. □

Corollary 4.5. *A cone $\delta \in \Sigma$ is a circuit if and only if O_δ is the generic orbit of some $F \in \mathcal{C}(X_\Sigma^{K^*})$.*

Proof. O_σ is fixed with respect to the action of K^* if σ is dependent. Thus $O_\sigma \subset \overline{O}_\delta$ where δ is the unique circuit in σ (Lemma 4.3). □

4.3. Morelli cobordisms

Definition 4.6 (Morelli [27], [4]). A fan Σ in $N^{\mathbb{Q}+} \supset N^+$ is called a *polyhedral cobordism* or simply a cobordism if the sets of cones

$$\partial_-(\Sigma) := \{\sigma \in \Sigma \mid \text{there is } p \in \operatorname{int}(\sigma) \text{ so that } p - \varepsilon \cdot v_0 \notin |\Sigma| \text{ for all small } \varepsilon > 0\},$$

$$\partial_+(\Sigma) := \{\sigma \in \Sigma \mid \text{there is } p \in \operatorname{int}(\sigma) \text{ so that } p + \varepsilon \cdot v_0 \notin |\Sigma| \text{ for all small } \varepsilon > 0\}$$

are subfans of Σ and $\pi(\partial_-(\Sigma)) := \{\pi(\tau) \mid \tau \in \partial_-(\Sigma)\}$ and $\pi(\partial_+(\Sigma)) := \{\pi(\tau) \mid \tau \in \partial_+(\Sigma)\}$ are fans in $N^{\mathbb{Q}}$.

4.4. Dependence relation. Let $\sigma = \langle v_1, \dots, v_k \rangle$ be a dependent (simplicial) cone. Then, by definition $v_0 \in \operatorname{span}(v_1, \dots, v_k)$ where $v_1, \dots, v_k$ are linearly independent. There exists a unique up to rescaling integral relation

$$r_1 v_1 + \cdots + r_k v_k = a v_0, \quad \text{where } a > 0. \tag{$*$}$$

Definition 4.7 ([27]). The rays of σ are called *positive, negative* and *null* vectors, according to the sign of the coefficient in the defining relation.

Remark 4.8. Note that the relation $(*)$ defines a unique relation

$$r'_1 w_1 + \cdots + r'_k w_k = 0 \tag{$**$}$$

where w_i are generating vectors in the rays $\pi(\langle v_i \rangle)$, $r'_i w_i = r_i \pi(v_i)$. In particular $r'_i / r_i > 0$.

Lemma 4.9. *Let $\sigma = \langle v_1, \dots, v_k \rangle$ be a dependent cone. Then an independent face τ is in $\partial_+(\sigma)$ (resp. $\tau \in \partial_+(\sigma)$) if τ is a face of $\langle v_1, \dots, \check{v}_i, \dots, v_k \rangle$ for some index i such that $r_i < 0$ (resp. $r_i > 0$).*

Proof. By definition $\tau \in \partial_+(\sigma)$ there exists $p \in \operatorname{int}(\tau)$ such that for any sufficiently small $\varepsilon > 0$, $p + \varepsilon v_0 \notin \sigma$. Write $p = \sum \alpha_i v_i = \sum_{r_i > 0} \alpha_i v_i + \sum_{r_i < 0} \alpha_i v_i + \sum_{r_i = 0} \alpha_i v_i$, where $\alpha_i \geq 0$. Then one of the coefficients in

$$p + \varepsilon v_0 = \sum_{r_i > 0} (\alpha_i + r_i \varepsilon) v_i + \sum_{r_i < 0} (\alpha_i + r_i \varepsilon) v_i + \sum_{r_i = 0} (\alpha_i + r_i \varepsilon) v_i$$

is negative for small $\varepsilon > 0$. This is possible if $\alpha_i = 0$ for some index i with $r_i < 0$. □

Lemma 4.10. *A cone τ is in $\partial_+(\sigma)$ iff there exists $F \in \sigma^\vee \cap \tau^\perp$ such that $F(v_0) < 0$.*

Proof. If $\tau \in \partial_+(\sigma)$ then there exists $p \in \operatorname{int}(\tau)$ for which $p + \varepsilon v_0 \notin \sigma$. Hence there exists $F \in \sigma^\vee$ such that $F(p + \varepsilon v_0) < 0$ for small $\varepsilon > 0$. Then $F(p) = 0$ and $F(v_0) < 0$. Since $p \in \operatorname{int}(\tau)$ we have $F_{|\tau} = 0$. □

Corollary 4.11. *$\partial_+(\sigma)$ (resp. $\partial_-(\sigma)$) is a fan.*

Proof. By the lemma above, if $\tau \in \sigma^+$ then every face τ' of τ is in σ^+. □

Lemma 4.12. *Let σ be a dependent cone in $N^{\mathbb{Q}+}$. Then $B := X_\sigma$ is a birational cobordism such that*

- $(X_\sigma)_+ = X_{\partial_-(\sigma)}$, $(X_\sigma)_- = X_{\partial_+(\sigma)}$.
- $(X_\sigma)_+ / K^* \cong X_{\pi(\partial_-(\sigma))}$, $(X_\sigma)_- / K^* \cong X_{\pi(\partial_+(\sigma))}$.
- *$\pi(\partial_-(\sigma))$ and $\pi(\partial_+(\sigma))$ are both decompositions of $\pi(\sigma)$.*
- *There is a factorization into a sequence of proper morphisms $(X_\sigma)_+ / K^* \to (X_\sigma) /\!/ K^* \leftarrow (X_\sigma)_- / K^*$.*

Proof. We have $p \in O_\tau$ where $O_\tau \subset (X_\sigma)_-$ iff $\lim t^{v_0} p \notin X_\sigma$. This is equivalent to existence of a functional $F \in \sigma^\vee$ for which $x^F(t^{v_0} p) = t^{F(v_0)} x^F(p)$ has a pole at $t = 0$. This means exactly that $x^F(p) \neq 0$ and $F(v_0) < 0$. The last condition says $F_{|\tau} = 0$ and $F(v_0) < 0$, which is equivalent to $\tau \in \partial_+(\sigma)$.

Suppose that $x \in \pi(\sigma)$. Then $\pi^{-1}(x) \cap \sigma$ is a line segment or a point. Let $y = \sup\{\pi^{-1}(x) \cap \sigma\}$. Then $y \in \operatorname{int}(\tau)$, where $\tau \prec \sigma$ and $y + \varepsilon v_0 \notin \sigma$, which implies that $\tau \in \partial_+(\sigma)$. Thus every point in $\pi(\sigma)$ belongs to a relative interior of a unique cone $\pi(\tau) \in \pi(\partial_+(\sigma))$. Since $\pi_{|\tau}$ is a linear isomorphism and $\partial_+(\sigma)$ is a fan, all faces of $\pi(\tau)$ are in $\pi(\partial_-(\sigma))$. Finally, $\pi(\partial_+(\sigma))$ and $\pi(\partial_-(\sigma))$ are both decompositions of $\pi(\sigma)$ corresponding to toric varieties $(X_\sigma)_-/K^* = X_{\pi(\partial_+(\sigma))}$ and $(X_\sigma)_+/K^* = X_{\pi(\partial_-(\sigma))}$. □

The above yields

Lemma 4.13. *$B = X_\sigma$ is an elementary cobordism with a single fixed point component $F := \overline{O}_\delta$, where $\delta = \langle v_i \mid r_i \neq 0\rangle$ is a circuit. Moreover $(X_\sigma)_+ = X_{\partial_-(\sigma)} = X_\sigma \setminus \overline{O}_{\sigma_+}$, where*

$$\sigma_+ := \langle v_i \mid r_i > 0\rangle, \quad \sigma_- := \langle v_i \mid r_i < 0\rangle.$$

In particular $F^+ = (\overline{O}_\delta)^+ = \overline{O}_{\sigma_+}$ and $F^- = (\overline{O}_\delta)^- = \overline{O}_{\sigma_-}$.

4.5. Example 2.7 revisited. The cobordism X_σ from the lemma generalizes the cobordism $B = \mathbb{A}^{l+m+r}_K \supset T = (K^*)^{l+m+r}$ from Example 2.7. The action of K^* determines a 1-parameter subgroup of T which corresponds to a vector $v_0 = [a_1, \ldots, a_l, -b_1, \ldots, -b_m, 0, \ldots, 0]$. The cobordism B is associated with a nonsingular cone $\Delta \subset N_{\mathbb{Q}}$, while B_- and B_+ correspond to the fans $\partial_+(\Delta)$ and $\partial_-(\Delta)$ consisting of the faces of Δ visible from above and below respectively.

The quotients B_+/K^*, B_-/K^* and $B/\!/K^*$ are toric varieties corresponding to the fans $\pi(\partial_+(\Delta)) = \{\pi(\sigma) \mid \sigma \in \partial_+(\Delta)\}$, $\pi(\partial_-(\Delta)) = \{\pi(\sigma) \mid \sigma \in \Delta^-\}$ and $\pi(\Delta)$ respectively, where π is the projection defined by v_0.

The relevant birational map $\phi\colon B_-/K^* \dashrightarrow B_+/K^*$ for $l, m \geq 2$ is a toric flip associated with a bistellar operation replacing the triangulation $\pi(\partial_-(\Delta))$ of the cone $\pi(\Delta)$ with $\pi(\partial_+(\Delta))$.

