**1.2.2. Projection methods.** Projection methods which are defined as solutions of (1) restricted to finite dimensional subspaces $\mathbb{H}_N$ and $\mathbb{K}_N$ (of dimension $N$) also give rise to attractive approximations of $f$, by properly choosing the subspaces and the tuning parameter $N$ (Dicken and Maass [10], Mathé and Pereverzev [31] together with their non linear counterparts Cavalier and Tsybakov [6], Cavalier et al. [7], Tsybakov [41], Goldenshluger and Pereverzev [19], Efromovich and Koltchinskii [16]). In the case where $\mathbb{H} = \mathbb{K}$ and $K$ is a self-adjoint operator, the system is particularly simple to solve since the restricted operator $K_N$ is symmetric positive definite. This is the so-called Galerkin method. Obviously, restricting to finite subspaces has similar effects and can also be seen as a *Tychonov regularisation*, i.e. minimizing the least square functional penalised by a regularisation term.

The advantage of the Galerkin method is to allow the choice of the basis. However the Galerkin method suffers from the drawback of being unstable in many cases.

Comparing the SVD and Galerkin methods exactly states one main difficulty of the problem. The possible antagonism between the SVD basis where the inversion of the system is easy, and a 'localised' basis where the signal is sparsely represented, will be the issue we are trying to address here.

**1.3. Cut-off, linear methods, thresholding.** *The reader may profitably look at Subsections* 5.3 *and* 5.4*, where the linear methods and thresholding techniques are presented in detail in the direct case.*

SVD as well as Galerkin methods are very sensitive with respect to the choice of the tuning parameter $N(\varepsilon)$. This problem can be solved theoretically. However the solution heavily depends on prior assumptions of regularity on the solution, which have to be known in advance.

In the last ten years, many nonlinear methods have been developed especially in the direct case with the objective of automatically adapting to the unknown smoothness and local singular behavior of the solution. In the direct case, one of the most attractive methods is probably wavelet thresholding, since it allies numerical simplicity to asymptotic optimality on a large variety of functional classes such as Besov or Sobolev classes.

To adapt this approach in inverse problems, Donoho [11] introduced a wavelet-like decomposition, specifically adapted to the operator $K$ (wavelet–vaguelette-decomposition) and provided a thresholding algorithm on this decomposition. In Abramovitch and Silverman [1], this method was compared with the similar vaguelette–wavelet-decomposition. Other wavelet approaches, might be mentioned such as Antoniadis and Bigot [2], Antoniadis et al. [3] and, especially for the deconvolution problem, Penski and Vidakovic [37], Fan and Koo [17], Kalifa and Mallat [24], Neelamani et al. [34].

Later, Cohen et al. [8] introduced an algorithm combining a Galerkin inversion with a thresholding algorithm.

The approach developed in the sequel is greatly influenced by these previous works. The accent we put here is on constructing (when necessary) new generation wavelet-type bases well adapted to the operator $K$, instead of sticking to the standard wavelet bases and reducing the range of potential operators covered by the method.

## 2. Wave-VD-type estimation

We explain here the basic idea of the method, which is very simple. Let us expand $f$ using a well-suited basis ('the wavelet-type' basis', to be defined later):

$$f = \sum (f, \psi_\lambda)_{\mathbb{H}} \psi_\lambda.$$

Using Parseval's identity we have $\beta_\lambda = (f, \psi_\lambda)_{\mathbb{H}} = \sum f_i \psi_\lambda^i$ for $f_i = (f, e_i)_{\mathbb{H}}$ and $\psi_\lambda^i = (\psi_\lambda, e_i)_{\mathbb{H}}$. Let us put $Y_i = (Y_\varepsilon, g_i)_{\mathbb{K}}$. We then have

$$Y_i = (Kf, g_i)_{\mathbb{K}} + \varepsilon\xi_i = (f, K^* g_i)_{\mathbb{K}} + \varepsilon\xi_i = \Big( \sum_j f_j e_j, K^* g_i \Big)_{\mathbb{H}} + \varepsilon\xi_i = b_i f_i + \varepsilon\xi_i,$$

where the $\xi_i$'s are forming a sequence of independent centered gaussian variables with variance 1. Furthermore,

$$\hat{\beta}_\lambda = \sum_i \frac{Y_i}{b_i} \psi_\lambda^i$$

is such that $\mathbb{E}(\hat{\beta}_\lambda) = \beta_\lambda$ (i.e. its average value is $\beta_\lambda$). It is a plausible estimate of $\beta_\lambda$. Let us now put ourselves in a multiresolution setting, taking $\lambda = (j, k)$ for $j \geq 0$, $k$ belonging to a set $\chi_j$, and consider

$$\hat{f} = \sum_{j=-1}^{J} \sum_{k \in \chi_j} t(\hat{\beta}_{jk}) \psi_{jk},$$

where $t$ is a thresholding operator. (*The reader who is unfamiliar with thresholding techniques is referred to Section* 5.4.)

$$t(\hat{\beta}_{jk}) = \hat{\beta}_{jk} I\{|\hat{\beta}_{jk}| \geq \kappa t_\varepsilon \sigma_j\}, \quad t_\varepsilon = \varepsilon \sqrt{\log 1/\varepsilon}, \tag{6}$$

where $I\{A\}$ denotes the indicator function of the set $A^*$. Here $\kappa$ is a tuning parameter of the method which will be properly chosen later. A main difference here with the direct case is the fact that the thresholding is depending on the resolution level through the constant $\sigma_j$ which also will be stated more precisely later. Our main discussion will concern the choice of the basis $(\psi_{jk})$. In particular, we shall see that coherence properties with the SVD basis are of special interest.

We will particularly focus on two situations (corresponding to the two examples discussed in the introduction). In the first type of cases, the operator has as SVD bases the Fourier basis. In this case, this 'coherence' is easily obtained with 'standard' wavelets (still, not any kind of standard wavelet as will be seen). However, more difficult problems (and typically Wicksell's problem) require, when we need to mix these coherence conditions with the desired property of localisation of the basis, the construction of new objects: second generation-type wavelets.

**2.1. WAVE-VD in a wavelet scenario.** In this section we take $\{\psi_{jk},\ j \geq -1,\ k \in \chi_j\}$ to be a standard wavelet basis. More precisely, we suppose as usual that $\psi_{-1}$ stands for the scaling function and, for any $j \geq -1$, $\chi_j$ is a set of order $2^j$ contained in $\mathbb{N}$. Moreover, we assume that the following properties are true. There exist constants $c_p, C_p, d_p$ such that

$$c_p 2^{j(\frac{p}{2}-1)} \leq \|\psi_{jk}\|_p^p \leq C_p 2^{j(\frac{p}{2}-1)}, \tag{7}$$

$$\Big\| \sum_{k \in \chi_j} u_k \psi_{jk} \Big\|_p^p \leq D_p \sum_{k \in \chi_j} |u_k^p| \|\psi_{jk}\|_p^p \quad \text{for any sequence } u_k. \tag{8}$$

It is well known (see for instance Meyer [32]) that wavelet bases provide characterisations of smoothness spaces such as Hölder spaces $\mathrm{Lip}(s)$, Sobolev spaces $W_p^s$ as well as Besov spaces $B_{pq}^s$ for a range of indices $s$ depending on the wavelet $\psi$. For the scale of Besov spaces which includes as particular cases $\mathrm{Lip}(s) = B_{\infty\infty}^s$ (if $s \notin \mathbb{N}$) and $W_p^s = B_{pp}^s$ (if $p = 2$), the characterisation has the following form:

$$\text{If } f = \sum_{j \geq -1} \sum_{k \in \mathbb{Z}} \beta_{jk} \psi_{jk}, \text{ then } \|f\|_{B_{pq}^s} \sim \Big\| \big(2^{j[s+\frac{1}{2}-\frac{1}{p}]} \|\beta_{j\cdot}\|_{l_p}\big)_{j \geq -1} \Big\|_{l_q}. \tag{9}$$

As in Section 5, we consider the loss of a decision $\hat{f}$ if the truth is $f$ as the $\mathbb{L}_p$ norm $\|\hat{f} - f\|_p$, and its associated risk

$$\mathbb{E}\|\hat{f} - f\|_p^p.$$

Here $\mathbb{E}$ denotes the expectation with respect to the random part of the observation $y_\varepsilon$. The following theorem is going to evaluate this risk, when the strategy is the one introduced in the previous section, and when the true function belongs to a Besov ball ($f \in B^s_{\pi,r}(M) \iff \|f\|_{B^s_{pq}} \le M$). One nice property of this estimation procedure is that it does not need the a priori knowledge of this regularity to get a good rate of convergence. If $(e_k)$ is the SVD basis introduced in Section 1.2, $b_k$ are the singular values and $\psi^i_{jk} = \langle e_i, \psi_{jk}\rangle$, we consider the estimator $\hat{f}$ defined in the beginning of Section 2.

**Theorem 2.1.** *Assume that* $1 < p < \infty$, $2\nu + 1 > 0$ *and*

$$\sigma_j^2 := \sum_i \left[\frac{\psi^i_{jk}}{b_i}\right]^2 \le C 2^{2j\nu} \quad \textit{for all } j \ge 0. \tag{10}$$

*Put* $\kappa^2 \ge 16p$, $2^J = [t_\varepsilon]^{\frac{-2}{2\nu+1}}$. *If* $f$ *belongs to* $B^s_{\pi,r}(M)$ *with* $\pi \ge 1$, $s \ge 1/\pi$, $r \ge 1$ (*with the restriction* $r \le \pi$ *if* $s = (2\nu+1)\left(\frac{p}{2\pi} - \frac{1}{2}\right)$), *then we have*

$$\mathbb{E}\|\hat{f} - f\|_p^p \le C \log(1/\varepsilon)^{p-1} [\varepsilon^2 \log(1/\varepsilon)]^{\alpha p}, \tag{11}$$

*with*

$$\alpha = \frac{s}{1 + 2(\nu + s)} \qquad \textit{if } s \ge (2\nu+1)\left(\tfrac{p}{2\pi} - \tfrac{1}{2}\right),$$
$$\alpha = \frac{s - 1/\pi + 1/p}{1 + 2(\nu + s - 1/\pi)} \quad \textit{if } \tfrac{1}{\pi} \le s < (2\nu+1)\left(\tfrac{p}{2\pi} - \tfrac{1}{2}\right).$$

**Remarks.** 1. Condition (10) is essential here. As will be shown later, this condition is linking the wavelet system with the singular value decomposition of the kernel $K$. If we set ourselves in the deconvolution case, the SVD basis is the *Fourier* basis in such a way that $\psi^i_{jk}$ is simply the Fourier coefficient of $\psi_{jk}$. If we choose as wavelet basis the periodized Meyer wavelet basis (see Meyer [32] and Mallat [30]), conditions (7) and (8) are satisfied. In addition, as the Meyer wavelet has the remarkable property of being compactly supported in the Fourier domain, simple calculations prove that, for any $j \ge 0$, $k$, the number of $i$'s such that $\psi^i_{jk} \ne 0$ is finite and equal to $2^j$. Then if we assume to be in the so-called 'regular' case ($b_k \sim k^{-\nu}$, for all $k$), it is easy to establish that (10) is true. This condition is also true for more general cases in the deconvolution setting such as the box-car deconvolution, see [22], [27].

2. These results are minimax (see [43]) up to logarithmic factors. This means that if we consider the best estimator in its worst performance over a given Besov

ball, this estimator attains a rate of convergence which is the one given in (11) up to logarithmic factors.

3. If we compare these results with the rates of convergence obtained in the direct model (see Subsections 5.3 and 5.4), we see that the difference (up to logarithmic terms) essentially lies in the parameter $\nu$ which acts as a reducing factor of the rate of convergence. This parameter quantifies the extra difficulty offered by the inverse problem. It is often called coefficient of illposedness. If we recall that in the deconvolution case, the coefficients $b_k$ are the Fourier coefficients of the function $\gamma$, the illposedness coefficient then clearly appears to be closely related to the regularity of the blurring function.

This result has been proved in the deconvolution case in [22]. The proof of the theorem is given in Appendix I.

**2.2. WAVE-VD in Jacobi scenario: NEED-VD.** We have seen that the results given above are true under the condition (10) on the wavelet basis.

Let us first appreciate how the condition (10) links the 'wavelet-type' basis to the SVD basis $(e_k)$. To see this let us put ourselves in the regular case:

$$b_i \sim i^{-\nu}.$$

(By this we mean more precisely that there exist two positive constants $c$ and $c'$ such that $c' i^{-\nu} \leq b_i \leq c i^{-\nu}$.)

If (10) is true, we have

$$C 2^{2j\nu} \geq \sum_m \sum_{2^m \leq i < 2^{m+1}} \left[ \frac{\psi_{jk}^i}{b_i} \right]^2.$$

Hence, for all $m \geq j$,

$$\sum_{2^m \leq i < 2^{m+1}} [\psi_{jk}^i]^2 \leq c 2^{2\nu(j-m)}.$$

This suggests the necessity to construct a 'wavelet-type' basis having support, at the level $j$, with respect to the SVD basis (sum in $i$) concentrated on the integers between $2^j$ and $2^{j+1}$ and exponentially decreasing after this band. This is exactly the case of Meyer's wavelet, when the SVD basis is the Fourier basis.

In the general case of an arbitrary linear operator giving rise to an arbitrary SVD basis $(e_k)$, and if in addition to (10) we add a localisation condition on the basis, we do not know if such a construction can be performed. However, in some cases, even quite as far from the deconvolution as the Wicksell problem, one can build a 'second generation wavelet-type' basis, with exactly these properties.

The following construction due to Petrushev and collaborators ([33], [39], [38]) exactly realizes the paradigm mentioned above, producing a frame (the needlet basis) in the case of Jacobi polynomials (as well as in different other cases such as spherical harmonics, Hermite functions, Laguerre polynomials) which has the property of being localised.

## 3. Petrushev construction of needlets

Frames were introduced in the 1950s by Duffin and Schaeffer [15] to represent functions via over-complete sets. Frames including tight frames arise naturally in wavelet analysis on $\mathbb{R}^d$. Tight frames which are very close to orthonormal bases are especially useful in signal and image processing.

We will see that the following construction has the advantage of being easily computable and producing well-localised tight frames constructed on a specified orthonormal basis.

We recall the following definition.

**Definition 3.1.** Let $\mathbb{H}$ be a Hilbert space. A sequence $(e_n)$ in $\mathbb{H}$ is said to be a *tight frame* (with constant 1) if

$$\|f\|^2 = \sum_n |\langle f, e_n\rangle|^2 \quad \text{for all } f \in \mathbb{H}.$$

Let now $\mathcal{Y}$ be a metric space, $\mu$ a finite measure. Let us suppose that we have the decomposition

$$\mathbb{L}_2(\mathcal{Y}, \mu) = \bigoplus_{k=0}^{\infty} H_k,$$

where the $H_k$'s are finite dimensional spaces. For the sake of simplicity we suppose that $H_0$ is reduced to the constants.

Let $L_k$ be the orthogonal projection on $H_k$:

$$L_k(f)(x) = \int_{\mathcal{Y}} f(y) L_k(x, y) d\mu(y) \quad \text{for all } f \in \mathbb{L}_2(\mathcal{Y}, \mu),$$

where

$$L_k(x, y) = \sum_{i=1}^{l_k} e_i^k(x) \bar{e}_i^k(y),$$

$l_k$ is the dimension of $H_k$ and $(e_i^k)_{i=1,\dots,l_k}$ is an orthonormal basis of $H_k$. Observe that we have the following property of the projection operators:

$$\int L_k(x, y) L_m(y, z) d\mu(z) = \delta_{k,m} L_k(x, z). \tag{12}$$

The construction, also inspired by the paper of Frazier, Jawerth and Weiss [18], is based on two fundamental steps: Littlewood–Paley decomposition and discretization, which are summarized in the following two subsections.

**3.1. Littlewood–Paley decomposition.** Let $\varphi$ be a $C^\infty$ function supported in $|\xi| \le 1$ such that $1 \ge \varphi(\xi) \ge 0$ and $\varphi(\xi) = 1$ if $|\xi| \le \frac{1}{2}$. We define

$$a^2(\xi) = \varphi(\xi/2) - \varphi(\xi) \ge 0$$

so that

$$\sum_j a^2(\xi/2^j) = 1 \quad \text{for all } |\xi| \ge 1. \tag{13}$$

We further define the operator

$$\Lambda_j = \sum_{k\ge 0} a^2(k/2^j) L_k$$

and the associated kernel

$$\Lambda_j(x, y) = \sum_{k\ge 0} a^2(k/2^j) L_k(x, y) = \sum_{2^{j-1}<k<2^{j+1}} a^2(k/2^j) L_k(x, y).$$

The following assertion is true.

**Proposition 3.2.** *For all* $f \in \mathbb{H}$

$$f = \lim_{J\to\infty} L_0(f) + \sum_{j=0}^{J} \Lambda_j(f) \tag{14}$$

*and*

$$\Lambda_j(x, y) = \int M_j(x, z) M_j(z, y) d\mu(z) \quad \textit{for } M_j(x, y) = \sum_k a(k/2^j) L_k(x, y). \tag{15}$$

*Proof.*

$$L_0(f) + \sum_{j=0}^{J} \Lambda_j(f) = L_0 + \sum_{j=0}^{J} \Big( \sum_k a^2(k/2^j) L_k \Big) = \sum_k \varphi(k/2^{J+1}) L_k \tag{16}$$

Hence

$$\begin{aligned} &\Big\| \sum_k \varphi(k/2^{J+1}) L_k(f) - f \Big\|^2 \\ &\quad = \sum_{l\ge 2^{J+1}} \|L_l(f)\|^2 + \sum_{2^J \le l < 2^{J+1}} \|L_l(f)(1 - \varphi(l/2^{J+1})\|^2 \\ &\quad \le \sum_{l\ge 2^J} \|L_l(f)\|^2 \longrightarrow 0, \quad \text{when } J \to \infty. \end{aligned}$$

(15) is a simple consequence of (12). □

**3.2. Discretization.** Let us define

$$\mathcal{K}_k = \bigoplus_{m=0}^{k} H_m,$$

and let us assume that some additional assumptions are true:

1. $f \in \mathcal{K}_k \Longrightarrow \bar{f} \in \mathcal{K}_k$.
2. $f \in \mathcal{K}_k, g \in \mathcal{K}_l \Longrightarrow fg \in \mathcal{K}_{k+l}$.
3. Quadrature formula: for all $k \in \mathbb{N}$, there exists a finite subset $\chi_k$ of $\mathcal{Y}$ and positive real numbers $\lambda_\xi > 0$ indexed by the elements $\xi$ of $\chi_k$ such that

$$\int f\,d\mu = \sum_{\xi\in\chi_k} \lambda_\xi f(\xi) \quad \text{for all } f \in \mathcal{K}_k.$$

Then the operator $M_j$ defined in the subsection above is such that $M_j(x,z) = \overline{M_j(z,x)}$ and

$$z \mapsto M_j(x,z) \in \mathcal{K}_{2^{j+1}-1}.$$

Hence

$$z \mapsto M_j(x,z)M_j(z,y) \in \mathcal{K}_{2^{j+2}-2},$$

and we can write

$$\Lambda_j(x,y) = \int M_j(x,z)M_j(z,y)\,d\mu(z) = \sum_{\xi\in\chi_{2^{j+2}-2}} \lambda_\xi M_j(x,\xi)M_j(\xi,y).$$

This implies

$$\begin{aligned}\Lambda_j f(x) &= \int \Lambda_j(x,y)f(y)\,d\mu(y) = \int \sum_{\xi\in\chi_{2^{j+2}-2}} \lambda_\xi M_j(x,\xi)M_j(\xi,y)f(y)\,d\mu(y)\\ &= \sum_{\xi\in\chi_{2^{j+2}-2}} \sqrt{\lambda_\xi}M_j(x,\xi)\int \overline{\sqrt{\lambda_\xi}M_j(y,\xi)}f(y)\,d\mu(y).\end{aligned}$$

This can be summarized in the following way if we put $\sqrt{\lambda_\xi}M_j(x,\xi) = \psi_{j,\xi}(x)$ and $\chi_{2^{j+2}-2} = \mathbb{Z}_j$:

$$\Lambda_j f(x) = \sum_{\xi\in\mathbb{Z}_j} \langle f, \psi_{j,\xi}\rangle \psi_{j,\xi}(x).$$

**Proposition 3.3.** *The family $(\psi_{j,\xi})_{j\in\mathbb{N},\xi\in\mathbb{Z}_j}$ is a tight frame.*

*Proof.* As

$$f = \lim_{J\to\infty} (L_0(f) + \sum_{j\le J} \Lambda_j(f)),$$

we have

$$\|f\|^2 = \lim_{J\to\infty} (\langle L_0(f), f\rangle + \sum_{j\le J} \langle \Lambda_j(f), f\rangle),$$

but

$$\langle \Lambda_j(f), f\rangle = \sum_{\xi\in\mathbb{Z}_j} \langle f, \psi_{j,\xi}\rangle\langle \psi_{j,\xi}, f\rangle = \sum_{\xi\in\mathbb{Z}_j} |\langle f, \psi_{j,\xi}\rangle|^2,$$

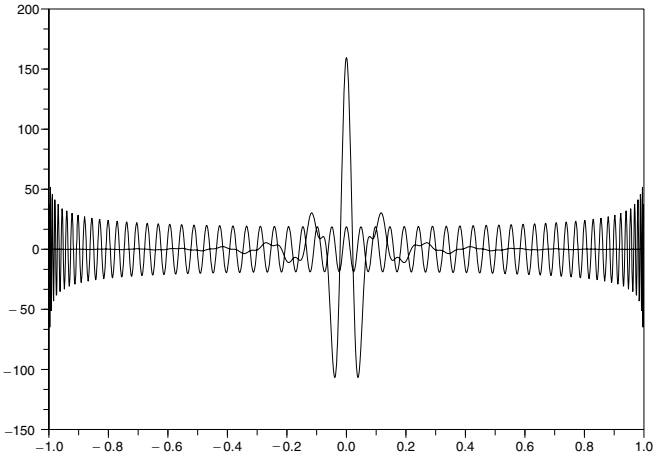
and if $\psi_0$ is a normalized constant we have $\langle L_0(f), f\rangle = |\langle f, \psi_0\rangle|^2$ so that

$$\|f\|^2 = |\langle f, \psi_0\rangle|^2 + \sum_{j\in\mathbb{N},\ \xi\in\mathbb{Z}_j} |\langle f, \psi_{j,\xi}\rangle|^2.$$

But this is exactly the characterization of a tight frame. □

**3.3. Localisation properties.** This construction has been performed in different frameworks by Petrushev and coauthors giving in each situation very nice localisation properties.

The following figure (thanks to Paolo Baldi) is an illustration of this phenomenon: it shows a needlet constructed as explained above using Legendre polynomials of degree $2^8$. The highly oscillating function is a Legendre polynomial of degree $2^8$, whereas the localised one is a needlet centered approximately in the middle of the interval. Its localisation properties are remarkable considering the fact that both functions are polynomials of the same order.



In the case of the sphere of $\mathbb{R}^{d+1}$, where the spaces $H_k$ are spanned by spherical harmonics, the following localisation property is proved in Narcowich, Petrushev and Ward [33]: for any $k$ there exists a constant $C_k$ such that

$$|\psi_{j\eta}(\xi)| \leq \frac{C_k 2^{dj/2}}{[1+2^j \arccos < \eta, \xi >]^k}.$$

A similar result exists in the case of Laguerre polynomials on $\mathbb{R}_+$ [25].

In the case of Jacobi polynomials on the interval with Jacobi weight, the following localisation property is shown by Petrushev and Xu [38]. For any $k$ there exist constants $C$, $c$ such that

$$|\psi_{j\eta}(\cos\theta)| \leq \frac{C 2^{j/2}}{(1+(2^j|\theta - \arccos\eta|)^k \sqrt{w_{\alpha\beta}(2^j, \cos\theta)}},$$

where $w_{\alpha\beta}(n,x) = (1-x+n^{-2})^{\alpha+1/2}(1+x+n^{-2})^{\beta+1/2}$, $-1 \leq x \leq 1$ if $\alpha > -1/2$, $\beta > -1/2$.

## 4. NEED-VD in the Jacobi case

Let us now come back to the estimation algorithm.

We consider the inverse problem (2) with

$$\mathbb{H} = \mathbb{L}_2(I, d\gamma(x)), \quad I = [-1,1], \quad d\gamma(x) = \omega_{\alpha,\beta}(x)dx,$$
$$\omega_{\alpha,\beta}(x) = (1-x)^\alpha (1+x)^\beta; \quad \alpha > -1/2,\ \beta > -1/2.$$

For the sake of simplicity, let us suppose $\alpha \geq \beta$. (Otherwise we can exchange the parameters.)

Let $P_k$ be the normalized Jacobi polynomial for this weight. We suppose that these polynomials appear as SVD basis of the operator $K$, as it is the case for the Wicksell problem with $\beta = 0$, $\alpha = 1$, $b_k \sim k^{-1/2}$.

**4.1. Needlets and condition (10).** Let us define the 'needlets' as constructed above:

$$\psi_{j,\eta_k}(x) = \sum_l \hat{a}(l/2^{j-1}) P_l(x) P_l(\eta_k) \sqrt{b_{j,\eta_k}}. \tag{17}$$

The following proposition asserts that such a construction always implies the condition (10) in the regular case.

**Proposition 4.1.** *Assume that $\psi_{j,\eta_k}$ is a frame. If $b_i \sim i^{-\nu}$ then*

$$\sigma_j^2 := \sum_i \left[\frac{\psi_{jk}^i}{b_i}\right]^2 \leq C 2^{2j\nu}.$$

*Proof.* Suppose the family $\psi_{j,\eta_k}$ is a frame (not necessarily tight). As the elements of a frame are bounded and the set $\{i,\ \psi^i_{jk} \neq 0\}$ is included in the set $\{C_1 2^j, \ldots, C_2 2^j\}$, we have

$$\sum_i \left[\frac{\psi^i_{jk}}{b_i}\right]^2 \leq C 2^{j\nu} \|\psi_{j,\eta_k}\|^2 \leq C' 2^{j\nu}. \qquad \square$$

**4.2. Convergence results in the Jacobi case.** The following theorem is the analogous of Theorem 2.1 in this case. As can be seen, the results there are at the same time more difficult to obtain (the following theorem does not cover the same range as the previous one) and richer since they furnish new rates of convergence.

**Theorem 4.2.** *Suppose that we are in the Jacobi case as stated above* ($\alpha \geq \beta > -\frac{1}{2}$). *We put*

$$t_\varepsilon = \varepsilon\sqrt{\log 1/\varepsilon},$$
$$2^J = t_\varepsilon^{-\frac{2}{1+2\nu}},$$

*choose* $\kappa \geq 16p\big[1 + \big(\frac{\alpha}{2} - \frac{\alpha+1}{p}\big)_+\big]$, *and suppose that we are in the regular case, i.e.*

$$b_i \sim i^{-\nu}, \quad \nu > -\frac{1}{2}.$$

*Then, if* $f = \sum_j \sum_k \beta_{j,\eta_k}\psi_{j,\eta_k}$ *is such that*

$$\Big(\sum |\beta_{j,\eta_k}|^p \|\psi_{j,\eta_k}\|_p^p\Big)^{1/p} \leq \rho_j 2^{-js}, \quad (\rho_j) \in l_r,$$

*it follows that*

$$\mathbb{E}\|\hat{f} - f\|_p^p \leq C[\log(1/\varepsilon)]^{p-1}\big[\varepsilon\sqrt{\log(1/\varepsilon)}\,\big]^{\mu p}$$

*with*

1. *if* $p < 2 + \frac{1}{\alpha+1/2}$, *then*
$$\mu = \frac{s}{s + \nu + \frac{1}{2}};$$

2. *if* $p > 2 + \frac{1}{\alpha+1/2}$, *then*
$$\mu = \frac{s}{s + \nu + \alpha + 1 - \frac{2(1+\alpha)}{p}}.$$

This theorem is proved in Kerkyacharian et al. [26]. Simulation results on these methods are given there, showing that their performances are far above the usual SVD methods in several cases. It is interesting to notice that the rates of convergence which are obtained here agree with the minimax rates evaluated in Johnstone and Silverman [23] where the case $p = 2$ is considered. But the second case ($p > 2 + \frac{1}{\alpha+1/2}$) shows a rate of convergence which is new in the literature. In [26], where the whole range of Besov bodies is considered, more atypical rates are given.

## 5. Direct models ($K = I$): a memento

**5.1. The density model.** The most famous nonparametric model consists in observing $n$ i.i.d. random variables having a common density $f$ on the interval $[0, 1]$, and in trying to give an estimation of $f$.

A standard route to perform this estimation consists in expanding the density $f$ in an orthonormal basis $\{e_k,\ k \in \mathbb{N}\}$ of a Hilbert space $\mathbb{H}$ – assuming implicitly that $f$ belongs to $\mathbb{H}$:

$$f = \sum_{l \in \mathbb{N}} \theta_l e_l.$$

If $\mathbb{H}$ happens to be the space $\mathbb{L}_2 = \{g :\ [0, 1] \mapsto \mathbb{R},\ \|g\|_2^2 := \int_0^1 g^2 < \infty\}$, we observe that

$$\theta_l = \int_0^1 e_l(x) f(x) dx = \mathbb{E} e_l(X_i).$$

Replacing the expectation by the empirical one leads to a standard estimate for $\theta_l$:

$$\hat{\theta}_l = \frac{1}{n} \sum_{i=1}^{n} e_l(X_i).$$

At this step, the simplest choice of estimate for $f$ is obviously:

$$\hat{f}_m = \sum_{i=1}^{m} \hat{\theta}_l e_l. \tag{18}$$

**5.2. From the density to the white noise model.** Before analysing the properties of the estimator defined above, let us observe that the previous approach (representing $f$ by its coefficients $\{\theta_k,\ k \geq 0\}$, leads to summarize the information in the following sequence model:

$$\{\hat{\theta}_k,\ k \geq 0\}. \tag{19}$$

We can write $\hat{\theta}_k =: \theta_k + u_k$, with

$$u_k = \frac{1}{n} \sum_{i=1}^{n} [e_k(X_i) - \theta_k],$$

The central limit theorem is a relatively convincing argument that the model (19) may be approximated by the following one:

$$\left\{\hat{\theta}_k = \theta_k + \frac{\eta_k}{\sqrt{n}},\ k \geq 0\right\}, \tag{20}$$

where the $\eta_k$'s are forming a sequence of i.i.d. gaussian, centered variables with fixed variance $\sigma^2$, say. Such an approximation requires more delicate calculations than these quick arguments and is rigourously proved in Nussbaum [35], see also Brown

and Low [5]. This model is the sequence space model associated to the following global observation, the so-called white noise model (with $\varepsilon = n^{-1/2}$):

$$dY_t = f(t)dt + \varepsilon dW_t, \quad t \in [0, 1],$$

where for any $\varphi \in \mathbb{L}^2([0, 1], dt)$, $\int_{[0,1]} \varphi(t)dY_t = \int_{[0,1]} f(t)\varphi(t)dt + \varepsilon \int_{[0,1]} \varphi(t)dW_t$ is observable.

(20) formally consists in considering all the observables obtained for $\varphi = e_k$ for all $k$ in $\mathbb{N}$. Among nonparametric situations, the white noise model considered above is one of the simplest, at least technically. Mostly for this reason, this model has been given a central place in statistics, particularly by the Russian school, following Ibraguimov and Has'minskii (see for instance their book [20]). However it arises as an appropriate large sample limit to more general nonparametric models, such as regression with random design, or non independent spectrum estimation, diffusion models – see for instance [21], [4],. . . .

**5.3. The linear estimation: how to choose the tuning parameter *m*?** In (18), the choice of $m$ is crucial.

To better understand the situation let us have a look at the risk of the strategy $\hat{f}_m$. If we consider that, when deciding $\hat{f}_m$ when $f$ is the truth, we have a loss of order $\|\hat{f}_m - f\|_2^2$, then our risk will be the following mathematical expectation:

$$\mathbb{E}\|\hat{f}_m - f\|_2^2.$$

Of course this way of measuring our risk is arguable since there is no particular reason for the $\mathbb{L}_2$ norm to reflect well the features we want to recover in the signal. For instance, an $\mathbb{L}_\infty$-norm could be preferred because it is easier to visualize. In general, several $\mathbb{L}_p$ norms are considered (as it is the case in Sections 2.1 and 4.2). Here we restrict to the $\mathbb{L}_2$ case for sake of simplicity.

To avoid technical difficulties, we set ourselves in the case of a white noise model, considering that we observe the sequence defined in (20). Hence,

$$\mathbb{E}(\hat{\theta}_l - \theta_l)^2 = \frac{1}{n}\int_0^1 e_l(x)^2 dx = \frac{1}{n} := \varepsilon^2.$$

We are now able to obtain

$$\mathbb{E}\|\hat{f}_m - f\|_2^2 = \sum_{l \le m}(\hat{\theta}_l - \theta_l)^2 + \sum_{l>m}\theta_l^2 \le m\varepsilon^2 + \sum_{l>m}\theta_l^2.$$

Now assume that $f$ belongs to the following specified compact set of $l_2$:

$$\sum_{l>k}\theta_l^2 \le Mk^{-2s} \quad \text{for all } k \in \mathbb{N}_*, \tag{21}$$

for some $s > 0$ which is here an index of regularity directly connected to the size of the compact set in $l_2$ containing the function $f$. Then we obtain

$$\mathbb{E}\|\hat{f}_m - f\|_2^2 \leq m\varepsilon^2 + Mm^{-2s}.$$

We observe that the RHS is the sum of two factors: one (called the stochastic term) is increasing in $m$ and reflects the fact that because of the noise, the more coefficients we have to estimate, the larger the global error will be. The second one (called the bias term or approximation term) does not depend on the noise and is decreasing in $m$. The RHS is optimised by choosing $m = m_*(s) =: c(s, M)\varepsilon^{\frac{-2}{1+2s}}$. Then

$$\mathbb{E}\|\hat{f}_{m_*(s)} - f\|_2 \leq c'(s, M)\varepsilon^{\frac{-4s}{1+2s}}.$$

Let us observe that the more $f$ is supposed to be regular (in the sense the larger $s$ is), the less coefficients we need to estimate: a very irregular function ($s$ close to 0) requires almost as much as $\varepsilon^{-2} = n$ coefficients, which corresponds to estimate as many coefficients as the number of available observations – in the density model for instance. The rate obtained in (5.3) can be proved to be optimal in the following sense (minimax): if we consider the best estimator in its worst performance over the class of functions verifying (21), this estimator attains a rate of convergence which is (up to a constant) the one given in (5.3). See Tsybakov [40] for a detailed review of the minimax point of view.

**5.4. The thresholding estimation.** Let us now suppose that the constant $s$, which plays an essential role in the construction of the previous estimator is not known. This is realistic, since it is extremely rare to know in advance that the function we are seeking has a specified regularity. Also, the previous approach takes very seriously into account the order in which the basis is taken. Let us now present a very elegant way of addressing at the same time both of these issues. The thresholding techniques which have been known for long by engineers in electronic and telecommunications, was introduced in statistics in Donoho and Johnstone [14] and later in a series of papers on wavelet thresholding [12], [13]. It allies numerical simplicity to asymptotic optimality.

It starts from a different kind of observation. Let us introduce the following estimate:

$$\widetilde{f} = \sum_{k=0}^{B} \hat{\theta}_k \mathbb{I}\{|\hat{\theta}_k| \geq \kappa t_\varepsilon\} e_k. \tag{22}$$

Here the point of view is the following. We choose $B$ very large (i.e. almost corresponding to $s = 0$):

$$B = \varepsilon^{-2}\log 1/\varepsilon.$$

But instead of keeping all the coefficients $\theta_k$ such that $k$ is between 0 and $B$, we decide to kill those which are not above the threshold $t_\varepsilon$. The intuitive justification of

this choice is as follows. Assuming that $f$ has some kind of regularity condition like (21) (unknown, but real...), essentially means that the coefficients $\theta_k$ of $f$ are of small magnitude except perhaps a small number of them. Obviously, in the reconstruction of $f$, only the large coefficients will be significant. $t_\varepsilon$ is chosen in such a way that the noise $\hat{\theta}_k - \theta_k$ due to the randomness of the observation might be neglected:

$$t_\varepsilon = \varepsilon[\log 1/\varepsilon]^{-1/2}.$$

Now let us assume another type of condition on $f$ – easily interpreted by the fact that $f$ is sparsely represented in the basis $(e_k)$ – namely: there exists a positive constant $0 < q < 2$ such that

$$\sup_{\lambda>0} \lambda^q \#\{k,\ |\theta_k| \geq \lambda\} \leq M \quad \text{for all } k \in \mathbb{N}_*, \tag{23}$$

$$\begin{aligned}
\mathbb{E}\|\widetilde{f} - f\|_2^2 &= \sum_{l\leq B}(\hat{\theta}_l \mathbb{I}\{|\hat{\theta}_l| \geq \kappa t_\varepsilon\} - \theta_l)^2 + \sum_{l>B}\theta_l^2 \\
&\leq \sum_l (\hat{\theta}_l - \theta_l)^2 \mathbb{I}\{|\theta_l| \geq \kappa t_\varepsilon/2\} + \sum_l \theta_l^2 \mathbb{I}\{|\theta_l| \leq 2\kappa t_\varepsilon\} \\
&\quad + \sum_{l\leq B}[(\hat{\theta}_l - \theta_l)^2 + \theta_l^2]\mathbb{I}\{|\hat{\theta}_l - \theta_l| \geq \kappa t_\varepsilon/2\} + \sum_{l>B}\theta_l^2.
\end{aligned}$$

Now, using the probabilistic bounds

$$\mathbb{E}(\hat{\theta}_l - \theta_l)^2 = \varepsilon^2, \qquad \mathbb{P}(|\hat{\theta}_l - \theta_l| \geq \lambda) \leq 2\exp -\frac{\lambda^2}{2\varepsilon^2} \quad \text{for all } \lambda > 0,$$

and the fact that condition (23) implies

$$\sum_l \theta_l^2 \mathbb{I}\{|\theta_l| \leq 2\kappa t_\varepsilon\} \leq C t_\varepsilon^{2-q},$$

we get

$$\mathbb{E}\|\widetilde{f} - f\|_2^2 \leq M\varepsilon^2 t_\varepsilon^{-q} + C' t_\varepsilon^{2-q} + \varepsilon^{\kappa^2/8} B + \sum_{l>B}\theta_l^2.$$

It remains now to choose $\kappa^2 \geq 32$ in order to get

$$\mathbb{E}\|\widetilde{f} - f\|_2^2 \leq C' t_\varepsilon^{2-q} + \sum_{l>B}\theta_l^2,$$

and if we assume in addition to (23) that

$$\sum_{l>k}\theta_l^2 \leq M k^{-\frac{2-q}{2}} \quad \text{for all } k \in \mathbb{N}_*, \tag{24}$$

then we get

$$\mathbb{E}\|\widetilde{f} - f\|_2^2 \leq C'' t_\varepsilon^{2-q}$$

Note that the interesting point in this construction is that the regularity conditions imposed on the function $f$ are *not known* by the statistician, since they do not enter into the construction of the procedure. This property is called adaptation.

Now, to compare with the previous section, let us take $q = \frac{2}{1+2s}$. It is not difficult to prove that as soon as $f$ verifies (21), it automatically verifies (23) and (24). Hence $\widetilde{f}$ and $\hat{f}_{m*(s)}$ have the same rate of convergence up to a logarithmic term. If we neglect this logarithmic loss, we substantially gain here the fact that we need not know the apriori regularity conditions on the aim function. It can also be proved that in fact conditions (23) and (24) are defining a set which is substantially larger than the set defined by condition (21): for instance its entropy is strictly larger (see [28]).

## 6. Appendix: Proof of Theorem 2.1

In this proof, $C$ will denote an absolute constant which may change from one line to the other.

We can always suppose $p \geq \pi$. Indeed, if $\pi \geq p$ it is very simple to see that $B^s_{\pi,r}(M)$ is included into $B^s_{p,r}(M)$: as $2^{j[s+\frac{1}{2}-\frac{1}{p}]}\|\beta_{j\cdot}\|_{l_p} \leq 2^{j[s+\frac{1}{2}-\frac{1}{\pi}]}\|\beta_{j\cdot}\|_{l_\pi}$ (since $\chi_j$ is of cardinality $2^j$).

First we have the following decomposition:

$$\mathbb{E}\|\hat{f} - f\|_p^p \leq 2^{p-1}\left\{\mathbb{E}\Big\|\sum_{j=-1}^{J}\sum_{k\in\chi_j}(t(\hat{\beta}_{jk}) - \beta_{jk})\psi_{jk}\Big\|_p^p + \Big\|\sum_{j>J}\sum_{k\in\chi_j}\beta_{jk}\psi_{jk}\Big\|_p^p\right\}$$
$$=: \mathrm{I} + \mathrm{II}.$$

The term II is easy to analyse: since $f$ belongs to $B^s_{\pi,r}(M)$, using standard embedding results (which in this case simply follows from direct comparisons between $l_q$ norms) we have that $f$ also belong to $B^{s-(\frac{1}{\pi}-\frac{1}{p})_+}_{p,r}(M')$, for some constant $M'$. Hence

$$\Big\|\sum_{j>J}\sum_{k\in\chi_j}\beta_{jk}\psi_{jk}\Big\|_p \leq C2^{-J\left[s-(\frac{1}{\pi}-\frac{1}{p})_+\right]}.$$

Then we only need to verify that $\frac{s-(\frac{1}{\pi}-\frac{1}{p})_+}{1+2\nu}$ is always larger that $\alpha$, which is not difficult.

Bounding the term I is more involved. Using the triangular inequality together

with Hölder's inequality and property (8) for the second line, we get

$$\mathrm{I} \le 2^{p-1} J^{p-1} \sum_{j=-1}^{J} \mathbb{E} \Big\| \sum_{k\in\chi_j} (t(\hat\beta_{jk}) - \beta_{jk})\psi_{jk} \Big\|_p^p$$
$$\le 2^{p-1} J^{p-1} D_p \sum_{j=-1}^{J} \sum_{k\in\chi_j} \mathbb{E}|t(\hat\beta_{jk}) - \beta_{jk}|^p \|\psi_{jk}\|_p^p.$$

Now, we separate four cases:

$$\sum_{j=-1}^{J} \sum_{k\in\chi_j} \mathbb{E}|t(\hat\beta_{jk}) - \beta_{jk}|^p \|\psi_{jk}\|_p^p$$
$$= \sum_{j=-1}^{J} \sum_{k\in\chi_j} \mathbb{E}|t(\hat\beta_{jk}) - \beta_{jk}|^p \|\psi_{jk}\|_p^p \big\{ I\{|\hat\beta_{jk}| \ge \kappa t_\varepsilon \sigma_j\} + I\{|\hat\beta_{jk}| < \kappa t_\varepsilon \sigma_j\}\big\}$$
$$\le \sum_{j=-1}^{J} \sum_{k\in\chi_j} \Big[ \mathbb{E}|\hat\beta_{jk} - \beta_{jk}|^p \|\psi_{jk}\|_p^p I\{|\hat\beta_{jk}| \ge \kappa t_\varepsilon \sigma_j\}$$
$$\Big\{ I\Big\{|\beta_{jk}| \ge \frac{\kappa}{2} t_\varepsilon \sigma_j\Big\} + I\Big\{|\beta_{jk}| < \frac{\kappa}{2} t_\varepsilon \sigma_j\Big\}\Big\}$$
$$+ |\beta_{jk}|^p \|\psi_{jk}\|_p^p I\{|\hat\beta_{jk}| \le \kappa t_\varepsilon \sigma_j\}$$
$$\big\{ I\{|\beta_{jk}| \ge 2\kappa t_\varepsilon \sigma_j\} + I\{|\beta_{jk}| < 2\kappa t_\varepsilon \sigma_j\}\big\}\Big]$$
$$\le: Bb + Bs + Sb + Ss.$$

Notice that $\hat\beta_{jk} - \beta_{jk} = \sum_i \frac{Y_i - b_i f_i}{b_i} \psi_{jk}^i = \varepsilon \sum_i \xi_i \frac{\psi_{jk}^i}{b_i}$ is a centered gaussian random variable with variance $\varepsilon^2 \sum_i \big[\frac{\psi_{jk}^i}{b_i}\big]^2$. Also recall that we set $\sigma_j^2 =: \sum_i [\frac{\psi_{jk}^i}{b_i}]^2 \le C 2^{2j\nu}$ and denote by $s_q$ the $q$th absolute moment of the gaussian distribution when centered and with variance 1. Then, using standard properties of the gaussian distribution, for any $q \ge 1$ we have

$$\mathbb{E}|\hat\beta_{jk} - \beta_{jk}|^q \le s_q \sigma_j^q \varepsilon^q, \quad \mathbb{P}\{|\hat\beta_{jk} - \beta_{jk}| \ge \frac{\kappa}{2} t_\varepsilon \sigma_j\} \le 2\varepsilon^{\kappa^2/8}.$$

Hence

$$Bb \le \sum_{j=-1}^{J} \sum_{k\in\chi_j} s_p \sigma_j^p \varepsilon^p \|\psi_{jk}\|_p^p I\{|\beta_{jk}| \ge \frac{\kappa}{2} t_\varepsilon \sigma_j\},$$
$$Ss \le \sum_{j=-1}^{J} \sum_{k\in\chi_j} |\beta_{jk}|^p \|\psi_{jk}\|_p^p I\{|\beta_{jk}| < 2\kappa t_\varepsilon \sigma_j\}$$

and

$$
\begin{aligned}
Bs &\le \sum_{j=-1}^{J}\sum_{k\in\chi_j}[\mathbb{E}|\hat\beta_{jk}-\beta_{jk}|^{2p}]^{1/2}\Big[\mathbb{P}\Big\{|\hat\beta_{jk}-\beta_{jk}|\ge\frac{\kappa}{2}t_\varepsilon\sigma_j\Big\}\Big]^{1/2}\\
&\qquad\qquad \|\psi_{jk}\|_p^p I\Big\{|\beta_{jk}|<\frac{\kappa}{2}t_\varepsilon\sigma_j\Big\}\\
&\le \sum_{j=-1}^{J}\sum_{k\in\chi_j} s_{2p}^{1/2}\sigma_j^p\varepsilon^p 2^{1/2}\varepsilon^{\kappa^2/16}\|\psi_{jk}\|_p^p I\Big\{|\beta_{jk}|<\frac{\kappa}{2}t_\varepsilon\sigma_j\Big\}\\
&\le C\sum_{j=-1}^{J}2^{jp(\nu+\frac12)}\varepsilon^p\varepsilon^{\kappa^2/16}\le C\varepsilon^{\kappa^2/16}.
\end{aligned}
$$

Now, if we remark that the $\beta_{jk}$'s are necessarily all bounded by some constant (depending on $M$) since $f$ belongs to $B^s_{\pi,r}(M)$, and using (7),

$$
\begin{aligned}
Sb &\le \sum_{j=-1}^{J}\sum_{k\in\chi_j}|\beta_{jk}|^p\|\psi_{jk}\|_p^p\mathbb{P}\{|\hat\beta_{jk}-\beta_{jk}|\ge 2\kappa t_\varepsilon\sigma_j\}I\{|\beta_{jk}|\ge 2\kappa t_\varepsilon\sigma_j\}\\
&\le \sum_{j=-1}^{J}\sum_{k\in\chi_j}|\beta_{jk}|^p\|\psi_{jk}\|_p^p 2\varepsilon^{\kappa^2/8}I\{|\beta_{jk}|\ge 2\kappa t_\varepsilon\sigma_j\}\\
&\le C\sum_{j=-1}^{J}2^{j\frac{p}{2}}\varepsilon^{\kappa^2/8}\le C\varepsilon^{\frac{\kappa^2}{8}-\frac{p}{2(2\nu+1)}}.
\end{aligned}
$$

It is easy to check that in all cases, if $\kappa^2\ge 16p$ the terms $Bs$ and $Sb$ are smaller than the rates given in the theorem.

Using (7) and condition (10), for any $z\ge 0$ we have

$$
\begin{aligned}
Bb &\le C\varepsilon^p\sum_{j=-1}^{J}2^{j(\nu p+\frac{p}{2}-1)}\sum_{k\in\chi_j}I\Big\{|\beta_{jk}|\ge\frac{\kappa}{2}t_\varepsilon\sigma_j\Big\}\\
&\le C\varepsilon^p\sum_{j=-1}^{J}2^{j(\nu p+\frac{p}{2}-1)}\sum_{k\in\chi_j}|\beta_{jk}|^z[t_\varepsilon\sigma_j]^{-z}\\
&\le Ct_\varepsilon{}^{p-z}\sum_{j=-1}^{J}2^{j[\nu(p-z)+\frac{p}{2}-1]}\sum_{k\in\chi_j}|\beta_{jk}|^z.
\end{aligned}
$$

Also, for any $p \geq z \geq 0$,

$$Ss \leq C \sum_{j=-1}^{J} 2^{j(\frac{p}{2}-1)} \sum_{k\in\chi_j} |\beta_{jk}|^z \sigma_j^{p-z} [t_\varepsilon]^{p-z}$$
$$\leq C[t_\varepsilon]^{p-z} \sum_{j=-1}^{J} 2^{j(\nu(p-z)+\frac{p}{2}-1)} \sum_{k\in\chi_j} |\beta_{jk}|^z.$$

So in both cases we have the same bound to investigate. We will write this bound in the following form (forgetting the constant):

$$\mathrm{I} + \mathrm{II} = {t_\varepsilon}^{p-z_1} \Big[ \sum_{j=-1}^{j_0} 2^{j[\nu(p-z_1)+\frac{p}{2}-1]} \sum_{k\in\chi_j} |\beta_{jk}|^{z_1} \Big]$$
$$+ {t_\varepsilon}^{p-z_2} \Big[ \sum_{j=j_0+1}^{J} 2^{j[\nu(p-z_2)+\frac{p}{2}-1]} \sum_{k\in\chi_j} |\beta_{jk}|^{z_2} \Big].$$

The constants $z_i$ and $j_0$ will be chosen depending on the cases.

Let us first consider the case where $s \geq \big(\nu + \frac{1}{2}\big)\big(\frac{p}{\pi} - 1\big)$. Put

$$q = \frac{p(2\nu+1)}{2(s+\nu)+1}$$

and observe that, on the considered domain, $q \leq \pi$ and $p > q$. In the sequel it will be used that we automatically have $s = \big(\nu + \frac{1}{2}\big)\big(\frac{p}{q} - 1\big)$. Taking $z_2 = \pi$ we get

$$\mathrm{II} \leq {t_\varepsilon}^{p-\pi} \Big[ \sum_{j=j_0+1}^{J} 2^{j[\nu(p-\pi)+\frac{p}{2}-1]} \sum_{k\in\chi_j} |\beta_{jk}|^{\pi} \Big].$$

Now, as

$$\frac{p}{2q} - \frac{1}{\pi} + \nu\left(\frac{p}{q} - 1\right) = s + \frac{1}{2} - \frac{1}{\pi}$$

and

$$\sum_{k\in\chi_j} |\beta_{jk}|^{\pi} = 2^{-j(s+\frac{1}{2}-\frac{1}{\pi})} \tau_j$$

with $(\tau_j)_j \in l_r$ (this is a consequence of the fact that $f \in B^s_{\pi,r}(M)$ and (6)), we can write

$$\mathrm{II} \leq {t_\varepsilon}^{p-\pi} \sum_{j=j_0+1} 2^{jp(1-\frac{\pi}{q})(\nu+\frac{1}{2})} \tau_j^{\pi}$$
$$\leq C {t_\varepsilon}^{p-\pi} 2^{j_0 p(1-\frac{\pi}{q})(\nu+\frac{1}{2})}.$$

The last inequality is true for any $r \geq 1$ if $\pi > q$ and for $r \leq \pi$ if $\pi = q$. Notice that $\pi = q$ is equivalent to $s = (\nu + \frac{1}{2})(\frac{p}{\pi} - 1)$. Now if we choose $j_0$ such that $2^{j_0 \frac{p}{q}(\nu+\frac{1}{2})} \sim {t_\varepsilon}^{-1}$ we get the bound

$$ {t_\varepsilon}^{p-q} $$

which exactly gives the rate asserted in the theorem for this case.

As for the first part of the sum (before $j_0$), we have, taking now $z_1 = \widetilde{q}$, with $\widetilde{q} \leq \pi$, so that $\big[\frac{1}{2^j}\sum_{k\in\chi_j} |\beta_{jk}|^{\widetilde{q}}\big]^{\frac{1}{\widetilde{q}}} \leq \big[\frac{1}{2^j}\sum_{k\in\chi_j} |\beta_{jk}|^{\pi}\big]^{\frac{1}{\pi}}$, and using again (6),

$$\begin{aligned}
\mathrm{I} &\leq {t_\varepsilon}^{p-\widetilde{q}}\Big[\sum_{-1}^{j_0} 2^{j[\nu(p-\widetilde{q})+\frac{p}{2}-1]} \sum_{k\in\chi_j} |\beta_{jk}|^{\widetilde{q}}\Big] \\
&\leq {t_\varepsilon}^{p-\widetilde{q}}\Big[\sum_{-1}^{j_0} 2^{j[\nu(p-\widetilde{q})+\frac{p}{2}-\frac{\widetilde{q}}{\pi}]} \sum_{k\in\chi_j} |\beta_{jk}|^{\pi}]^{\frac{\widetilde{q}}{\pi}}\Big] \\
&\leq {t_\varepsilon}^{p-\widetilde{q}} \sum_{-1}^{j_0} 2^{j[(\nu+\frac{1}{2})p(1-\frac{\widetilde{q}}{q})]} \tau_j^{\widetilde{q}} \\
&\leq C {t_\varepsilon}^{p-\widetilde{q}} 2^{j_0[(\nu+\frac{1}{2})p(1-\frac{\widetilde{q}}{q})]} \\
&\leq C {t_\varepsilon}^{p-q}.
\end{aligned}$$

The last two lines are valid if $\widetilde{q}$ is chosen strictly smaller than $q$ (this is possible since $\pi \geq q$).

Let us now consider the case where $s < \big(\nu + \frac{1}{2}\big)\big(\frac{p}{q} - 1\big)$, and choose

$$ q = \frac{p}{2\big(s + \nu - \frac{1}{\pi}\big) + 1} $$

in such a way that we easily verify that $p - q = 2\frac{s-1/\pi+1/p}{1+2(\nu+s-1/\pi)}$, $q - \pi = \frac{(p-\pi)(1+2\nu)}{2\big(s+\nu-\frac{1}{\pi}\big)+1} > 0$, because $s$ is supposed to be larger than $\frac{1}{\pi}$. Furthermore we also have $s + \frac{1}{2} - \frac{1}{\pi} = \frac{p}{2q} - \frac{1}{q} + \nu\big(\frac{p}{q} - 1\big)$.

Hence taking $z_1 = \pi$ and using again the fact that $f$ belongs to $B^s_{\pi,r}(M)$,

$$\begin{aligned}
\mathrm{I} &\leq {t_\varepsilon}^{p-\pi}\Big[\sum_{-1}^{j_0} 2^{j[\nu(p-\pi)+\frac{p}{2}-1]} \sum_{k\in\chi_j} |\beta_{jk}|^{\pi}\Big] \\
&\leq {t_\varepsilon}^{p-\pi} \sum_{-1}^{j_0} 2^{j[(\nu+\frac{1}{2}-\frac{1}{p})\frac{p}{q}(q-\pi)]} \tau_j^{\pi} \\
&\leq C {t_\varepsilon}^{p-\pi} 2^{j_0[(\nu+\frac{1}{2}-\frac{1}{p})\frac{p}{q}(q-\pi)]}.
\end{aligned}$$

This is true since $\nu + \frac{1}{2} - \frac{1}{p}$ is also strictly positive because of our constraints. If we now take $2^{j_0 \frac{p}{q}(\nu+\frac{1}{2}-\frac{1}{p})} \sim {t_\varepsilon}^{-1}$ we get the bound

$$ {t_\varepsilon}^{p-q} $$

which is the rate stated in the theorem for this case.

Again, for II, we have, taking now $z_2 = \widetilde{q} > q \ (> \pi)$,

$$\begin{aligned}
\mathrm{II} &\le {t_\varepsilon}^{p-\widetilde{q}} \Big[ \sum_{j=j_0+1}^{J} 2^{j[\nu(p-\widetilde{q})+\frac{p}{2}-1]} \sum_{k\in\chi_j} |\beta_{jk}|^{\widetilde{q}} \Big] \\
&\le C {t_\varepsilon}^{p-\widetilde{q}} \sum_{j=j_0+1} 2^{j[(\nu+\frac{1}{2}-\frac{1}{p})\frac{p}{q}(q-\widetilde{q})]} z_j^{\frac{\widetilde{q}}{\pi}} \\
&\le C {t_\varepsilon}^{p-\widetilde{q}} 2^{j_0[(\nu+\frac{1}{2}-\frac{1}{p})\frac{p}{q}(q-\widetilde{q})]} \\
&\le C {t_\varepsilon}^{p-q}.
\end{aligned}$$

# Conformal restriction properties

Wendelin Werner*

**Abstract.** We give an introduction to some aspects of recent results concerning conformally invariant measures. We focus in this note on the conformal restriction properties of some measures on curves and loops in the plane, and see that these properties in fact almost characterize the measures and allow to classify them. For example, there basically exists a unique measure $\mu$ on the set of self-avoiding loops in the plane, such that for any two conformally equivalent domains $D$ and $D'$, the restrictions of $\mu$ to the set of loops remaining in $D$ and in $D'$ are conformally equivalent.

This enables to show that a priori different discrete models define the same curves in the scaling limit and exhibit some surprising symmetries. It gives also a way to tie links between these concrete measures on curves and conformal field theory. Important roles in this theory are played by Brownian loops and by the Schramm–Loewner Evolutions (SLE).

Most of the results described in this paper were derived in joint work with Greg Lawler, and Oded Schramm.

**Keywords.** Conformal invariance, random curves, random loops, Brownian motion, percolation.

## 1. A very brief introduction

The last years have seen progress in the mathematical understanding of random two-dimensional structures arising as scaling limits of two-dimensional systems from statistical physics. These probabilistic questions are related to complex analysis considerations (because conformal invariance plays an important role in the description of these objects) and to conformal field theory (that had been developed by theoretical physicists precisely to understand these questions).

Mathematically speaking, one can broadly distinguish two types of questions: Firstly, proving the convergence of the natural discrete lattice-based models from statistical physics to conformally invariant scaling limits. This aspect based on specific lattice models will be discussed in Schramm's and Smirnov's papers in the present proceedings, and will not be the main focus of the present paper. The second type of questions is to define directly the possible continuous limiting objects and to study their

*The author acknowledges the support of the Institut Universitaire de France.

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

properties. Two ideas have emerged and can be fruitfully combined to study these continuous objects: The Schramm–Loewner Evolutions (SLE) are random planar curves that are explicitly defined via iterations of random conformal maps, and they appear to be the only ones that combine conformal invariance with a certain Markov property. This shows that they are the only possible conformally invariant scaling limits of interfaces of the critical lattice models. Another instrumental idea is to study how close or how different the random objects defined in different but close domains are, and to see what the conformally invariant possibilities are. This very last approach will be the main focus of the present survey. We warn the reader that we will here remain on a rather general introductory level.

## 2. Conformal invariance of planar Brownian paths

In this section, we first recall Paul Lévy's result on conformal invariance of planar Brownian paths. We then describe some conformally invariant measures on Brownian loops and Brownian excursions.

**2.1. Paul Lévy's theorem.** Consider a simple random walk $(S_n, n \geq 0)$ on the square lattice $\mathbb{Z}^2$ (but in fact any planar lattice with some rotational symmetry would do) started from the origin (i.e. $S_0 = 0$). At each integer time, this random walk moves independently to one of its four neighbors with probability $1/4$. In other words, the probability that the first $n$ steps of $S$ are exactly a given nearest-neighbor path on the lattice is equal to $4^{-n}$. It is a simple consequence of the central limit theorem that when $N \to \infty$, the law of $(S_{[2Nt]}/\sqrt{N}, t \geq 0)$ converges in some suitable topology to that of a continuous random two-dimensional path $(B_t, t \geq 0)$ with Gaussian independent increments called planar Brownian motion.

It should be noted that planar Brownian paths have a rather complicated geometry. Even if their Lebesgue measure in the plane is almost surely equal to zero, the Hausdorff dimension of a Brownian path is equal to 2 (this can be related to the $\sqrt{N}$ normalization of the simple random walk). Also, there almost surely exists exceptional points of any (including infinite) multiplicity on planar Brownian paths (see [24] and the references therein).

Elementary properties of Gaussian random variables show that the law of the process $B$ is invariant under rotations in the plane, and that it is also scale-invariant (this is also quite clear from the normalization of the random walk) in the following sense: For each given $\lambda > 0$, the laws of $(B_{\lambda^2 t}, t \geq 0)$ and of $(\lambda B_t, t \geq 0)$ are identical. In other words, if one looks at the path of a Brownian motion with a magnifying glass, one sees exactly a Brownian motion, but running at a faster "speed". Paul Lévy (see e.g. [25]) has observed more than fifty years ago that planar Brownian paths exhibit conformal invariance properties that generalize scale-invariance and rotation-invariance, and that we are now describing:

Consider two given conformally equivalent planar domains $D$ and $D'$: These are two open subsets of $\mathbb{C}$ such that there exists an angle-preserving (and orientation-preserving) bijection (i.e. a conformal map) $\Phi$ from $D$ onto $D'$. Recall that when $D$ and $D'$ are two simply connected proper open subsets of the plane, then by Riemann's mapping Theorem, there exists a three-dimensional family of such conformal maps from $D$ onto $D'$. Consider a point $z$ in $D$ and define its image $z' = \Phi(z)$. Then, define a planar Brownian motion $(B_t, t \geq 0)$ that is started from $B_0 = z$, and denote by $T$ its exit time from the domain $D$ (i.e. $T = \inf\{t \geq 0 : B_t \notin D\}$). For each $t < T$, one can therefore define $\Phi(B_t)$, and when $t \to T$, $\Phi(B_t)$ hits the boundary of $D' = \Phi(D)$. Then:

**Theorem 2.1** (Paul Lévy). *The path $(\Phi(B_t), t \leq T)$ is a time-changed planar Brownian motion in $D'$, started at $z'$ and stopped at its first exit time of $D'$.*

The time-change means that there exists a (random continuous increasing) time-reparametrization $t = t(s)$ such that $(\Phi(B_{t(s)}), s \geq 0)$ is exactly a Brownian motion in $D'$. In order to state exact conformal invariance properties, we will from now on consider paths defined "modulo increasing time reparametrization".

Lévy's Theorem is nowadays usually viewed as a standard application of stochastic calculus (Itô's formula). It has led to probabilistic approaches to aspects of potential theory and complex analysis.

**2.2. Brownian excursions, Brownian loops.** It might be desirable to define conformally invariant random objects in a domain $D \subset \mathbb{C}$, but where no marked point in $D$ is given. In Lévy's Theorem, the starting point of the Brownian path is such a special prescribed point. There are (at least) two natural ways to get rid of it without loosing conformal invariance, that both give rise to infinite measures (i.e. measures with an infinite total mass) on Brownian curves.

- A first possibility, described in [22], is to consider Brownian paths that start and end at the boundary of $D$: Call an excursion in $D$ a continuous path $(e(t), 0 \leq t \leq T)$ such that $e(0, T) \subset D$ and $e(0) \in \partial D$, $e(T) \in \partial D$. Then, for each $D$, one can define an infinite measure $\mathrm{exc}_D$ on the set of "Brownian" excursions in $D$ (with unprescribed time-length) in such a way that the image under a conformal map $\Phi$ from $D$ onto $D'$ of the measure $\mathrm{exc}_D$ is identical to $\mathrm{exc}_{D'}$ modulo time-change.

  One way to describe the measure in the case where $D$ is equal to the unit disc $\mathbb{U}$ (and therefore in the case of all other simply connected domains $D$ via conformal invariance) is to take the limit when $\varepsilon$ goes to zero of $\varepsilon^{-1}$ times the law of a Brownian motion started uniformly on the circle $(1 - \varepsilon)\partial\mathbb{U}$ and stopped at its first hitting time of the unit circle $\partial\mathbb{U}$. One can also view these measures $\mathrm{exc}_D$ as the scaling limits (when $\delta \to 0$) of the measures on discrete excursions on approximations of $D$ by a subset of $\delta\mathbb{Z}^2$ that assign a mass $4^{-n}$ to each discrete excursion with $n$ steps (see e.g. [12] for precise estimates).

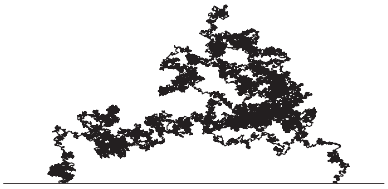

Figure 1. A Brownian excursion in the upper half-plane.

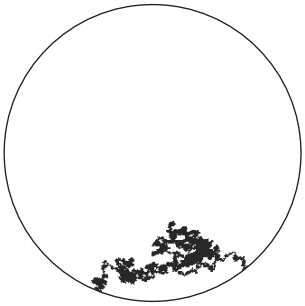

Figure 2. Its conformal image in the unit disc.

- A second possibility, described in [23], that will be important in the present paper, is to consider loops instead of open-ended paths. We say that a continuous planar path $(\ell_t, 0 \leq t \leq T)$ is a rooted loop if $\ell_0 = \ell_T$. The term rooted is used to emphasize that with this definition, there is a marked point on the loop, namely the starting point $\ell_0$. Note that it is possible to re-root a given loop by defining $(\ell'_t = \ell_{t+t_0},\ 0 \leq t \leq T)$ for a given fixed $t_0$ (where $\ell$ is extended into a $T$-periodic function). We may want to say however that $\ell$ and $\ell'$ define in fact the same unrooted loop. Hence, we call an unrooted loop the equivalence class of a rooted loop modulo the equivalence defined by this re-rooting procedure. In order to simplify the conformal invariance statements, we will also say that an unrooted loop is defined modulo increasing continuous time-reparametrizations.

  Then [23], there exists a measure $M$ on the set of unrooted (Brownian) loops in the plane with strong conformal invariance properties: For any two conformally equivalent open domains $D$ and $D' = \Phi(D)$, if $M_D$ (resp. $M'_D$) denotes the measure $M$ restricted to the set of loops that stay in $D$ (resp. $D'$), then the image measure of $M_D$ under the conformal map $\Phi$ from $D$ onto $D'$ is exactly the measure $M_{D'}$.

  One can view this measure $M$ as the limit when $\delta$ goes to zero of the measures on discrete unrooted loops in $\delta\mathbb{Z}^2$ that assign a mass $4^{-n}$ to each loop with $n$

Figure 3. A Brownian loop.

steps (see e.g. [20] for precise estimates). A direct construction of $M$ goes as follows ([23]): It is easy to define the law $P_{z,T}$ of a Brownian loop with a given time-length $T$ that starts and ends at a given point $z$. This can be viewed as the conditioning of a Brownian path $(B_t, t \leq T)$ started from $B_0 = z$ by the event $B_T = z$ (this event has zero probability but it is no big deal to make sense of this). Then, one can define a measure $\tilde{M}$ on rooted Brownian loops by integrating the starting point $z$ with respect to the Lebesgue measure in the plane, and the time-length by the measure $dT/T^2$. Then, $M$ is just the measure on the set of unrooted loops induced by $\tilde{M}$.

Note that $\mathrm{exc}_D$ and $M$ are infinite measures (this follows readily from the scale invariance of $M$ and from the scale-invariance of the excursion measure $\mathrm{exc}_{\mathbb{H}}$ in the upper half-plane), so that we can in both cases choose a normalization constant as we wish (i.e. multiply the measures by a well-chosen constant). In fact, the different descriptions of the measures that we did (and will) give differ by a multiplicative constant, and we will not really care here about the exact choice of the constant in the definition of $M$.

Since these are measures on Brownian paths, they are supported on the set of paths with Hausdorff dimension equal to two, but that the mass of the set of paths that go through any given prescribed point $z$ is equal to zero.

In a way, both these measures are invariant under a larger class of conformal transformations than the killed Brownian motions defined in the previous subsection because no marked starting point is prescribed. Just as killed Brownian motions describe conformally invariant quantities associated to a given marked point such as the harmonic measure, these two measures define also natural conformally invariant quantities that can be related to extremal distances or Schwarzian derivatives for

instance.

Let us finally define a further useful Brownian measure, the Brownian excursion measure with prescribed endpoints: The excursion measure $\mathrm{exc}_{\mathbb{U}}$ can be decomposed according to the starting and endpoints of the Brownian excursions. This gives rise for each $A \neq B$ on $\partial\mathbb{U}$ to a probability measure $e_{\mathbb{U},A,B}$ on the set of Brownian excursions from $A$ to $B$ in $\mathbb{U}$. This defines (not surprisingly) again a conformally invariant family of probability measures $(e_{D,A,B})$ where $(D, A, B)$ spans the set $\mathcal{T}$ the set of triplets $(D, A, B)$ such that $D$ is a simply connected proper subset of $\mathbb{C}$ and $A$ and $B$ denote two distinct prime ends of $D$. When the boundary of $D$ is a smooth self-avoiding loop, this means that $A$ and $B$ are two distinct boundary points. When $\Phi$ is a conformal map from $D$ onto $D'$, then "$\Phi(A)$" and "$\Phi(B)$" are then by definition distinct prime ends of $D' = \Phi(D)$.

## 3. Conformal restriction

We have so far defined some measures on Brownian paths with conformal invariance properties. This means that for each (simply connected) domain, we had a measure $m_D$ on paths in $D$, and that the family $(m_D)$ is conformally invariant (i.e. $\Phi \circ m_D = m_{\Phi(D)}$). But when $D' \subset D$, it is also natural to compare $m_{D'}$ with the measure $m_D$ restricted to those paths that stay in $D'$. The conformal restriction property basically requires that these two measures coincide (and that conformal invariance also holds).

**3.1. Loops.** Suppose that $\nu$ is a measure on loops in the plane. As in the rest of the paper, the loops are unrooted and defined modulo increasing time-reparametrizations. For each open domain $D$, we define $\nu_D$ to be the measure $\nu$ restricted to the set of loops that stay in $D$.

**Definition 3.1.** We say that $\nu$ satisfies conformal restriction (resp. conformal restriction for simply connected domains) if for any open domain (resp. open simply connected domain) $D$ and any conformal map $\Phi\colon D \to \Phi(D)$, one has $\Phi \circ \nu_D = \nu_{\Phi(D)}$.

We have already seen one measure satisfying conformal restriction in the previous section: The measure $M$ on Brownian loops in the plane.

Let us now describe a simple argument that shows that all measures that satisfy conformal restriction are closely related. Before that, let us introduce the notion of the filling of a loop. If $\gamma$ is a loop in the plane, we define its filling $K(\gamma)$ to be the complement of the unbounded connected component of $\mathbb{C} \setminus \gamma$. In other words, $K(\gamma)$ is obtained by filling in all the bounded connected components of the complement of $\gamma$. Clearly, any measure on loops defines a measure on their fillings, and we can also define the conformal restriction property for measures on fillings.

**Proposition 3.2** ([42]). *Up to multiplication by a positive constant, there exists a unique measure on fillings that satisfies conformal restriction for simply connected domains. It can be defined as the measure on filling of Brownian loops.*

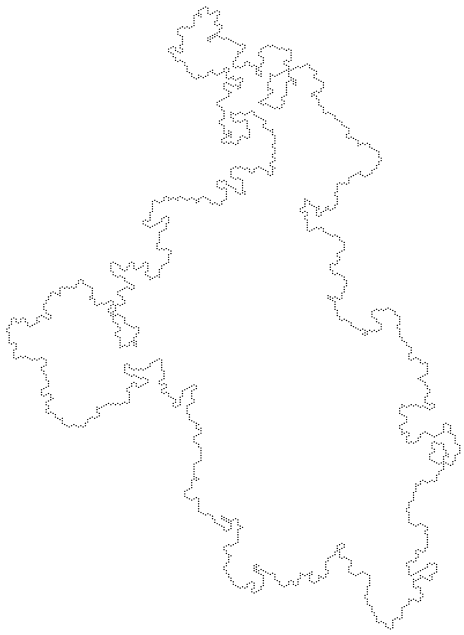

Figure 4. A self-avoiding loop.

*Proof* (*sketch*). In this proof, we will always discuss conformal restriction *for simply connected domains*. The existence part of the proposition follows from the fact that the measure $M$ on Brownian loops exists and satisfies conformal restriction (so that the fillings of Brownian loops satisfy conformal restriction as well). It remains to prove the uniqueness statement.

Consider the family $\mathcal{U}$ of conformal maps $\varphi$ from some (unprescribed) simply connected subset $U$ of the unit disc $\mathbb{U}$ containing the origin onto the unit disc $\mathbb{U}$, such that $\varphi(0) = 0$ and $\varphi'(0)$ is a positive real number. Riemann's mapping theorem shows that for any simply connected domain $U \subset \mathbb{U}$ with $0 \in U$, there exists a unique $\varphi = \varphi_U \in \mathcal{U}$ from $U$ onto $\mathbb{U}$. Note that $\mathcal{U}$ is closed under composition: If $\varphi_U$ and $\varphi_V$ are in $\mathcal{U}$, then so is $\psi = \varphi_U \circ \varphi_V$ (it is a conformal map from $\varphi_V^{-1} \circ \varphi_U^{-1}(\mathbb{U}) = \varphi_V^{-1}(U)$ onto $\mathbb{U}$ with the right properties at the origin). Note that of course, $\log \psi'(0) = \log \varphi_U'(0) + \log \varphi_V'(0)$. It is also straightforward to check that $\varphi_V'(0) \geq 1$ because $V \subset \mathbb{U}$.

Suppose now that a measure $\nu$ on fillings satisfies conformal restriction. Let us define for each $\varphi_U \in \mathcal{U}$,

$$A(\varphi_U) = \nu(\{K : 0 \in K,\ K \subset \mathbb{U},\ K \not\subset U\}).$$

This is the mass of fillings containing the origin, that stay in $\mathbb{U}$ but not in $U$. Then, it is easy to see that

$$A(\varphi_U \circ \varphi_V) = A(\varphi_U) + A(\varphi_V).$$

Indeed, there are two types of fillings that contain the origin, stay in $\mathbb{U}$ but not in $\varphi_V^{-1} \circ \varphi_U^{-1}(\mathbb{U})$:

- Those that do not stay in $V = \varphi_V^{-1}(\mathbb{U})$ and the set of these fillings has a $\nu$-mass equal to $A(\varphi_V)$ by definition.
- Those that stay in $V = \varphi_V^{-1}(\mathbb{U})$ but not in $\varphi_V^{-1}(\varphi_U^{-1})(\mathbb{U}) = \varphi_V^{-1}(U)$. But by conformal invariance (via the mapping $\varphi_V$), this set is conformally equivalent to the set of loops that stay in $\mathbb{U}$ and not in $U$. So, its $\nu$-mass is $A(\varphi_U)$.

Rather soft considerations (for instance involving Loewner's approximation of any mapping in $\mathcal{U}$ by iterations of slit mappings) then imply that the functional $A$ is necessarily of the form $A(\varphi_U) = c \log \varphi_U'(0)$ for a positive constant $c$.

Hence, it follows by conformal invariance that for each $z \in D' \subset D$, the $\nu$-mass of the set of fillings that contain $z$, stay in the simply connected domain $D$ but not in the simply connected domain $D'$ is equal to $c$ times the logarithm of the derivative at $z$ of the conformal map from $D'$ onto $D$ that fixes $z$ and has positive derivative at $z$. Soft arguments (of the type "a finite measure is characterized by its values on a intersection-stable set that generates the $\sigma$-field") then show that (for each choice of $c$) this characterizes the measure $\nu$ uniquely. This implies the uniqueness part of the proposition. □

It is possible to show that the boundary of a Brownian loop is almost surely a self-avoiding loop (the fact that it is a continuous loop is straightforward, but the fact that it has no double point requires some estimates, see e.g. [4]). Hence, the proposition shows that modulo multiplication by a positive constant, there is a unique measure $\mu$ on self-avoiding loops that satisfies conformal restriction for simply connected domains. As we shall see later, it turns out that it satisfies also the general conformal restriction property.

In [15], [16] (see also Schramm's contribution in these proceedings), it is proved that the Hausdorff dimension of the outer boundary of a Brownian path is almost surely $4/3$ (the proof uses SLE considerations and we shall explain why later in this paper). Hence:

**Corollary 3.3.** *For the* (*up-to-constants*) *unique measure on fillings that satisfies conformal restriction, the boundary of the filling is almost surely a self-avoiding loop with dimension* $4/3$.

**3.2. The chordal case.** Suppose that for each $(D, A, B) \in \mathcal{T}$, we have the law $P_{D,A,B}$ of a random excursion from $A$ to $B$ in $D$. We say that the family $(P_{D,A,B})$ is conformally invariant if for any $D, A, B$ and any conformal map from $D$ onto some domain $D' = \Phi(D)$, the image measure of $P_{D,A,B}$ under $\Phi$ is the measure $P_{\Phi(D),\Phi(A),\Phi(B)}$.

This implies in particular that $P_{D,A,B}$ is invariant under any conformal map from $D$ onto itself that preserves the boundary points $A$ and $B$. For instance, for $D = \mathbb{H}$, $A = 0$ and $B = \infty$, this means that $P_{\mathbb{H},0,\infty}$ is scale-invariant (i.e. for each $\lambda > 0$, $\gamma$ and $\lambda\gamma$ have the same law modulo time-reparametrization). We then say that the probability measure $P_{D,A,B}$ is conformally invariant.

Conversely, if one has a probability measure $P$ on excursions from $A_0$ to $B_0$ in $D_0$ for some given triplet $(D_0, A_0, B_0)$ that is conformally invariant, one can simply define for each $D, A, B$ in $\mathcal{T}$ the measure $P_{D,A,B}$ to be the conformal image of $P$ under a conformal map from $(D_0, A_0, B_0)$ onto $(D, A, B)$. The obtained family $(P_{D,A,B})$ is then conformally invariant.

We say that the family $(P_{D,A,B})$ is restriction-invariant if for any $D, A, B$, and any simply connected subset $D'$ of $D$ such that the distance between $\{A, B\}$ and $D \setminus D'$ is positive (this implies in particular that $A$ and $B$ are on $\partial D'$), one has

$$P_{D,A,B}(\cdot \mid \gamma \subset D') = P_{D',A,B}(\cdot).$$

In other words, if $\gamma$ is defined under $P_{D,A,B}$, the conditional law of $\gamma$ given $\gamma \subset D'$ is exactly $P_{D',A,B}$.

**Definition 3.4.** We say that the probability measure $P_{D,A,B}$ for some $(D, A, B) \in \mathcal{T}$ satisfies conformal restriction if:

- It is conformally invariant.
- The conformally invariant family that it defines is restriction-invariant

Note that an excursion $\gamma$ from $A$ to $B$ in $D$ defines also a filling $K(\gamma)$, and that one can generalize the conformal restriction property to fillings also.

For a fixed triplet $D, A, B$, we call $\mathcal{D}_{D,A,B}$ the set of all simply connected domains $D' \subset D$ such that the distance between $D \setminus D'$ and $\{A, B\}$ is strictly positive. For each such $D'$, we define a conformal map from $D'$ back onto $D$ with $\Phi(A) = A$ and $\Phi(B) = B$. In the case where $\partial D$ is smooth in the neighborhood of $A$ and $B$, one can define $\Phi'(A)$ and $\Phi'(B)$ (which are real numbers) and note that the product of these two derivatives does not depend on which $\Phi$ (in the possible one-dimensional family of maps) one did choose. When $\partial D$ is not smooth in the neighborhood of $A$ and $B$, it is still possible to make sense of the quantity "$\Phi'(A)\Phi'(B)$" by conformal invariance (map $D$ onto the unit disc, and look at the corresponding quantity for the image of $A$, $B$ and $D'$). In short, the quantity $\Phi'(A)\Phi'(B)$ is a conformally invariant quantity that measures how smaller $D'$ is compared to $D$, seen from the two points/prime ends $A$ and $B$.

**Theorem 3.5** ([17]). *For each triple $(D, A, B) \in \mathcal{T}$, there exists exactly* (*and in particular: no more than*) *a one-parameter family of measures on fillings that satisfy conformal restriction. It is parametrized by a number $\alpha \in [5/8, \infty)$ and for each $\alpha$, the corresponding measure $P^{\alpha}_{D,A,B}$ is characterized by the property that for each $D' \in \mathcal{D}_{D,A,B}$,*

$$P^{\alpha}_{D,A,B}(K \subset D') = (\Phi'(A)\Phi'(B))^{\alpha}.$$

*Proof* (*sketch*). The uniqueness part is analogous to the loop case: By conformal invariance, we may choose $D$, $A$, $B$ to be $\mathbb{U}, -1, 1$. Then, the set $\mathcal{D} := \mathcal{D}_{\mathbb{U},-1,1}$ is the family of simply connected subsets $U$ of $\mathbb{U}$ such that $\mathbb{U} \setminus U$ is at positive distance from 1 and $-1$. For each such $U$, we define $\psi = \psi_U$ to be the unique conformal map from $U$ onto $\mathbb{U}$ such that $\psi(-1) = -1$, $\psi(1) = 1$ and $\psi'(-1) = 1$. The family of these conformal maps is closed under composition, and for two such maps $\psi_1$ and $\psi_2$, $(\psi_1 \circ \psi_2)'(1) = \psi_1'(1)\psi_2'(1)$.

Suppose that the measure $P$ on fillings of excursions from $-1$ to 1 in $\mathbb{U}$ satisfies conformal restriction. We then define for each such $U \in \mathcal{D}$,

$$A(\psi_U) = P(K \subset U).$$

Conformal restriction implies readily that $A(\psi_U \circ \psi_V) = A(\psi_U) \times A(\psi_V)$ for all $U$ and $V$ in $\mathcal{D}$, and this leads to the fact that there exists a positive constant $\alpha$ such that

$$P(K \subset U) = A(\psi_U) = \psi_U'(1)^{\alpha}.$$

But the probability measure $P$ is fully characterized by the knowledge of all the probabilities $P(K \subset U)$ for $U \in \mathcal{D}$.

It then remains to see that for each $\alpha \geq 5/8$, these identities indeed describe a probability measure on fillings, and that when $\alpha < 5/8$, no such measure exists. The way we prove this in [17] is that we explicitly construct the measure when $\alpha \geq 5/8$ using the Schramm–Loewner Evolution (SLE) process. For $\alpha < 5/8$, we also construct what would be the unique possible candidate (that satisfies a weaker condition – called the one-sided conformal restriction property – than the conformal restriction property that we described) for $P$ (via SLE or Brownian means), and we show that this candidate fails to satisfy the actual conformal restriction property. □

It is easy to check that the Brownian excursions from $A$ to $B$ in $D$ (and their fillings therefore also) defined by $e_{D,A,B}$ do satisfy conformal restriction for $\alpha = 1$, so that for $P^{1}_{D,A,B}$ the boundary of the filling is almost surely supported on sets of Hausdorff dimension $4/3$.

Let us give a partial description of the boundary of these fillings for general $\alpha$ in terms of Brownian excursions. Let us stick to case of the triplet $\mathbb{U}, -1, 1$. Suppose that $K$ is a filling satisfying conformal restriction. Then it turns out that $K \cap \partial\mathbb{U} = \{-1, 1\}$ and that the complement of $K$ in $\mathbb{U}$ consists of two connected components: The upper one $O^+$ such that $\partial O^+$ contains the upper half-circle $\partial_+ := \{e^{i\theta},\ \theta \in (0, \pi)\}$ and the lower one $O^-$, such that $\partial O^-$ contains the lower semi-circle $\partial_-$. The boundary

Figure 5. A Brownian excursion from $-1$ to 1 in the unit disc (sketch).

of $O^+$ (resp. $O^-$) then consists of the upper (resp. lower) semi-circle and a continuous curve $\gamma^+$ (resp. $\gamma^-$) joining $-1$ to $+1$ in $\mathbb{U}$. It is then not difficult to see that the law of $\gamma^+$ is characterized by the fact that for any $U \in \mathcal{D}$, such that $\mathbb{U} \setminus U$ is at positive distance of the lower semi-circle (i.e. $\mathbb{U} \setminus U$ is attached to the upper semi-circle)

$$P^\alpha(\gamma^+ \subset U) = \varphi'_U(1)^\alpha$$

(we will call $\mathcal{D}^+$ this subset of $\mathcal{D}$). One way to construct such a random curve uses a Poissonization argument and the Brownian excursion measure that we described earlier. Since a similar Poissonization argument will be useful in another setup a little bit later, let us briefly describe this classical idea in abstract terms:

Suppose that $N$ is a $\sigma$-finite measure without atoms on some space $\mathcal{X}$. We can define the law of a random countable family $X = \{X_j, j \in J\}$ of elements of $X$ in such a way that:

- For each $A_1, A_2 \subset \mathcal{X}$ in the $\sigma$-field on which $N$ is defined, such that $A_1 \cap A_2 = \emptyset$, the random families $X \cap A_1$ and $X \cap A_2$ are independent.
- For each $A_1$ as above, the probability that $X \cap A_1$ is empty equals $\exp(-N(A_1))$.

The law of $X$ is in fact characterized by these two properties. It is easy to see that for each $A$, the cardinality of $X \cap A$ is a Poisson random variable with mean $N(A)$ (so that it is a.s. infinite if and only if $N(A) = \infty$). $X$ is called a Poisson point process with intensity $N$.

Note that if $X_1$ and $X_2$ are two independent Poisson point processes on the same space $\mathcal{X}$ with respective intensity $N_1$ and $N_2$, then $X_1 \cup X_2$ is a Poisson point process with intensity $N_1 + N_2$.

Using this idea, one can define on the same probability space a collection $(X_c, c \geq 0)$ of Poisson point processes in such a way that $X_c \subset X_{c'}$ for all $c \leq c'$, and such that the intensity of $X_c$ is $cN$. One intuitive way to view this is to say that with time, elements of $\mathcal{X}$ appear independently. During a time-interval $dt$, an element of

a set $A \subset \mathcal{X}$ will appear with probability $dt \times N(A)$. Then, $X_c$ denotes the family of elements that did appear before time $c$.

Let us now use this construction for a measure $N$ on the space of excursions in $\mathbb{U}$. More precisely, we define $\mathcal{X}$ the set of excursions in $\mathbb{U}$ that start and end on the lower semi-circle $\partial_-$, and we define $N$ to be $\mathrm{exc}_{\mathbb{U}}$ restricted to this set of excursions.

Hence, for each $c$, the previous procedure defines a random countable collection of Brownian excursions $E_c = (e_j, j \in J_c)$ starting and ending on the negative half-circle. Despite the fact that this collection is almost surely infinite (because the total mass of $N$ is infinite), the total number of excursions of diameter greater than $\varepsilon$ is almost surely finite for all positive $\varepsilon$ (because the $N$-mass of this set of excursions is finite). In particular, this implies that the "upper boundary" $\gamma^+$ of the union of all excursions in $E_c$ does not intersect the upper semi-circle $\partial_+$. It does not exit a given $U \in \mathcal{D}^+$ if and only if no excursion in $E_c$ does exit $U$, and by definition, this happens with probability $\exp(-cN(\{\gamma : \gamma \not\subset U\}))$.

The conformal restriction property of the excursion measure shows that for each $U \in \mathcal{D}^+$, the image under $\varphi_U$ of the measure $N$ restricted to the set of excursions that stay in $U$ is exactly equal to $N$. It follows readily from this fact that $\exp(-N(\{\gamma : \gamma \not\subset U\})) = \varphi'_U(1)^{\alpha_1}$ for some $\alpha_1$. Hence, for each $\alpha > 0$, if one chooses $c = \alpha/\alpha_1$, the curve $\gamma^+$ does indeed satisfy $P(\gamma^+ \subset U) = \varphi'_U(1)^{c\alpha_1} = \varphi'_U(1)^{\alpha}$.

The fact that $\alpha < 5/8$ is not possible corresponds to the fact that the probability that $\gamma^+$ goes "below" the origin becomes larger than $1/2$, which is not possible for symmetry reasons if it is equal to the upper boundary of a filling satisfying conformal restriction.

For more precise statements and also other possible descriptions of the joint law of $(\gamma^+, \gamma^-)$, see [17], [39], [40].

## 4. Related models

So far, we have defined only measures on Brownian curves, and we have basically shown that any measure satisfying conformal restriction defines the same outer boundary as that of these Brownian measures. The theory becomes interesting when we note that some a priori different measures do also satisfy conformal restriction.

**4.1. Percolation.** We now very briefly describe the percolation model that has been proved by Smirnov [35] to be conformally invariant in the scaling limit. Consider the honeycomb lattice (the regular tiling of the plane by hexagons) with mesh size $\delta$. Each hexagon is colored independently in black or in white with probability $1/2$. Then, we are interested in the connectivity properties of the set of white (resp. black) cells. We call white (resp. black) cluster a connected component of the union of the white (resp. black) cells. This model is sometimes called "critical site-percolation on the triangular lattice".

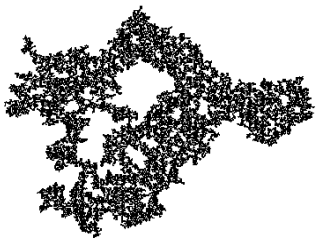

Figure 6. A rescaled large percolation cluster.

By now classical arguments due to Russo, Seymour and Welsh show that the number of clusters that are of diameter $\varepsilon > 0$ in the unit disc remains tight when $\delta \to 0$. This suggests the existence of a scaling limit for the joint law on all clusters when $\delta$ (in an appropriately chosen topology). Smirnov [35] proved the existence of the limit of certain observables (the crossing probabilities) and their conformal invariance.

A consequence of this result is [36] that it is possible to use SLE computations from [14], [15] and earlier results from Kesten [11] to deduce the existence and the value of the critical exponents for critical percolation as predicted by theoretical physicists such as Cardy, Duplantier, Saleur (see e.g. the references in [36]). But, we would here like to focus on the conformal restriction aspect of the scaling limit of percolation and its consequences. We will remain on a heuristic level, but what follows can be made rigorous:

A percolation configuration is described by its white (say) clusters $(C_j,\ j \in J)$. Smirnov's result can be shown to imply (see [5]) the convergence in law of this family when $\delta \to 0$ to the joint law of a collection of "clusters" $(C_j,\ j \in J)$ in the plane. A slightly weaker statement is that the measure on clusters $\pi^\delta$ that assigns to each possible cluster the probability that this cluster indeed occurs converges when $\delta \to 0$ towards a measure on "clusters" $\pi$. The measure $\pi$ satisfies conformal restriction. This is due to the combination of conformal invariance (due to Smirnov's result) and of the independence properties of percolation from which restriction immediately follows in the scaling limit. Hence:

**Proposition 4.1.** *The measure $\pi$ on scaling limits of critical percolation clusters satisfies conformal restriction.*

So, $\pi$ defines exactly the same fillings as (a multiple) of the Brownian loop measure $M$, and it defines a measure on outer boundaries that is exactly a multiple of $\mu$. In other words, the shape of the outer perimeter of a very large percolation cluster has (in the scaling limit) the same law than the outer boundary of a Brownian loop.

**4.2. The self-avoiding walk conjectures.** A classical open problem is to understand the behavior of very long self-avoiding paths, sampled uniformly among all such long self-avoiding paths on some planar lattice with a given starting point and a given length $N$, in the limit when $N \to \infty$.

It is believed that in the scaling limit (for regular periodic lattices with some rotational symmetry) these paths exhibit conformal invariance properties. This led to various striking predictions by theoretical physicists concerning this model and its critical exponents.

For instance, it is believed that the diameter of a typical self-avoiding path with $N$ steps is of the order of $N^{3/4}$. This can be loosely phrased in terms of "fractal dimension" since it means that one requires $N$ steps of size $N^{-3/4}$ to cover a long self-avoiding walk of macroscopic size on the lattice $N^{-3/4}\mathbb{Z}^2$. More precisely, this could mean that in the scaling limit, self-avoiding walks converge in law to some continuous measure on paths supported on the set of paths with dimension equal to $4/3$.

Note that the number of self-avoiding walks of length $N$ on $\mathbb{Z}^2$ that start at the origin can easily (via a sub-multiplicativity argument) be shown to behave like $\lambda^{N+o(N)}$ when $N \to \infty$, where $\lambda$ is a positive real number called the connectivity constant of $\mathbb{Z}^2$. One of the striking conjectures in this field is the more precise prediction $\lambda^N N^{11/32+o(1)}$ by Nienhuis [28].

Here are two possible ways to state this existence of scaling-limit conjecture (in the case of the square lattice):

- Self-avoiding loops: The measure on self-avoiding loops on $\delta\mathbb{Z}^2$ that assigns a mass $\lambda^{-N}$ to each loop with $N$ steps has a (non-trivial) limit when $\delta \to 0$.
- Excursions: The probability measure on self-avoiding excursions from $-1$ to $1$ in an approximation of $\mathbb{U}$ by a sublattice of $\delta\mathbb{Z}^2$ that assigns a probability proportional to $\lambda^{-N}$ to each excursion with $N$ steps converges (when $\delta \to 0$) to a (non-trivial) scaling limit.

In the first case, the scaling limit is then a measure $S$ supported on the set of loops in the plane. In the second one, it is then a probability measure $P^S$ on the set of excursions from $-1$ to $1$ in $\mathbb{U}$.

If one assumes furthermore that these measures exhibit conformal invariance properties, then $S$ should be a measure on self-avoiding loops satisfying conformal restriction: By the previously described results, it is therefore a multiple of the measure $\mu$ on outer boundaries of Brownian loops and of the measure on outer boundaries of percolation clusters. Similarly, we get that $P^S$ should satisfy chordal conformal restriction. Hence, it should be a measure on excursions without double points that coincides with one of the $P^\alpha$'s. This gives an explanation (but not a proof) of the $4/3$-dimension conjecture for self-avoiding walks.

Let us note that in his book [26], Mandelbrot had already proposed the name "self-avoiding Brownian motion" for the outer boundary of a planar Brownian loop.

The above results show that this would be indeed an appropriate name.

## 5. Related SLEs

The (chordal) Schramm–Loewner Evolutions (SLE) first introduced in [31] are conformally invariant random planar excursions in a domain with prescribed endpoints. They are defined via iterations of random conformal maps and they are the only ones satisfying a certain Markov property. Since the discrete analogue of this Markovian property is obviously satisfied by the interfaces of many discrete lattice-models from statistical physics (including for instance percolation), this shows that if these discrete interfaces converge to conformally invariant scaling limits, then they have to be one of the SLE curves. For details on the definition and properties of SLEs, their relations (conjectured and proved) to lattice-models, there are now many surveys, lecture notes, a book (e.g. [13], [37] and the references therein); see also Schramm's contribution to the present ICM proceedings.

There exists a one-parameter family of SLE's: For each $\kappa > 0$, the SLE with parameter $\kappa$ (in short: $\mathrm{SLE}_\kappa$) is a mathematically well-defined random planar excursion joining prescribed boundary points in a simply connected domain [30], [18]. One can then see if these random excursions satisfy conformal restriction (in the chordal case). It turns out that:

**Proposition 5.1** ([17]). *$SLE_{8/3}$ is a random excursion without double points that satisfies chordal restriction. Its law is exactly $P^{5/8}$. No other SLE satisfies chordal conformal restriction.*

In fact, one can prove that it is the only measure supported on excursions without double points that satisfies chordal conformal restriction (i.e. that for all $\alpha > 5/8$, the measure $P^\alpha$ is not supported on self-avoiding curves). Hence, the $\mathrm{SLE}_{8/3}$ is the conjectural scaling limit of self-avoiding excursions, i.e. $P^S = P^{5/8}$. Not surprisingly given all what we have said so far, it can be proved directly that it is supported on the set of excursions with Hausdorff dimension $4/3$ [17], [2]. The computation of the critical exponents for SLE (e.g. [14], [15]) allow also to recover the physicists' predictions on critical exponents such as the $11/32$ mentioned above (see e.g. [19]).

Also, there is a rather direct relation between discrete self-avoiding loops and self-avoiding excursions (the self-avoiding excursion tells how to finish a loop if we know part of it). This suggests a direct relation between the outer boundaries of planar Brownian loops and the $\mathrm{SLE}_{8/3}$ processes. Indeed (see e.g. [23]), it is possible to define a measure on $\mathrm{SLE}_{8/3}$ loops and to see that it is a measure on self-avoiding loops in the plane that satisfies conformal restriction:

**Proposition 5.2.** *The measure $\mu$ can be viewed as a measure on $SLE_{8/3}$ loops.*

In fact, this has a deeper consequence, which is not really surprising if one thinks

of $\mu$ in terms of the conjectural scaling limit $S$ of the measure on discrete self-avoiding loops:

**Theorem 5.3** ([42]). *The measure $\mu$ on self-avoiding loops satisfies conformal restriction also for non-simply connected domains $D$.*

A particular instance of the theorem is that the measure $\mu$ is invariant under the inversion $z \mapsto 1/z$. This implies [42] that the inner boundaries of Brownian loops (and those of the scaling limits of critical percolation clusters) have exactly the same distribution than the outer boundaries. More precisely, if one looks at the boundary of the connected component that contains the origin of the complement of a Brownian loop (defined under $M$) then it is defined under exactly the same measure as the outer boundary. This is by no means an obvious fact.

Another consequence is the following:

**Corollary 5.4** ([42]). *It is possible to extend the definition of the planar measure $\mu$ on self-avoiding loops to any Riemann surface (possibly with boundaries) in such a way that conformal restriction still holds.*

This gives a direct description of various conformally invariant quantities in the framework of Riemann surfaces.

The $SLE_6$ process can be shown (see e.g. [14], [15]) to be the only SLE satisfying a so-called locality property that makes it the only possible candidate for the (conformally invariant) scaling limit of percolation interfaces. In fact, using Smirnov's result [35] and ideas, it is possible to deduce [5] that $SLE_6$ is indeed this scaling limit for critical percolation on the triangular lattice. Hence, it should not be surprising that it is possible to define directly (from the definition of $SLE_6$) conformally invariant measures on loops and excursions that satisfy conformal restriction (see e.g. [17]). This is one of the ways to see that chordal restriction for $\alpha = 2$ is very closely related to the loop measure $\mu$.

## 6. Restriction defect

Most models arising from statistical physics should however not satisfy conformal restriction in the scaling limit. Self-avoiding walks and percolation are in this respect rather exceptional cases. We now describe how one can extend the conformal restriction property to cover the more generic cases. It is useful to start with a specific model to illustrate the basic ideas and to show why the Brownian loop-soup can be useful.

**6.1. Loop-erased random walks.** Suppose that $S = (S_n, n \leq N)$ is a discrete nearest neighbor-walk of length $N$ on a finite connected graph $G$. It is as a path joining the two points $o = S_0$ and $e = S_N$ that can have double points. One can however associate to $S$ a path from $o$ to $e$ without double-points by following $S$ and

erasing the loops as they appear. This gives rise to the loop-erasure $L = L(S)$ of $S$. It is the only simple path from $o = L_0$ to $e = L_p$ (the length $p$ of $L$ is not greater than $N$ but it can be smaller and it depends on the length of the loops erased during this procedure) with the property that for each $i \leq p-1$, $L_{i+1} = S_{n_i+1}$, where $n_i = \sup\{n \leq N : S_n = L_i\}$.

If we are given the two points $o$ and $e$, we can choose $S$ randomly to be a simple random walk on the graph, started at $o$ and stopped at its first hitting of $e$. Its loop-erasure $L = L(S)$ is then the so-called loop-erased random walk from $o$ to $e$. It has many nice combinatorial features, that are not obvious at first sight. For instance, the law of the loop-erased random walk from $o$ to $e$ and of the loop-erased random walk from $e$ to $o$ are the same (modulo time-reversal of course). It can also be interpreted as the law of the unique (simple) path joining $o$ to $e$ in a spanning tree chosen uniformly among all spanning trees of the graph $G$ (i.e. choose uniformly a subgraph of $G$ with just one connected component but no cycle, and look at the unique path joining $o$ to $e$ in this subgraph). This result by Pemantle [29] has been extended by Wilson into a complete construction of a uniformly chosen spanning tree of $G$ using loop-erased random walks [43]. It shows that loop-erased random walks belong to a wider general class of models from statistical physics (the random-cluster models) that includes also the Ising models.

A fine-grid approximation of the Brownian excursion measure $e_{\mathbb{U},-1,1}$ goes as follows: Consider a fine-mesh approximation of the unit disc with two boundary points $o$ and $e$ close to $-1$ and 1, and consider a simple random walk started from $o$, stopped at $e$, and conditioned to exit $\mathbb{U}$ through $e$.

**Theorem 6.1** ([18]). *The loop-erasure of this discrete excursion converges when the mesh-size converges to zero to a conformally invariant scaling limit, the $SLE_2$ from $-1$ to 1 in $\mathbb{U}$. Similarly, for any triplet $(D, A, B) \in \mathcal{T}$, the loop-erasure of a fine-grid approximation of an excursion defined under $e_{D,A,B}$ converges to the $SLE_2$ from $A$ to $B$ in $D$.*

For a given $U \subset \mathbb{U}$ that still has $-1$ and 1 on its boundary, it happens with positive probability that the loop-erasure $L$ of the discrete excursion $S$ stays in $U$, but that the path $S$ does exit $U$ (i.e. one of the erased loops went out of $U$). This feature pertains in the scaling limit and shows that conformal restriction is not satisfied by $SLE_2$. The lack of restriction can be quantified in terms of the erased random walk loops (i.e. in the scaling limit in terms of a quantity involving Brownian loops). More precisely, for a given simple nearest neighbor path from $o \sim -1$ to $e \sim 1$ on the $\delta\mathbb{Z}^2$-approximation of $U \subset \mathbb{U}$, the ratio between the probability that $L = l$ for the LERW from $o$ to $e$ in $U$ and the probability that $L = l$ for the LERW in $\mathbb{U}$ is given by

$$F_\delta(l) = \mathrm{cst}(U)\, P_{\mathbb{U}}(\text{none of the erased loops did exit } U \mid L = l).$$

This function $F_\delta$ converges to a non-trivial function $F$ when $\delta \to 0$ that measures the restriction-defect of $SLE_2$ and that can be expressed in terms of Brownian loops.