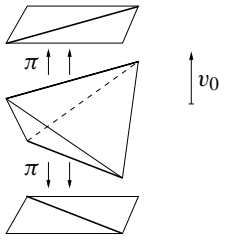

Figure 6. Morelli cobordism

4.6. π-nonsingular cones

Definition 4.14 (Morelli). An independent cone τ is *π-nonsingular* if $\pi(\tau)$ is nonsingular. A fan Σ is *π-nonsingular* if all independent cones in Σ are π-nonsingular. In particular a dependent cone σ is *π-nonsingular* if all its independent faces are π-nonsingular.

Lemma 4.15. *Let $\sigma = \langle v_1, \dots, v_k\rangle$ be a dependent cone and w_i be primitive generators of the rays $\pi(v_i)$. Let $\sum r_i' w_i = 0$ be the unique relation $(**)$ between vectors w_i. Then the ray $\varrho := \pi(\sigma_+) \cap \pi(\sigma_-)$ is generated by the vector $\sum_{r_i'>0} r_i' w_i = \sum_{r_i'<0} -r_i' w_i$ and $\varrho \cdot \pi(\partial_+(\sigma)) = \varrho \cdot \pi(\partial_-(\sigma))$. If σ is a π-nonsingular dependent cone then the ray ϱ defines regular star subdivisions of $\pi(\partial_+(\sigma))$ and $\pi(\partial_-(\sigma))$.*

Proof. Note that $\pi(\partial_+(\sigma)) \setminus \pi(\partial_-(\sigma))$ are exactly the cones containing $\pi(\sigma_+)$. That is, $\pi(\partial_+(\sigma)) \setminus \pi(\partial_-(\sigma)) = \mathrm{Star}(\pi(\sigma_+), \pi(\partial_+(\sigma)))$. This gives $\varrho \cdot \pi(\partial_+(\sigma)) = (\pi(\sigma_+) \cap \pi(\sigma_-)) \cup \{\varrho + \tau \mid \tau \in \pi(\sigma_+) \cap \pi(\sigma_-)\} = \varrho \cdot \pi(\sigma_-)$. Assume now that σ is π-nonsingular and all the coefficients r_i' are coprime. By Lemma 4.9 and the π-nonsingularity the set of vectors $w_1, \dots, \check{w}_i, \dots, w_k$ where $r_i' \neq 0$ is a basis of the lattice $\pi(\sigma) \cap N$. Thus every vector w_i, where $r_i' \neq 0$, can be written as an integral combination of others. Since the relation $(**)$ is unique it follows that the coefficient r_i' is equal to ± 1. Thus ϱ is generated by the vector $\sum_{r_i'>0} w_i = \sum_{r_i'<0} w_i$ and determines regular star subdivisions. □

Corollary 4.16. *If σ is dependent then there exists a factorization*

$$(X_\sigma)_-/K^* \xleftarrow{\phi_-} \Gamma((X_\sigma)_-/K^*, (X_\sigma)_+/K^*) \xrightarrow{\phi_+} (X_\sigma)_+/K^*,$$

where $\Gamma((X_\sigma)_-/K^*, (X_\sigma)_+/K^*)$ is the normalization of the graph of $(X_\sigma)_-/K^* \to (X_\sigma)_+/K^*$. If σ is π-nonsingular the morphisms ϕ_-, ϕ_+ are blow-ups of smooth centers.

Proof. By definition $\Gamma((X_\sigma)_-/K^*, (X_\sigma)_+/K^*)$ is a toric variety. By the universal property of the graph (dominating component of the fiber product) it corresponds to the coarsest simultaneous subdivision of both $\pi(\sigma_-)$ and $\pi(\sigma_+)$, that is, to the fan $\{\tau_1 \cap \tau_2 \mid \tau_1 \in \pi(\sigma_-), \tau_2 \in \pi(\sigma_+)\} = \varrho \cdot \pi(\sigma_-) = \varrho \cdot \pi(\sigma_+)$. □

4.7. The π-desingularization lemma of Morelli and centers of blow-ups.

For any simplicial cone $\sigma = \langle v_1, \dots, v_k\rangle$ in N set

$$\mathrm{par}(\sigma) := \{v \in \sigma \cap N_\sigma \mid v = \alpha_1 v_1 + \cdots + \alpha_k v_k, \text{ where } 0 \le \alpha_i < 1\},$$

$$\overline{\mathrm{par}(\sigma)} := \{v \in \sigma \cap N_\sigma \mid v = \alpha_1 v_1 + \cdots + \alpha_k v_k, \text{ where } 0 \le \alpha_i \le 1\}.$$

We associate with a dependent cone σ and an integral vector $v \in \pi(\sigma)$ a vector $\mathrm{Mid}(v, \sigma) := \pi^{-1}_{|\partial_-(\sigma)}(v) + \pi^{-1}_{|\partial_+(\sigma)}(v) \in \sigma$ ([27]), where $\pi_{|\partial_-(\sigma)}$ and $\pi_{|\partial_+(\sigma)}$ are the restrictions of π to $\partial_-(\sigma)$ and $\partial_+(\sigma)$.

We also set $\mathrm{Ctr}_-(\sigma) := \sum_{r_i<0} w_i$, $\mathrm{Ctr}_+(\sigma) := \sum_{r_i>0} w_i$.

Lemma 4.17 (Morelli [27], [28], [4]). *Let Σ be a simplicial cobordism in N^+. Then there exists a simplicial cobordism Δ obtained from Σ by a sequence of star subdivisions such that Δ is π-nonsingular. Moreover, the sequence can be taken so that any independent and already π-nonsingular face of Σ remains unaffected during the process. All the centers of the star subdivisions are of the form $\pi_{|\tau}^{-1}(\mathrm{par}(\pi(\tau)))$ where τ is independent, and* $\mathrm{Mid}(\mathrm{Ctr}_{\pm}(\sigma), \sigma)$*, where σ is dependent.*

Remark 4.18. It follows from Lemma 4.17 that π-desingularization can be done for an open affine neighborhood of a point x of $F \in \mathcal{C}(B^{K^*})$ on the smooth cobordism B which is étale isomorphic with the tangent space Tan_x. We need to show how to globalize this procedure in a coherent and possibly canonical way. This will replace the tangent space Tan_x in the local description of flips defined by elementary cobordisms (as in Proposition 2.25) with π-nonsingular X_σ.

By Corollary 4.16 we get a factorization into a blow-up and a blow-down at smooth centers: $(B_a)_-/K^* \xleftarrow{\phi_-} \Gamma((B_a)_-/K^*, (B_a)_+/K^*) \xrightarrow{\phi_+} (B_a)_+/K^*$.

5. π-desingularization of birational cobordisms

5.1. Stratification by isotropy groups on a smooth cobordism. Let B be a smooth cobordism of dimension n. Denote by Γ_x the isotropy group of a point $x \in B$. Define the stratum $s = s_x$ through x to be an irreducible component of the set $\{p \in B \mid \Gamma_x = \Gamma_p\}$.

We can find Γ_x-semiinvariant parameters in the affine open neighborhood U of x such that Γ_x acts nontrivially on $u_1, \ldots, u_k$ and trivially on $u_{k+1}, \ldots, u_n$.

After suitable shrinking of U the parameters define an étale Γ_x-equivariant morphism $\varphi\colon U \to \mathrm{Tan}_x = \mathbb{A}^n$. By definition the stratum s is locally described by $u_1 = \cdots = u_k = 0$. The parameters $u_1, \ldots, u_k$ determine a Γ_x-equivariant smooth morphism

$$\psi\colon U \to \mathrm{Tan}_{B,x}/\mathrm{Tan}_{s,x} = \mathbb{A}^k.$$

We shall view $\mathbb{A}^k = X_\sigma$ as a toric variety with a torus T_σ and refer to ψ as a *toric chart*. This assigns to a stratum s the cone σ and the relevant group Γ_σ acting on X_σ. Then Luna's [24] fundamental lemma implies that the morphisms ϕ and ψ preserve stabilizers, the induced morphism $\psi_\Gamma\colon U/\!/\Gamma_x \to X_\sigma/\!/\Gamma_\sigma$ is smooth and $U \simeq U/\!/\Gamma_x \times_{\mathbb{A}^k/\!/\Gamma_x} \mathbb{A}^k$.

The invariant Γ_x can be defined for $X_\sigma = \mathbb{A}^k$ and determine the relevant T_σ-invariant stratification S_σ on X_σ. By shrinking U we may assume that the strata on U are inverse images of the strata on X_σ. Any stratum s_y on U through y after a suitable rearrangement of $u_1, \ldots, u_k$ is described in the neighborhood $U' \subset U$ of y by $u_1 = \cdots = u_\ell = 0$, where $\Gamma_y \leq \Gamma_x$ acts nontrivially on $u_1, \ldots, u_\ell$ and trivially on $u_{\ell+1} \ldots, u_k, u_{k+1}, \ldots, u_n$. The remaining Γ_y-invariant parameters at y are $u_{\ell+1} - u_{\ell+1}(y), \ldots, u_n - u_n(y)$. Then the closure of $\bar{s}_y$ is described on U by $u_1 = \cdots = u_\ell = 0$ and contains s_x. This shows

Lemma 5.1. *The closure of any stratum is a union of strata.*

We can introduce an order on the strata by setting

$$s' \leq s \quad \text{iff} \quad \bar{s}' \subseteq s.$$

Lemma 5.2. *If $s' \leq s$ then there exists an inclusion $i_{\sigma'\sigma} : \sigma' \hookrightarrow \sigma$ onto a face of σ. The inclusion $i_{\sigma'\sigma}$ defines a $\Gamma_{\sigma'}$-equivariant morphism of toric varieties $X_{\sigma'} \to X_{\sigma'} \times 1 \hookrightarrow X_{\sigma'} \times T \subset X_\sigma$, where $T_{\sigma'} \times T = T_\sigma$ and $\Gamma_{\sigma'} \subset T_{\sigma'}$. Moreover we can write $X_\sigma \cong X_{\sigma'} \times \mathbb{A}^r$ where $\Gamma_{\sigma'}$ acts trivially on $\mathbb{A}^r$ and nontrivially on all coordinates of $X_{\sigma'} \simeq \mathbb{A}^\ell$.*

In the above situation we shall write

$$\sigma' \leq \sigma.$$

The lemma above immediately implies

Lemma 5.3. *If $\tau < \sigma$ (that is, $\tau \leq \sigma$, $\tau \neq \sigma$) then $\Gamma_\tau \subsetneq \Gamma_\sigma$.*

Consider the stratification S_σ on X_σ. Every stratum $s_\tau \in S_\sigma$, where $\tau \leq \sigma$, is a union of orbits $O_{\tau'}$. Set

$$\bar{\tau} := \{\tau' \mid O_{\tau'} \subset s_\tau\}.$$

Lemma 5.4. *Any cone from the set $\tau' \in \bar{\tau}$ can be expressed as $\tau' \simeq \tau \times \langle e_1, \ldots, e_r \rangle \subset \sigma$, and $X_{\tau'} = X_\tau \times \mathbb{A}^s \times T^{r-s}$ where Γ_τ acts trivially on $\mathbb{A}^r \times T^{r-s}$.*

Lemma 5.5. *We have $\Gamma_\tau = \Gamma_{\tau'} := \{g \in \Gamma_\sigma \mid \text{for all } x \in O_{\sigma'},\ gx = x\}$ for any $\tau' \in \bar{\tau}$.*

5.2. Local projections

Definition 5.6. A cone σ in $N^{\mathbb{Q}}$ is *of maximal dimension* if $\dim \sigma = \dim N^{\mathbb{Q}}$.

Every cone σ in $N^{\mathbb{Q}}$ defines a cone of maximal dimension in $N^{\mathbb{Q}} \cap \operatorname{span}\{\sigma\}$ with lattice $N \cap \operatorname{span}\{\sigma\}$. We denote it by $\underline{\sigma}$. There is a noncanonical isomorphism

$$X_\sigma = X_{\underline{\sigma}} \times O_\sigma.$$

The vector space $\operatorname{span}\{\sigma\} \subset N^{\mathbb{Q}}$ corresponds to a subtorus $T_{\underline{\sigma}} \subset T_\sigma$ defined as $T_{\underline{\sigma}} := \{t \in T_\sigma \mid tx = x \text{ for } x \in O_\sigma\}$. Then O_σ is isomorphic to the torus $T_\sigma / T_{\underline{\sigma}}$ with dual lattice $\sigma^\perp \subset M^{\mathbb{Q}}$.

Lemma 5.7. *If $\Gamma \subset T_\sigma$ acts freely on $X_\sigma = X_{\underline{\sigma}} \times O_\sigma$ then*

$$X_\sigma / \Gamma = X_{\underline{\sigma}} \times O_\sigma / \Gamma,$$

where $O_\sigma \simeq O_\sigma / \Gamma$ if Γ is finite, while O_σ / Γ is isomorphic to a torus of dimension $\dim O_\sigma - 1$ if $\Gamma = K^*$.

Proof. By assumption $\Gamma \cap T_{\underline{\sigma}}$ is trivial. Hence Γ acts trivially on $X_{\underline{\sigma}}$ and $X_\sigma/\Gamma = X_{\underline{\sigma}} \times O_\sigma/\Gamma$. □

Let $\pi_\sigma : (\sigma, N_\sigma) \to (\sigma^\Gamma, N_\sigma^\Gamma)$ denote the projection corresponding to the quotient map $X_\sigma \to X_\sigma//\Gamma_\sigma$.

Lemma 5.8. *If $\tau \le \sigma$ then $\pi_\tau(\tau) \simeq \pi_\sigma(\tau)$.*

Proof. $X_{\underline{\tau}} \times O_\tau$ is an open subvariety in X_σ and Γ_τ acts trivially on O_τ. We have

$$(X_{\underline{\tau}} \times O_\tau)/\Gamma_\tau = X_{\underline{\tau}}/\Gamma_\tau \times O_\tau = X_{\pi_\tau(\tau)} \times O_\tau.$$

$\Gamma_\sigma/\Gamma_\tau$ acts freely on $(X_{\underline{\tau}} \times O_\tau)/\Gamma_\tau = X_{\pi_\tau(\tau)} \times O_\tau$. Thus by the previous lemma $X_{\pi_\sigma(\tau)} \cong X_{\pi_\tau(\tau)} \times O_\tau/\Gamma_\sigma$. □

Lemma 5.9. *Let Γ be a subgroup of Γ_σ, and $\pi_\Gamma : \sigma \to \sigma^\Gamma$ be the projection corresponding to the quotient $X_\sigma \to X_\sigma/\Gamma$. For any $\tau \le \sigma$ and $\tau' \in \bar{\tau}$ we have $\tau' = \tau \oplus \langle e_1, \dots, e_k\rangle$ where $\langle e_1, \dots, e_k\rangle$ is regular and $\pi_\Gamma(\tau') = \pi_\Gamma(\tau) \oplus \langle e_1, \dots, e_k\rangle$.*

Proof. $X_{\tau'} = X_\tau \times \mathbb{A}^k \times O_{\tau'}$ where the action of $\Gamma_\tau \cap \Gamma$ on $\mathbb{A}^k \times O_\tau$ is trivial. Thus $X_{\tau'}/\Gamma_\tau = X_\tau/\Gamma_\tau \times \mathbb{A}^k \times O_{\tau'}$. Now $\Gamma/(\Gamma_\tau \cap \Gamma)$ acts freely on $O_{\tau'} \subset s_\tau$ and we use Lemma 5.7. □

5.3. Independent and dependent cones. By Lemma 5.8 there exists a lattice isomorphism $j_{\tau\sigma} : \pi_\tau(\tau) \to \pi_\sigma(\tau)$, where $\tau \le \sigma$. Thus the projections π_τ and π_σ are coherent and related: $j_{\tau\sigma}\pi_\tau = \pi_\sigma$.

Case 1: $\Gamma_\sigma = K^*$. The action of K^* on X_σ corresponds to a primitive vector $v_\sigma \in N_\sigma$. The invariant characters $M_\sigma^\Gamma \subset M_\sigma$ are precisely those $F \in M_\sigma^\Gamma$ such that $F(v_\sigma) = 0$. The dual morphism is a projection $\pi_\sigma : N_\sigma \to N_\sigma/\mathbb{Z} \cdot v_\sigma = N_\sigma^\Gamma$.

The quotient morphism of toric varieties $X_\sigma \to X_\sigma/\Gamma_\sigma$ corresponds to the projection $\sigma \to \pi_\sigma(\sigma)$.

Case 2: $\Gamma_\sigma \cong \mathbb{Z}_n$. The invariant characters $M_\sigma^\Gamma \subset M_\sigma$ form a sublattice of dimension $\dim(M_\sigma^\Gamma) = \dim(M_\sigma)$, where $M_\sigma/M_\sigma^\Gamma \simeq \mathbb{Z}_n$. The dual morphism defines an inclusion $\pi : N_\sigma \hookrightarrow N_\sigma^\Gamma$. The projection $\sigma \to \pi_\sigma(\sigma)$ is a linear isomorphism which does not preserve lattices. This gives

Lemma 5.10. *X_τ is independent iff Γ_τ is finite. X_σ is dependent iff $\Gamma_\sigma = K^*$.*

Definition 5.11. Let Δ^σ be a decomposition of a cone $\sigma \in \Sigma$. A cone $\tau \in \Delta^\sigma$ is *independent* if $\pi_{\sigma|\tau}$ is a linear isomorphism. A cone τ is *dependent* if $\pi_{\sigma|\tau}$ is not a linear isomorphism.

5.4. Semicomplexes and birational modification of cobordisms. By glueing cones σ corresponding to strata along their faces we construct a *semicomplex* Σ, that is, a partially ordered set of cones such that for $\sigma \leq \sigma'$ there exists a face inclusion $i_{\sigma\sigma'}\colon \sigma \to \sigma'$.

Remark 5.12. The glueing need not be transitive: for $\sigma \leq \sigma' \leq \sigma''$ we have $i_{\sigma'\sigma''}i_{\sigma\sigma'} \neq i_{\sigma\sigma''}$. Instead, there exists an automorphism α_σ of σ such that $i_{\sigma'\sigma''}i_{\sigma\sigma'} = i_{\sigma\sigma''}\alpha_\sigma$.