**6.2. The Brownian loop soup.** Consider the (properly normalized) Brownian loop-measure $M$. Recall that it is a measure on the set of unrooted Brownian loops in the entire plane. For each $c > 0$, we define a Poisson point process with intensity $cM$. This is a random countable collection $\{b_j, j \in J\}$ of Brownian loops in the plane.

For each domain $D$, we define $J(D) = \{j \in J : b_j \subset D\}$. It is clear from the definition that this corresponds to a Poisson point process with intensity $cM_D$.

In [23], we show that:

**Proposition 6.2** ([23]). *The function $F(l)$ is equal to the probability that no loop in the loop-soup with intensity $2M_{\mathbb{U}}$ intersects both the excursion $l$ and the complement of $U$.*

This indicates that the loops that have been erased correspond to the loops in the loop-soup that the path $l$ intersects. This is not so surprising if one thinks of Wilson's algorithm (that in some sense shows that the law of the constructed uniform spanning tree is independent of the erased loops).

It shows [23] that if one adds to an $\mathrm{SLE}_2$ the loops that it intersects in a Brownian loop-soup, one recovers exactly a path satisfying conformal restriction (in fact with parameter $\alpha = 1$, the one of the Brownian excursion $\mathrm{exc}_{\mathbb{U},-1,1}$).

A similar coupling of the $\mathrm{SLE}_\kappa$'s for $\kappa < 8/3$ with a Brownian loop-soup of parameter $c = c(\kappa) = (8 - 3\kappa)(6 - \kappa)/2\kappa$. By adding the loops of this loop-soup to the SLE curve, one compensates its lack of restriction and constructs a filling that satisfies conformal restriction with parameter $\alpha = (6 - \kappa)/2\kappa$. These relations correspond to the relation between the central charge $(-c)$, the highest weight $(\alpha)$ and the degeneracy factor $(\kappa/4)$ of degenerate highest-weight representations of the Virasoro Algebra, as predicted by conformal field theory (see e.g. [9], [1], [3]).

**6.3. Loop-soup clusters, CLEs.** This does not describe the type of restriction-defects of the SLE's with parameter $\kappa > 8/3$ that should arise as scaling limits of various lattice models, corresponding in the physics language to models with positive central charge. Loosely speaking, these are the curves that are attracted by the boundaries of a domain (as opposed for instance to the $\mathrm{SLE}_2$ that was "repelled" from the boundary). The previous case $\kappa < 8/3$ corresponded to a negative central charge.

For this, it is useful to consider the geometry of the union of all loops in a loop-soup of intensity $c\mu_{\mathbb{U}}$ (recall that the measure $\mu_{\mathbb{U}}$ corresponds to the outer boundaries of the Brownian loops defined by $M_{\mathbb{U}}$). This loop-soup is a countable collection $C_c = \{\ell_j, j \in J_c\}$ of self-avoiding loops in the unit disc that can overlap with each other. Recall that can couple all $C_c$'s in such a way that $c \mapsto C_c$ is increasing.

When $c$ is large and fixed, it is not difficult to see that almost surely every point in $\mathbb{U}$ is surrounded by a loop in $C_c$, so that all the loops hook up into one single connected component i.e. the set $\bigcup_{j \in J_c} \ell_j$ has just one connected component.

On the other hand, when $c$ is small, it is also easy for instance by coupling this problem with the so-called fractal percolation (sometimes also called Mandelbrot percolation) studied in [7], [27] to see that this phenomenon does not pertain: The

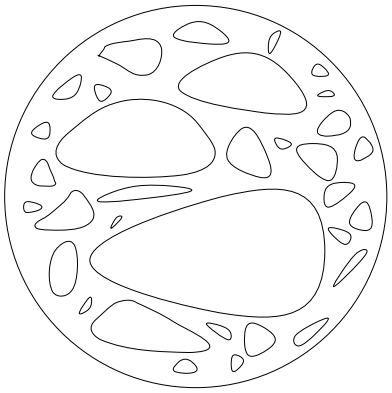

Figure 7. A CLE (very very sketchy).

set $\bigcup_{j\in J_c} \ell_j$ has countably many connected components. The outermost boundaries of these clusters of loops define a family of non-overlapping and non-nested loops $\boldsymbol{u}^c = \{u_i^c,\ i \in I_c\}$ in $\mathbb{U}$.

This leads to the following definition [34]:

**Definition 6.3.** Suppose that $\boldsymbol{u} = \{u_i, i \in I\}$ is a random collection of non-intersecting and non-nested self-avoiding loops in $\mathbb{U}$. We say that it is a simple conformal loop-ensemble (CLE) if the following properties hold:

- It is invariant under the conformal transformation from $\mathbb{U}$ onto itself. This allows to define the law $P_U$ of the collection of loops in any simply connected domain $U$ by taking the conformal image of $\boldsymbol{u}$.
- Let $U$ be any simply connected subset of $\mathbb{U}$ with $d(\mathbb{U} \setminus U, 1) > 0$. Consider $I' = \{i \in I, u_i \not\subset U\}$ and let $\tilde{U}$ denote the connected component of $U \setminus \bigcup_{i\in I'} u_i$ that has 1 on its boundary. Then, conditionally on $\{u_i, i \in I'\}$, the law of $\{u_i, i \in I \text{ and } u_i \subset \tilde{U}\}$ is $P_{\tilde{U}}$.

Loosely speaking, this means that each loop (once it is discovered) plays the role of the boundary of the domain in which the others are yet to be discovered. Note that a CLE almost surely is an infinite collection of loops (because the number of loops contained in $\mathbb{U}$ and in $\tilde{U} \subset \mathbb{U}$ have the same law).

The previous considerations show that the outermost boundaries of cluster of loops for sub-critical (i.e. for small $c$) loop-soups, are conformal loop ensembles (so that CLEs exist). This gives rise to measures on loops that do not satisfy conformal restriction, but have the same type of restriction defect as that of SLEs for $\kappa \in (8/3, 4]$. The intensity $c$ of the loop-soup corresponds to the central charge of the model.

Conformal loop-ensembles (and SLEs) arise also in the context of level-lines (or flow-lines) of the Gaussian Free Field [33] in the ongoing work of Oded Schramm and

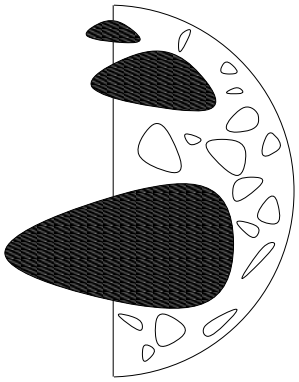

Figure 8. The CLE in $\tilde{U}$ when $U$ is the semi-disc.

Scott Sheffield [32]. Combining all these arguments should [34] describe all CLEs as loop-cluster boundaries and their boundaries as SLE loops for $\kappa \leq 4$.

**Acknowledgments.** I would like to express many thanks to Greg Lawler and Oded Schramm for the opportunity to interact and work with them during these last years. I also thank Pierre Nolin for Figures 4 and 6.

# The complexity of generating functions for integer points in polyhedra and beyond

Alexander Barvinok*

**Abstract.** Motivated by the formula for the sum of the geometric series, we consider various classes of sets $S \subset \mathbb{Z}^d$ of integer points for which an a priori "long" Laurent series or polynomial $\sum_{m \in S} \boldsymbol{x}^m$ can be written as a "short" rational function $f(S; \boldsymbol{x})$. Examples include the sets of integer points in rational polyhedra, integer semigroups, and Hilbert bases of rational cones, among others. We discuss applications to efficient counting and optimization and open questions.

**Mathematics Subject Classification (2000).** Primary 05A15; Secondary 68W30, 11P21, 52C07, 11H06.

**Keywords.** Lattice point, rational polytope, generating function, rational function, Laurent polynomial, integer semigroup, Hilbert basis, efficient counting, computational complexity.

## 1. Introduction

Our inspiration comes from a formula for the sum of a finite geometric series:

$$\sum_{m=0}^{n} x^m = \frac{1 - x^{n+1}}{1 - x}. \tag{1.1}$$

We look at the formula from several points of view.

Geometrically, the left hand side of (1.1) represents the sum over all integer points in a one-dimensional polytope. Namely, with every integer point $m$ we associate a monomial $x^m$ and then consider the sum over all integer points in the interval $[0, n]$.

From the computational complexity point of view, the left hand side of (1.1) is a "long" polynomial whereas the right hand side of (1.1) is a "short" rational function. More precisely, to write an integer $m$ we need about $\log m$ digits or bits. Consequently, to write the left hand side of (1.1), we need about $n \log n$ bits. On the other hand, to write the right hand side of (1.1) we need only about $\log n$ bits. Thus the left hand side is exponentially longer than the right hand side.

Finally, let us read (1.1) from right to left. We can ask how to extract various facts about the set $S$ of integer points in the interval $[0, n]$ from the rational function

*The author is grateful to Microsoft (Redmond) for hospitality during his work on this paper. This work was partially supported by NSF Grant DMS 0400617

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

encoding. For example, to compute the number $|S|$ of points we substitute $x = 1$ into the right hand side of (1.1). Although $x = 1$ is a pole of the rational function, we can compute the desired value by applying l'Hospital's rule.

Let $\mathbb{R}^d$ be Euclidean space with the standard basis $e_1, \ldots, e_d$, so a point $x \in \mathbb{R}^d$ is identified with the $d$-tuple $x = (\xi_1, \ldots, \xi_d)$ of its coordinates, and let $\mathbb{Z}^d \subset \mathbb{R}^d$ be the standard integer lattice, that is the set of points with integer coordinates. With every integer point $m = (\mu_1, \ldots, \mu_d)$ we associate the Laurent monomial

$$\boldsymbol{x}^m = x_1^{\mu_1} \ldots x_d^{\mu_d}$$

in $d$ complex variables $\boldsymbol{x} = (x_1, \ldots, x_d)$. We agree that $x_i^0 = 1$.

Let $S \subset \mathbb{Z}^d$ be a finite set and let us consider the sum

$$f(S; \boldsymbol{x}) = \sum_{m \in S} \boldsymbol{x}^m.$$

Thus $f(S; \boldsymbol{x})$ is a Laurent polynomial that is the generating function of the set $S$. We are interested in the following general questions:

• For which sets $S \subset \mathbb{Z}^d$ a potentially long Laurent polynomial $f(S; \boldsymbol{x})$ can be written as a short rational function?

• What information about the set $S$ can be extracted from $f(S; \boldsymbol{x})$ given as a short rational function?

The paper is organized as follows.

In Section 2, we discuss necessary preliminaries from the theory of computational complexity, define what "long" and "short" means and show that if $S$ is the set of integer points in a rational polyhedron $P \subset \mathbb{R}^d$ then the generating function $f(S; \boldsymbol{x})$ can be computed in polynomial time as a short rational function, provided the dimension $d$ of the ambient space is fixed in advance. We discuss applications to efficient counting and optimization and practical implementations of the algorithms.

In Section 3, we discuss what information can we extract from a set $S \subset \mathbb{Z}^d$ *defined* by its generating function $f(S; \boldsymbol{x})$ written as a rational function. In particular, we show that if $S_1, S_2 \subset \mathbb{Z}^d$ are two finite sets defined by their rational generating functions $f(S_1; \boldsymbol{x})$ and $f(S_2; \boldsymbol{x})$, then the generating function $f(S; \boldsymbol{x})$ of their intersection $S = S_1 \cap S_2$ can be computed in polynomial time as a rational function.

In Section 4, we show that if $S \subset \mathbb{Z}_+$ is an integer semigroup with a fixed number $d$ of generators, then $f(S; x)$ can be computed in polynomial time as a short rational function. This result is obtained as a corollary of a more general result that the *projection* of the set of integer points in a rational polytope admits a polynomial time computable rational generating function. We mention some other examples such as Hilbert bases of rational cones.

In Section 5, we consider the results of Sections 2 and 4 in the general context of Presburger arithmetic. We argue that the "natural" class of sets $S \subset \mathbb{Z}^d$ with short rational generating functions $f(S; \boldsymbol{x})$ would have been the class of sets defined by

formulas of Presburger arithmetic where all combinatorial parameters (the number of variables and Boolean operations) are fixed and only numerical constants are allowed to vary. As the paper is being written, this is still a conjecture.

In Section 6, we try to identify the natural boundaries of the developed theory. We also discuss the emerging picture of what happens if the dimension $d$ of the ambient space is allowed to grow.

## 2. Rational polyhedra

Formula (1.1) admits an extension to general rational polyhedra.

**Definition 2.1.** The set $P \subset \mathbb{R}^d$ of solutions to a system of finitely many linear inequalities is called a *polyhedron*:

$$P = \left\{(\xi_1, \ldots, \xi_d) : \sum_{j=1}^{d} \alpha_{ij}\xi_j \le \beta_i,\ i = 1, \ldots, n\right\}. \tag{2.1}$$

Here $\alpha_{ij}$ and $\beta_i$ are real numbers. A bounded polyhedron is called a *polytope*. A polyhedron $P$ is called *rational* if in (2.1) one can choose all $\alpha_{ij}$ and $\beta_i$ integer.

To state an analogue of formula (1.1) we need to discuss the notion of the input size. As we remarked earlier, to write an integer $a$ we need roughly $\lceil \log_2(|a|+1)\rceil + 1$ bits. Consequently, to define a rational polyhedron $P \subset \mathbb{R}^d$ by the inequalities (2.1) we need about

$$\mathcal{L} = n(d+1) + \sum_{i,j} \lceil \log_2(|\alpha_{ij}| + 1)\rceil + \sum_{i} \lceil \log_2(|\beta_i| + 1)\rceil \tag{2.2}$$

bits. The number $\mathcal{L}$ is called the *input size* of representation (2.1) of $P$.

We are interested in the computational complexity of formulas and algorithms. In particular, we are interested in *polynomial time* algorithms, that is, in the algorithms whose running time is at most $\mathcal{L}^{O(1)}$, where $\mathcal{L}$ is the input size. In what follows, often the dimension $d$ of the ambient space will be fixed in advance and the algorithms will run in polynomial time *for any fixed dimension* $d$. In other words, the running time of such an algorithm is at most $\mathcal{L}^{\phi(d)}$ for some function $\phi$. We use [28] as a general reference in the area of computational complexity and algorithms.

Let $P \subset \mathbb{R}^d$ be a rational polyhedron with a vertex (equivalently, a non-empty polyhedron without lines), possibly unbounded, and let $S = P \cap \mathbb{Z}^d$ be the set of integer points in $P$.

To simplify notation, we denote the generating function

$$f(S; \boldsymbol{x}) = \sum_{m \in S} \boldsymbol{x}^m,$$

where $S = P \cap \mathbb{Z}^d$, just by $f(P, \boldsymbol{x})$.

It is not hard to show that there exists a non-empty open set $U \subset \mathbb{C}^d$ such that for all $\boldsymbol{x} \in U$ the series

$$f(P, \boldsymbol{x}) = \sum_{m \in P \cap \mathbb{Z}^d} \boldsymbol{x}^m$$

converges absolutely and uniformly on compact subsets of $U$ to a rational function in $\boldsymbol{x}$. It turns out that this rational function can be efficiently computed as long as the dimension $d$ of the ambient space is fixed in advance.

The following result was proved, essentially, in [3] although the formal statement and better complexity bounds did not appear until [4].

**Theorem 2.2.** *Let us fix $d$. Then there exists a polynomial time algorithm, which, for a rational polyhedron $P \subset \mathbb{R}^d$ without lines defined by inequalities* (2.1) *computes the generating function*

$$f(P, \boldsymbol{x}) = \sum_{m \in P \cap \mathbb{Z}^d} \boldsymbol{x}^m$$

*in the form*

$$f(P, \boldsymbol{x}) = \sum_{i \in I} \varepsilon_i \frac{\boldsymbol{x}^{v_i}}{(1 - \boldsymbol{x}^{u_{i1}}) \ldots (1 - \boldsymbol{x}^{u_{id}})}, \tag{2.3}$$

*where $\varepsilon_i \in \{-1, 1\}$, $v_i, u_{ij} \in \mathbb{Z}^d$, and $u_{ij} \neq 0$ for all $i$, $j$.*

The complexity of the algorithm is $\mathcal{L}^{O(d)}$, where $\mathcal{L}$ is the input size of $P$ defined by (2.2). In particular, the number $|I|$ of terms in (2.3) is $\mathcal{L}^{O(d)}$, which is why we call (2.3) a *short rational function*.

Rational cones play the crucial role in the proof of Theorem 2.2.

**2.1. Rational cones.** A non-empty rational polyhedron $K$ is called a *rational cone* if for every $x \in K$ and $\lambda \geq 0$ we have $\lambda x \in K$. We are interested in *pointed* rational cones, that is, cones not containing lines (equivalently, cones for which 0 is the vertex). A basic example of a pointed rational cone is provided by the non-negative orthant $\mathbb{R}^d_+$ consisting of the points with non-negative coordinates. The generating function for the set of integer points in $\mathbb{R}^d_+$ is a multiple geometric series

$$f(\mathbb{R}^d_+, \boldsymbol{x}) = \sum_{m \in \mathbb{Z}^d_+} \boldsymbol{x}^m = \prod_{i=1}^d \frac{1}{1 - x_i}.$$

A *unimodular cone* $K$ is the set of non-negative linear combinations of a given basis $u_1, \ldots, u_d$ of the lattice $\mathbb{Z}^d$. Up to an integral change of coordinates, a unimodular cone $K$ looks like the non-negative orthant $\mathbb{R}^d_+$. Consequently, the generating function for the set of integer points in $K$ is a multiple geometric series

$$f(K, \boldsymbol{x}) = \sum_{m \in K \cap \mathbb{Z}^d} \boldsymbol{x}^m = \prod_{i=1}^d \frac{1}{1 - \boldsymbol{x}^{u_i}}.$$

It is well known that any rational cone $K$ can be subdivided into unimodular cones, cf., for example, Section 2.6 of [16]. However, even for $d = 2$, the number of the unimodular cones may have to be exponentially large in the input size: consider the cone $K \subset \mathbb{R}^2$ spanned by $(1, 0)$ and $(1, n)$ for a positive integer $n$. Nevertheless, where exists a computationally efficient procedure for constructing a more general *decomposition* of a rational cone into unimodular cones.

**Definition 2.3.** For a set $A \subset \mathbb{R}^d$, let $[A]\colon \mathbb{R}^d \longrightarrow \mathbb{R}$ be the indicator of $A$ defined by

$$[A](x) = \begin{cases} 1 & \text{if } x \in A \\ 0 & \text{if } x \notin A. \end{cases}$$

Let $\mathcal{P}(\mathbb{Q}^d)$ be the vector space (over $\mathbb{C}$) spanned by the indicators $[P]$ of rational polyhedra $P \subset \mathbb{R}^d$. We call $\mathcal{P}(\mathbb{Q}^d)$ the *algebra of rational polyhedra*. The vector space $\mathcal{P}(\mathbb{Q}^d)$ possesses an interesting and useful algebra structure, cf. [26], which we do not discuss here.

The idea is to write the indicator $[K]$ of a given rational cone $K \subset \mathbb{R}^d$ as a linear combination of indicators of unimodular cones. For $d = 2$ such an efficient procedure has long been known via the *continued fractions* method, cf., for example, [22]. We give a simple example below.

Suppose that $K \subset \mathbb{R}^2$ is the cone spanned by vectors $(1, 0)$ and $(31, 164)$. Writing the continued fraction expansion, we obtain

$$\frac{164}{31} = 5 + \cfrac{1}{3 + \cfrac{1}{2 + \cfrac{1}{4}}} \quad ,$$

so we write $164/31 = [5; 3, 2, 4]$. Next, we compute the *convergents*

$$[5; 3, 2] = 5 + \cfrac{1}{3 + \cfrac{1}{2}} = \frac{37}{7}, \quad [5; 3] = 5 + \frac{1}{3} = \frac{16}{3}, \quad \text{and} \quad [5] = \frac{5}{1}$$

and notice that

$$[K] = [K_0] - [K_1] + [K_2] - [K_3] + [K_4],$$

where $K_0$ is spanned by $(1, 0)$ and $(0, 1)$, $K_1$ is spanned by $(0, 1)$ and $(1, 5)$, $K_2$ is spanned by $(1, 5)$ and $(3, 16)$, $K_3$ is spanned by $(3, 16)$ and $(7, 37)$, and $K_4$ is spanned by $(7, 37)$ and $(31, 164)$. Since $K_i$ turn out to be unimodular for $i = 0, 1, 2, 3, 4$, we get the short rational function expression

$$f(K, \boldsymbol{x}) = \frac{1}{(1 - x_1)(1 - x_2)} - \frac{1}{(1 - x_2)(1 - x_1 x_2^5)} + \frac{1}{(1 - x_1 x_2^5)(1 - x_1^3 x_2^{16})} - \frac{1}{(1 - x_1^3 x_2^{16})(1 - x_1^7 x_2^{37})} + \frac{1}{(1 - x_1^7 x_2^{37})(1 - x_1^{31} x_2^{164})}.$$

A polynomial time algorithm for computing a unimodular cone decomposition in any (fixed in advance) dimension $d$ was suggested in [3]. Using triangulations, it is not hard to reduce the case of an arbitrary rational cone to that of a *simple rational cone* $K \subset \mathbb{R}^d$

$$K = \left\{ \sum_{i=1}^{d} \lambda_i u_i : \ \lambda_i \geq 0 \right\}$$

spanned by linearly independent vectors $u_1, \ldots, u_d \in \mathbb{Z}^d$, which may not, however, constitute a basis of the lattice $\mathbb{Z}^d$. As a measure of how far is $K$ from being unimodular, we introduce the *index* $\mathrm{ind}(K)$ of $K$ as the index of the sublattice generated by $u_1, \ldots, u_d$ in the ambient lattice $\mathbb{Z}^d$. Thus $\mathrm{ind}(K)$ is a positive integer and $\mathrm{ind}(K) = 1$ if and only if $K$ is a unimodular cone.

Let us consider the parallelepiped

$$\Pi = \left\{ \sum_{i=1}^{d} \lambda_i u_i : \ |\lambda_i| \leq \mathrm{ind}^{-1/d}(K) \text{ for } i = 1, \ldots, d \right\}.$$

Then $\Pi$ is a convex body symmetric about the origin and $\mathrm{vol}\, \Pi = 2^d$. Therefore, by the Minkowski Theorem there is a non-zero point $w \in \Pi \cap \mathbb{Z}^d$, cf., for example, Section VII.3 of [5]. Moreover, such a point $w$ can be constructed in polynomial time as long as the dimension $d$ is fixed, cf. Section 6.7 of [17]. Replacing $w$ by $-w$ if needed, we can also ensure that $w$ lies in the same halfspace as $u_1, \ldots, u_d$. Let $K_i$ be the cone spanned by $u_1, \ldots, u_d$ with the vector $u_i$ replaced by $w$ and let $\varepsilon_i = 1$ or $\varepsilon_i = -1$ depending on whether this replacement preserves or reverses the orientation of the set $u_1, \ldots, u_d$ (we choose $\varepsilon_i = 0$ if we obtain a linearly dependent set). Then we observe that

$$\begin{aligned} &[K] = \sum_{i=1}^{d} \varepsilon_i [K_i] \ \pm \ \text{indicators of lower-dimensional cones, and} \\ &\mathrm{ind}(K_i) \leq \mathrm{ind}^{(d-1)/d}(K) \quad \text{if } \dim K_i = d. \end{aligned} \tag{2.4}$$

As we iterate the above procedure, on the $n$th step, we obtain a decomposition of the cone $K$ as a linear combination of at most $d^n$ cones $K_i$ (not counting smaller-dimensional cones) with

$$\mathrm{ind}(K_i) \leq (\mathrm{ind}(K))^{\left(\frac{d-1}{d}\right)^n}.$$

To ensure that all $K_i$ are unimodular, we can choose $n = O(d \log\log \mathrm{ind}(K))$, which results in a polynomial time algorithm for a fixed $d$.

To prove a weaker version of Theorem 2.2 (with $d$ replaced by $d+2$ in (2.3) and $\mathcal{L}^{O(d^2)}$ complexity) one can note that a rational polyhedron $P \subset \mathbb{R}^d$ without lines

can be represented as the section of a pointed rational cone $K \subset \mathbb{R}^{d+1}$ by the affine hyperplane $\xi_{d+1} = 1$. Consequently, we have

$$f(P, \boldsymbol{x}) = \frac{\partial}{\partial x_{d+1}} f(K, (\boldsymbol{x}, x_{d+1}))\big|_{x_{d+1}=0}. \tag{2.5}$$

**2.2. Using identities in the algebra of polyhedra.** The following remarkable result was proved by A. G. Khovanskii and A. V. Pukhlikov [23], and, independently, by J. Lawrence [25].

**Theorem 2.4.** *Let $\mathcal{P}(\mathbb{Q}^d)$ be the vector space spanned by the indicators of rational polyhedra and let $\mathbb{C}(\boldsymbol{x})$ be the vector space of rational functions in $d$ complex variables $\boldsymbol{x} = (x_1, \ldots, x_d)$. There exists a linear transformation $\mathcal{F}: \mathcal{P}(\mathbb{Q}^d) \longrightarrow \mathbb{C}(\boldsymbol{x})$ such that the following holds.*

(1) *If $P \subset \mathbb{R}^d$ is a rational polyhedron with a vertex then $\mathcal{F}([P]) = f(P, \boldsymbol{x})$, where $f(P, \boldsymbol{x})$ is the rational function defined as the sum of the series*

$$\sum_{m \in P \cap \mathbb{Z}^d} \boldsymbol{x}^m$$

*when the series converges absolutely.*

(2) *If $P \subset \mathbb{R}^d$ is a rational polyhedron without vertices then $\mathcal{F}([P]) = 0$.*

*Proof.* Let us fix a decomposition

$$\mathbb{R}^d = \sum_{i \in I} \alpha_i [Q_i] \tag{2.6}$$

for some rational polyhedra $Q_i$ with vertices and some numbers $\alpha_i$. Multiplying (2.6) by $[P]$, we get

$$[P] = \sum_{i \in I} \alpha_i [P \cap Q_i], \tag{2.7}$$

from which we deduce that $\mathcal{P}(\mathbb{Q}^d)$ is spanned by indicators of rational polyhedra with vertices.

Suppose that we have a linear relation

$$\sum_{j \in J} \beta_j [P_j] = 0 \tag{2.8}$$

for some polyhedra $P_j$ with vertices. Multiplying (2.8) by $[Q_i]$, we get

$$\sum_{j \in J} \beta_j [P_j \cap Q_i] = 0.$$

Since $Q_i$ has a vertex and $P_j \cap Q_i \subset Q_i$, there exists a non-empty open set $U_i \subset \mathbb{C}^d$ such that for all $\boldsymbol{x} \in U_i$ all the series defining $f(P_j \cap Q_i, \boldsymbol{x})$ converge absolutely and uniformly on compact subsets of $U_i$. Therefore, we must have

$$\sum_{j \in J} \beta_j f(P_j \cap Q_i, \boldsymbol{x}) = 0 \quad \text{for all } i \in I.$$

Similarly, from (2.7) we get

$$f(P_j, \boldsymbol{x}) = \sum_{i \in I} \alpha_i f(P_j \cap Q_i, \boldsymbol{x}) \quad \text{for all } j \in J.$$

Combining the last two equations, we conclude that

$$\sum_{j \in j} \beta_j f(P_j, \boldsymbol{x}) = \sum_{i \in I, j \in J} \alpha_i \beta_j f(P_j \cap Q_i, \boldsymbol{x}) = 0. \tag{2.9}$$

Thus a linear dependence (2.8) among indicators of rational polyhedra $P_j$ with vertices implies the corresponding linear dependence (2.9) among the generating functions $f(P_j, \boldsymbol{x})$. Therefore, the correspondence

$$[P] \longmapsto f(P, \boldsymbol{x})$$

extends to a linear transformation $\mathcal{F}: \mathcal{P}(\mathbb{Q}^d) \longrightarrow \mathbb{C}(\boldsymbol{x})$. It remains to show that $\mathcal{F}([P]) = 0$ if $P$ is a rational polyhedron with a line.

We observe that if $P' = P + u$ is a translation of $P$ by a lattice vector $u$, we must have $f(P', \boldsymbol{x}) = \boldsymbol{x}^u f(P, \boldsymbol{x})$ for all rational polyhedra $P$ with vertices. By linearity, we must have $\mathcal{F}([P + u]) = \boldsymbol{x}^u \mathcal{F}([P])$ for all rational polyhedra $P$. However, if $P$ contains a line then there is a vector $u \in \mathbb{Z}^d \setminus \{0\}$ such that $P + u = P$. Therefore, we must have $\mathcal{F}([P]) = 0$ for $P$ with a line. □

Theorem 2.4 provides a powerful tool for computing the generating function of the set of integer points in a rational polyhedron. The following "duality trick" going back to the seminal paper of M. Brion [11] turns out to be particularly useful.

Let $\langle \cdot, \cdot \rangle$ be the standard scalar product in $\mathbb{R}^d$ and let $K \subset \mathbb{R}^d$ be a cone. The cone

$$K^* = \{x \in \mathbb{R}^d : \langle x, y \rangle \geq 0 \text{ for all } y \in K\}$$

is called the *dual* to $K$. It is easy to see that if $K$ is rational (resp. unimodular) cone then $K^*$ is a rational (resp. unimodular) cone, and that if $K$ contains a line (resp. lies in a proper subspace of $\mathbb{R}^d$) then $K^*$ lies in a proper subspace of $\mathbb{R}^d$ (resp. contains a line). A standard duality argument implies that $(K^*)^* = K$ for closed convex cones $K$. A less obvious observation is that duality preserves linear relations among indicators of closed convex cones:

$$\sum_{i \in I} \alpha_i [K_i] = 0 \quad \text{implies} \quad \sum_{i \in I} \alpha_i [K_i^*] = 0,$$

see, for example, Section IV.1 of [5] for a proof.

Now, to compute the generating function $f(K, \boldsymbol{x})$ one can do the following. First, we compute the dual cone $K^*$, and, iterating (2.4), we compute unimodular cones $K_i$ and numbers $\varepsilon_i \in \{-1, 1\}$ such that

$$[K^*] \equiv \sum_{i \in I} \varepsilon_i [K_i] \quad \text{modulo indicators of lower-dimensional cones.}$$

Then, dualizing again, we get

$$[K] \equiv \sum_{i \in I} \varepsilon_i [K_i^*] \quad \text{modulo indicators of cones with lines.} \tag{2.10}$$

In view of Theorem 2.4, cones with lines can be ignored as far as generating functions are concerned. This gives us

$$f(K, \boldsymbol{x}) = \sum_{i \in I} \varepsilon_i f(K_i^*, \boldsymbol{x}).$$

Since $K_i^*$ are unimodular cones, this completes computation of $f(K, \boldsymbol{x})$. This trick allows us to reduce the complexity of the algorithm in Theorem 2.2 from $\mathcal{L}^{O(d^2)}$ to $\mathcal{L}^{O(d)}$, where $\mathcal{L}$ is the size of the input.

Another important identity is Brion's Theorem [11], which expresses the generating function of the set of integer points in $P$ as the sum of generating functions for the sets of integer points in the tangent (supporting) cones at the vertices of $P$. Namely, for a vertex $v$ of a polyhedron $P$ let us define the tangent cone $K_v$ as

$$K_v = \{x : \varepsilon x + (1 - \varepsilon)v \in P \text{ for all sufficiently small } \varepsilon > 0\}.$$

We note that $K_v$ is not a cone per se but rather a translation of the cone $K_v - v$.

**Theorem 2.5** (Brion's Theorem). *For a rational polyhedron $P$ we have*

$$f(P, \boldsymbol{x}) = \sum_{v} f(K_v, \boldsymbol{x}),$$

*where the sum is taken over all vertices of $P$ and the identity is understood as the identity among rational functions.*

Discovered by M. Brion [11], Theorem 2.5 started an avalanche of research. The original proof of Theorem 2.5 was based on algebro-geometric methods. Later, elementary proofs were discovered in [23] and [25]. One can deduce Theorem 2.5 from Theorem 2.4 and an elementary identity

$$[P] \equiv \sum_{v} [K_v] \quad \text{modulo indicators of polyhedra with lines,}$$

cf. Section VIII.4 of [5].

Theorem 2.5 together with the unimodular decomposition of Section 2.1 and the duality trick provide the proof of Theorem 2.2 as stated. Another advantage of using Theorem 2.5 is that it allows us to understand how the generating function $f(P, \boldsymbol{x})$ changes as the facets of $P$ move parallel to themselves so that the combinatorial structure of $P$ does not change. In this case, the tangent cones $K_v$ get translated by vectors linearly depending on the displacements of the facets of $P$. Writing $K_v$ as combinations of translated unimodular cones $K_i + v$ as in (2.10), we notice that as far as lattice points are concerned, a *rational* translation $K_i + v$ of a *unimodular* cone $K_i$ is equivalent to a certain *integer* translation $K_i + u$:

$$(K_i + v) \cap \mathbb{Z}^d = (K_i + u) \cap \mathbb{Z}^d \quad \text{for some } u \in \mathbb{Z}^d$$

and hence we have

$$f(K_i + v, \boldsymbol{x}) = f(K_i + u, \boldsymbol{x}) = \boldsymbol{x}^u f(K_i, \boldsymbol{x}).$$

If $K = \mathbb{R}^d_+$ then $u$ is obtained from $v$ by rounding up the coordinates to the nearest integer. The case of a general unimodular cone differs by a unimodular linear transformation, see [4] for details.

**2.3. Implementation.** The algorithm of Theorem 2.2 appears to be practical. First, it was implemented by J. De Loera et al. [12], who wrote the `LattE` (Lattice point enumeration) software package. The authors of `LattE` discovered that often the most practically efficient way to handle computations is to represent a polyhedron $P$ as a hyperplane section of a higher-dimensional cone as in (2.5) and then use the "dualized" decomposition (2.10). The package allows one to compute the number of integer points in a given rational polytope. Formally speaking, to compute the number $|P \cap \mathbb{Z}^d|$ of integer points in a given rational polytope $P$, we should substitute $\boldsymbol{x} = (1, \ldots, 1)$ into the rational function $f(P, \boldsymbol{x})$. However, we need to be careful since this particular value is a pole of every fraction in (2.3). Nevertheless, the substitution can be done efficiently, see Section 3.1 and [3], [4], [7], and [12] for details.

In addition, `LattE` allows one to compute the Ehrhart (quasi)-polynomial of a given rational polytope $P$, that is, to find a formula for the number of integer points in the dilated polytope $nP$, where $n$ is a positive integer, see also Section 6.1.

Testing whether a given rational polyhedron $P$ contains an integer point, or, equivalently, whether $f(P, \boldsymbol{x}) \not\equiv 0$ is a non-trivial problem related to the general *integer programming problem* of optimizing a given linear function on the set $P \cap \mathbb{Z}^d$. `LattE` package contains also an implementation of an integer programming algorithm based on rational functions $f(P, \boldsymbol{x})$.

Another implementation, called `barvinok`, was written by S. Verdoolaege, see [36]. Among other features, the implementation allows one to obtain closed explicit formulas for the number of integer points in a parametric polytope as a function of displacement parameters when the facets of the polytope move parallel to themselves, see Theorem 2.5 and the subsequent discussion.

There is an extensive literature devoted to the lattice point enumeration in polytopes, whether from algorithmic, structural, or application points of view. For the classical Ehrhart theory in the context of enumerative combinatorics, see [34] and [9] for a clever simplification of the proofs of the main results of the theory. For an approach featuring Dedekind sums and other analytic tools, see [8]. It does not seem to be possible to survey all the literature in the paper. In addition to already mentioned papers, we provide only a few references among many good papers which appeared after the survey [4].

Efficient counting in special situations with applications to computational questions in representation theory and network flows is discussed in [2]. For a recent advance connecting lattice point counting with algebraic geometry, see [29]. For a computationally efficient version of the Euler–Maclaurin formula, satisfying, in addition, some natural "local" conditions, see [10].

## 3. Operations on sets and generating functions

Motivated in part by Theorem 2.2, let us consider sets $S \subset \mathbb{Z}^d$ *defined* by their generating functions

$$f(S; \boldsymbol{x}) = \sum_{m \in S} \boldsymbol{x}^m$$

written as rational functions in the form

$$f(S; \boldsymbol{x}) = \sum_{i \in I} \varepsilon_i \frac{\boldsymbol{x}^{a_i}}{(1 - \boldsymbol{x}^{b_{i1}}) \dots (1 - \boldsymbol{x}^{b_{ik}})}. \tag{3.1}$$

Here $I$ is a finite set of indices, $\varepsilon_i \in \mathbb{Q}$, $a_i, b_{ij} \in \mathbb{Z}^d$, and $b_{ij} \neq 0$ for all $i, j$. To avoid ambiguity, we assume that either $S$ is finite, or, if $S$ is infinite, then there is a nonempty open set $U \subset \mathbb{C}^d$ such that the series defining $f(S; \boldsymbol{x})$ converges absolutely and uniformly on compact subsets of $U$ and for every fraction in (3.1) there is the Laurent series (multiple geometric series) expansion

$$\frac{\boldsymbol{x}^{a_i}}{(1 - \boldsymbol{x}^{b_{i1}}) \dots (1 - \boldsymbol{x}^{b_{ik}})} = \sum_{(\mu_1, \dots, \mu_k) \in \mathbb{Z}_+^k} \boldsymbol{x}^{a_i + \mu_1 b_{i1} + \dots + \mu_k b_{ik}}$$

in $U$.

To indicate the computational complexity level of our set $S$, we consider the two parameters *fixed* in formula (3.1): the number $d$ of variables and the number $k$ of binomials in the denominator of each fraction. Note that if we happen to have a smaller number of binomials in some fraction, we can formally "pad" it to $k$ by multiplying both the numerator and denominator of the fraction by some artificial binomials. Since $k$ is fixed, that would increase the length of the formula by a constant factor.

Next, we discuss what information about the set $S$ can be extracted from $f(S; \boldsymbol{x})$ given in the form of (3.1).

**3.1. Monomial substitutions and differentiation.** One piece of information we can get is the cardinality $|S|$ of a finite set $S$. To compute $|S|$, we would like to substitute $\boldsymbol{x} = (1, \ldots, 1)$ in (3.1), but this should be done carefully since this particular value of $\boldsymbol{x}$ is the pole of every single fraction in (3.1). The procedure is introduced in [3].

We choose a sufficiently generic vector $c \in \mathbb{Z}^d$, $c = (\gamma_1, \ldots, \gamma_d)$, so that $\langle c, b_{ij} \rangle \neq 0$ for all $i, j$. For a $\tau \in \mathbb{C}$, let

$$\boldsymbol{x}(\tau) = (e^{\tau\gamma_1}, \ldots, e^{\tau\gamma_d}).$$

Thus we want to compute

$$\lim_{\tau \longrightarrow 0} f(S; \boldsymbol{x}(\tau)).$$

Let us compute

$$\alpha_i = \langle c, a_i \rangle \quad \text{and} \quad \beta_{ij} = \langle c, b_{ij} \rangle.$$

Then

$$f(S; \boldsymbol{x}(\tau)) = \sum_{i \in I} \varepsilon_i \frac{e^{\alpha_i \tau}}{(1 - e^{\beta_{i1}\tau}) \ldots (1 - e^{\beta_{ik}\tau})}. \tag{3.2}$$

Next, we note that $f(S; \boldsymbol{x}(\tau))$ is a meromorphic function in $\tau$ and that we want to compute the constant term of its Laurent expansion in the neighborhood of $\tau = 0$. To do that, we deal with every fraction separately. We write each fraction of (3.2) as

$$\frac{e^{\alpha_i \tau}}{(1 - e^{\beta_{i1}\tau}) \ldots (1 - e^{\beta_{ik}\tau})} = \tau^{-k} e^{\alpha_i \tau} \prod_{j=1}^{k} g_{ij}(\tau), \quad \text{where } g_{ij}(\tau) = \frac{\tau}{1 - e^{\beta_{ij}\tau}}.$$

Now, each $g_{ij}(\tau)$ is an analytic function of $\tau$ and we compute is Taylor series expansion $p_{ij}(\tau)$ up to the $\tau^{k+1}$ term:

$$\frac{\tau}{1 - e^{\beta_{ij}\tau}} \equiv p_{ij}(\tau) \mod \tau^{k+1}.$$

Similarly, we compute a polynomial $q_i(\tau)$ such that

$$e^{\alpha_i \tau} \equiv q_i(\tau) \mod \tau^{k+1}.$$

Finally, successively multiplying polynomials $\mod \tau^{k+1}$ we compute the polynomial $h_i(\tau)$ with $\deg h_i \leq k$ such that

$$q_i \, p_{i1} \ldots p_{ik} \equiv h_i \mod \tau^{k+1}.$$

Letting

$$h(\tau) = \sum_{i \in I} h_i(\tau),$$

we conclude that the coefficient of $\tau^k$ in $h(\tau)$ is the desired value of (3.2) at $\tau = 0$ and hence is the value $f(S; \boldsymbol{x})$ at $\boldsymbol{x} = (1, \ldots, 1)$. We note that the procedure has a

polynomial time complexity even if both $k$ and $d$ are allowed to vary and if we allow different numbers $k_i \leq k$ of binomials in different fractions of (3.1).

A more general operation which can be computed in polynomial time is that of a *monomial substitution*. Let $f(\boldsymbol{x})$ be an expression of the type (3.1). Let $\boldsymbol{z} = (z_1, \ldots, z_n)$ be a new set of variables, let $l_1, \ldots, l_d \in \mathbb{Z}^n$ be vectors, and let $\phi\colon \mathbb{C}^n \longrightarrow \mathbb{C}^d$ be the transformation defined by

$$(z_1, \ldots, z_n) \longmapsto (x_1, \ldots, x_d) \quad \text{where } x_i = \boldsymbol{z}^{l_i}.$$

If the image $\phi(\mathbb{C}^n)$ does not lie in the set of poles of $f$, one can define a rational function $g(\boldsymbol{z}) = f(\phi(\boldsymbol{z}))$. Function $g$ can be computed in polynomial time in the form

$$g(\boldsymbol{z}) = \sum_{i \in I'} \delta_i \frac{\boldsymbol{z}^{q_i}}{(1 - \boldsymbol{z}^{b_{i1}}) \ldots (1 - \boldsymbol{z}^{b_{ik_i}})},$$

where $\delta_i \in \mathbb{Q}$, $q_i, b_{ij} \in \mathbb{Z}^n$, $b_{ij} \neq 0$ for all $i$, $j$ and $k_i \leq k$ for all $i \in I'$.

The case of $l_1 = \cdots = l_d = 0$ corresponds to the case of $\boldsymbol{x} = (1, \ldots, 1)$ considered above. As above, the general case of a monomial substitution is handled by a one-parametric perturbation and computation with univariate polynomials. Details can be found in [7] (the assumption that $k$ is fixed in advance is not needed there).

The operation of monomial substitution has the following geometric interpretation. Let $T\colon \mathbb{R}^d \longrightarrow \mathbb{R}^n$ be the linear transformation whose matrix in the standard bases consists of the integer column vectors $l_1, \ldots, l_d$. Let $S \subset \mathbb{Z}^d$ be a set and suppose that for all $m \in T(S)$ the set $T^{-1}(m) \cap S$ is finite. The monomial substitution $x_i = \boldsymbol{z}^{l_i}$ into the generating function $f(S; \boldsymbol{x})$ produces the weighted generating function $g(\boldsymbol{z})$ of the image $T(S) \subset \mathbb{Z}^n$, where each monomial $\boldsymbol{z}^m$ for $m \in T(S)$ is counted with multiplicity $|T^{-1}(m) \cap S|$.

Another useful operation is that of differentiation. Let $p$ be a $d$-variate polynomial. We can write

$$\sum_{m \in S} p(m) \boldsymbol{x}^m = p\left(x_1 \frac{\partial}{\partial x_1}, \ldots, x_d \frac{\partial}{\partial x_d}\right) f(S; \boldsymbol{x}).$$

As long as $k$ is fixed in advance, the result can be computed in polynomial time in the form

$$\sum_{i \in I'} \delta_i \frac{\boldsymbol{x}^{q_i}}{(1 - \boldsymbol{x}^{b_{i1}})^{\gamma_{i1}} \ldots (1 - \boldsymbol{x}^{b_{ik}})^{\gamma_{ik}}},$$

where $\delta_i \in \mathbb{Q}$, $a_i, b_{ij} \in \mathbb{Z}^d$, $b_{ij} \neq 0$, and $\gamma_{ij}$ are non-negative integers such that $\gamma_{i1} + \cdots + \gamma_{ik} \leq k + \deg p$ for all $i$, see [6].

This observation is used in [6], see also [10] and [13].

One corollary of Theorem 2.2 is that we can efficiently perform set-theoretic operations (intersection, union, difference) of finite sets defined by (3.1). The following result is proved in [7].

**Theorem 3.1.** *Let us fix positive integers $d$ and $k$. Then there exists a polynomial time algorithm, which, for any two finite sets $S_1, S_2 \subset \mathbb{Z}^d$ given by their rational generating functions*

$$f(S_1; \boldsymbol{x}) = \sum_{i \in I_1} \alpha_i \frac{\boldsymbol{x}^{p_i}}{(1 - \boldsymbol{x}^{a_{i1}}) \dots (1 - \boldsymbol{x}^{a_{ik}})} \tag{3.3}$$

*and*

$$f(S_2; \boldsymbol{x}) = \sum_{i \in I_2} \beta_i \frac{\boldsymbol{x}^{q_i}}{(1 - \boldsymbol{x}^{b_{i1}}) \dots (1 - \boldsymbol{x}^{b_{ik}})} \tag{3.4}$$

*computes the generating function $f(S; \boldsymbol{x})$ of their intersection $S = S_1 \cap S_2$ in the form*

$$f(S; \boldsymbol{x}) = \sum_{i \in I} \gamma_i \frac{\boldsymbol{x}^{u_i}}{(1 - \boldsymbol{x}^{v_{i1}}) \dots (1 - \boldsymbol{x}^{v_{is}})},$$

*where $s \leq 2k$.*

*Proof.* The idea of the proof is to *linearize* the operation of intersection of sets. Suppose we have two Laurent series

$$g_1(\boldsymbol{x}) = \sum_{m \in \mathbb{Z}^d} \rho_{1m} \boldsymbol{x}^m \quad \text{and} \quad g_2(\boldsymbol{x}) = \sum_{m \in \mathbb{Z}^d} \rho_{2m} \boldsymbol{x}^m.$$

Let us define their *Hadamard product* $g_1(\boldsymbol{x}) \star g_2(\boldsymbol{x})$ as

$$g(\boldsymbol{x}) = \sum_{m \in \mathbb{Z}^d} \rho_m \boldsymbol{x}^m \quad \text{where } \rho_m = \rho_{1m} \rho_{2m}.$$

Then, clearly,

$$f(S_1 \cap S_2; \boldsymbol{x}) = f(S_1; \boldsymbol{x}) \star f(S_2; \boldsymbol{x}).$$

Without loss of generality, we assume that there is a non-empty open set $U \subset \mathbb{C}^d$ such that for all $\boldsymbol{x} \in U$ and every fraction of (3.3) and (3.4) we have the multiple geometric series expansions:

$$\frac{\boldsymbol{x}^{p_i}}{(1 - \boldsymbol{x}^{a_{i1}}) \dots (1 - \boldsymbol{x}^{a_{ik}})} = \sum_{(\mu_1, \dots, \mu_k) \in \mathbb{Z}_+^k} \boldsymbol{x}^{p_i + \mu_1 a_{i1} + \dots + \mu_k a_{ik}} \tag{3.5}$$

and

$$\frac{\boldsymbol{x}^{q_i}}{(1 - \boldsymbol{x}^{b_{i1}}) \dots (1 - \boldsymbol{x}^{b_{ik}})} = \sum_{(\nu_1, \dots, \nu_k) \in \mathbb{Z}_+^k} \boldsymbol{x}^{q_i + \nu_1 b_{i1} + \dots + \nu_k b_{ik}}. \tag{3.6}$$

As usual, we assume that for all $\boldsymbol{x} \in U$ the convergence in (3.5) and (3.6) is absolute and uniform on all compact subsets of $U$. To ensure that such a set $U$ indeed exists, we choose a sufficiently generic linear function $\ell \colon \mathbb{R}^d \longrightarrow \mathbb{R}$ and make sure that

$\ell(a_{ij}), \ell(b_{ij}) > 0$ for all $i, j$ by reversing, if necessary, the direction of $a_{ij}$ and $b_{ij}$ via the identity

$$\frac{1}{1-\boldsymbol{x}^{a}} = -\frac{\boldsymbol{x}^{-a}}{1-\boldsymbol{x}^{-a}}.$$

Here we use that $S_1$ and $S_2$ are finite so that $f(S_1; \boldsymbol{x})$ and $f(S_2; \boldsymbol{x})$ are, in fact, Laurent polynomials.

Since the Hadamard product is a bilinear operation on series, in order to compute $f(S_1; \boldsymbol{x}) \star f(S_2; \boldsymbol{x})$ it suffices to compute the Hadamard product of every pair of series (3.5) and (3.6).

In the space $\mathbb{R}^{2k}$ of $2k$-tuples $(x, y)$, where $x = (\xi_1, \ldots, \xi_k)$ and $y = (\eta_1, \ldots, \eta_k)$, let us introduce the polyhedron

$$Q_i = \left\{ (x, y) : \begin{array}{l} \xi_1, \ldots, \xi_k;\ \eta_1, \ldots, \eta_k \geq 0 \\ p_i + \xi_1 a_{i1} + \cdots + \xi_k a_{ik} = q_i + \eta_1 b_{i1} + \cdots + \eta_k b_{ik} \end{array} \right\} \tag{3.7}$$

and let $\mathbb{Z}^{2k} \subset \mathbb{R}^{2k}$ be the standard integer lattice.

Since the Hadamard product is bilinear and for monomials we have

$$\boldsymbol{x}^{m_1} \star \boldsymbol{x}^{m_2} = \begin{cases} \boldsymbol{x}^{m} & \text{if } m_1 = m_2 = m \\ 0 & \text{if } m_1 \neq m_2, \end{cases}$$

the Hadamard product of the series (3.5) and (3.6) can be expressed as the sum

$$\sum_{(m,n) \in Q_i \cap \mathbb{Z}^{2k}} \boldsymbol{x}^{p_i + \mu_1 a_{i1} + \cdots + \mu_k a_{ik}}, \tag{3.8}$$

where $m = (\mu_1, \ldots, \mu_k)$ and $n = (\nu_1, \ldots, \nu_k)$. On the other hand, (3.8) is obtained from the generating function $f(Q_i, \boldsymbol{z})$ with $\boldsymbol{z} = (z_1, \ldots, z_{2k})$ by the monomial substitution

$$z_i = \boldsymbol{x}^{a_i} \ \text{ for } i = 1, \ldots, k \quad \text{and} \quad z_i = 1 \ \text{ for } i = k+1, \ldots, 2k \tag{3.9}$$

and multiplication by $\boldsymbol{x}^{p_i}$.

We use Theorem 2.2 to compute $f(Q_i, \boldsymbol{z})$. The monomial substitution (3.9) can also be computed in polynomial time, cf. Section 3.1. □

Therefore, one can compute the generating functions of the union and difference:

$$f(S_1 \cup S_2; \boldsymbol{x}) = f(S_1; \boldsymbol{x}) + f(S_2; \boldsymbol{x}) - f(S_1 \cap S_2; \boldsymbol{x})$$

and

$$f(S_1 \setminus S_2; \boldsymbol{x}) = f(S_1; \boldsymbol{x}) - f(S_1 \cap S_2; \boldsymbol{x}).$$

Theorem 3.1 allows us to work with generating functions (3.1) directly as with data structures bypassing any more explicit descriptions of sets $S$ in question. Of course, there is a price to pay: with every set-theoretic operation, the complexity level of the set, the number $k$ of binomials in the denominator of each fraction in (3.1), doubles. From the definition (3.7) of $Q_i$ we can notice that in a sufficiently general position we will have $\dim Q_i = 2k-d$, so we would be able to choose $s = 2k-d$ in Theorem 3.1. Theorem 3.1 admits an extension to infinite sets $S_1$ and $S_2$ provided there is a non-empty open set $U \subset \mathbb{C}^d$ such that the multiple geometric series expansions (3.5) and (3.6) hold for all fractions in (3.3) and (3.4). K. Woods [38] used the construction of the Hadamard product to show that in any fixed dimension there is a polynomial time algorithm to check if a given integer is a period of the Ehrhart quasi-polynomial of a given rational polytope.

## 4. Beyond polyhedra: projections

There are other interesting sets admitting short rational generating functions (3.1). We start with examples.

**4.1. Integer semigroups.** Let $S$ be the semigroup generated by positive coprime integers $a_1$ and $a_2$, that is, the set of all non-negative integer combinations of $a_1$ and $a_2$:

$$S = \{\mu_1 a_1 + \mu_2 a_2 : \ \mu_1, \mu_2 \in \mathbb{Z}_+\}.$$

It is not hard to show that

$$f(S; x) = \frac{1 - x^{a_1 a_2}}{(1 - x^{a_1})(1 - x^{a_2})}$$

(the series defining $f(S; x)$ converges for all $|x| < 1$).

Let $S$ be the semigroup generated by positive coprime integers $a_1$, $a_2$, and $a_3$,

$$S = \{\mu_1 a_1 + \mu_2 a_2 + \mu_3 a_3 : \ \mu_1, \mu_2, \mu_3 \in \mathbb{Z}_+\}.$$

Then there exist positive integers $p_1$, $p_2$, $p_3$, $p_4$, and $p_5$, not necessarily distinct, such that

$$f(S; x) = \frac{1 - x^{p_1} - x^{p_2} - x^{p_3} + x^{p_4} + x^{p_5}}{(1 - x^{a_1})(1 - x^{a_2})(1 - x^{a_3})}.$$

This interesting result was rediscovered a number of times. It was explicitly stated by M. Morales [27]; the proof was not published though. Independently, the proof was rediscovered by G. Denham [14]. Both proofs are algebraic and based on the interpretation of $f(S; x)$ as the Hilbert series of a graded ring $\mathbb{C}[t^{a_1}, t^{a_2}, t^{a_3}]$. In this special case (a Cohen–Macaulay ring of codimension 2), the Hilbert series can

be computed via the Hilbert–Burch Theorem, cf. also [18]. Meanwhile, a combinatorial proof of a somewhat weaker result (up to 12 monomials in the numerator) independently appeared in [35].

The pattern breaks down for semigroups with $d \geq 4$ generators, meaning that if we choose the denominator of $f(S; x)$ in the form $(1-x^{a_1}) \dots (1-x^{a_d})$, the number of monomials in the numerator does not remain constant for a particular value of $d$, and, moreover, grows exponentially with the input size of $a_1, \dots, a_d$. As shown in [35], for $d = 4$ the number of the monomials in the numerator can grow as fast as $\min^{1/2}\{a_1, a_2, a_3, a_4\}$, whereas the input size is only about $\log(a_1 a_2 a_3 a_4)$.

Nevertheless, the generating function $f(S; x)$ admits a short rational function representation for any number $d$ of generators fixed in advance. The following result was proved in [7].

**Theorem 4.1.** *Let us fix $d$. Then there exists a positive integer $s = s(d)$ and a polynomial time algorithm, which, given positive integers $a_1, \dots, a_d$, computes the generating function $f(S; x)$ of the semigroup*

$$S = \left\{ \sum_{i=1}^{d} \mu_i a_i \,:\, \mu_1, \dots, \mu_d \in \mathbb{Z}_+ \right\}$$

*generated by $a_1, \dots, a_d$ in the form*

$$f(S; x) = \sum_{i \in I} \alpha_i \frac{x^{p_i}}{(1 - x^{b_{i1}}) \dots (1 - x^{b_{is}})}, \tag{4.1}$$

*where $\alpha_i \in \mathbb{Q}$, $p_i, b_{ij} \in \mathbb{Z}$ and $b_{ij} \neq 0$ for all $i, j$.*

In particular, for any fixed $d$, the number $|I|$ of fractions in (4.1) is bounded by a polynomial in the input size, that is, in $\log(a_1 \dots a_d)$.

Theorem 4.1 is obtained as a corollary of a more general result that the *projection* of the set of integer points in a rational polytope of a fixed dimension admits a short rational generating function [7].

**Theorem 4.2.** *Let us fix $d$. Then there exists a number $s = s(d)$ and a polynomial time algorithm, which, given a rational polytope $P$ and a linear transformation $T : \mathbb{R}^d \longrightarrow \mathbb{R}^k$ such that $T(\mathbb{Z}^d) \subset \mathbb{Z}^k$, computes the generating function $f(S; \boldsymbol{x})$ for $S = T(P \cap \mathbb{Z}^d)$, $S \subset \mathbb{Z}^k$, in the form*

$$f(S; \boldsymbol{x}) = \sum_{i \in I} \frac{\boldsymbol{x}^{p_i}}{(1 - \boldsymbol{x}^{b_{i1}}) \dots (1 - \boldsymbol{x}^{b_{is}})}, \tag{4.2}$$

*where $\alpha_i \in \mathbb{Q}$, $p_i, b_{ij} \in \mathbb{Z}^k$ and $b_{ij} \neq 0$ for all $i, j$.*

One can observe that Theorem 4.1 is a corollary of Theorem 4.2. Indeed, let $T : \mathbb{R}^d \longrightarrow \mathbb{R}$ be the linear transformation defined by

$$T(\xi_1, \dots, \xi_d) = a_1 \xi_1 + \dots + a_d \xi_d.$$

Then the semigroup $S$ generated by $a_1, \dots, a_d$ is the image $S = T(\mathbb{Z}_+^d)$ of the set $\mathbb{Z}_+^d$ of integer points in the rational polyhedron $\mathbb{R}_+^d \subset \mathbb{R}^d$. The polyhedron $\mathbb{R}_+^d$ is unbounded, so Theorem 4.2 cannot be applied immediately. However, it is not hard to show that $S \subset \mathbb{Z}_+$ stabilizes after a while (if $a_1, \dots, a_d$ are coprime then $S$ includes all sufficiently large positive integers). Thus only the initial interval of $S$ is of interest, to get which we replace $\mathbb{R}_+^d$ by a sufficiently large simplex

$$P = \left\{(\xi_1, \dots, \xi_d) : \sum_{i=1}^{d} \xi_i \leq t \text{ and } \xi_i \geq 0 \text{ for } i = 1, \dots, d\right\},$$

see [7] for details.

We sketch the proof of Theorem 4.2 below.

Without loss of generality we assume that $\dim \ker T = d - k$. The proof then proceeds by induction on $d - k$. If $d = k$ we are in the situation of Theorem 2.2. We note that for any $k$ and $d$, if the restriction $T : P \cap \mathbb{Z}^d \longrightarrow S$ is one-to-one, we can compute the generating function $f(S; \boldsymbol{x})$ from that of the set $P \cap \mathbb{Z}^d$ using an appropriate monomial substitution, cf. Section 3.1. Otherwise, the monomial substitution will account for each point $m \in S$ with the multiplicity equal to the number of the points in $P \cap \mathbb{Z}^d$ mapped onto $m$. Thus our goal is to eliminate multiplicities.

The case of $d = k + 1$ illuminates some of the ideas used in the proof for an arbitrary $d - k$. Suppose that

$$T : \mathbb{R}^{k+1} \longrightarrow \mathbb{R}^k, \quad (\xi_1, \dots, \xi_{k+1}) \longmapsto (\xi_1, \dots, \xi_k)$$

is the projection (this is a sufficiently general case). Let $\hat{S} = P \cap \mathbb{Z}^{k+1}$ and let us consider the restriction $T : \hat{S} \longrightarrow S$. Then, for every point $m \in S$, the preimage $T^{-1}(m) \subset \hat{S}$ is the set of integer points in the interval $T^{-1}(m) \cap P$ which all agree in their first $k$ coordinates and disagree in the last coordinate. Let $e_{k+1}$ be the last basis vector and let us consider

$$Y = \hat{S} \setminus (\hat{S} + e_{k+1}).$$

In words: we subtract from $\hat{S}$ its translation by 1 in the last coordinate.

Then the restriction $T : Y \longrightarrow S$ is one-to-one since the preimage $T^{-1}(m) \subset Y$ consists of the single point in $T^{-1}(m) \subset \hat{S}$ with the smallest last coordinate. Now, $\hat{S}$ is the set of integer points in a rational polytope and we compute its generating function using Theorem 2.2. Then we compute the generating function of $Y$ using Theorem 3.1. Finally, we obtain $f(S; \boldsymbol{x})$ by substituting $x_{k+1} = 1$ in the generating function $f(Y; (\boldsymbol{x}, x_{k+1}))$, cf. Section 3.1.

Let us consider the case of general $k$ and $d$. Let $\mathrm{pr} : \mathbb{Z}^{k+1} \longrightarrow \mathbb{Z}^k$ be the natural projection, $\mathrm{pr}(\mu_1, \dots, \mu_{k+1}) = (\mu_1, \dots, \mu_k)$. Let $\hat{T} : \mathbb{Z}^d \longrightarrow \mathbb{Z}^{k+1}$ be a linear transformation which is a lifting of $T$ so that $\mathrm{pr}(\hat{T}(m)) = T(m)$ for all $m \in \mathbb{Z}^d$. We define $\hat{S} = \hat{T}(S)$, $\hat{S} \subset \mathbb{Z}^{k+1}$, and consider the restriction

$$\mathrm{pr} : \hat{S} \longrightarrow S.$$

For every $m \in S$ the preimage $\mathrm{pr}^{-1}(m) \subset \hat{S}$ consists of the points which differ in their last coordinate only. Suppose that we managed to construct $\hat{T}$ in such a way that the set $\mathrm{pr}^{-1}(m) \subset \hat{S}$ has *small gaps*, meaning that there exists a constant $l = l(d)$ such that if there are two points in $\mathrm{pr}^{-1}(m)$ whose $(k+1)$st coordinates differ by more than $l$, there must be a point in $\mathrm{pr}^{-1}(m)$ lying strictly between them.

In this case, we compute $f(S; \boldsymbol{x})$ as follows. Let us define

$$Y = \hat{S} \setminus \bigcup_{j=1}^{l} (\hat{S} + j e_{k+1}).$$

In words: we subtract from $\hat{S}$ its $l$ translates by $1, \ldots, l$ in the last coordinate. Because of the small gap property, the restriction $\mathrm{pr}: Y \longrightarrow S$ is one-to-one: now, the preimage $\mathrm{pr}^{-1}(m) \subset Y$ consists of the single point in $\mathrm{pr}^{-1}(m) \subset \hat{S}$ with the smallest last coordinate. Using the induction hypothesis, we compute the generating function of $\hat{S}$. Then, applying Theorem 3.1 $l$ times, we compute the generating function of $Y$. Finally, $f(S; \boldsymbol{x})$ is obtained from $f(Y; (\boldsymbol{x}, x_{k+1}))$ by the substitution $x_{k+1} = 1$, see Section 3.1.

In general, we cannot construct a lifting $\hat{T}$ with the small gap property but the next best thing is possible. Namely, we can construct in polynomial time a decomposition $\mathbb{R}^k = \bigcup_i Q_i$ of $\mathbb{R}^k$ into a union of non-overlapping rational polyhedra $Q_i$ such that for each piece $S_i = S \cap Q_i$ a lifting $\hat{T}_i$ with the small gap property indeed exists. The generating functions $f(S_i; \boldsymbol{x})$ are computed as above and then patched together into a single generating function $f(S; \boldsymbol{x})$. The construction of such polyhedra $Q_i$ and liftings $\hat{T}_i$ is based on the results of [21] and [20]. The main tool is the following *Flatness Theorem*, see, for example, Section 6.7 of [17] or Section VII.8 of [5].

**Theorem 4.3** (Flatness Theorem). *For each dimension $d$ there exists a constant $\omega(d)$ with the following property: if $V$ is a $d$-dimensional real vector space, $\Lambda \subset V$ is a lattice of rank $d$, $\Lambda^* \subset V^*$ is the reciprocal lattice, and $K \subset V$ is a convex compact set with non-empty interior such that $K \cap \Lambda = \emptyset$ then there is an $\ell \in \Lambda^* \setminus \{0\}$ such that*

$$\max_{x \in K} \ell(x) - \min_{x \in K} \ell(x) \leq \omega(d). \tag{4.3}$$

In words: a lattice-free convex body is flat in some lattice direction. The number in the left hand side of (4.3) is called the *width of $K$ with respect to $\ell$* and denoted $\mathrm{width}(K, \ell)$. The infimum of $\mathrm{width}(K, \ell)$ over all $\ell \in \Lambda^*$ is called the *lattice width of $K$* and denoted $\mathrm{width}(K)$. A simple and crucial observation relating the lattice width and the small gap property is that if for $\ell \in \Lambda^*$ we have $\mathrm{width}(K, \ell) \leq \gamma\, \mathrm{width}(K)$ then the gaps between the consecutive integers in the set $\ell(K \cap \Lambda)$ do not exceed $\gamma\omega(d)$.

We go back to finish the sketch of the proof of Theorem 4.2. Let $\Lambda = \mathbb{Z}^k \cap \ker(T)$ be the lattice in $\ker(T)$. For $y \in \mathbb{R}^d$, let $P_y = P \cap T^{-1}(x)$ be the fiber of the polytope $P$ over $x$. We will measure the lattice width of $P_y$ with respect to $\Lambda$. The results of [21]

and [20] allow us to construct a polyhedral decomposition $\mathbb{R}^k = \bigcup_i Q_i$ and vectors $\ell_i \in \Lambda^*$ such that for all $y \in Q_i$ we have either $\text{width}(P_y, \ell_i) \leq 2\,\text{width}(P_y)$ or $\text{width}(P_y, \ell_i) \leq 1$. We then define

$$\hat{T}_i(x) = (T(x), \ell_i(x)) \quad \text{if } T(x) \in Q_i.$$

This completes the sketch of proof of Theorem 4.2.

**4.2. Applications.** Theorem 4.1 implies polynomial time solvability of a variety of problems about integer semigroups. Suppose that the generators $a_1, \ldots, a_d$ are coprime. As is known, all sufficiently large integers lie in the semigroup $S$ generated by $a_1, \ldots, a_d$. In the situation when the number $d$ of generators is fixed, R. Kannan [20] constructed a polynomial time algorithm to compute the largest integer not in $S$. Theorem 4.1 implies that one can compute in polynomial time the number of positive integers not in $S$, the number of integers in $S$ belonging to a particular interval, etc.

Unlike the algorithm of Theorem 2.2, the algorithms of Theorems 4.1 and 4.2 seem to be unimplementable at the moment. Indeed, the way Theorem 4.2 is proved gives $s = d^{\Omega(d)}$ at best and, similarly, in Theorem 4.1. It is not clear at the moment whether a smaller value of $s$ is possible.

In Theorem 4.1, apart from $d = 1, 2, 3$, the value of $d = 4$ seems to indicate a possibility of a "special treatment". The approach of [33] combined with the continued fraction method, see Section 2.1, may lead to a practically efficient algorithm to compute $f(S; x)$.

Theorem 4.2 implies that some other interesting sets admit short rational generating functions. One class of such sets consists of the Hilbert bases of rational cones. Let $K \subset \mathbb{R}^d$ be a pointed rational cone. The set $S \subset K \cap \mathbb{Z}^d$, $0 \notin S$, is called the (minimal) *Hilbert basis* of the semigroup $K \cap \mathbb{Z}^d$ if every point in $K \cap \mathbb{Z}^d$ can be represented as a sum of some points in $S$ and if no point in $S$ is a sum of other points in $S$. In other words, $S$ consists of the points in $K \cap \mathbb{Z}^d$ that cannot be written as a sum of non-zero points in $K \cap \mathbb{Z}^d$. Theorem 4.2 implies that as long as the dimension $d$ remains fixed, given a rational cone $K$, the generating function $f(S; \boldsymbol{x})$ can be computed in polynomial time as a short rational function of the type (3.1). Consequently, the number $|S|$ of points in the Hilbert basis of $K \cap \mathbb{Z}^d$ can be computed in polynomial time.

To deduce this result from Theorem 4.2, let $Q \subset K$ be a rational polyhedron containing all integer points in $K$ except 0 (to get $Q$ from $K$, we cut the vertex of $K$ by a hyperplane), let $P = Q \times Q \subset \mathbb{R}^d \oplus \mathbb{R}^d = \mathbb{R}^{2d}$ and let $T$ be the projection $P \longmapsto K$, $T(x, y) = x + y$. Then the Hilbert basis $S$ is the complement in $Q \cap \mathbb{Z}^d$ of the image $T(P \cap \mathbb{Z}^{2d})$. The obstacle that the polyhedron $Q$ is not bounded, so Theorem 4.2 cannot be applied immediately, can be easily fixed since only the "initial part" of the semigroup $K \cap \mathbb{Z}^d$ is of interest, see [7].

Another class of sets allowing short rational generating functions via Theorem 4.2 are the *test sets* in integer programming, see [30].

It should be noted that the short rational function description provides only very general characterization of the set. For example, many of the fine properties of test sets [30] do not seem to be picked up by rational generating functions and some empirically observed phenomena are still waiting for their explanation. For structural results (without complexity estimates) regarding $f(S; \boldsymbol{x})$, where $S$ is the projection of the set of integer points in a rational polyhedron, see [24].

## 5. Beyond projections: Presburger arithmetic

Let us consider formulas we can construct by using integer variables, operations of addition, subtraction, and multiplication by an integer constant (but not multiplication of two integer variables), comparison ($<$, $>$, $=$), Boolean operations ("and", "or", "not"), and quantifiers ($\forall$, $\exists$). The realm of such formulas is *Presburger arithmetic*. Thus the set $P \cap \mathbb{Z}^d$ of integer points in a rational polyhedron can be described by a quantifier-free formula of Presburger arithmetic: the set $P \cap \mathbb{Z}^d$ consists of the $d$-tuples of integer variables that satisfy a number of linear constraints with constant integer coefficients. Similarly, the projection $T(P \cap \mathbb{Z}^d)$ of the set of integer points in a polyhedron is described by a formula of Presburger arithmetic with existential quantifiers only (no quantifier alternations).

With a little work, Theorem 2.2 can be extended as follows. Let us fix the number $d$ of variables. Then there exists a polynomial time algorithm, which, given a quantifier-free formula $F$ of Presburger arithmetic, computes the generating function $f(S; \boldsymbol{x})$ of the set $S \subset \mathbb{Z}^d$ defined by $F$ as a rational function (2.3). Some routine precautions regarding convergence of the series defining $f(S; \boldsymbol{x})$, if $S$ is infinite, should be taken. The general case of a set defined by a quantifier-free formula $F$ reduces to that of the set integer points in a rational polyhedron by some more or less straightforward "cutting and pasting" of polyhedra. Since the dimension $d$ of the ambient space is fixed, this cutting and pasting can be performed in polynomial time.

Theorem 4.2 can be extended as follows. Let us fix the number of variables *and* the number of Boolean operations used. Then there exists a polynomial time algorithm, which, given a formula $F$ of Presburger arithmetic without quantifier alternations, computes the generating function $f(S; \boldsymbol{x})$ of the finite set $S \subset \mathbb{Z}^k$ defined by $F$ as a rational function (4.2). Note that here we have to fix not only the number of variables but also the number of Boolean operations. For example, unless $\mathbf{P} = \mathbf{NP}$ one cannot hope to compute the generating function of the projection of the set of integer points in a union of rational polytopes if the number of polytopes is allowed to vary, cf. Section 5.3 of [37] and [31].

One can ask whether the results can be extended even further. Let us fix the number of variables and the number of Boolean operations, making numerical constants essentially the only parameters of the formula. Is there a polynomial time algorithm which computes the generating function (3.1) of the (finite) set $S$ of points described by such a formula? This indeed seems very plausible, see the discussion in Chapter V

of [37]. Intuitively, such sets should have some "hidden periodicity" and short rational generating functions should reveal that periodicity. Besides, it seems hard to prove that a particular finite, but large, set $S \subset \mathbb{Z}^d$ does not admit a short rational generating function: if a particular candidate expression for $f(S; \boldsymbol{x})$ is not short, one can argue that we have not searched hard enough and that there is another, better candidate.

We mention that the result of R. Kannan [19] establishes polynomial time solvability of decision problems for formulas with not more than one quantifier alternation. If the number of variables is not fixed, the complexity of decision problems in Presburger arithmetic is double exponential by the result of M. Fischer and M. Rabin [15].

## 6. Concluding remarks

One can ask whether some of the technique discussed in this paper can be extended to lattice points satisfying some non-linear constraints. The answer seems to be "no". For example, lattice points in the standard Euclidean ball exhibit phenomena explained not by rational but rather by theta functions. Let

$$B_n = \{(\xi_1, \xi_2, \xi_3, \xi_4) : \ \xi_1^2 + \xi_2^2 + \xi_3^2 + \xi_4^2 \leq n\}$$

be the Euclidean ball of radius equal to $\sqrt{n}$. Jacobi's formula asserts that the number $|B_n \cap \mathbb{Z}^4| - |B_{n-1} \cap \mathbb{Z}^4|$ of integer points on the sphere of radius $\sqrt{n}$ is equal to

$$8 \sum_{4 \nmid r \mid n} r$$

(in words: eight times the sum of divisors of $n$ that are not divisible by four). One can then show ([1]) that if one can count points in a 4-dimensional ball efficiently (in polynomial time), one can factor integers efficiently (in randomized polynomial time).

We note also that lattice points in *irrational* polyhedra exhibit a very interesting behavior, see [32].

**6.1. Large dimensions.** Almost everywhere in this paper we assumed that the dimension $d$ of the ambient space is fixed in advance. But what if the dimension is allowed to grow? Given a rational polyhedron $P \subset \mathbb{R}^d$, it is an NP-hard problem to determine whether $P \cap \mathbb{Z}^d = \emptyset$ (even when $P$ is a rational simplex). Thus there is little hope to compute the generating function $f(P, \boldsymbol{x})$ in polynomial time. However, it appears that some interesting "residues" or "shadows" of $f(P, \boldsymbol{x})$ can be efficiently computed even when the dimension $d$ is allowed to grow, cf. [10] and [6].

The number $e(P) = |P \cap \mathbb{Z}^d|$ of integer points in a rational polyhedron is an example of a lattice invariant *valuation*, see [26]. That is, the map $P \longmapsto e(P)$ extends to a linear functional on the space spanned by the indicators $[P]$ of rational polyhedra, cf. Definition 2.3, and the linear functional is invariant under lattice shifts:

$e(P) = e(P+u)$, $u \in \mathbb{Z}^d$. One can ask if there is another lattice invariant valuation $\nu$ on rational polytopes which is efficiently computable in interesting cases and which, in some sense, approximates the counting valuation $e(P)$. For example, the volume vol $P$ may serve as the "0th" approximation to $e(P)$.

With every lattice invariant valuation $\nu$ one can associate the expression

$$\nu(nP) = \sum_{i=0}^{d} \nu_i(P; n) n^i, \tag{6.1}$$

where $nP$ is a dilation of $P$ by an integer factor $n$ and the coefficients $\nu_i(P; n)$ are quasi-periodic: $\nu_i(P; n + t) = \nu_i(P; n)$ provided $tP$ is a polytope with integer vertices, cf. [26]. In the case of the counting valuation $e$, the expression (6.1) is called the *Ehrhart quasi-polynomial* of $P$ and $e_d(P; n) = \text{vol}\, P$. As the $k$th approximation to the counting valuation $e$ we consider a lattice invariant valuation $\nu$ which agrees with $e$ in the $k+1$ highest terms:

$$\nu_i(P; n) = e_i(P; n) \quad \text{for} \quad i = d, d-1, \ldots, d-k.$$

A natural goal is to construct such a valuation $\nu$, which is computable in polynomial time (at least, in some interesting cases) for any $k$ fixed in advance.

Abstractly speaking, to define the counting valuation $e$, we have to choose a finite-dimensional real vector space $V$ and a lattice $\Lambda \subset V$. Then we define $e(P) = |P \cap \Lambda|$ for every polytope $P \subset V$ such that the vertices of $tP$ belong to $\Lambda$ for some integer $t$. Apparently, to make a canonical choice of $\nu$, we have to fix some additional structure in $V$. In [6] a canonical valuation $\nu$ is constructed for rational polytopes whose facets are parallel to hyperplanes from a given finite collection of hyperplanes. Valuation $\nu$ agrees with $e$ in the $k+1$ highest terms and for any fixed $k$ valuation $\nu$ is polynomially computable on polytopes with the number facets exceeding the dimension $d$ by not more than a constant fixed in advance (in particular, on rational simplices). In [10] a different canonical valuation $\mu$ is constructed provided a scalar product on $V$ is chosen. Valuation $\mu$ also agrees with $e$ on the $k+1$ highest terms and polynomially computable on the same class of polytopes.

# Rational and algebraic series in combinatorial enumeration

Mireille Bousquet-Mélou

**Abstract.** Let $\mathcal{A}$ be a class of objects, equipped with an integer size such that for all $n$ the number $a_n$ of objects of size $n$ is finite. We are interested in the case where the generating function $\sum_n a_n t^n$ is rational, or more generally algebraic. This property has a practical interest, since one can usually say a lot on the numbers $a_n$, but also a combinatorial one: the rational or algebraic nature of the generating function suggests that the objects have a (possibly hidden) structure, similar to the *linear structure* of words in the rational case, and to the *branching structure* of trees in the algebraic case. We describe and illustrate this combinatorial intuition, and discuss its validity. While it seems to be satisfactory in the rational case, it is probably incomplete in the algebraic one. We conclude with open questions.

**Keywords.** Enumerative combinatorics, generating functions, rational and algebraic power series, formal languages.

## 1. Introduction

The general topic of this paper is the enumeration of discrete objects (words, trees, graphs,…) and more specifically the *rational* or *algebraic* nature of the associated generating functions. Let $\mathcal{A}$ be a class of discrete objects equipped with a size:

$$\begin{array}{rccc} \text{size}: & \mathcal{A} & \to & \mathbb{N} \\ & A & \mapsto & |A|. \end{array}$$

Assume that for all $n$, the number $a_n$ of objects of size $n$ is finite. The *generating function of the objects of* $\mathcal{A}$, *counted by their size*, is the following formal power series in the indeterminate $t$:

$$A(t) := \sum_{n\geq 0} a_n t^n = \sum_{A\in\mathcal{A}} t^{|A|}. \tag{1}$$

To take a very simple example, if $\mathcal{A}$ is the set of words on the alphabet $\{a, b\}$ and the size of a word is its number of letters, then the generating function is $\sum_{n\geq 0} 2^n t^n = 1/(1-2t)$.

Generating functions provide both a tool for solving counting problems, and a concise way to encode their solution. Ideally, one would probably dream of finding a closed formula for the numbers $a_n$. But the world of mathematical objects would be extremely poor if this was always possible. In practise, one is usually happy with an

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

expression of the generating function $A(t)$, or even with a recurrence relation defining the sequence $a_n$, or a functional equation defining $A(t)$.

Enumerative problems arise spontaneously in various fields of mathematics, computer science, and physics. Among the most generous suppliers of such problems, let us cite discrete probability theory, the analysis of the complexity of algorithms [56], [44], and the discrete models of statistical physics, like the famous Ising model [5]. More generally, counting the objects that occur in one's work seems to answer a natural curiosity. It helps to understand the objects, for instance to appreciate how restrictive are the conditions that define them. It also forces us to get some understanding of the *structure* of the objects: an enumerative result never comes for free, but only after one has elucidated, at least partly, what the objects really are.

We focus in this survey on objects having a rational, or, more generally, algebraic generating function. Rational and algebraic formal power series are well-behaved objects with many interesting properties. This is one of the reasons why several classical textbooks on enumeration devote one or several chapters to these series [43], [74], [75]. These chapters give typical examples of objects with a rational [resp. algebraic] generating function (GF). After a while, the collection of these examples builds up a general picture: one starts thinking that yes, all these objects have something in common in their structure. At the same time arises the following question: do all objects with a rational [algebraic] GF look like that? In other words, what does it mean, what does it suggest about the objects when they are counted by a rational [algebraic] GF?

This question is at the heart of this survey. For each of the two classes of series under consideration, we first present a general family of enumerative problems whose solution falls invariably in this class. These problems are simple to describe: the first one deals with walks in a directed graph, the other with plane trees. Interestingly, these families of objects admit alternative descriptions in language theoretic terms: they correspond to *regular languages*, and to *unambiguous context-free languages*, respectively. The words of these languages have a clear recursive structure, which explains directly the rationality [algebraicity] of their GF.

The series counting words of a regular [unambiguous context-free] language are called $\mathbb{N}$-*rational* [$\mathbb{N}$-*algebraic*]. It is worth noting that a rational [algebraic] series with non-negative coefficients is not necessarily $\mathbb{N}$-rational [$\mathbb{N}$-algebraic]. Since we want to appreciate whether our two generic classes of objects are good representatives of objects with a rational [algebraic] GF, the first question to address is the following: do we always fall in the class of $\mathbb{N}$-rational [$\mathbb{N}$-algebraic] series when we count objects with a rational [algebraic] GF? More informally, do these objects exhibit a structure similar to the structure of regular [context-free] languages? Is such a structure usually clearly visible? That is to say, is it easy to feel, to predict rationality [algebraicity]?

We shall see that the answer to all these questions tends to be *yes* in the rational case (with a few warnings...) but is probably *no* in the algebraic case. In particular, the rich world of *planar maps* (planar graphs embedded in the sphere) abounds in candidates for non-$\mathbb{N}$-algebraicity. The algebraicity of the associated GFs has been

known for more than 40 years (at least for some families of maps), but it is only in the past 10 years that a general combinatorial explanation of this algebraicity has emerged. Moreover, the underlying constructions are more general that those allowed in context-free descriptions, as they involve taking *complements*.

Each of the main two sections ends with a list of questions. In particular, we present at the end of Section 3 several counting problems that are simple to state and have an algebraic GF, but for reasons that remain mysterious.

The paper is sometimes written in an informal style. We hope that this will not stop the reader. We have tried to give precise references where he/she will find more details and more material on the topics we discuss. In particular, this survey borrows a lot to two books that we warmly recommend: Stanley's *Enumerative Combinatorics* [74], [75], and Flajolet & Sedgewick's *Analytic Combinatorics* [43].

**Notation and definitions.** Given a (commutative) ring $R$, we denote by $R[t]$ the ring of polynomials in $t$ having coefficients in $R$. A *Laurent series* in $t$ is a series of the form $A(t) = \sum_{n \geq n_0} a_n t^n$, with $n_0 \in \mathbb{Z}$ and $a_n \in R$ for all $n$. If $n_0 \geq 0$, we say that $A(t)$ is a *formal power series*. The coefficient of $t^n$ is denoted $a_n := [t^n]A(t)$. The set of Laurent series forms a ring, and even a field if $R$ is a field. The *quasi-inverse* of $A(t)$ is the series $A^*(t) := 1/(1 - A(t))$. If $A(t)$ is a formal power series with constant term 0, then $A^*(t)$ is a formal power series too.

In most occasions, the series we consider are GFs of the form (1) and thus have rational coefficients. However, we sometimes consider refined enumeration problems, in which every object $A$ is *weighted*, usually by a monomial $w(A)$ in some additional indeterminates $x_1, \ldots, x_m$. The weighted GF is then $\sum_{A \in \mathcal{A}} w(A) t^{|A|}$, so that the coefficient ring is $\mathbb{Q}[x_1, \ldots, x_m]$ rather than $\mathbb{Q}$.

We denote $[\![k]\!] = \{1, 2, \ldots, k\}$. We use the standard notation $\mathbb{N}$, $\mathbb{Z}$, $\mathbb{Q}$, and $\mathbb{P} := \{1, 2, 3, \ldots\}$.

## 2. Rational generating functions

**2.1. Definitions and properties.** The Laurent series $A(t)$ with coefficients in the field $R$ is said to be *rational* if it can be written in the form

$$A(t) = \frac{P(t)}{Q(t)}$$

where $P(t)$ and $Q(t)$ belong to $R[t]$.

There is probably no need to spend a lot of time explaining why such series are simple and well-behaved. We refer to [74, Ch. 4] and [43, Ch. IV] for a survey of their properties. Let us review briefly some of them, in the case where $R = \mathbb{Q}$. The set of (Laurent) rational series is closed under sum, product, derivation, reciprocals – but *not under integration* as shown by $A(t) = 1/(1 - t)$. The coefficients $a_n$ of a rational series $A(t)$ satisfy a linear recurrence relation with constant coefficients:

for $n$ large enough,

$$a_n = c_1 a_{n-1} + c_2 a_{n-2} + \cdots + c_k a_{n-k}.$$

The partial fraction expansion of $A(t)$ provides a closed form expression of these coefficients of the form:

$$a_n = \sum_{i=0}^{k} P_i(n)\mu_i^n \tag{2}$$

where the $\mu_i$ are the reciprocals of the roots of the denominator $Q(t)$, and the $P_i$ are polynomials. In particular, if $A(t)$ has non-negative integer coefficients, its radius of convergence $\rho$ is one its the poles (Pringsheim) and the "typical" asymptotic behaviour of $a_n$ is

$$a_n \sim \kappa \rho^{-n} n^d \tag{3}$$

where $d \in \mathbb{N}$ and $\kappa$ is an algebraic number. The above statement has to be taken with a grain of salt: *all* poles of minimal modulus may actually contribute to the dominant term in the asymptotic expansion of $a_n$, as indicated by (2).

Let us add that Padé approximants allow us to *guess* whether a generating function whose first coefficients are known is likely to be rational. For instance, given the 10 first coefficients of the series

$$A(t) = t + 2\,t^2 + 6\,t^3 + 19\,t^4 + 61\,t^5 + 196\,t^6 + 629\,t^7 + 2017\,t^8 + 6466\,t^9 + 20727\,t^{10} + O(t^{11}),$$

it is easy to conjecture that actually

$$A(t) = \frac{t\,(1-t)^3}{1 - 5\,t + 7\,t^2 - 4\,t^3}.$$

Padé approximants are implemented in most computer algebra packages. For instance, the relevant MAPLE command is `convert/ratpoly`.

**2.2. Walks on a digraph.** We now introduce our typical "rational" objects. Let $G = (V, E)$ be a directed graph with (finite) vertex set $V = [\![p]\!]$ and (directed) edge set $E \subset V \times V$. A *walk of length* $n$ on $G$ is a sequence of vertices $w = (v_0, v_1, \ldots, v_n)$ such that for all $i$, the pair $(v_i, v_{i+1})$ is an edge. Such a walk *goes from* $v_0$ *to* $v_n$. We denote $|w| = n$. Now assign to each directed edge $e$ a weight (an indeterminate) $x_e$. Define the weight $x_w$ of the walk $w$ as the product of the weights of the edges it visits: more precisely,

$$x_w = \prod_{i=0}^{n-1} x_{(v_i, v_{i+1})}.$$

See Figure 1 (a) for an example. Let $X$ denote the (weighted) adjacency matrix of $G$: for $i$ and $j$ in $[\![p]\!]$, the entry $X_{i,j}$ is $x_e$ if $(i, j) = e$ is an edge of $G$ and 0 otherwise.

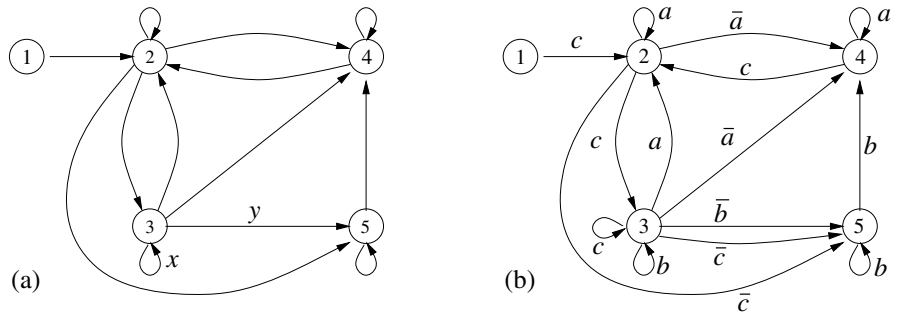

Figure 1. (a) A weighted digraph. The default value of the weight is 1. (b) A deterministic automaton on the alphabet $\{a, b, c, \bar{a}, \bar{b}, \bar{c}\}$. The initial state is 1 and the final states are 2 and 3.

Let $W_{i,j}(t)$ be the weighted generating function of walks going from $i$ to $j$:

$$W_{i,j}(t) = \sum_{w:\, i \rightsquigarrow j} x_w t^{|w|}.$$

It is well-known, and easy to prove, that $W_{i,j}$ is a rational function in $t$ with coefficients in $\mathbb{Q}[x_e, e \in E]$ (see [74, Thm. 4.7.1]).

**Theorem 2.1.** *The series $W_{i,j}(t)$ is the $(i, j)$-entry in the matrix $(1 - tX)^{-1}$.*

This theorem reduces the enumeration of walks on a digraph to the calculation of the inverse of a matrix with polynomial coefficients. It seems to be little known in the combinatorics community that this inverse matrix can be computed by studying the elementary cycles of the digraph $G$. This practical tool relies on Viennot's theory of *heaps of pieces* [81]. Since it is little known, and often convenient, let us advertise it here. It will be illustrated further down.

An *elementary cycle* of $G$ is a closed walk $w = (v_0, v_1, \ldots, v_{n-1}, v_0)$ such that $v_0, \ldots, v_{n-1}$ are distinct. It is defined up to a cyclic permutation of the $v_i$. That is, $(v_1, v_2, \ldots, v_{n-1}, v_0, v_1)$ is the same cycle as $w$. A collection $\gamma = \{\gamma_1, \ldots, \gamma_r\}$ of (elementary) cycles is *non-intersecting* if the $\gamma_i$ are pairwise disjoint. The weight $x_\gamma$ of $\gamma$ is the product of the weights of the $\gamma_i$. We denote $|\gamma| = \sum |\gamma_i|$.

**Proposition 2.2** ([81]). *The generating function of walks going from $i$ to $j$ reads*

$$W_{i,j}(t) = \frac{N_{i,j}}{D},$$

*where*

$$D = \sum_{\gamma = \{\gamma_1, \ldots, \gamma_r\}} (-1)^r x_\gamma t^{|\gamma|} \quad \text{and} \quad N_{i,j} = \sum_{w; \gamma = \{\gamma_1, \ldots, \gamma_r\}} (-1)^r x_w x_\gamma t^{|w|+|\gamma|}.$$

*The polynomial $D$ is the alternating generating function of non-intersecting collections of cycles. In the expression of $N$, $\gamma$ a non-intersecting collection of cycles and $w$ a self-avoiding walk going from $i$ to $j$, disjoint from the cycles of $\gamma$.*

To illustrate this result, let us determine the generating function of walks going from 1 to 2 and from 1 to 3 on the digraph of Figure 1 (a). This graph contains 4 cycles of length 1, 2 cycles of length 2, 2 cycles of length 3 and 1 cycle of length 4. By forming all non-intersecting collections of cycles, one finds:

$$\begin{aligned} D(t) &= 1-(3+x)t+(3+3x-2)t^2+(-1-3x+3+x-2)t^3+(x-1-x+1+x-y)t^4 \\ &= 1-(3+x)t+(1+3x)t^2-2xt^3+(x-y)t^4. \end{aligned}$$

There is only one self-avoiding walk (SAW) going from 1 to 2, and one SAW going from 1 to 3 (via the vertex 2). The collections of cycles that do not intersect these walks are formed of loops, which gives

$$N_{1,2} = t(1-t)^2(1-xt) \quad \text{and} \quad N_{1,3} = t^2(1-t)^2.$$

Hence the generating function of walks that start from 1 and end at 2 or 3 is:

$$W_{1,2}+W_{1,3} = \frac{N_{1,2}+N_{1,3}}{D} = \frac{t(1-t)^2(1+t-xt)}{1-(3+x)t+(1+3x)t^2-2xt^3+(x-y)t^4}. \quad (4)$$

**2.3. Regular languages and automata.** There is a very close connection between the collection of walks on a digraph and the words of *regular languages*. Let $\mathcal{A}$ be an *alphabet*, that is, a finite set of symbols (called *letters*). A *word* on $\mathcal{A}$ is a sequence $u = u_1u_2\dots u_n$ of letters. The number of occurrences of the letter $a$ in the word $u$ is denoted $|u|_a$. The *product* of two words $u_1u_2\dots u_n$ and $v_1v_2\dots v_m$ is the concatenation $u_1u_2\dots u_nv_1v_2\dots v_m$. The empty word is denoted $\varepsilon$. A *language* on $\mathcal{A}$ is a set of words. We define two operations on languages:

- the product $\mathcal{L}\mathcal{K}$ of two languages $\mathcal{L}$ and $\mathcal{K}$ is the set of words $uv$, with $u \in \mathcal{L}$ and $v \in \mathcal{K}$; this product is easily seen to be associative,
- the star $\mathcal{L}^*$ of the language $\mathcal{L}$ is the union of all languages $\mathcal{L}^k$, for $k \geq 0$. By convention, $\mathcal{L}^0$ is reduced to the empty word $\varepsilon$.

A *finite state automaton* on $\mathcal{A}$ is a digraph $(V, E)$ *with possibly multiple edges*, together with:

– a labelling of the edges by letters of $\mathcal{A}$, that is to say, a function $L: E \to \mathcal{A}$,

– an initial vertex $i$,

– a set $V_f \subset V$ of final vertices.

The vertices are usually called the *states* of the automaton. The automaton is *deterministic* if for every state $v$ and every letter $a$, there is at most one edge labelled $a$ starting from $v$.

To every walk on the underlying multigraph, one associates a word on the alphabet $\mathcal{A}$ by reading the letters met along the walk. The language $\mathcal{L}$ *recognized* by the automaton is the set of words associated with walks going from the initial state $i$ to

one of the states of $V_f$. For $j \in V$, let $\mathcal{L}_j$ denote the set of words associated with walks going from $i$ to $j$. These sets admit a recursive description. For the automaton of Figure 1 (b), one has $\mathcal{L} = \mathcal{L}_2 \cup \mathcal{L}_3$ with

$$\begin{aligned}
&\mathcal{L}_1 = \{\varepsilon\},\\
&\mathcal{L}_2 = \mathcal{L}_1 c \cup \mathcal{L}_2 a \cup \mathcal{L}_3 a \cup \mathcal{L}_4 c, \quad \mathcal{L}_4 = \mathcal{L}_2 \bar{a} \cup \mathcal{L}_3 \bar{a} \cup \mathcal{L}_4 a \cup \mathcal{L}_5 b,\\
&\mathcal{L}_3 = \mathcal{L}_2 c \cup \mathcal{L}_3 b \cup \mathcal{L}_3 c, \qquad\qquad \mathcal{L}_5 = \mathcal{L}_2 \bar{c} \cup \mathcal{L}_3 \bar{b} \cup \mathcal{L}_3 \bar{c} \cup \mathcal{L}_5 b.
\end{aligned}$$

Remarkably, there also exists a non-recursive combinatorial description of the languages that are recognized by an automaton [52, Thms. 3.3 and 3.10].

**Theorem 2.3.** *Let $\mathcal{L}$ be a language on the alphabet $\mathcal{A}$. There exists a finite state automaton that recognizes $\mathcal{L}$ if and only if $\mathcal{L}$ can be expressed in terms of finite languages on $\mathcal{A}$, using a finite number of unions, products and stars of languages.*

*If these conditions hold, $\mathcal{L}$ is said to be* regular. *Moreover, there exists a* deterministic *automaton that recognizes $\mathcal{L}$.*

**Regular languages and walks on digraphs.** Take a deterministic automaton, and associate with it a weighted digraph as follows: the vertices are those of the automaton, and for all vertices $j$ and $k$, if $m$ edges go from $j$ to $k$ in the automaton, they are replaced by a *single* edge labelled $m$ in the digraph. For instance, the automaton of Figure 1 (b) gives the digraph to its left, with $x = y = 2$. Clearly, the length GF of words of $\mathcal{L}$ is the GF of (weighted) walks of this digraph going from the initial vertex $i$ to one of the final vertices of $V_f$. For instance, according to (4), the length GF of the language recognized by the automaton of Figure 1 (b) is

$$A(t) = \frac{t\,(1-t)^3}{1 - 5\,t + 7\,t^2 - 4\,t^3}. \tag{5}$$

Take a regular language $\mathcal{L}$ recognized by a deterministic automaton $\mathcal{A}$. There exists another deterministic automaton that recognizes $\mathcal{L}$ and does not contain multiple edges. The key is to create a state $(j, a)$ for every edge labelled $a$ ending at $j$ in the automaton $\mathcal{A}$. The digraph associated with this new automaton has all its edges labelled 1, so that there exists a length preserving bijection between the words of $\mathcal{L}$ and the walks on the digraph going from a specified initial vertex $v_0$ to one of the vertices of a given subset $V_f$ of vertices.

Conversely, starting from a digraph with all edges labelled 1, together with a specified vertex $v_0$ and a set $V_f$ of final vertices, it is easy to construct a regular language that is in bijection with the walks of the graph going from $v_0$ to $V_f$ (consider the automaton obtained by labelling all edges with distinct letters). This shows that *counting words of regular languages is completely equivalent to counting walks in digraphs.* In particular, the set of rational series obtained in both types of problems coincide, and have even been given a name:

**Definition 2.4.** A series $A(t) = \sum_{n\geq 0} a_n t^n$ with coefficients in $\mathbb{N}$ is said to be $\mathbb{N}$-*rational* if there exists a regular language having generating function $A(t) - a_0$.

The description of regular languages given by Theorem 2.3 implies that the set of $\mathbb{N}$-rational series contains the smallest set of series containing $\mathbb{N}[t]$ and closed under sum, product and quasi-inverse. The converse is true [71, Thm. II.5.1]. There exists a simple way to decide whether a given rational series with coefficients in $\mathbb{N}$ is $\mathbb{N}$-rational [71, Thms. II.10.2 and II.10.5].

**Theorem 2.5.** *A series $A(t) = \sum_{n\geq 0} a_n t^n$ with coefficients in $\mathbb{N}$ is $\mathbb{N}$-rational if and only if there exists a positive integer $p$ such that for all $r \in \{0, \dots, p\}$, the series*

$$A_{r,p}(t) := \sum_{n\geq 0} a_{np+r} t^n$$

*has a unique singularity of minimal modulus* (*called* dominant).

There exist rational series with non-negative integer coefficients that are *not* $\mathbb{N}$-rational. For instance, let $\alpha$ be such that $\cos\alpha = 3/5$ and $\sin\alpha = 4/5$, and define $a_n = 25^n \cos(n\alpha)^2$. It is not hard to see that $a_n$ is a non-negative integer. The associated series $A(t)$ reads

$$A(t) = \frac{1 - 2t + 225t^2}{(1 - 25t)(625t^2 + 14t + 1)}.$$

It has 3 distinct dominant poles. As $\alpha$ is not a rational multiple of $\pi$, the same holds for all series $A_{0,p}(t)$, for all values of $p$. Thus $A(t)$ is not $\mathbb{N}$-rational.

**2.4. The combinatorial intuition of rational generating functions.** We have described two families of combinatorial objects that naturally yield rational generating functions: walks in a digraph and words of regular languages. We have, moreover, shown that the enumeration of these objects are equivalent problems. It seems that these families convey the "right" intuition about objects with a rational GF. By this, we mean informally that:

(i) "every" family of objects with a rational GF has actually an $\mathbb{N}$-rational GF,

(ii) for almost all families of combinatorial objects with a rational GF, it is easy to foresee that there will be a bijection between these objects and words of a regular language.

Point (ii) means that most of these families $\mathcal{F}$ have a clear *automatic structure*, similar to the automatic structure of regular languages: roughly speaking, the objects of $\mathcal{F}$ can be constructed recursively using unions of sets and concatenation of *cells* (replacing letters). A more formal definition would simply paraphrase the definition of automata.

Point (i) means simply that I have never met a counting problem that would yield a rational, but not $\mathbb{N}$-rational GF. This includes problems coming from algebra, like growth functions of groups. On the contrary, Point (ii) only concerns purely combinatorial problems (but I do not want to be asked about the border between

combinatorics and algebra). It admits very few counter-examples. Some will be discussed in Section 2.5. For the moment, let us illustrate the two above statements by describing the automatic structure of certain classes of objects (some being rather general), borrowed from [74, Ch. 4].

**2.4.1. Column-convex polyominoes.** A *polyomino* is a finite union of cells of the square lattice, whose interior is connected. Polyominoes are considered up to a translation. A polyomino is *column-convex* (cc) if its intersection with every vertical line is connected. Let $a_n$ be the number of cc-polyominoes having $n$ cells, and let $A(t)$ be the associated generating function. We claim that these polyominoes have an automatic structure.

Consider a cc-polyomino $P$ having $n$ cells. Let us number these cells from 1 to $n$ as illustrated in Figure 2. The columns are visited from left to right. In the first column, cells are numbered from bottom to top. In each of the other columns, the lowest cell that has a left neighbour gets the smallest number; then the cells lying

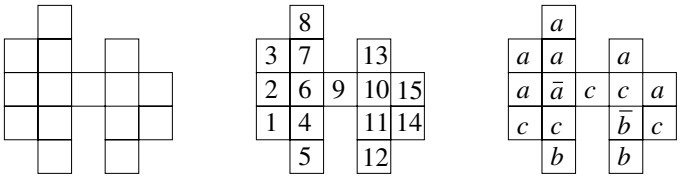

Figure 2. A column-convex polyomino, with the numbering and encoding of the cells.

below it are numbered from top to bottom, and finally the cells lying above it are numbered from bottom to top. Note that for all $i$, the cells labelled $1, 2, \ldots, i$ form a cc-polyomino. This will be essential in our description of the automatic structure of these objects. Associate with $P$ the word $u = u_1 \ldots u_n$ on the alphabet $\{a, b, c\}$ defined by

– $u_i = c$ (like Column) if the $i$th cell is the first to be visited in its column,

– $u_i = b$ (like Below) if the $i$th cell lies below the first visited cell of its column,

– $u_i = a$ (like Above) if the $i$th cell lies above the first visited cell of its column.

Then, add a bar on the letter $u_i$ if the $i$th cell of $P$ has a South neighbour, an East neighbour, but no South-East neighbour. (In other words, the barred letters indicate where to start a new column, when the bottommost cell of this new column lies above the bottommost cell of the previous column.) This gives a word $v$ on the alphabet $\{a, b, c, \bar{a}, \bar{b}, \bar{c}\}$. It is not hard to see that the map that sends $P$ on the word $v$ is a size-preserving bijection between cc-polyominoes and words recognized by the automaton of Figure 1 (b). Hence by (5), the generating function of column-convex polyominoes is [76]:

$$A(t) = \frac{t\,(1-t)^3}{1 - 5\,t + 7\,t^2 - 4\,t^3}.$$

**2.4.2. *P*-partitions.** A *partition* of the integer $n$ into at most $k$ parts is a non-decreasing $k$-tuple $\lambda = (\lambda_1, \dots, \lambda_k)$ of nonnegative integers that sum to $n$. This classical number-theoretic notion is generalized by the notion of *P-partitions*. Let $P$ be a *natural* partial order on $[\![k]\!]$ (by *natural* we mean that if $i < j$ in $P$, then $i < j$ in $\mathbb{N}$). A *$P$-partition* of $n$ is a $k$-tuple $\lambda = (\lambda_1, \dots, \lambda_k)$ of nonnegative integers that sum to $n$ and satisfy $\lambda_i \leq \lambda_j$ if $i \leq j$ in $P$. Thus when $P$ is the natural total order on $[\![k]\!]$, a $P$-partition is simply a partition[1].

We are interested in the following series:

$$F_P(t) = \sum_{\lambda} t^{|\lambda|},$$

where the sum runs over all $P$-partitions and $|\lambda| = \lambda_1 + \cdots + \lambda_k$ is the *weight* of $\lambda$.

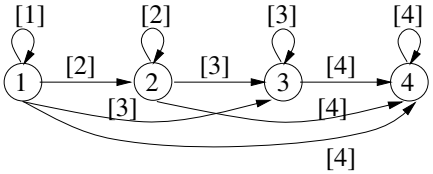
The case of ordinary partitions is easy to analyze: every partition can be written in a unique way as a linear combination

$$c_1\lambda^{(1)} + \cdots + c_k\lambda^{(k)} \tag{6}$$

where $\lambda^{(i)} = (0, 0, \dots, 0, 1, 1, \dots, 1)$ has exactly $i$ parts equal to 1 and $c_i \in \mathbb{N}$. The weight of $\lambda^{(i)}$ is $i$, and one obtains:

$$F_P(t) = \frac{1}{(1-t)(1-t^2)\dots(1-t^k)}. \tag{7}$$

The automatic structure of (ordinary) partitions is transparent: since they are constructed by adding a number of copies of $\lambda^{(1)}$, then a number of copies of $\lambda^{(2)}$, and so on, there is a size preserving bijection between these partitions and walks starting from 1 and ending anywhere in the following digraph:



Note that this graph corresponds to $k = 4$, and that an edge labelled $[\ell]$ must be understood as a *sequence* of $\ell$ edges. These labels do *not* correspond to multiplicities. Observe that the only cycles in this digraph are loops. This, combined with Proposition 2.2, explains the factored form of the denominator of (7).

Consider now the partial order on $[\![4]\!]$ defined by $1 < 3$, $2 < 3$ and $2 < 4$. The partitions of weight at most 2 are

$$(0,0,0,0),\ (0,0,1,0),\ (0,0,0,1),\ (1,0,1,0),\ (0,0,1,1),\ (0,0,2,0),\ (0,0,0,2),$$

[1] A $P$-partition is usually defined as an *order-reversing* map from $[\![k]\!]$ to $\mathbb{N}$ [74, Section 4.5]. Both notions are of course completely equivalent.

so that $F_P(t) = 1 + 2t + 4t^2 + O(t^3)$. If one is brave enough to list $P$-partitions of weight at most 20, the Padé approximant of the truncated series thus obtained is remarkably simple:

$$F_P(t) = \frac{1 + t + t^2 + t^3 + t^4}{(1-t)(1-t^2)(1-t^3)(1-t^4)} + O(t^{21}),$$

and allows one to make a (correct) conjecture.

It turns out that the generating function of $P$-partitions is always a rational series of denominator $(1-t)(1-t^2)\dots(1-t^k)$. Moreover, $P$-partitions obey our general intuition about objects with a rational GF. The following proposition, illustrated below by an example, describes their automatic structure: the set of $P$-partitions can be partitioned into a finite number of subsets; in each of these subsets, partitions have a structure similar to (6). Recall that a *linear extension* of $P$ is a bijection $\sigma$ on $[\![k]\!]$ such that $\sigma(i) < \sigma(j)$ if $i <_P j$.

**Proposition 2.6** ([74], Section 4.5). *Let $P$ be a natural order on $[\![k]\!]$.*

*For every $P$-partition $\lambda$, there exists a unique linear extension $\sigma$ of $P$ such that for all $i$, $\lambda_{\sigma(i)} \le \lambda_{\sigma(i+1)}$, the inequality being strict if $\sigma(i) > \sigma(i+1)$. We say that $\lambda$ is* compatible *with $\sigma$.*

*Given a linear extension $\sigma$, the $P$-partitions that are compatible with $\sigma$ can be written in a unique way as a linear combination with coefficients in $\mathbb{N}$:*

$$\lambda^{(\sigma,0)} + c_1\lambda^{(\sigma,1)} + \cdots + c_k\lambda^{(\sigma,k)} \tag{8}$$

*where $\lambda^{(\sigma,0)}$ is the smallest $P$-partition compatible with $\sigma$:*

$$\lambda^{(\sigma,0)}_{\sigma(j)} = |\{i < j : \sigma(i) > \sigma(i+1)\}| \quad \text{for } 1 \le j \le k,$$

*and for $1 \le i \le k$,*

$$(\lambda^{(\sigma,i)}_{\sigma(1)}, \dots, \lambda^{(\sigma,i)}_{\sigma(k)}) = (0, 0, \dots, 0, 1, 1, \dots, 1)$$

*has exactly $i$ parts equal to 1. Thus the GF of these $P$-partitions is*

$$F_{P,\sigma}(t) = \frac{t^{e(\sigma)}}{(1-t)(1-t^2)\dots(1-t^k)}$$

*where $e(\sigma)$ is a variant of the* Major index *of $\sigma$:*

$$e(\sigma) = \sum_{i:\sigma(i)>\sigma(i+1)} (k-i).$$

**Example.** Let us return to the order $1 < 3$, $2 < 3$ and $2 < 4$. The 5 linear extensions are 1234, 2134, 1243, 2143 and 2413. Take $\sigma = 2143$. The $P$-partitions $\lambda$ that are compatible with $\sigma$ are those that satisfy $\lambda_2 < \lambda_1 \le \lambda_4 < \lambda_3$. The smallest of them is thus $\lambda^{(\sigma,0)} = (1, 0, 2, 1)$. Then $\lambda^{(\sigma,1)} = (0, 0, 1, 0)$, $\lambda^{(\sigma,2)} = (0, 0, 1, 1)$, $\lambda^{(\sigma,3)} = (1, 0, 1, 1)$ and $\lambda^{(\sigma,4)} = (1, 1, 1, 1)$.

**2.4.3. Integer points in a convex polyhedral cone ([74], Sec. 4.6).** Let $\mathcal{H}$ be a finite collection of linear half-spaces of $\mathbb{R}^m$ of the form $c_1\alpha_1 + \cdots + c_m\alpha_m \geq 0$, with $c_i \in \mathbb{Z}$. We are interested in the set $\mathcal{E}$ of *non-negative integer points* $\alpha = (\alpha_1, \ldots, \alpha_m)$ lying in the intersection of those half-spaces. For instance, we could have the following set $\mathcal{E}$, illustrated in Figure 3 (a):

$$\mathcal{E} = \{(\alpha_1, \alpha_2) \in \mathbb{N}^2 : 2\alpha_1 \geq \alpha_2 \text{ and } 2\alpha_2 \geq \alpha_1\}. \tag{9}$$

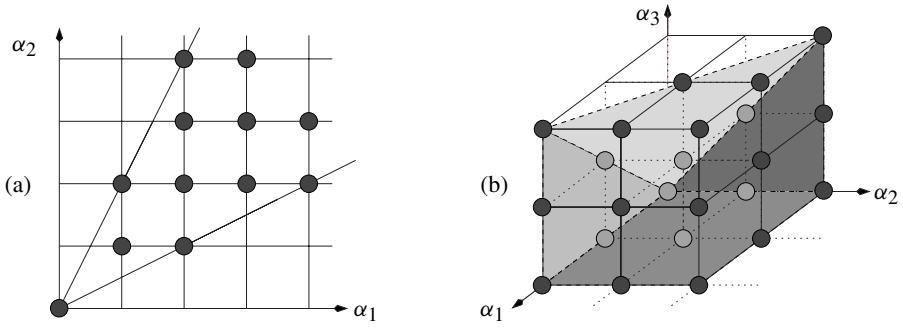


Figure 3. Integer points in a polyhedral cone.

Numerous enumerative problems (including $P$-partitions) can be formulated in terms of linear inequalities as above. The generating function of $\mathcal{E}$ is

$$E(t) = \sum_{\alpha \in \mathcal{E}} t^{|\alpha|},$$

where $|\alpha| = \alpha_1 + \cdots + \alpha_m$. In the above example, $E(t) = 1 + t^2 + 2t^3 + t^4 + 2t^5 + 3t^6 + 2t^7 + O(t^8)$.

The set $\mathcal{E}$ is a monoid (it is closed under summation). In general, it is not a *free* monoid. Geometrically, the set $\mathcal{C}$ of non-negative *real* points in the intersection of the half-spaces of $\mathcal{H}$ forms a *pointed convex polyhedral cone* (the term *pointed* means that it does not contain a line), and $\mathcal{E}$ is the set of integer points in $\mathcal{C}$.

**The simplicial case.** In the simplest case, the cone $\mathcal{C}$ is simplicial. This implies that the *monoid* $\mathcal{E}$ is *simplicial*, meaning that there exists linearly independent vectors $\alpha^{(1)}, \ldots, \alpha^{(k)}$ such that

$$\mathcal{E} = \{\alpha \in \mathbb{N}^m : \alpha = q_1\alpha^{(1)} + \cdots + q_k\alpha^{(k)} \text{ with } q_i \in \mathbb{Q},\ q_i \geq 0\}.$$

This is the case in Example (9), with $\alpha^{(1)} = (1, 2)$ and $\alpha^{(2)} = (2, 1)$. The *interior* of $\mathcal{E}$ (the set of points of $\mathcal{E}$ that are not on the boundary of $\mathcal{C}$) is then

$$\overline{\mathcal{E}} = \{\alpha \in \mathbb{N}^m : \alpha = q_1\alpha^{(1)} + \cdots + q_k\alpha^{(k)} \text{ with } q_i \in \mathbb{Q}, q_i > 0\}. \tag{10}$$

Then there exists a finite subset $\mathcal{D}$ of $\mathcal{E}$ [resp. $\overline{\mathcal{D}}$ of $\overline{\mathcal{E}}$] such that every element of $\mathcal{E}$ [resp. $\overline{\mathcal{E}}$] can be written uniquely in the form

$$\alpha = \beta + c_1\alpha^{(1)} + \cdots + c_k\alpha^{(k)}, \tag{11}$$

with $\beta \in \mathcal{D}$ [resp. $\beta \in \overline{\mathcal{D}}$] and $c_i \in \mathbb{N}$ [74, Lemma 4.6.7]. In our running example (9), taken with $\alpha^{(1)} = (1, 2)$ and $\alpha^{(2)} = (2, 1)$, one has $\mathcal{D} = \{(0, 0), (1, 1), (2, 2)\}$ while $\overline{\mathcal{D}} = \{(1, 1), (2, 2), (3, 3)\}$. Compare (11) with the structure found for $P$-partitions (8). Thus $\mathcal{E}$ and $\overline{\mathcal{E}}$ have an automatic structure and their GFs read

$$E(t) = \frac{\sum_{\beta\in\mathcal{D}} t^{|\beta|}}{\prod_{i=1}^{k}(1 - t^{|\alpha^{(i)}|})} \quad \text{resp.} \quad \overline{E}(t) = \frac{\sum_{\beta\in\overline{\mathcal{D}}} t^{|\beta|}}{\prod_{i=1}^{k}(1 - t^{|\alpha^{(i)}|})}.$$

In Example (9), one thus obtains

$$E(t) = \frac{1 + t^2 + t^4}{(1 - t^3)^2} = \frac{1 - t + t^2}{(1 - t)(1 - t^3)} \quad \text{and} \quad \overline{E}(t) = t^2E(t).$$

**The general case.** The set $\mathcal{E}$ can always be partitioned into a finite number of sets $\overline{\mathcal{F}}$ of the form (10), where $\mathcal{F}$ is a simplicial monoid [74, Ch. 4, Eq. (24)]. Thus $\mathcal{E}$, as a finite union of sets with an automatic structure, has an automatic structure as well. The associated generating function $E(t)$ is $\mathbb{N}$-rational, with a denominator which is a product of cyclotomic polynomials.

Consider, for example, the set

$$\mathcal{E} = \{(\alpha_1, \alpha_2, \alpha_3) \in \mathbb{N}^3 : \alpha_3 \le \alpha_1 + \alpha_2\}.$$

The cone $\mathcal{C}$ of non-negative *real* points $\alpha$ satisfying $\alpha_3 \le \alpha_1+\alpha_2$ is *not* simplicial, as it has 4 faces of dimension 2, lying respectively in the hyperplanes $\alpha_i = 0$ for $i = 1, 2, 3$ and $\alpha_3 = \alpha_1+\alpha_2$ (Figure 3 (b)). But it is the union of two simplicial cones $\mathcal{C}_1$ and $\mathcal{C}_2$, obtained by intersecting $\mathcal{C}$ with the half-spaces $\alpha_1 \ge \alpha_3$ and $\alpha_1 \le \alpha_3$, respectively. Let $\mathcal{E}_1$ [resp. $\mathcal{E}_2$] denote the set of integer points of $\mathcal{C}_1$ [resp. $\mathcal{C}_2$].

The fastest way to obtain the generating function $E(t)$ is to write

$$E(t) = E_1(t) + E_2(t) - E_{12}(t) \tag{12}$$

where $E_{12}(t)$ counts integer points in the intersection of $\mathcal{C}_1$ and $\mathcal{C}_2$ (that is, in the plane $\alpha_1 = \alpha_3$). Since $\mathcal{E}_1$, $\mathcal{E}_2$ and $\mathcal{E}_1 \cap \mathcal{E}_2$ are simplicial cones (of dimension 3, 3 and 2 respectively), the method presented above for simplicial cones applies. Indeed, $\mathcal{E}_1$ [resp. $\mathcal{E}_2$; $\mathcal{E}_{12}$] is the set of linear combinations (with coefficients in $\mathbb{N}$) of $(1, 0, 1)$, $(0, 1, 0)$ and $(1, 0, 0)$ [resp. $(1, 0, 1)$, $(0, 1, 0)$ and $(0, 1, 1)$; $(1, 0, 1)$ and $(0, 1, 0)$]. This implies:

$$E(t) = \frac{1}{(1 - t)^2(1 - t^2)} + \frac{1}{(1 - t)(1 - t^2)^2} - \frac{1}{(1 - t)(1 - t^2)} = \frac{1 + t + t^2}{(1 - t)(1 - t^2)^2}.$$

However, the "minus" sign in (12) prevents us from seeing directly the automatic nature of $\mathcal{E}$ (the difference of $\mathbb{N}$-rational series is not always $\mathbb{N}$-rational). This structure only becomes clear when we write $\mathcal{E}$ as the disjoint union of the interiors of all simplicial monoids induced by the triangulation of $\mathcal{C}$ into $\mathcal{C}_1$ and $\mathcal{C}_2$. These monoids are the integer points of the faces (of all possible dimensions) of $\mathcal{C}_1$ and $\mathcal{C}_2$. As there are 12 such faces (more precisely, 1 [resp. 4, 5, 2] faces of dimension 0 [resp. 1, 2, 3]), this gives $\mathcal{E}$ as the disjoint union of 12 sets having an automatic structure of the form (10).

### 2.5. Rational generating functions: more difficult questions.

**2.5.1. Predicting rationality.** We wrote in Section 2.4 that it is usually easy to foresee, to predict when a class of combinatorial objects has a rational GF. There are a few exceptions. Here is one of the most remarkable ones.

**Example 2.7** (*Directed animals*). A *directed animal with a compact source of size k* is a finite set of points $A$ on the square lattice $\mathbb{Z}^2$ such that:

– the points $(-i, i)$ for $0 \leq i < k$ belong to $A$; they are called the *source points*,

– all the other points in $A$ can be reached from one of the source points by a path made of North and East steps, having all its vertices in $A$.

See Figure 4 for an illustration. A similar notion exists for the triangular lattice. It turns out that these animals have extremely simple generating functions [50], [10].

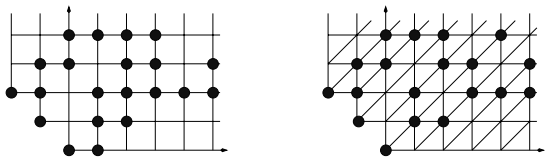

Figure 4. Compact-source directed animals on the square and triangular lattices.

**Theorem 2.8.** *The number of compact-source directed animals of cardinality $n$ is $3^{n-1}$ on the square lattice, and $4^{n-1}$ on the triangular lattice.*

The corresponding GFs are respectively $t/(1-3t)$ and $t/(1-4t)$, and are as rational as a series can be. There is at the moment no simple combinatorial intuition as to why these animals have rational GFs. A bijection between square lattice animals and words on a 3-letter alphabet was described in [50], but it does not shed a clear light on the structure of these objects. Still, there is now a convincing explanation of the *algebraicity* of these series (see Section 3.4.2).

**Example 2.9** (*The area under Dyck paths*). Another family of (slightly less natural) examples is provided by the enumeration of points lying below certain lattice paths.

For instance, let us call *Dyck path of length* $2n$ any path $P$ on $\mathbb{Z}^2$ formed of steps $(1, 1)$ and $(1, -1)$, that starts from $(0, 0)$ and ends at $(2n, 0)$ without ever hitting a point with a negative ordinate. The *area* below $P$ is the number of non-negative integer points $(i, j)$, with $i \leq 2n$, lying weakly below $P$ (Figure 5). It turns out that the sum of the areas of Dyck paths of length $2n$ is simply

$$\sum_{P:|P|=2n} a(P) = 4^n.$$

Again, the rationality of the associated generating function does not seem easy to predict, but there are good combinatorial reasons explaining why it is *algebraic*. See [33], [65] for a direct explanation of this result, references, and a few variations on this phenomenon, first spotted by Kreweras [58].

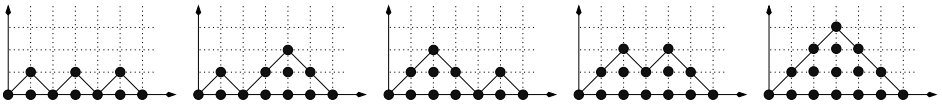

Figure 5. The 5 Dyck paths of length 6 and the $4^3 = 64$ points lying below.

Finally, let us mention that our optimistic statement about how easy it is to predict the rationality of a generating function becomes less and less true as we move from purely combinatorial problems to more algebraic ones. For instance, it is not especially easy to foresee that a group has an automatic structure [39]. Let us give also an example coming from number theory. Let $P(x) \equiv P(x_1, \ldots, x_r)$ be a polynomial with integer coefficients, and take $p$ a prime. For $n \geq 0$, let $a_n$ be the number of $x \in (\mathbb{Z}/p^n\mathbb{Z})^r$ such that $P(x) = 0 \mod p^n$. Then the generating function $\sum_n a_n t^n$ is rational. A related result holds with $p$-adic solutions [37], [53].

**2.5.2. Computing a rational generating function.** Let us start with an elementary, but important observation. Many enumerative problems, including some very hard, can be *approximated* by problems having a rational GF. To take one example, consider the notoriously difficult problem of counting *self-avoiding polygons* (elementary cycles) on the square lattice. It is easy to convince oneself that the generating function of SAP lying in a horizontal strip of height $k$ is rational for all $k$. This does not mean that it will be easy (or even possible, in the current state of affairs) to compute the corresponding generating function when $k = 100$. Needless to say, there is at the moment no hope to express this GF for a *generic* value of $k$. The generating function of SAP having $2k$ horizontal steps can also be seen to be rational. Moreover, these SAP can be described in terms of linear inequalities (as in Section 2.4.3), which implies that the denominator of the corresponding series $G_k$ is a product of cyclotomic polynomials. But again, no one knows what this series is for a generic value of $k$, or even for $k = 100$. Still, some progress have been made recently, since it has been

proved that the series $G_k$ have more and more poles as $k$ increases, which means that their denominators involve infinitely many cyclotomic polynomials [68]. This may be considered as a *proof of the difficulty* of this enumerative problem [51].

In general, computing the (rational) generating function of a family of objects depending on a parameter $k$ may be non-obvious, if not difficult, even if the objects are clearly regular, and even if the final result turns out to be nice. A classical example is provided by the growth functions of Coxeter groups [61]. Here is a more combinatorial example. A partition $\lambda = (\lambda_1, \ldots, \lambda_k)$ is said to be a *$k$-Lecture Hall partition* ($k$-LHP) if

$$0 \leq \frac{\lambda_1}{1} \leq \frac{\lambda_2}{2} \leq \cdots \leq \frac{\lambda_k}{k}.$$

Since these partitions are defined by linear inequalities, it follows from Section 2.4.3 that their weight generating function is rational, with a denominator formed of cyclotomic polynomials. Still, there is no clear reason to expect that [15]:

$$\sum_{\lambda\ k-\mathrm{LHP}} t^{|\lambda|} = \frac{1}{(1-t)(1-t^3)\ldots(1-t^{2k-1})}.$$

Several proofs have been given for this result and variations on it. See for instance [16], [35] and references in the latter paper. Some of these proofs are based on a bijection between lecture hall partitions and partitions into parts taken in $\{1, 3, \ldots, 2k-1\}$, but these bijections are never really simple [82], [40].

**2.5.3. $\mathbb{N}$-rationality.** As we wrote in Section 2.4, we do not know of a counting problem that would yield a rational, but not $\mathbb{N}$-rational series. It would certainly be interesting to find one (even if it ruins some parts of this paper).

Let us return to Soittola's criterion for $\mathbb{N}$-rationality (Theorem 2.5). It is not always easy to prove that a rational series has non-negative coefficients. For instance, it was conjectured in [46] that for any odd $k$, the number of partitions of $n$ into parts taken in $\{k, k+1, \ldots, 2k-1\}$ is a non-decreasing function of $n$, for $n \geq 1$. In terms of generating functions, this means that the series

$$q + \frac{1-q}{(1-q^k)(1-q^{k+1})\ldots(1-q^{2k-1})}$$

has non-negative coefficients. This was only proved recently [67]. When $k$ is even, a similar result holds for the series

$$q + \frac{1-q}{(1-q^k)(1-q^{k+1})\ldots(1-q^{2k})(1-q^{2k+1})}.$$

Once the non-negativity of the coefficients has been established, it is not hard to prove that these series are $\mathbb{N}$-rational. This raises the question of finding a family of combinatorial objects that they count.

## 3. Algebraic generating functions

**3.1. Definitions and properties.** The Laurent series $A(t)$ with coefficients in the field $R$ is said to be *algebraic* (over $R(t)$) if it satisfies a non-trivial *algebraic* equation:

$$P(t, A(t)) = 0$$

where $P$ is a bivariate polynomial with coefficients in $R$. We assume below $R = \mathbb{Q}$.

Again, the set of algebraic Laurent series possesses numerous interesting properties [75, Ch. 6], [43, Ch. VII]. It is closed under sum, product, derivation, reciprocals, but not under integration. These closure properties become effective using either the theory of elimination or Gröbner bases, which are implemented in most computer algebra packages. The coefficients $a_n$ of an algebraic series $A(t)$ satisfy a linear recurrence relation with polynomial coefficients: for $n$ large enough,

$$p_0(n)a_n + p_1(n)a_{n-1} + p_2(n)a_{n-2} + \cdots + p_k(n)a_{n-k} = 0.$$

Thus the first $n$ coefficients can be computed using a linear number of operations.

There is no systematic way to express the coefficients of an algebraic series in closed form. Still, one can sometimes apply the *Lagrange inversion formula*:

**Proposition 3.1.** *Let $\Phi$ and $\Psi$ be two formal power series and let $U \equiv U(t)$ be the unique formal power series with no constant term satisfying*

$$U = t\Phi(U).$$

*Then for $n > 0$, the coefficient of $t^n$ in $\Psi(U)$ is:*

$$[t^n]\Psi(U) = \frac{1}{n}[t^{n-1}]\left(\Psi'(t)\Phi(t)^n\right).$$

Given an algebraic equation $P(t, A(t)) = 0$, one can decide whether there exists a series $U(t)$ and two *rational* series $\Phi$ and $\Psi$ satisfying

$$U = t\Phi(U) \quad \text{and} \quad A = \Psi(U). \tag{13}$$

Indeed, such series exist if and only if the *genus* of the curve $P(t, a)$ is zero [1, Ch. 15]. Moreover, both the genus and a parametrization of the curve in the form (13) can be determined algorithmically.

**Example 3.2 (Finding a rational parametrization).** The following algebraic equation was recently obtained [22], after a highly non-combinatorial derivation, for the GF of certain planar graphs carrying a *hard-particle configuration*:

$$\begin{aligned} 0 = {} & 23328\,t^6A^4 + 27\,t^4(91 - 2088\,t)A^3 \\ & + t^2(86 - 3951\,t + 46710\,t^2 + 3456\,t^3)A^2 \\ & + (1 - 69\,t + 1598\,t^2 - 11743\,t^3 - 14544\,t^4)A \\ & - 1 + 66\,t - 1495\,t^2 + 11485\,t^3 + 128\,t^4. \end{aligned} \tag{14}$$

The package `algcurves` of MAPLE, and more precisely the commands `genus` and `parametrization`, reveal that a rational parametrization is obtained by setting

$$t = -3\,\frac{(3\,U+7)\left(9\,U^2+33\,U+37\right)}{(3\,U+1)^4}.$$

Of course, this is just the net result of MAPLE, which is not necessarily very meaningful for combinatorics. Still, starting from this parametrization, one obtains after a few attempts an alternative parametrizing series $V$ with positive coefficients:

$$V = \frac{t}{(1-2V)(1-3V+3V^2)}. \tag{15}$$

The main interest of such a parametrization for this problem does *not* lie in the possibility of applying the Lagrange inversion formula. Rather, it suggests that a more combinatorial approach exists, based on the enumeration of certain *trees*, in the vein of [19], [27]. It also gives a hint of what these trees may look like.

Another convenient tool borrowed from the theory of algebraic curves is the possibility to explore all branches of the curve $P(t, A(t)) = 0$ in the neighbourhood of a given point $t_0$. This is based on Newton's polygon method. All branches have a *Puiseux expansion*, that is, an expansion of the form:

$$A(t) = \sum_{n \geq n_0} a_n (t - t_0)^{n/d}$$

with $n_0 \in \mathbb{Z}$, $d \in \mathbb{P}$. The coefficients $a_n$ belong to $\mathbb{C}$ (in general, to an algebraic closure of the ground field). These expansions can be computed automatically using standard software. For instance, the MAPLE command `puiseux` of the `algcurves` package tells us that (14) has a unique solution that is a formal power series, the other three solutions starting with a term $t^{-2}$.

Such Puiseux expansions are crucial for studying the *asymptotic behaviour* of the coefficients of an algebraic series $A(t)$. As in the rational case, one has first to locate the singularities of $A(t)$, considered as a function of a complex variable $t$. These singularities are found among the roots of the *discriminant* and of the leading coefficient of $P(t, a)$ (seen as a polynomial in $a$). The singular expansion of $A(t)$ near its singularities of smallest modulus can then be converted, using certain *transfer theorems*, into an asymptotic expansion of the coefficients [42], [43, VII.4].

**Example 3.3** (*Asymptotics of the coefficients of an algebraic series*). Consider the series $V(t)$ defined by (15). Its singularities lie among the roots of the discriminant

$$\Delta(t) = -3 + 114t - 4635t^2 + 55296t^3.$$

Only one root is real. Denote it $t_0 \sim 0.065$. The modulus of the other two roots is smaller than $t_0$, so they could, in theory, be candidates for singularities. However,

$V(t)$ has non-negative coefficients, and this implies, by Pringsheim's theorem, that one of the roots of minimal modulus is real and positive. Hence $V(t)$ has a unique singularity, lying at $t_0$. A Puiseux expansion at this point gives

$$V(t) = c_0 - c_1\sqrt{1 - t/t_0} + O(t - t_0),$$

for some explicit (positive) algebraic numbers $c_0$ and $c_1$, which translates into

$$[t^n]V(t) = \frac{c_1}{2\sqrt{\pi}} t_0^{-n} n^{-3/2} \left(1 + o(1)\right).$$

The determination of asymptotic expansions for the coefficients of algebraic series is probably not far from being completely automated, at least in the case of series with non-negative coefficients [31], [43]. The "typical" behaviour is

$$a_n \sim \frac{\kappa}{\Gamma(d+1)} \rho^{-n} n^d, \tag{16}$$

where $\kappa$ is an algebraic number and $d \in \mathbb{Q} \setminus \{-1, -2, -3, \dots\}$. Compare with the result (3) obtained for rational series. Again, the above statement is not exact, as the contribution of *all* dominant singularities must be taken into account. See [43, Thm. VII.6] for a complete statement.

Let us add that, again, one can guess if a series $A(t)$ given by its first coefficients satisfies an algebraic equation $P(t, A(t)) = 0$ of a given bi-degree $(d, e)$. The guessing procedure requires to know at least $(d + 1)(e + 1)$ coefficients, and amounts to solving a system of linear equations. It is implemented in the package `Gfun` of MAPLE [72]. For instance, given the 10 first coefficients of the series $V(t)$ satisfying $V(0) = 0$ and (15), one automatically conjectures (15).

**3.2. Plane trees.** Our typical "algebraic" objects will be (plane) trees. Let us begin with their usual intuitive recursive definition. A *tree* is a graph formed of a distinguished vertex (called the *root*) to which are attached a certain number (possibly zero) of trees, ordered from left to right. The number of these trees is the *degree* of the root. The roots of these trees are the *children* of the root. A more rigorous definition describes a tree as a finite set of words on the alphabet $\mathbb{P}$ satisfying certain conditions [63]. We hope that our less formal definition and Figure 6 (a) suffice to understand what we mean. The vertices of a tree are often called *nodes*. Nodes of degree 0 are called *leaves*, the others are called *inner* nodes.

The enumeration of classes of trees yields very often algebraic equations. Let us consider for instance the *complete binary trees*, that is, the trees in which all vertices have degree 0 or 2 (Figure 12). Let $a_n$ be the number of such trees having $n$ leaves. Then, by looking at the two (sub)trees of the root, one gets, for $n > 1$:

$$a_n = \sum_{k=1}^{n-1} a_k a_{n-k}.$$

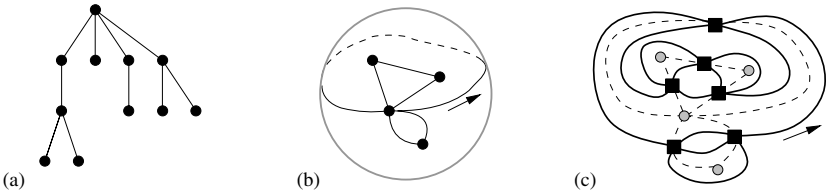

Figure 6. (a) A plane tree. (b) A rooted planar map. (c) The corresponding 4-valent map (thick lines).

The initial condition is $a_1 = 1$. In terms of GFs, this gives $A(t) = t + A(t)^2$, which is easily solved:

$$A(t) = \frac{1-\sqrt{1-4t}}{2} = \sum_{n\geq 0} \frac{1}{n+1}\binom{2n}{n} t^{n+1}. \tag{17}$$

More generally, many algebraic series obtained in enumeration are given as the first component of the solution of a system of the form

$$A_i = P_i(t, A_1, \ldots, A_k), \tag{18}$$

for some polynomials $P_i(t, x_1, \ldots, x_k)$ having coefficients in $\mathbb{Z}$. This system is said to be *proper* if $P_i$ has no constant term ($P_i(0, \ldots, 0) = 0$) and does not contain any linear term $x_i$. It is *positive* if the coefficients of the $P_i$ are non-negative. For instance,

$$A_1 = t^2 + A_1 A_2 \quad \text{and} \quad A_2 = 2tA_1^3$$

is a proper positive system. The system is *quadratic* if every $P_i(t, x_1, \ldots, x_k)$ is a linear combination of the monomials $t$ and $x_\ell x_m$, for $1 \leq \ell \leq m \leq k$.

**Theorem 3.4** ([75], Thm. 6.6.10 and [71], Thm. IV.2.2). *A proper algebraic system has a unique solution $(A_1, \ldots, A_k)$ in the set of formal power series in $t$ with no constant term. This solution is called the* canonical *solution of the system. The series $A_1$ is also the first component of the solution of*

*– a proper quadratic system,*

*– a proper system of the form $B_i = tQ_i(t, B_1, \ldots, B_\ell)$, for $1 \leq i \leq \ell$.*

*These two systems can be chosen to be positive if the original system is positive.*

*Proof.* Let us prove the last property, which we have not found in the above references. Assume $A_1$ satisfies (18) and that this system is quadratic. The $i$th equation reads $A_i = m_i t + n_i A_{\sigma(i)} A_{\tau(i)}$. Rewrite each monomial $A_i A_j$ as $tU_{ij}$ and add the equations $U_{ij} = t\left(m_i m_j + m_i n_j U_{\sigma(j)\tau(j)} + m_j n_i U_{\sigma(i)\tau(i)} + n_i n_j U_{\sigma(i)\tau(i)} U_{\sigma(j)\tau(j)}\right)$. The new system has the required properties. □

**Definition 3.5.** A series $A(t)$ is $\mathbb{N}$-*algebraic* if it has coefficients in $\mathbb{N}$ and if $A(t) - A(0)$ is the first component of the solution of a proper positive system.

Proper positive systems like (18) can always be given a combinatorial interpretation in terms of trees. Every vertex of these trees carries a label $(i, c)$ where $i \in [\![k]\!]$ and $c \in \mathbb{P}$. We say that $i$ is the *type* of the vertex and that $c$ is its colour. The *type* of a tree is the type of its root. Write $A_0 = t$, so that $A_i = P_i(A_0, A_1, \ldots, A_k)$. Let $\mathcal{A}_0$ be the set reduced to the tree with one node, labelled $(0, 1)$. For $i \in [\![k]\!]$, let $\mathcal{A}_i$ be the set of trees such that

– the root has type $i$,

– the types of the subtrees of the root, visited from left to right, are $0, \ldots, 0, 1, \ldots, 1, \ldots, k, \ldots, k$, in this order,

– if exactly $e_j$ children of the root have type $j$, the colour of the root is any integer in the interval $[1, m]$, where $m$ is the coefficient of $x_0^{e_0} \ldots x_k^{e_k}$ in $P_i(x_0, \ldots, x_k)$.

Then it is not hard to see that $A_i(t)$ is the generating function of trees of type $i$, counted by the number of leaves. This explains why trees will be, in the rest of this paper, our typical "algebraic" objects.

**3.3. Context-free languages.** As in the case of rational (and, more precisely, $\mathbb{N}$-rational) series, there exists a family of languages that is closely related to algebraic series. A *context-free grammar* $G$ consists of

– a set $\mathcal{S} = \{S_1, \ldots, S_k\}$ of *symbols*, with one distinguished symbol, say, $S_1$,

– a finite alphabet $\mathcal{A}$ of *letters*, disjoint from $\mathcal{S}$,

– a set of *rewriting rules* of the form $S_i \to w$ where $w$ is a non-empty word on the alphabet $\mathcal{S} \cup \mathcal{A}$.

The grammar is *proper* if there is no rule $S_i \to S_j$. The language $\mathcal{L}(G)$ generated by $G$ is the set of words *on the alphabet* $\mathcal{A}$ that can be obtained from $S_1$ by applying iteratively the rewriting rules. A language is *context-free* is there exists a context-free grammar that generates it. In this case there exists also a proper context-free grammar that generates it.

**Example 3.6** (*Dyck words*). Consider the grammar $G$ having only one symbol, $S$, alphabet $\{a, b\}$, and rules $S \to ab + abS + aSb + aSbS$ (which is short for $S \to ab$, $S \to abS$, $S \to aSb$, $S \to aSbS$). It is easy to see that $\mathcal{L}(G)$ is the set of non-empty words $u$ on $\{a, b\}$ such that $|u|_a = |u|_b$ and for every prefix $v$ of $u$, $|v|_a \geq |v|_b$. These words, called *Dyck words*, provide a simple encoding of the Dyck paths met in Example 2.9.

A *derivation tree* associated with $G$ is a plane tree in which all inner nodes are labelled by symbols, and all leaves by letters, in such a way that if a node is labelled $S_i$ and its children $w_1, \ldots, w_k$ (from left to right), then the rewriting rule $S_i \to w_1 \ldots w_k$ is in the grammar. If the root is labelled $S_1$, then the word obtained by reading the labels of the leaves in prefix order (*i.e.*, from left to right) belongs to the language generated by $G$. Conversely, for every word $w$ in $\mathcal{L}(G)$, there exists at least one derivation tree with root labelled $S_1$ that gives $w$. The grammar is said to be *unambiguous* if every word of $\mathcal{L}(G)$ admits a unique derivation tree.

Assume $G$ is proper. For $1 \leq i \leq k$, let $A_i(t)$ be the generating function of derivation trees rooted at $S_i$, counted by the number of leaves. With each rule $r$, associate the monomial $M(r) = x_0^{e_0} \dots x_k^{e_k}$ where $e_0$ [resp. $e_i$, with $i > 0$] is the number of letters of $\mathcal{A}$ [resp. occurrences of $S_i$] in the right-hand side of $r$. Then the series $A_1, \dots, A_k$ form the canonical solution of the proper positive system (18), with

$$P_i(x_0, x_1, \dots, x_k) = \sum_r M(r),$$

where the sum runs over all rules $r$ with left-hand side $S_i$.

Conversely, starting from a positive system $B_i = tQ_i(t, B_1, \dots, B_k)$ and its canonical solution, it is always possible to construct an unambiguous grammar with symbols $S_1, \dots, S_k$ such that $B_i$ is the generating function of derivation trees rooted at $S_i$ (the idea is to introduce a new letter $a_i$ for each occurrence of $t$). In view of Theorem 3.4 and Definition 3.5, this gives the following alternative characterization of $\mathbb{N}$-algebraic series:

**Proposition 3.7.** *A series $A(t)$ is $\mathbb{N}$-algebraic if and only if only $A(0) \in \mathbb{N}$ and there exists an unambiguous context-free language having generating function $A(t) - A(0)$.*

**3.4. The combinatorial intuition of algebraic generating functions.** We have described two families of combinatorial objects that naturally yield algebraic GFs: plane trees and words of unambiguous context-free languages. We have, moreover, shown a close relationship between these two types of objects. These two families convey the standard intuition of what a family with an algebraic generating function looks like: the algebraicity suggests that it *may* (or should...) be possible to give a recursive description of the objects based on disjoint union of sets and concatenation of objects. Underlying such a description is a context-free grammar. This intuition is the basis of the so-called Schützenberger methodology, according to which the "right" combinatorial way of proving algebraicity is to describe a bijection between the objects one counts and the words of an unambiguous context-free language. This approach has led in the 80s and 90s to numerous satisfactory explanations of the algebraicity of certain series, and we describe some of them in this subsection. Let us, however, warn the reader that the similarities with the rational case will stop here. Indeed, it seems that the "context-free" intuition is far from explaining all algebraicity phenomena in enumerative combinatorics. In particular,

(i) it is very likely that many families of objects have an algebraic, but not $\mathbb{N}$-algebraic generating function,

(ii) there are many families of combinatorial objects with an algebraic GF that do not exhibit a clear "context-free" structure, based on union and concatenation. For several of these families, there is just no explanation of this type, be it clear or not.

This will be discussed in the next subsections. For the moment, let us illustrate the "context-free" intuition.

**3.4.1. Walks on a line.** Let $\mathcal{S}$ be a finite subset of $\mathbb{Z}$. Let $\mathcal{W}$ be the set of walks on the line $\mathbb{Z}$ that start from 0 and take their steps in $\mathcal{S}$. The *length* of a walk is its number of steps. Let $\mathcal{W}_k$ be the set of walks ending at position $k$. For $k \geq 0$, let $\mathcal{M}_k$ be the subset of $\mathcal{W}_k$ consisting of walks that never visit a negative position, and let $\mathcal{M}$ be the union of the sets $\mathcal{M}_k$. In probabilistic terms, the walks in $\mathcal{M}$ would be called *meanders* and the walks of $\mathcal{M}_0$ *excursions.* Of course, a walk is simply a sequence of steps, hence a word on the alphabet $\mathcal{S}$. Thus the sets of walks we have defined can be considered as languages on this alphabet.

**Theorem 3.8.** *The language $\mathcal{W}$ is simply $\mathcal{S}^*$ and is thus regular. The languages $\mathcal{M}$, $\mathcal{W}_k$ and $\mathcal{M}_k$ are unambiguous context-free for all $k$.*

*Proof.* We only describe the (very simple) case $\mathcal{S} = \{+1, -1\}$, to illustrate the ideas that are involved in the construction of the grammar. We encode the steps $+1$ by the letter $a$, the steps $-1$ by $b$, and introduce some auxiliary languages:

- $\mathcal{M}_0^-$, the subset of $\mathcal{W}_0$ formed of walks that never visit a positive position,
- $\mathcal{W}_0^+$ [resp. $\mathcal{W}_0^-$], the subset of $\mathcal{W}_0$ formed of walks that start with $a$ [resp. $b$].

The language $\mathcal{M}_0$ will be generated from the symbol $M_0$, and similarly for the other languages. By looking at the first time a walk of $\mathcal{M}_0$ [resp. $\mathcal{M}_0^-$] reaches position 0 after its first step, one obtains

$$M_0 \to a(1 + M_0)b(1 + M_0) \quad \text{and} \quad M_0^- \to b(1 + M_0^-)a(1 + M_0^-).$$

By considering the last visit to 0 of a walk of $\mathcal{M}_k$, one obtains, for $k > 0$:

$$M_k \to (1 + M_0)a\,(1_{k=1} + M_{k-1})\,.$$

This is easily adapted to general meanders:

$$M \to M_0 + (1 + M_0)a\,(1 + M)\,.$$

Considering the first step of a walk of $\mathcal{W}_0$ gives

$$W_0 \to W_0^+ + W_0^- \quad \text{with} \quad W_0^+ \to M_0(1 + W_0^-) \text{ and } W_0^- \to M_0^-(1 + W_0^+).$$

Finally, for $k > 0$, looking at the first visit at 1 [resp. $-1$] of a walk of $\mathcal{W}_k$ [resp. $\mathcal{W}_{-k}$] yields

$$W_k \to (1 + M_0^-)a\,(1_{k=1} + W_{k-1}) \quad [\text{resp. } W_{-k} \to (1 + M_0)b(1_{k=1} + W_{-(k-1)})].$$

For a general set of steps $\mathcal{S}$, various grammars have been described for the languages $\mathcal{M}_k$ of meanders [38], [60], [59]. For $\mathcal{W}_k$, we refer to [59, Section 4] where the (representative) case $\mathcal{S} = \{-2, -1, 0, 1, 2\}$ is treated. □

Theorem 3.8 is often described in terms of walks in $\mathbb{Z}^2$ starting from $(0, 0)$ and taking their steps in $\{(1, j),\ j \in \mathcal{S}\}$. The conditions on the positions of the walks

that lead to the definition of $\mathcal{M}_k$ and $\mathcal{W}_k$ are restated in terms of conditions on the *ordinates* of the vertices visited by the walk. A harmless generalization is obtained by taking steps in a finite subset $\mathcal{S}$ of $\mathbb{P} \times \mathbb{Z}$. A walk is still encoded by a word on the alphabet $\mathcal{S}$. The languages $\mathcal{W}_k$ remain unambiguous context-free. If each step $(i, j)$ is, moreover, weighted by a rational number $w_{i,j}$, then the generating function of walks of $\mathcal{W}$, counted by the coordinates of their endpoint, is

$$W(t, s) = \frac{1}{1 - \sum_{(i,j)\in\mathcal{S}} w_{i,j} t^i s^j}.$$

The generating function $W_k(t)$ that counts (weighted) walks ending at ordinate $k$ is the coefficient of $s^k$ in $W(t, s)$. Since $\mathcal{W}_k$ is unambiguous context-free, the series $W_k(t)$ is algebraic. This gives a combinatorial explanation of the following result [75, Thm. 6.3.3].

**Theorem 3.9** (Diagonals of rational series). *Let $A(x, y) = \sum_{m,n\geq 0} a_{m,n} x^m y^n$ be a series in two variables $x$ and $y$, with coefficients in $\mathbb{Q}$, that is rational. Then the diagonal of $A$, that is, the series $\Delta A(t) = \sum_{n\geq 0} a_{n,n} t^n$, is algebraic.*

*Proof.* By linearity, it suffices to consider the case

$$A(x, y) = \frac{x^a y^b}{1 - \sum_{0\leq m,n\leq d} c_{m,n} x^m y^n},$$

with $c_{0,0} = 0$. Set $x = ts$ and $y = t/s$. The diagonal of $A$ satisfies

$$\Delta A(t^2) = [s^0]A(ts, t/s) = t^{a+b}[s^{b-a}]\frac{1}{1 - \sum_{0\leq m,n\leq d} c_{m,n} t^{m+n} s^{m-n}},$$

which is algebraic as it counts weighted paths in $\mathcal{W}_{b-a}$, for a certain set of steps. Hence $\Delta A(t)$ is algebraic too. □

The converse of Theorem 3.9 holds: every series $B(t)$ that is algebraic over $\mathbb{Q}(t)$ is the diagonal of a bivariate rational series $A(x, t)$ [70].

**Note.** If one is simply interested in obtaining a set of algebraic equations defining the GFs of the sets $\mathcal{M}_k$ and $\mathcal{W}_k$, a more straightforward approach is to use a partial fraction decomposition (for $\mathcal{W}_k$) and the kernel method (for $\mathcal{M}_k$). See [75, 6.3], and [17, Example 3].

**3.4.2. Directed animals.** Let us move to an example where a neat context-free exists, but is uneasy to discover. We return to the *directed animals* defined in Section 2.5.1. As discussed there, there is no simple explanation as to why the number of compact-source animals is so simple (Theorem 2.8). Still, there is a convincing explanation for the *algebraicity* of the corresponding series: directed animals have, indeed, a context-free structure. This structure was discovered a few years after the proof of

Theorem 2.8, with the development by Viennot of the theory of *heaps* [81], a geometric version of partially commutative monoids [30]. Intuitively, a heap is obtained by dropping vertically some solid pieces, the one after the other. Thus, a piece lies either on the "floor" (then it is said to be *minimal*), or covers, at least partially, another piece.

Directed animals *are*, in essence, heaps. To see this, replace every point of the animal by a *dimer* (Figure 7). Note that if the animal has a unique source, the associated heap has a unique minimal piece. Such heaps are named *pyramids*.

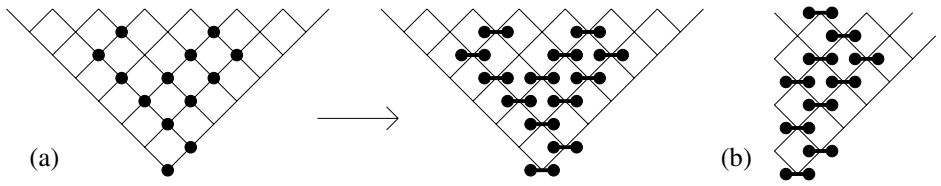

Figure 7. (a) A directed animal and the associated pyramid. (b) A half-pyramid.

What makes heaps interesting here is that there exists a *monoid structure* on the set of heaps: The product of two heaps is obtained by putting one heap above the other and dropping its pieces. This product is the key in our context-free description of directed animals.

Let us begin with the description of pyramids (one-source animals). A pyramid is either a *half-pyramid* (Figure 7 (b)), or the product of a half-pyramid and a pyramid (Figure 8, top). Let $P(t)$ denote the GF of pyramids counted by the number of dimers, and $H(t)$ denote the GF of half-pyramids. Then $P(t) = H(t)(1 + P(t))$. Now, a half-pyramid may be reduced to a single dimer. If it has several dimers, it is the product of a single dimer and of one or two half-pyramids (Figure 8, bottom), which implies $H(t) = t + tH(t) + tH^2(t)$.

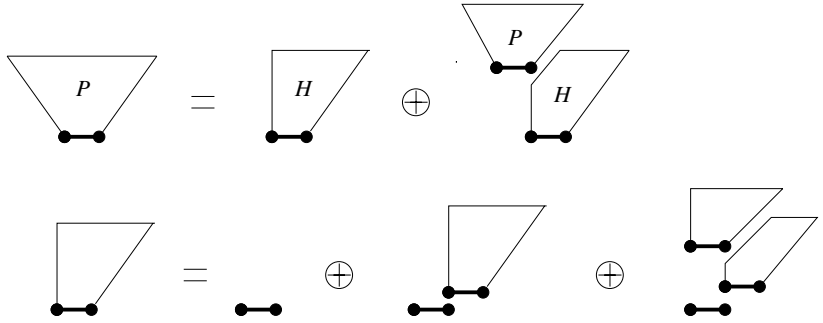

Figure 8. Decomposition of pyramids (top) and half-pyramids (bottom).

A trivial computation finally provides the GF of directed (single-source) animals:

$$P(t) = \frac{1}{2}\left(\sqrt{\frac{1+t}{1-3t}} - 1\right) \qquad \left(\text{while } H(t) = \frac{1-t-\sqrt{(1+t)(1-3t)}}{2t}\right).$$

The enumeration of compact-source directed animals is equivalent to the enumeration of heaps having a compact *basis* (the minimal dimers are adjacent). The generating function of heaps having a compact basis formed with $k$ dimers is $P(t)H(t)^{k-1}$ (Figure 9), which implies that the generating function of compact-source animals is

$$\frac{P(t)}{1-H(t)} = \frac{t}{1-3t}.$$

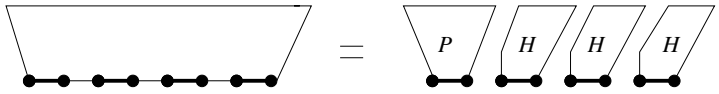

Figure 9. Decomposition of heaps having a compact basis.

**3.5. The world of planar maps.** We have seen in Section 3.2 that plane trees are the paradigm for objects with an algebraic generating function. A more general family of plane objects seems to be just as deeply associated with algebraic series, but for reasons that are far more mysterious: *planar maps*.

A (planar) map is a proper embedding of a planar graph in the sphere (Figure 6 (b)). In order to avoid symmetries, all the maps we consider are *rooted*: this means that one edge is distinguished and oriented. Maps are only considered up to a continuous deformation of the sphere. A map induces a 2-cell decomposition of the sphere: the cells of dimension 0 [resp. 1, 2] are called *vertices* [resp. *edges*, *faces*]. Hence plane trees are maps with a single face.

The interest for the enumeration of planar maps dates back to the early 60s, in connection with the 4-colour theorem. The first results are due to Tutte [77], [78], [79]. Ten to fifteen years later, maps started to be investigated independently in theoretical physics, as a model for 2-dimensional *quantum gravity* [28], [9]. However, neither the recursive approach used by Tutte and his disciples, nor the physics approach based on matrix integrals were able to explain in a combinatorially satisfactory way the following observations:

– the generating functions of many classes of planar maps are algebraic,

– the associated numbers are often irritatingly simple.

Let us illustrate this with three examples.

**1. General maps.** The number of planar maps having $n$ edges is [80]:

$$g_n = \frac{2.3^n}{(n+1)(n+2)}\binom{2n}{n}. \tag{19}$$

The associated generating function $G \equiv G(t) = \sum_{n\geq 0} g_n t^n$ satisfies:

$$-1 + 16t + (1 - 18t)G + 27t^2G^2 = 0. \tag{20}$$

**2. Loopless triangulations.** The number of loopless *triangulations* (maps in which all faces have degree 3) having $2n + 2$ faces is [62]:

$$t_n = \frac{2^n}{(n+1)(2n+1)}\binom{3n}{n}.$$

The associated generating function $T \equiv T(t) = \sum_n t_n t^n$ satisfies

$$1 - 27t + (-1 + 36t)T - 8tT^2 - 16t^2T^3 = 0.$$

**3. Three-connected triangulations.** The number of 3-connected triangulations having $2n + 2$ faces is [77]:

$$m_n = \frac{2}{(n+1)(3n+2)}\binom{4n+1}{n}.$$

The associated generating function $M \equiv M(t) = \sum_n t_n t^n$ satisfies

$$-1 + 16t + (1 - 20t)M + (3t + 8t^2)M^2 + 3t^2M^3 + t^3M^4 = 0.$$

These maps are in bijection with rooted *maximal* planar simple graphs (graphs with no loop nor multiple edge that lose planarity as soon as one adds an edge).

At last, in the past ten years, a general combinatorial picture has emerged, suggesting that maps are, in essence, unrooted plane trees. In what follows, we illustrate on the example of general maps the main three approaches that now exist, and give references for further developments of these methods.

**3.5.1. The recursive approach.** We leave to the reader to experience personally that maps do not have an obvious context-free structure. Still, maps *do* have a simple recursive structure, based on the deletion of the root-edge. However, in order to exploit this structure, one is forced to keep track of the degree of the *root-face* (the face lying to the right of the root edge). The decomposition illustrated in Figure 10 leads in a few lines to the following equation:

$$G(u,t) = 1 + tu^2G(u,t)^2 + tu\,\frac{uG(u,t) - G(1,t)}{u-1}, \tag{21}$$

where $G(u,t)$ counts planar maps by the number of edges ($t$) and the degree of the root-face ($u$).

It can be checked that the above equation defines $G(u,t)$ uniquely as a formal power series in $t$ (with polynomial coefficients in $u$). However, it is not clear on the equation why $G(1,t)$ (and hence $G(u,t)$) are algebraic. In his original paper,

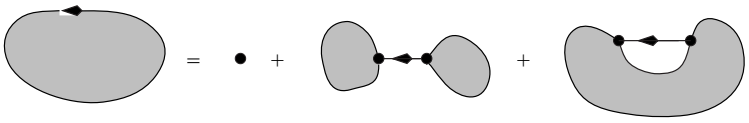

Figure 10. Tutte's decomposition of rooted planar maps.

Tutte first guessed the value of $G_1(t) := G(1,t)$, and then proved the existence of a series $G(u,t)$ that fits with $G_1(t)$ when $u = 1$, and satisfies the above equation. Still, a bit later, Brown came with a *method* for solving (21): the so-called *quadratic method* [29], [49, Sec. 2.9]. Write (21) in the form $(2aG(u,t)+b)^2 = \delta$, where $a$, $b$ and $\delta$ are polynomials in $t$, $u$ and $G_1(t)$. That is,

$$\begin{aligned}&\big(2tu^2(u-1)G(u,t) + tu^2 - u + 1\big)^2 \\ &\qquad = 4t^2u^3(u-1)G_1 + (1-u)^2 - 4tu^4 + 6tu^3 + u^4t^2 - 2tu^2.\end{aligned}$$

It is not hard to see, even without knowing the value of $G(u,t)$, that there exists a (unique) formal power series in $t$, say $U \equiv U(t)$, that cancels the left-hand side of this equation. That is,

$$U = 1 + tU^2 + 2tU^2(U-1)G(U,t).$$

This implies that the series $U$ is a *double root* of the polynomial $\delta$ that lies on the right-hand side. The discriminant of this polynomial (in $u$) thus vanishes: this gives the algebraic equation (20) satisfied by $G(1,t)$.

The enumeration of many other families of planar maps can also be attacked by a recursive description based on the deletion of an edge (or vertex, or face...). See for instance [62] for 2-connected triangulations, or [6] for maps with prescribed face degrees. (For maps with high connectivity, like 3-connected triangulations, an additional *composition formula* is often required [77], [3].) The resulting equations are usually of the form

$$P(F(u), F_1, \ldots, F_k, t, u) = 0, \tag{22}$$

where $F(u) \equiv F(t,u)$, the main generating function, is a series in $t$ with polynomial coefficients in $u$, and $F_1, \ldots, F_k$ are series in $t$ only, independent of $u$. Brown's *quadratic method* applies as long as the degree in $F(u)$ is 2 (for the linear case, see the *kernel method* in [17], [2]). Recently, it was understood how these equations could be solved in full generality [22]. Moreover, the solution of any (well-founded) equation of the above type was shown to be algebraic. This provides two types of enumerative results:

– the proof that many map generating functions are algebraic: it now suffices to exhibit an equation of the form (22), or to explain why such an equation *exists*,

– the solution of previously unsolved map problems (like the enumeration of hard-particle configurations on maps, which led to (14), or that of triangulations with high vertex degrees [8]).

**3.5.2. Matrix integrals.** In the late 70s, it was understood by a group of physicists that certain matrix integral techniques coming from quantum field theory could be used to attack enumerative problems on maps [28], [9]. This approach proved to be extremely efficient (even if it is usually not fully rigorous). The first step is fairly automatized, and consists in converting the description of maps into a certain integral. For instance, the relevant integral for the enumeration of 4-valent maps (maps in which all vertices have degree 4) is

$$Z(t, N) = \frac{2^{N(N-1)/2}}{(2\pi)^{N^2/2}} \int dH e^{\mathrm{tr}(-H^2/2+tH^4/N)},$$

where the integration space is that of hermitian matrices $H$ of size $N$, equipped with the Lebesgue measure $dH = \prod dx_{kk} \prod_{k<\ell} dx_{k\ell} dy_{k\ell}$ with $h_{k\ell} = x_{k\ell} + i y_{k\ell}$. As there is a classical bijection between 4-valent maps with $n$ vertices and planar maps with $n$ edges (Figure 6 (c)), we are still dealing with our reference problem: the enumeration of general planar maps. The connection between the above integral and maps is

$$G(t) = tE'(t) \quad \text{with } E(t) = \lim_{N\to\infty} \frac{1}{N^2} \log Z(t, N).$$

Other map problems lead to integrals involving several hermitian matrices [55]. We refer to [83] for a neat explanation of the encoding of map problems by integrals, and to [45], [41] (and references therein) for the evaluation of integrals.

**3.5.3. Planar maps and trees.** We finally come to a combinatorial explanation of the formula/equation for $g_n$ and $G(t)$. Take a plane binary tree with $n$ (inner) nodes, planted at a leaf, and add to every inner node a new distinguished child, called a *bud*. At each node, we have three choices for the position of the bud (Figure 11 (a)). The new tree, called *budding tree*, has now $n$ buds and $n + 2$ leaves. Now start from the root and walk around the tree in counterclockwise order, paying attention to the sequence of buds and leaves you meet. Each time a bud is immediately followed by

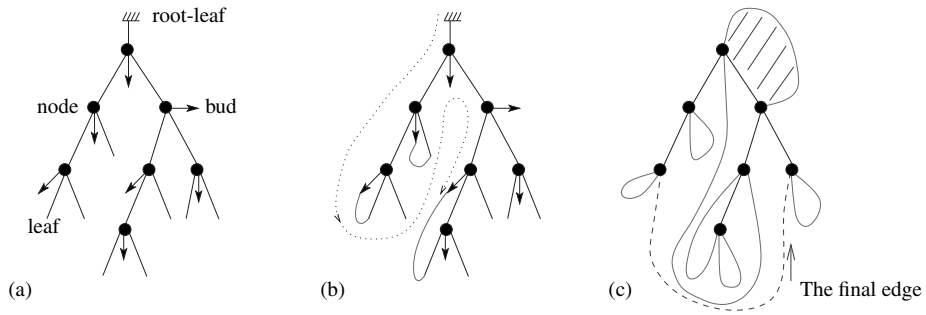

Figure 11. (a). A budding tree. (b) An intermediate step in the matching procedure. (c) The resulting 4-valent map, with its marked face.

a leaf in this sequence, match them by forming a new edge (Figure 11 (b)) and then go on walking around the plane figure thus obtained. At the end, exactly two leaves remain unmatched. Match them together and orient this final edge in one of the two possible ways. Also, mark the face to the left of the matching edge that ends at the root-leaf.

**Theorem 3.10** ([73]). *The above correspondence is a bijection between pairs* $(T, \varepsilon)$ *where* $T$ *is a budding tree having* $n$ *inner nodes and* $\varepsilon \in \{0, 1\}$*, and* 4*-valent maps with* $n$ *vertices and a marked face.*

The value of $\varepsilon$ tells how to orient the final matching edge. Schaeffer first used this bijection to explain combinatorially the formula (19). Indeed, the number of budding trees with $n$ inner nodes is clearly $3^n\binom{2n}{n}/(n+1)$ (see (17)), while the number of 4-valent maps with $n$ vertices and a marked face is $(n+2)g_n$. Eq. (19) follows.

Later, it was realized that this construction could also be used to explain the algebraicity of the series $G(t)$ [23]. Say that a budding tree is *balanced* if the root-leaf is not matched by a bud. Take such a tree, match all buds, and orient the final edge from the root-leaf to the other unmatched leaf. This gives a bijection between balanced budding trees and 4-valent maps. We thus have to count balanced trees, or, equivalently, the unbalanced ones. By re-rooting them at the bud that matches the root-leaf, one sees that they are in bijection with a node attached to three budding trees. This gives

$$G(t) = B(t) - tB(t)^3, \quad \text{where } B(t) = 3t(1 + B(t))^2$$

counts budding trees by (inner) nodes. The above construction involves taking a *difference* of $\mathbb{N}$-algebraic series, which needs not be $\mathbb{N}$-algebraic. We actually conjecture that the series $G(t)$ is not $\mathbb{N}$-algebraic (see Section 3.6.4).

There is little doubt that the above construction (once described in greater detail…) explains in a very satisfactory way both the simplicity of the formula giving $g_n$ and the algebraicity of $G(t)$. Moreover, this is not an *ad hoc*, isolated magic trick: over the past ten years, it was realized that this construction is one in a family of constructions of the same type, which apply to numerous families of maps (Eulerian maps [73], maps with prescribed vertex degrees [23], constellations [18], bipartite maps with prescribed degrees [19], maps with higher connectivity [66], [47]). Definitely, these constructions reveal a lot about the combinatorial nature of planar maps.

To conclude this section, let us mention that a different combinatorial construction for general planar maps, discovered in the early 80s [34], has recently been simplified [32] and adapted to other families of maps [36], [54], [25], [26]. It is a bit less easy to handle than the one based on trees with buds, but it allows one to keep track of the distances between some vertices of the map. This has led to remarkable connections with a random probability distribution called the *Integrated SuperBrownian Excursion* [32]. A third type of construction has emerged even more recently [7] for 2-connected triangulations, but no ones knows at the moment whether it will remain isolated or is just the tip of another iceberg.

**3.6. Algebraic series: some questions.** We begin with three simple classes of objects that have an algebraic GF, but for reasons that remain mysterious. We then discuss a possible criterion (or necessary condition) for $\mathbb{N}$-algebraicity, and finally the algebraicity of certain hypergeometric series.

**3.6.1. Kreweras' words and walks on the quarter plane.** Let $\mathcal{L}$ be the set of words $u$ on the alphabet $\{a, b, c\}$ such that for every prefix $v$ of $u$, $|v|_a \geq |v|_b$ and $|v|_a \geq |v|_c$. These words encode certain walks on the plane: these walks start at $(0, 0)$, are made of three types of steps, $a = (1, 1)$, $b = (-1, 0)$ and $c = (0, -1)$, and never leave the first quadrant of the plane, defined by $x, y \geq 0$. The *pumping lemma* [52, Thm. 4.7], applied to the word $a^n b^n c^n$, shows that the language $\mathcal{L}$ is not context-free. However, its generating function *is* algebraic. More precisely, let us denote by $\ell_{i,j}(n)$ the number of words $u$ of $\mathcal{L}$ of length $n$ such that $|u|_a - |u|_b = i$ and $|u|_a - |u|_c = j$. They correspond to walks of length $n$ ending at position $(i, j)$. Then the associated three-variable generating function is

$$\begin{aligned} L(u, v; t) &= \sum_{i,j,n} \ell_{i,j}(n) u^i v^j t^n \\ &= \frac{\left(1/W - \bar{u}\right)\sqrt{1 - uW^2} + \left(1/W - \bar{v}\right)\sqrt{1 - vW^2}}{uv - t(u + v + u^2v^2)} - \frac{1}{uvt} \end{aligned}$$

where $\bar{u} = 1/u$, $\bar{v} = 1/v$ and $W \equiv W(t)$ is the unique power series in $t$ satisfying $W = t(2 + W^3)$. Moreover, the number of walks ending at $(i, 0)$ is remarkably simple:

$$\ell_{i,0}(3n + 2i) = \frac{4^n(2i + 1)}{(n + i + 1)(2n + 2i + 1)} \binom{2i}{i} \binom{3n + 2i}{n}.$$

The latter formula was proved in 1965 by Kreweras, in a fairly complicated way [57]. This rather mysterious result has attracted the attention of several combinatorialists since its publication [14], [48], [64]. The first combinatorial explanation of the above formula (in the case $i = 0$) has just been found by Bernardi [7].

Walks in the quarter plane do not always have an algebraic GF: for instance, the number of *square lattice walks* (with North, South, East and West steps) of size $2n$ that start and end at $(0, 0)$ and remain in the quarter plane is

$$\frac{1}{(2n + 1)(2n + 4)} \binom{2n + 2}{n + 1}^2 \sim \frac{4^{2n+1}}{\pi n^3},$$

and this asymptotic behaviour prevents the corresponding generating function from being algebraic (see (16)). The above formula is easily proved by looking at the projections of the walk onto the horizontal and vertical axes.

**3.6.2. Walks on the slit plane.** Take now *any* finite set of steps $\mathcal{S} \subset \mathbb{Z} \times \{-1, 0, 1\}$ (we say that these steps have *small height variations*). Let $s_{i,j}(n)$ be the number of

walks of length $n$ that start from the origin, consist of steps of $\mathcal{S}$, never return to the non-positive horizontal axis $\{(-k, 0), k \geq 0\}$, and end at $(i, j)$. Let $S(u, v; t)$ be the associated generating function:

$$S(u, v; t) = \sum_{i,j \in \mathbb{Z}, n \geq 0} s_{i,j}(n) u^i v^j t^n.$$

Then this series is *always* algebraic, as well as the series $S_{i,j}(t) := \sum_n s_{i,j}(n) t^n$ that counts walks ending at $(i, j)$ [13], [20]. For instance, when $\mathcal{S}$ is formed of the usual square lattice steps (North, South, West and East), then

$$S(u, v; t) = \frac{\left(1 - 2t(1 + \bar{u}) + \sqrt{1 - 4t}\right)^{1/2} \left(1 + 2t(1 - \bar{u}) + \sqrt{1 + 4t}\right)^{1/2}}{1 - t(u + \bar{u} + v + \bar{v})}$$

with $\bar{u} = 1/u$ and $\bar{v} = 1/v$. Moreover, the number of walks ending at certain specific points is remarkably simple. For instance:

$$s_{1,0}(2n + 1) = C_{2n+1}, \quad s_{0,1}(2n + 1) = 4^n C_n, \quad s_{-1,1}(2n) = C_{2n},$$

where $C_n = \binom{2n}{n}/(n + 1)$ is the $n$th Catalan number, which counts binary trees (17), Dyck words, and numerous other combinatorial objects [75, Ch. 6]. The first of these three identities has been proved combinatorially [4]. The others still defeat our understanding.

**3.6.3. Embedded binary trees.** We consider again the complete binary trees met at the beginning of Section 3.2. Let us associate with each (inner) node of such a tree a label, equal to the difference between the number of right steps and the number of left steps one takes when going from the root to the node. In other words, the label of the node is its abscissa in the natural integer embedding of the tree (Figure 12).

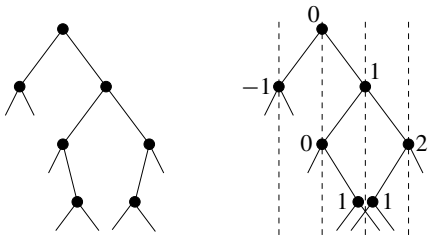

Figure 12. The integer embedding of a binary tree.

Let $S_j \equiv S_j(t, u)$ be the generating function of binary trees counted by the number of nodes (variable $t$) and the number of nodes at abscissa $j$ (variable $u$). Then for all $j \in \mathbb{Z}$, this series is algebraic of degree (at most) 8 (while $S_j(t, 1)$ is quadratic) [12]. Moreover, for $j \geq 0$,

$$S_j = T \, \frac{(1 + \mu Z^j)(1 + \mu Z^{j+5})}{(1 + \mu Z^{j+2})(1 + \mu Z^{j+3})},$$

where

$$T = 1 + tT^2, \qquad Z = t\,\frac{(1+Z^2)^2}{(1-Z+Z^2)},$$

and $\mu \equiv \mu(t,u)$ is the unique formal power series in $t$ satisfying

$$\mu = (u-1)\frac{Z(1+\mu Z)^2(1+\mu Z^2)(1+\mu Z^6)}{(1+Z)^2(1+Z+Z^2)(1-Z)^3(1-\mu^2 Z^5)}.$$

Why is that so? This algebraicity property holds as well for other families of labelled trees [12], [24]. From these series, one can derive certain limit results on the distribution of the number of nodes at abscissa $\lfloor \lambda n^{1/4} \rfloor$ in a random tree with $n$ nodes [12]. These results provide some information about the law of the *integrated super-Brownian excursion* [12], [21].

**3.6.4. $\mathbb{N}$-algebraicity.** $\mathbb{N}$-algebraic series have been defined in Section 3.2 in terms of positive proper algebraic systems. The author has been unable to find in the literature a criterion, or even a necessary condition for an algebraic series with coefficients in $\mathbb{N}$ to be $\mathbb{N}$-algebraic. Nor even an algebraic series with coefficients in $\mathbb{N}$ that would *not* be $\mathbb{N}$-algebraic (together with a proof of this statement...).

A partial answer could be provided by the study of the possible asymptotic behaviour of coefficients of $\mathbb{N}$-algebraic series. It is very likely that not all behaviours of the form (16) are possible. An important result in this direction states that, if a proper positive system (18) is *strongly connected*, the $n$th coefficient of, say, $A_1$ follows the general pattern (16), but with $d = -3/2$ [43, Thm. VII.7]. The system is *strongly connected* if, roughly speaking, the expression of every series $A_i$ involves (possibly after a few iterations of the system) every other series $A_j$. For instance, the system defining the walks ending at 0 in Section 3.4.1 reads

$$M_0 = t^2(1+M_0)^2 \quad \text{and} \quad W_0 = M_0(2+W_0).$$

This system is not strongly connected, as $M_0$ does not involve $W_0$. Accordingly, the number of $2n$-step walks returning to 0 is $\binom{2n}{n} \sim \kappa 4^n n^{-1/2}$.

If one can rule out the possibility that $d = -5/2$ for $\mathbb{N}$-algebraic series, then this will prove that most map generating functions are not $\mathbb{N}$-algebraic (see the examples in Section 3.5).

**3.6.5. Some algebraic hypergeometric series.** Consider the following series:

$$F(t) = \sum_{n\geq 0} f_n t^n = \sum_{n\geq 0} \frac{\prod_{i=1}^{d}(a_i n)!}{\prod_{j=1}^{e}(b_j n)!} t^n,$$

where $a_1, \ldots, a_d, b_1, \ldots, b_e$ are positive integers. This series is algebraic for some values of the $a_i$'s and $b_j$'s, as shown by the case

$$\sum_{n\geq 0} \frac{(2n)!}{n!^2} t^n = \frac{1}{\sqrt{1-4t}}.$$

Can we describe all algebraic cases? Well, one can easily obtain some necessary conditions on the sequences $a$ and $b$ by looking at the asymptotics of $f_n$. First, an algebraic power series has a finite, positive radius of convergence (unless it is a polynomial). This, combined with Stirling's formula, gives at once

$$a_1 + \cdots + a_d = b_1 + \cdots + b_e. \tag{23}$$

Moreover, by looking at the dominant term in the asymptotic behaviour of $f_n$, and comparing with (16), one obtains that either $e = d$, or $e = d+1$. The case $d = e$ only gives the trivial solution $F(t) = 1/(1-t)$, and the complete answer to this problem is as follows [11], [69]:

**Theorem 3.11.** *Assume* (23) *holds and* $F(t) \neq 1/(1-t)$. *The series* $F(t)$ *is algebraic if and only if* $f_n \in \mathbb{N}$ *for all* $n$ *and* $e = d + 1$.

Here are some algebraic instances:

$$f_n = \frac{(6n)!(n)!}{(3n)!(2n)!^2}, \quad f_n = \frac{(10n)!(n)!}{(5n)!(4n)!(2n)!}, \quad f_n = \frac{(20n)!(n)!}{(10n)!(7n)!(4n)!}.$$

The degree of these series is rather big: 12 [resp. 30] for the first [second] series above. This theorem provides a collection of algebraic series with nice integer coefficients: are these series $\mathbb{N}$-algebraic? Do they count some interesting objects?

**Acknowledgements.** The parts of this survey that do not deal exactly with the enumeration of combinatorial objects have often been influenced by discussions with some of my colleagues, including Frédérique Bassino, Henri Cohen, Philippe Flajolet, François Loeser, Géraud Sénizergues. Still, they should not be hold responsible for any of the flaws of this paper.

# Towards a structure theory for matrices and matroids

Jim Geelen, Bert Gerards, and Geoff Whittle*

**Abstract.** We survey recent work that is aimed at generalizing the results and techniques of the Graph Minors Project of Robertson and Seymour to matrices and matroids.

**Mathematics Subject Classification (2000).** 05B35.

**Keywords.** Matroids, minors, representability, well-quasi-ordering.

## 1. Introduction

We are currently undertaking a program of research aimed at extending the results and techniques of the Graph Minors Project of Robertson and Seymour to matrices and matroids. Here we report on where we stand and where we expect to go.

In particular, we discuss the structure of "minor-closed" classes of matrices over a fixed finite field. This requires a peculiar synthesis of graphs, topology, connectivity, and algebra. In addition to proving several long-standing conjectures in the area, we expect the structure theory will help to find efficient algorithms for a general class of problems on matrices and graphs.

Most combinatorial computational problems are trivial in the sense that they are typically finite. However, even for modest size problems, enumerating the possibilities is practically infeasible; it often results in algorithms whose running time is exponential in the size of the problem. We seek smarter, more efficient, algorithms. In the theory of algorithms *efficient* typically means that the running time is polynomial in the size of the problem.

Often the problems are modeled by graphs (networks) or matrices. The better picture we have of the model, the more likely it is that we can develop a quick algorithm for the problem. For instance, the problem at hand may be more tractable if the modeling graph can be drawn in the plane, or some other particular surface, without crossings. Then it is relevant that we can test efficiently if the graph has such advantageous appearance. Surface embeddability, and other related properties, are preserved when deleting an edge from the graph or contracting an edge (*contracting* means deleting the edge and identifying its ends). The result of any series of such deletions and contractions is called a *minor* of the graph. In this terminology, testing

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

surface embeddability is testing a particular minor-closed graph property. So motivated by real-word computational problems, we end up with the fundamental question if minor-closed graph properties can be tested efficiently.

That this is possible indeed for any fixed minor-closed graph property is one of the consequences of the ground-breaking work of Robertson and Seymour in their Graph Minors Project. One major outcome of this project is their proof of Wagner's Conjecture that graphs are "well-quasi-ordered" under the minor-order, which is the following theorem.

**The Graph Minors Theorem** ([31]). *Any infinite family of graphs contains two members such that one is isomorphic to a minor of the other.*

This implies that for any minor-closed graph property there are only finitely many *excluded minors*, these are graphs that do not have the property but whose proper minors do have the property. For planarity, for instance, there are exactly two excluded minors: $K_5$ and $K_{3,3}$; this is Kuratowski's famous characterization of planarity [22].

So, by the Graph Minors Theorem, to test a minor-closed graph property we only need to test containment of each of its excluded minors individually. That this is possible is another crucial outcome of Robertson and Seymour's work.

**The Graph Minor Recognition Theorem** ([29]). *For each graph $H$, there exists a polynomial-time algorithm for testing if a graph has a minor isomorphic to $H$.*

This answered one of the twelve open problems in Garey and Johnson's 1979 book on computational complexity [8].

So minor-closed graph properties can be tested efficiently. However, as noted earlier, also matrices are widely used as modeling tools, for example in integer programming models for operations research. Integer programming models are very general and powerful, but in a sense too general; they lead to "NP-hard" problems. However if the matrix in an integer programming model is *totally unimodular*, that means if all subdeterminants are 0, 1 or $-1$, then linear programming methods do solve the problem [20], and these methods are efficient. So this raises the issue of testing totally unimodularity, another open problem back in '79, in Garey and Johnson's book. Now, it turns out that a matrix being totally unimodular means that it is in a certain sense representable over any field, and also this embeddability property is closed under certain minor-operations. So also here the fundamental issue of testing minor-closed properties arises. For that we work at extending Robertson and Seymour's graph minor theory to matrices. As the issues involved do not so much concern the actual matrices, but rather the underlying "matroids", we work in that setting.

A *matroid* consists of a finite set $E$, the *ground set* of the matroid, and a function $r$, the *rank function* of the matroid. This rank function is defined on the subsets of $E$ and satisfies the following properties: $0 \leq r(X) \leq |X|$ for $X \subseteq E$; $r(X) \leq r(Y)$ for all $X \subseteq Y \subseteq E$ and $r(X \cup Y) + r(X \cap Y) \leq r(X) + r(Y)$ for all $X, Y \subseteq E$. We call $r(X)$ the *rank* of $X$ and $r(E)$ the *rank* of the matroid. The rank function of a matroid $M$ is

denoted by $r_M$. Two matroids are *isomorphic* if there is a rank-preserving bijection between their ground sets.

Matrices yield matroids: If $A = (a_e : e \in E)$ is a matrix with columns $a_e$ over a field $\mathbb{F}$, then the linear rank of the column submatrices $(a_e : e \in F)$ with $F \subseteq E$ is the rank function of a matroid, the *vector matroid* $M(A)$ of $A$. If a matroid is isomorphic to a vector matroid of a matrix over $\mathbb{F}$, we say that the matroid is *representable over* $\mathbb{F}$ or $\mathbb{F}$-*representable*. (A vector matroid is often described as a configuration of points in a linear, affine or projective space instead of as the collection of columns of a matrix.)

Also graphs yield matroids: Let $G$ be a graph with edge set $E$ and vertex set $V$. The *rank* of a graph is the number of its vertices minus the number of its components. If $F \subseteq E$, then the *rank* of $F$ is the rank of the subgraph of $G$ with edge set equal to $F$. This rank yields the rank function of a matroid, the *cycle matroid* $M(G)$ of $G$. A matroid isomorphic to such a cycle matroid of a graph is called *graphic*. A graphic matroid is representable over any field by a matrix with two non-zero entries in every column, one equal to 1 and one equal to $-1$. We assume the reader to be familiar with the standard notions from graph theory. For matroid theory we refer to Oxley [25] or Welsh [43], but we will define the matroid terminology we use, as we go.

Now we define matroid minors. Let $e$ be an element of the ground set $E$ of a matroid $M$. *Deleting* $e$ *from* $M$ is replacing $M$ by the matroid with ground set $E - \{e\}$ and with rank function equal to the restriction of $r_M$ to subsets of $E - \{e\}$. *Contracting* $e$ *from* $M$ is replacing $M$ by the matroid with ground set $E - \{e\}$ and with rank function $r_M(X \cup \{e\}) - r_M(\{e\})$ for each $X \subseteq E - \{e\}$. A *minor* of a matroid is the result of any sequence of deletions and contractions.

A minor of a vector matroid over a field $\mathbb{F}$ is representable over the field as well. Indeed, deleting an element amounts to just deleting the corresponding column whereas contracting an element $f$ amounts to removing $a_f$ from $(a_e : e \in E)$ and projecting all other columns in the direction of $a_f$ on some arbitrary hyperplane not containing $a_f$. Deletions and contractions in a graph are in one-one correspondence with deletions and contractions in its cycle matroid. Thus the cycle matroid of a minor of a graph is a minor of the cycle matroid of the graph.

So the notion of graph minors is in essence algebraic, or geometric, and in that sense it generalizes to matrices and matroids. This raises the question to what extent Robertson and Seymour's graph minor theory extends to matroids. The following conjecture was by Robertson and Seymour, although to our knowledge not in print.

**The Well-Quasi-Ordering Conjecture.** Let $\mathbb{F}$ be a finite field. Then any infinite set of $\mathbb{F}$-representable matroids contains two matroids, one of which is isomorphic to a minor of the other.

As yet, the Well-Quasi-Ordering Conjecture has not been resolved for any finite field. Note that it is equivalent to the conjecture that, for a finite field $\mathbb{F}$, any minor-closed class of $\mathbb{F}$-representable matroids has a finite number of $\mathbb{F}$-representable excluded minors.

The finiteness of the field in the Well-Quasi-Ordering Conjecture is essential. Indeed, suppose $\mathbb{F}$ is an infinite field and consider for each integer $n \geq 3$, a $2n \times 3$ matrix with columns $p_1, \ldots, p_n$ and $q_1, \ldots, q_n$, where $p_1, \ldots, p_n$ are vectors in general position in $\mathbb{F}^3$ and each $q_i$ is spanned by $p_i$ and $p_{i+1}$, but is not spanned by any other pair among $p_1, \ldots, p_n$ (where $p_{n+1} = p_1$). As $\mathbb{F}$ is infinite, such matrices clearly exist. Among the vector matroids of these matrices none is a minor of another. Indeed, all members of the collection have rank 3, so all minors that use a contraction have too low rank to be in the collection; deleting an element from a member of the collection destroys the unique cyclic arrangement of linearly dependent triples $p_i, q_i, p_{i+1}$ in a way that cannot be repaired by further deletions.

We conjecture additionally that for matroids that are representable over a finite field minor-closed properties can be recognized in polynomial time, in other words we conjecture that also the Graph Minor Recognition Theorem extends.

**The Minor-Recognition Conjecture.** For any finite field $\mathbb{F}$ and any $\mathbb{F}$-representable matroid $N$, there is a polynomial-time algorithm for testing whether an $\mathbb{F}$-representable matroid contains a minor isomorphic to $N$.

At the heart of the Graph Minors Project is Robertson and Seymour's Graph Minors Structure Theorem [30]. It describes constructively the graphs that do not contain a given graph as a minor. This constructive description enables techniques to establish the well-quasi-ordering and algorithmic consequences. For matroids, Seymour [36] used this approach successfully for characterizing total unimodularity (see Section 3). Our hope is to use the same strategy for general matroids that are representable over finite fields. Therefore we are developing a structure theory for such matroids. As a major role in the theory of graph minors is played by connectivity, we need an extension of graph connectivity to matroids.

The basic ingredients of graph connectivity are separations, which tell where the connectivity is not that high, and Menger's Theorem, which provides a way of certifying that the connectivity is not that low. A *separation* of a graph $G$ is a pair $(G_1, G_2)$ of subgraphs of $G$ such that $G = G_1 \cup G_2$; the *order* of the separation $(G_1, G_2)$ is the number of vertices of $G$ that lie in both $G_1$ and $G_2$. A graph is *k-connected* if it has no separation $(G_1, G_2)$ of order $l$ less than $k$ such that $G_1$ and $G_2$ have at least $l$ edges each. One of the fundamental theorems of graph theory is Menger's Theorem.

**Menger's Theorem** ([24]). *If $G$ is a graph and $S$ and $T$ are two sets of vertices, then there either exist $k$ disjoint paths, each connecting a vertex in $S$ with a vertex in $T$, or (exclusively) $G$ has a separation $(G_1, G_2)$ of order less than $k$ such that $S$ lies in $G_1$ and $T$ in $G_2$.*

As an illustration of how this theorem plays a role in finding minors consider the following easy result of Dirac [4]: *A 3-connected graph with at least 4 vertices has a minor isomorphic to $K_4$.* ($K_n$ denotes the complete graph with $n$ vertices; *complete* means that every pair of vertices is connected by an edge.) Here is a proof of Dirac's

result: we may assume the graph has two non-adjacent vertices $s$ and $t$, otherwise the graph is complete and we are done. Apply Menger's Theorem to the set $S$ of neighbours of $s$ and the set $T$ of neighbours of $t$. This yields three $P_1$, $P_2$ and $P_3$ from $s$ to $t$ that only meet at their ends. As $G$ is 3-connected, $G - s - t$ is connected, so there exists a path $Q$ that connects two of these paths and misses the third path. The union of $P_1$, $P_2$, $P_3$ and $Q$ clearly has a minor isomorphic to $K_4$. So Dirac's result follows. This is a very easy result of course, but it may convince the reader of the need of a notion of matroid connectivity and a matroidal version of Menger's Theorem.

A *separation* of a matroid $M$ is a partition $(X, Y)$ of the ground set $E$. The *order* of the separation $(X, Y)$ is $r_M(X) + r_M(Y) - r_M(E) + 1$; for a representable matroid this is the dimension of the intersection of the subspaces spanned by $X$ and $Y$ plus 1. A matroid is *k-connected* if it has no separation $(X, Y)$ of order $l$ less than $k$ such that $X$ and $Y$ have size $l$ or more. If $(G_1, G_2)$ is a separation of $G$ where $E_1$ and $E_2$ are the edge sets of $G_1$ respectively $G_2$, then $(E_1, E_2)$ is a separation of $M(G)$. When $G_1$, $G_2$, and $G$ are connected graphs, the orders of these separations are the same. This is enough to consider matroid separations and matroid connectivity as genuine generalizations of these notions for graphs. And there is a matroidal generalization of Menger's Theorem as well.

**Tutte's Linking Theorem** ([42]). *Let $M$ be a matroid and $X$ and $Y$ be disjoint subsets of its ground set. Then there exists a minor of $M$ in which $(X, Y)$ is a separation of order at least $k$ or (exclusively) $M$ has a separation $(A, B)$ of order less than $k$ with $X$ in $A$ and $Y$ in $B$.*

This follows quite easily from Edmonds' Matroid Intersection Theorem [7], which is one of the fundamental theorems of matroid theory. So we see that the basic theory of graph connectivity does extend quite well to matroids.

Besides the fact that a matroid structure theory will help proving the Well-Quasi-Ordering Conjecture and Minor-Recognition Conjecture for matroids, we also expect that it will provide a handle on the following conjecture, probably the most famous open question in matroid theory.

**Rota's Conjecture** ([33]). Let $\mathbb{F}$ be a finite field. There are, up to isomorphism, only finitely many excluded minors for the class of $\mathbb{F}$-representable matroids.

This also has computational relevance, namely for the question how hard it is to decide if a matroid given by an oracle for the rank function is representable over a field $\mathbb{F}$. Unfortunately, it does take exponentially many oracle calls to decide this, for any field [38]. But if Rota's conjecture is true, then for every finite field $\mathbb{F}$ there exists, for every non-$\mathbb{F}$-representable matroid, a polynomial-length certificate for this non-representability, that requires only a constant number of oracle calls. (It is known that this can be done by a quadratic number of oracle calls [14].)

For the three smallest fields all excluded minors for representability over the field are known: there is one for GF(2) (Tutte [40]), there are four for GF(3) (Bixby [1]

and Seymour [37], independently), and there are seven for GF(4) (Geelen, Gerards and Kapoor [9]). For all other finite fields, Rota's conjecture is still open. A structure theory could well provide a way to prove it.

Also in Rota's conjecture finiteness of the field is essential. Lazarson [23] showed that there are an infinite number of excluded minors for representability over the reals and this is certainly true for all other infinite fields.

Summarizing, en route for these three conjectures we are working at establishing the structure of minor-closed proper subclasses of matroids representable over a finite field. This work has already had some success. It turns out that excluding the cycle matroid of a planar graph as a minor imposes tangible structure on matroids over finite fields, so we begin with discussing that.

## 2. Excluding a planar graph

Let $\mathbb{F}$ be a finite field and let $H$ be a planar graph. We give a constructive structural description of $\mathbb{F}$-representable matroids with no $M(H)$-minor and show that this description enables significant progress on the three conjectures in Section 1. Essentially the structure is to be decomposable into small pieces along low-order separations. We will first explain what that means.

A *branch-decomposition* of matroid $M$ is a tree $T$ in which all vertices have degree 1 or 3, where the degree-1 vertices of $T$ are in 1-1 correspondence with the elements of the ground set $E$ of $M$. The *width* of an edge $e$ in $T$ is the order of the separation $(X, Y)$ of $M$ where $X$ contains the elements of $E$ that correspond to the degree-1 vertices of $T$ in one component of $T - e$ and $Y$ the elements of $E$ that correspond to the degree-1 vertices of $T$ in the other component of $T - e$. So a branch-decomposition is a data-structure for a collection of separations. The *width* of a branch-decomposition is the maximum of the widths of its edges and the *branch-width* of a matroid is the minimum of the widths of all its branch-decompositions. So roughly low branch-width means to be decomposable into small pieces along low-order separations.

Branch-width is a matroid generalization of branch-width for graphs defined by Robertson and Seymour [28]. For graphs it is, up to a constant multiplicative bound, the same as tree-width, also introduced by Robertson and Seymour. In the Graph Minors Project they mainly use tree-width and that notion does extend to matroids [19] as well. But branch-width is easier to work with for matroids, so here we will only use branch-width, also for graphs. Robertson and Seymour prove the following result.

**The Grid Theorem for graphs** ([27]). *For each planar graph $H$ there is an integer $k$ such that any graph with branch-width at least $k$ has a minor isomorphic to $H$.*

This result is called the Grid Theorem because, as every planar graph is a minor of a grid, it suffices to prove it for the case that $H$ is a grid. Here, *a grid*, or rather

*an n by n grid*, refers to the graph with a vertex $(i, j)$ for each pair of integers $i$ and $j$ between 1 and $n$ and an edge between any two pairs $(i_1, j_1)$ and $(i_2, j_2)$ with $|i_1 - i_2| + |j_1 - j_2| = 1$. If a matroid has a minor isomorphic to a cycle matroid of an $n$ by $n$ grid, we say it has a *grid-minor*. To convince oneself that each planar graph $H$ is a minor of a sufficiently large grid, visualize $H$ as drawn without crossings and with the edges and vertices as thick lines and dots on a piece of grid paper with a very fine grid.

Consider a class of graphs that do not have a fixed planar graph as a minor. By the Grid Theorem for graphs, the members of that class have bounded branch-width. This constructive characterization provides considerable traction for both algorithmic and structural problems. For example, Robertson and Seymour [26] prove that any class of graphs of bounded branch-width is well-quasi-ordered. This extends to matroids over finite fields.

**Theorem** ([12]). *Let $\mathbb{F}$ be a finite field and $k$ an integer. Then each infinite set of $\mathbb{F}$-representable matroids with branch-width at most $k$ has two members such that one is isomorphic to a minor of the other.*

Johnson, Robertson, and Seymour [21] conjectured that also the Grid Theorem for graphs extends to matroids over finite fields and this is indeed the case.

**The Grid Theorem for matroids** ([13]). *For each finite field $\mathbb{F}$ and each planar graph $H$, there exists an integer $k$ such that each $\mathbb{F}$-representable matroid with branch-width at least $k$ has a minor isomorphic to $M(H)$.*

As a consequence we obtain the following partial result towards the Well-Quasi-Ordering Conjecture.

**Corollary.** *Let $\mathbb{F}$ be a finite field and $H$ a planar graph. Then any infinite set of $\mathbb{F}$-representable matroids with no minor isomorphic to $M(H)$ contains two matroids such that one is isomorphic to a minor of the other.*

In combination with results of Hliněný [18], we also obtain partial progress towards the Minor-Recognition Conjecture.

**Corollary.** *For each finite field $\mathbb{F}$ and each planar graph $H$, there is a polynomial-time algorithm for testing whether or not an $\mathbb{F}$-representable matroid contains a minor isomorphic to $M(H)$.*

So for matroids over a fixed finite field we can efficiently test all minor-closed properties that do not hold for the cycle matroid of all planar graphs.

Geelen and Whittle [17] show that for a finite field $\mathbb{F}$ and integer $k$, the number of excluded minors for $\mathbb{F}$-representability that have branch width at most $k$ is finite. In combination with the Grid Theorem for matroids this yields the following result.

**Corollary.** *For each finite field $\mathbb{F}$ and each planar graph $H$, there are only finitely many excluded minors for $\mathbb{F}$-representability that do not have $M(H)$ as a minor.*

We see that the structure imposed on a class of matroids by excluding the matroid of a planar graph as a minor yields restricted solutions to the Well-Quasi-Ordering Conjecture, the Minor-Recognition Conjecture, and Rota's Conjecture, and that is a promising beginning.

The Grid Theorem for matroids is absolutely central in developing a structure theory for matroids. When specialized to graphs, the proof in [13] is different from the existing proofs in [3], [27], [32]. It is important to note that we had access to an extraordinary 150-page handwritten manuscript [21] of Johnson, Robertson, and Seymour describing their progress towards a grid theorem for matroids. The techniques we learned from their manuscript played a crucial role in parts of our proof. The proof also makes use of earlier results we obtained together with Neil Robertson [10], [11].

Regarding the result above on well-quasi-ordering of $\mathbb{F}$-representable matroids of bounded branch-width it is interesting to note that the finiteness of $\mathbb{F}$ is essential there. This is illustrated by the sequence of matrices given in Section 1, below the Well-Quasi-Ordering Conjecture; they all have branch-width at most 3, as they all have rank 3. On the other hand, there are only finitely many excluded minors for the class of all matroids of branch width at most $k$, representable or not [11].

We conclude this section with a comment regarding Rota's Conjecture. We have seen that for every finite field $\mathrm{GF}(q)$ there are a finite number of excluded minors for $\mathrm{GF}(q)$-representability of any given branch width. In [15] it is proved that an excluded minor for $\mathrm{GF}(q)$-representability of sufficiently large branch width cannot contain a $\mathrm{PG}(q+6, q)$-minor. ($\mathrm{PG}(n, q)$ is the matroid represented by points of the projective geometry of order $n$ over $\mathrm{GF}(q)$.) So it follows that if Rota's Conjecture fails for $\mathrm{GF}(q)$, then there must exist excluded minors with arbitrarily large grid-minors and no large projective geometry as a minor.

## 3. An example: the structure of regular matroids

With the results in the previous section in hand we proceed towards a structure theory for matroids over finite fields. One of the prototypes of structural matroid theory and its algorithmic consequences concerns the totally unimodular matrices mentioned in Section 1. The question if a certain given matrix is totally unimodular can be translated into the question if a related, easy-to-construct, GF(2)-representable matroid is representable over all fields. Such matroids are called *regular*. Regularity is a minor-closed property. Tutte [40] proved that a GF(2)-representable matroid is regular if and only if it does not have a minor isomorphic to PG(2, 2), also called the *Fano matroid*, or to the dual of PG(2, 2). Here the *dual* of a matroid $M$ is the matroid $M^*$ with the same ground set $E$ as $M$ and with rank-function $r_{M^*}(X) = |X| - r_M(E-X) + r_M(E)$. Representability over a field $\mathbb{F}$ is closed under duality, hence so is regularity. Taking minors commutes with duality; although the roles of deletion and contraction swap.

Tutte's excluded minor characterization of regular matroids is one of the gems of matroid theory, but it does not tell how to decide if a given GF(2)-representable matroid is regular or not. That question was answered by a structural result, Seymour's Regular Matroid Decomposition Theorem [36]: *A matroid over* GF(2) *is regular if and only if it is the* 1*-,* 2*- or* 3*-sum of graphic matroids, duals of graphic matroids and copies of a particular* 10*-element matroid called* $R_{10}$. Here a 1-, 2- or 3-sum of two (representable) matroids is carried out by embedding each of them in a distinct projective space and then combining these projective spaces by taking either their direct sum, in case of a 1-sum, or identifying single points or lines, in case of a 2-sum or a 3-sum. These "meeting" points or lines should be in both matroids and may or may not be deleted from the matroid after the composition. The sums as well as the reversed "decomposition" operations preserve regularity.

So Seymour's result gives a structural description of the class of regular matroids. Their "global structure" is that they are composed from smaller pieces along low-order separations. The pieces sit together in a tree-like fashion. The description of these pieces provides the "local structure": each piece is either a graphic matroid, the dual of a graphic matroid or isomorphic to $R_{10}$. This combination of global and local structure is typical for all structural results in this paper.

Seymour's structural characterization of regular matroids is constructive, it can be used to design an algorithm for testing regularity in polynomial time. This goes as follows. First decide if the matroid is a 1-, 2- or 3-sum of smaller matroids. This can be done in polynomial time, as gluing two matrices together leaves a separation of order at most 3 in the composed matroid and Cunningham and Edmonds [2] observed that detecting these is a matroid intersection problem, which is solvable in polynomial time (Edmonds [7]). When the matroid is fully decomposed into "4-connected pieces", each piece is tested for being isomorphic to $R_{10}$, which is trivial, or being a graphic matroid or the dual of a graphic matroid, which can be done by Tutte's polynomial-time algorithm for testing graphicness [41]. If all pieces pass the test, the original matroid is regular, otherwise it is not.

By the relation between regularity and total unimodularity this yields an algorithm for testing if a real matrix is totally unimodular or not (see Schrijver [35, Chapter 20] for a description of this algorithm in terms of the matrices). This is the only known polynomial-time algorithm for testing totally unimodularity. Thus the structure of matroids is crucial for the algorithmic aspects of this central property in operations research and combinatorial optimization. Actually matroids in general do play a major role in the theory of combinatorial optimization, see Schrijver [34]. A book on matroid decomposition is Truemper [39], it mainly concerns regular matroid decomposition and related topics.

With Seymour's regular matroid decomposition in mind we next discuss what we expect to be the structure of minor-closed classes of matroids that are representable over a finite field. It should be noted that the results will not be as "tight" as in Seymour's decomposition theorem. Seymour provided a constructive description of all binary matroids that contain neither the Fano matroid nor its dual as a minor. More-

over, none of the matroids obtained via that construction contain the Fano matroid or its dual. In contrast, the Grid Theorem for graphs provides a construction for the graphs that do not contain a given planar graph $H$ as a minor, but some graphs obtained via the construction may contain $H$ as a minor. The construction is, however, sufficiently restrictive that it does not build all planar graphs. For algorithmic and well-quasi-ordering purposes, this is good enough.

## 4. Global structure and local structure

In Section 2 we discussed the structure of classes of matroids over finite fields that do not have a minor isomorphic to the cycle matroid of a particular planar graph: they can be decomposed into small pieces along low-order separations; they have low branch-width. So explorations beyond that concern matroids with high branch-width. The existence of large grid-minors in such matroids is useful in investigating their structure, but a matroid may have several high branch-width parts that are separated by low-order separations and we have to describe the structure of these parts separately. To get a handle on these parts, Robertson and Seymour [28] introduce tangles. A tangle really just indicates for each low-order separation on which side a particular high branch-width part lies. Formally, a *tangle of order* $t$ assigns to each separation $(X, Y)$ of order less than $t$ one of $X$ and $Y$ as the *small side of* $(X, Y)$ and the other side as the *big side of* $(X, Y)$. It is required that no three small sides of the tangle cover the ground set of the matroid and that no singletons are big. It turns out that the maximum order of a tangle in a matroid is the branch-width of the matroid; for graphs this was shown by Robertson and Seymour [28] and for matroids by Dhamatilike [5] (although this result was implicit in [28]).

Combining this with the Grid Theorem, we see that grid-minors yield tangles. Indeed, if $F \subseteq M$ is the set of elements of an $n$ by $n$ grid-minor of $M$, then $F$ partitions naturally in the "horizontal" and "vertical" *lines* of the grid. If we consider for each separation $(X, Y)$ of order less than $n$ the side that contains a line in $F$ as big, then that yields a tangle of order $n$. It was shown in [16] that for any finite field $\mathbb{F}$ and any $n$ there exists an integer $t$ such that in any $\mathbb{F}$-representable matroid any tangle of order $t$ controls an $n$ by $n$ grid-minor. This generalizes a result from [32] for graphs. Here a tangle *controls* a minor $N$ of $M$ if no small side of a separation of order less than the rank of $N$ contains all elements of $N$.

So tangles "locate" highly connected areas of the matroid. If all small sides of one tangle are small in some other tangle, then they both seem to refer to the same highly connected part but the latter tangle does that more accurately. Therefore we are mainly interested in the *maximal* tangles, those for which the collection of small sets is inclusion-wise maximal. It turns out that matroids, like graphs [28], can be viewed as consisting of their maximal tangles put together in a tree-shaped structure, see [16] for details. This provides a global picture of a matroid. To complete that picture we have to describe the individual tangles, the local structure.