For any fan Σ denote by $\mathrm{Vert}(\Sigma)$ the set of all 1-dimensional faces (rays) in Σ. Denote by $\mathrm{Aut}(\sigma)$ the automorphisms of σ inducing Γ_σ-equivariant automorphisms.

Definition 5.13. By a *subdivision* of Σ we mean a collection $\Delta = \{\Delta^\sigma \mid \sigma \in \Sigma\}$ of subdivisions Δ^σ of σ such that:

1. If $\tau \leq \sigma$ then the restriction $\Delta^\sigma_{|\tau}$ of Δ^σ to τ is equal to Δ^τ.
2. All rays in $\mathrm{Vert}(\Delta^\sigma) \setminus \mathrm{Vert}(\sigma)$ are contained in $\bigcup_{\tau\leq\sigma} \mathrm{int}(\tau)$.
3. Δ^σ is $\mathrm{Aut}(\sigma)$-invariant.

Remark 5.14. Condition 3 is replaced with a stronger one in the following proposition.

Lemma 5.15. *If $\tau' \in \bar{\tau}$, $\tau' \prec \sigma \in \Sigma$ then* $\mathrm{Vert}(\Delta^\sigma_{|\tau'}) \setminus \mathrm{Vert}(\tau') \subset \tau$ *and*

$$\Delta^\sigma_{|\tau'} = \Delta^\sigma_{|\tau} \oplus \langle e_1, \ldots, e_k\rangle = \Delta^\tau \times \langle e_1, \ldots, e_k\rangle.$$

Lemma 5.16. *For every point $x \in B \setminus (B_+ \cap B_-)$, $x \in s'$ there exists a toric chart $x \in U_\sigma \to X_\sigma$, with $\Gamma_\sigma = K^*$, corresponding to a stratum $s \subset \bar{s}'$. In particular the maximal cones of Σ are circuits.*

Proof. Let τ correspond to a stratum $s' \ni x$. By definition of cobordism $\lim_{t\to 0} tx = x_0$ or $\lim_{t\to\infty} tx = x_0$ exists. The point x_0 is K^*-fixed and belongs to a stratum s, with $\Gamma_s = \Gamma_\sigma = K^*$. Since U is a K^*-invariant neighborhood of x_0 it contains an orbit $K^* \cdot x$ and the point x. Moreover $\bar{s}' \supset s$ and $\tau \leq \sigma$. □

Lemma 5.17. *Let σ be the cone corresponding to a stratum s on B and $x \in s$. Then* $\widehat{X}_x = \mathrm{Spec}\,\widehat{O}_{x,B} \simeq (X_\sigma \times \mathbb{A}^{\dim(s)})^\wedge \cong \mathrm{Spec}\,K[[x_1, \ldots, x_k, \ldots, x_n]]$.

Set $\widetilde{X}_\sigma := (X_\sigma \times \mathbb{A}^{\dim(s)})^\wedge$ and let G_σ denote the group of all Γ_σ-equivariant autorphisms of $\widetilde{X}_\sigma$.

The subdivision Δ^σ of σ defines a toric morphism and induces a proper birational Γ_σ-equivariant morphism

$$\widetilde{X}_{\Delta^\sigma} := X_{\Delta^\sigma} \times_{X_\sigma} \widetilde{X}_\sigma \to \widetilde{X}_\sigma.$$

Proposition 5.18. *Let $\Delta = \{\Delta^\sigma \mid \sigma \in \Sigma\}$ be a subdivision of Σ such that:*

$$\text{For every } \sigma \in \Sigma \text{ the morphism } \widetilde{X}_{\Delta^\sigma} \to \widetilde{X}_\sigma \text{ is } G_\sigma\text{-equivariant.} \tag{1}$$

Then Δ defines a K^*-equivariant birational modification $f\colon B' \to B$ such that for every toric chart $\varphi_\sigma\colon U \to X_\sigma$ there exists a Γ_σ-equivariant fiber square

$$\begin{array}{rcl} U_\sigma \times_{X_\sigma} X_{\Delta^\sigma} \simeq f^{-1}(U_\sigma) & \to & X_{\Delta^\sigma} \\ \downarrow f & & \downarrow \\ U_\sigma & \to & X_\sigma. \end{array} \tag{2}$$

Definition 5.19. A decomposition Δ of Σ is *canonical* if it satisfies condition (1).

Proof. The above diagrams define open subsets $f_\sigma^{-1}(U_\sigma)$ together with proper birational Γ_σ-equivariant morphisms $f_\sigma^{-1}(U_\sigma) \to U_\sigma$. Let $s' \le s$ be a stratum corresponding to the cone $\tau \le \sigma$. By Lemma 5.15, the restriction of the diagram (2) defined by $U_\sigma \to X_\sigma$ to a neighborhood U_τ of $y \in s'$ determines a diagram defined by the induced toric chart $U_\tau \to X_\tau$ and the decomposition Δ^τ of τ. In order to show that the $f_\sigma^{-1}(U)$ glue together we need to prove that for $x \in s$ and two different charts of the form $\varphi_{1,\sigma}\colon U_{1,\sigma} \to X_\sigma$ and $\varphi_{2,\sigma}\colon U_{2,\sigma} \to X_\sigma$ where $x \in U_{1,\sigma}, U_{2,\sigma}$ the induced varieties $V_1 := f_{1,\sigma}^{-1}(U_{1,\sigma})$ and $V_2 := f_{2,\sigma}^{-1}(U_{2,\sigma})$ are isomorphic over $U_{1,\sigma} \cap U_{2,\sigma}$. For simplicity assume that $U_{1,\sigma} = U_{2,\sigma} = U$ by shrinking $U_{1,\sigma}$ and $U_{2,\sigma}$ if necessary. The charts $\varphi_{1,\sigma}, \varphi_{2,\sigma}\colon U \to X_\sigma$ are defined by the two sets of semiinvariant parameters, $u_1^1, \dots, u_k^1$ and $u_1^2, \dots, u_k^2$ with a nontrivial action of Γ_σ. These sets can be extended to full sets of parameters $u_1^1, \dots, u_k^1, u_{k+1}, \dots, u_n$ and $u_1^2, \dots, u_k^2, u_{k+1}, \dots, u_n$ where Γ_σ acts trivially on $u_{k+1}, \dots, u_n$, and $u_{k+1} \dots, u_n$ define parameters on the stratum s at x. These two sets of parameters define étale morphisms $\varphi_{1,\sigma}, \varphi_{2,\sigma}\colon U \to X_\sigma \times \mathbb{A}^{n-k}$ and fiber squares

$$\begin{array}{rcl} \bar{\varphi}_{i,\sigma}\colon\ V_i & \to & X_{\Delta^\sigma} \times \mathbb{A}^{n-k} \\ \downarrow & & \downarrow \\ \varphi_{i,\sigma}\colon\ U & \to & X_\sigma \times \mathbb{A}^{n-k}. \end{array}$$

Suppose the induced Γ-equivariant birational map $f\colon V_1 \dashrightarrow V_2$ is not an isomorphism over U.

Let V be the graph of f which is a dominating component of the fiber product $V_1 \times_U V_2$. Then either $V \to V_1$ or $V \to V_2$ is not an isomorphism (i.e. collapses a curve to a point) over some $x \in s \cap U$. Consider an étale Γ_σ-equivariant morphism $e\colon \widehat{X}_x \to U$. Pull-backs of the morphisms $V_i \to U$ via e define two different nonisomorphic Γ_σ-equivariant liftings $Y_i \to \widehat{X}_x$, since the graph Y of $Y_1 \dashrightarrow Y_2$ (which is a pull-back of V) is not isomorphic to at least one Y_i. But these two liftings are defined by two isomorphisms $\widehat{\varphi}_1, \widehat{\varphi}_2\colon \widehat{X}_x \simeq \widetilde{X}_\sigma$. These isomorphisms differ by some automorphism $g \in G_\sigma$, so we have $\widehat{\varphi}_1 = g \circ \widehat{\varphi}_2$. Since g lifts to the automorphism of $\widetilde{X}_{\Delta^\sigma}$ we get $Y_1 \simeq Y_2 \simeq \widetilde{X}_{\Delta^\sigma}$, which contradicts the choice of Y_i.

Thus V_1 and V_2 are isomorphic over any $x \in s$ and B' is well defined by glueing pieces $f_\sigma^{-1}(U)$ together. We need to show that the action of K^* on B lifts to the action of K^* on B'.

Note that B' is isomorphic to B over the open generic stratum $U \supset B_+ \cup B_-$ of points x with $\Gamma_x = \{e\}$. By Lemma 5.16 every point $x \in B \setminus (B_+ \cap B_-)$ is in U_σ, with $\Gamma_\sigma = K^*$. Then the diagram (2) defines the action of K^* on $f^{-1}(U_\sigma)$. □

5.5. Basic properties of valuations. Let $K(X)$ be the field of rational functions on an algebraic variety or an integral scheme X. A *valuation* on $K(X)$ is a group homomorphism $\mu\colon K(X)^* \to G$ from the multiplicative group $K(X)^*$ to a totally ordered group G such that $\mu(a+b) \geq \min(\mu(a), \mu(b))$. By the *center* of a valuation μ on X we mean an irreducible closed subvariety $Z(\mu) \subset X$ such that for any open affine $V \subset X$, intersecting $Z(\mu)$, the ideal $I_{Z(\mu)\cap V} \subset K[V]$ is generated by all $f \in K[V]$ such that $\mu(f) > 0$ and for any $f \in K[V]$, we have $\mu(f) \geq 0$. Each vector $v \in N^{\mathbb{Q}}$ defines a linear function on M which determines a valuation $\mathrm{val}(v)$ on a toric variety $X_\Sigma \supset T$.