To explain what we mean with that, we first explain what it means to reduce a set $S$ in an $\mathbb{F}$-represented matroid $M$. Consider $M$ as a collection $E$ of points in a projective geometry. Let $X$ be the span of $E - S$ in that projective geometry. For each $S' \subseteq S$ whose span meets $X$ in a single point, we call that point $x_{S'}$. Let $Y$ be the set of all points $x_{S'}$ for all such sets $S'$. Replacing $M$ by the matroid represented by the union of $Y$ and $E - S$ is called *reducing* $S$. (For graphs, this more or less means to remove the edges in $S$ and to add an edge between any pair of vertices that both lie in $S$ and in the complement of $S$.)

Let $\mathcal{C}$ be a class of matroids. A tangle has *local structure in* $\mathcal{C}$ if there exist separations $(S_1, B_1), \ldots, (S_k, B_k)$ in $M$ with disjoint small sides $S_1, \ldots, S_k$ such that the matroid obtained from $M$ by reducing each of $S_1, \ldots, S_k$ is in $\mathcal{C}$. To describe the full structure we only need to characterize the minor-closed classes $\mathcal{C}$ that provide the local structure of tangles in matroids over the finite field that do not contain a particular minor.

## 5. The local structure of graph tangles

The Graph Minor Structure Theorem says that for any $n$ there exists a surface $\Sigma$ and integers $m, d, k$ such that the tangles of a graph with no minor isomorphic to $K_n$ have local structure in the class of graphs that lie on a surface $\Sigma$ with $m$ vortices of depth at most $d$ and $k$ extra vertices. We explain what this means.

A *vortex with connectors* $v_1, \ldots, v_p$ is a graph $H$ that is the union of graphs $H_1, \ldots, H_p$ such that $v_i$ is a vertex in $H_i$ for each $i = 1, \ldots, p$ and such that if a vertex $v$ of $H$ occurs in $H_i$ and $H_j$ for some $i, j = 1, \ldots, p$ then $v$ either occurs in all of $H_{i+1}, \ldots, H_{j-1}$ or in all of $H_{j+1}, \ldots, H_{i-1}$ (indices modulo $n$). The maximum size of the subgraphs $H_1, H_2, \ldots, H_p$ is the *depth* of the vortex.

A graph is *on a surface* $\Sigma$ *with m vortices of depth at most d* if it can be constructed as follows: take a graph drawn on $\Sigma$, select $m$ faces and add to each of these faces a vortex of depth $d$ to $G$ that meets $G$ and the other added vortices only in its connectors $v_1, \ldots, v_n$ which lie in that order around the boundary of the face. If we additionally add $k$ new vertices and new edges from these vertices to each other and to the rest of the graph, we obtain *a graph that lies on a surface* $\Sigma$ *with m vortices of depth at most d and k extra vertices*.

## 6. The local structure of matroid tangles

What are the minor-closed classes needed to describe the local structure of matroids that are representable over a finite field? One natural minor-closed class is the class of graphic matroids. Also, if $\mathbb{F}'$ is a subfield of $\mathbb{F}$, then the class of $\mathbb{F}'$-representable matroids is a minor-closed class of $\mathbb{F}$-representable matroids. There is another natural class, of Dowling matroids. They are like graphs and originally introduced by Dowling [6] and studied in greater depth by Zaslavsky [44], [45].

A *Dowling matroid* is a matroid that can be represented over a field $\mathbb{F}$ by a matrix with the property that every column has at most two non-zero elements. We call such matrix a *Dowling representation* of the matroid. If the ratio between the non-zero elements in each column of a Dowling representation is in a subgroup $\Gamma$ of the multiplicative group of $\mathbb{F}$, we call the matroid *a Dowling matroid over* $\Gamma$. One can naturally associate a graph $G(A)$ with a Dowling representation $A$. Each row of $A$ is a vertex of $G(A)$ and each column of $A$ with two non-zeroes yields an edge in $G(A)$ connecting the vertices corresponding to the rows that have the non-zeroes in that column. Thus we get for each surface and each subgroup of the multiplicative group of $\mathbb{F}$ the class of $\mathbb{F}$-representable Dowling matroids that have Dowling representations over the subgroup and whose associated graphs embed on the surface. Obviously such a class is minor-closed.

In fact, we can extend such minor-closed class by allowing a bounded number of "vortices" of bounded depth, these are obtained by adding matroid elements into bounded-rank subspaces arranged in a cyclic manner around a face in the embedding, similar to vortices in graphs.

Finally we can extend a minor-closed class $\mathcal{C}$ of matroids by considering for some integer $k$ the class of all rank-$l$ perturbations of the members of $\mathcal{C}$ with $l \leq k$. Here an $\mathbb{F}$-representable matroid $M$ is a *rank-$l$ perturbation* of an $\mathbb{F}$-representable matroid $N$ if $M$ and $N$ have representations $A$ and $B$, respectively, with the linear rank of $A - B$ equal to $l$.

Splitting a vertex in a graph amounts to a rank-1 perturbation of its cycle matroid. So adding $k$ vertices to a graph amounts to adding a single vertex followed by a rank-$(k-1)$ perturbation of the cycle matroid. Adding a single vertex to a graph $G$ does in general not correspond to a low-rank perturbation. However, fortunately, the cycle matroid of the resulting graph has a Dowling representation $A$ with $G(A) = G$. Hence the Graph Minors Structure Theorem is captured by the matroid classes given above.

Now we state our main results and conjectures on the structure of minor-closed classes over a finite field GF($q$), where $q = p^k$ for some fixed prime $p$ and some fixed integer $k$. We distinguish between three types of minor-classes. The first type are the classes that do not contain the cycle matroid of large complete graphs nor their duals. The second type are the classes that do not contain large projective geometries over the prime field GF($p$) of GF($q$). The third type are the classes that do not contain large projective geometries over GF($q$). In each of the cases, $\mathcal{T}$ is a tangle in a GF($q$)-representable matroid.

Below $n$ is a fixed integer and each of the qualitative bounds "low", "bounded", or "sufficiently large" indicates a bound only depending on $q$ and $n$, so not on the particular tangles or matroids.

**Excluding $M(K_n)$ and $M(K_n)^*$.** We believe that we have proved that if $\mathcal{T}$ has sufficiently large order and does not control a minor isomorphic to $M(K_n)$ or to $M(K_n)^*$, then $\mathcal{T}$ has local structure in the class of low-rank perturbations of GF($q$)-

representable matroids that can be obtained by adding a bounded number of vortices of bounded depth to a Dowling matroid whose associated graph is embedded in a surface of low genus, or of the duals of such matroids. This implies the Graph Minors Structure Theorem.

With this result and duality, we can now restrict our attention to tangles that control the cycle matroid of a large complete graph.

**Excluding PG($n$, $p$).** We conjecture that if $\mathcal{T}$ controls a minor isomorphic to $M(K_m)$ for a sufficiently large integer $m$ but $\mathcal{T}$ does not control a minor isomorphic to PG($n$, $p$), then $\mathcal{T}$ has local structure in the class of low-rank perturbations of GF($q$)-representable Dowling matroids.

Roughly speaking the conjectures above state that if $M$ is a GF($q$)-representable matroid with no minor isomorphic to PG($n$, $p$), then $M$ admits a tree-like decomposition such that each part is either essentially a Dowling matroid or is essentially the dual of a Dowling matroid. For a field of prime order this would give the required constructive structural characterization of the minor-closed proper subclasses of matroids representable over the field.

It is interesting to note here that a slight extension of Seymour's regular matroid decomposition says that if a GF(2)-representable matroid has no minor isomorphic to PG(2, 2) then it can be constructed from graphic matroids, their duals, and copies of $R_{10}$ and copies of the dual of PG(2, 2), by 1-, 2- and 3-sums [36]. As graphic matroids are GF(2)-representable Dowling matroids and as $R_{10}$ and the dual of PG(2, 2) are low-rank perturbations of a trivial matroid, this result of Seymour's implies the conjecture above for case that $q = 2$ and $n = 2$.

**Excluding PG($n$, $q$).** For the case that $q$ is not prime, we conjecture that if $\mathcal{T}$ controls a minor isomorphic to PG($m$, $p$) for a sufficiently large integer $m$ but $\mathcal{T}$ does not control a minor isomorphic to PG($n$, $q$), then $\mathcal{T}$ has local structure in the class of GF($q$)-representable low-rank perturbations of matroids that are representable over a proper subfield of GF($q$).

Finally we can summarize all of the above into a single conjecture. For any minor-closed proper subclass $\mathcal{M}$ of GF($q$)-representable matroids, each matroid in $\mathcal{M}$ admits a tree-like decomposition such that each part is either essentially a Dowling matroid, or is essentially the dual of a Dowling matroid, or is essentially represented over a proper subfield of GF($q$).

# Cherednik algebras, Macdonald polynomials and combinatorics

Mark Haiman*

**Abstract.** In the first part of this article we review the general theory of Cherednik algebras and non-symmetric Macdonald polynomials, including a formulation and proof of the fundamental *duality theorem* in its proper general context. In the last section we summarize some of the combinatorial results in this area which we have recently obtained in collaboration with J. Haglund and N. Loehr.

**Mathematics Subject Classification (2000).** Primary 33D52; Secondary 05E10.

**Keywords.** Macdonald polynomials, affine Hecke algebras, Cherednik algebras.

## 1. Introduction

*The record is very long. The facts are few and may be briefly stated.*
*—Miller v. San Francisco Methodist Episcopal* (1932)

This article consists of an overview of the theory of Cherednik algebras and non-symmetric Macdonald polynomials, followed by the combinatorial formula for non-symmetric Macdonald polynomials of type $A_{n-1}$ recently obtained by Haglund, Loehr and the author.

The main points in the theory are duality (Theorems 4.10, 5.11), and its consequence, the intertwiner recurrence for Macdonald polynomials (Corollary 6.15), which is the key to the combinatorial study of non-symmetric Macdonald polynomials. The intertwiner recurrence can also be used to deduce other important results in the theory, such as the norm and evaluation formulas, but I have omitted those for lack of space.

The theory of course did not spring into being in the tidy form in which I have attempted to package it here. Rather, it has been gradually clarified over almost twenty years through the efforts of many people, in a large literature which I will not attempt to cite in full. Let me only mention the origins of the theory in the works of Macdonald [13], [14], [15], Opdam [17], and Cherednik [1], [2] and remark that further important contributions were made by Ion, Knop, Koornwinder, Sahi, and van Diejen, among others.

*Work supported in part by NSF grant DMS-0301072.

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

The overview given here necessarily has much in common with Macdonald's monograph [16], which serves a similar purpose, but there are also several differences. I have systematically used the lattice formulation for root systems, because it is most natural from related points of view (algebraic groups, quantum groups), because it puts affine and other root systems on an equal footing, and because important elements of the theory (§2, 5.1–5.5, 5.13–5.15) apply to arbitrary root systems. I give a new and somewhat more general proof of the duality theorem; Macdonald's proof, strictly speaking, applies to the root system of $\mathrm{SL}_n$, for instance, but not $\mathrm{GL}_n$ or $\mathrm{PGL}_n$, although it can be adjusted to cover these cases. For the triangularity property of the Macdonald polynomials $E_\lambda$ (Theorem 6.6), I use the affine Bruhat order on the weight lattice $X$, rather than the orbit-lexicographic order used by Macdonald. This simplifies some arguments, and is more natural in that the coefficient of $x^\mu$ in $E_\lambda$ is non-zero if and only if $\mu < \lambda$ in Bruhat order. I have also tried to use more transparent notation.

## 2. Root systems

**2.1.** We always consider root systems realized in a lattice. So, for us, a *root system* $\big(X, (\alpha_i), (\alpha_i^\vee)\big)$ consists of a finite-rank free abelian group $X$, whose dual lattice $\mathrm{Hom}(X, \mathbb{Z})$ is denoted $X^\vee$, a finite set of vectors $\alpha_1, \dots, \alpha_n \in X$, called *simple roots*, and a finite set of covectors $\alpha_1^\vee, \dots, \alpha_n^\vee \in X^\vee$, called *simple coroots*. We denote by $X_\mathbb{Q}$ (resp. $X_\mathbb{R}$) the $\mathbb{Q}$-vector space $X \otimes_\mathbb{Z} \mathbb{Q}$ (resp. $\mathbb{R}$-vector space $X \otimes_\mathbb{Z} \mathbb{R}$) spanned by $X$.

The $n \times n$ matrix $A$ with entries $a_{ij} = \langle \alpha_j, \alpha_i^\vee \rangle$ is assumed to be a *generalized Cartan matrix*, satisfying the axioms

$$\begin{aligned} &\text{(i)} && \langle \alpha_i, \alpha_i^\vee \rangle = 2, \\ &\text{(ii)} && \langle \alpha_j, \alpha_i^\vee \rangle \le 0 \text{ for all } j \ne i, \\ &\text{(iii)} && \langle \alpha_j, \alpha_i^\vee \rangle = 0 \text{ if and only if } \langle \alpha_i, \alpha_j^\vee \rangle = 0. \end{aligned}$$

The *Dynkin diagram* is the graph with nodes $i = 1, \dots, n$ and an edge $\{i, j\}$ for each $a_{ij} \ne 0$, usually with some decoration on the edges to indicate the values of $a_{ij}, a_{ji}$. If the Dynkin diagram is connected, $A$ is *indecomposable*. If there exist non-zero integers $d_i$ such that $\langle \alpha_j, d_i \alpha_i^\vee \rangle = \langle \alpha_i, d_j \alpha_j^\vee \rangle$ for all $i$, $j$, then $A$ is *symmetrizable*. The integers $d_i$ can be assumed positive. If $A$ is symmetrizable and indecomposable, the $d_i$ are unique up to an overall common factor. Then $d_i$ is *length* of the root $\alpha_i$. If there are only two root lengths, we call them *long* and *short*. If there is only one root length, every root is both long and short.

**2.2.** Let $\alpha \in X$ and $\alpha^\vee \in X^\vee$ satisfy $\langle \alpha, \alpha^\vee \rangle = 2$. The linear automorphism

$$s_{\alpha\alpha^\vee}(\lambda) = \lambda - \langle \lambda, \alpha^\vee \rangle \, \alpha$$

of $X$ is a *reflection*. It fixes the hyperplane $\langle \lambda, \alpha^\vee \rangle = 0$ pointwise, and sends $\alpha$ to $-\alpha$. Thus $(s_{\alpha,\alpha^\vee})^2 = 1$. The reflection on $X^\vee$ dual to $s_{\alpha,\alpha^\vee}$ is equal to $s_{\alpha^\vee,\alpha}$.

If $\alpha^\vee$ is implicitly associated to $\alpha$, we write $s_\alpha$ for both $s_{\alpha,\alpha^\vee}$ and $s_{\alpha^\vee,\alpha}$. When $\alpha = \alpha_i$ and $\alpha^\vee = \alpha_i^\vee$ are a simple root and corresponding coroot, we write $s_i$ for $s_{\alpha_i}$. The $s_i$ are called *simple reflections*.

**2.3.** The root system $\big(X, (\alpha_i), (\alpha_i^\vee)\big)$ is *non-degenerate* if the simple roots $\alpha_i$ are linearly independent. When the Cartan matrix $A$ is non-singular, *e.g.*, for any finite root system, then both $X$ and its dual $\big(X^\vee, (\alpha_i^\vee), (\alpha_i)\big)$ are necessarily non-degenerate. When $A$ is singular, for instance if the root system is affine (Definition 3.1), it is often convenient to take the simple roots to be a basis of $X_{\mathbb{Q}}$, in which case $X$ is non-degenerate but its dual is degenerate.

**2.4.** Assume in what follows that $\big(X, (\alpha_i), (\alpha_i^\vee)\big)$ is non-degenerate. The *Weyl group* $W$ is the group of automorphisms of $X$ (and of $X^\vee$) generated by the simple reflections $s_i$. The sets of *roots* and *coroots* are

$$R = \bigcup_i W(\alpha_i), \quad R^\vee = \bigcup_i W(\alpha_i^\vee).$$

The *root* and *coroot lattices* are

$$Q = \mathbb{Z}\{\alpha_1, \ldots, \alpha_n\} \subseteq X, \quad Q^\vee = \mathbb{Z}\{\alpha_1^\vee, \ldots, \alpha_n^\vee\} \subseteq X^\vee.$$

The set of *positive roots* is $R_+ = R \cap Q_+$, where

$$Q_+ = \mathbb{N}\{\alpha_1, \ldots, \alpha_n\}.$$

The *dominant weights* are the elements of the cone

$$X_+ = \{\lambda \in X : \langle \lambda, \alpha_i^\vee \rangle \geq 0 \text{ for all } i\}.$$

The root system $\big(X, (\alpha_i), (\alpha_i^\vee)\big)$ is *finite* if $W$ is a finite group, or equivalently, $R$ is a finite set. The Cartan matrix $A$ of a finite root system is symmetrizable, with positive definite symmetrization $DA$. Conversely, if $A$ has a positive definite symmetrization, then $R$ is finite. The finite root systems classify reductive algebraic groups $G$ over any algebraically closed field $k$. Then $X$ is the character group of a maximal torus in $G$, or *weight lattice*.

**Example 2.5.** Let $X = \mathbb{Z}^n$, and identify $X^\vee$ with $X$ using the standard inner product on $\mathbb{Z}^n$ such that the unit vectors $e_i$ are orthogonal. Let $\alpha_i = \alpha_i^\vee = e_i - e_{i+1}$ for $i = 1, \ldots, n-1$. This gives the root system of the group $\mathrm{GL}_n$.

Replacing $X$ with the root lattice $Q$ and restricting the simple coroots to $Q$, we obtain the root system of the adjoint group $\mathrm{PGL}_n$ ($\mathrm{GL}_n$ modulo its center).

The constant vector $\varepsilon = e_1 + \cdots + e_n$ satisfies $\langle \varepsilon, \alpha_i^\vee \rangle = 0$ for all $i$. Let $X' = X/(\mathbb{Z}\varepsilon)$, with simple roots and coroots induced by those of $X$. This gives the root system of the simply connected group $\mathrm{SL}_n$. It is dual to the root system of $\mathrm{PGL}_n$. All three root systems have the same Cartan matrix, of type $A_{n-1}$.

**2.6.** We recall some standard facts. First, $R = R_+ \cup -R_+$, *i.e.*, every root is positive or negative (note that $R = -R$, since $s_i(\alpha_i) = -\alpha_i$ for all $i$). The Weyl group $W$, with its generating set $S$ of simple reflections $s_i$, is a Coxeter group with defining relations

$$s_i^2 = 1, \tag{1}$$

$$s_i s_j s_i \ldots = s_j s_i s_j \ldots \quad (m_{ij} \text{ factors on each side}), \tag{2}$$

where if $a_{ij}a_{ji} = 0, 1, 2$ or $3$, then $m_{ij} = 2, 3, 4$, or $6$, respectively, and if $a_{ij}a_{ji} \geq 4$, there is no relation between $s_i, s_j$.

The *length* $l(w)$ of $w \in W$ is the minimal $l$ such that $w = s_{i_1} \ldots s_{i_l}$. Such an expression is called a reduced factorization. More generally, if $w = u_1 u_2 \ldots u_r$ with $l(w) = l(u_1) + \cdots + l(u_r)$ we call $u_1 \cdot u_2 \ldots u_r$ a reduced factorization.

If $w = s_{j_1} \ldots s_{j_l}$ is a second reduced factorization, then the identity $s_{j_1} \ldots s_{j_l} = s_{i_1} \ldots s_{i_l}$ holds in the monoid with generators $s_i$ and the *braid relations* (2), that is, it does not depend on the relations $s_i^2 = 1$.

The length of $w$ is equal to the number of positive roots carried into negative roots by $w$, *i.e.*, $l(w) = |R_+ \cap w^{-1}(-R_+)|$. In particular, $\alpha_i$ is the only positive root $\alpha$ such that $s_i(\alpha) \in -R_+$. The following conditions are equivalent: (i) $l(ws_i) < l(w)$; (ii) $w(\alpha_i) \in -R_+$; (iii) some reduced factorization of $w$ ends with $s_i$. We abbreviate these conditions to $ws_i < w$, and write $s_i w < w$ when $w^{-1}s_i < w^{-1}$.

If $\alpha = w(\alpha_i) = w'(\alpha_j)$, then $w(\alpha_i^\vee) = w'(\alpha_j^\vee)$, so there is a well-defined coroot $\alpha^\vee = w(\alpha_i^\vee)$ associated to $\alpha$ and satisfying $\langle \alpha, \alpha^\vee \rangle = 2$, and accordingly a well-defined reflection $s_\alpha = s_{\alpha,\alpha^\vee} = ws_i w^{-1}$. Warning: the correspondence $\alpha \mapsto \alpha^\vee$ need not be bijective if the dual root system is degenerate.

The map $W \to \{\pm 1\}$, $w \mapsto (-1)^{l(w)}$ is a group homomorphism. In particular, $l(s_\alpha)$ is always odd, and $l(ws_\alpha) \neq l(w)$. We put $ws_\alpha < w$ if $l(ws_\alpha) < l(w)$. The *Bruhat order* is the partial order on $W$ given by the transitive closure of these relations.

**2.7.** The *braid group* $\mathcal{B}(W)$ is the group with generators $T_i$ and the braid relations (2) with $T_i$ in place of $s_i$. If $w = s_{i_1} \ldots s_{i_l}$ is a reduced factorization, we set $T_w = T_{i_1} \ldots T_{i_l}$. These elements are well-defined and satisfy

$$T_u T_v = T_{uv} \quad \text{when } uv = u \cdot v \text{ is a reduced factorization.} \tag{3}$$

There is a canonical homomorphism $\mathcal{B}(W) \to W$, $T_i \mapsto s_i$. By the symmetry of the braid relations, there is an automorphism $T_i \leftrightarrow T_i^{-1}$ of $\mathcal{B}(W)$.

**2.8.** The *affine Weyl group* of $\big(X, (\alpha_i), (\alpha_i^\vee)\big)$ is the semidirect product $W \ltimes X$. In this context, we use multiplicative notation for the group $X$, denoting $\lambda \in X$ by $x^\lambda$. Explicitly, $W \ltimes X$ is generated by its subgroups $W$ and $X$ with the additional relations

$$s_i x^\lambda s_i = x^{s_i(\lambda)}. \tag{4}$$

**2.9.** The (left) *affine braid group* $\mathcal{B}(W, X)$ of $\big(X, (\alpha_i), (\alpha_i^\vee)\big)$ is the group generated by $\mathcal{B}(W)$ and $X$, with the additional relations

$$T_i x^\lambda = x^\lambda T_i \quad \text{if } \langle \lambda, \alpha_i^\vee \rangle = 0 \ \ (\textit{i.e.}, \text{if } s_i(\lambda) = \lambda); \tag{5}$$

$$T_i x^\lambda T_i = x^{s_i(\lambda)} \quad \text{if } \langle \lambda, \alpha_i^\vee \rangle = 1. \tag{6}$$

These two relations may be combined into the following analog of (4):

$$T_i^a x^\lambda T_i^b = x^{s_i(\lambda)}, \quad \text{where } a, b \in \{\pm 1\} \text{ and } \langle \lambda, \alpha_i^\vee \rangle = (a+b)/2 \tag{7}$$

(the case $a = b = -1$ follows by taking inverses on both sides in (6)). The canonical homomorphism $\mathcal{B}(W) \to W$ extends to a homomorphism $\mathcal{B}(W, X) \to W \ltimes X$ which is the identity on $X$.

For clarity when dealing with double affine braid groups later on, we define separately the *right* affine braid group $\mathcal{B}(X, W)$, generated by $W$ and $X$ with additional relations

$$T_i x^\lambda = x^\lambda T_i \quad \text{if } \langle \lambda, \alpha_i^\vee \rangle = 0\,; \tag{8}$$

$$T_i^{-1} x^\lambda T_i^{-1} = x^{s_i(\lambda)} \quad \text{if } \langle \lambda, \alpha_i^\vee \rangle = 1. \tag{9}$$

There is an isomorphism $\mathcal{B}(X, W) \cong \mathcal{B}(W, X)$ which maps $T_i \mapsto T_i^{-1}$ and is the identity on $X$.

**2.10.** If $\big(X, (\alpha_i), (\alpha_i^\vee)\big)$ is a non-degenerate root system, the root lattice $Q$ is free with basis $(\alpha_i)$. Identify $Q^\vee$ with a quotient of the free abelian group $\hat{Q}^\vee$ with basis $(\alpha_i^\vee)$, and set $P = \operatorname{Hom}(\hat{Q}^\vee, \mathbb{Z})$. The roots and coroots in $X$ are then given by homomorphisms $Q \to X \to P$, where the matrix of the composite $Q \to P$ is the Cartan matrix $A$. Suppose that $X \to P$ factors through a second lattice $X'$ as

$$Q \to X \underset{j}{\to} X' \to P.$$

This induces a root system $\big(X', (\alpha_i'), (\alpha_i'^\vee)\big)$ in $X'$ with the same Cartan matrix $A$ and canonically isomorphic Weyl and braid groups $W' = W$, $\mathcal{B}(W') = \mathcal{B}(W)$. There is an induced homomorphism of affine braid groups $j_{\mathcal{B}} \colon \mathcal{B}(W, X) \to \mathcal{B}(W, X')$ which restricts to $j$ on $X$ and to the canonical isomorphism on $\mathcal{B}(W)$.

**Theorem 2.11.** *The image of $j_{\mathcal{B}} \colon \mathcal{B}(W, X) \to \mathcal{B}(W, X')$ is normal in $\mathcal{B}(W, X')$, and the induced maps* $\ker(j) \to \ker(j_{\mathcal{B}})$, $\operatorname{coker}(j) \to \operatorname{coker}(j_{\mathcal{B}})$ *are isomorphisms.*

*Proof* (*outline*). First suppose that $X' = X \oplus \mathbb{Z}\nu$, where $\langle \nu, \alpha_i^\vee \rangle \in \{0, 1\}$ for all $i$. One proves that there exists an automorphism $\eta$ of $\mathcal{B}(W, X)$ which fixes $X$, such that $\eta(T_i) = T_i$ if $\langle \nu, \alpha_i^\vee \rangle = 0$, and $\eta(T_i) = T_i^{-1} x^{-\alpha_i}$ if $\langle \nu, \alpha_i^\vee \rangle = 1$. Then one checks that $\eta^{\mathbb{Z}} \ltimes \mathcal{B}(W, X) \cong \mathcal{B}(W, X')$, with $\eta \mapsto x^\nu$. Iterating this gives $\mathcal{B}(W, X \oplus P) \cong P \ltimes \mathcal{B}(W, X)$, and similarly, $\mathcal{B}(W, X' \oplus P) \cong P \ltimes \mathcal{B}(W, X')$.

Replacing $X$, $X'$ with $X \oplus P$, $X' \oplus P$, we may assume that $X \to P$ and $X' \to P$ are surjective.

Next one verifies that if $X \to X'$ is surjective, with kernel $Z$, then $\mathcal{B}(W, X') \cong \mathcal{B}(W, X)/Z$. Applying this to $0 \to Z \to X \to P \to 0$ and $0 \to Z' \to X' \to P \to 0$, we get surjections $\mathcal{B}(W, X) \to \mathcal{B}(W, P)$, $\mathcal{B}(W, X') \to \mathcal{B}(W, P)$ with kernels $Z$, $Z'$. The theorem then follows by some easy diagram chasing. □

**2.12.** Let $\big(X, (\alpha_i), (\alpha_i^\vee)\big)$ be a root system. It may happen that for one or more of the simple roots $\alpha_i$, we have $\alpha_i^\vee \in 2X^\vee$. Then we can form another (degenerate) root system by adjoining a new simple root $2\alpha_i$ and coroot $\alpha_i^\vee/2$. Note that $s_{(2\alpha_i),(\alpha_i^\vee/2)} = s_i$, so this new root system has the same Weyl group as the original one, but a larger set of roots $R' = R \cup W(2\alpha_i)$.

If a root system contains two simple roots $\alpha_i, \alpha_{i'}$ such that $s_i = s_{i'}$ and $\alpha_i \neq \pm\alpha_{i'}$, it is said to be *non-reduced*, otherwise it is *reduced*. We remark that $s_{i'} = s_i$ implies $\alpha_{i'} = d\alpha_i$, $\alpha_{i'}^\vee = (1/d)\alpha_i^\vee$, where $d \in \{\pm 1, \pm 2, \pm 1/2\}$. Hence every non-reduced root system is constructed by extensions as above from a reduced root system with the same Weyl group.

## 3. Affine root systems and affine Weyl groups

**Definition 3.1.** A root system $\big(X, (\alpha_i), (\alpha_i^\vee)\big)$ is *affine* if its Cartan matrix $A$ is singular, and for every proper subset $J$ of the indices, the root system $\big(X, (\alpha_i)_{i\in J}, (\alpha_i^\vee)_{i\in J}\big)$ is finite.

**3.2.** The definition implies that the nullspace of $A$ is one-dimensional. If $X$ is non-degenerate, then $\{\lambda \in Q : \langle \lambda, \alpha_i^\vee \rangle = 0 \text{ for all } i\}$ is a sublattice of rank 1. It always has a (unique) generator $\delta \in Q_+$, called the *nullroot*.

We index the simple roots by $i = 0, 1, \ldots, n$. We always assume that $i = 0$ is an *affine node*, meaning that $\alpha_0 \in \mathbb{Q}\alpha + \mathbb{Q}\delta$ for some root $\alpha$ of the finite root system $\big(X, (\alpha_1, \ldots, \alpha_n), (\alpha_1^\vee, \ldots, \alpha_n^\vee)\big)$. This condition is equivalent to $s_1, \ldots, s_n$ generating the finite Weyl group $W_0 = W/Q_0'$, where $W$ is the Weyl group and $Q_0'$ is the kernel of its induced action on $X/(X \cap \mathbb{Q}\delta)$. Every affine root system has at least one affine node.

**3.3.** The affine Cartan matrices are classified in Kac [8] and Macdonald [16]. They are symmetrizable and indecomposable. We refer to them using Macdonald's nomenclature, but with a tilde over the names to distinguish them from finite types. Those denoted $\widetilde{X}_n$, or $X_n^{(1)}$ in Kac, are the *untwisted types*, where $X_n = A_n$, $B_n$, $C_n$, $D_n$, $E_{6,7,8}$, $F_4$, or $G_2$ is a Cartan matrix of finite type. Their duals (if different) $\widetilde{B}_n^\vee$, $\widetilde{C}_n^\vee$, $\widetilde{F}_4^\vee$, $\widetilde{G}_2^\vee$ are the *dual untwisted types*, denoted $A_{2n-1}^{(2)}$, $D_{n+1}^{(2)}$, $E_6^{(2)}$, and $D_4^{(3)}$ in Kac.

The remaining *mixed* types, denoted $A_{2n}^{(2)}$ in Kac, are exceptional in that they have three root lengths. Although the mixed types are isomorphic to their duals, we prefer

to distinguish between them, denoting a mixed type as $\widetilde{BC}_n$ when the distinguished affine root $\alpha_0$ is the longest simple root, and $\widetilde{BC}_n^\vee$ when $\alpha_0$ is the shortest simple root.

Types $\widetilde{B}_n$, $\widetilde{C}_n^\vee$, $\widetilde{BC}_n$, $\widetilde{BC}_n^\vee$ contain one or more simple roots $\alpha_i$ such that $\langle \alpha_j, \alpha_i^\vee \rangle$ is even for all $j$. There exist affine root systems $X$ of these types such that $\alpha_i^\vee \in 2X^\vee$. A *non-reduced affine root system* is a non-reduced extension (§2.12) of such a root system $X$.

**3.4.** The Weyl group $W_a$ of any affine root system $\big(X, (\alpha_i), (\alpha_i^\vee)\big)$ is isomorphic to the affine Weyl group $W = Q_0' \rtimes W_0$ of some finite root system $\big(Y, (\alpha_i'), (\alpha_i'^\vee)\big)$. Conversely, the affine Weyl group $Y \rtimes W_0$ of any finite root system is a semidirect extension $\Pi \ltimes W_a$ of the Weyl group of a corresponding affine root system. We now fix precise notation and explain how this correspondence comes about.

**3.5.** Let $\big(Y, (\alpha_i'), (\alpha_i'^\vee)\big)$, $i = 1, \ldots, n$, be a finite root system, with Weyl group $W_0$ and root lattice $Q_0'$. Let $\phi'$ be the (unique) dominant short root. Let $W_e = Y \rtimes W_0$ be the affine Weyl group of $Y$, and set $W_a = Q_0' \rtimes W_0 \subseteq W_e$. Write $y^\lambda$ for $\lambda \in Y$ regarded as an element of $W_e$. The orbit $W_0(\phi')$ consists of all the short roots, and spans $Q_0$. Defining $s_0 = y^{\phi'} s_{\phi'}$, it follows that $s_0$ and $s_1, \ldots, s_n \in W_0$ generate $W_a$. We will construct an affine root system whose Weyl group $W$ is isomorphic to $W_a$, with simple reflections corresponding to the generators $s_0, \ldots, s_n$.

**3.6.** Let $X = Y^\vee \oplus \mathbb{Z}$, and fix a non-zero element $\delta$ in the second summand. We need not assume that $\delta$ is a generator, so in general we have $X = Y^\vee \oplus \mathbb{Z}\delta/m$ for some positive integer $m$. Define the pairing $\langle X, Y \rangle \to \mathbb{Z}$, extending the canonical pairing $\langle Y^\vee, Y \rangle \to \mathbb{Z}$, with $\langle \delta, Y \rangle = 0$.

Let $\theta = \phi'^\vee$ be the highest coroot. For $i \neq 0$, set $\alpha_i = \alpha_i'^\vee$ and $\alpha_i^\vee = \alpha_i'$ (regarded as a linear functional on $X$ via $\langle \cdot, \cdot \rangle$). Put $\alpha_0 = \delta - \theta$ and $\alpha_0^\vee = -\phi'$. The subgroup $W_0 \subseteq W_a$ acts via its original action on $Y^\vee$, fixing $\delta$. The subgroup $Q_0' \subseteq W_a$ acts by *translations*, given by the formula

$$y^{\beta'}(\mu^\vee) = \mu^\vee - \langle \mu^\vee, \beta' \rangle \delta, \tag{10}$$

One checks that the element $y^{\phi'} s_{\phi'} \in W_a$ acts as the simple reflection $s_0$, identifying $W_a$ with the Weyl group $W$ of $X$.

For $Y$ of type $Z_n$ ($Z = A, B, \ldots, G$), the affine root system $X$ just constructed is of untwisted type $\widetilde{Z}_n$, with nullroot $\delta$. In this case the affine roots are

$$R = R_0'^\vee + \mathbb{Z}\delta, \tag{11}$$

and the positive roots are $R_+ = (R_0'^\vee + \mathbb{Z}_{>0}\delta) \cup (R_0'^\vee)_+$.

**3.7.** Let $\big(X, (\alpha_0, \ldots, \alpha_n), (\alpha_0^\vee, \ldots, \alpha_n^\vee)\big)$ be any affine root system, $W$ its Weyl group. Let $Q_0$, $W_0$ be the root lattice and Weyl group of the finite root system $\big(X, (\alpha_1, \ldots, \alpha_n), (\alpha_1^\vee, \ldots, \alpha_n^\vee)\big)$. If $X$ is of untwisted type, we have just seen that $W \cong Q_0' \rtimes W_0$, where $Q_0' = Q_0^\vee$. If $X^\vee$ is of untwisted type, then $W \cong W(X^\vee) \cong$

$Q_0' \rtimes W_0$, where $Q_0' = (Q_0^\vee)^\vee = Q_0$. If $X$ is of mixed type, its Weyl group is of type $\widetilde{C}_n$, so $W \cong Q_0' \rtimes W_0$ where $Q_0'$ is of type $C_n$, hence $Q_0' = Q_0^\vee$ for $\widetilde{BC}_n$, and $Q_0' = Q_0$ for $\widetilde{BC}_n^\vee$.

**3.8.** Twisted affine root systems can also be constructed in the manner of §3.6, by taking $\theta$ to be any dominant coroot of $Y$ or of a non-reduced finite root system containing $Y$. This yields dual untwisted types when $\theta$ is short, and mixed types when $\theta$ is one-half of a long coroot or twice a short coroot. However, when $\theta \neq \phi'^\vee$, we no longer have $W = Q_0' \rtimes W_0$.

**3.9.** We now return to the situation of §3.5, fixing the finite root system $Y$ and untwisted affine root system $X = Y^\vee \oplus \mathbb{Z}\delta/m$ in what follows. The affine Weyl group $W_e = Y \rtimes W_0$ of $Y$ is called the *extended affine Weyl group*. The action of $Q_0'$ on $X$ given by (10) extends to an action of $Y$, hence the action of $W_a = Q_0' \rtimes W_0$ extends to $W_e$. By (11), $W_e$ preserves the set of affine roots $R$.

**3.10.** The further properties of $W_a$ and $W_e$ are best understood in terms of the following "alcove picture." Let $H = \{x \in X_{\mathbb{R}}^\vee : \langle \delta, x\rangle = 1\}$ be the *level 1 plane*, and let $\Lambda_0^\vee \in H$ be the linear functional $\Lambda_0^\vee(Y^\vee) = 0$, $\langle \delta, \Lambda_0^\vee\rangle = 1$. The group $W_e$ fixes $\delta$, hence acts on $H$. The translations $Y \subset W_e$ act on $H$ by

$$y^\lambda(\mu) = \mu + \lambda, \tag{12}$$

and the finite Weyl group $W_0$ is generated by reflections fixing $\Lambda_0^\vee$. In particular, the map $y^\lambda \mapsto \Lambda_0^\vee + \lambda$ identifies $Y \cong W_e/W_0$ with the orbit $W_e(\Lambda_0^\vee) \subset H$, equivariantly with respect to the original action of $W_0$ on $Y$, and the action of $Q_0' \subseteq Y$ by translations.

Each affine root $\alpha \in R$ induces an affine-linear functional $\alpha(x) = \langle \alpha, x\rangle$ on $H$. Its zero set $h_\alpha = \{x \in H : \alpha(x) = 0\}$ is an affine hyperplane in $H$, and $s_\alpha \in W = W_a$ fixes $h_\alpha$ pointwise. The space $H$ is tessellated by *affine alcoves* bounded by the root hyperplanes $h_\alpha$. We distinguish the *dominant alcove* $A_0 = H \cap (\mathbb{R}_+ X_+^\vee) = \{x \in H : \alpha(x) \geq 0 \text{ for all } \alpha \in R_+\}$.

The alcove $A_0$ is a fundamental domain for the action of $W_a$ on $H$. Its walls are the root hyperplanes $h_{\alpha_i}$ for the simple affine roots $\alpha_0, \ldots, \alpha_n$. Let $\Pi \subseteq W_e$ be the stabilizer of $A_0$, or equivalently, $\Pi = \{\pi \in W_e : \pi(R_+) = R_+\}$. Since $\Pi$ preserves the set of simple roots, it normalizes the subgroup $W_a \subseteq W_e$ and the set of Coxeter generators $S = \{s_0, \ldots, s_n\} \subseteq W_a$. The following are immediate.

**Corollary 3.11.** *With the notation above, we have $W_e = \Pi \ltimes W_a$. Moreover, $\Pi$ is the normalizer in $W_e$ of the set of Coxeter generators $S = \{s_0, \ldots, s_n\}$.*

**Corollary 3.12.** *The canonical homomorphism $Y \subset W_e \to W_e/W_a = \Pi$ induces an isomorphism $Y/Q_0' \cong \Pi$. In particular, $\Pi$ is abelian.*

To make this explicit, write $\pi \in \Pi$ uniquely as

$$\pi = y^{\lambda_\pi} \cdot v_\pi \in Y \rtimes W_0. \tag{13}$$

Then $\pi$ maps to the coset of $\lambda_\pi$ in $Y/Q_0'$. In the notation of §3.10, we have $\Lambda_0^\vee + \lambda_\pi = y^{\lambda_\pi}(\Lambda_0^\vee) = \pi(\Lambda_0^\vee) \in A_0$. Equivalently, $\lambda_\pi \in Y$ is a dominant weight such that $\langle \lambda, \phi'^\vee \rangle \leq 1$, or *minuscule weight*. Conversely, if $\lambda \in Y$ is minuscule, there is a unique $\pi \in \Pi$ such that $y^{\lambda - \lambda_\pi} \in W_a$. Then $\lambda = \lambda_\pi$, because both weights are minuscule and $A_0$ is a fundamental domain for $W_a$. The minuscule weights $\lambda_\pi$ (including $\lambda_1 = 0$) are thereby in bijection with $\Pi$.

**3.13.** The distinguished elements

$$y^{\phi'} = s_0 s_{\phi'}, \quad y^{\lambda_\pi} = \pi v_\pi^{-1}, \tag{14}$$

where $\phi'$ is the dominant short root and $\lambda_\pi$ are the minuscule weights, are characterized as the unique translations such that $s_0 \in y^{\phi'} W_0$, $\pi \in y^{\lambda_\pi} W_0$, consistent with our having written $W_e = Y \rtimes W_0$. If we write $W_e = W_0 \ltimes Y$, we instead distinguish the translations

$$y^{-\phi'} = s_{\phi'} s_0, \quad y^{-\lambda_\pi} = v_\pi \pi^{-1} \tag{15}$$

corresponding to the *anti-dominant* short root and the "anti-minuscule" weights. Of course (14) and (15) are equivalent, but the corresponding formulas for the left and right affine braid groups will not be (see Theorem 4.2, Corollary 4.3).

## 4. Double affine braid groups

**4.1.** Let $W_e = Y \rtimes W_0 = \Pi \ltimes W_a$ be an extended affine Weyl group (§3.9–3.13). By Corollary 3.11, $\Pi$ acts on $W_a$ by Coxeter group automorphisms. Hence $\Pi$ also acts on $\mathcal{B}(W_a)$, and we can form the *extended affine braid group* $\mathcal{B}(W_e) = \Pi \ltimes \mathcal{B}(W_a)$.

Define the length function on $W_e = \Pi \ltimes W_a$ by $l(\pi w) = l(w)$. Note that $l(w\pi) = l(\pi w^\pi) = l(w^\pi) = l(w)$. The length of $v = \pi w$ is again equal to $|R_+ \cap v^{-1}(-R_+)|$, or to the number of affine hyperplanes $h_\alpha$ separating $v(A_0)$ from $A_0$ in the alcove picture (§3.10). Identity (3) continues to hold in $\mathcal{B}(W_e)$.

The counterpart to Corollary 3.11 is the following theorem of Bernstein (see [9, (4.4)]).

**Theorem 4.2.** *The identification $\Pi \ltimes W_a = Y \rtimes W_0$ lifts to an isomorphism $\mathcal{B}(W_e) \cong \mathcal{B}(Y, W_0)$ between the extended affine braid group defined above, and the* (*right*) *affine braid group* (§2.9) *of the finite root system $Y$. The isomorphism is the identity on $\mathcal{B}(W_0)$ and given on the remaining generators by $y^{\phi'} \leftrightarrow T_0 T_{s_{\phi'}}$, $y^{\lambda_\pi} \leftrightarrow \pi T_{v_\pi^{-1}}$, in the notation of* §3.5 *and* (13).

We describe the restriction of the isomorphism to $Y \subseteq \mathcal{B}(Y, W_0)$ more explicitly. If $\lambda, \mu \in Y_+$ are dominant, the alcove picture shows that $l(y^{\lambda+\mu}) = l(y^\lambda) + l(y^\mu)$. Hence $T_{y^{\lambda+\mu}} = T_{y^\lambda} T_{y^\mu}$ in $\mathcal{B}(W_e)$. It follows that there is a well-defined group homomorphism $\phi\colon Y \to \mathcal{B}(W_e)$ such that $y^{\lambda-\mu} \mapsto T_{y^\lambda} T_{y^\mu}^{-1}$ for $\lambda, \mu \in Y_+$. In particular, this yields the formulas $y^{\phi'} \mapsto T_{y^{\phi'}} = T_0 T_{s_{\phi'}}$, $y^{\lambda_\pi} \mapsto T_{y^{\lambda_\pi}} = \pi T_{v_\pi^{-1}}$.

One verifies using the alcove picture that the elements $\phi(y^\lambda)$ and the generators $T_i$ of $\mathcal{B}(W_0)$ satisfy the defining relations of $\mathcal{B}(Y, W_0)$. Hence $\phi$ extends to a homomorphism $\mathcal{B}(Y, W_0) \to \mathcal{B}(W_e)$. Next one verifies (with the help of Lemma 4.20, below) that the element $y^{\phi'} T_{s_{\phi'}}^{-1} \in \mathcal{B}(Q_0', W_0)$ satisfies braid relations with the generators $T_i$, giving a homomorphism $\mathcal{B}(W_a) \to \mathcal{B}(Q_0', W_0)$ inverse to $\phi$. Hence $\phi$ maps $\mathcal{B}(Q_0', W_0)$ isomorphically onto $\mathcal{B}(W_a)$, and by Theorem 2.11, it follows that $\phi$ is an isomorphism.

**Corollary 4.3.** *For a (left) extended affine Weyl group $W_a \rtimes \Pi = W_0 \ltimes X$, there is an isomorphism $\mathcal{B}(W_e) \cong \mathcal{B}(W_0, X)$ between the extended affine braid group and the left affine braid group of $X$, which is the identity on $\mathcal{B}(W_0)$, and satisfies $x^{-\phi} \leftrightarrow T_{s_\phi} T_0$, $x^{-\lambda_\pi} \leftrightarrow T_{v_\pi} \pi^{-1}$.*

**4.4.** We come now to the key construction in the theory. Fix two finite root systems $\big(X, (\alpha_i), (\alpha_i^\vee)\big)$, $\big(Y, (\alpha_i'), (\alpha_i'^\vee)\big)$ with the same Weyl group $W_0$. More accurately, assume given an isomorphism of Coxeter groups $W_0 = (W(X), S) \cong (W(Y), S')$, and label the simple roots so that $s_i$ corresponds to $s_i'$ for each $i = 1, \dots, n$.

Let $\phi \in Q_0 \subseteq X, \phi' \in Q_0' \subseteq Y$ be the dominant short roots. Let $\theta \in Q_0, \theta' \in Q_0'$ be the dominant roots such that $s_\theta = s_{\phi'}$, $s_{\theta'} = s_\phi$. There are unique $W_0$-equivariant pairings $(X, Q_0') \to \mathbb{Z}$, $(Q_0, Y)' \to \mathbb{Z}$ such that $(\beta, \phi') = \langle \beta, \theta^\vee \rangle$ for all $\beta \in X$ and $(\phi, \beta')' = \langle \beta', \theta'^\vee \rangle$ for all $\beta' \in Y$. One checks that $(\phi, \phi') = (\phi, \phi')' = 2$ if $s_\phi = s_{\phi'}$, and $(\phi, \phi') = (\phi, \phi')' = 1$ if $s_\phi \neq s_{\phi'}$. By $W_0$-equivariance, the two pairings therefore agree on $Q_0 \times Q_0'$. Fix a $W_0$-invariant pairing $(X, Y) \to \mathbb{Q}$ extending the two pairings $(\cdot\,, \cdot)$ and $(\cdot\,, \cdot)'$, and choose $m$ such that $(X, Y) \subseteq \mathbb{Z}/m$.

**Remark 4.5.** The Cartan matrices of $X$ and $Y$ are clearly either of the same type $(Z_n, Z_n)$, or of dual types $(Z_n, Z_n^\vee)$. In the symmetric case $(Z_n, Z_n)$, the roots $\theta = \phi$, $\theta' = \phi'$ are short, and the pairing $(\cdot\,, \cdot)$ restricts on $Q_0 = Q_0'$ to the $W_0$-equivariant pairing such that $(\alpha, \alpha) = 2$ for short roots $\alpha$. In the dual case $(Z_n, Z_n^\vee)$, $\theta$ and $\theta'$ are long, and the pairing restricts to the canonical pairing between $Q_0$ and $Q_0' = Q_0^\vee$. Types $G_2$ and $F_4$ are isomorphic to their duals, but only after relabelling the simple roots. Thus there is a genuine difference between types $(G_2, G_2)$ and $(G_2, G_2^\vee)$, for instance. In particular, $\theta = \phi$ in the first case, and $\theta \neq \phi$ in the second.

**4.6.** Given the data in §4.4, set $\widetilde{X} = X \oplus \mathbb{Z}\delta/m$, $\widetilde{Y} = Y \oplus \mathbb{Z}\delta'/m$. Extend the linear functionals $\alpha_i^\vee$ on $X$ to $\widetilde{X}$ so that $\langle \delta, \alpha_i^\vee \rangle = 0$. Define $\alpha_0 = \delta - \theta$, and let $\alpha_0^\vee$ be the extension of $-\theta^\vee$ such that $\langle \delta, \alpha_0^\vee \rangle = 0$. Making similar definitions in $\widetilde{Y}$, we get two affine root systems

$$\big(\widetilde{X}, (\alpha_0, \dots, \alpha_n), (\alpha_0^\vee, \dots, \alpha_n^\vee)\big), \quad \big(\widetilde{Y}, (\alpha_0', \dots, \alpha_n'), (\alpha_0'^\vee, \dots, \alpha_n'^\vee)\big).$$

Let $Y$ act on $\widetilde{X}$ and $X$ on $\widetilde{Y}$ by

$$y^\lambda(\mu) = \mu - (\mu, \lambda)\delta, \quad x^\mu(\lambda) = \lambda - (\mu, \lambda)\delta'.$$

Since $(\cdot\,,\cdot)$ is $W_0$-invariant, this extends to actions of the extended affine Weyl groups

$$W_e = Y \rtimes W_0, \quad W_e' = W_0 \ltimes X$$

on $\widetilde{X}$ and $\widetilde{Y}$, respectively. The semidirect products $W_e \ltimes \widetilde{X}$, $\widetilde{Y} \rtimes W_e'$ are the (left, right) *extended double affine Weyl groups*. We have the following easy counterpart of Corollary 3.11.

**Corollary 4.7.** *There is a canonical isomorphism $W_e \ltimes \widetilde{X} \cong \widetilde{Y} \rtimes W_e'$, which is the identity on $X$, $Y$ and $W_0$, and maps $q = x^\delta$ to $y^{-\delta'}$. In fact, both groups are identified with $W_0 \ltimes (X \star Y)$, where $X \star Y$ is the Heisenberg group generated by $X$, $Y$ and central element $q^{1/m}$, with relations*

$$x^\mu y^\lambda = q^{(\mu,\lambda)} y^\lambda x^\mu.$$

**Remarks 4.8.** (a) For consistency, set $q = y^{-\delta'}$ in the "right" double affine Weyl group $\widetilde{Y} \rtimes W_e'$. Then the isomorphism maps $q$ to $q$.

(b) When $X$ and $Y$ are of dual types, the affine root systems $\widetilde{X}$, $\widetilde{Y}$ are of untwisted type (§3.6). When $X$ and $Y$ are of the same type, then $\widetilde{X}$, $\widetilde{Y}$ are of dual untwisted type (§3.8).

(c) The requirement that $(\cdot\,,\cdot)$ extend the pairings $(X, Q_0') \to \mathbb{Z}$ and $(Q_0, Y')' \to \mathbb{Z}$ in §4.4 ensures that

$$W_e \ni y^{\phi'} s_{\phi'} = s_0 \in W(\widetilde{X}), \quad W_e' \ni s_\phi x^{-\phi} = s_0' \in W(\widetilde{Y}).$$

Under the action of $W_e = Y \rtimes W_0 = \Pi \ltimes W_a$ on $\widetilde{X}$, the subgroup $W_a = Q_0' \rtimes W_0$ is therefore identified with the Weyl group of $\widetilde{X}$. By Corollary 3.11, $\Pi \subset W_e$ acts on $\widetilde{X}$ by automorphisms of the root system, *i.e.* it permutes the affine simple roots and coroots. So $W_e$ acts on $\widetilde{X}$ as the semi-direct product of the Weyl group $W_a$ and the group of automorphisms $\Pi$. In particular, the extended double affine Weyl group $W_e \ltimes \widetilde{X}$ is the semidirect product

$$\Pi \ltimes (W_a \ltimes \widetilde{X})$$

of $\Pi$ with the affine Weyl group (§2.8) of the affine root system $\widetilde{X}$. Similar remarks apply to $\widetilde{Y} \rtimes W_e'$.

**4.9.** Since $\Pi$ acts by automorphisms of the affine root system $\widetilde{X}$, it also acts naturally on $\mathcal{B}(W_a, \widetilde{X})$ (§2.9), and we can form the semidirect product $\Pi \ltimes \mathcal{B}(W_a, \widetilde{X})$, which we may regard as an extended (left) affine braid group $\mathcal{B}(W_e, \widetilde{X})$ of the affine root system $\widetilde{X}$. Similarly, we can define $\mathcal{B}(\widetilde{Y}, W_e') = \mathcal{B}(\widetilde{Y}, W_a') \rtimes \Pi'$. Define $q = x^\delta$ in $\mathcal{B}(W_e, \widetilde{X})$, and $q = y^{-\delta'} \in \mathcal{B}(\widetilde{Y}, W_e)$, as in Remark 4.8(a). We come now to the fundamental theorem.

**Theorem 4.10.** *The isomorphism $W_e \ltimes \widetilde{X} \cong \widetilde{Y} \rtimes W_e'$ lifts to an isomorphism $\mathcal{B}(W_e, \widetilde{X}) \cong \mathcal{B}(\widetilde{Y}, W_e')$, which is the identity on $X$, $Y$, and $\mathcal{B}(W_0)$, and maps*

$q = x^\delta$ *to* $q = y^{-\delta'}$. (*Here X, Y are identified with their images under* $\mathcal{B}(W_0, X) \cong \mathcal{B}(W_e') \to \mathcal{B}(\widetilde{Y}, W_e')$ *and* $\mathcal{B}(Y, W_0) \cong \mathcal{B}(W_e) \to \mathcal{B}(W_e, \widetilde{X})$, *using Theorem* 4.2 *and Corollary* 4.3)

The group $\mathcal{B}(W_e, \widetilde{X}) = \mathcal{B}(\widetilde{Y}, W_e')$ is the (extended) *double affine braid group*.

**4.11.** By §2.9, there is an isomorphism $\Phi\colon \mathcal{B}(\widetilde{Y}, W_e') \to \mathcal{B}(W_e', \widetilde{Y})$ given by

$$\begin{aligned} &\Phi(y^\lambda) = y^\lambda, && \Phi(T_0') = T_0'^{-1}, \\ &\Phi(\pi) = \pi' \quad (\pi' \in \Pi'), && \Phi(T_i) = T_i^{-1} \quad (i = 1, \dots, n). \end{aligned}$$

The element $T_0$ in $\mathcal{B}(\widetilde{Y}, W_e')$ is defined by $T_0 = y^{\phi'} T_{s_{\phi'}}^{-1}$, whereas $T_0$ in $\mathcal{B}(W_e', \widetilde{Y})$ is given by $T_0 = T_{s_{\phi'}}^{-1} y^{-\phi'}$. Similarly, $\Pi \to \mathcal{B}(\widetilde{Y}, W_e')$ is given by $\pi = y^{\lambda_\pi} v_\pi \mapsto y^{\lambda_\pi} T_{v_\pi^{-1}}^{-1}$, whereas $\Pi \to \mathcal{B}(W_e', \widetilde{Y})$ is given by $\pi^{-1} \mapsto T_{v_\pi}^{-1} y^{-\lambda_\pi}$, and therefore $\pi \mapsto y^{\lambda_\pi} T_{v_\pi}$. Moreover, $X$ is embedded in $\mathcal{B}(\widetilde{Y}, W_e')$ via the identification $\mathcal{B}(W_e') = \Pi' \ltimes \mathcal{B}(W_0, X)$, which is characterized by $x^{-\phi} \mapsto T_{s_\phi} T_0$ and $x^{-\lambda_{\pi'}} \mapsto T_{v_{\pi'}} \pi'^{-1}$, whereas $X \subset \mathcal{B}(W_e', \widetilde{Y})$ is given via $\mathcal{B}(W_e') = \mathcal{B}(X, W_0) \rtimes \Pi'$ by $x^\phi \mapsto T_0 T_{s_\phi}$, $x^{\lambda_{\pi'}} \mapsto \pi' T_{v_{\pi'}^{-1}}$. In $\mathcal{B}(W_e', \widetilde{Y})$, finally, $q$ denotes $y^{\delta'}$. Taking into account that $\Phi(T_w) = T_{w^{-1}}^{-1}$ for all $w \in W_0$, all this implies

$$\begin{aligned} &\Phi(x^\mu) = x^\mu, && \Phi(T_0) = T_0^{-1}, \\ &\Phi(\pi) = \pi \quad (\pi \in \Pi), && \Phi(q) = q^{-1}. \end{aligned}$$

Theorem 4.10 therefore has the following equivalent alternate formulation.

**Corollary 4.12.** *There is an isomorphism* $\mathcal{B}(W_e, \widetilde{X}) \cong \mathcal{B}(W_e', \widetilde{Y})$, *which is the identity on X, Y,* $\Pi$ *and* $\Pi'$, *maps* $q = x^\delta$ *to* $q^{-1} = y^{-\delta'}$, *and maps the generators* $T_i$ *of* $\mathcal{B}(W_0)$ *to* $T_i^{-1}$.

**4.13.** Cherednik [1] announced Theorem 4.10 in the case $X = Y$, and suggested a possible topological proof, which was completed by Ion [7]. Macdonald [16, 3.5–3.7] gave an elementary proof, which however involves quite a bit of case-checking and only applies when $X = \mathrm{Hom}(Q_0^\vee, \mathbb{Z})$, $Y = \mathrm{Hom}(Q_0'^\vee, \mathbb{Z})$. We now outline a different elementary proof. First assume that the theorem holds in the "unextended" case, $X = Q_0$, $Y = Q_0'$, $W_e = W_a$, $W_e' = W_a'$. We will deduce the general case.

By Theorem 2.11, $\mathcal{B}(\widetilde{Q}_0', W_a')$ embeds in $\mathcal{B}(\widetilde{Y}, W_a')$ as a normal subgroup, with quotient $\widetilde{Y}/\widetilde{Q}_0' = Y/Q_0' \cong \Pi$. Moreover, $\Pi \subseteq \mathcal{B}(W_e) = \mathcal{B}(Y, W_0)$ is a subgroup of $\mathcal{B}(\widetilde{Y}, W_a')$, giving the semidirect decomposition $\mathcal{B}(\widetilde{Y}, W_a') \cong \Pi \ltimes \mathcal{B}(\widetilde{Q}_0', W_a')$. By assumption, we have $\mathcal{B}(W_a, \widetilde{Q}_0) \cong \mathcal{B}(\widetilde{Q}_0', W_a')$, hence $\mathcal{B}(\widetilde{Y}, W_a') \cong \Pi \ltimes \mathcal{B}(W_a, \widetilde{Q}_0) = \mathcal{B}(W_e, Q_0)$. This establishes the case where $X = Q_0$ and $Y$ is general. Exchanging $X$ and $Y$, we also get the case $Y = Q_0'$, $W_e = W_a$, where now $X$ and $W_e'$ are general.

By definition, $\mathcal{B}(\widetilde{Q}_0', W_e') = \mathcal{B}(\widetilde{Q}_0', W_a') \rtimes \Pi'$ and $\mathcal{B}(\widetilde{Y}, W_e') = \mathcal{B}(\widetilde{Y}, W_a') \rtimes \Pi'$, with $\Pi' \cong X/Q_0$ the same for both groups. Again, Theorem 2.11 implies that the first group is a normal subgroup of the second, with quotient $\Pi$. So we can repeat the preceding argument to get the general case.

**4.14.** Now fix $X = Q_0$, $Y = Q_0'$, so $W_e = W_a$, $W_e' = W_a'$. Using Theorem 4.2 and Corollary 4.3, we identify $\mathcal{B}(W_a') = \mathcal{B}(W_0, X)$, $\mathcal{B}(W_a) = \mathcal{B}(Y, W_0)$. Then each group $\mathcal{B}(W_a, \widetilde{X})$, $\mathcal{B}(\widetilde{Y}, W_a')$ has generators $T_0, T_0', T_1, \dots, T_n, q^{1/m}$. In both groups, $q^{1/m}$ is central, the generators $T_0, T_1, \dots, T_n$ satisfy the braid relations of $\mathcal{B}(W_a)$, and $T_0', T_1, \dots, T_n$ satisfy those of $\mathcal{B}(W_a')$.

The additional relations (7) for $\lambda \in Q_0$ and $i = 0$ complete a presentation of $\mathcal{B}(W_a, \widetilde{X})$, since those for $i \neq 0$ already hold in $\mathcal{B}(W_0, X) = \mathcal{B}(W_a')$. For convenience, we write down these extra relations again here, after applying the identity $\langle \lambda, \alpha_0^\vee \rangle = -\langle \lambda, \theta^\vee \rangle$:

$$T_0^a x^\lambda T_0^b = x^{s_0(\lambda)}, \quad \text{where } a, b \in \{\pm 1\} \text{ and } -\langle \lambda, \theta^\vee \rangle = (a+b)/2. \tag{16}$$

In view of Corollary 4.12, to prove the theorem it suffices to express (16) in a "self-dual" form, in the sense that the substitutions $T_0 \leftrightarrow T_0'^{-1}$, $T_i \leftrightarrow T_i^{-1}$, $q \leftrightarrow q^{-1}$ ($i \neq 0$) should transform (16) into its counterpart with the roles of $X$ and $Y$ interchanged.

**Lemma 4.15.** *Relations* (16) *reduce to the case when $\lambda$ is a short positive root $\alpha \neq \theta$ (i.e., $\alpha \neq \phi$ if $\theta = \phi$ is short).*

*Proof.* The short roots $\beta \neq \pm\theta$ span $Q_0$. Hence we can always write $\lambda = \beta_1 + \cdots + \beta_m$, where $\beta_i \in (R_0)_{\text{short}} \setminus \{\pm\theta\}$. In particular, $\langle \beta_i, \theta^\vee \rangle \in \{0, \pm 1\}$ for all $i$. Given that $\langle \lambda, \theta^\vee \rangle \in \{0, \pm 1\}$, we can always order the $\beta_i$ so that those with $\langle \beta_i, \theta^\vee \rangle = 1$ and those with $\langle \beta_i, \theta^\vee \rangle = -1$ alternate. Writing (16) in the form $T_0^a x^\lambda = x^{s_0(\lambda)} T_0^{-b}$, it is easy to see that it follows from the same relation for each $\beta_i$. This reduces us to the case that $\alpha \neq \pm\theta$ is a short root. The case of (16) for $\langle \lambda, \theta^\vee \rangle = 1$ implies the case for $\langle \lambda, \theta^\vee \rangle = -1$, so positive roots $\alpha$ suffice. □

**4.16.** A *parabolic subgroup* of $W_0$ is a subgroup of the form $W_J = \langle s_i : i \in J \rangle$, where $J \subseteq \{1, \dots, n\}$. Since $\phi$ and $\phi'$ are dominant, their stabilizers are parabolic subgroups $W_J$, $W_{J'}$ respectively, where $J = \{i : \langle \phi, \alpha_i^\vee \rangle = 0\}$, and $J' = \{i : \langle \phi', \alpha_i'^\vee \rangle = 0\}$. Recall that each left, right and double coset $vW_J$, $W_{J'}v$, $W_{J'}vW_J$ has a unique representative of minimal length, which is also minimal in the Bruhat order.

**Proposition 4.17.** *Relations* (16) *for $\lambda = \alpha \neq \theta$ a short positive root reduce to relations of the following two forms:*

(a) *For $v$ such that $(v(\phi), \phi') = 0$ and $v$ minimal in $W_{J'}vW_J$, the relation*

$$T_0 T_v T_0'^{-1} T_v^{-1} = T_v T_0'^{-1} T_v^{-1} T_0.$$

(b) *For $v = v_1$ such that $(v(\phi), \phi') = 1$ and $v$ minimal in $W_{J'}vW_J$, define $v_2$, $v_3$, $v_4$ minimal respectively in $W_{J'}vs_\phi W_J$, $W_{J'}s_\theta vs_\phi W_J$, $W_{J'}s_\theta vW_J$; this given, the relation*

$$T_0^{-1}T_{v_1}T_0'^{-1}T_{v_2}^{-1}T_0^{-1}T_{v_3}T_0'^{-1}T_{v_4}^{-1} = q.$$

*Proof.* We can always write $\alpha = v(\phi)$ with $v$ minimal in $vW_J$. If $i \in J'$, then $T_i$ commutes with $T_0$. In $\mathcal{B}(W_a') = \mathcal{B}(W_0, Q_0)$ we have $x^{s_i(\alpha)} = T_i^{\epsilon} x^\alpha T_i^{\epsilon'}$, $\epsilon, \epsilon' = \pm 1$ for every positive short root $\alpha$. These facts imply that relations (16) are invariant under replacement of $\alpha$ with $w(\alpha) \in W_{J'}\alpha$. Hence we can assume $v$ minimal in $W_{J'}vW_J$.

We show that when $\langle \alpha, \theta^\vee \rangle = (v(\phi), \phi') = 0$, relation (16), which in this case reads $T_0 x^\alpha = x^\alpha T_0$, is equivalent to (a). The minimality of $v$ in $vW_J$ implies that if $v = s_{i_1} \dots s_{i_l}$ is a reduced factorization, then $\langle s_{i_{k+1}} \dots s_{i_l}(\phi), \alpha_{i_k}^\vee \rangle = 1$ for all $k$. Hence $x^\alpha = T_v x^\phi T_{v^{-1}} = T_v T_0'^{-1} T_{s_\phi}^{-1} T_{v^{-1}}$. The minimality also implies that $s_\phi = v^{-1}s_\alpha v$ is a reduced factorization. Therefore $T_{s_\phi}^{-1}T_{v^{-1}} = T_v^{-1}T_{s_\alpha}^{-1}$, and $x^\alpha = T_v T_0'^{-1} T_v^{-1} T_{s_\alpha}^{-1}$. Now, since $\langle \alpha, \theta^\vee \rangle = 0$, we have $s_0 s_\alpha = s_\alpha s_0$, and both sides of this equation are reduced factorizations. Hence $T_0$ commutes with $T_{s_\alpha}$, so (16) is equivalent to $T_0$ commuting with $T_v T_0'^{-1} T_v^{-1}$.

For $\langle \alpha, \theta^\vee \rangle = (v(\phi), \phi') = 1$, we have $s_0(\alpha) = \alpha + \alpha_0 = \alpha - \theta + \delta$, and thus relation (16) in this case reads $T_0^{-1} x^\alpha T_0^{-1} = q x^{-\beta}$, or $T_0^{-1} x^\alpha T_0^{-1} x^\beta = q$, where $\beta = -s_\theta(\alpha)$ satisfies $\alpha + \beta = \theta$. Let $u$ be the minimal representative of $s_\theta v s_\phi W_J$. Then $\beta = u(\phi)$, and the same reasoning as in the previous paragraph gives $x^\alpha = T_v T_0'^{-1} T_{vs_\phi}^{-1}$, $x^\beta = T_u T_0'^{-1} T_{us_\phi}^{-1}$. Our relation now takes the form

$$T_0^{-1}T_v T_0'^{-1} T_{vs_\phi}^{-1} T_0^{-1} T_u T_0'^{-1} T_{us_\phi}^{-1} = q. \tag{17}$$

Using §2.6 and the fact that $s_\phi(\alpha_i) = \alpha_i$ for all $i \in J$, we deduce (for any $J'$)

(*) *if $x$, $y$ are minimal in $W_{J'}x$, $W_{J'}y = W_{J'}xs_\phi$, respectively, and $xw$ is minimal in $W_{J'}xW_J$, then $yw$ is minimal in $W_{J'}yW_J$.*

By construction, $u$ and $v$ are minimal in their left $W_J$ cosets, and (*) implies the same for $us_\phi$ and $vs_\phi$. Hence the elements $v_1 = v$, $v_2$, $v_3$, $v_4$ defined in (b) are the minimal representatives of $W_{J'}v$, $W_{J'}vs_\phi$, $W_{J'}u$, $W_{J'}us_\phi$ respectively. By the analog of (*) for $s_\theta$ (operating on the left), we see that $v_1 = v$ implies $v_4 = us_\phi$, and if we set $v_2 = wvs_\phi$, then $v_3 = wu$. Now $w \in W_{J'}$ commutes with $T_0$, and the factorizations $vs_\phi = w^{-1}v_2$, $u = w^{-1}v_3$ are reduced, so (17) reduces to (b). □

**Corollary 4.18.** *The (unextended) double affine braid group $\mathcal{B}(W_a, \widetilde{Q}_0)$, where $\mathcal{B}(W_a) = \mathcal{B}(Q_0', W_0)$, has a presentation with generators $T_0$, $T_0'$, $T_1, \dots, T_n$, $q^{1/m}$ and the following (manifestly self-dual) relations: $q^{1/m}$ is central; braid relations for $T_0, T_1, \dots, T_n \in \mathcal{B}(W_a)$ and for $T_0', T_1, \dots, T_n \in \mathcal{B}(W_a')$; and the relations in Proposition* 4.17.

**Example 4.19.** Let $X = Y$ be of type $A_{n-1}$, with $\alpha_i = \alpha_i^\vee = e_i - e_{i+1}$ as in Example 2.5. Then $\phi = \theta = \phi' = \theta' = e_1 - e_n$, and $W_J = W_{J'} = \langle s_2, \dots, s_{n-2}\rangle$. The presentation of $\mathcal{B}(W_a, \widetilde{Q}_0)$ is given by $q$ central, braid relations and

(a) $T_0$ commutes with $T_1 T_{n-1} T_0'^{-1} (T_1 T_{n-1})^{-1}$,

(b) $T_0^{-1} T_1 T_0'^{-1} T_1^{-1} T_2^{-1} \dots T_{n-1}^{-1} T_0^{-1} T_{n-1} T_0'^{-1} T_{n-1}^{-1} T_{n-2}^{-1} \dots T_1^{-1} = q$.

There are seven double cosets $W_J v W_{J'}$. Two have $v(\phi) = \pm\phi$, one yields (a), and the other four provide the elements $v_1, \dots, v_4$ in (b). In fact, in every type there turns out to be only one relation of type (b) and at most two of type (a), except for $\widetilde{D}_4$, which has three of type (a).

**Lemma 4.20.** *If $\phi$ is the dominant short root of a finite root system $X$, and $v \in W_0$ is such that $\alpha = v(\phi) \in (R_0)_+$, then in $\mathcal{B}(W_0, X)$ we have*

$$T_v x^\phi T_{s_\phi} T_v^{-1} = x^\alpha T_{s_\alpha}.$$

*Proof.* This reduces to the case that $v$ is minimal in $vW_J$ (in the notation of §4.16). As in the proof of Proposition 4.17 we then have $T_v x^\phi T_{s_\phi} = x^\alpha T_{v^{-1}}^{-1} T_{s_\phi} = x^\alpha T_{s_\alpha} T_v$. □

Lemma 4.20 will be used in the proof of Theorem 5.11. Its variant for $\mathcal{B}(Y, W_0)$ is $T_{v^{-1}}^{-1} y^\phi T_{s_\phi}^{-1} T_{v^{-1}} = y^\alpha T_{s_\alpha}^{-1}$, which is useful for verifying the braid relations in the proof of Theorem 4.2.

## 5. Hecke algebras and Cherednik algebras

**5.1.** Let $\big(X, (\alpha_i), (\alpha_i^\vee)\big)$ be a non-degenerate root system, with Cartan matrix $A$, Weyl group $W$, and roots $R$. To each $W$-orbit in $R$ we associate a parameter $u_\alpha$, $u_\alpha = u_\beta$ if $\beta = w(\alpha)$. Set $u_i = u_{\alpha_i}$. The $u_i$ are assumed to be invertible elements of some commutative ground ring $\mathfrak{A}$. If $\alpha_i^\vee \in 2X^\vee$, we also introduce a second parameter $u_i'$.

**Lemma 5.2.** *Let $\mathcal{H}$ be an $\mathfrak{A}$-algebra containing the group algebra $\mathfrak{A}X$, and $T_i \in \mathcal{H}$.*

(i) *If $\alpha_i^\vee \notin 2X^\vee$, then commutation relations* (5)–(6) *and the quadratic relation*

$$(T_i - u_i)(T_i + u_i^{-1}) = 0 \tag{18}$$

*imply the more general commutation relations, for all $\lambda \in X$,*

$$T_i x^\lambda - x^{s_i(\lambda)} T_i = \frac{(u_i - u_i^{-1})}{1 - x^{\alpha_i}} (x^\lambda - x^{s_i(\lambda)}). \tag{19}$$

(ii) *If $\alpha_i^\vee \in 2X^\vee$, then* (5)–(6), (18) *and the additional quadratic relation*

$$(T_i^{-1} x^{-\alpha_i} - u_i')(T_i^{-1} x^{-\alpha_i} + u_i'^{-1}) \tag{20}$$

*imply*

$$T_i x^\lambda - x^{s_i(\lambda)} T_i = \frac{(u_i - u_i^{-1}) + (u_i' - u_i'^{-1}) x^{\alpha_i}}{1 - x^{2\alpha_i}} (x^\lambda - x^{s_i(\lambda)}) \tag{21}$$

(iii) *Given* (18)*, relation* (21) *implies* (20)*, and* (19) *implies that* (20) *holds with* $u_i' = u_i$.

Note that the denominators in (19), (21) divide $x^\lambda - x^{s_i(\lambda_i)}$.

For the well-known proof, observe that each side of (19), (21), viewed as an operator on $x^\lambda$, satisfies $F(x^\lambda x^\mu) = F(x^\lambda)x^\mu + x^{s_i(\lambda)} F(x^\mu)$. Hence (19), (21) for $x^\lambda, x^\mu$, imply the same for $x^{\lambda \pm \mu}$. This reduces (i) to the special cases $\langle \lambda, \alpha_i^\vee \rangle \in \{0, 1\}$, which in turn reduce to (5)–(6), using the identity $T_i^{-1} = T_i - u_i + u_i^{-1}$, which is equivalent to (18). Similarly, (ii) reduces to the special cases $\langle \lambda, \alpha_i^\vee \rangle = 0$, which is (5) ((6) is vacuous if $\alpha_i^\vee \in 2X^\vee$), and $\lambda = \alpha_i$ (since $\langle \alpha_i, \alpha_i^\vee \rangle = 2$). Modulo (18), this last case is equivalent to (20), which also gives (iii) in case (ii). For (iii) in case (i), observe that (19) is just (21) with $u_i' = u_i$.

**Definition 5.3.** The *affine Hecke algebra* $\mathcal{H}(W, X)$ is the quotient $(\mathfrak{A}\mathcal{B}(W, X))/\mathfrak{j}$, where $\mathfrak{j}$ is the 2-sided ideal generated by the quadratic relations (18) for all $i$, plus (20) for each $i$ such that $\alpha_i^\vee \in 2X^\vee$.

Equivalently, $\mathcal{H}(W, X)$ is generated by elements $x^\lambda$ ($\lambda \in X$) and $T_i$ satisfying the braid relations of $\mathcal{B}(W)$, quadratic relations (18), and relations (19) or (21) depending on whether or not $\alpha_i^\vee \in 2X^\vee$.

**Proposition 5.4.** *The subalgebra of* $\mathcal{H}(W, X)$ *generated by the elements* $T_i$ *is isomorphic to the ordinary Hecke algebra* $\mathcal{H}(W)$*, with basis* $\{T_w : w \in W\}$*, and* $\mathcal{H}(W, X)$ *has basis* $\{T_w x^\lambda\}$.

*Proof.* The commutation relations (19), (21) imply that the elements $T_w x^\lambda$ span; they are independent because the specialization $u_i = u_i' = 1$ collapses $\mathcal{H}(W, X)$ to the group algebra $\mathfrak{A} \cdot (W \ltimes X)$. (More precisely, specialization implies the result for $\mathfrak{A} = \mathbb{Z}[u_i^{\pm 1}, u_i'^{\pm 1}]$, and the general case follows by extension of scalars.) □

**5.5.** Let $\Pi$ be a group acting by automorphisms of the root system $\big(X, (\alpha_i), (\alpha_i^\vee)\big)$, and assume that $u_i = u_j$, $u_i' = u_j'$ for $\alpha_j \in \Pi(\alpha_i)$. Then $\Pi$ acts on $\mathcal{H}(W, X)$, and we define the *extended affine Hecke algebra* to be the twisted group algebra $\Pi \cdot \mathcal{H}(W, X)$ generated by $\Pi$ and $\mathcal{H}(W, X)$ with relations $\pi f = \pi(f)\pi$ for $\pi \in \Pi$, $f \in \mathcal{H}(W, X)$.

Up to now the root system $X$ was arbitrary. If $X$ is finite, with $W_0 \ltimes X = W_a \rtimes \Pi$ as in Corollary 4.3, then $\mathcal{H}(W_0, X)$ is isomorphic to the twisted group algebra $\mathcal{H}(W_a) \cdot \Pi$ of the ordinary Hecke algebra of $W_a$. The most interesting case is when $X$ is affine; specifically when $X = \widetilde{X}$ as constructed in §4.6.

**Definition 5.6.** Given $X$, $Y$, $(\cdot, \cdot)$, $\widetilde{X}$, $\widetilde{Y}$, $W_e = \Pi \ltimes W_a$, $W_e' = W_a' \rtimes \Pi'$ as in §4.4–4.9, the (left) *Cherednik algebra* $\mathcal{H}(W_e, \widetilde{X})$ is the extended affine Hecke algebra $\Pi \cdot \mathcal{H}(W_a, \widetilde{X})$.

Equivalently, $\mathcal{H}(W_e, \widetilde{X})$ is generated by $x^\lambda \in X$, $\pi \in \Pi$, $T_0, \ldots, T_n$ and $q^{\pm 1/m}$, satisfying the relations of the double affine braid group $\mathcal{B}(W_e, \widetilde{X})$ and the quadratic relations (18), plus (20) if $\alpha_i^\vee \in 2\widetilde{X}^\vee$.

**5.7.** We will also define a *right* Cherednik algebra $\mathcal{H}(\widetilde{Y}, W_e')$, but first we must re-index the parameters. For convenience, we define $u_j' = u_j$ if $\alpha_j^\vee \notin 2\widetilde{X}^\vee$. Define $u_{i'} = u_i$ for $i \neq 0$, and set $u_{0'} = u_j'$, where $\alpha_j$ is a short simple root of the finite root system $X$. If $\alpha_i'^\vee \in 2\widetilde{Y}^\vee$ for $i \neq 0$ (there is at most one such index $i$), set $u_{i'}' = u_0$ . If $\alpha_0'^\vee \in 2\widetilde{Y}^\vee$, set $u_{0'}' = u_0'$.

We now define $\mathcal{H}(\widetilde{Y}, W_e')$ to be the algebra with generators $y^\mu$ ($\mu \in Y$), $\pi' \in \Pi'$, $T_0', T_1, \ldots, T_n, q^{\pm 1/m}$ satisfying the relations of the right affine braid group $\mathcal{B}(\widetilde{Y}, W_e')$, relations (18) with $u_{i'}$ in place of $u_i$, and for $\alpha_i'^\vee \in 2\widetilde{Y}^\vee$, the relations

$$(T_i'^{-1} y^{\alpha_i'} - u_{i'}')(T_i'^{-1} y^{\alpha_i'} + u_{i'}'^{-1}), \tag{22}$$

where we define $T_i' = T_i$ if $i \neq 0$.

**Corollary 5.8.** *The elements* $\{y^\mu T_w x^\lambda\}$ ($\mu \in Y$, $\lambda \in X$, $w \in W_0$) *form an* $\mathfrak{A}[q^{\pm 1/m}]$-*basis of the Cherednik algebras* $\mathcal{H}(W_e, \widetilde{X})$, $\mathcal{H}(\widetilde{Y}, W_e')$.

This follows easily from Proposition 5.4 for $\mathcal{H}(W_e, \widetilde{X})$ and by symmetry for $\mathcal{H}(\widetilde{Y}, W_e')$. We remark that the factors $y^\mu T_w x^\lambda$ can be taken in any order.

**Lemma 5.9.** *We have* $\alpha_0'^\vee \in 2\widetilde{Y}^\vee$ *if and only if* $X$, $Y$ *are both of type* $B_n$ *and* $\Pi$ *acts trivially on the simple roots of* $\widetilde{X}$.

*Proof.* By definition, $\alpha_0'^\vee = -\theta'^\vee$. We can only have $\theta'^\vee \in 2Y^\vee$ if $Y$ is of type $B_n$ and $\theta = \phi$ is short, hence $X$ is also of type $B_n$. Let $P_0'$ be the image of the canonical homomorphism $Y \to \mathrm{Hom}(Q_0'^\vee, \mathbb{Z})$. For type $B_n$ we have either $Q_0' = P_0'$ or $P_0'/Q_0' \cong \mathbb{Z}/2\mathbb{Z}$, with $Q_0' = P_0'$ iff the short roots $\alpha'$ satisfy $\alpha'^\vee \in 2Y^\vee$. The isomorphism $\Pi \cong Y/Q_0'$ (Corollary 3.12) identifies $P_0'/Q_0'$ with the quotient of $\Pi$ by the kernel of its action on the simple roots of $\widetilde{X}$. □

**Remark 5.10.** If $X$, $Y$ are of type $B_n$, then $\widetilde{X}$, $\widetilde{Y}$ are of type $\widetilde{C}_n^\vee$. Label the Dynkin diagram

$$\begin{array}{ccccccccccc} \bullet & \Leftarrow & \bullet & - & \bullet & - & \cdots & - & \bullet & \Rightarrow & \bullet \\ 0 & & 1 & & 2 & & & & n-1 & & n \end{array} \quad . \tag{23}$$

If $\alpha_0'^\vee \notin 2\widetilde{Y}^\vee$, then $\Pi$ acts non-trivially, exchanging nodes 0 and $n$, and similarly for $\alpha_0^\vee$ and $\Pi'$. The four associated parameters are related by the diagram

$$\begin{array}{ccc} (u_0' = u_{0'}') & = & (u_n' = u_{0'}) \\ \| & & \| \\ (u_0 = u_{n'}') & = & (u_n = u_{n'}) \end{array} , \tag{24}$$

where the horizontal equalities hold if $\alpha'^\vee \notin 2Y^\vee$ for short roots $\alpha' \in Y$, and the vertical ones hold if $\alpha^\vee \notin 2X^\vee$ for short roots $\alpha \in X$.

**Theorem 5.11.** *There is an isomorphism $\mathcal{H}(W_e, \widetilde{X}) \cong \mathcal{H}(\widetilde{Y}, W'_e)$, which is the identity on all the generators $X$, $Y$, $q$, $T_i$, $T_0$, $T'_0$, $\pi$, $\pi'$.*

*Proof.* For the most part, this is Theorem 4.10, but we must prove that relations (22) and the case of (18) for $T'_0$ hold in $\mathcal{H}(W_e, \widetilde{X})$. By definition, $T'_0 = T_{s_\phi}^{-1} x^{-\phi}$. By Lemma 4.20, this is conjugate to $T_j^{-1} x^{-\alpha_j}$ for a short simple root $\alpha_j$. Then (20) for $T_j$ implies (18) for $T'_0$. Similarly, if $i \neq 0$ in (22), then $\alpha'_i$ is short, and $T_i'^{-1} y^{\alpha_i}$ is conjugate to $y^{\alpha_i} T_i'^{-1}$ and in turn to $T_0 = y^{\phi'} T_{s_{\phi'}}^{-1}$. By Lemma 5.9, we only have $i = 0$ in (22) when $X$, $Y$ are both of type $B_n$, so $\theta = \phi$, $\theta' = \phi'$. Then $T_0'^{-1} y^{\alpha'_0} = q^{-1} x^{\phi} T_{s_\phi} y^{-\phi'} = x^{-\alpha_0} T_0^{-1}$, which is conjugate to $T_0^{-1} x^{-\alpha_0}$. □

**Corollary 5.12.** *Assume given an automorphism $\varepsilon : \mathfrak{A} \to \mathfrak{A}$ such that $\varepsilon(u_i) = u_i^{-1}$, $\varepsilon(u'_i) = u_i'^{-1}$. Then there is an $\varepsilon$-linear isomorphism $\mathcal{H}(W_e, \widetilde{X}) \cong \mathcal{H}(W'_e, \widetilde{Y})$ which is the identity on $X$, $Y$, $\Pi$, $\Pi'$, maps $q$ to $q^{-1}$, and maps $T_i$ to $T_i^{-1}$ for all $i = 0', 0, 1, \ldots, n$, where the parameters $u_{i'}$, $u'_{i'}$ for $\mathcal{H}(W'_e, \widetilde{Y})$ are as in* §5.7.

*Proof.* The map $\Phi$ in §4.11, composed with $\varepsilon$, preserves (18) and interchanges (22) with the version of (20) for $\widetilde{Y}$ in place of $\widetilde{X}$. □

**5.13.** Let $\mathcal{H} = \Pi \cdot \mathcal{H}(W, X)$ be an extended affine Hecke algebra. The ordinary (extended) Hecke algebra $\Pi \cdot \mathcal{H}(W)$ has a one-dimensional representation $\mathbf{1} = \mathfrak{A}e$ such that $\pi e = e$, $T_i e = u_i e$. The induced representation $\mathrm{Ind}_{\Pi \mathcal{H}(W)}^{\mathcal{H}}(\mathbf{1})$ is the *polynomial representation*. Proposition 5.4 implies that it is isomorphic to the left regular representation $\mathfrak{A}X$ of $X$, with $\Pi$ acting via its action on $X$, and $T_0, \ldots, T_n$ acting as the operators

$$T_i = u_i s_i + \frac{(u_i - u_i^{-1})}{1 - x^{\alpha_i}}(1 - s_i) \tag{25}$$

$$= u_i - u_i^{-1} \frac{1 - u_i^2 x^{\alpha_i}}{1 - x^{\alpha_i}}(1 - s_i) \tag{26}$$

$$= -u_i^{-1} + u_i(1 + s_i) \frac{1 - u_i^{-2} x^{\alpha_i}}{1 - x^{\alpha_i}} \tag{27}$$

or, if $\alpha_i^\vee \in 2X^\vee$,

$$T_i = u_i s_i + \frac{(u_i - u_i^{-1}) + (u'_i - u_i'^{-1}) x^{\alpha_i}}{1 - x^{2\alpha_i}}(1 - s_i) \tag{28}$$

$$= u_i - u_i^{-1} \frac{(1 - u_i u'_i x^{\alpha_i})(1 + (u_i/u'_i) x^{\alpha_i})}{1 - x^{2\alpha_i}}(1 - s_i) \tag{29}$$

$$= -u_i^{-1} + u_i(1 + s_i) \frac{(1 - (u_i u'_i)^{-1} x^{\alpha_i})(1 + (u'_i/u_i) x^{\alpha_i})}{1 - x^{2\alpha_i}}. \tag{30}$$

In particular, these operators satisfy braid relations. The quadratic relations can be seen directly from (26)–(27) and (29)–(30). The polynomial representation specializes at $u_i = u_i' = 1$ to the $\mathfrak{A}$-linearization of the action of $\Pi \ltimes (W \ltimes X)$ on $X$. It is faithful if $\Pi$ acts faithfully.

**5.14.** For any root $\alpha \in R$, define a partial ordering on $X$ by $\mu <_\alpha \lambda$ if $\lambda - \mu \in \mathbb{Z}\alpha$ and $|\langle \mu, \alpha^\vee \rangle| < |\langle \lambda, \alpha^\vee \rangle|$, or $\langle \mu, \alpha^\vee \rangle = -\langle \lambda, \alpha^\vee \rangle > 0$. Each *root string* $\lambda + \mathbb{Z}\alpha$ is totally ordered by $<_\alpha$. Explicitly,

$$\begin{aligned} &\lambda <_\alpha \lambda + \alpha <_\alpha \lambda - \alpha <_\alpha \lambda + 2\alpha <_\alpha \lambda - 2\alpha <_\alpha \cdots \quad \text{if } \langle \lambda, \alpha^\vee \rangle = 0, \\ &\lambda <_\alpha \lambda - \alpha <_\alpha \lambda + \alpha <_\alpha \lambda - 2\alpha <_\alpha \lambda + 2\alpha <_\alpha \cdots \quad \text{if } \langle \lambda, \alpha^\vee \rangle = 1. \end{aligned}$$

If $B \subseteq R$, define $<_B$ to be the transitive closure of the union $\bigcup_{\alpha \in B} <_\alpha$. In general $<_B$ is not a partial order; we may have $\lambda <_B \lambda$.

**Proposition 5.15.** *Let $w \in W$, $B = R_+ \cap w^{-1}(-R_+)$. In the polynomial representation, we have*

$$T_w(x^\lambda) = u^{\rho_B(\lambda)} x^{w(\lambda)} + \sum_{\mu <_{w(B)} w(\lambda)} a_\mu x^\mu,$$

*where $a_\mu \in \mathfrak{A}$ and $u^{\rho_B(\lambda)} = \prod_{\alpha \in B} u_\alpha^{\sigma(-\langle \lambda, \alpha^\vee \rangle)}$, $\sigma(k) = \pm 1$ as $k \geq 0$ or $k < 0$.*

*Proof.* The case $w = s_i$ follows from formulas (25), (28), and the general case by induction on $l(w)$, using the fact that if $w = s_i v > v$ and $B' = R_+ \cap v^{-1}(-R_+)$, then $B = B' \cup \{v^{-1}(\alpha_i)\}$. □

## 6. Macdonald polynomials

**6.1.** Let $\left(\widetilde{X}, (\alpha_i), (\alpha_i^\vee)\right)$ be a non-degenerate reduced affine root system (§3). As always, we take $i = 0$ to be an affine node, denote the Weyl group, roots, etc. by $W$, $R$, $R_+$, $Q$, $Q_+$, and let $W_0$, $R_0$, $Q_0$, etc. denote the same for the finite root system with simple roots $\alpha_1, \ldots, \alpha_n$. We also allow non-reduced affine root systems, regarded as extensions (§2.12) of a reduced affine root system $\widetilde{X}$, with a larger set of roots $R$. In the non-reduced case, we do not give the extra simple roots their own symbols, but designate them simply as $2\alpha_i$.

Let $\delta$ be the nullroot, and assume that the dual of $\widetilde{X}$ is degenerate, *i.e.*, $\delta^\vee = 0$. Possibly after adjoining a fractional multiple of $\delta$, we can always assume that $\widetilde{X} = X \oplus \mathbb{Z}\delta/m$, where $Q_0 \subseteq X$. Fix such a decomposition.

To each $i$ such that $2\alpha_i \notin R$, we associate a parameter $u_i$ and put $t_i = u_i^2$. To each $i$ such that $2\alpha_i \in R$ we associate two parameters $u_i$, $u_i'$ and put $t_i = u_i u_i'$, $t_i' = u_i / u_i'$. We require that simple roots in the same $W$-orbit have the same parameters, and put $t_\alpha = t_{\alpha_i}$, $t_\alpha' = t_{\alpha_i}'$ if $\alpha \in W(\alpha_i)$. We denote by $\mathbb{Q}(t)$ the field of rational functions in the parameters. The group algebra $\mathbb{Q}(t)\widetilde{X}$ is the ring of Laurent polynomials

$\mathbb{Q}(t)[x^{\pm\varepsilon_1}, \ldots, x^{\pm\varepsilon_N}]$, where $\{\varepsilon_1, \ldots, \varepsilon_N\}$ is a basis of $\widetilde{X}$. As in §4, we let $q = x^\delta$. Then $\mathbb{Q}(t)\widetilde{X} = \mathbb{Q}(t)[q^{\pm 1/m}]X$, and we identify it with a subring of $\mathbb{Q}(q,t)X$.

As in §3.7, let $W = Q_0' \rtimes W_0$, where $Q_0' = Q_0^\vee$ if $\widetilde{X}$ is of untwisted type or $\widetilde{BC}_n$, and $Q_0' = Q_0$ otherwise. In either case, $Q_0'$ acts on $\mathbb{Q}(q,t)X$ by the formula

$$y^\mu(x^\lambda) = q^{-(\lambda,\mu)}x^\lambda, \tag{31}$$

in terms of the $W_0$-invariant pairing $(Q_0, Q_0') \to \mathbb{Z}$ in §4.4 (see also §4.6).

**6.2.** Let $\mathbb{Q}(q,t)\widehat{X}$ denote the $\mathbb{Q}(q,t)$-vector space of possibly infinite formal linear combinations $f = \sum_{\lambda\in X} a_\lambda x^\lambda$. The space $\mathbb{Q}(q,t)\widehat{X}$ is a $\mathbb{Q}(q,t)X$-module – *i.e.*, it makes sense to multiply $f \in \mathbb{Q}(q,t)\widehat{X}$ by $p \in \mathbb{Q}(q,t)X$. We regard $\mathbb{Q}(q,t)X$ as a submodule of $\mathbb{Q}(q,t)\widehat{X}$. Write

$$[x^\lambda]f = a_\lambda$$

for the coefficient of $x^\lambda$ in $f$. Let $\overline{\cdot}$ denote the involution on $\mathbb{Q}(q,t)$ and $\mathbb{Q}(q,t)X$ such that

$$\overline{u_i} = u_i^{-1}, \quad \overline{u_i'} = u_i'^{-1}, \quad \overline{t_\alpha} = t_\alpha^{-1}, \quad \overline{t_\alpha'} = t_\alpha'^{-1}, \quad \overline{q} = q^{-1}, \quad \overline{x^\lambda} = x^{-\lambda}.$$

It extends to $\mathbb{Q}(q,t)\widehat{X}$ by the rule $\overline{\sum_\lambda a_\lambda x^\lambda} = \sum_\lambda \overline{a_\lambda} x^{-\lambda}$. The following theorem is due to Cherednik.

**Theorem 6.3.** *There is a unique element $\Delta_0 = \overline{\Delta_0} \in \mathbb{Q}(q,t)\widehat{Q_0} \subseteq \mathbb{Q}(q,t)\widehat{X}$ with constant term $[1]\Delta_0 = 1$, such that for each Coxeter generator $s_i$ of $W$,*

$$s_i(\Delta_0) = \frac{1 - t_i x^{\alpha_i}}{t_i - x^{\alpha_i}}\Delta_0, \quad \textit{or} \quad s_i(\Delta_0) = \frac{(1 - t_i x^{\alpha_i})(1 + t_i' x^{\alpha_i})}{(t_i - x^{\alpha_i})(t_i' + x^{\alpha_i})}\Delta_0, \tag{32}$$

*where the second formula applies if $2\alpha_i \in R$.*

*Proof.* Define a formal series $\Delta \in \mathbb{Q}[\![q,t]\!]\widehat{Q_0}$ by

$$\Delta = \prod_{\substack{\alpha\in R_+ \\ 2\alpha\notin R,\, \alpha\notin 2R}} \frac{1 - x^\alpha}{1 - t_\alpha x^\alpha} \prod_{\substack{\alpha\in R_+ \\ 2\alpha\in R}} \frac{1 - x^{2\alpha}}{(1 - t_\alpha x^\alpha)(1 + t_\alpha' x^\alpha)}.$$

The coefficients $[x^\lambda]\Delta \in \mathbb{Q}[\![q,t]\!]$ are not rational functions. Define $\Delta_0 = \Delta/([1]\Delta)$. Since $s_i$ leaves the set $R_+ \setminus \{\alpha_i, 2\alpha_i\}$ invariant, it follows that $\Delta$ and $\Delta_0$ satisfy (32). By construction, $\Delta_0$ has constant term 1. These conditions can be expressed as a system of linear equations over $\mathbb{Q}(q,t)$ in the coefficients $[x^\lambda]\Delta_0$, which therefore have a solution $\Delta_0'$ with coefficients in $\mathbb{Q}(q,t)$.

Now, $\Delta_0'/\Delta_0$ is $W$-invariant. For $0 \neq \lambda \in Q_0$, choose $\mu \in Q_0'$ such that $(\lambda,\mu) \neq 0$. Then (31) implies that $[x^\lambda](\Delta_0'/\Delta_0) = 0$, *i.e.*, $\Delta_0'/\Delta_0$ is a constant. Hence $\Delta_0' = \Delta_0$, since they both have constant term 1. This shows that $\Delta_0$ has coefficients in $\mathbb{Q}(q,t)$ and is unique. One checks that (32) is $\overline{\cdot}$-invariant, which implies $\Delta_0 = \overline{\Delta_0}$ by uniqueness. □

The *Macdonald constant term identity* [16, (5.8.20)] provides an explicit infinite product expansion for $[1]\Delta$, but it is not practicable to compute the coefficients of $\Delta_0$ directly from the formula $\Delta_0 = \Delta/([1]\Delta)$. A better procedure is to equate the coefficients of $y^{\phi'}(\Delta_0) = s_0 s_{\phi'}(\Delta_0)$, as given by (31) on the one hand, and by (32) on the other. This leads to a recurrence which determines the coefficients.

**Definition 6.4.** *Cherednik's inner product* on $\mathbb{Q}(q,t)X$ is defined by the formula

$$\langle f, g\rangle_0 = [1](f\,\overline{g}\,\Delta_0).$$

It is linear in $f$ and $\overline{\cdot}$-hermitian by Theorem 6.3, *i.e.*, $\langle g, f\rangle_0 = \overline{\langle f, g\rangle_0}$.

**Lemma 6.5.** *Let $B = (R_0)_+$. Under the identification of $X$ with the set $W_e'/W_0$ of minimal left coset representatives in $W_e' = W_0 \ltimes X$, the ordering $<_B$ defined in* §5.14 *coincides with the Bruhat order $<$ in $W_e'$.*

*Proof.* Let $w_\lambda$ be minimal in $x^\lambda W_0$. If $s_\beta w_\lambda < w_\lambda$ for a reflection $s_\beta \in W_a'$, then clearly $w_{s_\beta(\lambda)} < w_\lambda$. The Bruhat order on $W_e'/W_0$ is the transitive closure of these relations. In the alcove picture (§3.10), $s_\beta$ belongs to a root $\beta = \alpha^\vee + k\delta'$ of the affine root system $X^\vee \oplus \mathbb{Z}\delta'$, where we can assume that $\alpha \in (R_0)_+$. The condition $s_\beta w_\lambda < w_\lambda$ means that $h_\beta$ separates $\Lambda_0^\vee + \lambda$ from the dominant alcove $A_0$. This is equivalent to $s_\beta(\lambda) <_\alpha \lambda$, and $<_B$ is by definition the transitive closure of these relations. □

We fix the partial ordering $<_B$ on $X$, with $B = (R_0)_+$, and denote it by $<$.

**Theorem 6.6.** *There is a unique basis $\{E_\lambda : \lambda \in X\}$ of $\mathbb{Q}(q,t)X$ satisfying the orthogonality and triangularity conditions*

(i) $\langle E_\lambda, E_\mu\rangle_0 = 0$ *for* $\lambda \neq \mu$,

(ii) $E_\lambda = x^\lambda + \sum_{\mu<\lambda} c_{\lambda\mu} x^\mu$, $c_{\lambda\mu} \in \mathbb{Q}(q,t)$.

The $E_\lambda$ are the (non-symmetric) *Macdonald polynomials*. Let us review how their existence and other properties are established using Cherednik algebras.

**6.7.** If $\widetilde{X}$ is of untwisted or dual untwisted type, choose $Y$ and $(X, Y) \to \mathbb{Z}/m$ as in §4.4. One can always take $Y = Q_0'$, but other choices may be more convenient – for instance, in type $A_{n-1}$, it is handy to let $X = Y = \mathbb{Z}^n$ be the weight lattice of $\mathrm{GL}_n$ (Example 2.5).

Non-reduced and mixed types are handled as follows. If $2\alpha_i \in R$, the specialization $u_i' = u_i$, hence $t_i' = 1$, collapses $\Delta_0$ and $\langle\cdot\,,\cdot\rangle_0$ to their counterparts for the root system with $2\alpha_i$ omitted. Similarly, specializing $u_i' = 1$ omits $\alpha_i$. The restriction of $<$ to cosets of the (possibly smaller) root lattice $Q_0$ in the resulting root system does not change. It follows that if Macdonald polynomials $E_\lambda$ exist for the original root system, then they specialize at $u_i' = 1$ (resp. $u_i' = u_i$) to $E_\lambda$ for the root system with $\alpha_i$ (resp. $2\alpha_i$) omitted. To be fully correct, we must also show that the coefficients of $E_\lambda$ do not have poles at these specializations. This will follow from Corollary 6.15.

Every affine root system $\widetilde{X}$ of mixed or non-reduced type embeds as above (perhaps after adjoining $\delta/2$) into a root system of one of two maximally non-reduced types: (a) $\widetilde{X}$ of type $\widetilde{C}_n^\vee$ with $2\alpha_0$, $2\alpha_n$ adjoined (indexing the simple roots as in (23)), or (b) $\widetilde{X}$ of type $\widetilde{B}_n$, with $2\alpha_n$ adjoined. For these types, choose $Y$ and $(\cdot\,,\cdot)$ as for $\widetilde{X}$ of *reduced* type $\widetilde{C}_n^\vee$ or $\widetilde{B}_n$, respectively. Specifically $X$, $Y$ are of types $(B_n, B_n)$ in (a), or $(B_n, C_n)$ in (b), and we have $\alpha^\vee \in 2\widetilde{X}^\vee$ for all short roots $\alpha$. In case (a) we also require $Y$ to satisfy $\alpha'^\vee \in 2\widetilde{Y}^\vee$ for short roots $\alpha'$, so as not to force the parameters for $i = 0$ and $i = n$ to coincide (Remark 5.10).

Let $\mathcal{H} = \mathcal{H}(W_e, \widetilde{X})$ be the Cherednik algebra (Definition 5.6) attached to $X$, $Y$, $(\cdot\,,\cdot)$, with ground ring $\mathfrak{A} = \mathbb{Q}(t)$, and parameters $u_i$ equated with those in §6.1, setting $u_i' = u_i$ in the reduced case. We identify $\mathbb{Q}(q,t)X$ with the underlying space of the polynomial representation (§5.13) of $\mathcal{H}$, after extension of scalars from $\mathbb{Q}(t)[q^{\pm 1}]$ to $\mathbb{Q}(q,t)$. Note that in formulas (25)–(30) for $i = 0$, we have $x^{\alpha_0} = qx^{-\theta}$, and $s_0(x^\lambda) = q^{\langle\lambda,\theta^\vee\rangle} s_\theta(x^\lambda)$, where $\delta = \alpha_0 + \theta$.

**Proposition 6.8.** *The operators $T_i$ (§5.13) are unitary with respect to $\langle\cdot\,,\cdot\rangle_0$.*

*Proof.* For any operator $T$, let $T^*$ denote its adjoint, $\langle T^* f, g\rangle_0 = \langle f, Tg\rangle_0$. We are to show that $T_i^* = T_i^{-1} = T_i - u_i + u_i^{-1}$, or equivalently, since $u_i^* = \overline{u_i} = u_i^{-1}$, that

$$(T_i - u_i)^* = (T_i - u_i).$$

From (32), we deduce that

$$s_i^* = \frac{1 - t_i x^{\alpha_i}}{t_i - x^{\alpha_i}} s_i = s_i \frac{t_i - x^{\alpha_i}}{1 - t_i x^{\alpha_i}}$$

if $2\alpha_i \notin R$, or

$$s_i^* = \frac{(1 - t_i x^{\alpha_i})(1 + t_i' x^{\alpha_i})}{(t_i - x^{\alpha_i})(t_i' + x^{\alpha_i})} s_i = s_i \frac{(t_i - x^{\alpha_i})(t_i' + x^{\alpha_i})}{(1 - t_i x^{\alpha_i})(1 + t_i' x^{\alpha_i})}$$

if $2\alpha_i \in R$. The fractions appearing in these expressions are self-adjoint, since $s_i^* s_i$ and $s_i s_i^*$ are self-adjoint. The result now follows easily from (26)–(27) in the first case (where $t_i = u_i^2$), and (29)–(30) in the second (where $t_i = u_i u_i'$, $t_i' = u_i / u_i'$). □

**Proposition 6.9.** *For $i \neq 0$, introduce formal "logarithms" $k_i$, $k_\alpha = k_i$ for $\alpha \in W_0(\alpha_i)$, with the convention that $q^{k_i} = u_i$. Set*

$$\rho^\vee = \sum_{\alpha \in (R_0)_+} k_\alpha \alpha^\vee, \quad \rho'^\vee = \sum_{\alpha \in (R_0)_+} k_\alpha \alpha'^\vee,$$

*where $\alpha' \in (R_0')_+$ is the positive root such that $s_{\alpha'} = s_\alpha$. Then the* Cherednik operators *$y^\mu \in \mathcal{H}$, acting on $\mathbb{Q}(q,t)X$, satisfy*

$$y^\mu(x^\lambda) = q^{-(\lambda,\mu) + \langle \mu, w_\lambda(\rho'^\vee)\rangle} x^\lambda + \sum_{\mu < \lambda} b_{\lambda\mu} x^\mu, \quad b_{\lambda\mu} \in \mathbb{Q}(q,t), \tag{33}$$

*where $w_\lambda$ is the minimal representative of $x^\lambda W_0$ in $W_e'$.*

*Proof.* It suffices to take $\mu \in Y_+$ dominant, so $y^\mu = T_{y^\mu}$. Bear in mind that $\widetilde{X}$ is now a reduced affine root system of untwisted or dual untwisted type (§6.7), not the root system we started with in §6.1. The affine roots are $\alpha + d\mathbb{Z}\delta$ for $\alpha \in R_0$, where $d = (\alpha, \alpha')/2$, both for untwisted types and their duals. We have $(\alpha, \mu) = d\langle \mu, \alpha'^\vee \rangle$ for all $\mu \in Y$.

If $\beta = \alpha + k\delta$ is a root, then $y^\mu(\beta) = \alpha + (k - (\alpha, \mu))\delta$, and the condition $\beta \in B = R_+ \cap y^{-\mu}(-R_+)$ holds if and only if $0 \le k < (\alpha, \mu)$ and $\alpha \in (R_0)_+$. It follows that for any $\alpha \in (R_0)_+$, the number of roots of the form $\alpha + k\delta \in B$ is equal to $\langle \mu, \alpha'^\vee \rangle$. We also have $x^{y^\mu(\lambda)} = q^{-(\lambda,\mu)} x^\lambda$ by (31). The form of (33) now follows from Proposition 5.15, with leading coefficient given by

$$q^{-(\lambda,\mu)} \prod_{\alpha \in (R_0)_+} u_\alpha^{\langle \mu, \alpha'^\vee \rangle \sigma(-\langle \lambda, \alpha^\vee \rangle)}.$$

This is equal to $q^{-(\lambda,\mu)+\langle \mu, w_\lambda(\rho'^\vee)\rangle}$ because $w_\lambda(\rho'^\vee) = \sum_{\alpha \in (R_0)_+} \pm k_\alpha \alpha'^\vee$, with a minus sign if $\alpha^\vee \in w_\lambda(-(R_0^\vee)_+)$, or equivalently, if $\langle \lambda, \alpha^\vee \rangle > 0$ (see the next remark). □

Note that $\rho^\vee$, $\rho'^\vee$ are characterized by $\langle \alpha_i, \rho^\vee \rangle = \langle \alpha_i', \rho'^\vee \rangle = 2k_i$.

**Remark 6.10.** The action of $W_e' = W_0 \ltimes X$ on $Y^\vee$ factors through $W_0$. Hence, $w_\lambda(\rho'^\vee)$ in (33) depends only on the image of $w_\lambda$ in $W_0$, which is the minimal element $v_\lambda$ such that $v_\lambda^{-1}(\lambda) \in -X_+$. A better way to write (33) is as follows. Define $\Lambda_0^\vee \in \widetilde{Y}_\mathbb{Q}^\vee$ by $\Lambda_0^\vee(Y) = 0$, $\langle \delta', \Lambda_0^\vee \rangle = 1$. Let $\eta\colon X \to Y_\mathbb{Q}^\vee$ be the homomorphism induced by the pairing $(X, Y) \to \mathbb{Q}$, that is, $(\lambda, \mu) = \langle \mu, \eta(\lambda) \rangle$. Then $w_\lambda(\Lambda_0^\vee) = \Lambda_0^\vee + \eta(\lambda)$, and (33) takes the form

$$y^\mu(x^\lambda) = q^{-\langle \mu, w_\lambda(\Lambda_0^\vee - \rho'^\vee)\rangle} x^\lambda + \sum_{\mu < \lambda} b_{\lambda\mu} x^\mu, \quad b_{\lambda\mu} \in \mathbb{Q}(q, t), \tag{34}$$

valid for all $\mu \in \widetilde{Y}$.

**Corollary 6.11.** *Theorem 6.6 holds with $E_\lambda \in (\mathbb{Q}(q,t)Q_0)x^\lambda$ determined uniquely as the joint eigenfunction with eigenvalue $q^{-\langle \mu, w_\lambda(\Lambda_0^\vee - \rho'^\vee)\rangle}$ of the operators $y^\mu$, normalized so that $[x^\lambda]E_\lambda = 1$.*

*Proof.* The $y^\mu$ act on $(\mathbb{Q}(q,t)Q_0)x^\lambda$ as commuting, lower-triangular operators without repeated joint eigenvalues. Since the $y^\mu$ are unitary by Proposition 6.8, their joint eigenfunctions $E_\lambda$ are orthogonal. □

**6.12.** Relation (19) can be written $\phi_i x^\lambda = x^{s_i(\lambda)}\phi_i$, where $\phi_i = T_i - (u_i - u_i^{-1})/(1 - x^{\alpha_i})$. By Corollary 5.12, we also have $\psi_i y^\mu = y^{s_i(\mu)}\psi_i$ for $i = 0', 1, \ldots, n$, where $\psi_i = T_i^{-1} - (u_i^{-1} - u_i)/(1 - y^{\alpha_i'}) = T_i - (u_i - u_i^{-1})/(1 - y^{-\alpha_i'})$, and similarly for (21). It is advantageous to use $u_i\psi_i$ instead here. To this end, set

$$\widetilde{T}_i = u_i T_i \quad (i = 1, \ldots, n);$$
$$\widetilde{T}_{0'} = u_{0'} T_{0'} = u_{0'} T_{s_\phi}^{-1} x^{-\phi} = u_j' T_v^{-1} T_j^{-1} x^{-\alpha_j} T_v = t_\phi \widetilde{T}_v^{-1} \widetilde{T}_j^{-1} x^{-\alpha_j} \widetilde{T}_v,$$

where $s_\phi = v^{-1}s_j v$ is a reduced factorization (Lemma 4.20). These operators depend only on the parameters $t_i, t_i'$. The intertwining relations $u_i\psi_i y^\mu = y^{s_i(\mu)}u_i\psi_i$, along with $\pi' y^\mu = y^{\pi'(\mu)}\pi'$ for $\pi \in \Pi'$ imply the following proposition.

**Proposition 6.13.** *If $E_\lambda$ is a joint eigenfunction of the operators $y^\mu$, $\mu \in \widetilde{Y}$ with eigenvalue $q^{\langle\mu,\Lambda\rangle}$, then $\Psi_i(E_\lambda)$ is a joint eigenfunction with eigenvalue $q^{\langle\mu,s_i(\Lambda)\rangle}$, where $i = 0', 1, \ldots, n$, and*

$$\Psi_i = \widetilde{T}_i + \frac{1-t_i}{1-q^{-\langle\alpha_i',\Lambda\rangle}}, \quad \text{or} \quad \Psi_i = \widetilde{T}_i + \frac{1-t_it_i'+(t_i'-t_i)q^{-\langle\alpha_i',\Lambda\rangle}}{1-q^{-2\langle\alpha_i',\Lambda\rangle}},$$

*the second formula applying in case $\alpha_i'^\vee \in 2\widetilde{Y}^\vee$. Similarly, $\pi'(E_\lambda)$ is a joint eigenfunction with eigenvalue $q^{\langle\mu,\pi'(\Lambda)\rangle}$, for any $\pi' \in \Pi'$.*

**Corollary 6.14.** *For $i \neq 0$, if $s_i(\lambda) = \lambda$, then $s_i E_\lambda = E_\lambda$.*

*Proof.* Proposition 6.13 implies that $T_i E_\lambda$ is a scalar multiple of $E_\lambda$, and from the leading coefficient we deduce $T_i E_\lambda = u_i E_\lambda$, which is equivalent to $s_i E_\lambda = E_\lambda$. □

**Corollary 6.15.** *The Macdonald polynomials satisfy the recurrence*

$$E_{v_{\pi'}(\lambda)+\lambda_{\pi'}} = q^{-\langle\lambda_{(\pi'^{-1})},w_\lambda(\rho^\vee)\rangle}x^{\lambda_{\pi'}}T_{v_{\pi'}}(E_\lambda), \quad \pi' = x^{\lambda_{\pi'}}v_{\pi'} \in \Pi', \tag{35}$$

$$E_{s_i(\lambda)} = \left(\widetilde{T}_i + \frac{1-t_i}{1-q^{\langle\lambda,\alpha_i'^\vee\rangle-\langle\alpha_i',w_\lambda(\rho'^\vee)\rangle}}\right)E_\lambda, \quad \langle\lambda,\alpha_i'^\vee\rangle > 0,\ i \neq 0',\ t_i' = 1, \tag{36}$$

$$E_{s_\phi(\lambda)+\phi} = t_\phi' q^{-\langle\phi,w_\lambda(\rho^\vee)\rangle}\left(\widetilde{T}_{0'} + \frac{1-t_{0'}}{1-q^{1-\langle\lambda,\theta'\rangle+\langle\theta',w_\lambda(\rho'^\vee)\rangle}}\right)E_\lambda, \quad \langle\lambda,\phi^\vee\rangle < 1,\ t_{0'}' = 1. \tag{37}$$

*If $t_i' \neq 1$,* (36) *becomes instead*

$$E_{s_i(\lambda)} = \left(\widetilde{T}_i + \frac{1-t_it_i'+(t_i'-t_i)q^{\langle\lambda,\alpha_i'^\vee\rangle-\langle\alpha_i',w_\lambda(\rho'^\vee)\rangle}}{1-q^{2(\langle\lambda,\alpha_i'^\vee\rangle-\langle\alpha_i',w_\lambda(\rho'^\vee)\rangle)}}\right)E_\lambda, \tag{38}$$

*with a corresponding modification to* (37) *if $t_{0'}' \neq 1$.*

The base of the recurrence is $E_\lambda = x^\lambda$ for $\lambda$ minuscule, *i.e.*, $\langle\lambda,\alpha_i^\vee\rangle \geq 0$ for $i \neq 0$ and $\langle\lambda,\phi^\vee\rangle \leq 1$. With this base, (35) is not essential to the recurrence, but it is often useful nevertheless.

To prove Corollary 6.15, first observe that the map $X \to \widetilde{Y}_\mathbb{Q}$, $\lambda \mapsto \Lambda_0^\vee + \lambda$ is equivariant with respect to the action of $W_e'$ on $\widetilde{Y}$ and on $X = W_e'/W_0$. Then Proposition 6.13 and Corollary 6.11 imply that $\Psi_i(E_\lambda)$ (resp. $\pi'(E_\lambda)$) is a scalar multiple of $E_{s_i(\lambda)}$ (resp. $E_{\pi'(\lambda)} = E_{v_{\pi'}(\lambda)+\lambda_{\pi'}}$).

The action of $\Pi'$ on $X = W_e'/W_0$ preserves the Bruhat order. Assuming by induction that (35) holds for $\nu < \lambda$, we conclude that $\pi' = x^{\lambda_{\pi'}}T_{v_{\pi'}}$ carries $\mathbb{Q}(q,t)\{x^\nu :$

$\nu < \lambda\}$ into $\mathbb{Q}(q,t)\{x^\nu : \nu < v_{\pi'}(\lambda) + \lambda_{\pi'}\}$. Hence the coefficient of $x^{v_{\pi'}(\lambda)}$ in $T_{v_{\pi'}}(x^\lambda)$ determines the scalar factor in (35). For $\langle\lambda, \alpha_i^\vee\rangle > 0$ (resp. $\langle\lambda, \phi^\vee\rangle < 1$), we have $s_i w_\lambda > w_\lambda$ (resp. $s_{0'} w_\lambda > w_\lambda$). We may assume by induction that $T_i$ (resp. $T_{0'}$) leaves invariant the space $\mathbb{Q}(q,t)\{x^\nu, x^{s_i(\nu)} : \nu < \lambda\}$. For $i \neq 0'$ and $s_i(\lambda) > \lambda$, we have $[x^{s_i(\lambda)}]\widetilde{T}_i(x^\lambda) = 1$, giving (36), and the coefficient of $x^{s_\phi(\lambda)+\phi}$ in $\widetilde{T}_{0'}(x^\lambda)$ determines the scalar factor in (37). The next lemma supplies the missing scalar factors.

**Lemma 6.16.** (i) *We have* $[x^{v_{\pi'}(\lambda)}]T_{v_{\pi'}}(x^\lambda) = q^{\langle\lambda_{(\pi'^{-1})}, w_\lambda(\rho^\vee)\rangle}$ *for any* $\pi' \in \Pi'$.

(ii) *For* $\langle\lambda, \phi^\vee\rangle < 1$, *we have* $[x^{s_\phi(\lambda)+\phi}]\widetilde{T}_{0'}(x^\lambda) = t_\phi'^{-1} q^{\langle\phi, w_\lambda(\rho^\vee)\rangle}$.

*Proof.* (i) Let $B = (R_0)_+ \cap v_{\pi'}^{-1}(-(R_0)_+)$. We claim that for any $\alpha \in (R_0)_+$, $\langle\lambda_{(\pi'^{-1})}, \alpha^\vee\rangle = 1$ if $\alpha \in B$, 0 otherwise. Then Proposition 5.15 gives

$$[x^{v_{\pi'}(\lambda)}]T_{v_{\pi'}}(x^\lambda) = \prod_{\alpha\in(R_0)_+} u_\alpha^{\langle\lambda_{(\pi'^{-1})},\alpha^\vee\rangle\sigma(-\langle\lambda,\alpha^\vee\rangle)} = q^{\langle\lambda_{(\pi'^{-1})}, w_\lambda(\rho^\vee)\rangle}$$

by the argument in the proof of Proposition 6.9.

As to the claim, if $v_{\pi'} = 1$, then $B = \emptyset$ and $\langle\lambda_{(\pi'^{-1})}, \alpha^\vee\rangle = 0$ for all $\alpha$. Otherwise, $\lambda_{(\pi'^{-1})} = -v_{\pi'}^{-1}(\lambda_{\pi'})$, and $\langle\lambda_{(\pi'^{-1})}, \alpha^\vee\rangle = -\langle\lambda_{\pi'}, v_{\pi'}(\alpha^\vee)\rangle \in \{0,1\}$ for all $\alpha \in (R_0)_+$, since $\lambda_{(\pi'^{-1})}$ is minuscule. Now, $v_{\pi'}(\alpha_j^\vee) = -\phi^\vee$, where $\pi'^{-1}(\alpha_0') = \alpha_j'$, and $v_{\pi'}(\alpha_i^\vee)$ is a simple coroot for $i \neq j$. Since $v_{\pi'} \neq 1$, we have $\langle\lambda_{\pi'}, \phi^\vee\rangle = 1$, and it follows that $\langle\lambda_{(\pi'^{-1})}, \alpha_i^\vee\rangle = \delta_{ij}$. Given $\alpha \in (R_0)_+$, if $\langle\lambda_{(\pi'^{-1})}, \alpha^\vee\rangle = 1$, then $v_{\pi'}(\alpha) \in -(R_0)_+$ since $\lambda_{\pi'} \in X_+$. Conversely, if $\langle\lambda_{(\pi'^{-1})}, \alpha^\vee\rangle = 0$, the coefficient of $\alpha_j^\vee$ in $\alpha^\vee$ must be zero, hence $v_{\pi'}(\alpha) \in (R_0)_+$.

(ii) Let $B = (R_0)_+ \cap s_\phi(-(R_0)_+)$. The operator $s_\phi T_{s_\phi}$ is lower-triangular by Proposition 5.15, hence so is $T_{s_\phi}^{-1} s_\phi$, and $[x^{s_\phi(\lambda)+\phi}]T_{s_\phi}^{-1}(x^{\lambda-\phi})$ is inverse to

$$[x^{\lambda-\phi}]T_{s_\phi}(x^{s_\phi(\lambda)+\phi}) = \prod_{\alpha\in B} u_\alpha^{\sigma(-\langle s_\phi(\lambda)+\phi\,,\,\alpha^\vee\rangle)} = \prod_{\alpha\in B} u_\alpha^{\sigma(\langle\lambda-\phi\,,\,\alpha^\vee\rangle)},$$

using $s_\phi(B) = -B$ in the last equation. Now, $\phi$ is short and dominant, hence $\langle\phi, \alpha^\vee\rangle \in \{0,1\}$ for $\alpha \in (R_0)_+ \setminus \{\phi\}$. Moreover, $s_\phi(\alpha^\vee) = \alpha^\vee - \langle\phi, \alpha^\vee\rangle\phi^\vee$, and since $\phi^\vee$ is the highest coroot, this implies that $\langle\phi, \alpha^\vee\rangle > 0$ if and only if $s_\phi(\alpha) \in -(R_0)_+$. Thus for $\alpha \in (R_0)_+ \setminus \{\phi\}$, we have $\langle\phi, \alpha^\vee\rangle = 1$ if $\alpha \in B$, 0 otherwise. Since $\langle\lambda, \phi^\vee\rangle \leq 0$, it follows that

$$\begin{aligned}[x^{s_\phi(\lambda)+\phi}]\widetilde{T}_{0'}(x^\lambda) &= u_\phi'[x^{s_\phi(\lambda)+\phi}]T_{s_\phi}^{-1}(x^{\lambda-\phi}) = u_\phi' u_\phi \prod_{\alpha\in B\setminus\{\phi\}} u_\alpha^{-\sigma(\langle\lambda,\alpha^\vee\rangle-1)} \\ &= (u_\phi'/u_\phi) \prod_{\alpha\in(R_0)_+} u_\alpha^{\langle\phi,\alpha^\vee\rangle\sigma(-\langle\lambda,\alpha^\vee\rangle)} = t_\phi'^{-1} q^{\langle\phi, w_\lambda(\rho^\vee)\rangle}.\end{aligned}$$

□

**6.17.** Suppose $\widetilde{X}$ is dual to an untwisted type. Then $X, Y$ are of the same type, $\phi = \theta$, $\phi' = \theta'$, $s_\phi = s_{\phi'}$, and in $\mathcal{H}$ we have the identities $T_{0'} = x^\phi T_0^{-1} y^{\phi'} + u_{0'} - u_{0'}^{-1}$ and $\pi' = x^{\lambda_{\pi'}} \pi y^{\lambda_{(\pi^{-1})}}$ for $\pi' \in \Pi'$, $\pi \in \Pi$ such that $v_{\pi'} = v_\pi$. Using these identities, (35) and (38) for $i = 0'$ become

$$E_{v_{\pi'}(\lambda)+\lambda_{\pi'}} = q^{-(\lambda,\lambda_{(\pi^{-1})})} x^{\lambda_{\pi'}} \pi(E_\lambda), \quad \pi' \in \Pi',\ \pi \in \Pi,\ v_\pi = v_{\pi'}$$

$$E_{s_\theta(\lambda)+\theta} = q^{1-(\lambda,\theta')} \left( u_\theta x^{-\alpha_0} T_0^{-1} + \frac{(u_\theta/u_0' - u_\theta u_0') + (u_\theta/u_{0'} - u_\theta u_{0'}) q^r}{1 - q^{2r}} \right) E_\lambda,$$

where $r = 1 - (\lambda, \theta') + \langle \theta', w_\lambda(\rho'^\vee) \rangle$. Note that the second formula simplifies to an analog of (36) if $u_{0'} = u_0'$.

**6.18.** Although our chief concern is with non-symmetric Macdonald polynomials, let us say a little about the symmetric version. Given $\lambda \in X_+$, let $V_\lambda = \mathbb{Q}(q,t)\{E_\nu : \nu \in W_0(\lambda)\}$. By Corollaries 6.14, 6.15, $V_\lambda$ is an $\mathcal{H}(W_0)$-submodule of $\mathbb{Q}(q,t)X$. It follows that there is a unique $W_0$-invariant element $P_\lambda \in V_\lambda$ such that $[x^\lambda]P_\lambda = 1$. The $P_\lambda$ are *symmetric Macdonald polynomials*. They are orthogonal and are joint eigenfunctions of all $W_0$-invariant operators $f(y) \in (\mathbb{Q}(q,t)Y)^{W_0}$. The coefficients of $P_\lambda$ in terms of the $E_\nu$ can be determined explicitly using Corollary 6.15.

The $P_\lambda$ are also orthogonal with respect to *Macdonald's inner product*, which is a symmetrization of $\langle \cdot\,, \cdot \rangle_0$. They were originally defined by Macdonald [14], [15] in terms of this orthogonality. When $t_i = q^{(\alpha_i, \alpha_i')/2}$, they specialize to the irreducible characters of the algebraic group $G$ with weight lattice $X$ and root system $Q_0$. Other specializations yield Hall–Littlewood and Jack polynomials, and spherical functions for classical and $p$-adic symmetric spaces.

For $\mathrm{GL}_n$, the $P_\lambda$ are symmetric polynomials in $x_1, \ldots, x_n$, with coefficients in $\mathbb{Q}(q,t)$. As $n \to \infty$, they converge to symmetric functions $P_\lambda(x; q, t)$ in infinitely many variables $x_i$. A transformed and renormalized variant $\widetilde{H}_\lambda(x; q, t)$ of $P_\lambda(x; q, t)$ was the subject of Macdonald's *positivity conjecture*, proved in [6] by identifying $\widetilde{H}_\lambda(x; q, t)$ with the character of the fiber of a certain vector bundle on the Hilbert scheme $H$ of 0-dimensional subschemes in $\mathbb{C}^2$, at a distinguished point of $H$ corresponding to $\lambda$.

**6.19.** Macdonald polynomials for the maximally non-reduced extensions of affine root systems of type $\widetilde{C}_n^\vee$ are *Koornwinder polynomials*. Their coefficients belong to $\mathbb{Q}(t_0, t_0', t_n, t_n', t_1, q)$. Specializing the five $t$ parameters in various ways yields most Macdonald polynomials for the infinite families of affine root systems.

## 7. A combinatorial formula

**7.1.** From Corollary 6.15 and the definition of the operators $\widetilde{T}_i$ it is clear that for a reduced affine root system, $E_\lambda$ can be expressed as a sum of terms of the form

$$\pm x^\mu q^r t^s \prod_j \frac{1-t_{i_j}}{1-q^{a_j}t^{b_j}},$$

where $t^s$, $t^{b_j}$ stand for monomials in the parameters $t_i$. It may be conjectured, at least for equal parameters $t_i = t$, that $E_\lambda$ is a *positive* sum of such terms. With Haglund and Loehr [5], we proved this for type $\widetilde{A}_{n-1}$ by means of a combinatorial formula, which we will now present (referring the reader to [5] for the proof). Some of the combinatorial structure is the same as in Knop and Sahi's earlier formula [10] for non-symmetric Jack polynomials, but the lift to Macdonald polynomials requires more ingredients.

**7.2.** Take $X = Y = \mathbb{Z}^n$ the root system of $\mathrm{GL}_n$, as in Example 2.5. The pairing $(X, Y) \to \mathbb{Z}$ (§4.4) is the standard inner product on $\mathbb{Z}^n$. We have $\phi = \theta = \phi' = \theta' = e_1 - e_n$, and $\Pi = \Pi'$ is cyclic, with generator $\pi'$ acting on $X = W'_e/W_0$ by

$$\pi'(\lambda) = (\lambda_n + 1, \lambda_1, \ldots, \lambda_{n-1}).$$

To $\pi'$ corresponds an element $\pi \in \Pi$ such that $v_\pi = v_{\pi'}$, which acts on $\mathbb{Q}(q,t)\widetilde{X}$ by

$$\pi(x^\lambda) = q^{-\lambda_n} x^{(\lambda_n, \lambda_1, \ldots, \lambda_{n-1})}, \quad \text{or} \quad \pi f(x_1, \ldots, x_n) = f(x_2, \ldots, x_n, x_1/q).$$

We have $\lambda_{\pi'} = \lambda_\pi = e_1$, $\lambda_{(\pi'^{-1})} = \lambda_{(\pi^{-1})} = -e_n$.

The simple roots are all $W$-conjugate, so there is a single parameter $t_i = t$ for all $i$. For $i \neq 0$, the operators $\widetilde{T}_i$ (§5.13, 6.12) are given by

$$\widetilde{T}_i = t s_i - \frac{1-t}{1-x_i/x_{i+1}}(1-s_i), \tag{39}$$

where $s_i$ is the transposition $x_i \leftrightarrow x_{i+1}$. The analogous formula for $i = 0$ has $qx_n/x_1$ in place of $x_i/x_{i+1}$, and $s_0$ acts as $x_1 \mapsto qx_n$, $x_n \mapsto x_1/q$.

Let $\overline{\lambda}$ be the rearrangement of $(1, 2, \ldots, n)$ such that $\overline{\lambda}_i > \overline{\lambda}_j$ if and only if $\lambda_i > \lambda_j$, for $i < j$. Then $w_\lambda(\rho^\vee) = -k\overline{\lambda}$, modulo a constant vector. From §6.17 and (36), we obtain *Knop's recurrence*, which determines $E_\lambda$ for all $\lambda \in X$:

$$E_{(0,\ldots,0)} = 1, \tag{40}$$

$$E_{(\lambda_n+1, \lambda_1, \ldots, \lambda_{n-1})} = q^{\lambda_n} x_1 E_\lambda(x_2, \ldots, x_n, x_1/q), \tag{41}$$

$$E_{s_i(\lambda)} = \left(\widetilde{T}_i + \frac{1-t}{1-q^{\lambda_i-\lambda_{i+1}}t^{\overline{\lambda}_i-\overline{\lambda}_{i+1}}}\right) E_\lambda, \quad \lambda_i > \lambda_{i+1},\ i \neq 0. \tag{42}$$

**7.3.** By (41), we have $E_{\lambda+(r,r,\dots,r)} = (x_1 \dots x_n)^r E_\lambda$. Without loss of generality, therefore, we restrict attention to *compositions* $\lambda$ such that $\lambda_i \geq 0$ for all $i$. The *column diagram* of $\lambda$ is

$$\mathrm{dg}(\lambda) = \{(i, j) \in \mathbb{N}^2 : 1 \leq i \leq n,\ 1 \leq j \leq \lambda_i\},$$

pictured as an array of $n$ columns of boxes, with $\lambda_i$ boxes in column $i$. The *augmented diagram* of $\lambda$,

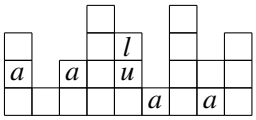
$$\widehat{\mathrm{dg}}(\lambda) = \mathrm{dg}(\lambda) \cup \{(i, 0) : 1 \leq i \leq n\},$$

is formed by adjoining an extra box in row 0 at the bottom of each column. The *arm* and *leg* of a box $u = (i, j) \in \mathrm{dg}(\lambda)$ are defined by

$$l(u) = \mu_i - j,$$
$$a(u) = |\{(i', j) \in \mathrm{dg}(\lambda) : i' < i,\ \lambda_{i'} \leq \lambda_i\} \cup \{(i', j-1) \in \widehat{\mathrm{dg}}(\lambda) : i' > i,\ \lambda_{i'} < \lambda_i\}|.$$

In the example below, the box marked $l$ contributes to the leg of $u$, and those marked $a$ contribute to the arm, giving $l(u) = 1$, $a(u) = 4$.

$\lambda = (2, 0, 1, 3, 2, 0, 3, 1, 2)$, $\widehat{\mathrm{dg}}(\lambda) =$



With these definitions, if $\lambda_i > \lambda_{i+1}$ and $u = (i,\ \mu_{i+1} + 1)$, equation (42) can be written

$$E_{s_i(\lambda)} = \Big(\widetilde{T}_i + \frac{1-t}{1 - q^{l(u)+1} t^{a(u)}}\Big) E_\lambda.$$

A *filling of* $\lambda$ is a function $\sigma : \mathrm{dg}(\lambda) \to [n] = \{1, \dots, n\}$. Its associated *augmented filling* is the extension $\hat{\sigma} : \widehat{\mathrm{dg}}(\lambda) \to [n]$ of $\sigma$ such that $\hat{\sigma}((j, 0)) = j$ for $j = 1, \dots, n$. Distinct boxes $u = (i, j),\ v = (i', j') \in \widehat{\mathrm{dg}}(\lambda)$ *attack* each other if either

(a) they are in the same row, $j = j'$, or

(b) they are in consecutive rows, and the lower box is to the right of the upper box: $j' = j - 1$ and $i < i'$ or vice versa.

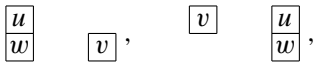
A filling $\sigma$ is *non-attacking* if $\hat{\sigma}(u) \neq \hat{\sigma}(v)$ whenever $u$ and $v$ attack each other (non-attacking fillings are called *admissible* in [10]).

**7.4.** Let $d(u) = (i, j-1)$ denote the box directly below a box $u = (i, j)$. A box $u \in \mathrm{dg}(\lambda)$ is a *descent* of a filling $\sigma$ if $\hat{\sigma}(u) > \hat{\sigma}(d(u))$. Define

$$\mathrm{Des}(\sigma) = \{\text{descents of } \sigma\}, \quad \mathrm{maj}(\sigma) = \sum_{u \in \mathrm{Des}(\sigma)} (l(u) + 1).$$

The *reading order* is the total ordering $<$ of the boxes in $\widehat{\mathrm{dg}}(\lambda)$ row by row, from top to bottom, and from *right to left* within each row. A *triple* consists of three boxes

$u < v < w = d(u)$ in $\widehat{\mathrm{dg}}(\lambda)$, as shown:



Type I Type II

with the proviso that the column containing $u$, $w$ is strictly taller than the column containing $v$ in Type I, and weakly taller in Type II, *i.e.*, $v$ contributes to the arm of $u$. A *co-inversion triple* of $\sigma$ is a triple such that $\sigma(u) < \sigma(v) < \sigma(w)$ or $\sigma(v) < \sigma(w) < \sigma(u)$ or $\sigma(w) < \sigma(u) < \sigma(v)$. Define

$$\mathrm{coinv}(\sigma) = |\{\text{co-inversion triples of } \sigma\}|.$$

**Example 7.5.** The figure below shows the augmentation $\hat{\sigma}$ of a non-attacking filling $\sigma$ of $\lambda = (2, 1, 3, 0, 0, 2)$.

$$\hat{\sigma} = \begin{array}{|c|c|c|c|c|c|}\hline \multicolumn{1}{|c|}{\textcircled{6}} & & \multicolumn{1}{c|}{2} & & & \\ \hline \multicolumn{1}{|c|}{1} & \multicolumn{1}{c|}{2} & \multicolumn{1}{c|}{\textcircled{4}} & & & \multicolumn{1}{c|}{5} \\ \hline \multicolumn{1}{|c|}{1} & \multicolumn{1}{c|}{2} & \multicolumn{1}{c|}{3} & & & \multicolumn{1}{c|}{5} \\ \hline \multicolumn{1}{|c|}{1} & \multicolumn{1}{c|}{2} & \multicolumn{1}{c|}{3} & \multicolumn{1}{c|}{4} & \multicolumn{1}{c|}{5} & \multicolumn{1}{c|}{6} \\ \hline \end{array}.$$

The circled boxes are $\mathrm{Des}(\sigma)$, giving $\mathrm{maj}(\sigma) = 3$. Row 0 is the bottom row. There are two co-inversion triples, one of Type I formed by the 3 and the 5 in row 1 with the 4 in row 2, and one of Type II formed by the 6 and the 4 in row 2 with the 3 in row 1, giving $\mathrm{coinv}(\sigma) = 2$.

**Theorem 7.6.** *The Macdonald polynomials $E_\lambda$ for* $\mathrm{GL}_n$ *are given by*

$$E_\lambda = \sum_{\substack{\sigma:\,\lambda\to[n] \\ \textit{non-attacking}}} x^\sigma q^{\mathrm{maj}(\sigma)} t^{\mathrm{coinv}(\sigma)} \prod_{\substack{u\in\mathrm{dg}(\lambda) \\ \hat{\sigma}(u)\neq\hat{\sigma}(d(u))}} \frac{1-t}{1-q^{l(u)+1}t^{a(u)+1}}, \qquad (43)$$

*where* $x^\sigma = \prod_{u\in\mathrm{dg}(\lambda)} x_{\sigma(u)}$.

**7.7.** Earlier, in [4], we gave a combinatorial formula for the symmetric Macdonald polynomials $P_\lambda$ for $\mathrm{GL}_n$, which had originally been conjectured by Haglund [3]. The combinatorial statistics $\mathrm{coinv}(\sigma)$ and $\mathrm{maj}(\sigma)$ first appeared in the formula for the symmetric case, which is expressed similarly as a sum over fillings of a diagram. Our work in the symmetric case relies heavily on the special theory of $\mathrm{GL}_n$ Macdonald polynomials in the $n \to \infty$ stable limit. It seems likely that the non-symmetric formula will provide better clues as to what we might expect for other root systems.

**7.8.** The proof of Theorem 7.6 is a direct verification that (43) satisfies Knop's recurrence (40)–(42). It is not difficult to check (41), and (40) is trivial. The hard part is to verify (42). In fact, we were only able to do it in the special case that $\lambda_{i+1} = 0$, which fortunately is enough. The difficulty lies in applying the operator $\widetilde{T}_i$ in (39) to (43), which is intractable if attempted head-on. To get around this, we recast (42) as asserting that certain expressions related to (43) are $s_i$-invariant. This is proved with the help of a symmetry lemma which originated in the theory of *LLT polynomials* [11], [12], and was also at the heart of our work in [4]. We invite the reader to consult [5] for more detail.

# Poisson cloning model for random graphs

Jeong Han Kim

**Abstract.** In the random graph $G(n, p)$ with $pn$ bounded, the degrees of the vertices are almost i.i.d. Poisson random variables with mean $\lambda := p(n-1)$. Motivated by this fact, we introduce the Poisson cloning model $G_{\mathrm{PC}}(n, p)$ for random graphs in which the degrees are i.i.d. Poisson random variables with mean $\lambda$.

We first establish a theorem that shows that the new model is equivalent to the classical model $G(n, p)$ in an asymptotic sense. Next, we introduce a useful algorithm to generate the random graph $G_{\mathrm{PC}}(n, p)$, called the cut-off line algorithm. Then $G_{\mathrm{PC}}(n, p)$ equipped with the cut-off line algorithm enables us to very precisely analyze the sizes of the largest component and the $t$-core of $G(n, p)$. This new approach for the problems yields not only elegant proofs but also improved bounds that are essentially best possible.

We also consider the Poisson cloning model for random hypergraphs and the $t$-core problem for random hypergraphs.

**Keywords.** Random graph, giant component, core, Poisson distribution.

## 1. Introduction

The notion of a random graph was first introduced in 1947 by Erdős [14] to show the existence of a graph with a certain Ramsey property. A decade later, the theory of random graphs began with the paper entitled *On Random Graphs I* by Erdős and Rényi [15], and they further developed the theory in a series of papers [16], [17], [18], [19], [20]. Since then, the subject has become one of the most active research areas. Many researchers have devoted themselves to studying various properties of random graphs, such as the emergence of the giant component [16], [5], [32], the connectivity [15], [17], [11], the existence of perfect matching [18], [19], [20], [11], the existence of Hamiltonian cycle(s) [31], [6], [10], the $k$-core problem [6], [34], [38], and the graph invariants like the independence number [9], [36] and the chromatic number [39], [8], [33]. (The list of references here is far from being exhaustive.)

There are two canonical models for random graphs, both of which were originated in the simple model introduced in [14]. In the binomial model $G(n, p)$ on a set $V$ of $n$ vertices, each of $\binom{n}{2}$ possible edges is in the graph with probability $p$, independently of other edges. Thus, the probability of $G(n, p)$ being a fixed graph $G$ with $m$ edges is $p^m(1-p)^{\binom{n}{2}-m}$. The uniform model $G(n, m)$ on $V$ is a graph chosen uniformly at random from the set of all graphs on $V$ with $m$ edges. Hence $G(n, m)$ becomes a fixed

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

graph $G$ with probability $\binom{\binom{n}{2}}{m}^{-1}$, provided $G$ has $m$ edges. Most of the asymptotic behavior of the two models is almost identical if their expected numbers of edges are the same. (See Proposition 1.13 in [27].) The random graph process, in which random edges are added one by one, is also extensively studied. For more about models and/or basics of random graphs we recommend two books with the same title: *Random Graphs* by Bollobás [7] and by Janson, Łuczak and Ruciński [27].

The phase transition phenomenon is one of the interesting topics in random graphs. Specifically, the phase transition phenomena regarding the emergences of the giant (connected) component and the $t$-core have attracted much attention. In the monumental paper *On the Evolution of Random Graphs* [16], Erdős and Rényi proved that, for the size $\ell_1(n, p)$ of the largest component of $G(n, p)$,

$$\ell_1(n, p) = \begin{cases} O(\log n), & \text{if } \limsup_{n\to\infty} p(n-1) < 1, \\ (1 + o(1))\theta_\lambda n, & \text{if } \lim_{n\to\infty} pn = \lambda > 1, \end{cases}$$

where $\theta_\lambda$ is the positive solution of the equation $1 - \theta - e^{-\lambda\theta} = 0$ and all other components are of size $O(\log n)$.

Why does the size of the largest component change so dramatically around $\lambda = 1$? It was Karp [28] who nicely explained the reason. To find a component $C(v)$ of a fixed vertex $v$ in $G(n, p)$, one may first expose the vertices that are adjacent to $v$ and keep on repeating the same procedure by taking each of those adjacent vertices. Initially, $v$ is active and all other vertices are neutral. At each step we take an active vertex $w$ and expose all neutral vertices adjacent to $w$. This can be done by checking $\{w, w'\} \in G(n, p)$ or not for all neutral vertices $w'$. Then activate all neutral vertices that are adjacent to $w$. The vertex $w$ is no longer active, and only non-activated neutral vertices remain neutral. The process terminates when there is no more active vertex left. Clearly, the process will stop after finding all the vertices in the component containing $v$. If the number of neutral vertices does not decrease so fast, the number of newly activated vertices is close to the binomial random variable $\mathrm{Bin}(n-1, p)$, where

$$\Pr[\mathrm{Bin}(n-1, p) = \ell] = \binom{n-1}{\ell} p^\ell (1-p)^{n-1-\ell}.$$

Particularly, the mean number is close to $pn$. If $pn \le 1 - \delta$ for a fixed $\delta > 0$, then the process is expected to die out quickly almost every time. Thus, all $C(v)$ are expected to be small. If $pn \ge 1 + \delta$, then the process may survive forever with positive probability. Hence, $C(v)$ can be large with positive probability. As there are $n$ trials, at least one of the $C(v)$'s is expected to be large. Applying this approach to the random directed graph, Karp was able to prove a phase transition phenomenon for the size of the largest strong component.

Notice that, when $pn = \Theta(1)$, the distribution of $\mathrm{Bin}(n-1, p)$ is very close the Poisson distribution with parameter $\lambda := p(n-1)$. Hence we may further expect that the process described above could be approximated by the Galton–Watson branching

process defined by a Poisson random variable $\mathrm{Poi}(\lambda)$ with mean $\lambda$, where

$$\Pr[\mathrm{Poi}(\lambda) = \ell] = e^{-\lambda}\frac{\lambda^{\ell}}{\ell!}.$$

Generally, the Galton–Watson branching process defined by a random variable $X$ starts with a single unisexual organism. The organism will give birth to $X_1$ children, where $X_1$ is a random variable with the same distribution as $X$. The same but independent birth process continues from each of the children, the grandchildren and so on, until no more descendant exists. (For more information regarding Galton–Watson branching processes, one may refer [4].) For simplicity we call the Galton–Watson branching process defined by $\mathrm{Poi}(\lambda)$ the *Poisson*$(\lambda)$ *branching process*.

**The Poisson cloning model.** To convert the above observation to a rigorous proof, it is needed to overcome or bypass two main obstacles. Firstly, the degrees of vertices of $G(n, p)$ are not exactly i.i.d. Poisson random variables. Though they have the same distribution as $\mathrm{Bin}(n-1, p)$, they are not mutually independent. For example, the sum of all degrees must be even as it is twice the number of edges, which cannot be guaranteed if the degrees are independent. Secondly, the number of neutral vertices keeps decreasing. Even if both obstacles do not cause substantial differences in many cases, one needs at least to keep tracking small differences for rigorous proofs. Since this kind of small differences occurs almost everywhere in the analysis, it sometimes makes rigorous analysis significantly difficult, if not impossible.

As an approach to bypass the first obstacle, we introduce the Poisson cloning model $G_{\mathrm{PC}}(n, p)$ for random graphs in which the degrees are i.i.d. Poisson random variables with mean $\lambda = p(n-1)$. Moreover, the new model is equivalent to the classical model $G(n, p)$ in an asymptotic sense. Actually, defining the model is not extremely difficult: First take i.i.d. Poisson $\lambda$ random variables $d(v)'s$ indexed by all vertices in the vertex set $V$. Then take $d(v)$ copies, or clones, of each vertex $v$. If the sum of $d(v)$'s is even, then we generate a uniform random perfect matching on the set of all clones. An edge $\{v, w\}$ is in the random graph $G_{\mathrm{PC}}(n, p)$ if a clone of $v$ is matched to a clone of $w$ in the random perfect matching. If the sum is odd, one may just take a graph with a self loop. Hence the graph is not simple if the sum is odd.

It is also possible to extend the model to uniform hypergraphs, where a $k$-uniform hypergraph on the vertex set $V$ is a collection of subsets of $V$ with size $k$. A graph is then a 2-uniform hypergraph. In the binomial model $H(n, p; k)$ for random $k$-uniform hypergraphs each of $\binom{n}{k}$ edges is in the hypergraph with probability $p$, independently of other edges. The Poisson cloning model for random $k$-uniform hypergraphs is denoted by $H_{\mathrm{PC}}(n, p; k)$. In the next section the Poisson cloning model is defined in detail.

The following theorem shows that the Poisson cloning model is essentially equivalent to the binomial model.

**Theorem 1.1.** *Suppose $k \geq 2$ and $p = \Theta(n^{1-k})$. Then for any collection $\mathcal{H}$ of $k$-uniform simple hypergraphs,*

$$c_1 \Pr[H_{\mathrm{PC}}(n, p; k) \in \mathcal{H}] \leq \Pr[H(n, p; k) \in \mathcal{H}] \leq c_2\big(\Pr[H_{\mathrm{PC}}(n, p; k) \in \mathcal{H}]^{\frac{1}{k}} + e^{-n}\big),$$

*where*

$$c_1 = k^{1/2} e^{\frac{p}{n}\binom{k}{2}\binom{n}{k} + \frac{p^2}{2}\binom{n}{k}} + O(n^{-1/2}), \quad c_2 = \Big(\frac{k}{k-1}\Big)\big(c_1(k-1)\big)^{1/k} + o(1),$$

*and $o(1)$ goes to 0 as $n$ goes to infinity.*

To overcome the second obstacle we present an algorithm, called the cut-off line algorithm, that enables us to generate the Poisson cloning model and analyze problems simultaneously. As a consequence the size of the largest component of $G_{\mathrm{PC}}(n, p)$ can be described very precisely. It is also possible to analyze the size of $t$-core of the random hypergraph $H_{\mathrm{PC}}(n, p; k)$, where the $t$-core of a hypergraph $H$ is the largest subhypergraph of $H$ with minimum degree at least $t$.

**The emergence of the giant component.** After the phase transition result of Erdős and Rényi it remained to determine the size of the largest component when $pn \to 1$. Though Erdős and Rényi suggested that the size $\ell_1(n, p)$ of the largest component could be one of $O(\log n)$, $\Theta(n^{2/3})$, and $\Theta(n)$, Bollobás [5] showed that $\ell_1(n, p)$ increases rather continuously by estimating it quite accurately for $pn - 1 \geq n^{-1/3}\sqrt{\log n}/2$. Later Łuczak [32] was able to estimate $\ell_1(n, p)$ for $pn - 1 \gg n^{-1/3}$.

Before stating the result of Łuczak a convention is introduced: when the expression $x \gg y$ is used as part of the hypotheses, it means 'there exists a (large) constant $K > 0$ so that, if $x \geq Ky \ldots$'. We also denote $\lambda(n, p) = p(n-1)$.

**Theorem 1.2** (Supercritical phase). *Suppose $\lambda = \lambda(p, n) = 1 + \varepsilon$ with $\varepsilon \gg n^{-1/3}$. Then for large enough $n$, with probability at least $1 - 7(\varepsilon^3 n/8)^{-1/9}$*

$$|\ell_1(n, p) - \theta_\lambda n| \leq \frac{n^{2/3}}{5},$$

*and all other components are smaller than $n^{2/3}$.*

Using estimations for the numbers of connected graphs with certain number of vertices and edges and the first and second moment methods, one may also obtain the following result for the subcritical phase.

**Theorem 1.3** (Subcritical phase). *Let $\lambda(n, p) = 1 - \varepsilon$ with $n^{-1/3} \ll \varepsilon \ll 1$. Then for any positive constant $\delta \leq 1/3$ and large enough $n$, with probability at least $1 - \big(\frac{8}{\varepsilon^3 n}\big)^{\delta/4}$*

$$\left|\ell_1(n, p) - \frac{2\log(\varepsilon^3 n)}{\varepsilon^2}\right| \leq \frac{\delta \log(\varepsilon^3 n)}{\varepsilon^2}.$$

For results regarding the structure of the largest component readers are referred to [27], [32], [25], [35] and references therein.

For Poisson branching processes a duality principle has been known. A pair $(\mu, \lambda)$ with $\mu < 1 < \lambda$ is called a *conjugate pair* if $\mu e^{-\mu} = \lambda e^{-\lambda}$. It is easy to see that $\mu = (1 - \theta_\lambda)\lambda$ for a conjugate pair $(\mu, \lambda)$. For a conjugate pair $(\mu, \lambda)$ the distribution of the Poisson($\lambda$) branching process conditioned that the process dies out is exactly the same as that of the Poisson($\mu$) branching process. (See e.g. [2], p. 164.) A similar duality was observed for the random graph $G(n, p)$ and $G(n^*, p)$ with $\lambda = \lambda(n, p) > 1$ and $n^* = (1 - \theta_\lambda)n$. (Recall that $\lambda(n, p) = p(n - 1)$.) Notice that $1 - \theta_\lambda$ is the extinction probability for the Poisson($\lambda$) branching process. It is known that the component sizes of $G(n^*, p)$ and those of $G(n, p)$ excluding the largest component are the same in an asymptotic sense (see [2]).

The Poisson cloning model $G_{\mathrm{PC}}(n, p)$ equipped with the cut-off line algorithm enables us to not only estimate $\ell_1(n, p)$ more accurately but also to establish a discrete duality principle: in the supercritical phase $\lambda := \lambda(n, p) = 1 + \varepsilon$ with $n^{-1/3} \ll \varepsilon \ll 1$; $G_{\mathrm{PC}}(n, p)$ can be decomposed by three vertex disjoint graphs $C$, $S$ and $G$ whp (with high probability), where $C$ is a connected graph of size about $\theta_\lambda n$, $S$ is a smaller graph of size about $\varepsilon^{-2} \ll \theta_\lambda n$, and $G$ has the same distribution as $G_{\mathrm{PC}}(n^*, p^*)$ with $n^* \approx (1 - \theta_\lambda)n$ and $p^* \approx p$, which yields $\lambda(n^*, p^*) \approx \mu := (1 - \theta_\lambda)\lambda$. In the subcritical phase $\lambda = 1 - \varepsilon$ with $n^{-1/3} \ll \varepsilon \ll 1$ the largest component is of size

$$\frac{\log(\varepsilon^3 n) - 2.5 \log\log(\varepsilon^3 n) + O(1)}{-(\varepsilon + \log(1 - \varepsilon))}$$

whp. The precise statements are as follows. We concentrate on the cases $\varepsilon \ll 1$ for which more careful analysis is required. It is believed that the proofs are easily modified for the cases of positive constants $\varepsilon$.

**Theorem 1.4.** *Supercritical phase: Let $\lambda := \lambda(n, p) = 1 + \varepsilon$ with $n^{-1/3} \ll \varepsilon \ll 1$, $\mu := (1-\theta_\lambda)\lambda$ and $1 \ll \alpha \ll (\varepsilon^3 n)^{1/2}$. Then with probability $1 - e^{-\Omega(\alpha^2)}$ $G_{\mathrm{PC}}(n, p)$ may be decomposed by three vertex disjoint graphs $C$, $S$ and $G$, where $C$ is connected and*

$$\theta_\lambda n - \alpha(n/\varepsilon)^{1/2} \le |C| \le \theta_\lambda n + \alpha(n/\varepsilon)^{1/2},$$

*$|S| \le \frac{\alpha^2}{\varepsilon^2}$, $G$ has the same distribution as $G_{\mathrm{PC}}(n^*, p^*)$ for some $n^*$ and $p^*$ satisfying*

$$(1 - \theta_\lambda)n - \alpha(n/\varepsilon)^{1/2} \le n^* \le (1 - \theta_\lambda)n + \alpha(n/\varepsilon)^{1/2},$$

*and*

$$\mu - \alpha(\varepsilon n)^{-1/2} \le \lambda(n^*, p^*) \le \mu + \alpha(\varepsilon n)^{-1/2}.$$

*Subcritical phase: Suppose $\lambda := \lambda(n, p) = 1 - \varepsilon$ with $n^{-1/3} \ll \varepsilon \ll 1$. Then the size $\ell_1^{\mathrm{PC}}(n, p)$ of the largest component of $G_{\mathrm{PC}}(n, p)$ satisfies*

$$\Pr\left[\ell_1^{\mathrm{PC}}(n, p) \ge \frac{\log(\varepsilon^3 n) - 2.5 \log\log(\varepsilon^3 n) + c}{-(\varepsilon + \log(1 - \varepsilon))}\right] \le 2e^{-\Omega(c)},$$

*and*

$$\Pr\left[\ell_1^{\mathrm{PC}}(n,p) \le \frac{\log(\varepsilon^3 n) - 2.5\log\log(\varepsilon^3 n) - c}{-(\varepsilon + \log(1-\varepsilon))}\right] \le 2e^{-e^{\Omega(c)}}$$

*for any constant $c > 0$.*

*Inside window: Suppose $\lambda := \lambda(n,p) = 1+\varepsilon$ with $|\varepsilon| = O(n^{1/3})$. Then whp*

$$\ell_1^{\mathrm{PC}}(n,p) = \Theta(n^{2/3}).$$

(*All constants in the $\Omega(\cdot)$'s do not depend on any of $\varepsilon$, $\alpha$ and $c$.*)

By Theorem 1.1 a corollary regarding $G(n,p)$ follows.

**Corollary 1.5.** *Supercritical region: Suppose $\lambda = \lambda(n,p) = 1+\varepsilon$ with $n^{-1/3} \ll \varepsilon \ll 1$, and $1 \ll \alpha \ll (\varepsilon^3 n)^{1/2}$. Then, in $G(n,p)$,*

$$\Pr[\,|\ell_1(n,p) - \theta_\lambda n| \ge \alpha(n/\varepsilon)^{1/2}] \le 2e^{-\Omega(\alpha^2)}.$$

*Moreover, for the size $\ell_2(n,p)$ of the second largest component and $\varepsilon^* = 1-(1-\theta_\lambda)\lambda$,*

$$\Pr\left[\ell_2(n,p) \ge \frac{\log((\varepsilon^*)^3 n) - 2.5\log\log((\varepsilon^*)^3 n) + c}{-(\varepsilon^* + \log(1-\varepsilon^*))}\right] \le 2e^{-\Omega(c)}$$

*and*

$$\Pr\left[\ell_2(n,p) \le \frac{\log((\varepsilon^*)^3 n) - 2.5\log\log((\varepsilon^*)^3 n) - c}{-(\varepsilon^* + \log(1-\varepsilon^*))}\right] \le 2e^{-e^{\Omega(c)}},$$

*for any constant $c > 0$.*

*Subcritical region: Suppose $\lambda = 1-\varepsilon$ with $n^{-1/3} \ll \varepsilon \ll 1$. Then for any constant $c > 0$,*

$$\Pr\left[\ell_1(n,p) \ge \frac{\log(\varepsilon^3 n) - 2.5\log\log(\varepsilon^3 n) + c}{-(\varepsilon + \log(1-\varepsilon))}\right] \le 2e^{-\Omega(c)}$$

*and*

$$\Pr\left[\ell_1(n,p) \le \frac{\log(\varepsilon^3 n) - 2.5\log\log(\varepsilon^3 n) - c}{-(\varepsilon + \log(1-\varepsilon))}\right] \le 2e^{-e^{\Omega(c)}}.$$

*Inside window: Suppose $\lambda := \lambda(n,p) = 1+\varepsilon$ with $|\varepsilon| = O(n^{1/3})$. Then whp*

$$\ell_1(n,p) = \Theta(n^{2/3}).$$

**The emergence of the $t$-core.** There are at least two possible directions to extend the problem of (connected) component. Observing that the minimum degree in a component must be larger than or equal to 1, one may consider subgraphs with minimum degree at least $t \ge 2$. For a graph $G$, the $t$-core is the largest subgraph with minimum degree at least $t$. Since the minimum degree of the union of two subgraphs is larger than or equal to the smaller minimum degree of the two, the $t$-core of a graph

is unique. It is also easy to see that the $t$-core must be an induced subgraph. For this reason the $t$-core of $G$ sometimes refers to its vertex set. Denote by $V_t(G)$ (the vertex set of) the $t$-core of $G$. As the 1-core $V_1(G)$ is the set of all non-isolated vertices, we consider the cases $t \geq 2$ throughout this paper. If there is no subgraph with minimum degree $t$, the $t$-core is defined to be empty.

Another direction is to consider the $t$-connectivity, where a graph is $t$-connected if the graph remains connected after any $t-1$ vertices are removed. Higher orders of connectivity have been used to understand various structures of graphs. Clearly, if a non-empty subgraph is $t$-connected, then its minimum degree must be $t$ or larger.

In 1984, Bollobás [6] initiated the study of $t$-core, $t \geq 2$, and observed that, provided $t \geq 3$ and $pn$ is larger than a fixed constant, the $t$-core of $G(n, p)$ is non-empty and $t$-connected whp. Łuczak [34] proved that for $t \geq 3$ there is an absolute constant $c$ such that the $t$-core of $G(n, p)$ is either empty, or larger than $cn$ and $t$-connected, whp. In particular, as far as the random graph $G(n.p)$ is concerned, the $t$-core problem is the same as the $t$-connectivity problem. Moreover, if $\lambda(n, p)$ is less than 1, then the $t$-core of $G(n, p)$ is empty whp since the size of the largest component is $O(n^{2/3})$ whp. As $p$ increases while $n$ is fixed, the probability of the $t$-core of $G(n, p)$ being non-empty keeps increasing. Let $p_t(n, \delta)$ be the infimum of all $p$ that makes the probability larger than or equal to a constant $\delta$ with $0 < \delta < 1$. Then Bollobás's result implies that $np_t(n, \delta)$ is bounded from above by a constant. Though $np_t(n, \delta)$ may still have no limit value as $n$ goes to infinity, it seems to be more natural to expect that the limit exists. Furthermore, as it happens often in phase transition phenomena, the limit, if it exists, is also expected to be independent of $\delta$. In other words, the phase transition is expected to be sharp.

For $t = 2$, the 2-core of a graph $G$ is non-empty if and only if $G$ contains a cycle. It is easy to see by the first moment method that $G(n, p)$ with $p = o(1/n)$ does not contain a cycle whp. For a constant $c$ with $0 < c < 1$, $G(n, p)$ may or may not have a cycle with positive probability. In particular, the phase transition for the existence of a non-empty 2-core is not sharp. In the graph process $(G(n, m))_{m=0,1,\ldots}$ in which a random edge is added one by one without repetition, Janson [24] found the limiting distribution for the length of the first cycle, especially he showed that the length is bounded whp. However, the expectation of the length is known to be $\Theta(n^{1/6})$ due to Flajolet et al. [23]. The two facts do not contradict each other, since there are random variables $X$ that are bounded whp, but $E[X]$ is not. For example, $\Pr[X = 1] = 1 - 1/n$ and $\Pr[X = n^2] = 1/n$.

Bollobás [6] proved that, if $t \geq 5$ and $\lambda(n, p) := p(n-1) \geq \max\{67, 2t + 6\}$, then $G(n, p)$ has a non-empty $t$-core. Chvátal [12] introduced the notion of critical $\lambda_t$, without proving existence, satisfying the following. As $n$ goes to infinity,

$$\Pr[G(n, p) \text{ has a non-empty } t\text{-core }] \longrightarrow \begin{cases} 0 & \text{if } \lambda(n, p) < \lambda_t - \delta, \\ 1 & \text{if } \lambda(n, p) > \lambda_t + \delta \end{cases}$$

for any constant $\delta > 0$. He also proved that $\lambda_3 \geq 2.88$ if it exists, and claimed that

$\lambda_4 \geq 4.52$ and $\lambda_5 \geq 6.06$ etc. could be proven by the same method. Pittel, Spencer and Wormald [38] proved a general theorem which implies that $\lambda_t$ exists for fixed $t \geq 3$ and identified their values. We present a slightly weaker version of this result.

For a Poisson random variable $\mathrm{Poi}(\rho)$ with mean $\rho$ let $P(\rho, i) = \Pr[\mathrm{Poi}(\rho) = i]$ and $Q(\rho, i) = \Pr[\mathrm{Poi}(\rho) \geq i]$, i.e.,

$$P(\rho, i) = e^{-\rho}\frac{\rho^i}{i!} \quad \text{and} \quad Q(\rho, i) := \sum_{j=i}^{\infty} P(\rho, j) = e^{-\rho}\sum_{j=i}^{\infty}\frac{\rho^j}{j!},$$

and let

$$\lambda_t = \min_{\rho>0}\frac{\rho}{Q(\rho, t-1)}.$$

**Theorem 1.6.** *Let $t \geq 3$, $\lambda(n, p) = p(n-1)$. Then*

$$\Pr[G(n, p) \text{ has a non-empty } t\text{-core}] \longrightarrow \begin{cases} 0 & \text{if } \lambda(n, p) < \lambda_t - n^{-\delta}, \\ 1 & \text{if } \lambda(n, p) > \lambda_t + n^{-\delta} \end{cases}$$

*for any $\delta \in (0, 1/2)$, and the $t$-core when $\lambda(n, p) > \lambda_t + n^{-\delta}$ has $(1+o(1))Q(\theta_\lambda\lambda, t)n$ vertices, whp, where $\theta_\lambda$ is the largest solution for the equation*

$$\theta - Q(\theta\lambda, t-1) = 0.$$

There are many studies about the $t$-cores of various types of random graphs and random hypergraphs. Fernholz and Ramachandran [21], [22] studied random graph conditions on given degree sequences. Cooper [13] found the critical values for $t$-cores of a uniform multihypergraph with given degree sequences that includes the random $k$-uniform hypergraph $H(n, p\,; k)$. Molloy [37] considered cores for random hypergraphs and random satisfiability problems for Boolean formulas. Recently, S. Janson and M. J. Luczak [26] also gave seemingly simpler proofs for $t$-core problems that contain the result of Pittel, Spencer and Wormald. For more information and techniques used in the above mentioned papers readers are referred to [26].

Using the Poisson cloning model for random hypergraphs together with the cut-off line algorithm we are able to completely analyze the $t$-core problem for the random uniform hypergraph. We also believe that the cut-off line algorithm can be used to analyze the $t$-core problem for random hypergraphs conditioned on certain degree sequences as in [13], [21], [22], [26].

As the 2-core of $G(n, p)$ behaves quite differently from the other $t$-cores of $H(n, p\,; k)$, we exclude the case $k = t = 2$, which will be studied in a subsequent paper. The critical value for the problem turns out to be the minimum $\lambda$ such that there is a positive solution for the equation

$$\theta - Q(\theta^{k-1}\lambda, t-1) = 0. \tag{1.1}$$

It is not difficult to check that the minimum is

$$\lambda_{\mathrm{crt}}(k, t) := \min_{\rho>0}\frac{\rho}{Q(\rho, t-1)^{k-1}}. \tag{1.2}$$

For $\lambda > \lambda_{\mathrm{crt}}(k,t)$, let $\theta_\lambda$ be the largest solution of the equation $\theta^{\frac{1}{k-1}} - Q(\theta\lambda, t-1) = 0$.

**Theorem 1.7.** *Let $k, t \geq 2$, excluding $k = t = 2$, and $\sigma \gg n^{-1/2}$.*

*Subcritical phase: If $\lambda(n, p; k) := p\binom{n-1}{k-1} = \lambda_{\mathrm{crt}} - \sigma$ is uniformly bounded from below by 0 and $i_0(k,t)$ is the minimum $i$ such that $\binom{i}{k} \geq ti/k$, then*

$$\Pr[V_t(H(n, p; k)) \neq \emptyset] = e^{-\Omega(\sigma^2 n)} + O\big(n^{-(t-1-t/k)i_0(k,t)}\big),$$

*and for any $\delta > 0$,*

$$\Pr[|V_t(H(n, p; k))| \geq \delta n] = e^{-\Omega(\sigma^2 n)} + e^{-\Omega(\delta^{2k/(k-1))} n)}. \tag{1.3}$$

*Supercritical phase: If $\lambda = \lambda(n, p; k) = \lambda_{\mathrm{crt}} + \sigma$ is uniformly bounded from above, then for all $\alpha$ in the range $1 \ll \alpha \ll \sigma n^{1/2}$,*

$$\Pr\big[\big||V_t(n, p; k)| - Q(\theta_\lambda\lambda, t)n\big| \geq \alpha(n/\sigma)^{1/2}\big] = e^{-\Omega(\alpha^2)}, \tag{1.4}$$

*and, for any $i \geq t$ and the sets $V_t(i)$ (resp. $W_t(i)$) of vertices of degree $i$ (resp. larger than or equal to $i$) in the $t$-core,*

$$\Pr\big[\big||V_t(i)| - P(\theta_\lambda\lambda, i)n\big| \geq \delta n\big] \leq 2e^{-\Omega(\min\{\delta^2\sigma n, \sigma^2 n\})},$$

*and*

$$\Pr\big[\big||W_t(i)| - Q(\theta_\lambda\lambda, i)n\big| \geq \delta n\big] \leq 2e^{-\Omega(\min\{\delta^2\sigma n, \sigma^2 n\})}.$$

*In particular, for $\lambda = \lambda_{\mathrm{crt}} + \sigma$ and $\rho_{\mathrm{crt}} := \theta_{\lambda_{\mathrm{crt}}(k,t)}\lambda_{\mathrm{crt}}(k,t)$,*

$$|V_t(i)| = \big(1 + O(\sigma^{1/2})\big)^i P(\rho_{\mathrm{crt}}, i)n + O\big((n/\sigma)^{1/2}\log n\big),$$

*with probability $1 - 2e^{-\Omega(\min\{\log^2 n, \sigma^2 n\})}$.*

As one might guess, we will prove a stronger theorem (Theorem 6.2) for the Poisson cloning model $H_{\mathrm{PC}}(n, p; k)$, from which Theorem 1.7 easily follows.

In the next section the Poisson cloning model is defined in detail. The cut-off line algorithm and the cut-off line lemma are presented in Section 3. In Section 4 we study Chernoff type large derivation inequalities that will be used in most of our proofs. In Section 5, a generalized core is defined and the main lemma is presented. Section 6 is devoted to the proof of Theorem 1.7. As the proof of Theorem 1.4 is more sophisticated, we only give the proof ideas in Section 7. We conclude this paper with final remarks in Section 8. Due to the space limitation, many proofs are omitted. They can be found on the author's web site.

## 2. The Poisson cloning model

To construct the Poisson cloning model $G_{\mathrm{PC}}(n, p)$ for random graphs, let $V$ be a set of $n$ vertices. We take i.i.d. Poisson $\lambda = p(n-1)$ random variables $d(v)$, $v \in V$, and then take $d(v)$ copies of each vertex $v \in V$. The copies of $v$ are called *clones of* $v$, or simply *$v$-clones*. Since the sum of Poisson random variables is also a Poisson random variable, the total number $N_\lambda := \sum_{v \in V} d(v)$ of clones is a Poisson $\lambda n$ random variable. It is sometimes convenient to take a reverse, but equivalent, construction. We first take a Poisson $\lambda n = 2p\binom{n}{2}$ random variables $N_\lambda$ and then take $N_\lambda$ unlabelled clones. Each clone is independently labelled as $v$-clone uniformly at random, in the sense that $v$ is chosen uniformly at random from $V$. It is well known that the numbers $d(v)$ of $v$-clones are i.i.d. Poisson random variables with mean $\lambda$.

If $N_\lambda$ is even, the multigraph $G_{\mathrm{PC}}(n, p)$ is defined by generating a (uniform) random perfect matching of those $N_\lambda$ clones, and contracting clones of the same vertex. That is, if a $v$-clone and a $w$-clone are matched, then the edge $\{v, w\}$ is in $G_{\mathrm{PC}}(n, p)$ with multiplicity. In the case that $v = w$, it produces a loop that contributes 2 to the degree of $v$. If $N_\lambda$ is odd, we may define $G_{\mathrm{PC}}(n, p)$ to be any graph with a special loop that, unlike other loops, contributes only 1 to the degree of the corresponding vertex. In particular, if $N_\lambda$ is odd, $G_{\mathrm{PC}}(n, p)$ is not a simple graph.

Strictly speaking, $G_{\mathrm{PC}}(n, p)$ varies depending on how to define it when $N_\lambda$ is odd. However, if only simple graphs are concerned, the case of $N_\lambda$ being odd would not matter. For example, the probability that $G_{\mathrm{PC}}(n, p)$ is a simple graph with a component larger than $0.1n$ does not depend on how $G_{\mathrm{PC}}(n, p)$ is defined when $N_\lambda$ is odd, as it is not a simple graph anyway. Generally, for any collection $\mathcal{G}$ of simple graphs, the probability that $G_{\mathrm{PC}}(n, p)$ is in $\mathcal{G}$ is totally independent of how $G_{\mathrm{PC}}(n, p)$ is defined when $N_\lambda$ is odd. Notice that properties of simple graphs are actually mean collections of simple graphs. Therefore, when properties of simple graphs are concerned, it is not necessary to describe $G_{\mathrm{PC}}(n, p)$ for odd $N_\lambda$.

Here are two specific ways to generate the uniform random matching.

**Example 2.1.** One may keep matching two clones chosen uniformly at random among all unmatched clones.

**Example 2.2.** One may keep choosing his or her favorite unmatched clone, and matching it to a clone selected uniformly at random from all other unmatched clones.

If $N_\lambda$ is even both examples would yield uniform random perfect matchings. If $N_\lambda$ is odd, then each of them would yield a matching and an unmatched clone. We may create the special loop consisting of the vertex for which the unmatched clone is labelled. More specific ways to choose random clones will be described in the next section.

Generally for $k \geq 3$, the Poisson cloning model $H_{\mathrm{PC}}(n, p\,; k)$ for $k$-uniform hypergraphs may be defined in the same way: We take i.i.d. Poisson $\lambda = p\binom{n-1}{k-1}$ random variables $d(v)$, $v \in V$, and then take $d(v)$ clones of each $v$. If $N_\lambda := \sum_{v \in V} d(v)$ is

divisible by $k$, the multihypergraph $H_{\mathrm{PC}}(n, p; k)$ is defined by generating a uniform random perfect matching consisting of $k$-tuples of those $N_\lambda$ clones, and contracting clones of the same vertex. That is, if $v_1$-clone, $v_2$-clone, …, $v_k$-clone are matched in the perfect matching, then the edge $\{v_1, v_2, \dots, v_k\}$ is in $H_{\mathrm{PC}}(n, p\,; k)$ with multiplicity. If $N_\lambda$ is not divisible by $k$, $H_{\mathrm{PC}}(n, p\,; k)$ may be any hypergraph with a special edge consisting of $N_\lambda - k\lfloor N_\lambda/k \rfloor$ vertices. In particular, $H_{\mathrm{PC}}(n, p\,; k)$ is not $k$-uniform when $N_\lambda$ is not divisible by $k$. Therefore, as long as properties of $k$-uniform hypergraphs are concerned, we do not have to describe $H_{\mathrm{PC}}(n, p\,; k)$ when $N_\lambda$ is not divisible by $k$.

We show that the Poisson cloning model $H_{\mathrm{PC}}(n, p\,; k)$, $k \geq 2$, is contiguous to the classical model $H(n, p\,; k)$ when the expected average degree is a constant.

**Theorem 1.1** (restated). *Suppose $k \geq 2$ and $p = \Theta(n^{1-k})$. Then for any collection $\mathcal{H}$ of $k$-uniform simple hypergraphs,*

$$c_1 \Pr[H_{\mathrm{PC}}(n, p\,; k) \in \mathcal{H}] \leq \Pr[H(n, p\,; k) \in \mathcal{H}] \leq c_2\big(\Pr[H_{\mathrm{PC}}(n, p\,; k) \in \mathcal{H}]^{\frac{1}{k}} + e^{-n}\big),$$

*where*

$$c_1 = k^{1/2} e^{\frac{p}{n}\binom{k}{2}\binom{n}{k} + \frac{p^2}{2}\binom{n}{k}} + O(n^{-1/2}), \quad c_2 = \Big(\frac{k}{k-1}\Big)\Big(c_1(k-1)\Big)^{1/k} + o(1),$$

*and $o(1)$ goes to 0 as $n$ goes to infinity.*

*Proof.* See [30]. □

## 3. The λ-cell and the cut-off line algorithm

To generate a uniform random perfect matching of $N_\lambda$ clones, we may keep matching $k$ unmatched clones uniformly at random (cf. Example 2.1). Another way is to choose the first clone as we like and match it to $k-1$ clones selected uniformly at random among all other unmatched clones (cf. Example 2.2). As there are many ways to choose the first clone, we may take a way that makes the given problem easier to analyze. Formally, a sequence $\mathcal{S} = (S_i)$ of choice functions determines how to choose the first clone at each step, where $S_i$ tells us which unmatched clone is to be the first clone for the $i^{\text{th}}$ edge in the random perfect matching. A choice function may be deterministic or random. If less than $k$ clones remain unmatched, the edge consisting of those clones will be added. The clone chosen by $S_i$ is called the $i^{\text{th}}$ chosen clone, or simply a chosen clone.

We also present a more specific way to select the $k-1$ random clones to be matched to the chosen clone. The way introduced here will be useful to solve problems mentioned in the introduction. First, independently assign to each clone a uniform

random real number between 0 and $\lambda = p\binom{n-1}{k-1}$. For the sake of convenience, a clone is called the largest, the smallest, etc. if so is the number assigned to it. In addition, a clone is called $\theta\lambda$-*large* (resp. $\theta\lambda$-small) if its assigned number is larger than or equal to (resp. smaller than) $\theta\lambda$. To visualize the labelled clones with assigned numbers, one may consider $n$ horizontal line segments from $(0, j)$ to $(\lambda, j)$, $j = 0, \ldots, n-1$ in the two-dimensional plane $\mathbb{R}^2$. The $v_j$-clone with assigned number $x$ can be regarded as the point $(x, j)$ in the corresponding line segment. Then each line segment with the points corresponding to clones with assigned numbers is an independent Poisson arrival process with density 1, up to time $\lambda$. The set of these Poisson arrival processes is called a *Poisson* $(\lambda, n)$*-cell* or simply a $\lambda$*-cell*.

We will consider sequences of choice functions that choose an unmatched clone without changing the joint distribution of the numbers assigned to all other unmatched clones. Such a choice function is called oblivious. A sequence of oblivious choice functions is also called oblivious. The choice function that chooses the largest unmatched clone is not oblivious, as the numbers assigned to the other clones must be smaller than the largest assigned number. As an example of an oblivious choice function one may consider the choice function that chooses a $v$-clone for a vertex $v$ with fewer than 3 unmatched clones. For a more general example, let a vertex $v$ and its clones be called $t$*-light* if there are fewer than $t$ unmatched $v$-clones.

**Example 3.1.** Suppose there is an order of all clones which is independent of the assigned numbers. The sequence of the choice functions that choose the first $t$-light clone is oblivious.

A cut-off line algorithm is determined by an oblivious sequence of choice functions. Once a clone is obliviously chosen, the largest $k-1$ clones among all unmatched clones are to be matched to the chosen clone. This may be further implemented by moving the cut-off line to the left until $k-1$ vertices are found: Initially, the cut-off line of the $\lambda$-cell is the vertical line in $\mathbb{R}^2$ containing the point $(\lambda, 0)$. The initial cut-off value, or cut-off number, is $\lambda$. At the first step, once the chosen clone is given, move the cut-off line to the left until exactly $k-1$ unmatched clones, excluding the chosen clone, are on or in the right side of the line. The new cut-off value, which is denoted by $\Lambda_1$, is to be the number assigned to the $(k-1)^{\text{th}}$ largest clone. The new cut-off line is, of course, the vertical line containing $(\Lambda_1, 0)$. Repeating this procedure, one may obtain the $i^{\text{th}}$ cut-off value $\Lambda_i$ and the corresponding cut-off line.

Notice that, after the $i^{\text{th}}$ step ends with the cut-off value $\Lambda_i$, all numbers assigned to unmatched clones are i.i.d. uniform random numbers between 0 to $\Lambda_i$, as the choice functions are oblivious. Let $N_i$ be the number of unmatched clones after step $i$. That is, $N_i = N_\lambda - ik$. Since the $(i+1)^{\text{th}}$ choice function tells how to choose the first clone to form the $(i+1)^{\text{th}}$ edge without changing the distribution of the assigned numbers, the distribution of $\Lambda_{i+1}$ is the distribution of the $(k-1)^{\text{th}}$ largest number among $N_i - 1$ independent uniform random numbers between 0 and $\Lambda_i$. Let $1 - T_j$ be the random variable representing the largest number among $j$ independent uniform random numbers between 0 and 1. Or equivalently, $T_j$ is the random variable

representing the smallest number among the random numbers. Then the largest number among the $N_i - 1$ random numbers has the same distribution as $\Lambda_i(1 - T_{N_i-1})$. Repeating this $k-1$ times, we have

$$\Lambda_{i+1} = \Lambda_i(1 - T_{N_i-1})(1 - T_{N_i-2}) \dots (1 - T_{N_i-k+1}),$$

and hence

$$\begin{aligned}\Lambda_{i+1} &= \Lambda_i(1 - T_{N_i-1}) \dots (1 - T_{N_i-k+1}) \\ &= \Lambda_{i-1}(1 - T_{N_{i-1}-1}) \dots (1 - T_{N_{i-1}-k+1}) \cdot (1 - T_{N_i-1}) \dots (1 - T_{N_i-k+1}) \\ &= \lambda \prod_{\substack{j=N_\lambda-1 \\ k\nmid N_\lambda-j}}^{N_\lambda-(i+1)k+1} (1 - T_j).\end{aligned}$$

It is crucial to observe that, once $N_\lambda$ is given, all $T_i$ are mutually independent random variables. This makes the random variable $\Lambda_i$ highly concentrated near its mean, which enables us to develop theories as if $\Lambda_i$ were a constant. The cut-off value $\Lambda_i$ will provide enough information to resolve some otherwise difficult problems.

For $\theta$ in the range $0 \le \theta \le 1$, let $\Lambda(\theta)$ be the cut-off value when $\big(1 - \theta^{\frac{k}{k-1}}\big)\lambda n$ or more clones are matched for the first time. Conversely, let $N(\theta)$ be the number of matched clones until the cut-off line reaches $\theta\lambda$.

**Lemma 3.2** (Cut-off line lemma). *Let $k \ge 2$ and $\lambda > 0$ be fixed. Then for $\theta_1 < 1$ uniformly bounded below from 0 and $0 < \Delta \le n$,*

$$\Pr\Big[\max_{\theta:\theta_1\le\theta\le1} |\Lambda(\theta) - \theta\lambda| \ge \tfrac{\Delta}{n}\Big] \le 2e^{-\Omega(\min\{\Delta, \frac{\Delta^2}{(1-\theta_1)n}\})}$$

*and*

$$\Pr\Big[\max_{\theta:\theta_1\le\theta\le1} |N(\theta) - (1 - \theta^{\frac{k}{k-1}})\lambda n| \ge \Delta\Big] \le 2e^{-\Omega(\min\{\Delta, \frac{\Delta^2}{(1-\theta_1)n}\})}.$$

*Proof.* See [30]. □

## 4. Large deviation inequalities

In this section a generalized Chernoff bound and an inequality for random process is given. Let $X_1, \dots, X_m$ be a sequence of random variables such that the distribution of $X_i$ is determined if all the values of $X_1, \dots, X_{i-1}$ are known. For example, $X_i = \Lambda(\theta_i)$ with $1 \ge \theta_1 \ge \cdots \ge \theta_m \ge 0$ in a Poisson $\lambda$-cell. If the upper and/or lower bounds are known for the conditional means $E[X_i|X_1, \dots, X_{i-1}]$ and for the conditional second and third monuments, then Chernoff type large deviation inequalities may be obtained not only for $\sum_{j=1}^m X_j$ but for $\min_{1\le i\le m} \sum_{j=1}^i X_j$ and/or

$\max_{1\le i\le m}\sum_{j=1}^{i} X_j$. Large deviation inequalities for such minima or maxima are especially useful in various situations. Lemma 3.2 can be shown using such inequalities too.

**Lemma 4.1.** *Let $X_1, \dots, X_m$ be a sequence of random variables. Suppose that*

$$E[X_i|X_1, \dots, X_{i-1}] \le \mu_i, \tag{4.1}$$

*and that there are positive constants $a_i$ and $b_i$ such that*

$$E[(X_i - \mu_i)^2|X_1, \dots, X_{i-1}] \le a_i, \tag{4.2}$$

*and*

$$E[(X_i - \mu_i)^3 e^{\xi(X_i-\mu_i)}|X_1, \dots, X_{i-1}] \le b_i \quad \text{for all } 0 \le \xi \le \xi_0. \tag{4.3}$$

*Then for any $\alpha$ with $0 < \alpha \le \xi_0\big(\sum_{i=1}^m a_i\big)^{1/2}$,*

$$\Pr\Big[\sum_{i=1}^m X_i \ge \sum_{i=1}^m \mu_i + \alpha\Big(\sum_{i=1}^m a_i\Big)^{1/2}\Big] \le \exp\bigg(-\frac{\alpha^2}{2}\bigg(1 + \frac{\alpha\sum_{i=1}^m b_i}{3\big(\sum_{i=1}^m a_i\big)^{3/2}}\bigg)\bigg).$$

*Similarly,*

$$E[X_i|X_1, \dots, X_{i-1}] \ge \mu_i \tag{4.4}$$

*together with* (4.2) *and*

$$E[(X_i - \mu_i)^3 e^{\xi(X_i-\mu_i)}|X_1, \dots, X_{i-1}] \ge b_i \quad \text{for all } \xi_0 \le \xi < 0 \tag{4.5}$$

*implies that*

$$\Pr\Big[\sum_{i=1}^m X_i \le \sum_{i=1}^m \mu_i - \alpha\Big(\sum_{i=1}^m a_i\Big)^{1/2}\Big] \le \exp\bigg(-\frac{\alpha^2}{2}\bigg(1 - \frac{\alpha\sum_{i=1}^m b_i}{3\big(\sum_{i=1}^m a_i\big)^{3/2}}\bigg)\bigg).$$

*Proof.* See [30]. □

As it is sometimes tedious to point out the value of $\alpha$ and to check the required bounds for it, the following forms of inequalities are often more convenient.

**Corollary 4.2** (Generalized Chernoff bound). *If $\delta\xi_0\sum b_i \le \sum a_i$ for some $0 < \delta \le 1$, then* (4.1)–(4.3) *imply*

$$\Pr\Big[\sum_{i=1}^m X_i \ge \sum_{i=1}^m \mu_i + R\Big] \le e^{-\frac{1}{3}\min\{\delta\xi_0 R,\ R^2/\sum_{i=1}^m a_i\}}$$

*for all $R > 0$. Similarly, if $-\delta\xi_0\sum b_i \le \sum a_i$ for some $0 < \delta \le 1$, then* (4.2), (4.4) *and* (4.5) *yield*

$$\Pr\Big[\sum_{i=1}^m X_i \le \sum_{i=1}^m \mu_i - R\Big] \le e^{-\frac{1}{3}\min\{\delta\xi_0 R,\ R^2/\sum_{i=1}^m a_i\}}$$

*for all $R > 0$.*

Let $X_\theta, \theta \geq 0$, be random variables which are possibly set-valued. Here $\theta$ may be integers as well as real numbers. Suppose that $\Gamma(\theta)$ is a random variable depending on $\{X_{\theta'}\}_{\theta' \leq \theta}$ and $\theta$, and

$$\psi = \psi(\{X_{\theta'}\}_{\theta' \leq \theta_1}; \theta_0, \theta_1) \quad \text{and} \quad \psi_\theta = \psi_\theta(\{X_{\theta'}\}_{\theta' \leq \theta_1}; \theta_0, \theta, \theta_1).$$

The random variables $\psi$ and $\psi_\theta$ are used to bound $\Gamma(\theta)$.

**Example 4.3.** Let $X_1, X_2, \ldots$ be i.i.d. Bernoulli random variables with mean $p$ and $S_i = \sum_{j=1}^{i} X_j$. Set $\Gamma(i) = |S_i - ip|$ and

$$\psi = \Gamma(n) \quad \text{and} \quad \psi_i = |S_n - S_i - (n-i)p|.$$

Then, since

$$S_i - ip = S_n - np - (S_n - S_i - (n-i)p)$$

we have

$$\Gamma(i) \leq \psi + \psi_i.$$

**Example 4.4.** Consider the $(\lambda, n)$-cell defined in the previous section. Let $v_\theta$ be the vertex that has its largest clone at $(1-\theta)\lambda$. If such a vertex does not exist, $v_\theta$ is defined to be $\aleph$, assuming $\aleph \notin V$. As there is no possibility that two distinct clones are assigned the same number, $v_\theta$ is well-defined. Let $X_\theta = v_\theta$ and $V(\theta)$ be the set of vertices that contain no clone larger than or equal to $(1-\theta)\lambda$. That is, $V(\theta) = V \setminus \{v_{\theta'} : 0 \leq \theta' \leq \theta\}$. Clearly, $E[|V(\theta)|] = e^{-\theta\lambda} n$. Observing that for $\theta_0 \leq \theta \leq \theta_1$ one has

$$e^{-(\theta_1-\theta)\lambda}\big||V(\theta)| - e^{-\theta\lambda}n\big| \leq \big||V(\theta_1)| - e^{-\theta_1\lambda}n\big| + \big||V(\theta_1)| - e^{-(\theta_1-\theta)\lambda}|V(\theta)|\big|,$$

we may set $\Gamma(\theta) = ||V(\theta)| - e^{-\theta\lambda}n|$,

$$\psi = e^{(\theta_1-\theta_0)}\Gamma(\theta_1) \quad \text{and} \quad \psi_\theta = e^{(\theta_1-\theta_0)}\big||V(\theta_1)| - e^{-(\theta_1-\theta)\lambda}|V(\theta)|\big|.$$

We bound the probabilities $\max_{\theta_0 \leq \theta \leq \theta_1} \Gamma(\theta) \geq R$ and $\min_{\theta_0 \leq \theta \leq \theta_1} \Gamma(\theta) \leq R$ under some conditions.

**Lemma 4.5.** *Let $0 \leq \theta_0 < \theta_1$, $R = R_1 + R_2$, $R_1, R_2 > 0$ and $\Phi_\theta$ be events depending on $\{X_{\theta'}\}_{\theta' \leq \theta}$. If*

$$\Gamma(\theta) \leq \psi + \psi_\theta \quad \textit{for all } \theta_0 \leq \theta \leq \theta_1,$$

*then*

$$\Pr\Big[\max_{\theta_0 \leq \theta \leq \theta_1} \Gamma(\theta) \geq R\Big] \leq \Pr\big[\psi \geq R_1\big] + \Pr\Big[\bigcup_{\theta:\theta_0 \leq \theta \leq \theta_1} \overline{\Phi}_\theta\Big] + \max_{\theta:\theta_0 \leq \theta \leq \theta_1} \max_{\{X_{\theta'}\}_{\theta' \leq \theta}} 1(\Phi_\theta) \Pr\big[\psi_\theta \geq R_2 \mid \{X_{\theta'}\}_{\theta' \leq \theta}\big].$$

*Similarly, if*

$$\Gamma(\theta) \geq \psi + \psi_\theta \quad \textit{for all } \theta_0 \leq \theta \leq \theta_1,$$

*then*

$$\Pr\Big[\min_{\theta_0 \leq \theta \leq \theta_1} \Gamma(\theta) \leq -R\Big] \leq \Pr\big[\psi \leq -R_1\big] + \Pr\Big[\bigcup_{\theta:\theta_0 \leq \theta \leq \theta_1} \overline{\Phi}_\theta\Big] + \max_{\theta:\theta_0 \leq \theta \leq \theta_1} \max_{\{X_{\theta'}\}_{\theta' \leq \theta}} 1(\Phi_\theta) \Pr\big[\psi_\theta \leq -R_2 \mid \{X_{\theta'}\}_{\theta' \leq \theta}\big].$$

*Proof.* See [30]. □

**Example 4.3** (continued). As

$$\Pr[\psi \geq R_1] \leq e^{-\Omega(\min\{R_1, \frac{R_1^2}{p(1-p)n}\})}$$

and

$$\Pr[\psi_i \geq R_2 | X_1, \ldots, X_i] = \Pr[\psi_i \geq R_2] \leq e^{-\Omega(\min\{R_2, \frac{R_2^2}{p(1-p)(n-i)}\})},$$

Lemma 4.5 for $R_1 = R_2 = R/2$ and $\Phi_\theta = \emptyset$ gives

$$\Pr[\max_{i:0 \leq i \leq n} |S_i - pi| \geq R] \leq e^{-\Omega(\min\{R, \frac{R^2}{p(1-p)n}\})}.$$

**Example 4.4** (continued). Since

$$|V(\theta)| = \sum_{v \in V} 1(v \text{ has no } (1-\theta)\lambda\text{-large clone})$$

is a sum of i.i.d. Bernoulli random variables with mean $e^{-\theta\lambda}$,

$$\Pr\big[\big||V(\theta)| - e^{-\theta\lambda}n\big| \geq R\big] \leq e^{-\Omega(\min\{R, \frac{R^2}{\theta n}\})},$$

especially

$$\Pr\big[\psi \geq R/2\big] \leq e^{-\Omega(\min\{R, \frac{R^2}{\theta_1 n}\})}.$$

Once $\{X_{\theta'}\}_{\theta' \leq \theta}$ is given, $V(\theta)$ is determined and

$$V(\theta_1) = \sum_{v \in V(\theta)} 1(v \text{ has no } (1-\theta_1)\lambda\text{-large clone})$$

is a sum of i.i.d. Bernoulli random variables with mean $e^{-(\theta_1-\theta)\lambda}$. Thus

$$\Pr\big[\psi_\theta \geq R/2 \mid \{X_{\theta'}\}_{\theta' \leq \theta}\big] \leq 2e^{-\Omega(\min\{R, \frac{R^2}{(\theta_1-\theta)|V(\theta)|}\})} \leq 2e^{-\Omega(\min\{R, \frac{R^2}{\theta n}\})},$$

and Lemma 4.5 for $\theta_0 = 0$ and $\Phi_\theta = \emptyset$ yields

$$\Pr\Big[\max_{\theta:0 \leq \theta \leq \theta_1} |V(\theta) - e^{-\theta\lambda}n| \geq R\Big] \leq 2e^{-\Omega(\min\{R, \frac{R^2}{\theta n}\})}.$$

## 5. Generalized cores and the main lemma

In this section we introduce generalized cores and the main lemma. The main lemma will play a crucial roles in the proofs of the theorems mentioned in the introduction.

We start with some terminology. A *generalized degree* is an ordered pair $(d_1, d_2)$ of non-negative integers. The inequality between two generalized degrees is determined by the inequality between the first coordinates and the reverse inequality between the second coordinates. That is, $(d_1, d_2) \geq (d_1', d_2')$ if and only if $d_1 \geq d_1'$ and $d_2 \leq d_2'$. A *property* for generalized degrees is simply a set of generalized degrees. A property $P$ is *increasing* if generalized degrees larger than an element in $P$ are also in $P$. When a property $P$ depends only on the first coordinate of generalized degrees, it is simply a property of degrees. For the $t$-core problem, we will use $P_{t\text{-core}} = \{(d_1, d_2) : d_1 \geq t\}$. To estimate the size of the largest component, we will set $P_{\text{comp}} = \{(d_1, d_2) : d_2 = 0\}$.

Given the Poisson $\lambda$-cell on the set $V$ of $n$ vertices and $\theta$ with $0 \leq \theta \leq 1$, let $d_v(\theta)$ be the number of $v$-clones smaller than $\theta\lambda$. Similarly, $\bar{d}_v(\theta)$ is the number of $v$-clones larger than or equal to $\theta\lambda$. Then $D_v(\theta) := (d_v(\theta), \bar{d}_v(\theta))$ are i.i.d. random variables. In particular, for any property $P$ the events $D_v(\theta) \in P$ are independent and occur with the same probability, say $p(\theta, \lambda; P)$, or simply $p(\theta)$.

For an increasing property $P$, the $P$-process is defined as follows. Construct the Poisson $\lambda$-cell as described in Section 3, where $\lambda = p\binom{n-1}{k-1}$. The vertex set $V = \{v_0, \ldots, v_{n-1}\}$ will be regarded as an ordered set so that the $i^{\text{th}}$ vertex is $v_{i-1}$. The $P$-process is a generalization of Example 2.2 for which choice functions choose $t$-light clones.

**The $P$-process.** Initially, the cut-off value $\Lambda = \lambda$. Activate all vertices $v$ with $D_v(1) \notin P$. All clones of the activated vertices are activated too. Put those clones in a stack in an arbitrary order. However, this does not mean that the clones are removed from the $\lambda$-cell.

(a) If the stack is empty, go to (b). If the stack is nonempty, choose the first clone in the stack and move the cut-off line to the left until the largest $k-1$ unmatched clones, excluding the chosen clone, are found. (So, the cut-off value $\Lambda$ keeps decreasing.) Then match the $k-1$ clones to the chosen clone. Remove all matched clones from the stack and repeat the process. A vertex that has not been activated is to be activated as soon as $D_v(\Lambda/\lambda) \notin P$. This can be done even before all $k-1$ clones are found. Its unmatched clones are to be activated too and put into the stack immediately. Clones found while moving the cut-off line are also in the stack until they are matched.

(b) Activate the first vertex in $V$ which has not been activated. Its clones are activated too. Put those clones into the stack. Then go to (a).

Clones in the stack are called active. The steps carried out by the instruction described in (b) are called forced steps as it is necessary to artificially activate a vertex.

When the cut-off line is at $\theta\lambda$, all $\theta\lambda$-large clones are matched or will be matched at the end of the step and all vertices $v$ with $D_v(\theta) \notin P$ have been activated. All other

vertices can have been activated only by forced steps. Let $V(\theta) = V_P(\theta)$ be the set of vertices $v$ with $D_v(\theta) \in P$, and let $M(\theta) = M_P(\theta)$ be the number of $\theta\lambda$-large clones plus the number of $\theta\lambda$-small clones of vertices $v$ not in $V(\theta)$. That is,

$$M(\theta) = \sum_{v\in V} \bar{d}_v(\theta) + d_v(\theta)1(v \notin V(\theta)) = \sum_{v\in V} \bar{d}_v(\theta) + d_v(\theta)1(D_v(\theta) \notin P).$$

Recalling that $N(\theta)$ is the number of matched clones until the cut-off line reaches $\theta\lambda$, the number $A(\theta)$ of active clones (when the cut-off value $\Lambda$ is) at $\theta\lambda$ is at least as large as $M(\theta) - N(\theta)$. On the other hand, the difference $A(\theta) - (M(\theta) - N(\theta))$ is at most the number $F(\theta)$ of clones activated in forced steps until $\theta\lambda$, i.e.,

$$M(\theta) - N(\theta) \le A(\theta) \le M(\theta) - N(\theta) + F(\theta). \tag{5.1}$$

As the cut-off lemma gives a concentration inequality for $N(\theta)$,

$$\Pr\Big[\max_{\theta:\theta_1\le\theta\le 1} |N(\theta) - (1 - \theta^{\frac{k}{k-1}})\lambda n| \ge \Delta\Big] \le 2e^{-\Omega(\min\{\Delta, \frac{\Delta^2}{(1-\theta_1)n}\}},$$

a concentration inequality for $M(\theta)$ will be enough to obtain a similar inequality for $B(\theta) := M(\theta) - N(\theta)$. More precisely, we will show that under appropriate hypotheses

$$\Pr\Big[\max_{\theta:\theta_1\le\theta\le 1} |M(\theta) - (\lambda - q(\theta))n| \le \Delta\Big] \le 2e^{-\Omega(\min\{\Delta, \frac{\Delta^2}{(1-\theta_1)n}\})},$$

where

$$q(\theta) = q(\theta, \lambda; P) = E\big[d_v(\theta)1(D_v(\theta) \in P)\big].$$

As the $d_v(\theta)$'s and $D_v(\theta)$'s are identically distributed, $q(\theta)$ does not depend on $v$. Also, recall that $p(\theta) = \Pr[D_v(\theta) \in P]$.

As we will see later, $B(\theta)$ is very close to $A(\theta)$. Hence a concentration inequality for $B(\theta)$ plays a very important roles in all of our proofs.

**Lemma 5.1** (Main lemma). *In the $P$-process, if $\theta_1 < 1$ uniformly bounded from below by 0, $1 - p(\theta_1) = O(1 - \theta_1)$ and $p(\theta_1) = \Omega(1)$, then for all $\Delta$ in the range $0 < \Delta \le n$ we have*

$$\Pr\Big[\max_{\theta:\theta_1\le\theta\le 1} \big||V(\theta)| - p(\theta)n\big| \le \Delta\Big] \le 2e^{-\Omega(\min\{\Delta, \frac{\Delta^2}{(1-\theta_1)n}\})}$$

*and*

$$\Pr\Big[\max_{\theta:\theta_1\le\theta\le 1} \big|B(\theta) - (\lambda\theta^{\frac{k}{k-1}} - q(\theta))n\big| \le \Delta\Big] \le 2e^{-\Omega(\min\{\Delta, \frac{\Delta^2}{(1-\theta_1)n}\})}.$$

*Proof.* See [30]. □

## 6. Cores of random hypergraphs

In this section we prove Theorem 1.7. Let $\lambda > 0$ and $H(\lambda) = H_{\mathrm{PC}}(n, p)$, where $\lambda = p\binom{n-1}{r-1}$. Let the property $P = \{(d_1, d_2) : d_1 \geq t\}$. Then

$$p(\theta) = Q(\theta\lambda, t) \quad \text{and} \quad q(\theta) = \theta\lambda Q(\theta\lambda, t-1).$$

The main lemma gives

**Corollary 6.1.** *For $\theta_1 \leq 1$ uniformly bounded from below by 0 and $\Delta$ in the range $0 < \Delta \leq n$,*

$$\Pr\Big[\max_{\theta:\theta_1\leq\theta\leq 1} \big||V(\theta)| - Q(\theta\lambda, t)n\big| \geq \Delta\Big] \leq 2e^{-\Omega(\min\{\Delta, \frac{\Delta^2}{n}\})}$$

*and*

$$\Pr\Big[\max_{\theta:\theta_1\leq\theta\leq 1} \big|B(\theta) - (\theta^{\frac{1}{k-1}} - Q(\theta\lambda, t-1))\theta\lambda n\big| \geq \Delta\Big] \leq 2e^{-\Omega(\min\{\Delta, \frac{\Delta^2}{n}\})}.$$

*Subcritical Region*: For $\lambda = \lambda_{\mathrm{crt}} - \sigma$, $\sigma > 0$ and $\theta_1 = \delta/\lambda_{\mathrm{crt}}$ with $\delta = 0.1$ it is easy to see that there is a constant $c > 0$ such that

$$(\theta^{\frac{1}{k-1}} - Q(\theta\lambda, t-1))\theta\lambda n \geq c\sigma n \quad \text{for all } \theta \text{ with } \theta_1 \leq \theta \leq 1.$$

Let $\tau$ be the first time the number $A(\theta)$ of active clones at $\theta\lambda$ becomes 0. Then the second part of Corollary 6.1 gives

$$\begin{aligned}\Pr[\tau \geq \theta_1] &\leq \Pr[B(\theta) = 0 \text{ for some } \theta \text{ with } \theta_1 \leq \theta \leq 1] \\ &\leq \Pr\Big[\max_{\theta:\theta_1\leq\theta\leq 1} \big|B(\theta) - (\theta^{\frac{1}{k-1}} - Q(\theta\lambda, t-1))\theta\lambda n\big| \geq c\sigma n\Big] \\ &\leq 2e^{-\Omega(\sigma^2 n)}.\end{aligned}$$

As $\theta_1\lambda \leq \theta_1\lambda_{\mathrm{crt}} = \delta$, and hence $Q(\theta_1\lambda, t) \leq \delta/2$ for $t \geq 2$, the first part of Corollary 6.1 yields

$$\Pr[|V_t(H_{\mathrm{PC}}(n, p\,; k))| \geq \delta n] \leq \Pr[\tau \geq \theta_1] + \Pr[|V(\theta_1)| \geq \delta n] \leq 2e^{-\Omega(\sigma^2 n)}.$$

Therefore Theorem 1.1 implies that

$$\Pr[|V_t(H(n, p\,; k))| \geq \delta n] \leq 2e^{-\Omega(\sigma^2 n)}.$$

To complete the proof, we observe that the $t$-core of size $i$ has at least $ti/k$ edges. Let $Z_i$ be the number of subgraphs on $i$ vertices with at least $ti/k$ edges, $i = i_0, \ldots, \delta n$, where $i_0 = i_0(k, t)$ is the least $i$ such that $\binom{i}{k} \geq ti/k$. Then

$$E[Z_i] \leq \binom{n}{i}\binom{\binom{i}{k}}{ti/k} p^{ti/k} \leq \frac{n^i}{i!}\frac{i^{ti}}{(ti/k)!}p^{ti/k} =: L_i, \tag{6.1}$$

where $ti/k$ actually means $\lceil ti/k \rceil$. Hence

$$\frac{L_{i+k}}{L_i} = O\left(\frac{n^k}{i^k}\frac{i^{kt}}{i^t}n^{-(k-1)t}\right) = O\left(\left(\frac{i}{n}\right)^{(k-1)t-k}\right) = O(\delta^{(k-1)(t-1)-1}).$$

That is, $L_{i+k}/L_i$ exponentially decreases. For $i = i_0, \ldots, i_0 + k - 1$,

$$L_i = O(n^i n^{-i(k-1)t/k}) = O(n^{-i(t-1-t/k)})$$

implies that

$$\Pr[V_t(H(n, p; k)) \neq \emptyset] \leq 2e^{-\Omega(\sigma^2 n)} + O(n^{-i_0(t-1-t/k)}),$$

as desired. □

*Supercritical region*: We will prove the following theorem.