For any regular function $f = \sum_{w\in M} a_w x^w \in K[T]$ set

$$\mathrm{val}(v)(f) := \min\{(v, w) \mid a_w \neq 0\}.$$

If $v \in \mathrm{int}(\sigma)$, where $\sigma \in \Delta$, then $\mathrm{val}(v)$ is positive for all x^F, where $F \in \sigma^\vee \setminus \sigma^\perp$. In particular we get

$$Z(\mathrm{val}(v)) = \overline{O}_\sigma \quad \text{iff} \quad v \in \mathrm{int}\,\sigma.$$

If $v \in \sigma$ then $\mathrm{val}(v)$ is a valuation on $R = K[X_\sigma] = K[\sigma^\vee]$, that is, $\mathrm{val}(v)(f) \geq 0$ for all $f \in K[\sigma^\vee] \setminus \{0\}$. We construct ideals for all $a \in \mathbb{N}$ which uniquely determine $\mathrm{val}(v)$:

$$I_{\mathrm{val}(v),a} = \{f \in R \mid \mathrm{val}(v)(f) \geq a\} = (x^F \mid F \in \sigma^\vee, F(v) \geq a) \subset R.$$

By glueing $I_{\mathrm{val}(v),a}$ for all $v \in \sigma$ and putting $\mathcal{I}_{\mathrm{val}(v),a|X_\sigma} = \mathcal{O}_{X_\sigma}$ if $v \notin \sigma$ we construct a coherent sheaf of ideals $\mathcal{I}_{\mathrm{val}(v),a}$ on X_Δ.

Lemma 5.20 ([23]). *The star subdivision $\langle v\rangle \cdot \Sigma$ corresponds to the normalized blow-up of $\mathcal{I}_{\mathrm{val}(v),a}$ on X_Σ for a sufficiently divisible $a \in \mathbb{N}$.*

5.6. Stable vectors. Let $g\colon X \to Y$ be any dominant morphism of integral schemes (that is, $\overline{g(X)} = Y$) and μ be a valuation of $K(X)$. Then g induces a valuation $g_*(\mu)$ on $K(Y) \simeq g(K(Y)) \subset K(X)$: $g_*\mu(f) = \mu(f \circ g)$.

Definition 5.21. Let Σ be the semicomplex defined for the cobordism B. A vector $v \in \mathrm{int}(\sigma)$, where $\sigma \in \Sigma$, is called *stable* if for every $\sigma \leq \sigma'$, $\mathrm{val}(v)$ is $G_{\sigma'}$-invariant on $\widetilde{X}_{\sigma'}$.

Lemma 5.22. *If $\widetilde{X}_{\Delta^\sigma} \to \widetilde{X}_\sigma$ is G_σ-equivariant and* $\mathrm{val}(v)$ *is G_σ-invariant then $\widetilde{X}_{\langle v\rangle\cdot\Delta^\sigma} \to \widetilde{X}_\sigma$ is G_σ-equivariant.*

Proof. The morphism $\widetilde{X}_{\langle v\rangle\cdot\Delta^\sigma} \to \widetilde{X}_{\Delta^\sigma}$ is a pull-back of the morphism $X_{\langle v\rangle\cdot\Delta^\sigma} \to X_{\Delta^\sigma}$. Thus, by Lemma 5.20, $\widetilde{X}_{\langle v\rangle\cdot\Delta^\sigma} \to \widetilde{X}_{\Delta^\sigma}$ is a normalized blow-up of $\mathcal{I}_{\mathrm{val}(v),a}$ on $\widetilde{X}_{\Delta^\sigma}$. But the latter sheaf is G_σ-invariant. □

Proposition 5.23. *Let $\Delta = \{\Delta^\sigma \mid \sigma \in \Sigma\}$ be a canonical subdivision of Σ and v be a stable on Σ. Then $\langle v\rangle \cdot \Delta := \{\langle v\rangle \cdot \Delta^\sigma \mid \sigma \in \Sigma\}$ is a canonical subdivision of Σ.*

5.7. Convexity

Lemma 5.24. *Let* $\mathrm{val}(v_1)$ *and* $\mathrm{val}(v_2)$ *be G_σ-invariant valuations on X_σ. Then all valuations* $\mathrm{val}(v)$*, where $v = av_1 + bv_2$, $a, b \geq 0$, $a, b \in \mathbb{Q}$, are G_σ-invariant.*

Proof. Let $\Delta = \langle v_1\rangle \cdot \langle v_2\rangle \cdot \sigma$ be a subdivision of σ. Then by Lemma 5.22, the morphism $\widetilde{X}_\Delta \to \widetilde{X}_\sigma$ is G_σ-equivariant. The exceptional divisors D_1 and D_2 of the morphism are G_σ-invariant and correspond to one-dimensional cones (rays) $\langle v_1\rangle, \langle v_2\rangle \in \Delta$. The cone $\tau = \langle v_1, v_2\rangle \in D$ corresponds to the orbit O_τ whose closure is $D_1 \cap D_2$ and thus the generic point is G_σ-invariant. The action of G_σ on $\widetilde{X}_\sigma$ induces an action on the local ring $\widetilde{X}_{\Delta,O_\tau}$ at the generic point of O_τ and on its completion $K(O_\tau)[[\underline{\tau}^\vee]]$. Note that for any $v \in \tau$, $\mathrm{val}(v)_{|K(O_\tau)} = 0$. For any $F \in \underline{\tau}^\vee = \frac{\tau^\vee}{\tau^\perp}$ the divisor (x^F) of the character x^F on $\widehat{X}_\tau := \operatorname{Spec} K(O_\tau)[[\underline{\tau}^\vee]]$ is a combination $n_1D_1 + n_2D_2$ for $n_1n_2 \in \mathbb{Z}$. Since D_1 and D_2 are G_σ-invariant, the divisor $(x^F) = n_1D_1 + n_2D_2$ is G_σ-invariant, that is, for any $g \in G$, we have $gx^F = u_{g,F} \cdot x^F$ where $u_{g,F}$ is invertible on $K(O_\tau)[[\underline{\tau}^\vee]]$. Thus for every $v \in \tau$ and $g \in G$ we have

$$\begin{aligned} g^*(I_{\mathrm{val}(v),a}) &= g^*(x^F | F \in \underline{\tau}^\vee, F(v) \geq a) \\ &= (u_{g,F}x^F | F \in \underline{\tau}^\vee, F(v) \geq a) = I_{\mathrm{val}(v),a}. \end{aligned}$$

Thus $\mathrm{val}(v)$ is G_σ-invariant on $K(O_\tau)[[\underline{\tau}^\vee]]$ and on its subring $\mathcal{O}_{\widetilde{X}_{\Delta,O_\tau}}$. The latter ring has the same quotient field as $\widetilde{X}_\sigma$ so $\mathrm{val}(v)$ is G_σ-invariant on $\widetilde{X}_\sigma$. □

Lemma 5.25. *Let $\sigma \in \Sigma$ and $v_1, v_2 \in \sigma$ be stable vectors. Then all vectors $v = av_1 + bv_2 \in \sigma$, where $a, b \in \mathbb{Q}_{>0}$, are stable.*

5.8. Basic properties of stable vectors

Lemma 5.26. *Let* $\mathrm{Tan}_0 = \mathbb{A}^n = \mathrm{Tan}_0^{a_0} \oplus \mathrm{Tan}_0^{a_1} \oplus \cdots \oplus \mathrm{Tan}_0^{a_k}$ *denote the tangent space of* $\widetilde{X}_\sigma = \operatorname{Spec} K[[u_1, \ldots, u_n]]$ *at* 0 *and its decomposition according to the weight distribution. Let $d\colon G_\sigma \to \mathrm{GL}(\mathrm{Tan}_0)$ be the differential morphism defined as $g \mapsto dg$. Then $d(G_\sigma) = \mathrm{GL}(\mathrm{Tan}_0^{a_1}) \times \cdots \times \mathrm{GL}(\mathrm{Tan}_0^{a_k})$.*

Lemma 5.27. *Let $v \in \sigma$, where $\sigma \in \Sigma$, be an integral vector such that for any $g \in G_\sigma$, there exists an integral vector $v_g \in \sigma$ such that $g_*(\mathrm{val}(v)) = \mathrm{val}(v_g)$. Then* $\mathrm{val}(v)$ *is G_σ-invariant on $\widetilde{X}_\sigma$.*

Proof. Set $W = \{v_g \mid g \in G\}$. For any natural number n, the ideals $I_{\mathrm{val}(v_g),a}$ are generated by monomials. They define the same Hilbert–Samuel function $k \mapsto \dim_K(K[\widetilde{X}_\sigma]/(I_{\mathrm{val}(v_g),a} + m^k))$, where $m \subset K[\widetilde{X}_\sigma]$ denotes the maximal ideal. It follows that the set W is finite. On the other hand since $I_{\mathrm{val}(v_g),a}$ are generated by monomials they are uniquely determined by the ideals $\mathrm{gr}(I_{\mathrm{val}(v_g),a})$ in the graded ring

$$\mathrm{gr}(O_{\widetilde{X}_\sigma}) = O_{\widetilde{X}_\sigma}/m \oplus m/m^2 \oplus \cdots .$$

The connected group $d(G_\sigma)$ acts algebraically on $\mathrm{gr}(O_{\widetilde{X}_\sigma})$ and on the connected component of the Hilbert scheme with fixed Hilbert polynomial. In particular it acts trivially on its finite subset W and consequently $d(G_\sigma)$ preserves $\mathrm{gr}(I_{\mathrm{val}(v_g),a})$ and G_σ preserves $I_{\mathrm{val}(v_g),a}$. □

Let $R \subset K$ be a ring contained in the field. We can order valuations by writing

$$\mu_1 > \mu_2 \quad \text{if} \quad \mu_1(a) \geq \mu_2(a) \text{ for all } a \in R \text{ and } \mu_1 \neq \mu_2.$$

A cone σ defines a partial ordering: $v_1 > v_2$ if $v_1 - v_2 \in \sigma$. Both orders coincide for $K[X_\sigma] \subset K(X_\sigma)$: $v_1 > v_2$ iff $\mathrm{val}(v_1) > \mathrm{val}(v_2)$.