**Theorem 6.2.** *Suppose that* $p\binom{n-1}{k-1} \geq \lambda_{\mathrm{crt}} + \sigma$ *and* $0 < \delta \leq 1$. *Then, with probability* $1 - 2e^{-\Omega(\min\{\delta^2\sigma n, \sigma^2 n\})}$, $V_t = V_t(H_{\mathrm{PC}}(n, p; k))$ *satisfies*

$$Q(\theta_\lambda \lambda, t)n - \delta n \leq |V_t| \leq Q(\theta_\lambda \lambda, t)n + \delta n, \tag{6.2}$$

*and the degrees of vertices of the* $t$*-core are i.i.d.* $t$*-truncated Poisson random variables with parameter* $\Lambda_t := \theta_\lambda \lambda + \beta$ *for some* $\beta$ *with* $|\beta| \leq \delta$. *Moreover, the distribution of the* $t$*-core is the same as that of the* $t$*-truncated Poisson cloning model with parameters* $|V_t|$ *and* $\Lambda_t$.

*Proof.* Let $\lambda = \lambda_{\mathrm{crt}} + \sigma$, $\sigma > 0$ and $\theta_\lambda$ be the largest solution for the equation

$$\theta^{\frac{1}{k-1}} - Q(\theta\lambda, t-1) = 0.$$

Then it is not hard to check that there are constants $c_1, c_2 > 0$ such that for $\theta$ in the range $\theta_\lambda \leq \theta \leq 1$,

$$\theta^{\frac{1}{k-1}} - Q(\theta\lambda, t-1) \geq c_1\sigma^{1/2}(\theta - \theta_\lambda),$$

and for $\theta$ in the range $\theta_\lambda - c_2\sigma^{1/2} \leq \theta \leq \theta_\lambda$,

$$\theta^{\frac{1}{k-1}} - Q(\theta\lambda, t-1) \leq -c_1\sigma^{1/2}(\theta_\lambda - \theta).$$

Let $\tau$ be the largest $\theta$ with $A(\theta) = 0$. Then $V(\tau)$ is the $t$-core of $H_{\mathrm{PC}}(n, p; k)$. For $\theta_1 = \theta_\lambda + \delta$ and $\theta_2 = \theta_\lambda - \min\{\delta, c_2\sigma^{1/2}\}$ with $0 < \delta \leq 1$, Corollary 6.1 gives

$$\begin{aligned}\Pr[\tau \geq \theta_1] &\leq \Pr[B(\theta) = 0 \text{ for some } \theta \text{ with } \theta_1 \leq \theta \leq 1] \\ &\leq \Pr\Big[\max_{\theta:\theta_1\leq\theta\leq 1} |B(\theta) - (\theta^{\frac{1}{k-1}} - Q(\theta\lambda, t-1))\theta\lambda n| \geq c_1\sigma^{1/2}\delta n\Big] \\ &\leq 2e^{-\Omega(\delta^2\sigma n)}\end{aligned}$$

and

$$\begin{aligned}\Pr[\tau < \theta_2] &\le \Pr[B(\theta_2) > 0] \\ &\le \Pr\left[|B(\theta_2) - (\theta_2^{\frac{1}{k-1}} - Q(\theta_2\lambda, t-1))\theta_2\lambda n| \ge c_1\sigma^{1/2}\min\{\delta, c_2\sigma^{1/2}\}n\right] \\ &\le 2e^{-\Omega(\min\{\delta^2\sigma n, \sigma^2 n\})}.\end{aligned}$$

Since $\frac{d}{d\theta}Q(\theta\lambda, t) = \lambda P(\theta\lambda, t-1) \le \lambda$, we have

$$Q(\theta_1\lambda, t) \le Q(\theta_\lambda\lambda, t) + \lambda\delta, \quad \text{and} \quad Q(\theta_2\lambda, t) \ge Q(\theta_\lambda\lambda, t) - \lambda\delta,$$

and Corollary 6.1 implies that

$$\Pr[V(\theta_1) - Q(\theta_\lambda\lambda, t)n \ge 2\lambda\delta n] \le 2e^{-\Omega(\delta^2 n)}$$

and

$$\Pr[V(\theta_2) - Q(\theta_\lambda\lambda, t)n \le -2\lambda\delta n] \le 2e^{-\Omega(\delta^2 n)}.$$

Therefore

$$\Pr[|\tau - \theta_\lambda| > \delta] \le \Pr[\tau \ge \theta_1] + \Pr[\tau \le \theta_2] \le 2e^{-\Omega(\min\{\delta^2\sigma n, \sigma^2 n\})}$$

and, replacing $\delta$ by $\frac{\delta}{2\lambda}$,

$$\begin{aligned}\Pr[|V(\tau) - Q(\theta_\lambda\lambda, t)n| \ge \delta n] &\le \Pr[\tau \ge \theta_1] + \Pr[\tau \le \theta_2] + 2e^{-\Omega(\delta^2 n)} \\ &\le 2e^{-\Omega(\min\{\delta^2\sigma n, \sigma^2 n\})}.\end{aligned}$$

Clearly, once $V(\tau)$ and $\Lambda_t := \tau\lambda$ are given, the residual degrees $d_v(\tau)$, $v \in V(\tau)$, are i.i.d. $t$-truncated Poisson random variables with parameter $\Lambda_t$. □

Once $V_t$ and $\Lambda_t$ are given, $|V_t(i)|$, $i \ge t$, is the sum of i.i.d. Bernoulli random variables with mean $p_i(\Lambda_t) := \frac{P(\Lambda_t, i)}{Q(\Lambda_t, t)}$. Similarly, the size of $W_t(i) = \bigcup_{j \ge i} V_t(j)$ is the sum of i.i.d. Bernoulli random variables with mean $q_i(\Lambda_t) := \frac{Q(\Lambda_t, i)}{Q(\Lambda_t, t)}$. Applying the generalized Chernoff bound (Lemma 4.2), we have

$$\Pr\left[\left||V_t(i)| - p_i(\Lambda_t)|V_t|\right| \ge \delta|V_t||V_t, \Lambda_t\right] \le 2e^{-\Omega(\delta^2|V_t|)}$$

and

$$\Pr\left[\left||W_t(i)| - q_i(\Lambda_t)|V_t|\right| \ge \delta|V_t||V_t, \Lambda_t\right] \le 2e^{-\Omega(\delta^2|V_t|)}.$$

Combining this with Lemma 6.2 and using

$$|P(\rho, i) - P(\rho', i)| \le |\rho - \rho'|, \quad \text{and} \quad |Q(\rho, i) - Q(\rho', i)| \le |\rho - \rho'|,$$

we obtain, for any $i$,

$$\Pr\left[\left||V_t(i)| - P(\theta_\lambda\lambda, i)n\right| \ge \delta n\right] \le 2e^{-\Omega(\min\{\delta^2\sigma n, \sigma^2 n\})},$$

and

$$\Pr\big[\big||W_t(i)| - Q(\theta_\lambda\lambda, i)n\big| \geq \delta n\big] \leq 2e^{-\Omega(\min\{\delta^2\sigma n, \sigma^2 n\})}.$$

In particular, as $\theta_\lambda = \theta_{\rm crt} + \Theta(\sigma^{1/2})$ for uniformly bounded $\sigma$ it follows that for $\lambda = \lambda_{\rm crt} + \sigma$,

$$|V_t(i)| = (1 + O(\sigma^{1/2}))^i P(\theta_{\rm crt}\lambda_{\rm crt}, i)n + O\big((n/\sigma)^{1/2}\log n\big),$$

with probability $1 - 2e^{-\Omega(\min\{\log^2 n, \sigma^2 n\})}$.

## 7. The emergence of the giant component

In this section we just give ideas for the proof of Theorem 1.4. Let the property $P$ be $\{(d_1, d_2) : d_2 = 0\}$. Then $p(\theta) = e^{-(1-\theta)\lambda}$ and $q(\theta) = \theta\lambda e^{-(1-\theta)\lambda}$, and the main lemma gives

**Corollary 7.1.** *For $\theta_1 \geq 1$ uniformly bounded from above by 1 and $\Delta$ in the range $0 < \Delta \leq n$,*

$$\Pr\Big[\max_{\theta:0\leq\theta\leq\theta_1}\big||V(\theta)| - e^{-(1-\theta)\lambda}n\big| \geq \Delta\Big] \leq 2e^{-\Omega(\min\{\Delta, \frac{\Delta^2}{(1-\theta_1)n}\})}$$

*and*

$$\Pr\Big[\max_{\theta:0\leq\theta\leq\theta_1}\big|B(\theta) - (\theta - e^{-(1-\theta)\lambda})\theta\lambda n\big| \geq \Delta\Big] \leq 2e^{-\Omega(\min\{\Delta, \frac{\Delta^2}{(1-\theta_1)n}\})}.$$

To estimate $A(\theta)$ it is now enough for us to estimate $F(\theta)$ by (5.1). Once good estimations for $F(\theta)$ are established, we may take similar (but slightly more complicated) approaches used in the previous section.

It is convenient to consider an (imaginary) secondary stack with parameter $\rho$, or simply $\rho$-secondary stack. Initially, the secondary stack with parameter $\rho$ consists of the first $\rho n$ vertices $v_0, \ldots, v_{\rho n-1}$ of $V$. The set of those $\rho n$ vertices is denoted by $V_\rho$. Whenever the primary stack is empty, the first vertex in the secondary stack that has not been activated must be activated. Its clones are activated too and put into the primary stack. The activated vertex as well as vertices activated by other means are no longer in the secondary stack. If the secondary stack is empty, go back to the regular procedure. This does not change the $P$-process at all, but will be used just for the analysis. Let $\tau_\rho$ be the largest $\tau$ such that, at $\tau\lambda$, the primary stack becomes empty after the secondary stack is empty. Thus, once the cut-off line reaches $\tau_\rho\lambda$, no active clones are provided from the secondary stack. Denote by $C(\rho)$ the union of the components containing any vertex in $V_\rho$.

The following lemma is useful to predict how large $\tau_\rho$ is.

**Lemma 7.2.** *Suppose* $0 < \delta,\ \rho < 1$ *and* $\theta_1, \theta_2 \le 1$ *are uniformly bounded from below by* 0. *Then*

$$\Pr[\tau_\rho \ge \theta_1] \le \Pr\Big[\min_{\theta:\theta_1\le\theta\le 1} B(\theta) \le -(1-\delta)\theta_1\lambda e^{-(1-\theta_1)\lambda}\rho n\Big] + 2e^{-\Omega(\delta^2\rho n)},$$

*and conversely,*

$$\Pr[\tau_\rho \le \theta_2] \le \Pr[B(\theta_2) \ge -(1+\delta)\theta_2\lambda e^{-(1-\theta_2)\lambda}\rho n] + 2e^{-\Omega(\delta^2\rho n)}.$$

*Proof.* See [30]. □

Once the value of $\tau_\rho$ is known quite precisely, a good estimation of $F(\theta)$ is possible. Using similar (but slightly more complicated) arguments used in the previous section, estimation of $A(\theta)$ is also possible. Due to space limitation, the proof of Theorem 1.4 is omitted.

## 8. Closing remarks

The Poisson $\lambda$-cell is introduced to analyze those properties of $G_{\mathrm{PC}}(n, p)$, for which the degrees are i.i.d. Poisson random variables with mean $\lambda = p(n-1)$. Then various nice properties of Poisson random variables are used to analyze sizes of the largest component and the $t$-core of $G_{\mathrm{PC}}(n, p)$. We believe that the approaches presented in this paper are useful to analyze problems with similar flavors, especially problems related to branching processes. For example, we can easily modify the proofs of Theorem 1.7 to analyze the pure literal rule for the random $k$-SAT problems, $k \ge 3$. Another example may be the Karp–Sipser Algorithm to find a large matching of the random graph. (See [29], [3].) In a subsequent paper, we will analyze the structure of the 2-core of $G(n, p)$ and the largest strong component of the random directed graph as well as the pure literal rule for the random 2-SAT problem.

For the random (hyper)graph with a given sequence $(d_i)$, we may also introduce the $(d_i)$-cell, in which the vertex $v_i$ has $d_i$ clones and each clone is assigned a uniform random real number between 0 and the average degree $\frac{1}{n}\sum_{i=0}^{n-1} d_i$. Though it is not possible to use all of the nice properties of Poisson random variables any more, we believe that the $(d_i)$-cell equipped the cut-off line algorithm can be used to prove stronger results for the $t$-core problems considered in various papers including [13], [21], [22], [26], [37].

Recall that the degrees in $G(n, p)$ has the binomial distribution with parameters $n-1$ and $p$. By introducing the Poisson cloning model, we somehow first take the limit of the binomial distribution, which is the Poisson distribution. In general, many limiting distributions like Poisson and Gaussian ones have nice properties. In our opinion this is because various small differences are eliminated by taking the limits, and limiting distributions have some symmetric and/or invariant properties. Thus

one may wonder whether there is an infinite graph that shares most properties of the random graphs $G(n, p)$ with large enough $n$. So, in a sense, the infinite graph, if it exists, can be regarded as the limit of $G(n, p)$. An infinite graph which Aldous [1] considered to solve the linear assignment problem may or may not be a (primitive) version of such an infinity graph. Though it may be impossible to construct such a graph, the approaches taken in this paper might be useful to find one, if any.

**Acknowledgement.** The author thanks C. Borgs, J. Chayes, B. Bollobás and Y. Peres for helpful discussions.

# Randomness and regularity

Tomasz Łuczak

**Abstract.** For the last ten years the theory of random structures has been one of the most rapidly evolving fields of discrete mathematics. The existence of sparse structures with good 'global' properties has been vital for many applications in mathematics and computer science, and studying properties of such objects led to many challenging mathematical problems. In the paper we report on recent progress on this subject related to some variants of Szemerédi's Regularity Lemma.

**Mathematics Subject Classification (2000).** Primary 05C80, 05D05; Secondary 05C35, 05C65, 05D40.

**Keywords.** Random graphs, extremal graph theory, regularity lemma, removal lemma, density theorems.

## 1. Introduction

In the paper we consider 'extremal' properties of families of sets, i.e., we study the size of maximal subfamilies of a given family with certain property. Let $[A]^r$ be the family of all $r$-sets (i.e. sets of $r$ elements) contained in $A$; if $A = [n] = \{1, 2, \ldots, n\}$ we put $[n]^r = [[n]]^r$. Two classical examples of extremal results for $[n]^r$ are Szemerédi's and Turán's theorems. Let us recall that Szemerédi's density theorem [17] states that if $r_k(n)$ denote the maximum size of a subset of $[n] = [n]^1$ which contains no non-trivial arithmetic progression of length $k$, then, $r_k(n) = o(n)$. In order to formulate Turán's theorem, we need some notation. For given $r, s, n$, $n \geq s > r \geq 2$, let $\mathrm{ex}([s]^r, [n]^r)$ denote the size of the largest family $\mathcal{A} \subseteq [n]^r$ such that for no set $B \subseteq [n]$, $|B| = s$, we have $[B]^r \subseteq \mathcal{A}$. Furthermore, let

$$\alpha(m, r) = \limsup_{n\to\infty} \frac{\mathrm{ex}([m]^r, [n]^r)}{\binom{n}{r}} \,. \tag{1}$$

Turán's theorem [21] states that $\alpha(m, 2) = \frac{m-2}{m-1}$ for $m \geq 2$. Let us remark that we do not know the value of $\alpha(m, r)$ for any pair $(m, r)$ with $m > r > 2$; e.g., the question whether $\alpha(4, 3) = 5/9$ is a well known open problem of extremal set theory.

The main problem we are concerned in this paper is the existence of families of $r$-sets which are 'sparse', or, at least, 'locally sparse', yet preserve some of the properties of $[n]^r$ stated in the theorems above. In the following section, we state a few specific problems on the existence of locally sparse structures with good 'global'

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

properties. Then, we explain why the standard probabilistic method cannot be directly used to study extremal properties of graphs and hypergraphs. Next we recall another important result of modern combinatorics: Szemerédi's Regularity Lemma and show how it could help in dealing with such problems. We conclude with a few remarks on possible generalizations of known results and some speculation on developments which are still to come.

## 2. Locally sparse structures with good extremal properties

Let us introduce first some notation. An $r$-uniform hypergraph is a pair $H = (V, E)$, where $V$ is the set of vertices of $H$ and $E \subseteq [V]^r$ denotes the set of its edges. We say that a hypergraph $H' = (V', E')$ is a subhypergraph of a hypergraph $H'' = (V'', E'')$, if $V' \subseteq V''$ and $E' \subseteq E''$. The complete $r$-uniform hypergraph $([m], [m]^r)$ we denote by $K_m^{(r)}$, and set $K_m^{(2)} = K_m$. A 2-uniform hypergraph is called a graph.

Let $H = (V, E)$ be an $r$-uniform hypergraph, and let $C = \{W_1, \ldots, W_t\}$ be a family of $s$-subsets of $V$ such that $[W_i]^r \subseteq E$, for $i = 1, \ldots, , t$. We say that $C$ is a loose $(s, t)$-circuit if $t \geq 3$, $(s, t) \neq (3, 3)$, $W_i \cap W_{i+1} \neq \emptyset$, for $i = 1, 2, \ldots, t-1$, and $W_1 \cap W_t \neq \emptyset$. We call $C$ a tight $(s, t)$-circuit if either $t = 2$ and $|W_1 \cap W_2| \geq r+1$, or $t \geq 3$ and $|W_i \cap W_{i+1}| \geq r$, for $i = 1, 2, \ldots, t-1$, as well as $|W_1 \cap W_t| \geq r$.

Finally, for $r$-uniform hypergraphs $H = (V, E)$ and $H' = (V', E')$, let $\mathrm{ex}(H', H)$ be the number of edges in the largest subhypergraph of $H$ which contains no copies of $H'$, and $\overline{\mathrm{ex}}(H', H) = \mathrm{ex}(H', H)/|E|$. It is easy to see (e.g., [8], Prop.8.4.), that for a given $H'$ the function $\overline{\mathrm{ex}}(H', H)$ is maximized for complete $H$, i.e., $\overline{\mathrm{ex}}(H', H) \leq \overline{\mathrm{ex}}(H', [V]^r)$.

One of the first results on the existence of locally sparse structures with good extremal properties was proved by Erdős [1] nearly fifty years ago. It states that there are graphs with large girth and no large independent sets (and so with large chromatic number).

**Theorem 2.1.** *For each $\ell$ and $\varepsilon > 0$ there exists a graph $G(\ell, \varepsilon) = (V, E)$ such that $G(\ell, \varepsilon)$ contains no $(2, t)$-circuits with $t \leq \ell$, but each subset $W \subseteq V$ such that $|W| \geq \varepsilon |V|$ contains an edge of $G(\ell, \varepsilon)$.*

In the following section we present Erdős' elegant non-constructive proof of this fact. Then we shall try to use a similar idea to get the following sparse version of Turan's theorem.

**Conjecture 2.2.** For any $r$, $s$, $\varepsilon > 0$, and $\ell$, there exist an $n = n(r, m, \ell, \varepsilon)$ and an $r$-uniform hypergraph $G^{(r)}(s, \ell, \varepsilon) = (V, E)$ such that

(i) $G^{(r)}(s, \ell, \varepsilon)$ contains no tight $(s, t)$-cycles with $2 \leq t \leq \ell$;

(ii) each subhypergraph $H^{(r)} \subseteq G^{(r)}(s, \ell, \varepsilon)$ with at least $(\alpha(s, r) + \varepsilon)|E|$ edges contains a subset $B$, $|B| = s$, such that $[B]^r \subseteq H^{(r)}$, i.e.,

$$\overline{\mathrm{ex}}([n]^s, G^{(r)}(s, \ell, \varepsilon)) \leq \alpha(s, r) + \varepsilon\,.$$

In Sections 3-5 below we describe how to approach Conjecture 2.2 using a special version of the Regularity Lemma. Here we remark only that the existence of $G^{(r)}(s, \ell, \varepsilon)$ has been shown only for $r = 2, s = 3$ (Frankl and Rödl [2] and Haxell *et al.* [7]), $r = 2, s = 4$ (Kohayakawa *et al.* [10]), and recently for $r = 2, s = 5$ (Gerke *et al.* [4]).

We conclude this section with a conjecture on a sparse version of Szemerédi's density theorem. Here a $(k, t)$-arithmetic circuit is a family of $t$ non-trivial arithmetic progressions $A_1, \ldots, A_t$ of length $k$ such that $A_i \cap A_{i+1} \neq \emptyset$ for $i = 1, 2 \ldots, t-1$, and $A_1 \cap A_t \neq \emptyset$.

**Conjecture 2.3.** For any $k$, $\ell$, and $\alpha > 0$, there exist an $\varepsilon = \varepsilon(\alpha, k, \ell) > 0$, $n = n(k, \alpha, \ell)$, and a set $A = A(k, \ell, \alpha, n) \subseteq [n]$ such that

(i) $A$ contains no $(k, t)$-arithmetic circuits for $t \leq \ell$;

(ii) any non-trivial arithmetic progression of length $n^{\varepsilon}$ in $[n]$ contains at most $k$ elements of $A$;

(iii) each subset $B$ of $A$ with at least $\alpha|A|$ elements contains a non-trivial arithmetic progression of length $k$.

Kohayakawa *et al.* [9] showed the existence of $A = A(3, \ell, \alpha, n)$ for any $\alpha > 0$ and $\ell$. Their proof was based on the idea used by Ruzsa and Szemerédi [16] to show that $r_3(n) = o(n)$. Let us also mention that since Szemerédi's density theorem can be deduced from some extremal results for hypergraphs (see Frankl and Rödl [3], Nagle *et al.* [13], and Rödl and Skokan [15]) it is in principle possible, although somewhat unlikely, that one can imitate the argument from [9] and verify Conjecture 2.3 for all $k \geq 4$ (cf., Conjecture 6.2 below).

## 3. Random structures

For $0 \leq p \leq 1$ and natural numbers $n, r$, let $\mathbb{G}^{(r)}(n, p)$ denote the random $r$-uniform hypergraph with vertex set $[n]$, where edges $\mathbb{G}^{(r)}(n, p)$ are chosen from $[n]^r$ independently with probability $p$. Thus, the number of edges of $\mathbb{G}^{(r)}(n, p)$ is a binomially distributed random variable with parameters $\binom{n}{r}$ and $p$. Typically, we are interested only in the asymptotic behavior of $\mathbb{G}^{(r)}(n, p)$ when $n \to \infty$ and the probability $p$ may depend on $n$. In particular, we say that for a given function $p = p(n)$ the hypergraph $\mathbb{G}^{(r)}(n, p)$ has a property $\mathcal{A}$ a.a.s. if the probability that $\mathbb{G}^{(r)}(n, p)$ has $\mathcal{A}$ tends to 1 as $n \to \infty$. Since in this note we deal mainly with graphs, instead of $\mathbb{G}^{(2)}(n, p)$ we write briefly $\mathbb{G}(n, p)$.

Let us recall Erdős' proof of Theorem 2.1. Fix $\ell$ and $\varepsilon > 0$. Let $n$ be very large and $p$ be the probability which is neither too small (so $\mathbb{G}(n, p)$ contains no large independent sets) nor too large (so $\mathbb{G}(n, p)$ is locally sparse). A good choice for $p$ is, say, $p = p(n) = n^{-1+1/2\ell}$, but, for $n$ large enough, any $p = p(n)$ such that $10/\varepsilon \leq np \leq n^{1/\ell}/10$ would do.

Let $X = X(n, \ell)$ be the random variable which counts $(2, t)$-circuits with $t \leq \ell$ in $\mathbb{G}(n, p)$. Then, for $n$ large enough, we have

$$\mathbb{E}X \leq \sum_{i=3}^{\ell} \binom{i}{2}\binom{i}{2}^{2i} p^i \leq \ell^{2\ell+3}(np)^{\ell} \leq n^{1/2}. \tag{2}$$

Thus, from Markov's inequality, $\Pr(X \geq n/2) \leq 2n^{-1/2}$, and so, for large enough $n$, with probability at least $2/3 > 1 - 2n^{-1/2}$, we have $X \leq n/2$. On the other hand, for the number $Y = Y(n, k)$ of independent sets of size $k$ in $\mathbb{G}(n, p)$ we have

$$\Pr(Y > 0) \leq \mathbb{E}X = \binom{n}{k}(1-p)^{\binom{k}{2}} \leq 2^n \exp\left(-p\binom{k}{2}\right). \tag{3}$$

If $k = \varepsilon n/2$ then $\Pr(Y > 0)$ tends to 0 as $n \to \infty$, i.e., for $n$ large enough we have $\Pr(Y > 0) < 2/3$. Now, let $G(\ell, \varepsilon)$ be a graph obtained from $\mathbb{G}(n, p)$ by removing one vertex from each $(2, t)$-circuit with $t \leq \ell$. Then, with probability at least $1/3$, $G(\ell, \varepsilon)$ fulfills the assertion of Theorem 2.1.

The main goal of this paper is to discuss how one can verify Conjecture 2.2 using a modified version of Erdős' approach. We shall concentrate on the simplest non-trivial case of Conjecture 2.2, when $s = 3$ and $r = 2$. In order to deduce the existence of $G^{(2)}(3, \ell, \varepsilon)$ from appropriate properties of the random graph $\mathbb{G}(n, p)$ first we need to guess what value of $p$ we are to use. More specifically, we should find the smallest possible value of $p_0 = p_0(n)$ such that a.a.s. in each subgraph of $\mathbb{G}(n, p_0)$ which contains, say, 51% of its edges one can find a triangle. Note that if a graph $G$ contains $m$ edges and $t$ triangles, then there is a triangle-free subgraph of $G$ with at least $m - t$ edges. Thus, it seems that in $\mathbb{G}(n, p_0)$ the expected number of triangles (equal to $\binom{n}{3}p_0^3$) must be at least of the order of the expected number of edges (equal $\binom{n}{2}p_0$), i.e., $p_0 = p_0(n)$ should be at least as large as $\Omega(n^{-1/2})$. It turns out that this necessary condition is also sufficient and the following holds (see Frankl and Rödl [2], Haxell *et al.* [7]).

**Theorem 3.1.** *For every $\delta > 0$ there exists $c = c(\delta)$ such that if $p = p(n) \geq cn^{-1/2}$, then a.a.s. each subgraph of $\mathbb{G}(n, p)$ with at least $(1/2 + \delta)\binom{n}{2}p$ edges contains a triangle.*

Let us try to prove Theorem 3.1 using Erdős' argument. To this end one has to bound the expected number of triangle-free subgraphs $H$ of $\mathbb{G}(n, p)$, containing 51% of edges of $\mathbb{G}(n, p)$, using a formula similar to (3). In order to do that one needs to estimate the probability that such a large subgraph $H$ of $\mathbb{G}(n, p)$ contains no triangles. The first problem which immediately emerges is the fact that our argument must depend strongly on the fact that $H$ has more than 51% of edges of $\mathbb{G}(n, p)$, since in every graph $G$ one can find a large bipartite subgraph which contains more than half of its edges. Thus, we have to use some property of $H$ shared by all subgraphs of $\mathbb{G}(n, p)$ with more than half of its edges, and does not hold for, say, bipartite

subgraphs of $\mathbb{G}(n, p)$; i.e., we should consider only graphs $H$ which are 'essentially non-bipartite'. Then, we need to show that a.a.s. each subgraph of $\mathbb{G}(n, p)$ containing at least 51% of its edges is 'essentially non-bipartite', and estimate the probability that a 'random essentially non-bipartite' graph is triangle-free.

However, now we face another, more serious obstacle. The number of subsets of the set of edges of $\mathbb{G}(n, p)$ is much larger then the number of subsets of the set of vertices of $\mathbb{G}(n, p)$. Consequently, the factor $2^n$ in (3) should be replaced by $\exp(\Omega(n^2 p))$. Hence, we should estimate the probability that a 'random essentially non-bipartite' subgraph $H$ of $\mathbb{G}(n, p)$ is triangle-free by a quantity which is much smaller than the probability that $\mathbb{G}(n, p)$ contains no edges at all! This is the crucial and most difficult part of the whole argument. It is also precisely the reason why we can show Conjecture 2.2 only for $r = 2$ and $s = 3, 4, 5$; for all other cases the proof breaks at this point.

Finally, it is easy to check that if $p = p(n) = n^{-1/2+o(1)}$, then for any given $\ell$ a.a.s. $\mathbb{G}(n, p)$ contains fewer than $o(n^2 p)$ tight $(3, t)$-circuits for $t \leq \ell$ which can be removed from $\mathbb{G}(n, p)$ without affecting much its extremal properties. Unfortunately, one cannot deal in the same way with loose $(3, t)$-circuits. The reason is quite simple: for $t \geq 4$ the number of loose $(3, t)$-circuits grows much faster than the number of triangles, because, roughly speaking, two triangles of $\mathbb{G}(n, p)$ are much more likely to share a vertex than an edge. Clearly, the same is true if instead of $\mathbb{G}(n, p)$ we consider a shadow of $\mathbb{G}^{(3)}(n, p)$, i.e., we randomly generate triples of vertices and then replace each of them by a triangle. Still, it is not inconceivable that Conjecture 2.2 can be settled in the affirmative by a non-constructive method using more sophisticated models of random hypergraphs; there have been a fair amount of attempts in this direction but so far all of them have failed miserably.

## 4. Regularity Lemma

One of the main ingredients of Szemerédi's ingenious proof of the density theorem was the Regularity Lemma which for the last thirty years has become one of the most efficient tools of modern graph theory. In order to formulate it rigorously we need a few technical definitions.

For a graph $G = (V, E)$ and $W, W' \subseteq V$ let $e(W, W')$ denote the number of edges joining $W$ and $W'$. A pair $(A, B)$ of disjoint subsets of vertices of $G$ is called an $\varepsilon$-regular pair, if for every subsets $A' \subseteq A$, $|A'| \geq \varepsilon|A|$, $B' \subseteq B$, $|B'| \geq \varepsilon|B|$,

$$\left| \frac{e(A', B')}{|A'||B'|} - \frac{e(A, B)}{|A||B|} \right| \leq \varepsilon. \tag{4}$$

An $\varepsilon$-regular pair behaves in many respects as the bipartite random graph $\mathbb{G}(A, B, \rho)$, in which edges between $A$ and $B$ appear independently with probability $\rho = e(A, B)/|A||B|$. In particular, it is easy to check, that if a pair $(A, B)$

is $\varepsilon$-regular then the number of subgraphs of a given size in the bipartite subgraph $G[A, B]$ induced by $A \cup B$ in $G$ is close to the expected number of such subgraphs in $\mathbb{G}(A, B, \rho)$. For instance, if $(A, B)$ is $\varepsilon$-regular, then the number of cycles of length four in $G[A, B]$ is equal $(\rho^4/4 \pm h(\varepsilon))|A|^2|B|^2$, where $h(\varepsilon)$ is a function which tends to 0 as $\varepsilon \to 0$. The implication in the other direction holds as well: if the number of cycles of length four in $G[A, B]$ is smaller than $(\rho^4/4 + \varepsilon)|A|^2|B|^2$, then the pair $(A, B)$ is $h'(\varepsilon)$-regular for some function $h'(\varepsilon)$ which tend to 0 as $\varepsilon \to 0$. Let us also mention that $\varepsilon$-regularity implies the correct number of small subgraphs even if we consider more than one $\varepsilon$-regular pair. For instance, if three disjoint sets $A_1, A_2, A_3 \subseteq V$ are such that each of the pairs $(A_1, A_2)$, $(A_2, A_3)$, $(A_1, A_3)$ is $\varepsilon$-regular with density $\rho$, the number of triangles in the tripartite graph induced in $G$ by these sets is $(\rho^3 \pm h''(\varepsilon))|A_1||A_2||A_3|$, where $h''(\varepsilon) \to 0$ as $\varepsilon \to 0$.

A partition $V = V_1 \cup \cdots \cup V_k$ of the vertex set of a graph $G = (V, E)$ is called a $(k, \varepsilon)$-partition if for all $i, j = 1, 2, \ldots, k$ we have $\big||V_i| - |V_j|\big| \leq 1$ and all except at most $\varepsilon k^2$ pairs $(V_i, V_j)$, $1 \leq i < j \leq k$, are $\varepsilon$-regular. Now Szemerédi's Regularity Lemma (see [17] and [18]) can be stated as follows.

**Lemma 4.1** (Szemerédi's Regularity Lemma). *For every $\varepsilon > 0$ there exists $K$ such that each graph $G$ with more than $1/\varepsilon$ vertices admits a $(k, \varepsilon)$-regular partition for some $k$, $1/\varepsilon < k < K$.*

Note that if $k > 1/\varepsilon$, then for a $(k, \varepsilon)$-regular partition there are at most $n^2/k + \varepsilon n^2 \leq 2\varepsilon n^2$ edges of $G$ which are either contained inside sets $V_i$ or join pairs which are not $\varepsilon$-regular. Thus, Szemerédi's Regularity Lemma says that all but $2\varepsilon n^2$ edges of any graph $G$ can be partitioned into at most $k$ $\varepsilon$-regular pairs, for some $1/\varepsilon \leq k \leq K$, where $K$ does not depend on the number of vertices in $G$. Unfortunately, $K = K(\varepsilon)$ grows very fast to infinity as $\varepsilon \to 0$ (see Gowers [5]), so most of the applications of the Regularity Lemma give very poor bounds of estimated quantities.

The Regularity Lemma can be reformulated and generalized in several ways. For instance, one can view it as a statement on the compactness of certain metric space (Lovász and Szegedy [12]); an information-theoretic approach to it can be found in Tao [19]. Another versions of the Regularity Lemma ensure the existence of 'weak' $(k, \varepsilon)$-partitions, or 'partial $\varepsilon$-covers' consisting of reasonably large $\varepsilon$-pairs. However the two most important developments in this area are, in my opinion, generalizations of the Regularity Lemma to sparse graphs and to hypergraphs. In the following sections we discuss how the Regularity Lemma can be modified to work efficiently for sparse graphs; here we say a few words on a much harder (both to state and to prove) version of the Regularity Lemma for hypergraphs. Several years ago Frankl and Rödl [3] generalized the Regularity Lemma to $r$-uniform hypergraphs and proved it, together with a supplementary 'counting lemma', for $r = 3$. The case $r \geq 4$ has been dealt with by Rödl and Skokan [15] and Nagle *et al.* [13], and, independently, by Gowers [6]. As was noticed by Frankl and Rödl [3], their version of the Regularity Lemma implies the following Removal Lemma which, in turn, can be used to show Szemerédi's density theorem (for details see Rödl *et al.* [14]).

**Lemma 4.2** (Removal Lemma). *For $m \geq r \geq 2$ and every $\delta > 0$ there exist $\eta > 0$ and $n_0$ so that for every $r$-uniform hypergraph $F$ on $m$ vertices and $r$-uniform hypergraph $H$ on $n$, $n \geq n_0$, vertices the following holds. If $H$ contains at most $\eta n^m$ copies of $F$, then one can delete $\delta n^r$ edges of $H$ to destroy all copies of $F$.*

Thus, the Removal Lemma states that if the number of copies of $F$ is large enough, then they must be, in some sense, uniformly distributed in $H$, i.e., the large number of copies of $F$ makes a hypergraph $H$, or at least parts of it, close to a random graph. In fact all known proofs of Lemma 4.2 are based on this idea. We should apply the Regularity Lemma to $H$, and then show that, if the number of copies of $F$ in $H$ is large, then there exists a big random-like subgraph $H'$ of $H$ which contains an anticipated number of copies of $F$.

## 5. Regularity Lemma: sparse graphs

Note that Lemma 4.1 is basically meaningless for sparse graphs since the definition (4) of $\varepsilon$-regular pair $(A, B)$ does not say much on the distribution of edges between $A$ and $B$ if the density $\rho = e(A, B)/|A||B|$ is smaller than $\varepsilon$. Thus, let us modify the definition of an $\varepsilon$-regular pair by 'scaling' the density of the pair by $d$ which, typically, is the density of the graph $G = (V, E)$. Hence, we say that a pair $(A, B)$ of disjoint subsets of vertices of a graph $G = (V, E)$ is $(d, \varepsilon)$-regular, if for each pair of subsets $A' \subseteq A$, $|A'| \geq \varepsilon|A|$, $B' \subseteq B$, $|B'| \geq \varepsilon|B|$, we have

$$\left| \frac{e(A', B')}{|A'||B'|} - \frac{e(A, B)}{|A||B|} \right| \leq d\varepsilon. \tag{5}$$

If $d_G = |E|/\binom{|V|}{2}$ we call a $(d_G, \varepsilon)$-regular pair strongly $\varepsilon$-regular. A strongly $(k, \varepsilon)$-regular partition of vertices of $G$ is defined in a similar way as $(k, \varepsilon)$-regular partition. Moreover, we say that a graph $G = (V, E)$ with density $d_G = |E|/\binom{|V|}{2}$ is $(\eta, b)$-bounded if each subgraph $H$ of $G$ with $r \geq \eta|V|$ vertices contains not more than $br^2$ edges. As was observed independently by Kohayakawa and by Rödl (see Kohayakawa and Rödl [11] and references therein), one can mimic the proof of Szemerédi's Regularity Lemma to get the following result.

**Lemma 5.1.** *For every $\varepsilon > 0$ and $b$ there exist $\eta$ and $K$ such that each $(\eta, b)$-bounded graph $G$ with more than $1/\varepsilon$ vertices admits a strongly $(k, \varepsilon)$-regular partition for some $k$, $1/\varepsilon < k < K$.*

The assumption that $G$ is $(\eta, b)$-bounded is typically not very restrictive. For instance, if $\eta > 0$ and $np \to \infty$ as $n \to \infty$, then the random graph $\mathbb{G}(n, p)$ is a.a.s. $(\eta, 2)$-bounded. Consequently, a.a.s. each subgraph of such $\mathbb{G}(n, p)$ which contains at least half of its edges is $(\eta, 4)$-bounded.

A more serious problem is that, unlike in the dense case, from the fact that a sparse pair is strongly $\varepsilon$-regular it does not follow that the number of cycles of length four

in that pair is close to the number of cycles of length four in the random bipartite graph of the same density. In a similar way, for every $\varepsilon > 0$ there exists $\delta > 0$ and a tripartite graph $G$ with vertex set $V_1 \cup V_2 \cup V_3$, $|V_1| = |V_2| = |V_3| = n$ such that all three pairs $(V_1, V_2)$, $(V_2, V_3)$, and $(V_1, V_3)$ are strongly $\varepsilon$-regular pairs with densities larger than $\delta$, yet $G$ is triangle-free. Nevertheless, Kohayakawa, Łuczak, and Rödl conjectured in [10] that such triangle-free tripartite graphs consisting of dense $\varepsilon$-regular triples are so rare that a.a.s. the random graph $\mathbb{G}(n, p)$ contains none of them as a subgraph.

In order to state the conjecture rigorously we need one more definition. Let $\mathbb{G}(n, p; \varepsilon, s)$ be a graph chosen at random from the family of all $s$-partite graphs with vertex set $V_1 \cup V_2 \cup \cdots \cup V_s$, $|V_1| = |V_2| = \cdots = |V_s| = n$, such that for each $i$, $j$, $1 \le i < j \le s$, the pair $(V_i, V_j)$ spans a bipartite strongly $\varepsilon$-regular graph with $\lceil pn^2 \rceil$ edges. Then the conjecture of Kohayakawa, Łuczak and Rödl for complete graphs goes as follows (for a more general statement see [10]).

**Conjecture 5.2.** For every $s$ and $\delta > 0$ there exist $\varepsilon > 0$ and $C$ such that if $n^s p^{\binom{s}{2}} > Cn^2 p$, then the probability that $\mathbb{G}(n, p; \varepsilon, s)$ contains no copies of $K_s$ is smaller than $\delta^{n^2 p}$.

A stronger 'counting' version of Conjecture 5.2 goes as follows.

**Conjecture 5.3.** For every $s$ and $\delta > 0$ there exist $\varepsilon > 0$ and $C$ such that if $n^s p^{\binom{s}{2}} > Cn^2 p$, then the probability that $\mathbb{G}(n, p; \varepsilon, s)$ contains fewer than $n^s p^{\binom{s}{2}}/2$ copies of $K_s$ is smaller than $\delta^{n^2 p}$.

So far Conjectures 5.2 and 5.3 have been shown only for $s = 3, 4, 5$ (see Gerke *et al.* [4] and the references therein).

Let us observe that Theorem 3.1 follows immediately from the fact that Conjecture 5.2 holds for $s = 3$. Indeed, let us fix $\delta > 0$ and let $p = C/\sqrt{n}$, where $C$ is a large constant. Take a subgraph $H$ of $\mathbb{G}(n, p)$ with at least $(1/2 + \delta)\binom{n}{2} p$ edges. Choose $\varepsilon > 0$ much smaller than $\delta$ and apply Lemma 5.1 to $H$ to find in it a strong $(k, \varepsilon)$-partition with $1/\varepsilon < k < K$ (as we have already pointed out for every $\eta > 0$, a.a.s. $\mathbb{G}(n, p)$ is $(2, \eta)$-bounded and so $H$ is $(4, \eta)$-bounded and fulfills assumptions of the lemma). Since $H$ contains more than half of the edges of $\mathbb{G}(n, p)$, and edges in $\mathbb{G}(n, p)$ are uniformly distributed around the graph, there exist three sets $V'$, $V''$, $V'''$ of the partition such that each of the pairs $(V', V'')$, $(V'', V''')$, $(V', V''')$, is strongly $\varepsilon$-regular and has density at least $\delta p/10$. (Let us remark that now a vague notion of an 'essentially non-bipartite' subgraph $H$ we have used in Section 3 can be made precise: a graph $H$ is essentially non-bipartite if it contains a balanced tripartite graph on $\Omega(n)$ vertices which consists of three dense strongly $\varepsilon$-regular pairs.) Now, one can use Conjecture 5.2 and argue as in (3) that a.a.s. each tripartite subgraph of $\mathbb{G}(n, p)$ of such a type contains a triangle. Thus, $H$ contains a triangle and Theorem 3.1 follows.

Finally, let us also note that if, say, $p = \log n/\sqrt{n}$, then elementary calculations similar to that used by Erdős (cf. (3)) reveal that for every fixed $\ell$ a.a.s. the number

of tight $(3, t)$-circuits in $\mathbb{G}(n, p)$ with $t \leq \ell$ is $o(n^2 p)$. Thus, one can obtain a graph $G^{(2)}(3, \ell, \delta)$ with all the properties specified in Conjecture 2.2 by deleting from $\mathbb{G}(n, p)$ all edges which belong to tight $(3, t)$-circuits, $t \leq \ell$.

## 6. Final remarks

It is easy to see that, arguing as in the proof of Theorem 3.1 above, one can show the existence of a graph $G^{(2)}(s, \ell, \delta)$ (see Conjecture 2.2) for every $s$ for which Conjecture 5.2 holds. A precise formulation of analogs of Conjectures 5.2 and 5.3 for hypergraphs would become very technical, thus we only mention that if appropriately stated hypergraph version of Conjecture 5.3 is true then the following straightforward 'probabilistic' generalization of the Removal Lemma holds.

**Conjecture 6.1.** For $s > r \geq 2$ and every $\delta > 0$ there exist $\eta > 0$ such that a.a.s. in each subhypergraph $H$ of the random $r$-uniform hypergraph $\mathbb{G}^{(r)}(n, p)$ which contains fewer than $\eta n^s p^{\binom{s}{r}}$ copies of $K_s^{(r)}$ one can destroy all these copies by removing fewer than $\delta n^r p$ hyperedges of $H$.

An analogous question on the validity of a probabilistic version of Szemerédi's density theorem can be stated as follows.

**Conjecture 6.2.** For every $\delta > 0$ and $k$ there exists $\eta > 0$ such that a.a.s. in each subset $A$ of $\mathbb{G}^{(1)}(n, p)$ with fewer than $\eta n^2 p^k$ non-trivial arithmetic progressions of length $k$ all these progressions can be destroyed by removing fewer than $\delta np$ elements from $A$.

Conjecture 6.1 states that a.a.s. a random hypergraphs $\mathbb{G}^{(r)}(n, p)$ has a property $\mathcal{A}$ such that if a hypergraph $G$ has $\mathcal{A}$ each subgraph $H$ of $G$ with fewer than $\eta n^s p^{\binom{s}{r}}$ copies of $K_s^{(r)}$ can be made $K_s^{(r)}$-free by deleting fewer than $\delta n^r p$ hyperedges. One can ask if $\mathcal{A}$ follows from some simple property $\mathcal{A}'$, i.e., whether there is a compact characterization of 'pseudorandom' sparse hypergraphs. A natural candidate for $\mathcal{A}'$ is the property that the number of some special subhypergraphs in $G$ is close to the expected value of the number of such subhypergraphs in the random hypergraph with the same density. In the case of graphs a good choice for 'probing' graphs seem to be cycles of length four. It is known (see Thomasson [20]) that if the number of cycles of length four in a graph $G$ is close to the anticipated one, then edges in $G$ are 'uniformly distributed' around $G$. Nonetheless we do not know if the 'correct' number of cycles of length four, possibly matched with some additional requirements ensuring that $G$ is locally sparse, can guarantee that $G$ has good 'extremal' properties like those described in Conjecture 6.1. Another challenging problem is to strengthen the definition of a strongly $\varepsilon$-regular pair to, say, a 'super $\varepsilon$-regular pair' such that the analog of Lemma 5.1 remains valid in this setting (i.e., each dense subgraph of a random-like graph $G$ admits a 'super $(k, \varepsilon)$-partition') and furthermore, each

tripartite graph which consists of three dense super $\varepsilon$-regular pairs contains a triangle. Similar questions can be asked for hypergraphs, as well as for the subsets of $[n]$ (or, in somewhat more natural setting, for subsets of $\mathbb{Z}_n$, where $n$ is a prime).

# Additive combinatorics and geometry of numbers

Imre Z. Ruzsa*

**Abstract.** We meditate on the following questions. What are the best analogs of measure and dimension for discrete sets? How should a discrete analogue of the Brunn–Minkowski inequality look like? And back to the continuous case, are we happy with the usual concepts of measure and dimension for studying the addition of sets?

**Mathematics Subject Classification (2000).** Primary 11B75; Secondary 05-99, 11H06, 52C07.

**Keywords.** Sumsets, additive combinatorics, lattice points, volume.

## 1. Introduction

"Additive combinatorics" is a name coined by (I think) Tao and Van for the title of their book in preparation to denote the study of additive properties of general sets – mainly of integers, but also in other structures. Works on this topics are generally classified as additive or combinatorial number theory.

The first result that connects additive properties to geometrical position is perhaps the following theorem of Freiman.

**Theorem 1.1** (Freiman [3], Lemma 1.14). *Let $A \subset \mathbb{R}^d$ be a finite set, $|A| = m$. Assume that $A$ is proper $d$-dimensional, that is, it is not contained in any affine hyperplane. Then*

$$|A + A| \geq (d + 1)m - \frac{d(d + 1)}{2}.$$

This theorem is exact, equality can occur, namely it holds when $A$ is a "long simplex", a set of the form

$$L_{dm} = \{0, e_1, 2e_1, \ldots, (m - d)e_1, e_2, e_3, \ldots, e_d\}. \tag{1.1}$$

In particular, if no assumption is made on the dimension, then the minimal possible cardinality of the sumset is $2m - 1$, with equality for arithmetic progressions.

This result can be extended to sums of different sets. This extension is problematic from the beginning, namely the assumption "$d$-dimensional" can be interpreted in

*Supported by Hungarian National Foundation for Scientific Research (OTKA), Grants No. T 38396, T 43623, T 42750.

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

different ways. We can stipulate that both sets be $d$-dimensional, or only one, or, in the weakest form, make this assumption on the sumset only.

An immediate extension of Freiman's above result goes as follows.

**Theorem 1.2** ([11], Corollary 1.1). *If $A, B \subset \mathbb{R}^d$, $|A| \le |B|$ and $\dim(A+B) = d$, then we have*

$$|A+B| \ge |B| + d|A| - \frac{d(d+1)}{2}.$$

We can compare these results to the continuous case. Let $A, B$ be Borel sets in $\mathbb{R}^d$; $\mu$ will denote the Lebesgue measure. The celebrated Brunn–Minkowski inequality asserts that

$$\mu(A+B)^{1/d} \ge \mu(A)^{1/d} + \mu(B)^{1/d}, \tag{1.2}$$

and here equality holds if $A$ and $B$ are homothetic convex sets, and under mild and natural assumptions this is the only case of equality. It can also be observed that the case $A = B$ is completely obvious here: we have

$$\mu(A+A) \ge \mu(2\cdot A) = 2^d \mu(A).$$

Also the constant $2^d$ is much larger than the constant $d+1$ in Theorem 1.1. This is necessary, as there are examples of equality, however, one feels that this is an exceptional phenomenon and better estimations should hold for "typical" sets. A further difference is the asymmetrical nature of the discrete result and the symmetry of the continuous one. Finally, when $|A|$ is fixed, Theorem 1.2 gives a linear increment, while (1.2) yields

$$\mu(A+B) \ge \mu(B) + d\mu(A)^{1/d}\mu(B)^{1-1/d}.$$

In the next section we tell what can be said if we use cardinality as the discrete analog of measure, and prescribe only the dimension of the sets. Later we try to find other spatial properties that may be used to study sumsets.

We meditate on the following questions (without being able to even conjecture a definitive answer). What are the best analogs of measure and dimension for discrete sets? How should a discrete analogue of the Brunn–Minkowski inequality look like? The partial answers also suggest questions in the continuous case. Should we be satisfied with the usual concepts of measure and dimension for studying the addition of sets?

Most of the paper is a survey, however, there are some new results in Sections 4 and 6.

We end the introduction by fixing some notations, which were tacitly used above.

For two sets $A, B$ (in any structure with an operation called addition) by their *sum* we mean the set

$$A+B = \{a+b : a \in A,\ b \in B\}.$$

We use $A - B$ similarly. For repeated addition we write

$$kA = A + \cdots + A \quad (k \text{ times}),$$

in contrast to

$$k \cdot A = \{ka : k \in A\}.$$

Mostly our sets will be in an Euclidean space $\mathbb{R}^d$, and $e_1, \dots, e_d$ will be the system of unit vectors. We define initially the *dimension* $\dim A$ of a set $A \subset \mathbb{R}^d$ as the dimension of the smallest affine hyperplane containing $A$. (This definition will be modified in Section 3).

## 2. Results using cardinality and dimension

We consider finite sets in an Euclidean space $\mathbb{R}^d$.

Put

$$F_d(m,n) = \min\{|A+B| : |A| = m, |B| = n,\ \dim(A+B) = d\},$$
$$F'_d(m,n) = \min\{|A+B| : |A| = m, |B| = n,\ \dim B = d\},$$
$$F''_d(m,n) = \min\{|A+B| : |A| = m, |B| = n,\ \dim A = \dim B = d\}.$$

$F_d$ is defined for $m+n \geq d+2$, $F'_d$ for $n \geq d+1$ and $F''_d$ for $m \geq d+1, n \geq d+1$. $F_d$ and $F''_d$ are obviously symmetric, while $F'_d$ may not be (and, in fact, we will see that for certain values of $m, n$ it is not), and they are connected by the obvious inequalities

$$F_d(m,n) \leq F'_d(m,n) \leq F''_d(m,n).$$

I determined the behaviour of $F_d$ and of $F'_d$ for $m \leq n$. The more difficult problem of describing $F''_d$ and $F'_d$ for $m > n$ was solved by Gardner and Gronchi [4]; we shall quote their results later.

To describe $F_d$ define another function $G_d$ as follows:

$$G_d(m,n) = n + \sum_{j=1}^{m-1} \min(d, n-j), \quad n \geq m \geq 1$$

and for $m > n$ extend it symmetrically, putting $G_d(m,n) = G_d(n,m)$. In other words, if $n - m \geq d$, then we have

$$G_d(m,n) = n + d(m-1).$$

If $0 \leq t = n - m < d$, then for $n > d$ we have

$$G_d(m,n) = n + d(m-1) - \frac{(d-t)(d-t-1)}{2} = n(d+1) - \frac{d(d+1)}{2} - \frac{t(t+1)}{2},$$

and for $n \leq d$

$$G_d(m,n) = n + \frac{(m-1)(2n-m)}{2}.$$

With this notation we have the following result.

**Theorem 2.1** ([11], Theorem 1). *For all positive integers $m$, $n$ and $d$ satisfying $m + n \geq d + 2$ we have*

$$F_d(m, n) \geq G_d(m, n).$$

Theorem 1.2 is an immediate consequence.

Theorem 2.1 is typically exact; the next theorem summarizes the cases when we have examples of equality.

**Theorem 2.2** ([11], Theorem 2). *Assume $1 \leq m \leq n$. We have*

$$F_d(m, n) = F'_d(m, n) = G_d(m, n)$$

*unless either $n < d + 1$ or $m \leq n - m \leq d$ (in this case $n \leq 2d$).*

The construction goes as follows.

Assume $1 \leq m \leq n$, $n \geq d + 1$. Let $B$ be a long simplex, $B = L_{dn}$ as defined in (1.1).

If $n - m \geq d$, we put

$$A = \{0e_1, 1e_1, \dots, (m-1)e_1\}.$$

This set satisfies $|A| = m$. The set $A + B$ consists of the vectors $ie_1$, $0 \leq i \leq n + m - d - 1$ and the vectors $ie_1 + e_j$, $0 \leq i \leq m - 1$, $2 \leq j \leq d$, consequently

$$|A + B| = n + d(m - 1) = G_d(m, n).$$

If $n - m = t < d$, write $t = d - k$ and assume $k \leq m$. Now $A$ is defined by

$$A = \{0e_1, 1e_1, \dots, (m-k)e_1\} \cup \{e_2, \dots, e_k\}.$$

This set satisfies $|A| = m$. The set $A+B$ consists of the vectors $ie_1, 0 \leq i \leq 2(n-d)$, the vectors $ie_1 + e_j$, $0 \leq i \leq n - d$, $2 \leq j \leq d$, finally $e_i + e_j$, $2 \leq i, j \leq k$, hence

$$\begin{aligned} |A + B| &= 2(n - d) + 1 + (d - 1)(n - d + 1) + \frac{k(k-1)}{2} \\ &= n(d + 1) - \frac{d(d+1)}{2} - \frac{t(t+1)}{2} = G_d(m, n). \end{aligned}$$

These constructions cover all pairs $m, n$ except those listed in Theorem 2.2. Observe that $A$ is also a long simplex of lower dimension. For a few small values the exact bounds are yet to be determined.

We now describe Gardner and Gronchi's [4] bound for $F'_d(m, n)$. Informally their main result (Theorem 5.1) asserts that the $|A + B|$ is minimalized when $B = L_{dn}$, a long simplex, and $A$ is as near to the set of points inside a homothetic simplex as possible. More exactly the define (for a fixed value of $n$) the weight of a point $x = (x_1, \dots, x_d)$ as

$$w(x) = \frac{x_1}{n - d} + x_2 + \cdots + x_d.$$

This defines an ordering by writing $x < y$ if either $w(x) < w(y)$ or $w(x) = w(y)$ and for some $j$ we have $x_j > y_j$ and $x_i = y_i$ for $i < j$.

Let $D_{dmn}$ be the collection of the first $m$ vectors with nonnegative integer coordinates in this ordering. We have $D_{dnn} = L_{dn} = B$, and, more generally, $D_{dmn} = rB$ for any integer $m$ such that

$$m = |rB| = (n-d)\binom{r+d-1}{d} + \binom{r+d-1}{d-1}.$$

For such values of $m$ we also have

$$|A+B| = |(r+1)B| = (n-d)\binom{r+d}{d} + \binom{r+d}{d-1}.$$

With this notation their result sounds as follows.

**Theorem 2.3** (Gardner and Gronchi [4], Theorem 5.1). *If $A, B \subset \mathbb{R}^d$, $|A| = m$, $|B| = n$ and $\dim B = d$, then we have*

$$|A+B| \geq |D_{dmn} + L_{dn}|.$$

For $m < n$ this reproves Theorem 2.2. For $m \geq n$ the extremal set $D_{dmn}$ is also $d$-dimensional, thus this result also gives the value of $F''_d$.

**Corollary 2.4.** *For $m \geq n > d$ we have*

$$F''_d(m,n) = F'_d(m,n) = |D_{dmn} + L_{dn}|.$$

A formula for the value of this function is given in [4], Section 6. We quote some interesting consequences.

**Theorem 2.5** (Gardner and Gronchi [4], Theorem 6.5). *If $A, B \subset \mathbb{R}^d$, $|A| = m \geq |B| = n$ and $\dim B = d$, then we have*

$$|A+B| \geq m + (d-1)n + (n-d)^{1-1/d}(m-d)^{1/d} - \frac{d(d-1)}{2}.$$

**Theorem 2.6** (Gardner and Gronchi [4], Theorem 6.6). *If $A, B \subset \mathbb{R}^d$, $|A| = m$, $|B| = n$ and $\dim B = d$, then we have*

$$|A+B|^{1/n} \geq m^{1/d} + \left(\frac{n-d}{d!}\right)^{1/d}.$$

This result is as close to the Brunn–Minkowski inequality as we can get by using only the cardinality of the summands.

## 3. The impact function and the hull volume

While we will focus our attention to sets in Euclidean spaces, some definitions and results can be formulated more clearly in a more general setting. So let now $G$ be a commutative group. For a fixed finite set $B \subset G$ we define its *impact function* by

$$\xi_B(m) = \xi_B(m, G) = \min\{|A + B| : A \subset G,\ |A| = m\}.$$

This is defined for all positive integers if $G$ is infinite, and for $m \le |G|$ if $G$ is finite.

This function embodies what can be told about cardinality of sumsets if one of the set is unrestricted up to cardinality. The name is a translation of Plünnecke's "Wirkungsfunktion", who first studied this concept systematically for density [9].

We will be interested mainly in the infinite case, and in this case the dependence on $G$ can be omitted.

**Lemma 3.1.** *Let $G$, $G'$ be infinite commutative groups, $G' \subset G$, and let $B \subset G'$ be a finite set. We have*

$$\xi_B(m, G) = \xi_B(m, G') \tag{3.1}$$

*for all $m$.*

*Proof.* Take an $A \subset G$, $|A| = m$ with $|A + B| = \xi_B(m, G)$. Let $A = A_1 \cup \dots \cup A_k$ be its decomposition according to cosets of $G'$. For each $1 \le i \le k$ take an element $x_i$ from the coset containing $A_i$ so that the sets $A_i - x_i$ are pairwise disjoint; this is easily done as long as $G'$ is infinite. The set

$$A' = \bigcup (A_i - x_i)$$

satisfies $A' \subset G'$, $|A'| = n$ and

$$|A' + B| \le \sum |A_i - x_i + B| = \sum |A_i + B| = |A + B| = \xi_B(m, G),$$

hence $\xi_B(m, G') \le \xi_B(m, G)$. The inequality in the other direction is obvious. □

In the case of finite groups the connection between $\xi_B(m, G)$ and $\xi_B(m, G')$ can also be described by arguments like in chapters 3 and 4 of Plünnecke's above mentioned book [9]. We restrict our attention to infinite groups, and henceforth omit the reference to $G$ and write just $\xi_B(m)$ instead.

Let $G$ be a torsionfree group. Take a finite $B \subset G$, and let $G'$ be the subgroup generated by $B - B$, that is, the smallest subgroup such that $B$ is contained in a single coset. Let $B' = B - a$ with some $a \in B$, so that $B' \subset G'$. The group $G'$, as any finitely generated torsionfree group, is isomorphic to the additive group $\mathbb{Z}^d$ for some $d$. Let $\varphi : G' \to \mathbb{Z}^d$ be such an isomorphism and $B'' = \varphi(B')$. By Lemma 3.1 we have

$$\xi_B = \xi_{B'} = \xi_{B''},$$

so when studying the impact function we can restrict our attention to sets in $\mathbb{Z}^d$ that contain the origin and generate the whole lattice; we then study the set "in its natural habitat".

**Definition 3.2.** Let $B$ be a finite set in a torsionfree group $G$. By the *dimension* of $B$ we mean the number $d$ defined above, and denote it by $\dim B$. By the *hull volume* of $B$ we mean the volume of the convex hull of the set $B''$ described above and denote it by $\mathrm{hv}\, B$.

The set $B''$ is determined up to an automorphism of $\mathbb{Z}^d$. These automorphisms are exactly linear maps of determinant $\pm 1$, hence the hull volume is uniquely defined.

Observe that this dimension is not the same as the dimension described in the Introduction; in the case when $B \subset \mathbb{R}^k$ with some $k$, this is its dimension over the field of rationals.

**Theorem 3.3.** *Let $B$ be a finite set in a torsionfree group $G$, $d = \dim B$, $v = \mathrm{hv}\, B$. We have*

$$\lim |kB| k^{-d} = v.$$

A proof can be found in [12], Section 11, though this form is not explicitly stated there. An outline is as follows. By using the arguments above we may assume that $B \subset \mathbb{Z}^d$, $0 \in B$ and $B$ generates $\mathbb{Z}^d$. Let $B^*$ be the convex hull of $B$. Then $kB$ is contained in $k \cdot B^*$. The number of lattice points in $k \cdot B$ is asymptotically $\mu(k \cdot B^*) = k^d v$; this yields an upper estimate. To get a lower estimate one proves that with some constant $p$, $kB$ contains all the lattice points inside translate of $(k-p) \cdot B^*$; this is Lemma 11.2 of [12].

This means that the hull volume can be defined without any reference to convexity and measure, and this definition can even be extended to commutative semigroups. This follows from the following result of Khovanskii [5], [6]; for a simple proof see [8].

**Theorem 3.4** (Khovanskii). *Let $B$ be a finite set in a commutative semigroup. There is a $k_0$, depending on the set $B$, such that $|kB|$ is a polynomial function of $k$ for $k > k_0$.*

**Definition 3.5.** Let $B$ be a finite set in a commutative semigroup, and let $vk^d$ be the leading term of the polynomial which coincides with $|kB|$ for large $k$. By the *dimension* of $B$ we mean the degree $d$ of this polynomial, and by the *hull volume* we mean the leading coefficient $v$.

It turns out that in $\mathbb{Z}^d$, hence in any torsionfree group, the dimension and hull volume determine the asymptotic behaviour of the impact function.

**Theorem 3.6.** *Let $B$ be a finite set in a torsionfree commutative group $G$, $d = \dim B$, $v = \mathrm{hv}\, B$. We have*

$$\lim(\xi_B(m)^{1/d} - m^{1/d}) = v^{1/d}.$$

This is the main result (Theorem 3.1) of [12]. In the same paper I announce the same result for non necessarily torsionfree commutative groups without proof (Theorem 3.4). In a general semigroup $A + B$ may consist of a single element, so an attempt to an immediate generalization fails.

**Problem 3.7.** Does the limit $\lim \xi_B(m)^{1/d} - m^{1/d}$ exist in general commutative semigroups? Is there a condition weaker than cancellativity to guarantee its positivity?

Theorem 3.6 can be effectivized as follows (Theorems 3.2 and 3.3 of [12]).

**Theorem 3.8.** *With the notations of the previous theorem, if $d \geq 2$ and $m \geq v$, we have*

$$\xi_B(m) \leq m + dv^{1/d}m^{1-1/d} + c_1 v^{2/d} m^{1-2/d},$$
$$\xi_B(m)^{1/d} - m^{1/d} \leq v^{1/d} + c_2 v^{2/d} m^{-1/d}.$$

*($c_1, c_2$ depend on $d$.) With $n = |B|$ for large $m$ we have*

$$\xi_B(m) \geq m + dv^{1/d}m^{1-1/d} - c_3 v^{\frac{d+3}{2d}} n^{-1/2} m^{1-\frac{3}{2d}},$$
$$\xi_B(m)^{1/d} - m^{1/d} \geq v^{1/d} - c_4 v^{\frac{d+3}{2d}} n^{-1/2} m^{-1/(2d)}.$$

Probably the real error terms are much smaller than these estimates. For $d = 1$ we have the obvious inequality $\xi_B(m) \leq m + v$, with equality for large $m$ because the integers $\xi_B(m) - m$ cannot converge to $v$ otherwise. For $d = 2$ already $\sqrt{\xi_B(m)} - \sqrt{m}$ can converge to $\sqrt{v}$ from both directions.

**Theorem 3.9.** *The impact function of the set $B = \{0, e_1, e_2\} \subset \mathbb{Z}^2$ satisfies*

$$\sqrt{\xi_B(m)} - \sqrt{m} > \sqrt{v} \tag{3.2}$$

*for all $m$.*

*The impact function of the set $B = \{0, e_1, e_2, -(e_1 + e_2)\} \subset \mathbb{Z}^2$ satisfies*

$$\sqrt{\xi_B(m)} - \sqrt{m} < \sqrt{v} \tag{3.3}$$

*for infinitely many $m$.*

Inequality (3.2) was announced in [12] without proof as Theorem 4.1, and it is a special case of Gardner and Gronchi's Theorem 2.6. Inequality 3.3 is Theorem 4.3 of [12].

I cannot decide whether there is a set such that $\sqrt{\xi_B(m)} - \sqrt{m} < \sqrt{v}$ for all $m$.

## 4. The impact volume

Besides cardinality we saw the hull volume as a contender for the title "discrete volume". For both we had something resembling the Brunn–Minkowski inequality;

for cardinality we had Gardner and Gronchi's Theorem 2.6, which has the (necessary) factor $d!$, and for the hull volume we have Theorem 3.6, which only holds asymptotically.

There is an easy way to find a quantity for which the analogue of the Brunn–Minkowski inequality hods exactly: we can make it a definition.

**Definition 4.1.** The $d$-dimensional *impact volume* of a set $B$ (in an arbitrarily commutative group) is the quantity

$$\mathrm{iv}_d(B) = \inf_{m\in\mathbb{N}} \left(\xi_B(m)^{1/d} - m^{1/d}\right)^d.$$

Note that the $d$ above may differ from the dimension of $B$, in fact, it need not be an integer. It seems, however, that the only really interesting case is $d = \dim B$.

The following statement list some immediate consequences of this definition.

**Statement 4.2.** *Let $B$ be a finite set in a commutative torsionfree group.*

(a) $\mathrm{iv}_d(B)$ *is a decreasing function of $d$.*

(b) *If $|B| = n$, then*

$$\mathrm{iv}_1(B) = n - 1$$

*and*

$$\mathrm{iv}_d(B) \le \left(n^{1/d} - 1\right)^d \tag{4.1}$$

*for every $d$.*

(c) $\mathrm{iv}_d(B) = 0$ *for $d > \dim B$.*

(d) *For every pair $A, B$ of finite sets in the same group and every $d$ we have*

$$\mathrm{iv}_d(A + B)^{1/d} \ge \mathrm{iv}_d(A)^{1/d} + \mathrm{iv}_d(B)^{1/d}. \tag{4.2}$$

The price we have to pay for the discrete Brunn–Minkowski inequality (4.2) is that there is no easy way to compute the impact volume for a general set. We have the following estimates.

**Theorem 4.3.** *Let $B$ be a finite set in a commutative torsionfree group,* $\dim B = d$, $|B| = n$. *We have*

$$\left(\frac{n-d}{d!}\right) \le \mathrm{iv}_d(B) \le \mathrm{hv}\, B, \tag{4.3}$$

*with equality in both places if $B$ is a long simplex.*

The first inequality follows form Theorem 2.6 of Gardner and Gronchi, the second from Theorem 3.6.

**Problem 4.4.** What is the *maximal* possible value of $\mathrm{iv}_d(B)$ for $n$-element $d$-dimensional sets? Is perhaps the bound in (4.1) exact?

We now describe the impact volume for another important class of sets, namely cubes.

**Theorem 4.5.** *Let $n_1, \dots, n_d$ be positive integers and let*

$$B = \{(x_1, \dots, x_d) \in \mathbb{Z}^d : 0 \le x_i \le n_i\}. \tag{4.4}$$

*We have*

$$\mathrm{iv}_d(B) = \mathrm{hv}\, B = v = n_1 \dots n_d.$$

**Problem 4.6.** Is is true that when $B$ is the set of lattice points within a convex lattice polytope, then hv $B$ and $\mathrm{iv}_d(B)$ are very near?

They may differ, as the second example in Theorem 3.9 shows.

We shall deduce Theorem 4.5 from the following one.

**Theorem 4.7.** *Let $G = G_1 \times G_2$ be a commutative group represented as the direct product of the groups $G_1$ and $G_2$. Let $B = B_1 \times B_2 \subset G$ be a finite set with $B_1 \subset G_1$, $B_2 \subset G_2$. We have*

$$\mathrm{iv}_d(B) \ge \mathrm{iv}_{d-1}(B_1)\mathrm{iv}_1(B_2). \tag{4.5}$$

*Proof.* Write $\mathrm{iv}_d(B) = v$, $\mathrm{iv}_{d-1}(B_1) = v_1$, $\mathrm{iv}_1(B_2) = v_2$ (which is $= |B| - 1$ if $G_2$ is torsionfree). We want to estimate $|A + B|$ from below for a general set $A \subset G$ with $|A| = m$.

Firs we transform them to some standard form; this will be the procedure what Gardner and Gronchi call compression. Let $A_1$ be the projection of $A$ to $G_1$, and for an $x \in A_1$ write

$$A(x) = \{y \in G_2 : (x, y) \in A\}.$$

Let

$$A' = \{(x, i) : x \in A_1, i \in \mathbb{Z},\ 0 \le i \le |A(x)| - 1\}$$

and

$$B' = \{(x, i) : x \in B_1, i \in \mathbb{Z},\ 0 \le i \le v_2\}.$$

We have $A', B' \subset G' = G_1 \times \mathbb{Z}$.

**Lemma 4.8.** *We have*

$$|A'| = |A|, \quad |A' + B'| \le |A + B|. \tag{4.6}$$

*Proof.* The equality is clear. To prove the inequality, write $S = A + B$, $S' = A' + B'$. With the obvious notation, we will show that

$$|S'(x)| \le |S(x)|$$

for each $x$. To this end observe that

$$S(x) = \bigcup_{x'+x''=x} (A(x') + B(x'')) = \bigcup_{x' \in x - B_1} A(x') + B_2,$$

hence

$$|S(x)| \geq \max_{x' \in x - B_1} |A(x') + B_2| \geq \max_{x' \in x - B_1} |A(x')| + v_2.$$

Similarly

$$S'(x) = \bigcup_{x'+x''=x} (A'(x') + B'(x'')) = \bigcup_{x' \in x - B_1} [0, |A(x')| + v_2 - 1],$$

and so

$$|S'(x)| = \max_{x' \in x - B_1} |A(x')| + v_2. \qquad \square$$

Now we continue the proof of the theorem. Decompose $A'$ into layers according to the value of the second component; write

$$A' = \bigcup_{i=0}^{k} L_i \times \{i\},$$

where $k = \max |A(x)|$, $L_i \subset G_1$. Write $|L_i| = m_i$. We have $L_0 \supset L_1 \supset \cdots \supset L_k$, consequently $m_0 \geq m_1 \geq \cdots \geq m_k$.

The set $S'$ is the union of the sets $(L_i + B_1) \times \{i + j\}$, $0 \leq i \leq v_2$. By the above inclusion it is sufficient to consider the $L_i$ with the smallest possible $i$, that is,

$$S' = (L_0 + B_1) \times \{0, 1, \ldots, v_2\} \cup \bigcup_{i=1}^{k} (L_i + B_1) \times \{i + v_2\}.$$

We obtain that

$$|S'| = v_2 |L_0 + B_1| + \sum_{i=0}^{k} |L_i + B_1|. \tag{4.7}$$

To estimate the summands we use the $d - 1$-dimensional impact of $B_1$, and we get

$$|L_i + B_1| \geq \left( m_i^{\frac{1}{d-1}} + v_1^{\frac{1}{d-1}} \right)^{d-1} \geq \frac{m_i}{m_0} \left( m_0^{\frac{1}{d-1}} + v_1^{\frac{1}{d-1}} \right)^{d-1};$$

the second inequality follows from $m_i \leq m_0$. By substituting this into (4.7) and recalling that $\sum m_i = m$ we obtain

$$|S| \geq \left( v_2 + \frac{m}{m_0} \right) \left( m_0^{\frac{1}{d-1}} + v_1^{\frac{1}{d-1}} \right)^{d-1}. \tag{4.8}$$

Consider the right side as a function of the real variable $m_0$. By differentiating we find that it assumes its minimum at

$$m_0 = v_1^{1/d} (m/v_2)^{1-1/d}.$$

(This minimum typically is not attained; this $m_0$ may be $< 1$ or $> m$, and it is generally not integer). Substituting this value of $m_0$ into (4.8) we obtain the desired bound

$$|S| \geq \left( m^{1/d} + (v_1 v_2)^{1/d} \right)^d. \qquad \square$$

**Problem 4.9.** Does equality always hold in Theorem 4.7?

I expect a negative answer.

**Problem 4.10.** Can Theorem 4.7 be extended to an inequality of the form

$$\mathrm{iv}_{d_1+d_2}(B_1 \times B_2) \geq \mathrm{iv}_{d_1}(B_1)\mathrm{iv}_{d_2}(B_2)?$$

*Proof of Theorem* 4.5. To prove $\geq$ we use induction on $d$. The case $d = 1$ is obvious, and Theorem 4.7 provides the inductive step.

This means that with the cube $B$ defined in (4.4) we have

$$|A + B| \geq \left(|A|^{1/d} + v^{1/d}\right)^d.$$

Equality can occur for infinitely many values of $|A|$, namely it holds whenever $A$ is also a cube of the form

$$A = \{(x_1, \ldots, x_d) \in \mathbb{Z}^d : 0 \leq x_i \leq kn_i - 1\}$$

with some integer $k$; we have $|A| = k^d v$, $|A + B| = (k + 1)^d v$. It may be difficult to describe $\xi_B(m)$ for values of $m$ which are not of the form $k^d v$. Possibly an argument like Gardner and Gronchi's for the simplex may work.

Observe that these special sets $A$ are not homothetic to $B$; in particular, $A = B$ may not yield a case of equality. □

As Theorem 4.3 shows, the impact volume can be $d!$ times smaller than cardinality. The example we have of this phenomenon, the long simplex, is, however, "barely" $d$-dimensional, and I expect that a better estimates hold for a "substantially" $d$-dimensional set.

**Definition 4.11.** The *thickness* $\vartheta(B)$ of a set $B \subset \mathbb{R}^d$ is the smallest integer $k$ with the property that there is a hyperplane $P$ of $\mathbb{R}^d$ and $x_1, \ldots, x_k \in \mathbb{R}^d$ such that $B \subset \bigcup_{i=1}^k P + x_j$.

**Conjecture 4.12.** For every $\varepsilon > 0$ and $d$ there is a $k$ such that for every $B \subset \mathbb{R}^d$ with $\vartheta(B) > k$ we have $\mathrm{iv}_d(B) > (1 - \varepsilon)|B|$.

This conjecture would yield a discrete Brunn–Minkowski inequality of the form

$$|A + B|^{1/d} \geq |A|^{1/d} + (1 - \varepsilon)|B|^{1/d}$$

assuming a bound on the thickness of $B$. Such an inequality is true at least in the special case $A = B$. This can be deduced from a result of Freiman ( [3], Lemma 2.12; see also Bilu [1]), which sounds as follows. If $A \subset \mathbb{R}^d$ and $|2A| < (2^d - \varepsilon)|A|$, then there is a hyperplane $P$ such that $|P \cap A| > \delta|A|$, with $\delta = \delta(d, \varepsilon) > 0$.

## 5. Meditation on the continuous case

Let $A, B$ be Borel sets in $\mathbb{R}^d$. The Brunn–Minkowski inequality (1.2) estimates $\mu(A+B)$ in a natural way, with equality if $A$ and $B$ are homothetic convex sets.

Like in the discrete case, we can define the *impact function* of the set $B$ by

$$\xi_B(a) = \inf\{\mu(A+B) : \mu(A) = a\}.$$

Thus (1.2) is equivalent to

$$\xi_B(a) \geq \left(a^{1/d} + \mu(B)^{1/d}\right)^d,$$

and this is the best possible estimate in terms of $\mu(B)$ only.

To measure the degree of nonconvexity we propose to use the measure of the convex hull beside the measure of the set. This is analogous to the hull volume, and it is sufficient to describe the asymptotic behaviour of $\xi$.

**Theorem 5.1** ([13], Theorem 1.). *For every bounded Borel set $B \subset \mathbb{R}^d$ of positive measure we have*

$$\lim_{a\to\infty} \xi_B(a)^{1/d} - a^{1/d} = \mu(\operatorname{conv} B)^{1/d}.$$

This is the continuous analogue of Theorem 3.6, and there is an analogue to the effective version Theorem 3.8 as well.

Note that by considering sets homothetic to conv $B$ we immediately obtain

$$\xi_B(a)^{1/d} \leq a^{1/d} + \mu(\operatorname{conv} B)^{1/d},$$

thus we need only to give a lower estimate. This is as follows.

**Theorem 5.2** ([13], Theorem 2.). *Let $\mu(B) = b$, $\mu(\operatorname{conv} B) = v$. We have*

$$\xi_B(a)^{1/d} \geq a^{1/d} + v^{1/d}\left(1 - c(v/b)^{1/2}(v/a)^{1/(2d)}\right)$$

$$\xi_B(a) \geq a + dv^{1/d}a^{1-1/d}\left(1 - c(v/b)^{1/2}(v/a)^{1/(2d)}\right)$$

*with a suitable positive constant $c$ depending on $d$.*

If $v > b$, we get a nontrivial improvement over the Brunn–Minkowski inequality for $a > a_0(b, v)$. It would be desirable to find an improvement also for small values of $a$, or, even more, to find the best estimate in terms of $\mu(B)$ and $\mu(\operatorname{conv} B)$.

The exact bound and the structure of the extremal set may be complicated. This is already so in the case $d = 1$, which was solved in [10]. Observe that in one dimension $\mu(\operatorname{conv} B)$ is the diameter of $B$.

**Theorem 5.3** ([10], Theorem 2). *Let $B \subset \mathbb{R}$, and write $\mu(B) = b$, $\mu(\operatorname{conv} B) = v$. If*

$$a \geq \frac{v(v-b)}{2b} + \frac{b\{v/b\}(1-\{v/b\})}{2}, \tag{5.1}$$

*then* $\xi_B(a) = a + v$. *If* (5.1) *does not hold, then let* $k$ *be the unique positive integer satisfying*

$$\frac{k(k-1)}{2} \le \frac{a}{b} < \frac{k(k+1)}{2}$$

*and define* $\delta$ *by*

$$\frac{a}{b} = \frac{k(k-1)}{2} + \delta k.$$

*We have*

$$\xi_B(a) \ge a + (k+\delta)b,$$

*and equality holds if* $B = [0, b] \cup \{v\}$.

A set $A$ such that $\xi_B(a) = \mu(A + B)$ for the above set $B$ is given by

$$A = [0, (k-1+\delta)b] \cup [v, v + (k-2+\delta)b] \cup \cdots \cup [(k-1)v, (k-1)v + \delta b].$$

A less exact, but simple and still quite good lower bound sounds as follows.

**Corollary 5.4** ([10], Theorem 1). *Let* $B \subset \mathbb{R}$, *and write* $\mu(B) = b$, $\mu(\operatorname{conv} B) = v$. *We have*

$$\xi_B(a) \ge \min\bigl(a + v, (\sqrt{a} + \sqrt{b/2})^2\bigr).$$

A comparison with the 2-dimensional Brunn–Minkowski inequality gives the following interpretation: initially a long one-dimensional set $B$ tries to behave as if it were a two-dimensional set of area $b/2$.

It can be observed that (5.4) is weaker than the obvious inequality

$$\mu(A + B) \ge \mu(A) + \mu(B) \tag{5.2}$$

for small $a$. For small values of $a$ Theorem 5.3 yields the following improvement of (5.2).

**Corollary 5.5** ([10], Corollary 3.1). *If* $a \le b$, *then we have*

$$\mu(A + B) \ge \min(2a + b, a + v).$$

*If* $b < a \le 3b$, *then we have*

$$\mu(A + B) \ge \min\left(\frac{3}{2}(a + b), a + v\right).$$

**Problem 5.6.** How large must $\mu(A+B)$ be if $\mu(A)$, $\mu(B)$, $\mu(\operatorname{conv} A)$ and $\mu(\operatorname{conv} B)$ are given?

What are the minima of $\mu(A + A)$ and $\mu(A - A)$ for fixed $\mu(A)$ and $\mu(\operatorname{conv} A)$?

The results above show that for $d = 1$ (like in the discrete case, but for less obvious reasons) the limit relation becomes an equality for $a > a_0$. Again, this is no longer the case for $d = 2$.

An example of a set $B \subset \mathbb{R}^2$ such that

$$\xi_B(a)^{1/2} < a^{1/2} + v^{1/2}$$

will hold for certain arbitrarily large values of $a$ is as follows.

Let $0 < c < 1$ and let $B$ consist of the square $[0, c] \times [0, c]$ and the points $(0, 1)$, $(1, 0)$ and $(1, 1)$. Hence $b = c^2$ and $v = 1$.

For an integer $n \geq 1$ put

$$A_n = [0, n] \times [0, n] \cup \bigcup_{j=0}^{n} [j, j + c] \times [n, n + c] \cup \bigcup_{j=0}^{n-1} [n, n + c] \times [j, j + c].$$

Thus $A_n$ consists of a square of side $n$ and $2n + 1$ small squares of side $c$, hence

$$\mu(A_n) = n^2 + (2n + 1)b.$$

We can easily see that $A_n + B = A_{n+1}$. Hence by considering the set $A = A_n$ we see that for a number $a$ of the form $a = n^2 + (2n + 1)b$ we have

$$\xi_B(a) \leq \mu(A_{n+1}) = (n + 1)^2 + (2n + 3)b < \left(\sqrt{a} + 1\right)^2.$$

A more detailed calculation leads to

$$\xi_B(a)^{1/2} \leq a^{1/2} + 1 - ca^{-1}$$

(for these special values of $a$).

If we tried to define an impact volume in the continuous case, we would recover the volume, at least for compact sets. Still, the above results and questions suggest that ordinary volume is not the best tool to understand additive properties. Perhaps one could try to modify the definition of impact volume by requiring $\mu(A) \geq \mu(B)$. So put

$$\mathrm{iv}_*(B) = \inf_{a \geq \mu(B)} \left(\xi_B(a)^{1/d} - a^{1/d}\right)^d.$$

**Problem 5.7.** Find a lower estimate for $\mathrm{iv}_*(B)$ in terms of $\mu(B)$ and $\mu(\mathrm{conv}\, B)$.

## 6. Back to one dimension

The results in the previous section, Theorem 5.3 and Corollaries 5.4 and 5.5 show that one can have nontrivial results in the seemingly uninteresting one-dimensional case. We now try to do the same, and will find bounds on $|A + B|$ using the cardinality and

hull volume of $B$. Observe that in one dimension the hull volume is the smallest $l$ such that $B$ is contained in an arithmetic progression $\{b, b+q, \dots, b+lq\}$: the *reduced diameter* of $B$.

It is possible to give bounds using nothing else than the hull volume.

**Theorem 6.1.** *Let $B$ be a one-dimensional set in a torsionfree commutative group,* $\mathrm{hv}\, B = v \geq 3$.

(a) *For*
$$m > \frac{(v-1)(v-2)}{2}$$
*we have $\xi_B(m) = m + v$.*

(b) *If*
$$\frac{(k-1)(k-2)}{2} < m \leq \frac{k(k-1)}{2}$$
*with some integer $2 \leq k < v$, then $\xi_B(m) \geq m + k$. Equality holds for the set $B = \{0, 1, v\} \subset \mathbb{Z}$.*

For $v \leq 2$ we have obviously $\xi_B(m) = m + v$ for all $m$ (such a set cannot be anything else than a $v+1$-term arithmetic progression).

This will be deduced from the following result, where the cardinality of $B$ is also taken into account.

**Theorem 6.2.** *Let $B$ be a one-dimensional set in a torsionfree commutative group,* $\mathrm{hv}\, B = v \geq 3$, $|B| = n$. *Define $w$ by*
$$w = \min_{d|v,\, d \leq n-2} d\left\lceil \frac{n-2}{d} \right\rceil. \tag{6.1}$$

*For every $m$ we have*
$$\xi_B(m) \geq m + \min\left(v, \frac{w}{2} + \min_{t \in \mathbb{N}} \left(\frac{m}{t} + \frac{tw}{2}\right)\right). \tag{6.2}$$

The minimum is attained either at the floor or at the ceiling of $\sqrt{2m/w}$. Unlike the previous theorem, typically we do not have examples of equality, and the extremal value and the structure of extremal sets is probably complicated. Also the value of $w$ depends on divisibility properties of $v$ and $n$. After the proof we give a less exact but simpler corollary.

*Proof.* By Lemma 3.1 we may assume that $B \subset \mathbb{Z}$, its smallest element is 0 and it generates $\mathbb{Z}$; then its largest element is just $v$.

**Lemma 6.3.** *Let $B'$ be the set of residues of elements of $B$ modulo $v$. For every nonempty $X \subset \mathbb{Z}_v$ we have*
$$|X + B'| \geq \min(|X| + w, v). \tag{6.3}$$

*Proof.* By Kneser's theorem we have

$$|X + B'| \geq |X + H| + |B' + H| - |H|$$

with some subgroup $H$ of the additive group $\mathbb{Z}_v$. Write $|H| = d$; clearly $d|v$. If $d = v$, we have $|X + H| = v$ and we are ready. Assume $d < v$. $B'$ contains 0 and it generates $\mathbb{Z}_v$, hence it cannot be contained in $H$ so we have $|B' + H| \geq 2|H| = 2d$. This gives the desired bound if $d > n - 2$. Assume $d \leq n - 2$. Since $|B' + H|$ is a multiple of $d$ and it is at least $|B'| = n - 1$, we obtain

$$|B' + H| \geq d \left\lceil \frac{n-1}{d} \right\rceil = d\left(1 + \left\lceil \frac{n-2}{d} \right\rceil\right) \geq d + w. \qquad \square$$

We resume the proof of Theorem 6.2. Take a set $A \subset \mathbb{Z}$, $|A| = m$. We are going to estimate $|A + B|$ from below.

For $j \in \mathbb{Z}_v$ let $u(j)$ be the number of integers $a \in A$, $a \equiv j \pmod{v}$ and let $U(j)$ be the corresponding number for the sumset $A + B$. We have

$$U(j) \geq u(j) + 1 \tag{6.4}$$

whenever $U(j) > 0$; this follows by adding the numbers $0, v$ to each element of $A$ in this residue class if $u(j) > 0$, and holds obviously for $u(j) = 0$. We also have

$$U(j) \geq u(j - b) \tag{6.5}$$

for every $b \in B'$. Write

$$r(k) = \{j : u(j) \geq k\},$$

$$R(k) = \{j : U(j) \geq k\}.$$

Inequality (6.4) implies

$$R(k) \supset r(k - 1) \quad (k \geq 2), \tag{6.6}$$

and inequality (6.5) implies

$$R(k) \supset r(k) + B' \quad (k \geq 1). \tag{6.7}$$

*First case.* $U(j) > 0$ for all $j$. In this case by summing (6.4) we get

$$|A + B| = \sum U(j) \geq v + \sum u(j) = |A| + v.$$

*Second case.* There is a $j$ with $U(j) = 0$. Then we have $|R(k)| < v$ for every $k > 0$. An application of Lemma 6.3 to the sets $r(k)$ yields, in view of (6.7),

$$|R(k)| \geq |r(k)| + w \tag{6.8}$$

as long as $r(k) \neq \emptyset$. Let $t$ be the largest integer with $r(t) \neq \emptyset$. We have (6.8) for $1 \leq k \leq t$, and (6.6) yields

$$|R(k)| \geq |r(k-1)| \tag{6.9}$$

for all $k \geq 2$. Consequently for $1 \leq k \leq t+1$ we have

$$|R(k)| \geq \frac{k-1}{t}|r(k-1)| + \left(1 - \frac{k-1}{t}\right)(|r(k)| + w). \tag{6.10}$$

Indeed, for $k = 1$ (6.10) is identical with (6.8), for $k = t+1$ it is identical with (6.9) and for $2 \leq k \leq t$ it is a linear combination of the two.

By summing (6.10) we obtain

$$\begin{aligned} |A+B| &= \sum_{k\geq 1} |R(k)| \geq \sum_{k=1}^{t+1} |R(k)| \geq \frac{t+1}{2}w + \left(1 + \frac{1}{t}\right)\sum_{k=1}^{t} |r(k)| \\ &= \frac{t+1}{2}w + \left(1 + \frac{1}{t}\right)|A|, \end{aligned}$$

as claimed in (6.2). □

**Corollary 6.4.** *With the assumptions and notations of Theorem* 6.2 *we have*

$$\xi_B(m) \geq \min\left(m + v, \left(\sqrt{m} + \sqrt{w/2}\right)^2\right). \tag{6.11}$$

*Proof.* This follows from (6.2) and the inequality of arithmetic and geometric means. □

This can be interpreted as that the set tries to imitate a two-dimensional set of area $w/2$.

*Proof of Theorem* 6.1. Parts (a)–(b) of the theorem can be reformulated as follows: if $\xi_B(n) \leq m + k$ with some $k < v$, then $m \leq k(k-1)/2$. Theorem 6.2 yields (using only that $w \geq 1$) the existence of a positive integer $t$ such that

$$\frac{m}{t} + \frac{t+1}{2} \leq k,$$

hence

$$m \leq kt + \frac{t(t+1)}{2}.$$

The right side, as a function of $t$, is increasing up to $k - 1/2$ and decreasing afterwards; the minimal values at integers are assumed at $t = k-1$ and $k$, and both are equal to $k(k-1)/2$.

To show the case of equality in case (b), write $m = k(k-1)/2 - l$ with $0 \leq l \leq k-2$. The set $A$ will contain the integers in the intervals $[iv, iv + k - 3 - i]$ for $0 \leq i \leq l-1$ and $[iv, iv + k - 2 - i]$ for $l \leq i \leq k-2$. □

We illustrate the strength of Theorem 6.2 by deducing from it the two-dimensional estimate

$$\xi_L(m) > \left(\sqrt{m} + \sqrt{(n-2)/2}\right)^2$$

for the long triangle $L = L_{2n}$. Indeed, a suitable linear mapping maps this set $L$ onto the set $B = \{0, 1, \dots, n-2, v\}$ with arbitrary $v$. If we choose $v$ to be prime, then in (6.1) we have $w = n-2$, and if $v$ is so large that $m + l > \left(\sqrt{m} + \sqrt{w}\right)^2$, then from Corollary 6.4 we obtain

$$\xi_L(m) \geq \xi_B(m) \geq \left(\sqrt{m} + \sqrt{w/2}\right)^2.$$

This is essentially the two-dimensional case of Theorem 2.6 of Gardner and Gronchi.

On the other hand, for small values of $m$ this inequality is weak, can even be worse than the obvious bound $|A + B| \geq |A| + |B| - 1$. There are results that are especially suited to the study of small values; we quote two of them. In both let $A, B \subset \mathbb{Z}$, $A = \{a_1, \dots, a_m\}$, $B = \{b_1, \dots, b_n\}$ with $0 = a_1 < \cdots < a_m = u$, $0 = b_1 < \cdots < b_n = v$.

**Theorem 6.5** (Freiman [2]). *If* $\gcd(a_1, \dots, a_m, b_1, \dots, b_n) = 1$ *and* $u \leq v$, *then*

$$|A + B| \geq \min(m + v, m + n + \min(m, n) - 3).$$

This bears a remarkable similarity to the two-dimensional case of Theorem 1.2 (and it can be deduced like Theorem 2.6)

**Theorem 6.6** (Lev and Smelianski [7]). *If* $\gcd(b_1, \dots, b_n) = 1$ *and* $u \leq v$, *then*

$$|A + B| \geq \min(m + v, n + 2m - \delta),$$

*where* $\delta = 3$ *if* $u = v$ *and* $\delta = 2$ *if* $u < v$.

Observe that the above theorems cannot be directly compared to ours because of the somewhat different structure of the assumptions.

**Problem 6.7.** Find a common generalization of Theorems 6.2 and 6.6.

# Geometric bistellar flips: the setting, the context and a construction

Francisco Santos *

**Abstract.** We give a self-contained introduction to the theory of secondary polytopes and geometric bistellar flips in triangulations of polytopes and point sets, as well as a review of some of the known results and connections to algebraic geometry, topological combinatorics, and other areas.

As a new result, we announce the construction of a point set in general position with a disconnected space of triangulations. This shows, for the first time, that the poset of strict polyhedral subdivisions of a point set is not always connected.

**Mathematics Subject Classification (2000).** Primary 52B11; Secondary 52B20.

**Keywords.** Triangulation, point configuration, bistellar flip, polyhedral subdivision, disconnected flip-graph.

## Introduction

Geometric bistellar flips are "elementary moves", that is, minimal changes, between triangulations of a point set in affine space $\mathbb{R}^d$. In their present form they were introduced around 1990 by Gel'fand, Kapranov and Zelevinskii during their study of discriminants and resultants for sparse polynomials [28], [29]. Not surprisingly, then, these bistellar flips have several connections to algebraic geometry. For example, the author's previous constructions of point sets with a disconnected graph of triangulations in dimensions five and six [64], [67] imply that certain algebraic schemes considered in the literature [4], [13], [33], [57], including the so-called toric Hilbert scheme, are sometimes not connected.

Triangulations of point sets play also an obvious role in applied areas such as computational geometry or computer aided geometric design, where a region of the plane or 3-space is triangulated in order to approximate a surface, answer proximity or visibility questions, etc. See, for example, the survey articles [8], [10], or [25]. In these fields, flips between triangulations have also been considered since long [40]. Among other things, they are used as the basic step to compute an optimal triangulation of a point set incrementally, that is, adding the points one by one. This *incremental flipping algorithm* is the one usually preferred for, for example, computing the Delaunay

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

triangulation, as "the most intuitive and easy to implement" [8], and yet as efficient as any other.

In both the applied and the theoretical framework, the situation is the same: a fixed set of points $\mathcal{A} \subset \mathbb{R}^d$ is given to us (the "sites" for a Delaunay triangulation computation, the test points for a surface reconstruction, or a set of monomials, represented as points in $\mathbb{Z}^d$, in the algebro-geometric context) and we need to either explore the collection of all possible triangulations of this set $\mathcal{A}$ or search for a particular one that satisfies certain optimality properties. Geometric bistellar flips are the natural way to do this. For this reason, it was considered one of the main open questions in polytope theory ten years ago whether point sets exist with triangulations that cannot be connected via these flips [80]. As we have mentioned above, this question was answered positively by the author of this paper, starting in dimension five. The question is still open in dimensions three and four.

This paper intends to be an introduction to this topic, organized in three parts.

The first section is a self-contained introduction to the theory of geometric bistellar flips and *secondary polytopes* in triangulations of point sets, aimed at the non-expert. The results in it are certainly not new (most come from the original work of Gel'fand, Kapranov and Zelevinskii mentioned above) but the author wants to think that this section has some expository novelty; several examples that illustrate the theory are given, and our introduction of geometric bistellar flips first as certain polyhedral subdivisions and only afterwards as transformations between triangulations is designed to show that the definition is as natural as can be. This section finishes with an account of the state-of-the-art regarding knowledge of the graph of flips for sets with "few" points or "small" dimension, with an emphasis on the differences between dimensions two and three.

The second section develops in more detail the two contexts in which we have mentioned that flips are interesting (*computational geometry* and *algebraic geometry*) together with other two, that we call "*combinatorial topology*" and "*topological combinatorics*". Combinatorial topology refers to the study of topological manifolds via triangulations of them. Bistellar flips have been proposed as a tool for manifold recognition [18], [46], and triangulations of the 3-sphere without bistellar flips other than "insertion of new vertices" are known [24]. Topological combinatorics refers to topological methods in combinatorics, particularly to the topology of *partially ordered sets* (posets) via their order complexes. The graph of triangulations of a point set $\mathcal{A}$ consists of the first two levels in the poset of polyhedral subdivisions of $\mathcal{A}$, which in turn is just an instance of several similar posets studied in combinatorics with motivations and applications ranging from oriented matroid theory to bundle theories in differential geometry.

The third section announces for the first time the construction of a point set *in general position* whose graph of triangulations is not connected. The details of the proof appear in [68]. The point set is also the smallest one known so far to have a disconnected graph of flips.

**Theorem.** *There is a set of* 17 *points in general position in* $\mathbb{R}^6$ *whose graph of triangulations is not connected.*

As usual in geometric combinatorics, a finite point set $\mathcal{A} \subset \mathbb{R}^d$ is said to be *in general position* if no $d+2$ of the points lie in an affine hyperplane. Equivalently, if none of the $\binom{|\mathcal{A}|}{d+1}$ determinants defined by the point set vanish. Point sets in general position form an open dense subset in the space $\mathbb{R}^{n\times d}$ of sets of dimension $d$ with $n$ elements. That is to say, "random point sets" are in general position. Point sets that are not in general position are said to be *in special position*.

The connectivity question has received special attention in general position even before disconnected examples in special position were found. For example, Challenge 3 in [80] and Problem 28 in [50] specifically ask whether disconnected graphs of flips exist for point sets in special position (the latter asks this only for dimension 3). Although it was clear (at least to the author of this paper) from the previous examples of disconnected graphs of flips that examples in general position should also exist, modifying those particular examples to general position and proving that their flip-graphs are still not connected is not an easy task for quite intrinsic reasons: the proofs of non-connectednes in [64], [67] are based on the fact that the point sets considered there are cartesian products of lower dimensional ones.

In our opinion, an example of a disconnected graph of flips in general position is interesting for the following three reasons:

1. The definition of flip that is most common in computational geometry coincides with ours (which is the standard one in algebraic geometry and polytope combinatorics) only for point sets in general position. In special position, the computational geometric definition is far more restrictive and, in particular, taking it makes disconnected graphs of flips in special position be "no surprise". For example, Edelsbrunner [25] says that the flip-graph among the (three) triangulations of a regular octahedron is not connected; see Section 2.1.
2. Leaving aside the question of definition, in engineering applications the coordinates of points are usually approximate and there is no loss in perturbing them into general position. That is, the general position case is sometimes the only case.
3. Even in a purely theoretical framework, point sets in general position have somehow simpler properties than those in special position. If a point set $\mathcal{A}$ in special position has a non-connected graph of flips then automatically some subset of $\mathcal{A}$ (perhaps $\mathcal{A}$ itself) has a disconnected poset of subdivisions. This poset is sometimes called the *Baues poset* of $\mathcal{A}$ and its study is (part of) the so-called generalized Baues problem. See Section 2.3, or [61] for more precise information on this. In particular, the present example is the first one (proven) to have a disconnected Baues poset.

**Corollary.** *There is a set of at most* 17 *points in* $\mathbb{R}^6$ *whose poset of proper polyhedral subdivisions is not connected.*

# 1. The setting

## 1.1. Triangulations. Regular triangulations and subdivisions

**Triangulations and polyhedral subdivisions.** A (convex) *polytope* $P$ is the convex hull of a finite set of points in the affine space $\mathbb{R}^d$. A *face* of $P$ is its intersection with any hyperplane that does not cross the relative interior of $P$. (Here, the *relative interior* of $S \subseteq \mathbb{R}^d$ is the interior of $S$ regarded as a subset of its affine span). We remind the reader that the faces of dimensions $0$, $1$, $d-2$ and $d-1$ of a $d$-polytope are called vertices, edges, ridges and facets, respectively. Vertices of $P$ form the minimal $S$ such that $P = \text{conv}(S)$.

A $k$-simplex is a polytope whose vertices (necessarily $k+1$) are affinely independent. It has $\binom{k+1}{i+1}$ faces of each dimension $i = 0, \ldots, k$, which are all simplices.

**Definition 1.1.** Let $\mathcal{A}$ be a finite point set in $\mathbb{R}^d$. A *triangulation* of $\mathcal{A}$ is any collection $T$ of affinely spanning and affinely independent subsets of $\mathcal{A}$ with the following properties:

1. if $\sigma$ and $\sigma'$ are in $T$, then $\text{conv}(\sigma) \cap \text{conv}(\sigma')$ is a face of both $\text{conv}(\sigma)$ and $\text{conv}(\sigma')$. That is, $T$ induces a geometric simplicial complex in $\mathbb{R}^k$;
2. $\bigcup_{\sigma \in T} \text{conv}(\sigma) = \text{conv}(\mathcal{A})$. That is, $T$ covers the convex hull of $\mathcal{A}$.

Note that our definition allows for some points of $\mathcal{A}$ not to be used at all in a particular triangulation. Extremal points (vertices of $\text{conv}(\mathcal{A})$) are used in every triangulation. The elements of a triangulation $T$ are called *cells*.

We can define *polyhedral subdivisions* of $\mathcal{A}$ by removing the requirement of the sets $\sigma$ to be affinely independent in Definition 1.1. Since a general subset $\sigma$ of $\mathcal{A}$ may contain points which are not vertices of $\text{conv}(\sigma)$, now the fact that the elements of a subdivision are subsets of $\mathcal{A}$ rather than "subpolytopes" is not just a formality: points which are not vertices of any "cell" in the subdivision may still be considered "used" as elements of some cells. In order to get a nicer concept of polyhedral subdivision, we also modify part 1 in Definition 1.1, adding the following (redundant for affinely independent sets) condition:

$$\text{conv}(\sigma \cap \sigma') \cap \sigma = \text{conv}(\sigma \cap \sigma') \cap \sigma' \quad \text{for all } \sigma, \sigma' \in T.$$

That is, if $\mathcal{A}$ contains some point in the common face $\text{conv}(\sigma \cap \sigma')$ of $\text{conv}(\sigma)$ and $\text{conv}(\sigma')$ but not a vertex of it, that point is either in both or in none of $\sigma$ and $\sigma'$.

Polyhedral subdivisions of $\mathcal{A}$ form a *partially ordered set* (or *poset*) with respect to the following refinement relation:

$$S \text{ refines } S' \ :\Leftrightarrow \ \text{for all } \sigma' \in S' \text{ there exists } \sigma \in S \text{ such that } \sigma \subseteq \sigma'.$$

Triangulations are, of course, the minimal elements in this poset. The poset has a unique maximal element, namely the *trivial suvdivision* $\{\mathcal{A}\}$.

**Example 1.2.** Let $\mathcal{A}$ be the following set of five points $a_1, \ldots, a_5$ in the plane. We take the convention that points are displayed as columns in a matrix, and that an extra homogenization coordinate (the row of 1's in the following matrix) is added so that linear algebra, rather than affine geometry, can be used for computations:

$$\mathcal{A} = \begin{array}{c} \begin{array}{ccccc} a_1 & a_2 & a_3 & a_4 & a_5 \end{array} \\ \begin{pmatrix} 0 & 3 & 0 & 3 & 1 \\ 0 & 0 & 3 & 3 & 1 \\ 1 & 1 & 1 & 1 & 1 \end{pmatrix} \end{array} \tag{1}$$

The following are the nine polyhedral subdivisions of $\mathcal{A}$. Arrows represent the refinement relation, pointing from the coarser to the finer subdivision. For clarity, we write "125" meaning $\{a_1, a_2, a_5\}$, and so on. Figure 1 shows pictures of the subdivisions. In the corners are the four triangulations of $\mathcal{A}$ and in the middle is the trivial subdivision.

$$\begin{array}{ccccc} \{125, 135, 235, 234\} & \leftarrow & \{1235, 234\} & \rightarrow & \{135, 234\} \\ \uparrow & & \uparrow & & \uparrow \\ \{125, 135, 2345\} & \leftarrow & \{12345\} & \rightarrow & \{1234\} \\ \downarrow & & \downarrow & & \downarrow \\ \{125, 135, 245, 345\} & \leftarrow & \{1245, 1345\} & \rightarrow & \{124, 134\} \end{array}$$

The last two columns of subdivisions geometrically induce the same decomposition

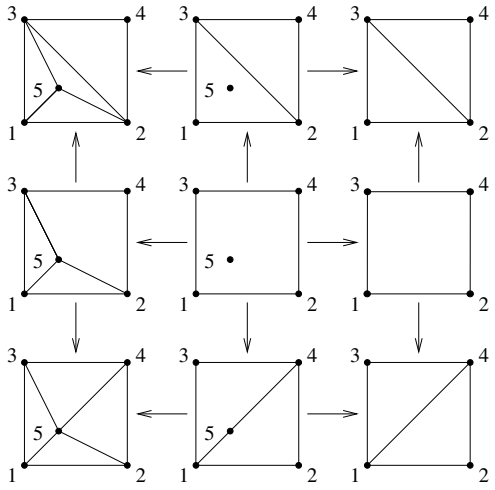

Figure 1. The nine polyhedral subdivisions of a certain point set.

of conv($\mathcal{A}$) into subpolygons. Still, we consider them different subdivisions since the middle column "uses" the interior point 5 while the right column does not.

**Regular subdivisions.** Let a point set $\mathcal{A}$ be given, and choose a function $w\colon \mathcal{A} \to \mathbb{R}$ to lift $\mathcal{A}$ to $\mathbb{R}^{d+1}$ as the point set

$$\mathcal{A}_w := \{(a, w(a) : a \in \mathcal{A}\}.$$

A *lower facet* of $\operatorname{conv}(\mathcal{A}_w)$ is a facet whose supporting hyperplane lies below the interior of $\operatorname{conv}(\mathcal{A}_w)$. The following is a polyhedral subdivision of $\mathcal{A}$, where $\pi : \mathbb{R}^{d+1} \to \mathbb{R}^d$ is the projection that forgets the last coordinate:

$$T_w := \{\pi(F \cap \mathcal{A}_w) : F \text{ is a lower facet of } \operatorname{conv}(\mathcal{A}_w)\}.$$

Geometrically, we are projecting down onto $\mathcal{A}$ the lower envelope of $\mathcal{A}_w$, keeping track of points that lie in the lower boundary even if they are not vertices of a facet.

**Definition 1.3.** The polyhedral subdivisions and triangulations that can be obtained in this way are called *regular*.

If $w$ is sufficiently generic then $T_w$ is clearly a triangulation. Regular triangulations are particularly simple and yet quite versatile. They appear in different contexts under different names such as *coherent* [29], *convex* [36], [77], *Gale* [49], or *generalized* (*or, weighted*) *Delaunay* [25] triangulations. The latter refers to the fact that the Delaunay triangulation of $\mathcal{A}$, probably the most used triangulation in applications, is the regular triangulation obtained with $w(a) = \|a\|^2$, where $\|\cdot\|$ is the euclidean norm.

**Example 1.4.** Let

$$\mathcal{A} = \begin{array}{c} \begin{matrix} a_1 & a_2 & a_3 & a_4 & a_5 & a_6 \end{matrix} \\ \begin{pmatrix} 4 & 0 & 0 & 2 & 1 & 1 \\ 0 & 4 & 0 & 1 & 2 & 1 \\ 0 & 0 & 4 & 1 & 1 & 2 \end{pmatrix} \end{array}.$$

This is a configuration of six points in the affine plane with equation $x_1 + x_2 + x_3 = 4$ in $\mathbb{R}^3$. Since the matrix is already homogeneous (meaning precisely that columns lie in an affine hyperplane) we do not need the extra homogenization row. The configuration consists of two parallel equilateral triangles, one inside the other. We leave it to the reader to check that the following are two non-regular triangulations (see Figure 2):

$$T_1 := \{124, 235, 136, 245, 356, 146, 456\},$$
$$T_2 := \{125, 236, 134, 145, 256, 346, 456\}.$$

This example is the smallest possible, since 1-dimensional point configurations and point configurations with at most $d + 3$ points in any dimension $d$ only have regular triangulations. The former is easy to prove and the latter was first shown in [44]. The earliest appearance of these two non-regular triangulations that we know of is in [20], although they are closely related to Schönhardt's classical example of a non-convex 3-polytope that cannot be triangulated [69].[1]

[1] We describe Schönhardt's polyhedron and its relation to this example in Example 1.21.

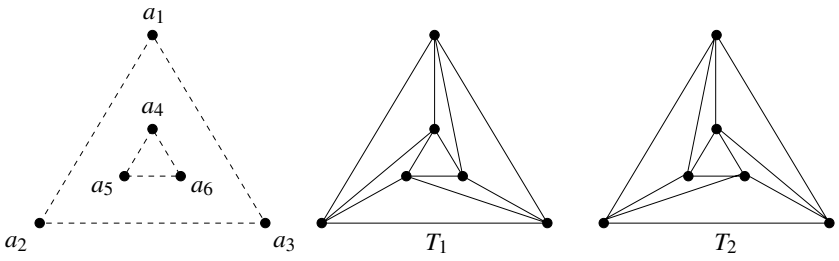

Figure 2. A point configuration with two non-regular triangulations.

**Remark 1.5.** Suppose that two point sets $\mathcal{A} = \{a_1, \ldots, a_n\}$ and $\mathcal{B} = \{b_1, \ldots, b_n\}$ have the same *oriented matroid* [17], or *order type*. This means that for every subset $I \subset \{1, \ldots, n\}$ of labels, the determinants of the point sets $\{a_i : i \in I\}$ and $\{b_i : i \in I\}$ have the same sign.[2] It is an easy exercise to check that then $\mathcal{A}$ and $\mathcal{B}$ have *the same* triangulations and subdivisions.[3] However, they do not necessarily have the same *regular* subdivisions. For example, the points of example 1.4 are in general position and, hence, their oriented matroid does not change by a small perturbation of coordinates. But any sufficiently generic perturbation makes one of the two non-regular triangulations $T_1$ and $T_2$ become regular.

Still, the following is true [65]: the *existence* of non-regular triangulations of $\mathcal{A}$ depends only on the oriented matroid of $\mathcal{A}$.

**The secondary polytope.** Let $L_{\mathcal{A}}$ denote the space of all lifting functions $w : \mathcal{A} \to \mathbb{R}$ on a certain point set $\mathcal{A} \subset \mathbb{R}^d$ with $n$ elements. In principle $L_{\mathcal{A}}$ is isomorphic to $\mathbb{R}^n$ in an obvious way; but we mod-out functions that lift all of $\mathcal{A}$ to a hyperplane, because adding one of them to a given lifting function $w$ does not (combinatorially) change the lower envelope of $\mathcal{A}_w$. We call these particular lifting functions *affine*. They form a linear subspace of dimension $d+1$ of $\mathbb{R}^n$. Hence, after we mod-out affine functions we have $L_{\mathcal{A}} \cong \mathbb{R}^{n-d-1}$.

For a given polyhedral subdivision $T$ of $\mathcal{A}$, the subset of $L_{\mathcal{A}}$ consisting of functions $w$ that produce $T = T_w$, is a (relatively open) polyhedral cone; that is, it is defined by a finite set of linear homogeneous equalities and strict inequalities. Equalities appear only if $T$ is not a triangulation and express the fact that if $\sigma \in T$ is not affinely independent then $w$ must lift all $\sigma$ to lie in a hyperplane. Inequalities express the fact that for each $\sigma \in T$ and point $a \in \mathcal{A} \setminus \sigma$, $a$ is lifted above the hyperplane spanned by the lifting of $\sigma$.

The polyhedral cones obtained for different choices of $T$ are glued together forming a polyhedral fan, that is, a "cone over a polyhedral complex", called the *secondary fan* of $\mathcal{A}$. The prototypical example of a fan is the normal fan of a polytope, whose

[2] Observe that the bijection between $\mathcal{A}$ and $\mathcal{B}$ implicit by the labels is part of the definition.

[3] More precisely, the implicit bijection between $\mathcal{A}$ and $\mathcal{B}$ induces a bijection between their polyhedral subdivisions.

cones are the exterior normal cones of different faces of $P$. A seminal result in the theory of triangulations of polytopes is that the secondary fan is actually polytopal; that is, it is the normal fan of a certain polytope:

**Theorem 1.6** (Gel'fand–Kapranov–Zelevinskii [28], [29]). *For every point set $\mathcal{A}$ of $n$ points affinely spanning $\mathbb{R}^d$ there is a polytope $\Sigma(\mathcal{A})$ in $L_{\mathcal{A}} \cong \mathbb{R}^{n-d-1}$ whose normal fan is the secondary fan of $\mathcal{A}$.*

In particular, the poset of regular subdivisions of $\mathcal{A}$ is isomorphic to the poset of faces of $\Sigma(\mathcal{A})$. Vertices correspond to regular triangulations and $\Sigma(\mathcal{A})$ itself (which is, by convention, considered a face) corresponds to the trivial subdivision. The polytope $\Sigma(\mathcal{A})$ is called the *secondary polytope of* $\mathcal{A}$.

There are two standard ways to construct the secondary polytope $\Sigma(\mathcal{A})$ of a point set $\mathcal{A}$.[4] The original one, by Gel'fand, Kapranov and Zelevinskii [28], [29] gives, for each regular triangulation $T$ of $\mathcal{A}$, coordinates of the corresponding vertex $v_T$ of $\Sigma(\mathcal{A})$ in terms of the volumes of simplices incident in $T$ to each point of $\mathcal{A}$.

The second one, by Billera and Sturmfels [14], describes the whole polytope $\sigma(\mathcal{A})$ as the Minkowski integral of the fibers of the affine projection $\pi : \Delta_{\mathcal{A}} \to \text{conv}(\mathcal{A})$, where $\Delta_{\mathcal{A}}$ is a simplex with $|\mathcal{A}|$ vertices (hence, of dimension $|\mathcal{A}| - 1$) and $\pi$ bijects the vertices of $\Delta_{\mathcal{A}}$ to $\mathcal{A}$ (see Theorem 2.8).

**Example 1.7** (Example 1.2 continued). Figure 3 shows the secondary fan of the five points. To mod-out affine functions we have taken $w(a_1) = w(a_2) = w(a_3) = 0$, and the horizontal and vertical coordinates in the figure give the values of $w(a_4)$ and $w(a_5)$, respectively. The triangulation corresponding to each two-dimensional cone is displayed. In this example all nine polyhedral subdivisions are regular (in agreement

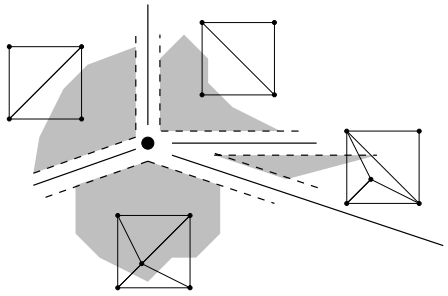

Figure 3. The secondary fan of Example 1.2.

with the result of [44] mentioned in Example 1.4) and the secondary polytope is a quadrilateral.

[4] Polytopality of a fan is equivalent to the feasibility of a certain system of linear equalities and strict inequalities. But here we mean more direct and intrinsic constructions of the secondary polytope.

**Example 1.8** (Example 1.4 continued). The secondary polytope of this point set is 3-dimensional, and contains a hexagonal face corresponding to the regular subdivision

$$\{1245, 2356, 1346, 456\}.$$

This regular subdivision can be refined to a triangulation in eight ways, by independently inserting a diagonal in the quadrilaterals 1245, 2356 and 1346. Six of these triangulations are regular, and correspond to the vertices of the hexagon. The other two, $T_1$ and $T_2$, are non-regular and they "lie" in the center of the hexagon.

We have mentioned that if the point set is perturbed slightly then one of the triangulations becomes regular. What happens in the secondary polytope is the following: the perturbation "inflates" the hexagon so that the eight points (the vertices of the hexagon and the two interior points representing $T_1$ and $T_2$) become, combinatorially, the vertices of a cube. The points corresponding to $T_1$ and $T_2$ move in opposite directions, one of them going to the interior of the secondary polytope and the other becoming a new vertex of it. The hexagonal face gets refined into three quadrilaterals. Of course, the vertices of the hexagon also move in the process, and are no longer coplanar.

**Example 1.9** (The convex $n$-gon and the associahedron). All triangulations of a convex $n$-gon are regular and their number is the $n-2$nd Catalan number

$$C_{n-2} := \frac{1}{n-1}\binom{2n-4}{n-2}.$$

The corresponding secondary polytope is called the *associahedron*. The name comes from the fact that there is a bijection between triangulations of the $n$-gon and the ways to put the $n-2$ parentheses in an associative product of $n-1$ factors.

The associahedron is a classical object in combinatorics, first studied[5] by Stasheff and Tamari [76], [72]. It was shown to be polytopal by Haiman (unpublished) and Lee [43]. That its diameter equals $2n-10$ "for every sufficiently big $n$"[6] was shown by Sleator, Tarjan and Thurston [71], with motivations coming from theoretical computer science and tools from hyperbolic geometry.

**Remark 1.10.** In Sections 2.3 and 2.4 we will mention triangulations of a set of *vectors* rather than *points*. They are defined exactly as triangulations of point sets, just changing the word "affinely" to "linearly" and the operator "conv" to "pos" ("positive span") in Definition 1.1. Put differently, a triangulation of a vector set $\mathcal{A} \subset \mathbb{R}^{d+1}$ is a simplicial fan covering $\mathrm{pos}(\mathcal{A})$ and whose rays are in the positive directions of (not necessarily all) the elements of $\mathcal{A}$. Equivalently, and perhaps closer to readers familiar with classical geometry, we can, without loss of generality, normalize all

[5] As a combinatorial cell complex, without an explicit polytopal realization.

[6] Sleator et al. do not say "how big" is "sufficiently big" in their statement, but conjecture that $n \geq 13$ is enough. We consider this an interesting and somehow shameful open question.

vectors of $\mathcal{A}$ to lie in the unit sphere $S^d$. Then, triangulations of $\mathcal{A}$ are the geodesic triangulations, with vertices contained in $\mathcal{A}$, of the spherical convex hull of $\mathcal{A}$.

The existence and properties of regular subdivisions and secondary fans (and of the bistellar flips introduced in the next section) generalize almost without change to vector configurations.[7]

### 1.2. Geometric bistellar flips

**Flips as polyhedral subdivisions.** In order to introduce the notion of local move (flip) between triangulations of $\mathcal{A}$, we use the secondary fan as a guiding light: whatever our definition is, restricted to regular triangulations a flip should correspond to crossing a "wall" between two full-dimensional cones in the secondary fan; that is, a flip between two regular triangulations $T_1$ and $T_2$ can be regarded as certain regular subdivision $T_0$ with the property that its only two regular refinements are precisely $T_1$ and $T_2$. Some thought will convince the reader that the necessary and sufficient condition for a lifting function $w\colon \mathcal{A} \to \mathbb{R}$ to produce a $T_w$ with this property is that *there is a unique minimal affinely dependent subset in $\mathcal{A}$ whose lifting is contained in some lower facet of the lifted point set $\mathcal{A}_w$*. This leads to the following simple, although perhaps not very practical, definition.

**Definition 1.11.** Let $T$ be a (not-necessarily regular) subdivision of a point set $\mathcal{A}$. We say that $T$ *is a flip* if there is a unique affinely dependent subset $C \in \mathcal{A}$ contained in some cell of $T$.

**Lemma 1.12.** *If $T$ is a flip, then there are exactly two proper refinements of $T$, which are both triangulations.*

*Proof.* Let $T_1$ be a refinement of $T$. Let $C$ be the unique affinely dependent subset of $\mathcal{A}$ contained in some cell of $T$. Each cell of $T$ containing $C$ gets refined in $T_1$, while each cell not containing $C$ is also a cell in $T_1$.

The statement then follows from the understanding of the combinatorics of point sets with a unique affinely dependent subset $C$. Let $S$ be such a point set. Each point in $S \setminus C$ is affinely independent of the rest, so $S$ is an "iterated cone" over $C$. In particular, there is a face $F$ of $S$ such that $S \cap F = C$ and every refinement of $S$ consists of a refinement of $F$ coned to the points of $S \setminus C$. Moreover, all cells of $T$ containing $C$ must have $F$ refined the same way, so that there is a bijection between the refinements of $T$ and the polyhedral subdivisions of $C$, as a point set. The result then follows from the fact (see below) that a minimal affinely dependent set $C$ has exactly three subdivisions: the trivial one and two triangulations. □

[7] Although with one notable difference. For a general vector configuration not every function $w\colon \mathcal{A} \to \mathbb{R}$ produces a lift with a well-defined "lower envelope". Only the functions that do, namely those for which a linear hyperplane exists containing or lying below all the lifted vectors, define a regular polyhedral subdivision. These functions form a cone in $L_{\mathcal{A}}$. The secondary fan is still well-defined but, of course, it cannot be the normal fan of a polytope. It is, however, the normal fan of an unbounded convex polyhedron, called the *secondary polyhedron* of $\mathcal{A}$ [12].

This lemma allows us to understand a flip, even in the non-regular case, as a relation or a transformation between its two refinements. This is the usual usage of the word "flip", and our next topic.

**Flips as elementary changes.** A minimal affinely dependent set $C$ is called a *circuit* in geometric combinatorics. The points in a circuit $C = \{c_1, \ldots, c_k\}$ satisfy a unique (up to a constant) affine dependence equation $\lambda_1 c_1 + \cdots + \lambda_k c_k = 0$ with $\sum \lambda_i = 0$, and all the $\lambda_i$ must be non zero (or otherwise $C$ is not minimally dependent). This affine dependence implicitly decomposes $C$ into two subsets

$$C_+ = \{c_i : \lambda_i > 0\}, \quad C_- = \{c_i : \lambda_i < 0\}.$$

The pair $(C_+, C_-)$ is usually called a *signed* or *oriented* circuit. We will slightly abuse notation and speak of "the circuit $C = (C_+, C_-)$", unless we need to emphasize the distinction between the set $C$ (the *support* of the circuit) and its partition.

A more geometric description is that $(C_+, C_-)$ is the only partition of $C$ into two subsets whose convex hulls intersect, and that they intersect in their relative interiors. This is usually called *Radon's property* [58] and the oriented circuit a *Radon partition*.

Spanning and affinely independent subsets of $C$ are all the sets of the form $C \setminus \{c_i\}$. Moreover, by Radon's property two such sets $C \setminus \{c_i\}$ and $C \setminus \{c_j\}$ can be cells in the same triangulation of $C$ if and only if $c_i$ and $c_j$ lie in the same side of the partition. In other words:

**Lemma 1.13.** *A circuit $C = (C_+, C_-)$ has exactly two triangulations:*

$$T_+^C := \{C \setminus \{c_i\} : c_i \in C_+\}, \quad T_-^C := \{C \setminus \{c_i\} : c_i \in C_-\}.$$

This leads to a second definition of flip, equivalent to Definition 1.11, but more operational. This is the definition originally devised by Gel'fand, Kapranov and Zelevinskii [29]. The *link* of a set $\tau \subseteq \mathcal{A}$ in a triangulation $T$ of $\mathcal{A}$ is defined as

$$\operatorname{link}_T(\tau) := \{\rho \subseteq \mathcal{A} : \rho \cap \tau = \emptyset, \rho \cup \tau \in T\}.$$

**Definition 1.14.** Let $T_1$ be a triangulation of a point set $\mathcal{A}$. Suppose that $T_1$ contains one of the triangulations, say $T_+^C$, of a circuit $C = (C_+, C_-)$. Suppose also that all cells $\tau \in T_+^C$ have the same link in $T_1$, and call it $L$.

Then, we say that $C$ *supports a geometric bistellar flip* (or a *flip*, for short) in $T_1$ and that the following triangulation $T_2$ of $\mathcal{A}$ is obtained from $T_1$ by this flip:

$$T_2 := T_1 \setminus \{\rho \cap \tau : \rho \in L, \tau \in T_+^C\} \cup \{\rho \cap \tau : \rho \in L, \tau \in T_-^C\}.$$

If $i = |C_+|$ and $j = |C_-|$ we say that the flip is of type $(i, j)$. Flips of types $(1, j)$ and $(i, 1)$ are called, *insertion* and *deletion* flips, since they add or remove a vertex in the triangulation.

The *graph of flips* of $\mathcal{A}$ has as vertices all the triangulations of $\mathcal{A}$ and as edges the geometric bistellar flips between them.

Of course, an $(i, j)$ flip can always be reversed, giving a $(j, i)$ flip. The reason for the words "geometric bistellar" in our flips can be found in Section 2.2.

**Example 1.15** (Examples 1.2 and 1.7 continued). The change between the two top triangulations in Figure 3 is a $(2, 2)$ flip, as is the change between the two bottom ones. The flip from the top-right to the bottom-right is a $(1, 3)$ flip ("1 triangle disappears and 3 are inserted") and the flip from the top-left to the bottom-left is a $(1, 2)$ flip ("one edge is removed, together with its link, and two are inserted, with the same link"). The latter is supported in the circuit formed by the three collinear points.

We omit the proof of the following natural statement.

**Theorem 1.16.** *Definitions* 1.11 *and* 1.14 *are equivalent: two triangulations $T_1$ and $T_2$ of a point set $\mathcal{A}$ are connected by a flip in the sense of* 1.14 *if and only if they are the two proper refinements of a flip in the sense of* 1.11.

The following two facts are proved in [65]:

**Remark 1.17.** 1. If all proper refinements of a subdivision $T$ are triangulations, then $T$ has exactly two of them and $T$ is a flip. That is to say, flips are exactly the "next-to-minimal" elements in the refinement poset of all subdivisions of $\mathcal{A}$.

2. Every non-regular subdivision can be refined to a non-regular triangulation. In particular, not only edges of the secondary polytope correspond to flips between two regular triangulations, but also every flip between two regular triangulations corresponds to an edge.

**Detecting flips.** Definitions 1.11 and 1.14 are both based on the existence of a *flippable circuit* $C$ with certain properties. But in order to detect flips only some circuits need to be checked:

**Lemma 1.18.** *Every flip in a triangulation $T$ other than an insertion flip is supported in a circuit contained in the union of two adjacent cells of $T$.*

Observe that the circuit contained in two adjacent cells always exists and is unique. Also, that the insertion flips left aside in this statement are easy to detect:[8] There is one for each point $a \in \mathcal{A}$ not used in $T$, that inserts the point $a$ by subdividing the minimum (perhaps not full-dimensional) simplex $\tau \subseteq \sigma \in T$ such that $a \in \text{conv}(\tau)$. The flippable circuit is $(\{a\}, \tau)$.

*Proof.* Let $C = (C_+, C_-)$ be a circuit that supports a flip in $T$, with $|C_+| \geq 2$. Observe that $|C_+|$ is also the number of many maximal simplices in $T_+^C$, so let $\tau_1$ and $\tau_2$ be two of them, which differ in a single element, and let $\rho$ be an element of $\text{link}_T(\tau_1) = \text{link}_T(\tau_2)$. Then, $\rho \cup \tau_1$ and $\rho \cup \tau_2$ are adjacent cells in $T$ and $C$ is the unique circuit contained in $\tau_1 \cup \tau_2 \cup \rho$. □

[8] We mean, theoretically. Algorithmically, insertion flips are far from trivial since they imply locating the simplex of $T$ that contains the point $a$ to be inserted, which takes about the logarithm of the number of simplices in $T$. This is very expensive, since algorithms in computational geometry that use flipping in triangulations usually are designed to take constant time per flip other than an insertion flip. See Section 2.1.

**Monotone sequences of flips.** The graph of flips among regular triangulations of a point set $\mathcal{A}$ of dimension $d$ is connected, since it is the graph of a polytope.[9] A fundamental fact exploited in computational geometry is that one can actually flip between regular triangulations *monotonically*, in the following sense.

Let $w\colon \mathcal{A} \to \mathbb{R}$ be a certain generic lifting function. We can use $w$ to lift every triangulation $T$ of $\mathcal{A}$ as a function $H_{T,w}\colon \operatorname{conv}(\mathcal{A}) \to \mathbb{R}$, by affinely interpolating $w$ in each cell of $T$. We say that $T_1 <_w T_2$ ("$T_1$ is below $T_2$, with respect to $w$") if $H_{T_1,w} \leq H_{T_2,w}$ pointwise and $H_{T_1,w} \neq H_{T_2,w}$ globally. This defines a partial order $<_w$ on the set of all triangulations, whose global minimum and maximum are, respectively, $T_w$ and $T_{-w}$.[10]

**Definition 1.19.** A sequence of flips is monotone with respect to $w$ if every flip goes from a triangulation $T$ to a triangulation $T' <_w T$.

By definition of the secondary polytope $\Sigma(\mathcal{A})$ as having the secondary fan as its normal fan, lifting functions are linear functionals on it. Then, it is no surprise that for the regular triangulations $T_1$ and $T_2$ corresponding to vertices $v_{T_1}$ and $v_{T_2}$ of the secondary polytope one has[11]:

$$T_1 <_w T_2 \;\Rightarrow\; \langle w, v_{T_1}\rangle < \langle w, v_{T_1}\rangle.$$

In fact, $\langle w, v_T\rangle$ equals the volume between the graphs of the functions $H_{T_w,w}$ and $H_{T,w}$. Since the converse implication holds whenever $T_1$ and $T_2$ are related by a flip, we have:

**Lemma 1.20.** *For every lifting function $w$ and every regular triangulation $T$ there is a $w$-monotone sequence of flips from $T$ to the regular triangulation $T_w$.*

If $T$ is not regular this may be false, even in dimension 2:

**Example 1.21** (Examples 1.4 and 1.8 continued). Let $\mathcal{A}$ be the point configuration of Example 1.4 (see Figure 2), except perturbed by slightly rotating the interior triangle "123" counter-clockwise. That is,

$$\mathcal{A} = \begin{array}{c} \begin{matrix} a_1 & a_2 & a_3 & a_4 & a_5 & a_6 \end{matrix} \\ \begin{pmatrix} 4-\varepsilon & 0 & \varepsilon & 2 & 1 & 1 \\ \varepsilon & 4-\varepsilon & 0 & 1 & 2 & 1 \\ 0 & \varepsilon & 4-\varepsilon & 1 & 1 & 2 \end{pmatrix} \end{array},$$

[9] Even more, it is $(|\mathcal{A}| - d - 1)$-connected. Remember that a graph is called $k$-connected if removing less than $k$ vertices from it it stays connected. A classical theorem of Balinski [79] says that the graph of a $k$-polytope is $k$-connected.

[10] In case they are triangulations. If not, every triangulation that refines $T_w$ or $T_{-w}$ is, respectively, minimal or maximal.

[11] The same is true for non-regular triangulations. The point $v_T$ is well-defined, via the Gel'fand-Kapranov-Zelevinskii coordinates for the secondary polytope, even if $T$ is not regular. The only difference is that if $T$ is not regular then $v_T$ is not a vertex of the secondary polytope.

for a small $\varepsilon > 0$. This perturbation keeps the triangulation $T_1$ non-regular and makes $T_2$ regular. Let $w\colon \mathcal{A} \to \mathbb{R}$ lift the exterior triangle 123 to height zero and the interior triangle 456 to height one. The graph of $H_{T_2,w}$ is a strictly concave surface (that is, $T_2 = T_{-w}$) and there is no $w$-monotone flip in $T_1$, since its only three flips are the diagonal-edge flips on "16", "24" and "35", which are "towards $H_{T_2,w}$". This example appeared in [26].

Another explanation of why no $w$-monotone flip exists in $T_1$ is that when we close the graph of the function $H_{T_1,w}$ by adding to it the triangle 123, it becomes a non-convex polyhedron $P$ with the property that no tetrahedron (with vertices contained in those of $P$) is completely contained in the region enclosed by $P$. This polyhedron is affinely equivalent to Schönhardt's [69] classical example of a non-convex polyhedron in $\mathbb{R}^3$ that cannot be triangulated without additional vertices.

**1.3. The cases of small dimension or few points.** Throughout this section $\mathcal{A}$ denotes a point set with $n$ elements and dimension $d$.

**Sets with few points.** If $n = d+1$, then $\mathcal{A}$ is independent and the trivial subdivision is its unique triangulation. If $n = d + 2$ then $\mathcal{A}$ has a unique circuit and exactly two triangulations, connected by a flip. If $n = d + 3$, it was proved by Lee [44] that all triangulations are regular. Since the secondary fan is 2-dimensional, the secondary polytope is a polygon, whose graph (a cycle) is the graph of flips. If $n = d+4$, then $\mathcal{A}$ can have non-regular triangulations (see Example 1.4). Still, it is proven in [7] that every triangulation has at least three flips and that the flip-graph is 3-connected.

For point sets with $n = d + 5$ the flip-graph is not known to be always connected.

**Dimension 1.** Triangulating a one-dimensional point set is just choosing which of the interior points are used. That is, $n$ points in dimension 1 have $2^{n-2}$ triangulations. The flip-graph is the graph of an $(n-2)$-dimensional cube and all triangulations are regular. The secondary polytope is the same cube.

**Dimension 2.** In dimension two the graph of $(2, 2)$-*flips among triangulations using all points of* $\mathcal{A}$ [12] is known to be connected since long [40], and connectivity of the whole graph—including the triangulations that do not use all points and the insertion or deletion flips—is straightforward from that. Even more, one can always flip monotonically[13] from any triangulation to the Delaunay triangulation using only $(2, 2)$ flips. Quadratically many (with respect to the number of points) flips are sometimes necessary and always suffice (see, e.g., [25, p. 11]).

However, with general flips:

**Proposition 1.22.** *The flip-graph of any* $\mathcal{A} \subseteq \mathbb{R}^2$ *has diameter smaller than* $4n$.

[12] This is the graph usually considered in two-dimensional computational geometry literature.

[13] With respect to the lift $w(a) := \|a\|^2$.

*Proof.* Let $a$ be an extremal point of $\mathcal{A}$ and $T$ an arbitrary triangulation. If $T$ has triangles not incident to $a$ then there is at least a flip that decreases the number of them (proof left to the reader). Since the number of triangles in a planar triangulation with $v_i$ interior vertices and $v_b$ boundary vertices is exactly $2v_i + v_b - 2$ (by Euler's formula) we can flip from any triangulation to one with every triangle incident to $a$ in at most $2v_i + v_b - 3 < 2n - n_b$ flips.

Now, exactly as in the 1-dimensional case, the graph of flips between triangulations in which every triangle is incident to $a$ is the graph of a cube of dimension equal to the number of "boundary but non-extremal" points of $\mathcal{A}$. Hence, we can flip between any two triangulations in $(2n - n_b) + n_b + (2n - n_b) < 4n$ flips. □

**Remark 1.23.** The preceding proof is another example of monotone flipping, this time with respect to any lifting function $w\colon \mathcal{A} \to \mathbb{R}$ with $w(a) << w(b)$, for all $b \in \mathcal{A} \setminus \{a\}$. In essence, this lifting produces the so-called *pulling* triangulation of $\mathcal{A}$. More precisely, for a point set $\mathcal{A}$ in arbitrary dimension and a given ordering $a_1, \ldots, a_n$ of the points in $\mathcal{A}$ one defines [17], [44], [45], [79]:

- The *pulling triangulation* of $\mathcal{A}$, as the regular triangulation given by the lift $w(a_i) := -t^i$, for a sufficiently big constant $t \in \mathbb{R}$. It can be recursively constructed as the triangulation that joins the last point $a_n$ to the pulling triangulation of every facet of $\text{conv}(\mathcal{A})$ that does not contain $a_n$.
- The *pushing triangulation* of $\mathcal{A}$, as the regular triangulation given by the lift $w(a_i) := t^i$, for a sufficiently big constant $t \in \mathbb{R}$. It can be recursively constructed as the triangulation that contains $T_{n-1}$ and joins $a_n$ to the part of the boundary of $T_{n-1}$ visible from $a_n$, where $T_{n-1}$ is the pushing triangulation of $\mathcal{A} \setminus \{a_n\}$.

Pushing and pulling triangulations are examples of *lexicographic* triangulations, defined by the lifts $w(a_i) := \pm t^i$ for sufficiently big $t$.

Summing up, monotone flipping in the plane (a) works even for non-regular triangulations if the "objective function" $w$ is either the Delaunay or a lexicographic one (the proof for the pushing case is left to the reader); (b) gives a linear sequence of flips for the pulling case, but may produce a quadratic one for the Delaunay case; (c) does not work for arbitrary $w$ (Example 1.21).

Let us also mention that in dimension two every triangulation is known to have at least $n-3$ flips [23] (the dimension of the secondary polytope), and at least $\lceil (n-4)/2 \rceil$ of them of type (2, 2) [35]. The flip-graph is not known to be $(n-3)$-connected.

**Dimension 3.** Things start to get complicated:

If $\mathcal{A}$ is in convex position [14] then every triangulation of it has at least $n-4$ flips [23], but otherwise $\mathcal{A}$ can have flip-deficient triangulations.[15] The smallest possible example, with eight points, is described in [7], based on Example 1.4. Actually, for every $n$

[14] *Convex position* means that all points are vertices of $\text{conv}(\mathcal{A})$.

there are triangulations with essentially $n^2$ vertices and only $O(n)$ flips [63]. This is true even in general position.[16]

The flip-graph is not known to be connected, even if $\mathcal{A}$ is in convex and general position. The main obstacle to proving connectivity (in case it holds!) is probably that one cannot, in general, *monotonically* flip to either the Delaunay, the pushing, or the pulling triangulations. For the Delaunay triangulation this was shown in [37]. For the other two we describe here an example.

**Example 1.24** (Examples 1.4, 1.8 and 1.21 continued). Let $\mathcal{A}$ consist of the following eight points in dimension three:

$$\mathcal{A} = \begin{array}{c} \begin{array}{cccccccc} a_1 & a_2 & a_3 & b_1 & b_2 & b_3 & c_1 & c_2 \end{array} \\ \begin{pmatrix} 4-\varepsilon & 0 & \varepsilon & 2 & 1 & 1 & 4/3 & 4/3 \\ \varepsilon & 4-\varepsilon & 0 & 1 & 2 & 1 & 4/3 & 4/3 \\ 0 & \varepsilon & 4-\varepsilon & 1 & 1 & 2 & 4/3 & 4/3 \\ 0 & 0 & 0 & 1 & 1 & 1 & 10 & -10 \end{pmatrix} \end{array},$$

The first six points are exactly the (lifted) point set of Example 1.21, and have the property that no tetrahedron with vertices contained in these six points is contained in the non-convex Schönhardt polyhedron $P$ having as boundary triangles $\{a_1, a_2, a_3\}$, $\{b_1, b_2, b_3\}$, $\{a_i, a_{i+1}, b_i\}$ and $\{a_{i+1}, b_i, b_{i+1}\}$ (the latter for the three values of $i$, and with indices regarded modulo three). The last two points $c_1$ and $c_2$ of the configuration lie far above and far below this polyhedron. $c_1$ sees every face of $P$ except the big triangle $\{a_1, a_2, a_3\}$, while $c_2$ sees only this triangle.

Let $T$ be the triangulation $T$ of $\mathcal{A}$ obtained removing the big triangle from the boundary of $P$, and joining the other seven triangles to both $c_1$ and $c_2$. We leave it to the reader to check that there is no monotone sequence of flips towards the pushing triangulation with respect to any ordering ending in $c_2$, and there is no monotone sequence of flips towards the pulling triangulation with respect to any ordering ending in $c_1$.

**Higher dimension.** There are the following known examples of "bad behavior":

- In *dimension four*, there are triangulations with arbitrarily many vertices and a bounded number of flips [63]. They are constructed adding several layers of "the same" triangulated 3-sphere one after another.
- In *dimension five*, there are point sets with a disconnected graph of triangulations [67]. The smallest one known has 26 points, but one with 50 points is easier to describe: It is the Cartesian product of $\{0, 1\}$ with the vertex set and the centroid of a regular 24-cell.

[15] We say a triangulation is *flip-deficient* if it has less than $n - d - 1$ flips; that is, less than the dimension of the secondary polytope.

[16] Although this is not mentioned in [63], the construction there can be perturbed without a significant addition of flips.

- In *dimension six*, there are triangulations without flips at all [64]. The example is again a cartesian product, now of a very simple configuration of four points in $\mathbb{R}^2$ and a not-so-simple (although related to the 24-cell too) configuration of 81 points in $\mathbb{R}^4$. There are also point sets *in general position* with a disconnected graph of triangulations (Section 3 of this paper and [68]). Only 17 points are needed.

## 2. The context

**2.1. Bistellar flips and computational geometry.** The first and most frequently considered flips in computational geometry are $(2, 2)$ flips in 2-dimensional point sets. Seminal papers of Lawson [40], [41] prove that every triangulation can be monotonically transformed to the Delaunay triangulation by a sequence of $O(n^2)$ such flips.

Lawson himself, in 1986 [42], is close to defining flips in arbitrary dimension, even in the case of special position. Around 1990,[17] B. Joe realizes that in dimension three one cannot, in general, monotonically flip from any triangulation to the Delaunay triangulation [37] but, still, the following incremental algorithm works [38]: insert the points one by one, each by an insertion flip in the Delaunay triangulation of the already inserted points. After each insertion, monotonically flip to the new Delaunay triangulation by flips that increase the star of the inserted point.

V. T. Rajan [59] does essentially the same in arbitrary dimension and Edelsbrunner and Shah [26], already aware at least partially of the theory of secondary polytopes, generalize this to flipping towards the regular triangulation $T_w$ by $w$-monotone flips, for an arbitrary $w$.

If one disregards the efficiency of the algorithm, the main result of [26] follows easily from Lemma 1.20. But efficiency is the main point in computational geometry, and one of the important features in [38] and [26] is to show that the sequence of flips can be found and performed spending constant time per flip (in fixed dimension). An exception to this time bound are the insertion steps. Theoretically, they are just another case of flip. But in the algorithm they have a totally different role since they involve locating where the new point needs to be inserted. To get good time bounds for the location step, the standard incremental algorithm is "randomized",[18] and it is proved that the total *expected* time taken by the $n$ insertion steps is bounded above by $O(n \log n)$ in the plane and $O(n^{\lceil d/2 \rceil})$ in higher dimension. The latter is the same as the worst-case size of the Delaunay triangulation, or actually of any triangulation.

This incremental-randomized-flipping method can be considered the standard algorithm for the Delaunay triangulation in current computational geometry. It is the only one described in the textbooks [21] and [25]. In the survey [8], it is the first of

[17] Birth year of secondary polytopes and geometric bistellar flips as we have defined them [28].

[18] That is, the ordering in which the points are inserted is considered random among the $n!$ possible orderings. This trick was first introduced in [19] for convex hulls, then applied to 2-D Delaunay triangulations in [32].

four described in the plane but the only one detailed in dimension three, as "the most intuitive and easy to implement".

**Remark 2.1.** Computational geometry literature normally only considers full-dimensional flips; that is, flips of type $(i, j)$ with $i + j = d + 2$. In particular, [8], [21], [25], [26] and [38] describe the incremental flipping algorithm only for point sets in general position. The only mention in those references to the effect of allowing special position in the flipping process seems to be that, according to [25], for the six vertices of a regular octahedron *"none of the three tetrahedrizations permits the application of a two-to-three or a three-to-two flip. The flip graph thus consists of three isolated nodes"*.

However, with the general definition of flip the incremental-flipping algorithm can be directly applied to point sets in special position, as done recently by Shewchuk [70]. Shewchuk's algorithm actually computes the so-called *constrained regular triangulation* of the point set for any lift $w$ and constraining complex $K$. This is defined as the unique[19] triangulation $T$ containing $K$ and in which every simplex of $T \setminus K$ is lifted by $w$ to have a locally convex star.[20]

**2.2. Bistellar flips and combinatorial topology.** Bistellar flips can be defined at a purely combinatorial level, for an abstract simplicial complex. Let $\Delta$ be a simplicial complex, and let $\sigma \in \Delta$ be a simplex, of any dimension. The *stellar subdivision* on the simplex $\sigma$ is the simplicial complex obtained inserting a point in the relative interior of $\sigma$. This subdivides $\sigma$, and every simplex $\tau$ containing it, into $\dim \sigma + 1$ simplices of the same dimension. Two simplicial complexes $\Delta_1$ and $\Delta_2$ are said to differ in a *bistellar flip* if there are simplices $\sigma_1 \in \Delta_1$ and $\sigma_2 \in \Delta_2$ such that the stellar subdivisions of $\Delta_1$ and $\Delta_2$ on them produce the same simplicial complex. The bistellar operation from $\Delta_1$ to $\Delta_2$ is said to be of type $(i, j)$ if $i = \dim \sigma_1 + 1$ and $j = \dim \sigma_2 + 1$. Observe that geometric bistellar flips, as defined in Definition 1.14, are combinatorially bistellar flips.

Combinatorial bistellar flips have been proposed as an algorithmic tool for exploring the space of triangulations of a manifold [21] or to recognize the topological type of a simplicial manifold [18], [46]. In particular, Pachner [56] has shown that any two triangulations of PL-homeomorphic manifolds are connected by a sequence of topological bistellar flips. But for this connectivity result additional vertices are allowed to be inserted into the complex, via flips of type $(i, 1)$.

[19] If it exists, which is not always the case.

[20] Shewchuk's algorithm is incremental, treating the simplices in $K$ similarly to the points in the standard incremental algorithm: they are inserted one by one (in increasing order of dimension) and after each insertion the regular, constrained to the already added simplices, triangulation is updated using geometric bistellar flips. The algorithm's running time is $O(n^{\lfloor d/2 \rfloor + 1} \log n)$. The extra $\log n$ factor comes from a priority queue that is needed to decide in which order the flips are performed, to make sure that no "local optima" instead of the true constrained Delaunay triangulation, is reached. The extra $n$ factor (only in even dimension) is what randomization saves in the standard incremental-flipping algorithm. Randomization would not do the same here (Shewchuk, personal communication).

[21] Besides its intrinsic interest, this problem arises in quantum gravity modelization [3], [54].

The situation is much different if we do not allow insertion flips: Dougherty et al. [24] show that there is a topological triangulation of the 3-sphere, with 15 vertices, that does not admit any flip other than insertion flips.[22] If this triangulation was realizable geometrically in $\mathbb{R}^3$ (removing from the 3-sphere the interior of any particular tetrahedron) it would provide a triangulation in dimension three without any geometric bistellar flips. Unfortunately, Dougherty et al. show that it cannot be geometrically embedded.

**2.3. Bistellar flips and topological combinatorics.** A standard construction in topological combinatorics [16] is to associate to a poset $P$ its *order complex*: an abstract simplicial complex whose vertices are the elements of $P$ and whose simplices are the finite chains (totally ordered subsets) of $P$. In this sense one can speak of the topology of the poset. If the poset has a unique maximum (as is the case with the refinement poset of subdivisions of a point set $\mathcal{A}$) or minimum, one usually removes them or otherwise the order complex is trivially contractible (that is, homotopy equivalent to a point). This is what we mean when we say that the refinement poset of subdivisions of the point set of Section 3 is not connected.

The refinement poset of polyhedral subdivisions of $\mathcal{A}$ is usually called the *Baues poset* of $\mathcal{A}$ and its study is *the generalized Baues problem*. To be precise, Baues posets were introduced implicitly in [14] and explicitly in [13] in a more general situation where one has an affine projection $\pi$ from the vertex set of a polytope $P \in \mathbb{R}^{d'}$ to a lower dimensional affine space $\mathbb{R}^d$. In this general setting, one considers the point set $\mathcal{A} := \pi(\text{vertices}(P))$ and is interested in the polyhedral subdivisions of $\mathcal{A}$ that are compatible with $\pi$ in a certain sense (basically, that the preimage of every cell is the set of vertices of a face in $P$). In the special case were $P$ is a simplex (and hence $d' = n - 1$, where $n$ is the number of points in $\mathcal{A}$) every polyhedral subdivision is compatible. This is the case of primal interest in this paper, but there are at least the following two other cases that have attracted attention. (See [61] for a very complete account of different contexts in which Baues posets appear, and [79, Chapter 9] for a different treatment of the topic):

- When $P$ is a cube, its projection is a *zonotope* $Z$ and the $\pi$-compatible subdivisions are the *zonotopal tilings* of $Z$ [79]. The finest ones are *cubical tilings*, related by *cubical flips*.
- When $d = 1$ and $P$ is arbitrary, the $\pi$-compatible subdivisions are called *cellular strings*, since they correspond to monotone sequences of faces of $P$. The finest ones are *monotone paths* of edges and are related by *polygon flips*.

[22] Dougherty et al. only say that their triangulation does not have any $(3, 2)$, $(2, 3)$ or $(1, 4)$ flips, which are the "full-dimensional" types of flips. But their arguments prove that even considering degenerate flips, the only possible ones in their triangulation are insertion flips of type $(i, 1)$. Indeed, the two basic properties that their triangulations has are that (a) its graph is complete, which prevents flips of type $(3, 2)$, but also $(2, 2)$ and $(1, 2)$ and (b) no edge is incident to exactly three tetrahedra, which prevents flips of type $(1, 4)$ and $(2, 3)$, but also $(1, 3)$.

The name *Baues* for these posets comes from the fact that H. J. Baues was interested in their homotopy type in a very particular case (in which, among other things, $d = 1$) and conjectured it to be that of a sphere of dimension $d' - 2$ [9]. Billera et al. [13] proved this conjecture for all Baues posets with $d = 1$, and the conjecture that the same happened for arbitrary $d$ (with the dimension of the sphere being now $d' - d - 1$) became known as the *generalized Baues conjecture*. It was inspired by the fact that the *fiber polytope* associated to the projection $\pi$—a generalization of the secondary polytope, introduced in [14]—has dimension $d' - d$ and its face lattice is naturally embedded in the Baues poset.

Even after the conjecture in its full generality was disproved by a relatively simple example with $d' = 5$ and $d = 2$ [60], the cases where $P$ is either a simplex or a cube remained of interest. As we have said, the latter is disproved in the present paper for the first time. The former remains open and has connections to oriented matroid theory, as we now show.

Recall that the oriented matroid (or order type) of a point set $\mathcal{A}$ of dimension $d$ (or of a vector configuration of rank $d + 1$) is just the information contained in the map $\binom{\mathcal{A}}{d+1} \to \{-1, 0, +1\}$ that associates to each $(d + 1)$-element subset of $\mathcal{A}$ the sign of its determinant (that is, its orientation). But oriented matroids (see [17] as a general reference) are axiomatically defined structures which may or may not be realizable as the oriented matroids of a real configuration, in much the same way as, for example, a topological space may or may not be metrizable.

It turns out that the theory of triangulations of point and vector configurations generalizes nicely to the context of perhaps-non-realizable oriented matroids, with the role of regular triangulations being played by the so-called *lifting triangulations*: triangulations that can be defined by an oriented matroid lift (see [17, Section 9.6] or [66, Section 4]).

One of the basic facts in oriented matroid duality is that the lifts of an oriented matroid $\mathcal{M}$ are in bijection to the one-point extensions of its dual $\mathcal{M}^*$. In particular, the space of lifts of $\mathcal{M}$ equals the so-called extension space of the dual oriented matroid $\mathcal{M}^*$. Here, both the space of lifts and the space of extensions are defined as the simplicial complexes associated to the natural poset structures in the set of all lifts/extensions of the oriented matroid. This makes the following conjecture of Sturmfels and Ziegler [75] be relevant to this paper:

**Conjecture 2.2.** The extension space of a realizable oriented matroid of rank $r$ is homotopy equivalent to a sphere of dimension $r - 1$.

The reader may be surprised that we call this a conjecture: if the extension space of an oriented matroid is the analogue of a secondary fan, should not the extension space of a realizable oriented matroid be automatically "a fan", hence a sphere? Well, no: even if an oriented matroid $\mathcal{M}$ is realizable, some of its extensions may not be realizable. Those will appear in the extension space. Even worse, if $\mathcal{M}$ is realized as a vector configuration $\mathcal{A}$, some realizable extensions of $\mathcal{M}$ may only be realizable as extensions of other realizations of $\mathcal{M}$. Actually, Sturmfels and Ziegler show that

the space of realizable extensions of a realizable oriented matroid *does not* in general have the homotopy type of a sphere!

**Example 2.3** (Example 1.4 continued). Consider the point configuration of Example 1.4 (two parallel triangles one inside the other). An additional point added to this configuration represents an extension of the underlying oriented matroid. In particular, there is an extension by a point collinear with each of the three pairs of corresponding vertices of the two triangles.

But any small perturbation of the point set gives another realization of the same oriented matroid, since the original point set is in general position. However, this perturbation will, in general, not keep the lines through those three pairs of vertices colliding. So, the extension we have described is no longer realizable as a geometric extension of the new realization.

There is a class of configurations specially interesting in this context: the so-called Lawrence polytopes. A *Lawrence oriented matroid* is an oriented matroid whose dual is centrally symmetric. Similarly, a *Lawrence polytope* is a polytope whose vertex set has a centrally symmetric *Gale transform*. There is essentially one Lawrence polytope associated to each and every realizable oriented matroid. The following result is a combination of a theorem of Bohne and Dress (see [79], for example) and one of the author of this paper [34], [66]:

**Theorem 2.4.** *Let $\mathcal{M}$ be a realizable oriented matroid and let $P$ be the associated Lawrence polytope. Then, the following three posets are isomorphic:*

1. *The refinement poset of polyhedral subdivisions of $P$.*
2. *The extension space of the* (*also realizable*) *dual oriented matroid $\mathcal{M}^*$.*
3. *The refinement poset of zonotopal tilings of the zonotope associated to* (*any realization of*) *$\mathcal{M}$.*

**Corollary 2.5.** *The following three statements are equivalent:*

1. *The generalized Baues conjecture for the polyhedral subdivisions of Lawrence polytopes.*
2. *The extension space conjecture for realizable oriented matroids.*
3. *The generalized Baues conjecture for the zonotopal tilings of zonotopes.*

Moreover, if $\mathcal{A}$ is a point configuration and $P$ its associated Lawrence polytope, then there is a surjective map between the poset of subdivisions of $P$ and the poset of *lifting* (in the oriented matroid sense) subdivisions of $\mathcal{A}$. This follows from that facts that "Lawrence polytopes only have lifting subdivisions" and "lifting subdivisions can be lifted to the Lawrence polytope", both proved in [66].

In particular, if the flip-graph of a certain point set $\mathcal{A}$ is not connected and has lifting triangulations in several connected components, then the graph of cubical flips

between zonotopal tilings of a certain zonotope is not connected either, thus answering question 1.3 in [61]. If, moreover, $\mathcal{A}$ is in general position, it would disprove the three statements in Corollary 2.5. We do not know whether the disconnected flip-graph in Section 3 has this property. The examples in [64], [67] are easily seen to be based in non-lifting triangulations.

**Remark 2.6.** The extension space conjecture is the case $k = d - 1$ of the following far-reaching conjecture by MacPherson, Mnëv and Ziegler [61, Conjecture 11]: that the poset of all strong images of rank $k$ of any realizable oriented matroid $\mathcal{M}$ of rank $d$ (the so-called *OM-Grassmannian of rank k* of $\mathcal{M}$) is homotopy equivalent to the real Grassmannian $G^k(\mathbb{R}^d)$. This conjecture is relevant in matroid bundle theory [5] and the *combinatorial differential geometry* of MacPherson [48].

An important achievement in this context is the recent result of Biss [15] proving this conjecture whenever $\mathcal{M}$ is a "free oriented matroid". In this case the OM-Grassmannian is the space of all oriented matroids of a given cardinality and rank, usually called the MacPhersonian. The result of Biss includes the case $n = \infty$ (in which the MacPhersonian is defined as a direct limit of all the MacPhersonians of a given rank) and implies that the theory of "oriented matroid bundles for combinatorial differential manifolds" developed by MacPherson [48] is equivalent to the theory of real vector bundles on real differential manifolds. A first, seminal, result in this direction was the "combinatorial formula" by Gel'fand and MacPherson for the Pontrjagin class of a triangulated manifold [30].

**2.4. Bistellar flips and algebraic geometry.** Bistellar flips are related to algebraic geometry from their very birth. Indeed, Definition 1.14, as well as that of secondary polytope and Theorem 1.6 were first given by Gel'fand, Kapranov and Zelevinskii during their study of discriminants of a sparse polynomial [28]. By a sparse polynomial we mean, here, a multivariate polynomial $f$ whose coefficients are considered parameters but whose set of (exponent vectors of) monomials is a fixed point set $\mathcal{A} \subseteq \mathbb{Z}^d$. Gel'fand, Kapranov and Zelevinskii prove that the secondary polytope of $\mathcal{A}$ equals the Newton polytope of the Chow polynomial of $f$, where the Chow polynomial is a certain resultant defined in terms of $f$. Similarly, the secondary polytope is related to the discriminant of $f$ (the $\mathcal{A}$-discriminant) although a bit less directly: it is a Minkowski summand of the Newton polytope of the $\mathcal{A}$-discriminant.

A stronger, and more classical, relation between triangulations of point sets and algebraic geometry comes from the theory of toric varieties [27], [55]. As is well-known, every rational convex polyhedral fan $\Sigma$ (in our language, every polyhedral subdivision of a rational vector configuration) has an associated toric variety $X_\Sigma$, of the same dimension. $X_\Sigma$ is non-singular if and only if $\Sigma$ is simplicial (i.e., a triangulation) and unimodular. The latter means that every cone is spanned by integer vectors with determinant $\pm 1$. If $\Sigma$ is a non-unimodular triangulation, then $X_\Sigma$ is an orbifold; that is, it has only quotient singularities.

A stellar subdivision, that is, an insertion flip, in $\Sigma$ corresponds to an equivariant

blow-up in $X_\Sigma$. Hence, a deletion flip produces a blow-down and a general flip produces a blow-up followed by a blow down. In this sense, the connectivity question for triangulations of a vector configuration is closely related to the following result, conjectured by Oda [51] and proved by Morelli and Włodarczyk [52], [78].[23]

**Theorem 2.7.** *Every proper and equivariant birational map $f : X_\Sigma \to X_{\Sigma'}$ between two nonsingular toric varieties can be factorized into a sequence of blowups and blowdowns with centers being smooth closed orbits* (*weak Oda's conjecture*).

More precisely, Oda's conjecture, in its weak form, is equivalent to saying that every pair of unimodular simplicial fans can be connected by a sequence of bistellar flips passing only through unimodular fans (and, actually, it is proved this way). But observe that in this result the set of vectors allowed to be used is not fixed in advance: additional ones are allowed to be flipped-in and eventually flipped-out. Our construction in [67] actually shows that the result is not true if we do not allow for extra vectors to be inserted.

The relation of the graph of flips to toric geometry is even closer if one looks at certain schemes associated to a toric variety. In order to define them we first look at secondary polytopes in a different way, as a particular case of fiber polytopes [14]:

Assume that $\mathcal{A}$ is an integer point configuration and let $\Delta$ be the unit simplex of dimension $|\mathcal{A}| - 1$ in $\mathbb{R}^{|\mathcal{A}|}$. Let $Q = \text{conv}(\mathcal{A})$ and let $\pi : \Delta \to Q$ be the affine projection sending the vertices of $\Delta$ to $\mathcal{A}$. The chamber complex of $\mathcal{A}$ is the coarsest common refinement of all its triangulations. It is a polyhedral complex with the property that for any $b$ and $b'$ in the same *chamber* the fibers $\pi^{-1}(b)$ and $\pi^{-1}(b')$ are polytopes with the same normal fan.

**Theorem 2.8** (Billera et al. [14]). *The secondary polytope of $\mathcal{A}$ equals the Minkowski integral of $\pi^{-1}(b)$ over $Q$.*

Combinatorially, then, the secondary polytope of $\mathcal{A}$ equals the Minkowski sum of a finite number of $\pi^{-1}(b)$'s, with one $b$ chosen in each chamber.

Now, for each $b \in Q$, consider the toric variety associated to the normal fan of the fiber $\pi^{-1}(b)$. Since the normal fan is the same whenever $b$ and $b'$ lie in (the relative interior of) the same cell of the chamber complex, we denote this toric variety $V_\sigma$, where $\sigma$ is a cell (of any dimension) of the chamber complex. If $b \in \sigma$ and $b' \in \tau$ for two chambers with $\tau \subseteq \overline{\sigma}$ then the normal fan of $\pi^{-1}(b)$ refines the normal fan of $\pi^{-1}(b')$, which implies that there is a natural equivariant morphism $f_{\sigma\tau} : V_\sigma \to V_\tau$. We finally denote $\Lambda_{\mathcal{A}} := \varprojlim V_\sigma$ the inverse limit of all the $V_\sigma$ and morphisms $V_{\sigma\tau}$. It has the following two interpretations:

1. Let $X_\Delta$ be the projective space of dimension $|\mathcal{A}| - 1$, which is the toric variety associated with the simplex $\Delta$ (what follows is valid for any polytope $\Delta$). The

[23] Morelli's paper [52] claimed to have proved the following: that we can insist on the sequence to consist of first a sequence of only blowups and then one of only blowdowns (strong Oda's conjecture). Some errors were found in this part of his paper [2, 53] and, according to [1], the strong conjecture is still open, even in dimension three.

toric varieties $V_\sigma$ are the different toric geometric invariant theory quotients of $X_\Delta$ modulo the algebraic sub-torus whose characters are the monomials with exponents in $\mathcal{A}$ [39, Section 3]. $\Lambda_\mathcal{A}$ is the inverse limit of all of them, which contains the Chow quotient as an irreducible component [39, Section 4].

2. In [4], Alexeev is interested, among other things, in the moduli space $M$ of *stable semi-abelic toric pairs* for an integer polytope $Q$ (see Sections 1.1.A and 1.2.B in [4] for the definitions). The author shows that there is a finite morphism $M \to \Lambda_\mathcal{A}$ (Corollary 2.11.11), where $\mathcal{A}$ is the set of all integer points in $Q$, and uses $\Lambda_\mathcal{A}$ (that he denotes $M_{\text{simp}}$) as a simplified model for studying $M$.

   Although there $\mathcal{A}$ is assumed to be the set of all lattice points in a polytope, the connection of $\Lambda_\mathcal{A}$ with $\Sigma_c(\mathcal{A})$ carried out in the proof of the following theorem is independent of this fact.

**Theorem 2.9.** *The scheme $\Lambda_\mathcal{A}$ is connected if and only if the graph of triangulations of $\mathcal{A}$ is connected.*

*Proof* (Sketch). Alexeev introduces the following poset structure on the set of all polyhedral subdivisions of $\mathcal{A}$: Given two subdivisions $S_1$ and $S_2$ we consider $S_1 < S_2$ if: (a) $S_1$ refines $S_2$, (b) the restriction of $S_1$ to each cell $B$ of $S_2$ is a regular subdivision $S_B$ of $B$, and (c) the lifting functions of the regular subdivisions of cells of $S_2$ can be chosen so that the restrictions of them to common faces of cells differ by an affine function.

This poset is called the "coherent poset of subdivisions of $\mathcal{A}$" in [64], to distinguish it from the usual poset of subdivisions, where only the first condition (refinement) is imposed. Then, he shows that the scheme $\Lambda_\mathcal{A}$ is connected if and only if the coherent refinement poset is connected. (More precisely, he shows that there is a natural moment map defined on $\Lambda_\mathcal{A}$ whose image is the topological model of the poset). In turn, it is proven in [64] that the coherent refinement poset is connected if and only if the graph of triangulations of $\mathcal{A}$ is connected. □

A second scheme that relates triangulations and toric geometry is precisely the so-called toric Hilbert scheme. The toric ideal $I_\mathcal{A} \subseteq K[x_1, \ldots, x_n]$ associated to $\mathcal{A} = \{a_1, \ldots, a_n\} \in \mathbb{R}^d$ is generated by the binomials

$$\left\{x^\lambda - x^\mu : \lambda, \mu \in \mathbb{N}^n,\ \sum \lambda_i a_i = \sum \mu_i a_i\right\}.$$

Here, $x^\lambda := x_1^{\lambda_1} \cdots x_n^{\lambda_n}$. In other words, $I_\mathcal{A}$ is the lattice ideal of the lattice of integer affine dependences among $\mathcal{A}$. $\mathcal{A}$ defines the following $\mathcal{A}$-grading of monomials in $K[x_1, \ldots, x_n]$: the $A$-degree of $x^\lambda$ is the vector $x_1^{\lambda_1} \cdots x_n^{\lambda_n} \in \mathbb{Z}^d$. Of course, $I_\mathcal{A}$ is homogeneous with respect to this grading.

If $I$ is another $\mathcal{A}$-homogeneous ideal, the Hilbert function of $I$ is the map $\mathbb{Z}^d \to \mathbb{N}$ defined by $b \mapsto \dim_K I_b$ where $I_b$ is the part of $I$ of degree $b$. The *toric Hilbert scheme*

of $\mathcal{A}$ consists, as a set, of all the $\mathcal{A}$-homogenous ideals with the same Hilbert function as the toric ideal $I_{\mathcal{A}}$. It contains $I_{\mathcal{A}}$ as well as all its initial ideals, which form an irreducible component in its scheme structure.

The toric Hilbert scheme was introduced by Sturmfels in [73] (see also [74]) although its scheme structure was explicited later by Peeava and Stillman [57], who ask whether non-connected toric Hilbert schemes exist.

Sturmfels shows, among other things, that there is a natural map from the toric Hilbert scheme to the set of polyhedral subdivisions of $\mathcal{A}$. Moreover, the map is continuous when the latter is given either the poset topology or the "coherent poset topology" introduced in the proof of Theorem 2.9. The map is not surjective in general, so disconnected graphs of triangulations do not automatically imply disconnected Hilbert schemes.[24] However, Maclagan and Thomas [47], modifying the arguments of Theorem 2.9, show that the image of the map contains at least al the unimodular triangulations of $\mathcal{A}$. In particular:

**Corollary 2.10.** *If the graph of triangulations of an integer point configuration $\mathcal{A}$ is not connected and contains unimodular triangulations in non-regular connected components, then the toric Hilbert scheme of $\mathcal{A}$ is not connected.*

The example in [67] satisfies the hypothesis of this corollary. Hence:

**Theorem 2.11** (Santos [67]). *Let $\mathcal{A}_{50} \subset \mathbb{R}^5$ be the point set $\mathcal{A}_{25} \times \{0, 1\}$ where $\mathcal{A}_{25} \subset \mathbb{R}^4$ consists of the centroid and the 24 vertices of a regular 24-cell. The toric Hilbert scheme of $\mathcal{A}$ and the scheme $\Lambda_A$ defined above are both non-connected. They have at least 13 connected components, each with at least $3^{48}$ torus-fixed points.*

## 3. A construction

Let $\mathcal{A}(t) \subset \mathbb{R}^6$ be the point set defined by the columns of the following matrix, where $t$ is a positive real number. The matrix is written in two pieces for typographic reasons. As usual, the first row is just a homogenization coordinate:

$$\mathcal{A}(t) := \begin{array}{c} \\ x_1 \\ x_2 \\ x_3 \\ x_4 \\ x_5 \\ x_6 \end{array} \begin{array}{c} \begin{array}{ccccccccc} O & a_1^+(t) & a_2^+(t) & a_3^+(t) & a_4^+(t) & a_5^+(t) & a_6^+(t) & a_7^+(t) & a_8^+(t) \end{array} \\ \begin{pmatrix} 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 \\ 0 & 1 & -t & 0 & 0 & 1 & t & 0 & 0 \\ 0 & t & 1 & 0 & 0 & -t & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 & -t & 0 & 0 & 1 & t \\ 0 & 0 & 0 & t & 1 & 0 & 0 & -t & 1 \\ 0 & \sqrt{2} & 1 & 0 & -1 & -\sqrt{2} & -1 & 0 & 1 \\ 0 & 0 & 1 & \sqrt{2} & 1 & 0 & -1 & -\sqrt{2} & -1 \end{pmatrix} \end{array} \cdots$$

[24] Haiman and Sturmfels [33] have shown that this map factors as a morphism from the toric Hilbert scheme to the scheme $\Lambda_{\mathcal{A}}$ of the previous discussion, followed by the natural map from that scheme to the poset of subdivisions. The first map is the non-surjective one.

$$\cdots \begin{array}{c} \begin{matrix} a_1^-(t) & a_2^-(t) & a_3^-(t) & a_4^-(t) & a_5^-(t) & a_6^-(t) & a_7^-(t) & a_8^-(t) \end{matrix} \\ \begin{pmatrix} 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 \\ -1 & t & 0 & 0 & -1 & -t & 0 & 0 \\ -t & -1 & 0 & 0 & t & -1 & 0 & 0 \\ 0 & 0 & -1 & t & 0 & 0 & -1 & -t \\ 0 & 0 & -t & -1 & 0 & 0 & t & -1 \\ \sqrt{2} & 1 & 0 & -1 & -\sqrt{2} & -1 & 0 & 1 \\ 0 & 1 & \sqrt{2} & 1 & 0 & -1 & -\sqrt{2} & -1 \end{pmatrix} \end{array}.$$

$\mathcal{A}(t)$ is not in general position. For example, for every $i = 1, 2, 3, 4$ we have:

$$a_i^+(t) + a_{i+4}^+(t) + a_i^-(t) + a_{i+4}^-(t) = 4O.$$

However, it is "sufficiently in general position" for the following to be true:

**Theorem 3.1.** *If $t$ is sufficiently small and $\mathcal{A}'(t)$ is any perturbation of $\mathcal{A}(t)$ in general position, then the graph of triangulations of $\mathcal{A}'(t)$ is not connected.*

When we say that a point set $\mathcal{A}'$ is a perturbation of another one $\mathcal{A}$ with the same cardinal $n$ and dimension $d$ we mean that all the determinants of $d+1$ points that are not zero in $\mathcal{A}$ keep their sign in $\mathcal{A}'$.[25] This concept also allows us to be precise as to how small do we need $t$ to be. Any $t$ such that $\mathcal{A}(t)$ is a perturbation of $\mathcal{A}(0)$ works.

The proof of Theorem 3.1 will appear in [68]. Here we only give a description of the combinatorics of $\mathcal{A}(t)$ and the ingredients that make the proof work. We look at $\mathcal{A}(0)$ first. In it:

- The projection to the first four coordinates $x_1, \ldots, x_4$ sends the eight pairs of points $\{a_i^+(t), a_{i+4}^+(t)\}$, and $\{a_i^-(t), a_{i+4}^-(t)\}$ $(i = 1, 2, 3, 4)$ to the eight vertices of a 4-dimensional cross-polytope (that is, to the standard basis vectors and their opposites).
- The projection to the last two coordinates $x_5, x_6$ sends the eight pairs of points $\{a_i^+(t), a_i^-(t)\}$ $(i = 1, \ldots, 8)$ to the eight vertices of a regular octagon.

The configuration $\mathcal{A}(0)$ already has a disconnected graph of triangulations.

**Theorem 3.2.** *There is a triangulation $K$ of the boundary of* $\mathrm{conv}(\mathcal{A}(0))$ *with the following two properties:*

1. *There are triangulations of $\mathcal{A}(0)$ inducing $K$ on the boundary.*
2. *No flip in a triangulation of $\mathcal{A}(0)$ inducing $K$ on the boundary affects the boundary.*

In fact, there are eight such triangulations. Hence:

[25] In oriented matroid language, the oriented matroid of $\mathcal{A}$ is a weak image of that of $\mathcal{A}'$.

**Corollary 3.3.** *The flip-graph of* $\mathcal{A}(0)$ *has at least nine connected components.*[26]

Of course, to describe the triangulation $K$ of the boundary of $\mathrm{conv}(\mathcal{A}_0)$ we need only specify how we triangulate each non-simplicial facet. The facets of $\mathrm{conv}(\mathcal{A}(0))$ are 96 simplices, and 16 non-simplicial facets $F_{\delta_1,\delta_2,\delta_3,\delta_4}$ ($\delta_i \in \{+,-\}$), each with eight vertices. More precisely,

$$F_{\delta_1,\delta_2,\delta_3,\delta_4} = \{a_1^{\delta_1}(0), a_2^{\delta_2}(0), a_3^{\delta_3}(0), a_4^{\delta_4}(0), a_5^{\delta_1}(0), a_6^{\delta_2}(0), a_7^{\delta_3}(0), a_8^{\delta_4}(0)\}.$$

All the $F_{*,*,*,*}$'s are equivalent under affine symmetries of $\mathcal{A}(0)$. For example, they are transitively permuted by the sixteen sign changes on the first four coordinates. Hence, the crucial point in the proof of Theorem 3.2 is to understand the triangulations of the point set $F_{+,+,+,+}$. This point set has dimension $d = 5$ and only eight ($= d+3$) points. In particular, all its triangulations are regular and their graph of flips is a cycle. Moreover, it is easy to check[27] that:

**Lemma 3.4.** 1. $\mathrm{conv}(F_{+,+,+,+})$ *has* 12 *facets. Eight of them are simplices and the other four have six points each, forming a* $(3,3)$ *circuit. In particular, there are sixteen ways to triangulate the boundary of* $F_{+,+,+,+}$.

2. $F_{+,+,+,+}$ *has eight triangulations.*

3. *Each flip in a triangulation of* $F_{+,+,+,+}$ *keeps the triangulation induced in three of the non-simplicial facets and switches the triangulation in the other.*

To construct the complex $K$ of Theorem 3.2 we choose the triangulations of the individual $F_{*,*,*,*}$ such that for every non-simplicial facet $G$ of an $F_{\delta_1,\delta_2,\delta_3,\delta_4}$, the triangulations chosen on $F_{\delta_1,\delta_2,\delta_3,\delta_4}$ and on the neighbor $F_{\delta_1',\delta_2',\delta_3',\delta_4'}$ agree on $G$ and one of them has the property that no flip on it changes the triangulation induced in $G$. In these conditions, no flip in any of the triangulations of the $F_{*,*,*,*}$'s is possible, since it would be incompatible with the triangulation of one of its neighbors.

**Example 3.5.** Lemma 3.4 implies, in particular, that only eight of the sixteen triangulations of the boundary of $F_{+,+,+,+}$ can be extended to the interior (without using additional interior points as vertices). Similar behavior occurs also in three-dimensional examples such as the set of vertices of a cube or a triangular prism.

Let us analyze the latter. It has three non-simplicial facets, whose vertex sets are $(2,2)$ circuits; in particular, there are eight ways to triangulate its boundary. But only six of them extend to the interior (all except the two "cyclic" ones). Each flip in a triangulation of $F_{+,+,+,+}$ keeps the triangulation induced in two of the non-simplicial facets and switches the triangulation in the other one.[28]

[26] Here, the ninth component is the one containing all the regular triangulations.

[27] For example, noting that a Gale transform of $F_{+,+,+,+}$ consists again of the eight vertices of a regular octagon, except in different order.

[28] The reader probably has noticed the similarities between this example and the configuration $F_{+,+,+,+}$. These similarities, and the fact that the constructions in [64] and [67] are ultimately based on glueing triangular prisms to one another, reflect the truth in (an instance of) Gian Carlo Rota's fifth lesson [62].

Let us now look at the perturbations $\mathcal{A}(t)$ and $\mathcal{A}'(t)$. The fact that $\mathcal{A}(t)$ (or $\mathcal{A}'(t)$) is a perturbation of $\mathcal{A}(0)$ implies that every triangulation of $\mathcal{A}(0)$ is still a geometric simplicial complex on $\mathcal{A}(t)$, except it may not cover the whole convex hull. In particular, the triangulation $K$ of the boundary of $\mathrm{conv}(\mathcal{A}_(0))$ mentioned in Theorem 3.2 can be embedded as a simplicial complex on $\mathcal{A}(t)$. We still call $K$ this perturbed simplicial complex. Then, Theorem 3.1 follows from the following more precise statement.

**Theorem 3.6.** *Let $t$ be a sufficiently small and positive constant. Then:*

1. *There are triangulations of $\mathcal{A}(t)$ containing the simplicial complex $K$.*
2. *If $T$ is a triangulation of $\mathcal{A}(t)$ containing the simplicial complex $K$, then every triangulation obtained from $T$ by a flip contains the simplicial complex $K$. In particular, the graph of triangulations of $\mathcal{A}(t)$ is not connected.*
3. *The previous two statements remain true if $\mathcal{A}(t)$ is perturbed into general position in an arbitrary way.*

# A survey of Pfaffian orientations of graphs

Robin Thomas*

**Abstract.** An orientation of a graph $G$ is Pfaffian if every even cycle $C$ such that $G\setminus V(C)$ has a perfect matching has an odd number of edges directed in either direction of the cycle. The significance of Pfaffian orientations is that if a graph has one, then the number of perfect matchings (a.k.a. the dimer problem) can be computed in polynomial time.

The question of which bipartite graphs have Pfaffian orientations is equivalent to many other problems of interest, such as a permanent problem of Pólya, the even directed cycle problem, or the sign-nonsingular matrix problem for square matrices. These problems are now reasonably well-understood. On the other hand, it is not known how to efficiently test if a general graph is Pfaffian, but there are some interesting connections with crossing numbers and signs of edge-colorings of regular graphs.

**Mathematics Subject Classification (2000).** Primary 05C75; Secondary 05C10, 05C20, 05C38, 05C70, 05C83, 05C85, 68R10, 82B20.

**Keywords.** Graph, matching, dimer problem, Pfaffian orientation, even directed cycle, brick, brace, Pólya's permanent problem, sign-nonsingular matrix, crossing number.

## 1. Introduction

All *graphs* in this paper are finite, do not have loops or multiple edges and are undirected. *Directed graphs*, or *digraphs*, do not have loops or multiple edges, but may have two edges between the same pair of vertices, one in each direction. Most of our terminology is standard and can be found in many textbooks, such as [4], [10], [65]. In particular, *cycles* and *paths* have no repeated vertices. A subgraph $H$ of a graph $G$ is called *central* if $G\setminus V(H)$ has a perfect matching (we use $\setminus$ for deletion). An even cycle $C$ in a directed graph $D$ is called *oddly oriented* if for either choice of direction of traversal around $C$, the number of edges of $C$ directed in the direction of traversal is odd. Since $C$ is even, this is clearly independent of the initial choice of direction of traversal. Finally, an orientation $D$ of (the edges of) a graph $G$ is *Pfaffian* if every even central cycle of $G$ is oddly oriented in $D$. We say that a graph $G$ is *Pfaffian* if it has a Pfaffian orientation.

The significance of Pfaffian orientations stems from the fact that if a graph $G$ has one, then the number of perfect matchings of $G$ (as well as other related problems) can be computed in polynomial time. We survey this in Section 2. The following

*Partially supported by NSF grants DMS-0200595 and 0354742.

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

is a classical theorem of Kasteleyn [23]. A special case is implicit in the work of Fisher [16] and Temperley and Fisher [55]. Different proofs may be found in [25], [26], [32], [38].

**Theorem 1.1.** *Every planar graph is Pfaffian.*

The smallest non-Pfaffian graph is the complete bipartite graph $K_{3,3}$. This paper is centered around the question of which graphs are Pfaffian. For bipartite graphs this is equivalent to many other problems of interest, and is by now reasonably well-understood. We list several such problems in Section 3, including a question of Pólya from 1913 whether the permanent of a square matrix can be calculated by a reduction to a determinant of a related matrix, the even directed cycle problem for digraphs, and the sign-nonsingular matrix problem. In Section 4 we discuss two characterizations of bipartite Pfaffian graphs. The first is in terms of excluded obstructions; it turns out that for bipartite graphs $K_{3,3}$ is the only obstruction with respect to the "matching minor" partial order, defined later. This is an analogue of the graph minor relation and is well-suited for problems involving perfect matchings. Unfortunately, it no longer has many of the nice properties of the usual minor order. The second characterization is structural and describes the structure of all bipartite Pfaffian graphs. It turns out those graphs and only those graphs can be built from planar graphs and one sporadic nonplanar graph by certain composition operations. This characterization implies a polynomial-time algorithm to decide whether a bipartite graph is Pfaffian, and hence solves all the problems listed in Section 3. Applications of the structure theorem are discussed in Section 5.

We then turn to general graphs. In Section 6 we review a matching decomposition procedure of Lovász and Plummer that decomposes every graph into "bricks" and "braces". The decomposition has the property that a graph is Pfaffian if and only if all its constituent bricks and braces are Pfaffian. Furthermore, braces are bipartite, and hence whether they are Pfaffian can be decided using the algorithm of Section 4. Thus in order to test whether an input graph is Pfaffian it suffices to design an algorithm for bricks. Motivated by this we present a recent theorem that describes how to construct an arbitrary brick, and later we discuss various examples and results that were obtained using this theorem.

In the next section we talk about results of Norine that relate Pfaffian graphs and crossing numbers. The starting point here is Theorem 7.1 that characterizes Pfaffian graphs in terms of drawings in the plane. Norine then generalized it to $T$-joins, whereby the generalization implies several well-known results about crossing numbers, and in a different direction proved an analogue for 4-Pfaffian graphs and drawings in the torus. The latter suggests a general conjecture that is still open.

In Section 8 we discuss the relationship between signs of edge-colorings (in the sense of Penrose [46]) and Pfaffian orientations. We mention a proof of a conjecture of Goddyn that in a $k$-regular Pfaffian graph all $k$-edge-colorings have the same sign, which holds more generally for graphs that admit a "Pfaffian labeling." We present a partial converse of this, and then describe two characterizations of graphs that admit a

Pfaffian labeling. The above research led Norine and the author to make the following conjecture [44].

**Conjecture 1.2.** Every 2-connected 3-regular Pfaffian graph is 3-edge-colorable.

Let us recall that by Tait's result [54] (see also [65]) the Four-Color Theorem is equivalent to the statement that every 2-connected 3-regular planar graph is 3-edge-colorable. Thus, if true, Conjecture 1.2 would imply the Four-Color Theorem by Theorem 1.1.

In the last section we discuss the prospects for characterizing general Pfaffian graphs, either structurally or by means of excluded matching minors.

## 2. Pfaffian orientations and counting perfect matchings

Pfaffian orientations were invented by the physicists M. E. Fisher, P. W. Kasteleyn, and H. N. V. Temperley as a tool for enumerating the number of perfect matchings in a graph (or, in physics terminology, to solve the dimer problem). Let us start by explaining their approach. Let $A = (a_{ij})$ be a skew symmetric $n \times n$ matrix; that is $a_{ij} = -a_{ji}$. For each partition $\pi = \{\{i_1, j_1\}, \{i_2, j_2\}, \ldots, \{i_k, j_k\}\}$ of the set $\{1, 2, \ldots, n\}$ into unordered pairs ("partition into pairs") we define the quantity

$$\sigma_\pi = \operatorname{sgn}\begin{pmatrix} 1 & 2 & 3 & 4 & \ldots & 2k-1 & 2k \\ i_1 & j_1 & i_2 & j_2 & \ldots & i_k & j_k \end{pmatrix} a_{i_1 j_1} a_{i_2 j_2} \ldots a_{i_k j_k}, \tag{1}$$

where sgn denotes the sign of the indicated permutation. Clearly, there is no partition into pairs if $n$ is odd. The *Pfaffian* of $A$ is defined by $\operatorname{Pf}(A) = \sum \sigma_\pi$, where the summation is over all partitions of $\{1, 2, \ldots, n\}$ into pairs. Since $A$ is skew symmetric the value of $\sigma_\pi$ does not depend on the order of blocks of $\pi$ or on the order in which the members of a block are listed, and hence $\operatorname{Pf}(A)$ is well-defined. We will need the following lemma from linear algebra [23], [37].

**Lemma 2.1.** *If $A$ is a skew symmetric matrix, then* $\det A = (\operatorname{Pf}(A))^2$.

Now let $G$ be a graph with vertex-set $\{1, 2, \ldots, n\}$, and let $D$ be an orientation of (the edges of) $G$. To the orientation $D$ there corresponds a skew adjacency matrix $A = (a_{ij})$ of $G$ defined by saying that $a_{ij} = 0$ if $i$ is not adjacent to $j$, and otherwise $a_{ij} = 1$ if the edge $ij$ is directed in $D$ from $i$ to $j$ and $a_{ij} = -1$ if the edge $ij$ is directed in $D$ from $j$ to $i$. If $\pi$ is a partition of $\{1, 2, \ldots, n\}$ into pairs, then $\sigma_\pi \neq 0$ if and only if each pair in $\pi$ is an edge of $G$, or, in other words, $\pi$ is a perfect matching of $G$. Thus the summation in the definition of $\operatorname{Pf}(A)$ might as well be restricted to perfect matchings of $G$. We define $\operatorname{sgn}_D(M)$, the *sign of a perfect matching $M$ of $D$*, as $\sigma_M$, or, equivalently, by

$$\operatorname{sgn}_D(M) = \operatorname{sgn}\begin{pmatrix} 1 & 2 & 3 & 4 & \ldots & 2k-1 & 2k \\ i_1 & j_1 & i_2 & j_2 & \ldots & i_k & j_k \end{pmatrix}, \tag{2}$$

where the edges of $M$ are listed as $i_1j_1, i_2j_2, \ldots, i_kj_k$ in such a way that $i_tj_t$ is directed from $i_t$ to $j_t$ in $D$. It is not hard to see that $D$ is a Pfaffian orientation of $G$ if and only if $\mathrm{sgn}_D(M)$ does not depend on $M$. If that is the case, then $|\mathrm{Pf}(A)|$ is equal to the number of perfect matchings of $G$, and by Lemma 2.1 the number of perfect matchings of $G$ can be computed efficiently.

This is significant, because Valiant [63] proved that counting the number of perfect matchings in general graphs (even in bipartite graphs) is #P-complete, and therefore is unlikely to be polynomial-time solvable. Furthermore, Theorem 1.1 guarantees that there is an interesting and useful class of graphs for which this technique can be applied.

The dimer problem of statistical mechanics is concerned with the properties of a system of diatomic molecules, or dimers, adsorbed on the surface of a crystal. Usually it is assumed that the adsorption points form the vertices of a lattice graph, such as the 2-dimensional grid. A crucial problem in the calculation of the thermodynamic properties of such a system of dimers is that of enumerating all ways in which a given number of dimers can be arranged on the lattice without overlapping each other. In the related monomer-dimer model some sites may be left unoccupied, but in the dimer model it is assumed that the dimers cover all the vertices of the graph; in other words, they form a perfect matching. Kasteleyn [21], [22], [23], Fisher [16] and Temperley and Fisher [55] used the method described in this section to solve the 2-dimensional dimer problem. The method is more general in the sense that it allows the computation of the dimer partition function, and that, in turn, can be used to solve the 2-dimensional Ising problem [23]. Let us remark that the 3-dimensional dimer problem remains open.

## 3. Some equivalent problems

Vazirani and Yannakakis [64] used a deep theorem of Lovász [31] to show the following.

**Theorem 3.1.** *The decision problems "Is a given orientation of a graph Pfaffian" and "Is an input graph Pfaffian" are polynomial-time equivalent.*

This is reasonably easy for bipartite graphs. There does not seem to be an elementary proof for general graphs, but the theorem can be easily deduced from the results discussed in Section 6.

Computing the permanent of a matrix seems to be of a different computational complexity from computing the determinant. While the determinant can be calculated using Gaussian elimination, no efficient algorithm for computing the permanent is known, and, in fact, none is believed to exist. More precisely, Valiant [63] has shown that computing the permanent is #P-complete even when restricted to 0-1 matrices.

It is therefore reasonable to ask if perhaps computing the permanent can be somehow reduced to computing the determinant of a related matrix. In particular, the

following question was asked by Pólya [47] in 1913. If $A$ is a 0-1 square matrix, does there exist a matrix $B$ obtained from $A$ by changing some of the 1's to $-1$'s in such a way that the permanent of $A$ equals the determinant of $B$? For the purpose of this paper let us say that $B$ (when it exists) is a *Pólya matrix* for $A$.

Let $G$ be a bipartite graph with bipartition $(X, Y)$. The *bipartite adjacency matrix of* $G$ has rows indexed by $X$, columns indexed by $Y$, and the entry in row $x$ and column $y$ is 1 or 0 depending on whether $x$ is adjacent to $y$ or not. Vazirani and Yannakakis [64] proved the following.

**Theorem 3.2.** *Let $G$ be a bipartite graph, and let $A$ be its bipartite adjacency matrix. Then $A$ has a Pólya matrix if and only if $G$ has a Pfaffian orientation.*

Let us turn to directed graphs now. A digraph $D$ is *even* if for every weight function $w\colon E(D) \to \{0, 1\}$ there exists a cycle in $D$ of even total weight. It was shown in [53] and is not difficult to see that testing evenness is polynomial-time equivalent to testing whether a digraph has an even directed cycle. (This is equivalent to Theorem 3.1 for bipartite graphs.) Let $G$ be a bipartite graph with bipartition $(A, B)$, and let $M$ be a perfect matching in $G$. Let $D = D(G, M)$ be obtained from $G$ by directing every edge from $A$ to $B$, and contracting every edge of $M$. Little [27] has shown the following.

**Lemma 3.3.** *Let $G$ be a bipartite graph, and let $M$ be a perfect matching in $G$. Then $G$ has a Pfaffian orientation if and only if $D(G, M)$ is not even.*

We say that two $n \times m$ matrices $A = (a_{ij})$ and $B = (b_{ij})$ have the same *sign-pattern* if for all pairs of indices $i$, $j$ the entries $a_{ij}$ and $b_{ij}$ have the same sign; that is, they are both strictly positive, or they are both strictly negative, or they are both zero. A square matrix $A$ is *sign-nonsingular* if every real matrix with the same sign pattern is nonsingular.

In economic analysis one may not know the exact quantitative relationships between different variables, but there may be some qualitative information such as that one quantity rises if and only if another does. For instance, it is generally agreed that the supply of a particular commodity increases as the price increases, even though the exact dependence may vary. Thus we may want to deduce qualitative information about the solution to a linear system $A\boldsymbol{x} = \boldsymbol{b}$ from the knowledge of the sign-patterns of the matrix $A$ and vector $\boldsymbol{b}$. That motivates the following definition. We say that the linear system $A\boldsymbol{x} = \boldsymbol{b}$ is *sign-solvable* if for every real matrix $B$ with the same sign-pattern as $A$ and every vector $\boldsymbol{c}$ with the same sign-pattern as $\boldsymbol{b}$ the system $B\boldsymbol{y} = \boldsymbol{c}$ has a unique solution $\boldsymbol{y}$, and its sign-pattern does not depend on the choice of $B$ and $\boldsymbol{c}$. The study of sign-solvability was first proposed by Samuelson [51].

It follows from standard linear algebra that sign-solvability can be decided efficiently if and only if sign-nonsingularity can. But for square matrices the latter is equivalent to testing whether a given orientation of a bipartite graph is Pfaffian. To state the result, let $D$ be a bipartite digraph with bipartition $(X, Y)$. The *directed bipartite adjacency matrix of* $D$ has rows indexed by $X$, columns indexed by $Y$, and the entry in row $x$ and column $y$ is 1, $-1$ or 0 depending on whether $D$ has an edge

directed from $x$ to $y$, or $D$ has an edge directed from $y$ to $x$, or $x$ and $y$ are not adjacent in $D$. By Theorem 3.1 the following result implies that testing sign-solvability is polynomial-time equivalent to testing whether a bipartite graph is Pfaffian.

**Theorem 3.4.** *Let $D$ be a directed bipartite graph with a perfect matching, and let $A$ be its directed bipartite adjacency matrix. Then $A$ is sign-nonsingular if and only if $D$ is a Pfaffian orientation of its underlying undirected graph.*

The next problem is about hypergraph coloring. A *hypergraph* $H$ is a pair $(V(H), E(H))$, where $V(H)$ is a finite set and $E(H)$ is a collection of distinct nonempty subsets of $V(H)$. We say that $H$ is 2-*colorable* if $V(H)$ can be colored using two colors in such a way that every edge includes vertices of both colors. We say that $H$ is *minimally non*-2-*colorable* if $H$ is not 2-colorable, has no isolated vertices, and the deletion of any member of $E(H)$ results in a 2-colorable hypergraph. Seymour [52] proved the following.

**Theorem 3.5.** *Let $H$ be a hypergraph with no isolated vertices and $|E(H)| = |V(H)|$, let $D$ be the digraph with bipartition $(V(H), E(H))$ defined by saying that $D$ has an edge directed from $v \in V(H)$ to $E \in E(H)$ if and only if $v \in E$, and let $G$ be the underlying undirected graph of $D$. Then $H$ is minimally non-2-colorable if and only if $G$ is connected, every edge of $G$ belongs to a perfect matching of $G$ and $D$ is a Pfaffian orientation of $G$.*

Our last problem is about the polytope of even permutation matrices. The convex hull of permutation matrices has been characterized by Birkhoff [3] as precisely the set of doubly stochastic matrices. It is an open problem to characterize the convex hull of even permutation matrices. More precisely, it is not known if there exists a polynomial-time algorithm to test whether a given $n \times n$ matrix belongs to this polytope. By a fundamental result of Grötschel, Lovász and Schrijver [19] this problem is solvable in polynomial time if there exists a polynomial-time algorithm for the optimization problem: Given a fixed $n \times n$ matrix $M$, find the maximum of $M \cdot X$ over all even permutation matrices $X$, where "$\cdot$" denotes the dot product in $\mathbb{R}^{n^2}$ and both matrices are regarded as vectors of length $n^2$.

A special case of the above optimization problem when $A$ is a 0-1 matrix and we want to determine if the maximum is $n$ can be reformulated as follows. Let $G$ be a bipartite graph with bipartition $(A, B)$, and let $D$ be the orientation of $G$ defined by orienting every edge from $A$ to $B$. The problem is: "Decide if $G$ has a perfect matching $M$ such that $\mathrm{sgn}_D(M) = 1$." By Theorem 3.1 this is polynomial-time equivalent to deciding whether a bipartite graph has a Pfaffian orientation.

## 4. Characterizing bipartite Pfaffian graphs

We have seen in the previous section that characterizing bipartite Pfaffian graphs is of interest. In this section we discuss two such characterizations and a recognition

algorithm. We begin with an elegant theorem of Little [27]. Let $H$ be a graph, and let $v$ be a vertex of $H$ of degree two. By *bicontracting* $v$ we mean contracting both edges incident with $v$ and deleting the resulting loops and parallel edges. A graph $G$ is a *matching minor* of a graph $H$ if $G$ can be obtained from a central subgraph of $H$ by repeatedly bicontracting vertices of degree two. It is fairly easy to see that a matching minor of a Pfaffian graph is Pfaffian.

**Theorem 4.1.** *A bipartite graph admits a Pfaffian orientation if and only if it has no matching minor isomorphic to* $K_{3,3}$.

By Lemma 3.3 the above implies a characterization of even digraphs. Seymour and Thomassen obtained such characterization from first principles in [53]. Interestingly, the latter involves infinitely many excluded minors, rather than one.

Unfortunately, Theorem 4.1 does not seem to imply a polynomial-time algorithm to test whether a bipartite graph is Pfaffian, the difficulty being that it is not clear how to efficiently test for the presence of a matching minor isomorphic to $K_{3,3}$. The next result gives a structural description of bipartite Pfaffian graphs, and can be used to derive a polynomial-time recognition algorithm. We need some definitions first.

Let $G_0$ be a graph, let $C$ be a central cycle of $G_0$ of length four, and let $G_1, G_2, G_3$ be three subgraphs of $G_0$ such that $G_1 \cup G_2 \cup G_3 = G_0$, and for distinct integers $i, j \in \{1, 2, 3\}$, $G_i \cap G_j = C$ and $V(G_i) - V(C) \neq \emptyset$. Let $G$ be obtained from $G_0$ by deleting some (possibly none) of the edges of $C$. In these circumstances we say that $G$ is a *trisum* of $G_1$, $G_2$ and $G_3$. The *Heawood graph* is the bipartite graph associated with the incidence matrix of the Fano plane (see Figure 1).

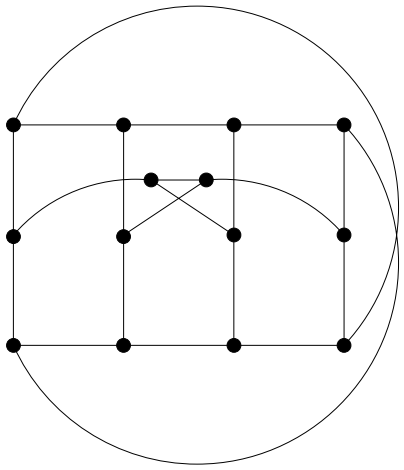

Figure 1. The Heawood graph.

A graph $G$ is *k-extendable*, where $k \geq 0$ is an integer, if every matching of size at most $k$ can be extended to a perfect matching. A connected 2-extendable bipartite

graph is called a *brace*. It is easy to see (and will be outlined in Section 6) that the problem of finding Pfaffian orientations of bipartite graphs can be reduced to braces. The following was shown in [35] and, independently, in [50].

**Theorem 4.2.** *A brace has a Pfaffian orientation if and only if either it is isomorphic to the Heawood graph, or it can be obtained from planar braces by repeated application of the trisum operation.*

Let us turn to testing whether a bipartite graph is Pfaffian. We wish to apply Theorem 4.2, and for that the following result [50, Theorem 8.3] is very helpful.

**Theorem 4.3.** *Let $G$ be a brace that has a Pfaffian orientation, and let $G$ be a trisum of $G_1$, $G_2$ and $G_3$. Then $G_1$, $G_2$ and $G_3$ have a Pfaffian orientation.*

A polynomial-time algorithm now follows easily. Given a bipartite graph $G$ we first decompose it into braces (more on that in Section 6), and apply the algorithm recursively to each brace in the decomposition. Thus we may assume that $G$ is a brace. Now we test if $G$ has a set $X \subseteq V(G)$ of size four such that $G\backslash X$ has at least three components. If it does, then $G$ can be expressed as a trisum of three smaller graphs, and by Theorem 4.3 we may apply the algorithm recursively to each of the three smaller graphs. On the other hand, if $G$ has no set $X$ as above, then by Theorem 4.2 $G$ is Pfaffian if and only if it is planar or isomorphic to the Heawood graph. It is clear that this is a polynomial-time algorithm. In [50] it is shown how to implement it to run in time $O(|V(G)|^3)$. By using more modern algorithmic results the running time can be reduced to $O(|V(G)|^2)$.

## 5. Applications of the characterization of bipartite Pfaffian graphs

As a corollary of Theorem 4.2 we get the following extremal result.

**Corollary 5.1.** *No brace with $n \geq 3$ vertices and more than $2n - 4$ edges has a Pfaffian orientation.*

*Proof.* Every planar bipartite graph on $n \geq 3$ vertices has at most $2n - 4$ edges. The result follows from Theorem 4.2 by induction. □

Since every digraph is isomorphic to $D(G, M)$ for some $G$ and $M$, Theorem 4.2 gives a characterization of even directed graphs, using Lemma 3.3. Let us state the characterization explicitly, but first let us point out a relation between extendability and strong connectivity. A digraph $D$ is *strongly connected* if for every two vertices $u$ and $v$ it has a directed path from $u$ to $v$. It is *strongly $k$-connected*, where $k \geq 1$ is an integer, if for every set $X \subseteq V(D)$ of size less than $k$, the digraph $D\backslash X$ is strongly connected. The following is straightforward.

**Lemma 5.2.** *Let $G$ be a connected bipartite graph, let $M$ be a perfect matching in $G$, and let $k \geq 1$ be an integer. Then $G$ is $k$-extendable if and only if $D(G, M)$ is strongly $k$-connected.*

Let $D$ be a digraph, and let $(X, Y)$ be a partition of $V(G)$ into two nonempty sets in such a way that no edge of $G$ has tail in $X$ and head in $Y$. Let $D_1 = D\backslash Y$ and $D_2 = D\backslash X$. We say that $D$ is a 0-*sum* of $D_1$ and $D_2$. Now let $v \in V(D)$, and let $(X, Y)$ be a partition of $V(D) - \{v\}$ into two nonempty sets such that no edge of $D$ has tail in $X$ and head in $Y$. Let $D_1$ be obtained from $D$ by deleting all edges with both ends in $Y \cup \{v\}$ and identifying all vertices of $Y \cup \{v\}$, and let $D_2$ be obtained by deleting all edges with both ends in $X \cup \{v\}$ and identifying all vertices of $X \cup \{v\}$. We say that $D$ is a 1-*sum* of $D_1$ and $D_2$. Let $D_0$ be a directed graph, let $u, v \in V(D_0)$, and let $uv, vu \in E(D_0)$. Let $D_1$ and $D_2$ be such that $D_1 \cup D_2 = D_0$, $V(D_1) \cap V(D_2) = \{u, v\}$, $V(D_1) - V(D_2) \neq \emptyset \neq V(D_2) - V(D_1)$ and $E(D_1) \cap E(D_2) = \{uv, vu\}$. Let $D$ be obtained from $D_0$ by deleting some (possibly neither) of the edges $uv, vu$. We say that $D$ is a 2-*sum* of $D_1$ and $D_2$. Now let $D_0$ be a directed graph, let $u, v, w \in V(D_0)$, let $uv, wv, wu \in E(D_0)$, and assume that $D_0$ has a directed cycle containing the edge $wv$, but not the vertex $u$. Let $D_1$ and $D_2'$ be such that $D_1 \cup D_2' = D_0$, $V(D_1) \cap V(D_2') = \{u, v, w\}$, $V(D_1) - V(D_2') \neq \emptyset \neq V(D_2') - V(D_1)$ and $E(D_1) \cap E(D_2') = \{uv, wv, wu\}$, let $D_2'$ have no edge with tail $v$, and no edge with head $w$. Let $D$ be obtained from $D_0$ by deleting some (possibly none) of the edges $uv, wv, wu$, and let $D_2$ be obtained from $D_2'$ by contracting the edge $wv$. We say that $D$ is a 3-*sum* of $D_1$ and $D_2$. Finally let $D_0$ be a directed graph, let $x, y, u, v \in V(D_0)$, let $xy, xv, uy, uv \in E(D_0)$, and assume that $D_0$ has a directed cycle containing precisely two of the edges $xy, xv, uy, uv$. Let $D_1$ and $D_2'$ be such that $D_1 \cup D_2' = D_0$, $V(D_1) \cap V(D_2') = \{x, y, u, v\}$, $V(D_1) - V(D_2') \neq \emptyset \neq V(D_2') - V(D_1)$ and $E(D_1) \cap E(D_2') = \{xy, xv, uy, uv\}$, let $D_2'$ have no edge with tail $y$ or $v$, and no edge with head $x$ or $u$. Let $D$ be obtained from $D_0$ by deleting some (possibly none) of the edges $xy, xv, uy, uv$, and let $D_2$ be obtained from $D_2'$ by contracting the edges $xy$ and $uv$. We say that $D$ is a 4-*sum* of $D_1$ and $D_2$. We say that a digraph is *strongly planar* if it has a planar drawing such that for every vertex $v \in V(D)$, the edges of $D$ with head $v$ form an interval in the cyclic ordering of edges incident with $v$ determined by the planar drawing. Let $F_7$ be the directed graph $D(H, M)$, where $H$ is the Heawood graph, and $M$ is a perfect matching of $H$. This defines $F_7$ uniquely up to isomorphism, irrespective of the choice of the bipartition of $H$ or the choice of $M$. Lemma 3.3 and Theorem 4.2 imply the following.

**Theorem 5.3.** *A digraph $D$ is not even if and only if it can be obtained from strongly planar digraphs and $F_7$ by means of* 0-, 1-, 2-, 3- *and* 4-*sums.*

From Corollary 5.1 and Lemmas 3.3 and 5.2 we deduce the following extremal result.

**Corollary 5.4.** *Let $D$ be a strongly 2-connected directed graph on $n \geq 2$ vertices. If $D$ has more than $3n - 4$ edges, then $D$ is even.*

Corollary 5.4 does not hold for strongly connected digraphs. However, Thomassen [59] has shown that every strongly connected directed graph with minimum in- and out-degree at least three is even. This is equivalent to the following by Lemma 3.3.

**Corollary 5.5.** *Let $G$ be a 1-extendable bipartite graph such that every vertex has degree at least four. Then $G$ does not have Pfaffian orientation.*

If $G$ is a brace, then the corollary follows from Corollary 5.1; otherwise the corollary follows by induction using the matching decomposition explained in the next section. The details may be found in [50, Corollary 7.8].

In [33] McCuaig used Theorem 4.2 to answer a question of Thomassen [58] by proving the following.