Lemma 5.28. *Let σ be a cone in $N_\sigma^{\mathbb{Q}}$ with the lattice of 1-parameter subgroups $N_\sigma \subset N_\sigma^Q$ and the dual lattice of characters M_σ. Let μ be any integral (or rational) valuation centered on $\overline{O}_\tau$, where $\tau \preceq \sigma$. Then the restriction of μ to $M_\sigma \subset K(\widetilde{X}_\sigma)^*$ defines a functional on $\tau^\vee \subseteq M_\sigma^Q$ corresponding to a vector $v_\mu \in \operatorname{int}\tau$ such that $F(v_\mu) = \mu(x^F)$ for $F \in M_\sigma$ and $\mu \geq \mathrm{val}(v_\mu)$ on $\widetilde{X}_\sigma$.*

Proof. $I_{\mu,a} \supseteq (x^F \mid \mu(x^F) \geq a) = (x^F \mid F(v_\mu) \geq a) = I_{\mathrm{val}(v_\mu),a}$. □

Lemma 5.29. *Let $\Gamma \subset \Gamma_\sigma$ be a finite group acting on $\widetilde{X}_\sigma$. Let $\pi : N^{\mathbb{Q}} \to (N^\Gamma)^{\mathbb{Q}}$ denote the projection corresponding to the geometric quotient $\widetilde{X}_\sigma \to \widetilde{X}_{\pi(\sigma)} = \widetilde{X}_\sigma/\Gamma$. Then* $\mathrm{val}(v)$ *is G_σ-invariant on $\widetilde{X}_\sigma$ iff* $\mathrm{val}(\pi(v))$ *is G_σ-invariant on $\widetilde{X}_{\pi(\sigma)}$.*

Proof. ($\Rightarrow$) $\mathrm{val}(v)$ is G_σ-invariant on $K[\widetilde{X}_\sigma]$ and it is invariant on $K[\widetilde{X}_\sigma]^\Gamma$.

($\Leftarrow$) Note that π defines an inclusion of same dimension lattices $N \hookrightarrow N^\Gamma$ and $M^\Gamma \hookrightarrow M$.

Assume that $\mathrm{val}(\pi(v))$ is G_σ-invariant. It defines a functional on the lattice M^Γ and its unique extension to $M \supset M^\Gamma$ corresponding to $\mathrm{val}(v)$. Since $g_*(\mathrm{val}(\pi(v))) = \mathrm{val}(\pi(v))$, we have $g_*(\mathrm{val}(v))_{|M^\Gamma} = \mathrm{val}(v)_{|M^\Gamma}$ and consequently $g_*(\mathrm{val}(v))_{|M} = \mathrm{val}(v)_{|M}$. By Lemma 5.28, $g_*(\mathrm{val}(v)) \geq \mathrm{val}(v)$ for all $g \in G_\sigma$. Thus $\mathrm{val}(v) \geq g_*^{-1}(\mathrm{val}(v))$ for all $g^{-1} \in G_\sigma$. Finally $g_*(\mathrm{val}(v)) = \mathrm{val}(v)$. □

5.9. Stability of centers from $\mathrm{par}(\pi(\tau))$. In the following let Δ^σ be a decomposition of $\sigma \in \Sigma$ such that $\widetilde{X}_{\Delta^\sigma} \to \widetilde{X}_\sigma$ is G_σ-equivariant, $\tau \in \Delta^\sigma$ be its face and Γ be a finite subgroup of Γ_σ. Denote by $\pi : (\sigma, N_\sigma) \to (\sigma^\Gamma, N_\sigma^\Gamma)$ the linear isomorphism and the lattice inclusion corresponding to the quotient $X_\sigma \to X_\sigma/\Gamma = X_{\pi(\sigma)}$.

Lemma 5.30. *Assume that for any $g \in G_\sigma$, there exists a cone $\tau_g \in \Delta^\sigma$ such that $g \cdot (\overline{O}_\tau) = \overline{O}_{\tau_g}$. Let $v \in \mathrm{int}(\pi(\tau)) \cap N_\sigma^\Gamma$ be an integral vector such that* val(v) *is not G_σ-invariant on $\widetilde{X}_\sigma/\Gamma$. Then there exist integral vectors $v_1 \in \mathrm{int}(\pi(\tau))$ and $v_2 \in \pi(\tau)$ such that*

$$v = v_1 + v_2.$$

Moreover if there exists $v_0 \in \pi(\sigma)$ (not necessarily integral) such that val(v_0) *is G_σ-invariant and $v > v_0$ on $\pi(\sigma)$ then $v_1 > v_0$ on $\pi(\sigma)$.*

Proof. If val(v) is not G_σ-invariant on $\widetilde{X}_\sigma/\Gamma$ then by Lemma 5.27 there exists an element $g \in G_\sigma$ such that $\mu_g := g_*(\mathrm{val}(v))$ is not a toric valuation. By the assumption μ_g is centered on $\overline{O}_{\pi(\tau_g)}$. Then by Lemma 5.28 it defines $v_g \in \mathrm{int}\,\pi(\tau_g)$ such that $\mu_g(x^F) = F(v_g)$ for $F \in \sigma^\vee$. Moreover $\mu_g > \mathrm{val}(v_g)$. Then the valuation $g_*^{-1}(\mathrm{val}(v_g))$ is centered on $\overline{O}_{\pi(\tau)}$. Thus it defines an integral $v_1 \in \mathrm{int}(\pi(\tau))$ such that $v \geq v_1$ on $\pi(\tau)$ and $v_2 := v - v_1$. Then

$$\mathrm{val}(v) = g_*^{-1}(\mu_g) > g_*^{-1}(\mathrm{val}(v_g)) \geq \mathrm{val}(v_1).$$

Note also that if $v \geq v_0$ then $\mu_g = g_*(\mathrm{val}(v)) \geq \mathrm{val}(v_0)$ and $\mathrm{val}(v_g) \geq \mathrm{val}(v_0)$. Thus also $\mathrm{val}(v_1) \geq \mathrm{val}(v_0)$. □

Lemma 5.31. *All valuations* val(v)*, where $v \in \varrho$, $\varrho \in \mathrm{Vert}(\Delta^\sigma) \setminus \mathrm{Vert}(\sigma)$, are G_σ-invariant.*

Proof. Let v_ϱ be the primitive generator of $\varrho \in \mathrm{Vert}(\Delta^\sigma) \setminus \mathrm{Vert}(\sigma)$. The ray ϱ corresponds to an exceptional divisor D_ϱ. By the definition there is no decomposition $v_\varrho = v_1 + v$. Thus by the previous lemma (for $\Gamma = \{e\}$), val(v) is G_σ-invariant. □

Lemma 5.32. *For any $\tau \leq \sigma$, the closure of the orbit $\overline{O}_\tau \subset \widetilde{X}_\sigma$ is G_σ-invariant.*

Proof. By Lemma 5.2, the ideal of $\overline{O}_\tau \subset \widetilde{X}_\sigma$ is generated by all functions with nontrivial Γ_σ-weights. □

Lemma 5.33. *The valuations* val(v)*, where $v \in \mathrm{par}(\pi(\tau))$, are G_σ-invariant on $\widetilde{X}_{\Delta^\sigma}$. Moreover $v \in \mathrm{int}(\pi(\sigma_0))$, for some $\sigma_0 \leq \sigma$.*

Proof. Let $v \in \mathrm{par}(\pi(\tau))$, where $\pi(\tau) \in \pi(\Delta)$ is a minimal integral vector such that val(v) is not G_σ-invariant. We may assume that $v \in \mathrm{int}(\pi(\tau))$ passing to its face if necessary. Let $\sigma' \in \bar{\sigma}_0$ be a face of σ such that $v \in \mathrm{int}\,\pi(\sigma')$. In particular $\pi(\sigma') \subset \pi(\tau)$. Then $\pi(\Delta^\sigma)_{|\pi(\sigma')} = \pi(\Delta^\sigma)_{|\pi(\sigma_0)} \oplus \langle e_1, \ldots, e_k \rangle$ by Lemmas 5.9 and 5.15 and $v \in \mathrm{par}(\pi(\tau)) \subset \pi(\sigma_0)$. Thus $\sigma' = \sigma_0$ and $v \in \mathrm{int}(\pi(\sigma_0))$. Let

$$\pi(\tau) = \langle v_1, \ldots, v_k, w_1, \ldots, w_\ell \rangle,$$

where $v_1, \ldots, v_k \in \mathrm{Vert}(\pi(\tau))$ and $w_1, \ldots, w_\ell \in \mathrm{Vert}(\pi(\Delta)) \setminus \mathrm{Vert}(\pi(\sigma))$. By Lemma 5.31, $\mathrm{val}(w_1), \ldots, \mathrm{val}(w_\ell)$ are G_σ-invariant. Write

$$v = \alpha_1 v_1 + \cdots + \alpha_k v_k + \alpha_{k+1} w_1 + \cdots + \alpha_{k+\ell} w_\ell,$$

where $0 < \alpha_i < 1$. Note that

$$v \geq v_0 = \alpha_{k+1} w_1 + \cdots + \alpha_{k+\ell} w_\ell$$

and $\overline{O}_{\pi(\sigma_0)} \subset \widetilde{X}_{\pi(\sigma)}$ is G_σ-invariant. By Lemma 5.30 for $v \in \pi(\sigma_0) \leq \pi(\sigma)$ and $v > v_0$ we can find integral vectors $v', v'' \in \pi(\sigma)$ such that $v = v' + v''$, $v' \geq v_0$. Then

$$v'' := v - v' \leq v - v_0 = \alpha_1 v_1 + \cdots + \alpha_k v_k.$$

Thus $v'' \in \mathrm{par}\langle v_1, \ldots, v_k\rangle \subseteq \mathrm{par}(\pi)(\tau)$. Write $v'' := \beta_1 v_1 + \cdots + \beta_k v_k$, where $\beta_i \leq \alpha_i$. Then

$$v' = v - v'' = (\alpha_1 - \beta_1)v_1 + \cdots + (\alpha_k - \beta_k)v_k + \alpha_{k+1} w_1 + \cdots + \alpha_{k+\ell} \in \mathrm{par}(\pi(\tau)).$$

By the minimality assumption, $\mathrm{val}(v')$ and $\mathrm{val}(v'')$ are G_σ-invariant and it follows from Lemma 5.24 that $\mathrm{val}(v) = \mathrm{val}(v' + v'')$ is G_σ-invariant. □

Corollary 5.34. *Let $\Delta = \{\Delta^\sigma \in \Sigma\}$ be a decomposition of Σ. Let $\tau \in \Delta^\sigma$ be an independent face. Then the vectors in $(\pi_{\sigma_{|\tau}})^{-1}(\mathrm{par}(\pi_\sigma(\tau)))$ are stable.*

Proof. Put $\Gamma = \Gamma_\tau$. Let $\pi : (\sigma, N_\sigma) \to (\sigma, N_\sigma^\Gamma)$ be the linear isomorphism and a lattice inclusion corresponding to the quotient $X_\sigma \to X_\sigma / \Gamma$. Then by Lemma 5.8, $\pi(\tau) \simeq \pi_\tau(\tau) \simeq \pi_\sigma(\tau)$ and by Lemma 5.33 vectors in $(\pi_{\sigma_{|\tau}})^{-1}(\mathrm{par}(\pi_\sigma(\tau))) = \pi^{-1}(\mathrm{par}(\pi(\tau)))$ are stable. □

Corollary 5.35. 1. *Assume that for any $g \in G_\sigma$, there exists $\tau_g \in \Delta^\sigma$ such that $g(\overline{O}_\tau) = \overline{O}_{\tau_g}$. Then $\overline{O}_\tau$ is G_σ-invariant. Moreover all valuations* $\mathrm{val}(v)$*, where $v \in \overline{\mathrm{par}}\,(\tau) \cap \mathrm{int}(\tau)$, are G_σ-invariant.*

2. *Let $\tau \in \Delta^\sigma$ be an independent cone such that $\overline{O}_\tau$ is G_σ-invariant. Then for any $v \in \pi_\sigma^{-1}(\overline{\mathrm{par}}\,(\pi(\tau)) \cap \mathrm{int}(\pi(\tau)))$ the valuation* $\mathrm{val}(v)$ *is G_σ-invariant.*

Proof. 1. Let $\tau = \langle v_1, \ldots, v_k\rangle$ and $v = \alpha_1 v_1 + \cdots + \alpha_k v_k$, where $0 < \alpha_i \leq 1$, be a minimal vector in $\mathrm{int}(\tau) \cap \overline{\mathrm{par}}\,(\tau)$ such that $\mathrm{val}(v)$ is not G_σ-invariant. Then by Lemma 5.30, the vector v can be written as $v = v' + v''$, where $v', v'' < v$, $v' \in \mathrm{int}(\tau)$, $v'' \in \tau$. Thus $v' = \alpha_1' v_1 + \cdots + \alpha_k' v_k$ where $0 < \alpha_i' \leq \alpha_i \leq 1$ and $v'' = \alpha_1'' v_1 + \cdots + \alpha_k'' v_k$, where $0 \leq \alpha_i'' = \alpha_i - \alpha_i' < 1$. Then $v' \in \mathrm{int}(\tau) \cap \overline{\mathrm{par}}\,(\tau)$ and $v'' \in \mathrm{par}(\tau)$. By Corollary 5.34, $\mathrm{val}(v'')$ is G_σ-invariant on $\widetilde{X}_\sigma$. By the minimality assumption $\mathrm{val}(v')$ is G_σ-invariant. Since $v = v' + v''$, the valuation $\mathrm{val}(v)$ is G_σ-invariant on $\widetilde{X}_\sigma$ and its center $Z(\mathrm{val}(v))$ equals $\overline{O}_\tau$.

2. Let $\pi : N \to N^\Gamma$ be the projection corresponding to the quotient $X_\sigma \to X_\sigma / \Gamma_\tau$. Then $\pi(\tau) \simeq \pi_\sigma(\tau)$. The proof is now exactly the same as the proof in 1 except that we replace $\widetilde{X}_{\Delta^\sigma}$ with $\widetilde{X}_{\Delta^\sigma}/\Gamma_\tau$. □

Corollary 5.36. *Let $\delta \in \Delta^\sigma$ be a circuit. Then $\overline{O}_\delta$ is G_σ-invariant.*

Proof. By Corollary 4.5, $\overline{O}_\delta$ is an irreducible component of a G_σ-invariant closed subscheme $\widetilde{X}_{\Delta^\sigma}^{K^*}$. Thus by the previous corollary it is G_σ-invariant. □

5.10. Stability of $\mathbf{Ctr_+(\sigma)}$. In the sequel $\delta = \langle v_1, \dots, v_k\rangle \in \Delta^\sigma$ is a circuit. Let $\Gamma \subset \Gamma_\sigma = K^*$ be a finite group. Denote by π (resp. π_Γ) the projection corresponding to the quotient $X_\delta \to X_\delta /\!/ K^*$ (resp. $X_\delta \to X_\delta/\Gamma$). Write $\pi(\delta) = \langle w_1, \dots, w_k\rangle$ and let $\sum_{r_i'>0} r_i' w_i = 0$ be the unique relation between vectors $(**)$ as in Section 4.4. Set $\mathrm{Ctr}_+(\delta) = \sum_{r_i'>0} w_i \in \overline{\mathrm{par}}(\pi(\delta_+)) \cap \mathrm{int}(\pi(\delta_+))$, where $\delta_+ = \langle v_i \mid r_i > 0\rangle$.

Denote by $\widehat{X}_\delta$ the completion of $\widetilde{X}_{\Delta^\sigma}$ at O_δ. By Corollary 5.36, the generic point $O_\delta \in \widetilde{X}_{\Delta^\sigma}$ is G_σ-invariant and thus G_σ acts on $\widehat{X}_\delta$. Moreover $K[\widehat{X}_\delta] = K(O_\delta)[[\delta^\vee]]$ is faithfully flat over a $\mathcal{O}_{\widetilde{X}_{\Delta^\sigma}, O_\delta}$. Also, $\widehat{\mathcal{O}}_{X_{\pi_\Gamma(\Delta)}, \widetilde{O}_{\pi_\Gamma(\delta)}} = K(\widetilde{O}_{\pi_\Gamma(\delta)})[[\underline{\pi_\Gamma(\delta)}^\vee]]$ is faithfully flat over $\mathcal{O}_{X_{\pi_\Gamma(\Delta)}, \widetilde{O}_{\pi_\Gamma(\delta)}}$ and we get

Lemma 5.37. *The valuation* $\mathrm{val}(v)$*, where* $v \in \pi_\Gamma(\delta)$*, is* G_σ*-invariant on* $\widehat{X}_\delta/\Gamma$ *iff it is* G_σ*-invariant on* $\widetilde{X}_{\Delta^\sigma}/\Gamma$.

Lemma 5.38. $\overline{O}_{\delta_-}, \overline{O}_{\delta_+} \subset \widehat{X}_\delta$ *and* $\overline{O}_{\delta_-}, \overline{O}_{\delta_+} \subset \widetilde{X}_{\Delta^\sigma}$ *are* G_σ*-invariant.*

Proof. By Lemmas 4.13 and 2.10, the ideal $I_{\overline{O}_{\delta_+}} \subset K[\widehat{X}_\sigma]$ of $\overline{O}_{\delta_+} = (O_\delta)^+$ is generated by functions with positive weights. □

Proposition 4.12, Lemma 4.13 and the above imply:

Corollary 5.39. *The morphisms* $\widehat{\phi}_-\colon (\widehat{X}_\delta)_-/K^* \to \widehat{X}_\delta /\!/ K^*$ *and* $\widehat{\phi}_+\colon (\widehat{X}_\delta)_+/K^* \to \widehat{X}_\delta /\!/ K^*$ *are* G_σ*-equivariant, proper and birational.*

Lemma 5.40. *The vector* $v := \mathrm{Mid}\,(\mathrm{Ctr}_+(\delta), \delta) = \pi^{-1}_{|\partial_-(\delta)}(\mathrm{Ctr}_+(\delta)) + \pi^{-1}_{|\partial_+(\delta)}(\mathrm{Ctr}_+(\delta))$ *is stable.*

Proof. Set $v_- := \pi^{-1}_{|\partial_-(\delta)}(\mathrm{Ctr}_+(\delta))$ and $v_+ := \pi^{-1}_{|\partial_+(\delta)}(\mathrm{Ctr}_+(\delta))$. By Lemma 5.38, $\overline{O}_{\delta_+} \subset \widetilde{X}_{\Delta^\sigma}$ is G_σ-invariant and, by Corollary 5.35(2) and Lemma 5.37, $\mathrm{val}(v_+)$ is G_σ-invariant on $\widetilde{X}_\sigma$ and on $\widehat{X}_\delta$. Hence the valuation $\mathrm{val}(v_+)$ descends to a G_σ-invariant valuation $\mathrm{val}(\pi(v_+))$ on $\widehat{X}_\delta /\!/ K^* = K(O_\delta)[[\delta^\vee]]^{K^*}$. By Corollary 5.39, $\mathrm{val}(\pi(v_-)) = \mathrm{val}(\pi(v_+))$ is G_σ-invariant on $(\widehat{X}_\delta)_+/K^* = \widehat{X}_{\partial_-(\delta)}/K^* = \widehat{X}_{\pi(\partial_-(\delta))}$. Let $\Gamma \subset K^*$ be the subgroup generated by all subgroups $\Gamma_\tau \subset K^*$, where $\tau \in \partial_-(\delta)$. Then K^*/Γ acts freely on $X_{\partial_-(\delta)}/\Gamma = (X_\delta)_+/\Gamma$. Let $j\colon (X_\delta)_+/\Gamma \to (X_\delta)_+/K^*$ be the natural morphism. Let $\pi_\Gamma\colon \delta \to \pi_\Gamma(\delta)$ be the projection corresponding to the quotient $X_\delta \to X_\delta/\Gamma$. By Lemma 5.7, for any $\tau \in \partial_-(\sigma)$, the restriction of j to $X_\tau/\Gamma \subset (X_\delta)_+/\Gamma$ is given by $j\colon X_\tau/\Gamma = X_{\underline{\tau}}/\Gamma \times O_\tau/\Gamma \to X_\tau/K^* = X_{\underline{\tau}}/\Gamma \times O_\tau/K^*$. Thus $\mathcal{I}_{\mathrm{val}(\pi_\Gamma(v_-)),a} = \hat{j}^*(\mathcal{I}_{\mathrm{val}(\pi(v_-)),a})$, where $\hat{j}\colon (\hat{X}_\delta)_+/\Gamma \to (\hat{X}_\delta)_+/K^*$ is the natural morphism induced by j. Since the morphism $\hat{j}$ is G_σ-equivariant it follows that $\mathrm{val}(\pi_\Gamma(v_-))$ is G_σ-equivariant on $(\widehat{X}_\delta)_+/\Gamma$. Since $(\widehat{X}_\delta)_+ \subset \widehat{X}_\delta$ is an open G_σ-equivariant inclusion and Γ is finite we get that the morphism $(\widehat{X}_\delta)_+/\Gamma \subset (\widehat{X}_\delta)/\Gamma$ is an open G_σ-equivariant inclusion. Thus the valuation $\mathrm{val}(\pi(v_-))$ is G_σ-equivariant on $\widehat{X}_\delta/\Gamma$ and on $\widetilde{X}_{\Delta^\sigma}/\Gamma$ (Lemma 5.37). Finally, by Lemma 5.29, $\mathrm{val}(v_-)$ it is G_σ-equivariant on $\widetilde{X}_{\Delta^\sigma}$. Thus by the convexity $\mathrm{val}(v) = \mathrm{val}(v_+ + v_-)$ is G_σ-equivariant on $\widetilde{X}_{\Delta^\sigma}$. □

5.11. π-desingularization of cobordisms. Let $\delta_1, \dots, \delta_k \in \Sigma$ be the circuits in Σ. Note that common faces of distinct circuits are independent. Also, every independent $\tau \in \Sigma$ is a face of some circuit $\tau < \delta$. Thus π-desingularization of circuits δ_i will determine π-desingularization of all faces in Σ. Apply Morelli π-desingularization to δ_1 to get $\Delta_1^{\sigma_1} := \langle v_{r_1}\rangle \dots \langle v_1\rangle \cdot \delta_1$. This defines a canonical subdivision Δ_1 of Σ, where $\Delta_1 := \langle v_{r_1}\rangle \dots \langle v_1\rangle \cdot \Sigma$. Next apply the π-desingularization to the subdivision $\Delta_1^{\sigma_2}$ of σ_2 to get $\Delta_2^{\sigma_2} := \langle v_{r_2}\rangle \dots \langle v_{r_1+1}\rangle \cdot \Delta_1^{\sigma_2}$ and $\Delta_2 = \langle v_{r_2}\rangle \dots \langle v_{r_1+1}\rangle \cdot \Delta_1$. Continue the process for other circuits to get the π-nonsingular subdivision $\Delta_k = \langle v_{r_k}\rangle \dots \langle v_1\rangle \cdot \Sigma$ of Σ.

5.12. Proof of the Weak Factorization Theorem. The decomposition Δ of Σ is obtained by a sequence of star subdivisions at stable centers (Lemmas 5.40, 5.34). By Propositions 5.23 and 5.18, Δ defines a birational projective modification $f\colon B^\pi \to B$. The modification does not affect points with trivial stabilizers $B_- = X^- \setminus X$ and $Y^+ \setminus Y$ (see Proposition 2.12). This means that $(B^\pi)_- = B_-$ and $(B^\pi)_+ = B_+$ and B^π is a cobordism between X and Y. Moreover B^π admits a projective compactification $\overline{B^\pi} = B^\pi \cup X \cup Y$. The cobordism $B^\pi \subset \overline{B^\pi}$ admits a decomposition into elementary cobordisms B_a^π, defined by the strictly increasing function χ_{B^π}. Let $F \in \mathcal{C}((B_a^\pi)^{K^*})$ be a fixed point component and $x \in F$ be a point. By Proposition 5.18 the modification $f\colon B^\pi \to B$ is locally described for a toric chart $\phi_\sigma\colon U \to X_\sigma$ by a smooth Γ_σ-equivariant morphism $\phi_{\Delta^\sigma}\colon f^{-1}(U) \to X_{\Delta^\sigma}$. Then by Lemma 4.4, $\phi_{\Delta^\sigma}(x)$ is in O_δ, where $\delta \in \Delta^\sigma$ is dependent and π-nonsingular. In particular the cone $\sigma \in \Sigma$ is also dependent and $\Gamma_\sigma = K^*$. So we locally have a smooth K^*-equivariant morphism

$$\phi_\delta\colon V_x \to X_\delta,$$

where $V_x \subset \phi_{\Delta^\sigma}^{-1}(X_\delta)$ is an affine K^*-invariant subset of B_a^π. This gives a diagram

$$\begin{array}{ccccc}
(B_a^\pi)_-/K^* & \supset & V_{x-}/K^* & \to & X_{\delta-}/K^* \\
\uparrow{\scriptstyle \psi_-} & & \uparrow & & \uparrow{\scriptstyle \phi_-} \\
\Gamma((B_a^\pi)_-/K^*, (B_a^\pi)_+/K^*) & \supset & \Gamma(V_{x-}/K^*, V_{x+}/K^*) & \to & \Gamma(X_{\delta-}/K^*, X_{\delta+}/K^*) \\
\downarrow{\scriptstyle \psi_+} & & \downarrow & & \downarrow{\scriptstyle \phi_+} \\
(B_a^\pi)_+/K^* & \supset & V_{x+}/K^* & \to & X_{\delta+}/K^*
\end{array}$$

with horizontal arrows smooth. Here $\Gamma(X_-/K^*, X_+/K^*)$ denotes the normalization of the graph of a birational map $X_-/K^* \dashrightarrow X_+/K^*$ for a relevant cobordism X. We use functoriality of the graph (a dominated component of the fiber product $X_-/K^* \times_{X//K^*} X_+/K^*$). By Corollary 4.16 the morphisms ϕ_- and ϕ_+ are blow-ups at smooth centers. Thus ψ_- and ψ_+ are locally blow-ups at smooth centers so they are globally blow-ups at smooth centers.