**Theorem 5.6.** *The digraph $F_7$ is the unique strongly 2-connected digraph with no even cycle.*

## 6. Matching decomposition

We have seen in the preceding sections that the problem of understanding which bipartite graphs are Pfaffian is reasonably well-understood and has applications outside of this subfield. We now turn our attention to the same question for general graphs. This problem seems much harder, but there are some interesting and unexpected connections.

The brick decomposition procedure of Lovász and Plummer [32] can be used to reduce the question of characterizing Pfaffian graphs to "bricks". The purpose of this section is to give an overview of this decomposition technique and to discuss recent additions to it.

A graph is *matching covered* if it is connected and every edge belongs to a perfect matching. Clearly, when deciding whether a graph $G$ is Pfaffian we may assume that $G$ is matching covered, for edges that belong to no perfect matching may be deleted without affecting the outcome.

Let $G$ be a graph, and let $X \subseteq V(G)$. We use $\delta(X)$ to denote the set of edges with one end in $X$ and the other in $V(G) - X$. A *cut* in $G$ is any set of the form $\delta(X)$ for some $X \subseteq V(G)$. A cut $C$ is *tight* if $|C \cap M| = 1$ for every perfect matching $M$ in $G$. Every cut of the form $\delta(\{v\})$ in a graph with a perfect matching is tight; those are called *trivial*, and all other tight cuts are called *nontrivial*.

Here are three important examples of tight cuts. Let $G$ be a matching covered graph. Assume first that $G$ is bipartite with bipartition $(A, B)$, and that $G$ is not a brace. Then by Hall's theorem there is a set $X \subseteq A$ such that $|N(X)| = |X| + 1$ and $N(X) \neq B$, where $N(X)$ denotes the set of all vertices $v \in V(G) - X$ with a neighbor in $X$. Then $\delta(X \cup N(X))$ is a nontrivial tight cut. Now assume that $G$ is not bipartite. If there exist distinct vertices $u, v \in V(G)$ such that $G \backslash u \backslash v$ has no perfect matching, then by Tutte's 1-factor theorem [61] there exists a nonempty set $X \subseteq V(G)$ such

that $G\backslash X$ has exactly $|X|$ odd components. Furthermore, by repeatedly adding to $X$ one vertex from each even component of $G\backslash X$ we may assume that $G\backslash X$ has no even components. Since $G$ is matching covered no edge of $G$ has both ends in $X$, and since $G$ is not bipartite some component of $G\backslash X$, say $C$, has more than one vertex. But then $\delta(V(C))$ is a nontrivial tight cut. Finally, if $G$ is not 3-connected, then let $u$, $v$ be distinct vertices of $G$ such that $G\backslash u\backslash v$ is disconnected. Let $A$ be the vertex-set of a component of $G\backslash u\backslash v$ and let $B$ be the union of all the remaining components. Notice that if $|A|$ is odd, then $G\backslash u\backslash v$ has no perfect matching. If $|A|$ is even, then $\delta(A\cup\{u\})$ is a nontrivial tight cut.

It is not true that every nontrivial tight cut arises as described above, but Theorem 6.1 below implies that if a graph has a nontrivial tight cut, then it has a nontrivial tight cut that arises in one of the ways described in the previous paragraph. A *brick* is a 3-connected graph $G$ such that $G\backslash u\backslash v$ has a perfect matching for every two distinct vertices $u$, $v$ of $G$.

Let $\delta(X)$ be a nontrivial tight cut in a graph $G$, let $G_1$ be obtained from $G$ by identifying all vertices in $X$ into a single vertex and deleting all resulting parallel edges, and let $G_2$ be defined analogously by identifying all vertices in $V(G)-X$. Then many matching-related problems can be solved for $G$ if we are given the corresponding solutions for $G_1$ and $G_2$.

The above decomposition process can be iterated, until we arrive at graphs with no nontrivial tight cuts. Lovász [31] proved that the list of indecomposable graphs obtained at the end of the procedure does not depend on the choice of tight cuts made during the process. These indecomposable graphs were characterized by Edmonds, Lovász and Pulleyblank [12], [13]:

**Theorem 6.1.** *Let $G$ be a matching covered graph. Then $G$ has no nontrivial tight cut if and only if $G$ is a brick or a brace.*

In light of this theorem and the previous discussion we say that a brick or a brace $H$ is a *brick* or a *brace of a graph $G$* if $H$ is obtained when the tight cut decomposition procedure is applied to $G$.

Vazirani and Yannakakis [64] used the tight cut decomposition procedure to reduce the study of Pfaffian graphs to bricks and braces:

**Theorem 6.2.** *A graph $G$ is Pfaffian if and only if every brick and brace of $G$ is Pfaffian.*

In particular, this justifies our earlier claim that in order to understand Pfaffian bipartite graphs it suffices to understand Pfaffian braces. Since Pfaffian braces are characterized by Theorem 4.2, in order to understand Pfaffian graphs it suffices to understand Pfaffian bricks. We return to this problem later, but in the remainder of this section we describe a characterization of bricks, developed for the purpose of studying Pfaffian bricks. We need a few definitions first.

Let $G$ be a graph, and let $v_0$ be a vertex of $G$ of degree two incident with the edges $e_1 = v_0v_1$ and $e_2 = v_0v_2$. Let $H$ be obtained from $G$ by contracting both $e_1$

and $e_2$ and deleting all resulting parallel edges. We say that $H$ was obtained from $G$ by *bicontracting* or *bicontracting the vertex* $v_0$, and write $H = G/v_0$. Let us say that a graph $H$ is a *reduction* of a graph $G$ if $H$ can be obtained from $G$ by deleting an edge and bicontracting all resulting vertices of degree two. By a *prism* we mean the unique 3-regular planar graph on six vertices. The following is a generation theorem of de Carvalho, Lucchesi and Murty [9].

**Theorem 6.3.** *If $G$ is a brick other than $K_4$, the prism, and the Petersen graph, then some reduction of $G$ is a brick other than the Petersen graph.*

Thus if a brick $G$ is not the Petersen graph, then the reduction operation can be repeated until we reach $K_4$ or the prism. By reversing the process Theorem 6.3 can be viewed as a generation theorem.

Theorem 6.3 has interesting applications. First of all, it implies several results about various spaces generated by perfect matchings, including a deep theorem of Lovász [31] that characterizes the matching lattice of a graph. Second, it implies Theorem 3.1 (more precisely the most difficult part of that theorem, namely that it holds for bricks). Third, it can be used to prove a uniqueness theorem for Pfaffian orientations [8]:

**Theorem 6.4.** *A Pfaffian orientation of a graph $G$ can be transformed to any other Pfaffian orientation of $G$ by repeatedly applying the following operations:*

(1) *reversing the direction of all edges of a cut of $G$,*
(2) *reversing all edges with both ends in $S$ for some tight cut $\delta(S)$,*
(3) *reversing the direction of all edges of $G$.*

There is a strengthening of Theorem 6.3, which we now describe. First, the starting graph can be any matching minor of $G$ except $K_4$ and the prism, and second, reduction can be replaced by a more restricted operation, the following. We say that a graph $H$ is a *proper reduction* of a graph $G$ if it is a reduction in such a way that the bicontractions involved do not produce parallel edges. Unfortunately, Theorem 6.3 does not hold for proper reductions, but all the exceptions can be conveniently described. Let us do that now.

Let $C_1$ and $C_2$ be two vertex-disjoint cycles of length $n \geq 3$ with vertex-sets $\{u_1, u_2, \ldots, u_n\}$ and $\{v_1, v_2, \ldots, v_n\}$ (in order), respectively, and let $G_1$ be the graph obtained from the union of $C_1$ and $C_2$ by adding an edge joining $u_i$ and $v_i$ for each $i = 1, 2, \ldots, n$. We say that $G_1$ is a *planar ladder*. Let $G_2$ be the graph consisting of a cycle $C$ with vertex-set $\{u_1, u_2, \ldots, u_{2n}\}$ (in order), where $n \geq 2$ is an integer, and $n$ edges with ends $u_i$ and $u_{n+i}$ for $i = 1, 2, \ldots, n$. We say that $G_2$ is a *Möbius ladder*. A *ladder* is a planar ladder or a Möbius ladder. Let $G_1$ be a planar ladder as above on at least six vertices, and let $G_3$ be obtained from $G_1$ by deleting the edge $u_1u_2$ and contracting the edges $u_1v_1$ and $u_2v_2$. We say that $G_3$ is a *staircase*. Let $t \geq 2$ be an integer, and let $P$ be a path with vertices $v_1, v_2, \ldots, v_t$ in order. Let $G_4$ be obtained from $P$ by adding two distinct vertices $x, y$ and edges $xv_i$ and $yv_j$ for $i = 1, t$ and all even $i \in \{1, 2, \ldots, t\}$ and $j = 1, t$ and all odd $j \in \{1, 2, \ldots, t\}$.

Let $G_5$ be obtained from $G_4$ by adding the edge $xy$. We say that $G_5$ is an *upper prismoid*, and if $t \geq 4$, then we say that $G_4$ is a *lower prismoid*. A *prismoid* is a lower prismoid or an upper prismoid. We are now ready to state a strengthening of Theorem 6.3, proved in [43].

**Theorem 6.5.** *Let $H$, $G$ be bricks, where $H$ is isomorphic to a matching minor of $G$. Assume that $H$ is not isomorphic to $K_4$ or the prism, and $G$ is not a ladder, wheel, staircase or prismoid. Then a graph isomorphic to $H$ can be obtained from $G$ by repeatedly taking proper reductions in such a way that all the intermediate graphs are bricks not isomorphic to the Petersen graph.*

As a counterpart to Theorem 6.5, [43] describes the starting graphs for the generation process. Notice that $K_4$ is a wheel, a Möbius ladder, a staircase and an upper prismoid, and that the prism is a planar ladder, a staircase and a lower prismoid.

**Theorem 6.6.** *Let $G$ be a brick not isomorphic to $K_4$, the prism or the Petersen graph. Then $G$ has a matching minor isomorphic to one of the following seven graphs: the graph obtained from the prism by adding an edge, the lower prismoid on eight vertices, the staircase on eight vertices, the staircase on ten vertices, the planar ladder on ten vertices, the wheel on six vertices, and the Möbius ladder on eight vertices.*

If $H$ is a brick isomorphic to a matching minor of a brick $G$ and $G$ is a ladder, wheel, staircase or prismoid, then $H$ itself is a ladder, wheel, staircase or prismoid, and can be obtained from a graph isomorphic to $G$ by taking (improper) reductions in such a way that all intermediate graphs are bricks. Thus Theorems 6.5 and 6.6 imply Theorem 6.3. Theorems 6.5 and 6.6 were used to prove two results about minimal bricks [42], and to generate interesting examples of Pfaffian bricks. We will discuss some of those later.

McCuaig [34] proved an analogue of Theorem 6.5 for braces and used it in his proof of Theorem 4.2 in [35]. To state his result we need another exceptional class of graphs. Let $C$ be an even cycle with vertex-set $v_1, v_2, \ldots, v_{2t}$ in order, where $t \geq 2$ is an integer and let $G_6$ be obtained from $C$ by adding vertices $v_{2t+1}$ and $v_{2t+2}$ and edges joining $v_{2t+1}$ to the vertices of $C$ with odd indices and $v_{2t+2}$ to the vertices of $C$ with even indices. Let $G_7$ be obtained from $G_6$ by adding an edge $v_{2t+1}v_{2t+2}$. We say that $G_7$ is an *upper biwheel*, and if $t \geq 3$ we say that $G_6$ is a *lower biwheel*. A *biwheel* is a lower biwheel or an upper biwheel. McCuaig's result is as follows.

**Theorem 6.7.** *Let $H$, $G$ be braces, where $H$ is isomorphic to a matching minor of $G$. Assume that if $H$ is a planar ladder, then it is the largest planar ladder matching minor of $G$, and similarly for Möbius ladders, lower biwheels and upper biwheels. Then a graph isomorphic to $H$ can be obtained from $G$ by repeatedly taking proper reductions in such a way that all the intermediate graphs are braces.*

Actually, Theorem 6.7 follows from a stronger version of Theorem 6.5 proved in [43].

## 7. Crossing numbers and $k$-Pfaffian graphs

By a drawing $\Gamma$ of a graph in a surface $\Sigma$ we mean an immersion of $G$ in $\Sigma$ such that edges are represented by homeomorphic images of $[0, 1]$, not containing vertices in their interiors. Edges are permitted to intersect, but there are only finitely many intersections and each intersection is a crossing. For edges $e, f$ of a drawing $\Gamma$ let $cr(e, f)$ denote the number of times the edges $e$ and $f$ cross. For a perfect matching $M$ let $cr_\Gamma(M)$, or $cr(M)$ when $\Gamma$ is understood from the context, denote $\sum cr(e, f)$, where the sum is taken over all unordered pairs of distinct edges $e, f \in M$. The following theorem was proved by Norine [38]. The "if" part was known to Kasteleyn [23] and was proved by Tesler [56]. Norine's proof of that implication is different.

**Theorem 7.1.** *A graph $G$ is Pfaffian if and only if there exists a drawing of $G$ in the plane such that $cr(M)$ is even for every perfect matching $M$ of $G$.*

The theory of crossing numbers is fairly well-developed, but only few results involve parity of crossing numbers, and I am not aware of any about crossings of perfect matchings. The closest relative of Theorem 7.1 seems to be the following classical result of Hanani [20] and Tutte [62].

**Theorem 7.2.** *Let $\Gamma$ be a drawing of a graph in the plane such that $cr(e, f)$ is even for every two distinct non-adjacent edges $e, f$ of $G$. Then $G$ is planar.*

In fact, there is a deeper connection between the last two theorems. Norine [40] generalized Theorem 7.1 to a statement about the parity of self-intersections of different $T$-joins of a graph, and this generalization implies Theorem 7.2 as well as other results about crossing numbers. We omit the precise statement and instead refer the readers to [40].

A graph $G$ is *$k$-Pfaffian* if there exist orientations $D_1, D_2, \ldots, D_k$ of $G$ and real numbers $\alpha_1, \alpha_2, \ldots, \alpha_k$ such that $\sum_{i=1}^{k} \alpha_i \mathrm{sgn}_{D_i}(M) = 1$ for every perfect matching $M$ of $G$. Thus if $k$ is fixed and the orientations and coefficients as above are given, then the number of perfect matchings of $G$ can be calculated efficiently, using Lemma 2.1. The following was noted by Kasteleyn [23] and proved by Galluccio and Loebl [17] and Tesler [56].

**Theorem 7.3.** *Every graph that has an embedding in the orientable surface of genus $g$ is $4^g$-Pfaffian.*

In light of Theorem 7.1 one might speculate that 4-Pfaffian graphs are related to graphs drawn on the torus subject to the parity condition of Theorem 7.1. That is indeed true, as shown by Norine [41].

**Theorem 7.4.** *Every 3-Pfaffian graph is Pfaffian. A graph $G$ is 4-Pfaffian if and only if it can be drawn on the torus such that $cr(M)$ is even for every perfect matching $M$ of $G$.*

It is therefore sensible to conjecture a generalization to surfaces of arbitrary genus, as does Norine in [41]:

**Conjecture 7.5.** For a graph $G$ and integer $g \geq 0$ the following conditions are equivalent:

(1) There exists a drawing of $G$ on the orientable surface of genus $g$ such that $cr(M)$ is even for every perfect matching $M$ of $G$.

(2) The graph $G$ is $4^g$-Pfaffian.

(3) The graph $G$ is $(4^{g+1} - 1)$-Pfaffian.

Norine [41] has shown that every 5-Pfaffian graph is 4-Pfaffian, but his method breaks down after that.

## 8. Signs of edge-colorings

In this section we relate signs of edge-colorings (as in Penrose [46]) with "Pfaffian labelings", a generalization of Pfaffian orientations, whereby edges are labeled by elements of an Abelian group with an element of order two.

A graph $G$ is called *$k$-list-edge-colorable* if for every set system $\{S_e : e \in E(G)\}$ such that $|S_e| = k$ there exists a proper edge coloring $c$ with $c(e) \in S_e$ for every $e \in E(G)$. The following famous list-edge-coloring conjecture was suggested independently by various researchers and first appeared in print in [5].

**Conjecture 8.1.** Every $k$-edge-colorable graph is $k$-list-edge-colorable.

In a $k$-regular graph $G$ one can define an equivalence relation on $k$-edge colorings as follows. Let $c_1, c_2 \colon E(G) \to \{1, \ldots, k\}$ be two (proper) $k$-edge colorings of $G$. For $v \in V(G)$ let $\pi_v \colon \{1, \ldots, k\} \to \{1, \ldots, k\}$ be the permutation such that $\pi_v(c_1(e)) = c_2(e)$ for every $e \in E(G)$ incident with $v$, and let $c_1 \sim c_2$ if $\prod_{v \in V(G)} sgn(\pi_v) = 1$. Obviously $\sim$ is an equivalence relation on the set of $k$-edge colorings of $G$ and $\sim$ has at most two equivalence classes. We say that $c_1$ and $c_2$ *have the same sign* if $c_1 \sim c_2$ and we say that $c_1$ and $c_2$ *have opposite signs* otherwise.

A powerful algebraic technique developed by Alon and Tarsi [2] implies [1] that if in a $k$-edge-colorable $k$-regular graph $G$ all $k$-edge colorings have the same sign then $G$ is $k$-list-edge-colorable. In [14] Ellingham and Goddyn prove the following theorem.

**Theorem 8.2.** *In a $k$-regular planar graph all $k$-edge colorings have the same sign. Therefore every $k$-edge-colorable $k$-regular planar graph is $k$-list-edge-colorable.*

Goddyn [18] conjectured that Theorem 8.2 generalizes to Pfaffian graphs. This turned out to be true, even for the somewhat larger class of graphs that admit Pfaffian labelings. Let us introduce those graphs now.

Let $\Gamma$ be an Abelian multiplicative group, let 1 be the identity of $\Gamma$ and let $-1$ be some element of order two in $\Gamma$. Let $G$ be a graph with $V(G) = \{1, 2, \ldots, n\}$,

and let $D$ be the orientation of $G$ in which every edge $ij$ is oriented from $i$ to $j$, where $i < j$. Let us recall that $\mathrm{sgn}_D(M)$ was defined in Section 2. We say that $l\colon E(G) \to \Gamma$ is a *Pfaffian labeling* of $G$ if for every perfect matching $M$ of $G$, $\mathrm{sgn}_D(M) = \prod_{e\in M} l(e)$. We say that $G$ admits a *Pfaffian $\Gamma$-labeling* if there exists a Pfaffian labeling $l\colon E(G) \to \Gamma$ of $G$. We say that $G$ admits a *Pfaffian labeling* if $G$ admits a Pfaffian $\Gamma$-labeling for some Abelian group $\Gamma$ as above. It is easy to see that a graph $G$ admits a Pfaffian $\mathbb{Z}_2$-labeling if and only if $G$ admits a Pfaffian orientation. Note also that the existence of a Pfaffian labeling of a graph does not depend on the ordering of its vertices. The results of the remainder of this section are from [44].

**Theorem 8.3.** *Let $G$ be a $k$-regular graph with $V(G) = \{1, \ldots, 2n\}$. If $G$ admits a Pfaffian labeling then all $k$-edge-colorings of $G$ have the same sign.*

Using the theory of Alon and Tarsi mentioned above this implies a proof of Goddyn's conjecture:

**Corollary 8.4.** *Every $k$-edge-colorable $k$-regular graph that admits a Pfaffian labeling is $k$-list-edge-colorable.*

Theorem 8.3 has the following partial converse.

**Theorem 8.5.** *If a graph $G$ does not admit a Pfaffian labeling then there exist an integer $k$, a $k$-regular multigraph $G'$ whose underlying simple graph is a spanning subgraph of $G$ and two $k$-edge colorings of $G'$ of different signs.*

The above two theorems suggest the study of graphs that admit a Pfaffian labeling. First, there is an analogue of Theorem 6.2.

**Lemma 8.6.** *Let $\Gamma$ be an Abelian group. A matching covered graph $G$ admits a Pfaffian $\Gamma$-labeling if and only if each of its bricks and braces admits a Pfaffian $\Gamma$-labeling.*

Thus it suffices to characterize bricks and braces that have a Pfaffian labeling. The Petersen graph is not Pfaffian, but it admits a Pfaffian $\mu_4$-labeling, where $\mu_n$ is the multiplicative group of the $n^{\text{th}}$ roots of unity. Figure 2 shows an example of such a labeling. Using Theorems 6.3 and 6.7 it is not hard to show that the Petersen graph is the only brick or brace with that property. Using Lemma 8.6 we obtain:

**Theorem 8.7.** *A graph $G$ admits a Pfaffian labeling if and only if every brick and brace in its decomposition is either Pfaffian or isomorphic to the Petersen graph. If $G$ admits a Pfaffian $\Gamma$-labeling for some Abelian group $\Gamma$ then $G$ admits a Pfaffian $\mu_4$-labeling.*

The last result of this section characterizes graphs that admit a Pfaffian labeling in terms of their drawing in the projective plane. We say that a region $C$ of the projective plane is *a crosscap* if its boundary is a simple closed curve and its complement is a disc. We say that a drawing $\Gamma$ of a graph $G$ in the projective plane is *proper with*

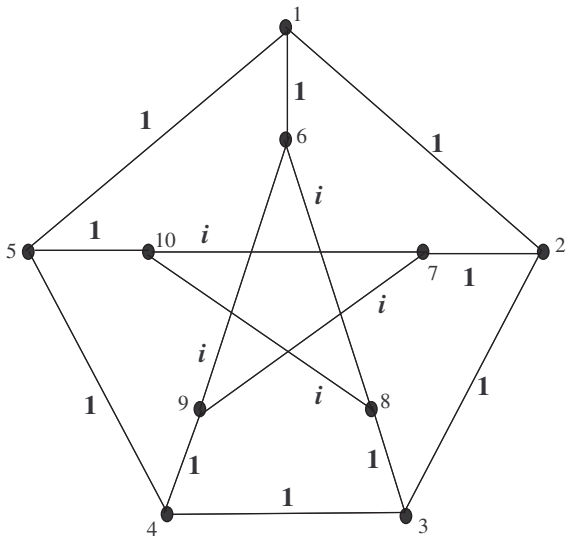

Figure 2. A $\mu_4$-labeling of the Petersen graph.

*respect to the crosscap C* if no vertex of $G$ is mapped to $C$ and for every edge $e \in E(G)$ intersecting $C$ and every crosscap $C' \subseteq C$ the image of $e$ intersects $C'$.

**Theorem 8.8.** *A graph $G$ admits a Pfaffian labeling if and only if there exists a crosscap $C$ in the projective plane and a proper drawing $\Gamma$ of $G$ in the projective plane with respect to $C$ such that $|M \cap S|$ and $cr_\Gamma(M)$ are even for every perfect matching $M$ of $G$, where $S \subseteq E(G)$ denotes the set of edges whose images intersect $C$.*

## 9. On characterizing Pfaffian graphs

Norine's theorem, Theorem 7.1, is a beautiful result, but, unfortunately, does not seem to help testing whether a graph is Pfaffian. Theorems 4.1 and 4.2 suggest two possible ways of characterizing Pfaffian graphs, but neither has been carried out, and there appear to be serious difficulties.

Fischer and Little [15] extended Theorem 4.1 as follows. A matching covered graph is *near bipartite* if it has two edges whose deletion makes the graph bipartite and matching covered. Let *Cubeplex* be the graph obtained from the (skeleton of the 3-dimensional) cube by subdividing three edges of a perfect matching and adding a vertex of degree three adjacent to the three resulting vertices, and let *Twinplex* be obtained from the Petersen graph by subdividing two edges that form an induced matching and joining the resulting vertices by an edge. This defines both graphs uniquely up to isomorphism. We say that a graph is a *weak matching minor* of another

if the first can be obtained from a matching minor of the second by contracting odd cycles and deleting all resulting loops and parallel edges.

**Theorem 9.1.** *A near bipartite graph is Pfaffian if an only if it has no weak matching minor isomorphic to $K_{3,3}$, Cubeplex or Twinplex.*

Let us say that a graph $G$ is *minimally non-Pfaffian* if $G$ is not Pfaffian but every proper weak matching minor of $G$ is. Thus $K_{3,3}$, Cubeplex and Twinplex are minimally non-Pfaffian, and so is the Petersen graph, as is easily seen. Fischer and Little (private communication) conjectured that those are the only minimally non-Pfaffian graphs; in other words they conjectured that upon adding the Petersen graph to the list of excluded weak matching minors, Theorem 9.1 holds for all graphs. Unfortunately, that is not the case. Here is an infinite family of minimally non-Pfaffian graphs [45].

Let $k \geq 2$, let $C_{2k+1}$ be the cycle of length $2k+1$ with vertices $1, 2, \ldots, 2k+1$ in order, and let $M$ be a matching in $C$, possibly empty. Let the graph $G(k, M)$ be defined by saying that its vertex-set is $\{u_1, u_2, \ldots, u_{2k+1}, v_1, v_2, \ldots, v_{2k+1}, w_1, w_2\}$ and that $G(k, M)$ has the following edges, where index arithmetic is taken modulo $2k+1$:

- $u_i v_i$ for all $i = 1, 2, \ldots, 2k+1$,
- $u_i u_{i+1}$ and $v_i w_2$ if $\{i, i+1\} \notin M$,
- $v_i w_1$ if $\{i-1, i\} \notin M$,
- $u_i v_{i+1}$ and $v_i u_{i+1}$ if $\{i, i+1\} \in M$.

Notice that the graph $G(2, \{\{1, 2\}, \{3, 4\}\})$ is isomorphic to Cubeplex.

**Theorem 9.2.** *For every integer $k \geq 2$ and every matching $M$ of $C_{2k+1}$ the graph $G(k, M)$ is minimally non-Pfaffian.*

Thus an extension of Theorem 9.1 to all graphs would have to involve infinitely many excluded weak matching minors. On the other hand, as noted in [45], the family $G(k, M)$ suggests a possible weakening of the weak matching minor ordering, and it is possible that if weak matching minor is replaced by this weakening, then the list of excluded might be finite (and of a reasonable size).

There is also the possibility of extending Theorem 4.2 to all graphs. That could be potentially very profitable, because it might lead to a polynomial-time recognition algorithm, but the prospects for that are not very bright. The class of planar graphs can be enlarged to a bigger class of Pfaffian graphs defined by means of surface embeddings. Let us say that an embedding of a graph $G$ in the Klein bottle is *cross-cap-odd* if every cycle $C$ in $G$ that does not separate the surface is odd if and only if it is 1-sided. If $G$ is embedded in the Klein bottle with all faces even (that is, bounded by a walk of even length), then the embedding is cross-cap-odd if and only if the 1-sided cycles are precisely the odd cycles in $G$. Please note that every planar graph can be embedded in the Klein bottle so that the embedding will be cross-cap-odd, and every embedding of a non-bipartite graph in the projective plane with all faces even may be regarded as a cross-cap-odd embedding in the Klein bottle. The following result,

proved in [39], resulted from earlier conversations of the author with Neil Robertson and Paul Seymour. By the remark above it implies Theorem 1.1.

**Theorem 9.3.** *Every graph that admits a cross-cap-odd embedding in the Klein bottle is Pfaffian.*

It may seem reasonable to expect an analogue of Theorem 4.2, something along the lines that every Pfaffian brick can be obtained from graphs that admit a cross-cap-odd embedding in the Klein bottle and a few sporadic exceptional graphs by means of certain composition operations. Unfortunately, the following construction of Norine seems to give a counterexample.

**Theorem 9.4.** *For every integer $n \geq 1$ there exists a Pfaffian brick that has a subgraph isomorphic to $K_n$.*

There is a chance that a notion analogous to tree-width can help us get around Norine's construction. A tree is *ternary* if all its vertices have degree one or three; the vertices of degree one are called *leaves*. A *matching decomposition* of a graph $G$ is a pair $(T, \tau)$, where $T$ is a ternary tree and $\tau$ is a bijection from the set of leaves of $T$ to $V(G)$. For an edge $e \in E(T)$ fix one of the two components of $T \setminus e$, and let $V_e$ be the set of all leaves of $T$ that belong to that component. We define the *width* of $e$ as the maximum, over all perfect matchings $M$ of $G$, of $|\delta(\tau(V_e)) \cap M|$. We define the *width* of $(T, \tau)$ as the maximum width of an edge of $T$, and we define the *matching-width* of a graph $G$ as the minimum width of a matching decomposition of $G$. The graphs Norine constructed in the proof of Theorem 9.4 all have low matching-width, and so that leaves open the possibility that Pfaffian graphs of high matching-width might exhibit more structure. Further, Norine [39] describes a polynomial-time algorithm to test whether an input graph $G$ is Pfaffian, assuming a matching decomposition of $G$ of bounded width is given as part of the input instance. Thus there is some hope, but at the moment it is not clear if these ideas can be turned into a meaningful theorem or a polynomial-time algorithm to test whether an input graph is Pfaffian. The following conjecture of Norine and the author [39], modeled after the excluded grid theorem of Robertson and Seymour [48] (see also [11], [49]), seems relevant.

**Conjecture 9.5.** There exists a function $f$ such that every graph of matching-width at least $f(k)$ has a matching minor isomorphic to the $2k \times 2k$ grid.

# Determinant versus permanent

Manindra Agrawal

**Abstract.** We study the problem of expressing permanents of matrices as determinants of (possibly larger) matrices. This problem has close connections to the complexity of arithmetic computations: the complexities of computing permanent and determinant roughly correspond to arithmetic versions of the classes NP and P respectively. We survey known results about their relative complexity and describe two recently developed approaches that might lead to a proof of the conjecture that the permanent can only be expressed as the determinant of exponential-sized matrices.

**Mathematics Subject Classification (2000).** Primary 68Q17; Secondary 68W30.

**Keywords.** Arithmetic computation, complexity classes, determinant, permanent.

## 1. Introduction

The determinant of square matrices plays a fundamental role in linear algebra. It is a linear function of rows (and columns) of the matrix, and has several nice interpretations. Geometrically it is the volume of the parallelopied defined by rows (or columns) of the matrix, and algebraically it is the product of all eigenvalues, with multiplicity, of the matrix. It also satisfies a number of other interesting properties, e.g., it is multiplicative, invariant under linear combinations of rows (and columns) etc. The *permanent* of a square matrix is a number that is defined in a way similar to the determinant. For a matrix $X = [x_{i,j}]_{1\le i,j\le n}$,

$$\operatorname{per} X = \sum_{\pi\in S_n}\prod_{i=1}^{n} x_{i,\pi(i)},$$

where $S_n$ is the symmetric group on $n$ elements. The only difference to the determinant is in the signs of terms:

$$\det X = \sum_{\pi\in S_n}\operatorname{sgn}(\pi)\cdot\prod_{i=1}^{n} x_{i,\pi(i)},$$

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

where $\mathrm{sgn}(\pi) \in \{1, -1\}$ is the sign of the permutation $\pi$.[1] Despite the similarity in definition, the permanent has much fewer properties than the determinant. No nice geometric or algebraic interpretation is known for permanent; and it is neither multiplicative nor invariant under linear combinations of rows or columns. Perhaps for this reason, permanents did not get much attention until the late 1970s, and just about everything known about it until then is in the book [10]. In 1979, Leslie Valiant [24] completely changed the view on permanents by showing that the complexity of computing permanent precisely captures the arithmetic version of the class NP, called VNP. Since then, properties of the permanent have been extensively studied by complexity theorists.

One of the most natural questions about permanents is to investigate its relationship with determinants. It is easy to see that the determinant of a matrix $X$ can be expressed as the permanent of a related matrix $\hat{X}$ whose entries are 0, 1, or $x_{i,j}$s and which is of size $O(n)$ (set up entries of $\hat{X}$ such that $\det \hat{X} = \det X$ and the product corresponding to every permutation that has an even cycle is zero). For the converse, the best known bound on the size of a matrix $\hat{X}$ whose entries are constants and $x_{i,j}$s, and for which $\det \hat{X} = \mathrm{per}\, X$ is $2^{\Omega(n)}$. This suggests that the complexity of computing the permanent is much higher than that of the determinant. Although widely believed, this remains a conjecture. This conjecture has a close connection to the conjectured separation of arithmetic NP from arithmetic P (the class of all functions that can be efficiently computed by arithmetic operations, see next section for a precise definition). It is known that the complexity of determinant is close to the complexity of arithmetic P: every function computed by $n$ arithmetic operations can be expressed as determinant of a matrix of size $n^{O(\log n)}$. This lends more importance to the problem of settling the conjecture.

There have been some attempts to answer the conjecture positively [14], [6], [15] [8]. A sequence of arithmetic operations can be modeled as an *arithmetic circuit*, and the size of an arithmetic circuit is the number of arithmetic operations in the sequence. In [8], *monotone* circuits were considered, these are circuits in which no constant is negative. For computability by such restricted circuits, an exponential lower bound was shown for the complexity of permanent. A different restriction on arithmetic circuits is that of depth – the number of layers of operations. These circuits were considered in [14], [19], [6] and lower bounds were shown for the complexity of computing permanent by depth three circuits. Finally, [15] considers yet another restriction. In this restriction, every gate of the circuit is required to compute a multilinear polynomial. A superpolynomial lower bound is shown on *formulas* (circuits with outdegree one) of this kind computing permanent.

All the above lower bounds hold for very restricted settings, and the techniques used do not seem to generalize. Over the last few years, however, two new tech-

[1] Both permanent and determinant are special forms of *immanents* defined as $\mathrm{imm}_\chi X = \sum_{\pi \in S_n} \chi(\pi) \cdot \prod_{i=1}^{n} x_{i,\pi(i)}$ where $\chi : S_n \mapsto \mathbb{C}$ is a character of $S_n$. For the permanent, $\chi = \mathrm{id}$ and for the determinant, $\chi$ equals the sign of the permutation.

niques have been proposed that hold some promise. The first of these was proposed by Mulmuley and Sohoni [11]. They transform the problem to algebraic geometry domain where it is reduced to showing that the permanent polynomial does not lie in the closure of a certain *orbit* of the determinant polynomial.

The second approach was proposed by Kabanets and Impagliazzo [9]. They reduced the problem to that of finding a deterministic, subexponential-time algorithm for the *Identity Testing*. The Identity Testing problem is defined as follows: given an arithmetic circuit computing polynomial $p$ in $n$ variables, test if $p = 0$. There exist several randomized polynomial-time algorithms for solving this. Kabanets and Impagliazzo show that *any* deterministic, subexponential-time algorithm for the problem will imply either a superpolynomial lower bound for arithmetic circuits computing permanent, or a boolean lower bound on the class NEXP. This connection was strengthened in [1] to show that if there exist special kinds of deterministic algorithms for testing identities given by superconstant depth arithmetic circuits, then permanent requires superpolynomial sized arithmetic circuits.

In this article, we will describe the known results on lower bounds on permanent as well as the two new approaches outlined above.

## 2. Definitions

$\mathbb{Q}$, $\mathbb{R}$, and $\mathbb{C}$ are respectively the fields of rational, real, and complex numbers.

An arithmetic circuit over a field $F$ is a directed, acyclic graph with labelled vertices. Vertices of indegree zero are labelled with either a variable $x_i$ or a constant from $F$. Vertices labelled with variables are called *input gates*. The remaining vertices are labelled with either '+' or '$*$' and are called *addition* or *multiplication gates* respectively. Vertices with outdegree zero are also called *output gates*. We restrict our attention to circuits with exactly one output gate. The *fanin* of a gate equals the number of edges incident to the gate. In this article, gates have unbounded fanin when not mentioned otherwise. The *size* of a circuit $C$ equals the number of gates in it. The *depth* of a circuit $C$ equals the length of the longest path from an input gate to an output gate. The *degree* of $C$ is inductively defined as follows: the degree of an input gate is one or zero depending on whether it is labelled by a variable or constant; the degree of an addition gate is the maximum of the degree of the gates whose edges are incident to the gate; the degree of a multiplication gate is the sum of the degrees of the gates whose edges are incident to the gate; finally, the degree of $C$ is the degree of its output gate.

An arithmetic circuit $C$ computes a polynomial as follows. The polynomial computed at an input gate equals the label of the gate. For any other gate $g$, let $g_1, \ldots, g_k$ be all the gates that have an edge incident to $g$ and let $p_{g_i}$ be the polynomial computed at gate $g_i$. Then the polynomial computed at the gate $g$ equals $\sum_{i=1}^{k} p_{g_i}$ if $g$ is an addition gate, and equals $\prod_{i=1}^{k} p_{g_i}$ if $g$ is a multiplication gate. The polynomial

computed by the circuit is the polynomial computed at its output gate.

Let $\{p_n\}_{n>0}$ be a family of polynomials with $p_n$ a polynomial of degree $d(n)$ in $n$ variables. A circuit family $\{C_n\}_{n>0}$ is said to compute $\{p_n\}$ if for every $n$, the polynomial computed by $C_n$ equals $p_n$. In the following we shall simply write $\{p_n\}$ for the family $\{p_n\}_{n>0}$.

*Arithmetic branching programs* are a restricted form of arithmetic circuits in which every multiplication gate has fanin exactly two, and in addition at least one of the two gates, from which edges are incident to the multiplication gate, is an input gate. Such circuits are also called *skew* circuits.

The class $\mathrm{VP}_F$, the arithmetic analog of class P, is defined to be the set of polynomial families $\{p_n\}$ over a field $F$ such that (1) each $p_n$ is of degree $n^{O(1)}$, and (2) there exists a circuit family $\{C_n\}$ computing $\{p_n\}$ such that $C_n$ is of size $n^{O(1)}$.[2] The class $\mathrm{VNP}_F$, the arithmetic analog of class NP, is defined to be the set of polynomial families $\{p_n\}$ over a field $F$ such that (1) each $p_n$ is of degree $n^{O(1)}$, and (2) there exists a family of polynomials $\{q_n\} \in \mathrm{VP}_F$ such that for every $n$,

$$p_n(x_1, x_2, \ldots, x_n) = \sum_{y_1=0}^{1} \sum_{y_2=0}^{1} \cdots \sum_{y_m=0}^{1} q_{n+m}(x_1, x_2, \ldots, x_n, y_1, y_2, \ldots, y_m)$$

with $m = n^{O(1)}$.[3]

Given two polynomials $p(x_1, x_2, \ldots, x_n)$ and $q(y_1, y_2, \cdots, y_m)$ over a field $F$, we say that $p$ is a *projection* of $q$ if $p(x_1, x_2, \ldots, x_n) = q(\alpha_1, \alpha_2, \cdots, \alpha_m)$ where each $\alpha_i \in F \cup \{x_1, x_2, \ldots, x_n\}$. Given two polynomial families $\{p_n\}$ and $\{q_n\}$, we say that $\{p_n\}$ is a *p-projection* of $\{q_n\}$ if for every $n$ there exists an $m = n^{O(1)}$ such that $p_n$ is a projection of $q_m$.[4]

Let $\mathrm{per}_F = \{\mathrm{per}_{F,n}\}$ and $\mathrm{det}_F = \{\mathrm{det}_{F,n}\}$ denote the families of permanent and determinant polynomials over a field $F$ respectively. Both these families contain polynomials in $n^2$ variables for each $n$.

Valiant [24] proved that:

**Theorem 2.1** ([24]). *For any $F$, $\mathrm{per}_F \in \mathrm{VNP}_F$. In addition, for any $F$, $\mathrm{char}(F) \neq 2$, for any polynomial family $\{p_n\}$ in $\mathrm{VNP}_F$, $\{p_n\}$ is a p-projection of $\mathrm{per}_F$.*

So permanent is as hard to compute as any polynomial family in VNP. In contrast, determinant can be computed efficiently. A nice characterization of determinant was shown in [4], [21], [25]:

**Theorem 2.2** ([4], [21], [25]). *For any $F$, $\mathrm{det}_F$ can be computed by polynomial-sized arithmetic branching programs. In addition, for any $F$ and for any polynomial*

[2] In addition, circuit $C_n$ must be efficiently computable given $1^n$. This property does not seem to play any role in obtaining lower bounds.

[3] The class $\#\mathrm{P}_F$ is the 'functional' version of the class $\mathrm{VNP}_F$: a polynomial family $\{p_n\} \in \mathrm{VNP}_F$ belongs to $\#\mathrm{P}_F$ when for each $n$, $p_n$ is viewed as a map from $F^n$ to $F$.

[4] Again, given $1^n$, the projection specified by $(\alpha_1, \alpha_2, \ldots, \alpha_m)$ should be efficiently computable.

*family* $\{p_n\}$ *computed by polynomial-sized arithmetic branching programs,* $\{p_n\}$ *is a p-projection of* $\det_F$.

In fact, all families in VP are *almost* p-projections of determinant.

**Theorem 2.3** ([23]). *Let C be a circuit of size s computing a polynomial of degree d. There exists another circuit computing the same polynomial of size* $s^{O(1)}$ *and depth* $O(\log s + \log d)$.

**Corollary 2.4.** *Any circuit family in* $\mathrm{VP}_F$ *can be computed by circuit families of polynomial size and logarithmic depth.*

**Corollary 2.5.** *For every circuit family* $\{p_n\} \in \mathrm{VP}_F$ *and for every n,* $p_n$ *is a projection of* $\det_{F,m}$ *where* $m = n^{O(\log n)}$.

The above characterizations of complexities of determinant and permanent imply that, in order to separate $\mathrm{VP}_F$ from $\mathrm{VNP}_F$, it is enough to show that $\mathrm{per}_F$ is not an almost p-projection of $\det_F$ (in the sense above).

## 3. Known lower bounds on permanent

Lower bounds are known on permanent only for restricted circuits. In this section, we describe important lower bounds of this kind. Three major restrictions have been considered for proving such lower bounds: *monotone* circuits, *constant depth* circuits, and *multilinear* formulas.

**3.1. Monotone circuits.** A circuit over $\mathbb{Q}$ or $\mathbb{R}$ is *monotone* if all the constants in the circuit are non-negative. This is a very restricted class of circuits since *no* cancellations can occur in it. Jerrum and Snir [8] showed that any monotone circuit family that computes permanent must have exponential size.

**3.2. Constant depth circuits.** In this restriction, the depth of a circuit family is fixed, i.e., it is independent of $n$. Permanent (or any polynomial of degree $n^{O(1)}$ for that matter) can be computed by an exponential size depth two circuit family. Conversely, it is easy to see that any depth two circuit family computing permanent must have exponential size.

Depth three circuit families are, however, non-trivial. A depth three circuit can be of the form "sum-of-products-of-sums" or "product-of-sums-of-products." The latter form can easily be seen to require exponential size to compute permanent (the topmost multiplication gate can be shown to be redundant transforming the circuit to a depth two circuit). Circuit families of the first form are powerful: Ben Or observed that they can efficiently compute all symmetric polynomials of degree $n^{O(1)}$ over fields of characteristic zero.

The best known lower bound in fields of characteristic zero is by Shpilka and Wigderson [19] who proved that permanent (and determinant) requires a circuit family of size $\Omega(n^2)$. Their idea is to consider the space spanned by all partial derivatives of the polynomials computed at each gate of a given circuit. They show that for a depth three circuit with small size, the space spanned by the derivatives of the output polynomial would be of small dimension while the space spanned by derivatives of permanent is of large dimension.

Over finite fields, the situation is better. Grigoriev and Razborov [6] showed an exponential lower bound on the size of depth three circuit families computing determinant and permanent. Their approach was to show that polynomial computed by a depth three circuit of small size can be 'approximated' by a low-degree polynomial (approximated in the sense that the two polynomials agree on a large set of points from the field). Then they observed that determinant and permanent cannot be approximated by low-degree polynomials.

**3.3. Multilinear formulas.** *Multilinear formulas* are circuits such that (1) the out-degree of every gate is at most one, and (2) the polynomial computed at every gate is multilinear. Such circuits have severely limited multiplication gates – the polynomials input to a multiplication gate must be over disjoint sets of variables. Using a combination of partial derivative technique and random restrictions (setting some input variables to random values), Raz [15] proved a lower bound of $n^{\Omega(\log n)}$ on the size of families of multilinear formulas computing permanent and determinant.

## 4. The algebraic geometry approach

Mulmuley and Sohoni [11] have offered a completely new approach to the problem of proving a lower bound on permanent for unrestricted circuits by transforming the problem to geometric settings. In this section, we give a brief overview of their approach.

Suppose, for $F = \mathbb{Q}$, $\mathrm{per}_{F,n}$ is a projection of $\det_{F,m}$, $m > n$. Define $\widehat{\mathrm{per}}_{F,m} = x_{m^2}^{m-n} \cdot \mathrm{per}_{F,n}$. It follows that $\widehat{\mathrm{per}}_{F,m}$ is also a projection of $\det_{F,m}$ (just multiply all constants of the projection by $x_{m^2}$). This can be written as

$$\widehat{\mathrm{per}}_{F,m}(x_1, x_2, \ldots, x_{m^2}) = A \cdot \det_{F,m} = \det_{F,m}((x_1, x_2, \ldots, x_{m^2}) \cdot A),$$

where $A$ is an $m^2 \times m^2$ matrix over $\mathbb{Q}$. The matrix $A$ is singular whenever $m > n$ since the variables $x_{n^2+1}, \ldots, x_{m^2-1}$ do not occur in $\widehat{\mathrm{per}}_{F,m}$. Let $A_{\bar{\varepsilon}}$ be a slight 'perturbation' of $A$ obtained by adding $\varepsilon_{i,j}$ to the $(i, j)$th entry of $A$. For nearly all values of $\bar{\varepsilon}$ close to zero, $A_{\bar{\varepsilon}}$ is non-singular and the polynomial $A_{\bar{\varepsilon}} \cdot \det_{F,m}$ approximates the polynomial $\widehat{\mathrm{per}}_{F,m}$ very well (all the coefficients of two polynomials are close to each other). Now consider the space $V = \mathbb{C}^M$ with $M = \binom{m^2+m-1}{m}$. Every homogeneous polynomial of degree $m$ in $m^2$ variables can be viewed as a point in this space (degree $m$ monomials

forming the basis). So both $\det_{F,m}$ and $\widehat{\text{per}}_{F,m}$ are points in $V$ (since $F = \mathbb{Q}$ and both polynomials are of degree $m$ in $m^2$ variables). Let $O$ be the orbit of $\det_{F,m}$ under the action of $\text{GL}_{m^2}(\mathbb{C})$, i.e.,

$$O = \{B \cdot \det_{F,m} \mid B \text{ is an invertible matrix over } \mathbb{C}\}.$$

Set $O$ can be viewed as a set of points in $V$. The above argument shows the following:

**Lemma 4.1** ([11]). *If* $\text{per}_{F,n}$ *is a projection of* $\det_{F,m}$ *then the point corresponding to* $\widehat{\text{per}}_{F,m}$ *in* $V$ *lies in the closure of the set* $O$ *in* $V$. *Conversely, if* $\widehat{\text{per}}_{F,m}$ *lies in the closure of* $O$ *then* $\text{per}_{F,n}$ *can be approximated by projections of* $\det_{F,m}$ *to any desired accuracy.*

This (near) characterization is the starting point of their approach. Instead of $V$, we can work in the projective space $P(V)$ too since both the polynomials are homogeneous. The same near characterization holds in $P(V)$ as well with $\text{GL}_{m^2}(\mathbb{C})$ replaced by $\text{SL}_{m^2}(\mathbb{C})$, the group of all matrices with determinant 1. The advantage of working in $P(V)$ is that the closure of $O$ (under the classical Euclidean topology) coincides with the closure of $O$ under *Zariski topology* [12]. In Zariski topology, there is the well-studied notion of *stability* that captures this problem: $\det_{F,m}$ is $\widehat{\text{per}}_{F,m}$*-stable under* $\text{SL}_{m^2}(\mathbb{C})$ if $\widehat{\text{per}}_{F,m}$ lies in the closure of the orbit $O$ (we abuse notation here by using the same names for polynomials and sets in $P(V)$ as for the corresponding ones in $V$).

Points in the orbit $O$ have a useful property. For any point $p \in P(V)$, let

$$G_p = \{A \in \text{SL}_{m^2}(\mathbb{C}) \mid A \cdot p = p\}.$$

The group $G_p$ is called the *stabilizer* of $p$.

**Lemma 4.2.** *For any point* $p \in O$, $G_p$ *is a conjugate of* $G_{\det_{F,m}}$.

*Proof.* Let $p = B \cdot \det_{F,m} \in O$. Then $G_p = B \cdot G_{\det_{F,m}} \cdot B^{-1}$. □

Suppose the orbit of the polynomial $\widehat{\text{per}}_{F,m}$ under $\text{SL}_{m^2}(\mathbb{C})$ is a closed set (such polynomials are called *stable*). Let $Q$ be the orbit of $\widehat{\text{per}}_{F,m}$ under $\text{SL}_{m^2}(\mathbb{C})$. By *Luna's slice theorem*, there is a neighborhood $N$ of $Q$ such that for any point $p \in N$, $G_p$ is a conjugate of a subgroup of $G_{\widehat{\text{per}}_{F,m}}$. Since the closure of $O$ contains $\widehat{\text{per}}_{F,m}$, there is a point in $N$, say $q$, such that $q = B \cdot \det_{F,m}$. This means $G_q$ is a conjugate of $G_{\det_{F,m}}$. Therefore, $G_{\det_{F,m}}$ is a conjugate of a subgroup of $G_{\widehat{\text{per}}_{F,m}}$. On the other hand, it is well known that $G_{\det_{F,m}}$ is 'larger' than $G_{\widehat{\text{per}}_{F,m}}$: $G_{\det_{F,m}}$ is characterized by the transformations of the kind $X \mapsto A \cdot X \cdot B^{-1}$ where $A, B \in \text{GL}_m(\mathbb{C})$ while $G_{\widehat{\text{per}}_{F,m}}$ is characterized by the transformations of the kind $X \mapsto A \cdot X \cdot B^{-1}$ where $A, B \in \text{GL}_m(\mathbb{C})$ and both $A$ and $B$ are either diagonal or permutation matrices. Therefore, $G_{\det_{F,m}}$ cannot be a conjugate of a subgroup of $G_{\widehat{\text{per}}_{F,m}}$. (This is a rough argument; to make it precise, more work is needed.)

Unfortunately, $\widehat{\text{per}}_{F,m}$ is *not* stable (interestingly, $\text{per}_{F,n}$ is stable in the smaller dimensional space defined by degree $n$ homogeneous polynomials in $n^2$ variables; the translation to higher dimensional space ruins the stability). Mulmuley and Sohoni define the notion of *partial stability* and show that $\widehat{\text{per}}_{F,m}$ is partially stable. Now their aim is to make the above argument work even for partially stable points. A more detailed explanation of their approach is in [16].

## 5. The derandomization approach

Kabanets and Impagliazzo [9] have discovered another new approach for proving lower bounds on permanent. Unlike the previous one, this approach is based on arithmetic circuits. In this section we outline their approach and its variation in [1].

The *Identity Testing* problem is defined as follows: given an arithmetic circuit $C$ over a field $F$ as input, decide if the polynomial computed by the circuit is the zero polynomial. This is a classical problem in computational algebra and there exist several randomized polynomial-time algorithms for it. Perhaps the simplest one is by Schwartz and Zippel [17], [26]: randomly choose values for variables of $C$ from a set in $F$ of size $2d$, here $d$ is the degree of $C$ (if $|F| < 2d$ then extend $F$ slightly); output ZERO if $C$ evaluates to zero, otherwise NON-ZERO. An easy argument shows that this test is correct with probability at least $\frac{1}{2}$ when $C$ computes a non-zero polynomial and always correct when $C$ computes a zero polynomial.

Kabanets and Impagliazzo show that if there exists a deterministic subexponential ($= 2^{n^{o(1)}}$) time algorithm for solving Identity Testing problem then at least one of the following two lower bounds hold:

1. NEXP requires superpolynomial sized boolean circuits.
2. Permanent requires superpolynomial sized arithmetic circuits.

To see this, suppose that permanent has polynomial sized arithmetic circuits for some field $F$ of characteristic different from two. Consider a non-deterministic machine that, on input $1^n$, guesses the circuit that computes $\text{per}_{F,n}$ and verifies it to be correct. It does this by inductively verifying that the circuit, under appropriate settings of its inputs, computes $\text{per}_{F,n-1}$ correctly and then verifying the equation for $\text{per}_{F,n}$ that expresses it in terms of $\text{per}_{F,n-1}$. Verifying the equation is an instance of Identity Testing problem and so can be done in subexponential time by assumption. Therefore, given any matrix $A \in F^{n^2}$, per $A$ can be computed in non-deterministic subexponential time. Now assume that NEXP has polynomial sized boolean circuits. By [3], [22], it follows that NEXP $\subseteq$ P$^{\#\text{P}}$. Since the complexity of #P is exactly the complexity of computing permanent, it follows that NEXP is in non-deterministic subexponential time contradicting the non-deterministic time hierarchy theorem [18].

This result falls short of pointing a way for proving lower bounds on permanent – besides finding a deterministic algorithm for Identity Testing, one needs to assume

NEXP has polynomial sized boolean circuits which is very unlikely to be true. However, it *does* point to a connection between Identity Testing problem and permanent lower bounds. This connection was strengthened in [1] by defining *pseudo-random generators* for arithmetic circuits. Pseudo-random generators in the boolean settings have been studied intensively (see, e.g., [5], [13], [7], [20]). It is known that constructing pseudo-random generators is equivalent to proving lower bounds in the boolean settings. In [1], pseudo-random generators are defined in arithmetic settings and a similar equivalence is observed.

Let $\mathcal{AC}_F$ be the class of all arithmetic circuits over $F$ and $\mathcal{A}_F \subseteq \mathcal{AC}_F$.

**Definition 5.1.** A function $f\colon \mathbb{N} \to (F[y])^*$ is called an $(\ell(n), n)$-*pseudo-random generator* against $\mathcal{A}_F$ if the following holds:

- $f(n) \in (F[y])^{n+1}$ for every $n > 0$.
- Let $f(n) = (f_1(y), \ldots, f_n(y), g(y))$. Then each $f_i(y)$ as well as $g(y)$ is a polynomial of degree at most $2^{\ell(n)}$.
- For any circuit $C \in \mathcal{A}_F$ of size $n$ with $m \leq n$ inputs:

$$C(x_1, x_2, \ldots, x_m) = 0 \text{ iff } C(f_1(y), f_2(y), \ldots, f_m(y)) = 0 \pmod{g(y)}.$$

A direct application of Schwartz–Zippel lemma [17], [26] shows that there always exist $(O(\log n), n)$-pseudo-random generators against $\mathcal{AC}_F$. Call such generators *optimal* pseudo-random generators. Pseudo-random generators that can be efficiently computed are of special interest.

**Definition 5.2.** An $(\ell(n), n)$-pseudo-random generator $f$ against $\mathcal{A}_F$ is *efficiently computable* if $f(n)$ is computable in time $2^{O(\ell(n))}$.

An easy argument shows that if there exists an efficiently computable $(\ell(n), n)$-pseudo-random generator against $\mathcal{AC}_F$ then the Identity Testing problem can be solved deterministically in time $2^{O(\ell(n))}$: evaluate the given circuit $C$ of size $n$ modulo $g(y)$ after substituting for the $i^{\text{th}}$ input variable the polynomial $f_i(y)$ where $f(n) = (f_1(y), \ldots, f_n(y), g(y))$. In particular, if there exists an efficiently computable optimal pseudo-random generator against $\mathcal{AC}_F$ then Identity Testing can be solved in polynomial time.

An efficiently computable pseudo-random generator also results in a lower bound.

**Theorem 5.3** ([1]). *Let $f$ be an efficiently computable $(\ell(n), n)$-pseudo-random generator against $\mathcal{A}_F$. Then there is a multilinear polynomial in $2\ell(n)$ variables, computable in time $2^{O(\ell(n))}$, that cannot be computed by any circuit in $\mathcal{A}_F$ of size $n$.*

*Proof.* For any $m = \ell(n)$, define the polynomial $q_f(x_1, x_2, \ldots, x_{2m})$ by

$$q_f(x_1, x_2, \ldots, x_{2m}) = \sum_{S \subseteq [1,2m]} c_S \cdot \prod_{i \in S} x_i.$$

The coefficients $c_S$ satisfy the condition

$$\sum_{S\subseteq[1,2m]} c_S \cdot \prod_{i\in S} f_i(y) = 0$$

where $f(n) = (f_1(y), f_2(y), \ldots, f_n(y), g(y))$. Such a $q_f$ always exists as the following argument shows.

> The number of coefficients of $q_f$ are exactly $2^{2m}$. These need to satisfy a polynomial equation of degree at most $2m \cdot 2^m$. So the equation gives rise to at most $2m \cdot 2^m + 1$ homogeneous constraints on the coefficients. Since $(2m \cdot 2^m + 1) < 2^{2m}$ for $m \geq 3$, there is always a non-trivial polynomial $q_f$ satisfying all the conditions.

The polynomial $q_f$ can be computed by solving a system of $2^{O(m)}$ linear equations in $2^{O(m)}$ variables over the field $F$. Each of these equations can be computed in time $2^{O(m)}$ using computability of $f$. Therefore, $q_f$ can be computed in time $2^{O(m)}$. Now suppose $q_f$ can be computed by a circuit $C \in \mathcal{A}_F$ of size $n$. By the definition of the polynomial $q_f$, it follows that $C(f_1(y), f_2(y), \ldots, f_{2m}(y)) = 0$. The size of circuit $C$ is $n$ and it computes a non-zero polynomial. This contradicts the pseudo-randomness of $f$. □

A partial converse of this theorem can also be shown: if there exists a polynomial family computable in time $2^{O(\ell(n))}$ that cannot be computed by any size $n$ circuit family in $\mathcal{A}_F$ then there exists an efficiently computable $(\ell^2(n), n)$-pseudo-random generator against $\mathcal{A}_F$, when the degree of every size $n$ circuit in $\mathcal{A}_F$ is bounded by $n^{O(1)}$.

An efficient optimal pseudo-random generator against $\mathcal{AC}_F$ yields a polynomial that requires exponential (in the number of variables) sized circuits. However, it is not clear whether the polynomial $q_f$ can be computed as permanent of a matrix of size $m^{O(1)}$. To get this, one needs to show that all the coefficients $c_S$ of $q_f$ are themselves efficiently computable. If this is done, then using the VNP characterization of permanent, it follows that $q_f$ equals the permanent of a matrix of size $m^{O(1)}$. This results in an exponential lower bound on permanent.

For a superpolynomial lower bound one needs either an $(n^{o(1)}, n)$-pseudo random generator against $\mathcal{AC}_F$ or an optimal pseudo-random generators against a much smaller class of circuits.

**Theorem 5.4** ([1]). *Let $f$ be an efficiently computable optimal pseudo-random generator against the class of circuits of depth $\omega(1)$ such that the associated polynomial $q_f$ is in* VNP. *Then permanent cannot computed by any polynomial sized circuit.*

*Proof.* From the previous theorem, it follows that the polynomial $q_f$ cannot be computed by exponential sized circuits of depth $\omega(1)$. A size $n^d$, depth $d \log n$ arithmetic circuit with fanin two multiplication gates can be translated to a subexponential sized

depth $d$ circuit by "cutting" the circuit into $\log n$ layers of depth $d$ each, and then "flattening" each layer to a subexponential sized circuit of depth two. Since every polynomial sized circuit computing permanent can be transformed to a depth $O(\log n)$, size $n^{O(1)}$ circuit with fanin two multiplication gates [23], the theorem follows. □

It is not clear at the moment how to construct optimal pseudo-random generators against constant depth circuits. In [1] a generator is conjectured. Unconditionally, we only know generators against depth two, polynomial sized circuits (the proof is easy, see [1]). We know an optimal generator against the following very special class of circuits too:

$$\mathcal{A} = \{C_n(x) \mid C_n(x) = (1+x)^n - 1 - x^n \text{ over the ring } \mathbb{Z}_n\}.$$

Notice that the circuits in the class $\mathcal{A}$ are not over a fixed field (or ring), and the size of the circuit $C_n$ is $O(\log n)$ and the degree is $n$. In [2], the following optimal generator was constructed against $\mathcal{A}$:

$$f(m) = \Big(x, 0, \ldots, 0, x^{16m^5} \cdot \prod_{r=1}^{16m^5} \prod_{a=1}^{4m^4} ((x-a)^r - 1)\Big).$$

## 6. Concluding remarks

The problem of proving that the permanent of a size $n$ matrix cannot be expressed as determinant of size $n^{O(\log n)}$ matrix is of great importance in complexity theory. While the existing approaches have failed to shed light on this, one hopes that at least one of the two new approaches will eventually lead to a solution of the problem.

# The additivity problem in quantum information theory

Alexander S. Holevo*

**Abstract.** In this lecture we survey the present status of the additivity problem for the classical capacity and related characteristics of quantum channels – one of the most profound mathematical problems of quantum information theory.

**Mathematics Subject Classification (2000).** Primary 94A15; Secondary 81P68.

**Keywords.** Quantum information theory, quantum channel, classical capacity, entanglement, additivity problem.

## 1. Introduction

The problems of data transmission and storage by quantum information carriers received increasing attention during past decade, owing to the burst of activity in the field of quantum information and computation [42], [22]. At present we are witnessing emergence of theoretical and experimental foundations of the quantum information science. It represents a new exciting research field addressing a number of fundamental issues both in quantum physics and in information and computer sciences. On the other hand, it provides a rich source of well-motivated mathematical problems, often having simple formulations but hard solutions.

A central result in the classical information theory is the *coding theorem*, establishing the possibility of reliable data transmission and processing at rates lower than the *capacity* of the communication channel. The issue of the information capacity of *quantum channels* arose soon after publication of Shannon's pioneering paper and goes back to the works of Gabor, Brillouin and Gordon, asking for fundamental limits on the rate and quality of information transmission. These works laid a physical foundation and raised the question of consistent mathematical treatment of the problem. Important steps in this direction were made in the seventies when quantum statistical decision theory was created, making a noncommutative probability frame for this circle of problems, see [21] for a survey.

A dramatic progress has been achieved during the past decade [42], [6], [22]. In particular, a number of coding theorems was discovered, moreover, it was realized

*This work was done partially when the author was Leverhulme Visiting Professor at CQC, DAMTP, University of Cambridge. The work was also supported by the Program "Theoretical Problems of Modern Mathematics" of the Mathematics Division of RAS. The author is grateful to A. Ekert, M. B. Ruskai, M. Shirokov, Yu. M. Suhov and R. F. Werner for fruitful discussions.

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

that the quantum channel is characterized by the whole spectrum of capacities depending on the nature of the information resources and the specific protocols used for the transmission, see [6], [14]. This new age of quantum information science is characterized by emphasis onto the new possibilities (rather than mere restrictions) inherent in the quantum nature of the information processing agent. On the other hand, the questions of information capacities turned out to be relevant to the theory of quantum computations, particularly in connection with quantum error-correction, communication protocols, algorithmic complexity and a number of other important issues.

The quantum information processing systems have a specifically novel resource, *entanglement*, a kind of non-classical correlation between parts of the composite quantum system. Among many other unusual features it underlies the *strict superadditivity* of Shannon information due to *entangled decodings* in a situation formally similar to the classical memoryless channels [20], [22], [6]. Namely, for independent quantum systems there are entangled measurements which can bear more information than the arithmetic sum of information from these systems. This property has profound consequences for the theory of quantum communication channels and their capacities.

A closely related issue is the additivity of the capacity-related quantities for the memoryless quantum channels with respect to *entangled encodings*. Should the additivity fail, this would mean that applying entangled inputs to several independent uses of a quantum channel may result in superadditive increase of its capacity for transmission of classical information. However so far there is neither a single evidence of such a non-additivity, nor a general proof for the additivity. In this lecture we survey the present status of this problem.

We start in Section 2 with the classical case, where the additivity holds for almost obvious reasons. We then describe the problem in the finite-dimensional quantum setting in Section 3, discussing also the various formulations of the additivity conjecture and connections between them. Positive results for several concrete classes of channels are briefly surveyed in Section 4, where also an important counterexample to the additivity of the minimal output quantum Rényi entropy is discussed. Since quantum communication channels are described mathematically as completely positive maps, we devote Subsection 4.1 to the description of their structure paying attention to the notion of complementary maps which leads to new examples of additivity. Section 5 is devoted to different formulations of the additivity conjecture using tools from convex analysis. In Subsection 5.4 we present an argument, essentially due to P. Shor, implying the global equivalence of different forms of the additivity conjecture. We conclude with Section 6, where we briefly outline the works treating the infinite-dimensional case.

## 2. Additivity in the classical information theory

Let $\mathcal{X}$, $\mathcal{Y}$ be two finite sets (alphabets), and let $[\Phi(x, y)]_{x\in\mathcal{X}, y\in\mathcal{Y}}$ be a *stochastic matrix*, i.e.,

1. $\Phi(x, y) \geq 0,\ x \in \mathcal{X}, y \in \mathcal{Y}$;
2. $\sum_{y\in\mathcal{Y}} \Phi(x, y) = 1,\ x \in \mathcal{X}$.

In information theory a stochastic matrix describes a (noisy) *channel* from $\mathcal{X}$ to $\mathcal{Y}$. It transforms an input probability distribution $\pi$ on $\mathcal{X}$ into the output probability distribution $\pi' = \Phi\pi$ on $\mathcal{Y}$. Denote by

$$\mathcal{P}(\mathcal{X}) = \left\{\pi : \pi(x) \geq 0,\ \sum_{x\in\mathcal{X}} \pi(x) = 1\right\}$$

the simplex of all probability distributions $\pi$ on $\mathcal{X}$. Extreme points of $\mathcal{P}(\mathcal{X})$ are the degenerate probability distributions $\delta_x$ on $\mathcal{X}$. Notice the following obvious property:

*For a direct product $\mathcal{X}_1 \times \mathcal{X}_2$ of two alphabets, extreme points of $\mathcal{P}(\mathcal{X}_1 \times \mathcal{X}_2)$ are precisely the products of extreme points of $\mathcal{P}(\mathcal{X}_j)$*:

$$\mathrm{ext}\mathcal{P}(\mathcal{X}_1 \times \mathcal{X}_2) = \mathrm{ext}\mathcal{P}(\mathcal{X}_1) \times \mathrm{ext}\mathcal{P}(\mathcal{X}_2). \tag{1}$$

The most important characteristic of a channel is its *capacity*

$$C(\Phi) = \max_{\pi\in\mathcal{P}(\mathcal{X})} \left\{H(\Phi\pi) - \sum_x \pi(x) H(\Phi\delta_x)\right\}, \tag{2}$$

where the expression in curly brackets is equal to the Shannon *mutual information* between the input and the output of the channel. Here

$$H(\pi) = -\sum_x \pi(x) \log \pi(x)$$

is the entropy of the probability distribution $\pi$.

One of the main results of information theory – the coding theorem for memoryless channels, see e.g. [10] – says that the quantity (2) is the ultimate rate of asymptotically perfect transmission of information by $n$ independent uses of the channel $\Phi$, when $n \to \infty$. The capacity has the fundamental additivity property

$$C(\Phi_1 \otimes \Phi_2) = C(\Phi_1) + C(\Phi_2). \tag{3}$$

Here the inequality $\geq$ (superadditivity) follows by restricting to the independent inputs, while the opposite inequality can be proved by using subadditivity of the output entropy $H(\Phi\pi)$ and the property (1) for the second term in the Shannon information (which is equal to minus the conditional output entropy). The additivity is an important ingredient of the proof of the coding theorem, implying

$$C(\Phi^{\otimes n}) = nC(\Phi),$$

where $\Phi^{\otimes n} = \underbrace{\Phi \otimes \cdots \otimes \Phi}_{n}$. It expresses the "memoryless" character of the information transmission scheme based on the independent uses of the channel. For schemes with memory the capacity can be strictly superadditive.

In what follows we are going to describe the noncommutative analog of the quantity $C(\Phi)$, as well as several other related quantities playing a basic role in quantum information theory. The corresponding additivity property was conjectured to hold also in the noncommutative case, although so far there is neither a general proof, nor a counterexample; moreover the additivity is no longer "natural" since an analog of the underlying basic fact (1) breaks dramatically in the noncommutative case.

## 3. Quantum channels

**3.1. The $\chi$-capacity.** Let $\mathcal{H}$ be a unitary space and let $\mathfrak{M}(\mathcal{H})$ be the algebra of all linear operators in $\mathcal{H}$. By choosing an orthonormal basis, $\mathcal{H}$ can be identified with the space $\mathcal{H}_d$ of $d$-dimensional complex vectors and $\mathfrak{M}(\mathcal{H})$ with the algebra $\mathfrak{M}_d$ of complex $d \times d$-matrices.

We shall consider linear maps $\Phi$ which take operators $F$ in $d$-dimensional unitary space $\mathcal{H}$ to operators $F' = \Phi(F)$ in a $d'$-dimensional space $\mathcal{H}'$. Sometimes these are called "superoperators" or "supermatrices" because they can be described as matrices with $d^2 \times d'^2$ entries [9].

Let $\Phi_j \colon \mathfrak{M}(\mathcal{H}_j) \to \mathfrak{M}(\mathcal{H}'_j)$; $j = 1, 2$, be two such maps, and let $\Phi_1 \otimes \Phi_2 : \mathfrak{M}(\mathcal{H}_1) \otimes \mathfrak{M}(\mathcal{H}_2) \to \mathfrak{M}(\mathcal{H}'_1) \otimes \mathfrak{M}(\mathcal{H}'_2)$ be their tensor product defined by the natural action on product operators and then extended by linearity.

An operator $F \in \mathfrak{M}(\mathcal{H})$ is called positive, $F \geq 0$, if the corresponding matrix is positive semidefinite and the map $\Phi \colon \mathfrak{M}(\mathcal{H}) \to \mathfrak{M}(\mathcal{H}')$ is called *positive* if $F \geq 0$ implies $\Phi(F) \geq 0$.

Especially important for us will be the class of completely positive (CP) maps [51], [9], [43]. The map $\Phi \colon \mathfrak{M}(\mathcal{H}) \to \mathfrak{M}(\mathcal{H}')$ is *completely positive*, if for $d = 1, 2, \ldots$ the maps $\Phi \otimes \mathrm{Id}_d$ are all positive, where $\mathrm{Id}_d \colon \mathfrak{M}_d \to \mathfrak{M}_d$ is the identity map of the algebra of $d \times d$- matrices. It follows that the tensor product of CP maps is again CP, since

$$\Phi_1 \otimes \Phi_2 = (\mathrm{Id}_{d'_1} \otimes \Phi_2) \circ (\Phi_1 \otimes \mathrm{Id}_{d_2}).$$

There are positive maps that are not CP, a basic example being provided by the matrix transposition $F \to F^\top$ in a fixed basis.

Finite quantum system is described by a unitary space $\mathcal{H}$. The convex subset

$$\mathfrak{S}(\mathcal{H}) = \{\rho : \rho \geq 0,\ \mathrm{Tr}\,\rho = 1\}$$

of $\mathfrak{M}(\mathcal{H})$ is called the *quantum state space*. The operators $\rho \in \mathfrak{S}(\mathcal{H})$ are called *density operators* or *quantum states*. The state space is a compact convex set with the

extreme boundary

$$\mathfrak{P}(\mathcal{H}) = \mathrm{ext}\mathfrak{S}(\mathcal{H}) = \{\rho : \rho \geq 0,\ \mathrm{Tr}\,\rho = 1,\ \rho^2 = \rho\}.$$

Thus extreme points of $\mathfrak{S}(\mathcal{H})$, which are also called *pure states*, are one-dimensional projectors, $\rho = P_\psi$ for a vector $\psi \in \mathcal{H}$ with unit norm, see, e.g. [42], [22].

Instead of the classical relation (1), one has the following relation for a tensor product $\mathcal{H}_1 \otimes \mathcal{H}_2$ of two unitary spaces

$$\mathrm{ext}\mathfrak{S}(\mathcal{H}_1 \otimes \mathcal{H}_2) \supsetneq \mathrm{ext}\mathfrak{S}(\mathcal{H}_1) \times \mathrm{ext}\mathfrak{S}(\mathcal{H}_2), \tag{4}$$

since apparently there are continually many pure states $P_\psi$ in $\mathcal{H}_1 \otimes \mathcal{H}_2$, given by vectors $\psi$ not representable as a tensor product $\psi_1 \otimes \psi_2$. In quantum theory the tensor product $\mathcal{H}_1 \otimes \mathcal{H}_2$ describes the composite (bipartite) system. Vectors that are not of the form $\psi_1 \otimes \psi_2$, as well as the corresponding pure states, are called *entangled*. In an entangled pure state of a bipartite quantum system, neither of the parts is in a pure state, in a sharp contrast to the classical systems.

A CP map $\Phi$ is called a (quantum) *channel*, if it is trace preserving, i.e. if it maps quantum states into quantum states (possibly in another unitary space $\mathcal{H}'$). A channel $\Phi$ is called *unital* if $d = d'$ and $\Phi(I) = I'$, where $I(I')$ is the identity operator in $\mathcal{H}$ resp. $\mathcal{H}'$.

The von Neumann entropy of a density operator $\rho$

$$H(\rho) = -\,\mathrm{Tr}\,\rho \log \rho$$

is nonnegative concave continuous function on $\mathfrak{S}(\mathcal{H})$ vanishing on $\mathfrak{P}(\mathcal{H})$ and taking the maximal value $\log d$ on the *chaotic state* $\rho = \frac{I}{d}$. The noncommutative analog of the quantity (2) is the $\chi$*-capacity* [20], [22] of the channel $\Phi$,

$$C_\chi(\Phi) = \max_\pi \left\{ H\Big(\Phi\Big(\sum_x \pi(x)\rho(x)\Big)\Big) - \sum_x \pi(x) H(\Phi(\rho(x))) \right\}, \tag{5}$$

where the maximum is taken over all *state ensembles* i.e. finite probability distributions $\pi$ on the quantum state space $\mathfrak{S}(\mathcal{H})$ ascribing probabilities $\pi(x)$ to density operators $\rho(x)$[1]. The *additivity conjecture* is whether the analog of the property (3) holds for quantum channels, i.e.

$$C_\chi(\Phi_1 \otimes \Phi_2) \stackrel{?}{=} C_\chi(\Phi_1) + C_\chi(\Phi_2). \tag{6}$$

Here again $\otimes$ is the tensor product of the two channels describing independent uses of the channels on the states of the composite system. This is the earliest additivity conjecture in quantum information theory which can be traced back to [5], see also [20], [6].

[1] In the finite dimensional case we are considering the maximum is indeed attained on $\pi$ with support having at most $d^2$ states, where $d = \dim\mathcal{H}$ [50].

In physical terms this problem can also be formulated as: "Can entanglement between input states help to send classical information through quantum channels?" The *classical capacity* of a quantum channel is defined as the maximal transmission rate per use of the channel, with coding and decoding chosen for an increasing number $n$ of independent uses of the channel

$$\Phi^{\otimes n} = \underbrace{\Phi \otimes \cdots \otimes \Phi}_{n}$$

such that the error probability goes to zero as $n \to \infty$. A basic result of quantum information theory – the quantum coding theorem [19], [49] – implies that the classical capacity $C(\Phi)$ and the $\chi$-capacity $C_\chi(\Phi)$ are connected by the formula

$$C(\Phi) = \lim_{n\to\infty}(1/n)C_\chi(\Phi^{\otimes n}).$$

Since $C_\chi(\Phi)$ is easily seen to be superadditive, i.e.

$$C_\chi(\Phi_1 \otimes \Phi_2) \geq C_\chi(\Phi_1) + C_\chi(\Phi_2),$$

one has $C(\Phi) \geq C_\chi(\Phi)$. If the additivity (6) holds, then $C_\chi(\Phi^{\otimes n}) = nC_\chi(\Phi)$, and this would imply $C(\Phi) = C_\chi(\Phi)$. Such a result would be very much welcome from a mathematical point of view, giving a relatively easily computable "single-letter" expression for the classical capacity of a quantum channel.

On the other hand, such an equality is rather counter-intuitive in view of the relation (4) and existence of waste variety of pure entangled states. In fact, there are several quantities that are nonadditive under the tensor product of quantum channels such as: a) the Shannon information maximized over entangled outputs [20]; b) the quantum capacity [6]; c) the minimal output Rényi entropy [53] and some others, the classical counterparts of which are additive. In the following we shall consider the case c) which is most relevant to our main problem (6).

**3.2. Entropic characteristics of CP maps and channels.** The quantum Rényi entropy of order $p > 1$ of a density operator $\rho$ is defined as

$$R_p(\rho) = \frac{1}{1-p}\log \operatorname{Tr} \rho^p, \tag{7}$$

so that the minimal output Rényi entropy of the channel $\Phi$ is

$$\check{R}_p(\Phi) = \min_{\rho\in\mathfrak{S}(\mathcal{H})} R_p(\Phi(\rho)) = \frac{p}{1-p}\log \nu_p(\Phi),$$

where

$$\nu_p(\Phi) = \max_{\rho\in\mathfrak{S}(\mathcal{H})} [\operatorname{Tr} \Phi(\rho)^p]^{1/p} \tag{8}$$

is a "measure of output purity" of the channel $\Phi$ introduced in [3][2]. In the limit $p \downarrow 1$ the quantum Rényi entropies monotonically increase and uniformly converge to the entropy of a density operator $\rho$,

$$\lim_{p\downarrow 1} R_p(\rho) = H(\rho),$$

so that introducing the minimal output entropy

$$\check{H}(\Phi) = \min_{\rho\in\mathfrak{S}(\mathcal{H})} H(\Phi(\rho)) \tag{9}$$

of the quantum channel $\Phi$, one has $\lim_{p\downarrow 1} \check{R}_p(\Phi) = \check{H}(\Phi)$.

The classical analog of the quantity (8) is

$$\nu_p(\Phi) = \max_{\pi\in\mathcal{P}(\mathcal{X})} \|\Phi\pi\|_p,$$

where $\|f\|_p = \left(\sum_{x\in\mathcal{X}} |f(x)|^p\right)^{1/p}$ is the $l_p$-norm of $f = (f(x))_{x\in\mathcal{X}}$. The function $\pi \to \|\Phi\pi\|_p$ is convex continuous and hence attains the maximum at an extreme point of $\mathcal{P}(\mathcal{X})$, i.e. on a degenerate probability distribution $\delta_x$. Hence the basic property (1) implies the multiplicativity relation

$$\nu_p(\Phi_1 \otimes \Phi_2) = \nu_p(\Phi_1)\nu_p(\Phi_2), \tag{10}$$

which is equivalent to the additivity property of the minimal output Rényi entropies

$$\check{R}_p(\Phi_1 \otimes \Phi_2) = \check{R}_p(\Phi_1) + \check{R}_p(\Phi_2), \tag{11}$$

implying in turn

$$\check{H}(\Phi_1 \otimes \Phi_2) = \check{H}(\Phi_1) + \check{H}(\Phi_2), \tag{12}$$

in the limit $p \downarrow 1$. Notice that the inequality $\leq$ is obvious in (11), (12).

Unlike the classical case, there is no apparent reason for these multiplicativity/additivity properties to hold in the case of quantum channels. Nevertheless there are several important classes of channels for which the multiplicativity (10) can be proved for all $p > 1$, although there is also an example where it breaks for sufficiently large $p$. This, however, does not preclude that it can hold for $p$ close to 1, and the validity of (10) for $p \in (1, 1+\varepsilon)$, with $\varepsilon > 0$, implies validity of the additivity property (12), which, as we shall see, is closely related to the additivity of the $\chi$-capacity (6).

Here we would also like to mention that multiplicativity of more general $(q \to p)$-norms was studied for the cases where at least some of the maps $\Phi_1$, $\Phi_2$ is not CP, see [38], [37], [35]. Basing on the advanced theory of the operator $L_p$-spaces [44], [43], there is an interesting study concerning the multiplicativity of *completely bounded* $p$-norms, which however is related to the additivity of a completely different entropic quantity [15].

[2] In the finite-dimensional case all the functions of the state we are considering are easily seen to be continuous and their extrema on the state space are attained. However it is not so in infinite-dimensional case, and then the attainability of the extrema requires separate study, see Section 6.

## 4. Some classes of CP maps and channels

**4.1. Representations of CP maps.** Here we recollect some facts concerning the structure of CP maps and channels. Given three unitary spaces $\mathcal{H}_A$, $\mathcal{H}_B$, $\mathcal{H}_C$ and a linear operator $V\colon \mathcal{H}_A \to \mathcal{H}_B \otimes \mathcal{H}_C$, the relation

$$\Phi(\rho) = \mathrm{Tr}_{\mathcal{H}_C} V\rho V^*, \quad \tilde{\Phi}(\rho) = \mathrm{Tr}_{\mathcal{H}_B} V\rho V^*; \quad \rho \in \mathfrak{M}(\mathcal{H}_A) \tag{13}$$

defines two CP maps $\Phi\colon \mathfrak{M}(\mathcal{H}_A) \to \mathfrak{M}(\mathcal{H}_B)$, $\tilde{\Phi}\colon \mathfrak{M}(\mathcal{H}_A) \to \mathfrak{M}(\mathcal{H}_C)$, which are called mutually *complementary* [25] (or conjugate [36]). If $V$ is an isometry then both maps are channels.

For any linear map $\Phi\colon \mathfrak{M}(\mathcal{H}) \to \mathfrak{M}(\mathcal{H}')$ the *dual* map $\Phi^*\colon \mathfrak{M}(\mathcal{H}') \to \mathfrak{M}(\mathcal{H})$ is defined by the formula

$$\mathrm{Tr}\,\Phi(\rho)X = \mathrm{Tr}\,\rho\Phi^*(X); \quad \rho \in \mathfrak{M}(\mathcal{H}),\ X \in \mathfrak{M}(\mathcal{H}').$$

If $\Phi$ is CP, then $\Phi^*$ is also CP. The relations (13) are equivalent to

$$\Phi^*(X) = V^*(X \otimes I_C)V; \quad X \in \mathfrak{M}(\mathcal{H}_B), \tag{14}$$

$$\tilde{\Phi}^*(X) = V^*(I_B \otimes X)V; \quad X \in \mathfrak{M}(\mathcal{H}_C). \tag{15}$$

The *Stinespring dilation theorem* [51] concerning CP maps on arbitrary $C^*$-algebras, for the particular case in question amounts to the statement that for a given CP map there are a space $\mathcal{H}_C$ and an operator $V$ satisfying (14). This implies that given a CP map $\Phi$, a complementary map $\tilde{\Phi}$ always exists.

By introducing a basis $\{e_j^C\}$ in $\mathcal{H}_C$ and operators $V_j\colon \mathcal{H}_A \to \mathcal{H}_B$ defined by

$$(\varphi, V_j\psi) = \left(\varphi \otimes e_j^C, V\psi\right); \quad \varphi \in \mathcal{H}_B,\ \psi \in \mathcal{H}_A,$$

the first relation in (13) can be rewritten as

$$\Phi(\rho) = \sum_{j=1}^{d_C} V_j \rho V_j^*; \quad \rho \in \mathfrak{M}(\mathcal{H}_A). \tag{16}$$

The map (16) is a channel if and only if $\sum_{j=1}^{d_C} V_j^* V_j = I$. The relation (16) is usually called the Kraus representation (see also Choi [9]). Of course, there are similar representations for the complementary map $\tilde{\Phi}$ and the dual maps.

**Theorem 4.1** ([25], [36]). *If one of the relations* (11), (12) *holds for the CP maps* (*channels*) $\Phi_1$, $\Phi_2$, *then similar relations holds for the pair of their complementary maps* $\tilde{\Phi}_1$, $\tilde{\Phi}_2$. *If one of these relations holds for a given* $\Phi_1$ *and arbitrary* $\Phi_2$, *then a similar relation holds for the complementary map* $\tilde{\Phi}_1$ *and arbitrary* $\Phi_2$.

Validity of the multiplicativity conjecture (10) for all $p \geq 1$ and of the additivity conjectures (12), (6) was established in a number of cases where one channel is arbitrary and the other belongs to one of the classes we are going to discuss.

**4.2. Entanglement-breaking maps and their complementary maps.** Any linear map $\Phi\colon \mathfrak{M}(\mathcal{H}) \to \mathfrak{M}(\mathcal{H}')$ admits a representation

$$\Phi(X) = \sum_j N'_j \operatorname{Tr} X M_j, \tag{17}$$

where $\{M_j\}$, $\{N'_j\}$ are finite collections of operators in $\mathcal{H}$ and $\mathcal{H}'$, respectively. This simply follows from the finite dimensionality of $\mathcal{H}$, $\mathcal{H}'$ and the fact that any linear functional on $\mathfrak{M}(\mathcal{H})$ has the form $X \to \operatorname{Tr} XM$, where $M \in \mathfrak{M}(\mathcal{H})$.

**Proposition 4.2.** *For a linear map $\Phi\colon \mathfrak{M}(\mathcal{H}) \to \mathfrak{M}(\mathcal{H}')$ the following conditions are equivalent:*

(i) *There is a representation* (17) *such that $M_j \geq 0$, $N'_j \geq 0$.*

(ii) *The map $\Phi$ is CP and has the representation* (16) *with rank one operators $V_j$.*

(iii) *For $d = 2, 3, \ldots$ and any $\rho_{12} \in \mathfrak{S}(\mathcal{H} \otimes \mathcal{H}_d)$,*

$$(\Phi \otimes \mathrm{Id}_d)(\rho_{12}) = \sum_\alpha A_\alpha \otimes B_\alpha \tag{18}$$

*where $A_\alpha \geq 0$ and $B_\alpha \geq 0$.*

Channels satisfying the condition (i) were introduced in [20], and the above characterization was obtained in [29] where such maps were termed *entanglement-breaking*. In the case of channels, (18) means that the output state $(\Phi \otimes \mathrm{Id}_d)(\rho_{12})$ is always *separable*, i.e. a convex combination of (unentangled) product states. Entanglement-breaking channels can be written in the form

$$\Phi(\rho) = \sum_j \rho'_j \operatorname{Tr} \rho M_j, \tag{19}$$

where $\{\rho'_j\}$ is a finite collection of states in $\mathcal{H}'$, and $\{M_j\}$ a *resolution of the identity* in $\mathcal{H}$, i.e. a collection of operators satisfying

$$M_j \geq 0, \quad \sum_j M_j = I.$$

Resolutions of the identity describe quantum *observables* [22], and the channel (19) corresponds to a measurement of the observable $\{M_j\}$ over an input state $\rho$ resulting in a probability distribution $\{\operatorname{Tr} \rho M_j\}$, which is followed by preparation of the output state $\rho'_j$. Thus, there is a classical information processing stage inside the channel which is responsible for the entanglement-breaking.

The simplest example is the *completely depolarizing channel*

$$\Phi(\rho) = \frac{I}{d} \operatorname{Tr} \rho$$

which maps an arbitrary state to the chaotic state $\frac{I}{d}$.

As shown in [25], [36], the complementary maps to the entanglement-breaking maps have the form

$$\tilde{\Phi}(\rho) = \sum_{j,k=1}^{d_C} c_{jk}\langle\psi_j|\rho|\psi_k\rangle E_{jk}, \quad \rho \in \mathfrak{M}(\mathcal{H}_A), \tag{20}$$

where $[c_{jk}]$ is a nonnegative definite matrix, $\{\psi_j\}_{j=\overline{1,d_C}}$ a system of vectors in $\mathcal{H}_A$, and the $E_{jk}$'s are the matrix units in $\mathcal{H}_C$. In the special case where $\{\psi_j\}_{j=\overline{1,d_C}}$ is an orthonormal basis, (20) is the *diagonal* CP map in the sense of [31]. Diagonal channels are characterized by the additional property $c_{jj} \equiv 1$.

A simplest example of the diagonal channel is the *ideal channel* Id, which is complementary to the completely depolarizing channel.

For general entanglement-breaking channels the additivity property (12) with arbitrary second channel was established by Shor [47], preceded by results in [20] on special subclasses of such channels. The multiplicativity property (10) for all $p > 1$ was established by King [32], basing on the Lieb–Thirring inequality [40]: for $A, B \in \mathfrak{M}(\mathcal{H})$, $A, B \geq 0$, and $p \geq 1$

$$\operatorname{Tr}(AB)^p \leq \operatorname{Tr} A^p B^p. \tag{21}$$

By Theorem 4.1 this implies the corresponding properties for the complementary maps and channels of the form (20).

**4.3. Covariant channels.** Let $G$ be a group (either finite or continuous) and let $g \to U_g^A, U_g^B$, $g \in G$, be two projective (unitary) representations of $G$ in $\mathcal{H}_A$, $\mathcal{H}_B$. The CP map $\Phi\colon \mathfrak{M}(\mathcal{H}_A) \to \mathfrak{M}(\mathcal{H}_B)$ is *covariant* if

$$\Phi(U_g^A \rho U_g^{A*}) = U_g^B \Phi(\rho) U_g^{B*} \tag{22}$$

for all $g \in G$ and all $\rho$. For a covariant CP map there exists a covariant Stinespring dilation: namely, there is a projective representation $g \to U_g^C$ in $\mathcal{H}_B$, such that

$$(U_g^B \otimes U_g^C)V = V U_g^A,$$

see e.g. [24]. It follows that the complementary map is also covariant:

$$\tilde{\Phi}(U_g^A \rho U_g^{A*}) = U_g^C \tilde{\Phi}(\rho) U_g^{C*}.$$

**Lemma 4.3.** *If the representation $U_g^A$ is irreducible, then*

$$C_\chi(\Phi) = H\left(\Phi\left(\frac{I_A}{d_A}\right)\right) - \check{H}(\Phi). \tag{23}$$

Since the tensor product of irreducible representations of possibly different groups $G_1$, $G_2$ is an irreducible representation of the group $G_1 \times G_2$, it follows that the additivity properties (12) and (6) are equivalent for channels satisfying the condition of Lemma 4.3. Symmetry considerations also help to compute explicitly the entropic characteristics of covariant channels. Then, in the case of additivity, $C = C_\chi$ gives an explicit expression for the classical capacity of the channel.

**4.4. The unital qubit channels.** The simplest and yet fundamental quantum system is the *qubit* (quantum bit), where $\dim\mathcal{H} = 2$. A convenient basis in $\mathfrak{M}_2$ is formed by the Pauli matrices

$$\sigma_0 \equiv I = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}, \quad \sigma_x = \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix}, \quad \sigma_y = \begin{bmatrix} 0 & -i \\ i & 0 \end{bmatrix}, \quad \sigma_z = \begin{bmatrix} 1 & 0 \\ 0 & -1 \end{bmatrix}.$$

It is known [45] that an arbitrary unital channel $\Phi\colon \mathfrak{M}_2 \to \mathfrak{M}_2$ can be decomposed as

$$\Phi(\rho) = U_2\Lambda(U_1\rho U_1^*)U_2^*, \tag{24}$$

where $U_1$, $U_2$ are unitary matrices and $\Lambda$ has the following canonical Kraus representation:

$$\Lambda(\rho) = \sum_{\gamma=0,x,y,z} \mu_\gamma \sigma_\gamma \rho \sigma_\gamma, \tag{25}$$

where $\{\mu_\gamma\}$ is a probability distribution. The unital qubit channels (25) are covariant with respect to the projective representation of the group $\mathbb{Z}_2 \times \mathbb{Z}_2$ defined by

$$U_{00} = \sigma_0, \quad U_{01} = \sigma_z, \quad U_{10} = \sigma_x, \quad U_{11} = -i\sigma_y.$$

Therefore the relation (23) holds for this class of channels.

By using a convex decomposition into diagonal channels of special form and applying to these the Lieb–Thirring inequality (21), King [33] established (10) for all $p > 1$, (12) and (6) for the case where $\Phi_1$ is an arbitrary unital qubit channel and $\Phi_2$ is an arbitrary channel. There are recent positive results concerning nonunital qubit channels [35].

**4.5. Depolarizing channel.** The *depolarizing channel* in $\mathcal{H}_d$ is

$$\Phi(\rho) = (1-p)\rho + p\frac{I}{d}\operatorname{Tr}\rho, \quad 0 \le p \le \frac{d^2}{d^2-1}. \tag{26}$$

If $p \le 1$ this describes a mixture of the ideal channel Id and the completely depolarizing channel. For the whole range $0 \le p \le \frac{d^2}{d^2-1}$ complete positivity can be proven by using the Kraus decomposition, see e.g. [42]. The depolarizing channel is characterized by the property of unitary covariance,

$$\Phi(U\rho U^*) = U\Phi(\rho)U^*,$$

for an arbitrary unitary operator $U$ in $\mathcal{H}$.

The properties (10) for all $p > 1$, (12) and (6) were proved in [34] for the case where $\Phi_1$ is a depolarizing channel and $\Phi_2$ is arbitrary, using a method similar to the case of the unital qubit channels.

Complementarity for depolarizing channels is computed in [11].

**4.6. A transpose-depolarizing channel.** Let us consider in some detail the *extreme transpose-depolarizing* channel

$$\Phi(\rho) = \frac{1}{d-1}\big[I \operatorname{Tr} \rho - \rho^{\top}\big], \tag{27}$$

where $\rho^{\top}$ is the transpose of $\rho$ in an orthonormal basis $\{e_j\}$ in $\mathcal{H}_d$. Complete positivity of the map (27) follows from the representation

$$\Phi(\rho) = \frac{1}{2(d-1)} \sum_{j,k=1}^{d} (E_{jk} - E_{kj})\rho(E_{jk} - E_{kj})^*. \tag{28}$$

It has the covariance property

$$\Phi(U\rho U^*) = \overline{U}\Phi(\rho)\overline{U}^*$$

for an arbitrary unitary $U$, where $\overline{U}$ is complex conjugate in the basis $\{e_j\}$. It follows that the relation (23) holds for this channel.

This channel is interesting in that it breaks the additivity of the minimal Rényi entropy (11) with $\Phi_1 = \Phi_2 = \Phi$ for $d > 3$ and large enough $p$ [53]. At the same time it fulfills (12), see [41], [12], and even (11) for $1 \le p \le 2$ [13]. For generalizations to broader classes of channels as well as to the more general forms of additivity, see [41], [1], [54]. This example also shows that although the Lieb–Thirring inequality can be used in several cases to prove the additivity conjecture (11) for all $p > 1$, it cannot serve for a general proof. Moreover, there is even no general proof covering all these cases, since each time application of the Lieb–Thirring inequality is supplied with an argument specific to the case under consideration.

The complementary channel which shares the multiplicativity/additivity properties with the channel (27) is

$$\tilde{\Phi}(\rho) = \frac{2}{(d-1)} P_-(\rho \otimes I_2) P_- \tag{29}$$

(see [25] for more details). Here $P_-$ is the projector onto the antisymmetric subspace of $\mathcal{H} \otimes \mathcal{H}$ of dimension $\frac{d(d-1)}{2}$. The covariance property of the channel (29) is

$$\tilde{\Phi}(U\rho U^*) = (U \otimes U)\tilde{\Phi}(\rho)(U^* \otimes U^*),$$

as follows from the fact that $P_-(U \otimes U) = (U \otimes U)P_-$.

## 5. A hierarchy of the additivity conjectures

**5.1. Convex closure.** To find out the intrinsic connection between the output entropy and the $\chi$-capacity, let us define the average $\bar{\rho}_\pi = \sum_x \pi(x)\rho(x)$ of the ensemble $\pi$ and rewrite the expression (5) in the form

$$C_\chi(\Phi) = \max_{\rho \in \mathfrak{S}(\mathcal{H})} \big[H(\Phi(\rho)) - \hat{H}_\Phi(\rho)\big], \tag{30}$$

where

$$\hat{H}_\Phi(\rho) = \min_{\pi:\bar{\rho}_\pi=\rho} \sum_x \pi(x) H(\Phi(\rho(x)))$$

is the *convex closure* [30] of the output entropy $H(\Phi(\rho))$[3]. The function $\hat{H}_\Phi(\rho)$ is a natural generalization of another important quantity in quantum information theory, namely the "entanglement of formation" [6] and reduces to it when the channel $\Phi$ is a partial trace. This quantity has the conjectured superadditivity property: *for an arbitrary state* $\rho_{12} \in \mathfrak{S}(\mathcal{H}_1 \otimes \mathcal{H}_2)$ *and arbitrary channels* $\Phi_1$, $\Phi_2$,

$$\hat{H}_{\Phi_1\otimes\Phi_2}(\rho_{12}) \geq \hat{H}_{\Phi_1}(\rho_1) + \hat{H}_{\Phi_2}(\rho_2), \tag{31}$$

*where* $\rho_1$, $\rho_2$ *are the partial traces of* $\rho_{12}$ *in* $\mathcal{H}_1$, $\mathcal{H}_2$ .

It is not difficult to see that this property implies additivity of both the minimal output entropy and the $\chi$-capacity:

**Proposition 5.1.** *The superadditivity property* (31) *implies the additivity properties* (12) *and* (6) *for given channels* $\Phi_1$, $\Phi_2$.

In the spirit of Theorem 4.1, one can prove ([25]) that

*if the relation* (31) *holds for the pair of CP maps* (*channels*) $\Phi_1$, $\Phi_2$, *then similar relation holds for the pair of their complementary maps* $\tilde{\Phi}_1$, $\tilde{\Phi}_2$. *If one of these relations holds for given* $\Phi_1$ *and arbitrary* $\Phi_2$, *then a similar relation holds for the complementary map* $\tilde{\Phi}_1$ *and arbitrary* $\Phi_2$.

Let $\{p_j\}$ be a finite probability distribution and let $\Phi_j : \mathfrak{M}(\mathcal{H}) \to \mathfrak{M}(\mathcal{H}'_j)$ be a collection of channels. The channel $\Phi\colon\ \mathfrak{M}(\mathcal{H}) \to \mathfrak{M}\big(\sum_j \oplus \mathcal{H}'_j\big)$ is called *orthogonal convex sum* of the channels $\Phi_j$, if $\Phi(\rho) = \sum_j \oplus p_j \Phi_j(\rho)$ for all $\rho \in \mathfrak{S}(\mathcal{H})$.

**Proposition 5.2** ([26]). *Let* $\Phi_2$ *be an arbitrary channel. The properties* (11), (12), (31) *hold if* $\Phi_1$ *is an orthogonal convex sum of either an ideal channel or completely depolarizing channel and a channel* $\Phi^{(0)}$ *such that the corresponding property holds for* $\Phi^{(0)}$ *and* $\Phi_2$.

It follows that such a $\Phi_1$ fulfils the additivity of $\chi$-capacity (6).

In this way, for example, one obtains all the additivity properties for the important case of the *erasure channel*

$$\Phi(\rho) = \begin{bmatrix} p\rho & 0 \\ 0 & (1-p)\operatorname{Tr}\rho \end{bmatrix},$$

as it is the orthogonal convex sum of an ideal and a completely depolarizing channel.

[3] Here the same comment applies as to the attainability of the maximum in (5).

**5.2. Additivity for constrained channels.** In this section we consider several equivalent formulations of the additivity conjecture for channels with arbitrarily constrained inputs [26], which formally is substantially stronger than additivity of the unconstrained $\chi$-capacity. Let us denote

$$\chi_\Phi(\rho) = H(\Phi(\rho)) - \hat{H}_\Phi(\rho), \tag{32}$$

then the function $\chi_\Phi(\rho)$ is continuous and concave on the set $\mathfrak{S}(\mathcal{H})$ of all states in $\mathcal{H}$.

Consider the constraint on the ensemble $\pi$ with the average $\bar{\rho}_\pi = \sum_x \pi(x)\rho(x)$, defined by the requirement $\bar{\rho}_\pi \in \mathcal{A}$, where $\mathcal{A}$ is a closed subset of states. A particular case is the linear constraint $\mathcal{A} = \{\rho : \operatorname{Tr}\rho A \le \alpha\}$ for a positive operator $A$ and a number $\alpha \ge 0$. Define the *$\chi$-capacity of the $\mathcal{A}$-constrained channel* $\Phi$ by

$$C_\chi(\Phi; \mathcal{A}) = \max_{\rho\in\mathcal{A}} \chi_\Phi(\rho). \tag{33}$$

Note that the $\chi$-capacity for the unconstrained channel is $C_\chi(\Phi) = C(\Phi; \mathfrak{S}(\mathcal{H}))$. On the other hand, $\chi_\Phi(\rho) = C_\chi(\Phi; \{\rho\})$.

Let $\Phi_1$, $\Phi_2$ be two channels with the constraints $\mathcal{A}_1$, $\mathcal{A}_2$. For the channel $\Phi_1 \otimes \Phi_2$ we introduce the constraint $\mathcal{A}_1 \otimes \mathcal{A}_2 \equiv \{\rho : \operatorname{Tr}_{\mathcal{H}_2}\rho \in \mathcal{A}_1, \operatorname{Tr}_{\mathcal{H}_1}\rho \in \mathcal{A}_2\}$ and consider the conjecture

$$C_\chi(\Phi_1 \otimes \Phi_2; \mathcal{A}_1 \otimes \mathcal{A}_2) = C_\chi(\Phi_1; \mathcal{A}_1) + C_\chi(\Phi_2; \mathcal{A}_2), \tag{34}$$

which apparently implies (6).

**Theorem 5.3.** *Let $\Phi_1$ and $\Phi_2$ be two fixed channels. The following properties are equivalent:*

(i) *Equality* (34) *holds for arbitrary linear constraints $\mathcal{A}_1$, $\mathcal{A}_2$.*

(ii) *Equality* (34) *holds for arbitrary closed $\mathcal{A}_1$, $\mathcal{A}_2$.*

(iii) *For arbitrary $\rho_{12} \in \mathfrak{S}(\mathcal{H}_1 \otimes \mathcal{H}_2)$,*

$$\chi_{\Phi_1\otimes\Phi_2}(\rho_{12}) \le \chi_{\Phi_1}(\rho_1) + \chi_{\Phi_2}(\rho_2). \tag{35}$$

(iv) *Inequality* (31) *holds for arbitrary $\rho_{12} \in \mathfrak{S}(\mathcal{H}_1 \otimes \mathcal{H}_2)$.*

Here each property is easily seen to imply the preceding one, while the implication (i) $\Rightarrow$ (iv) is nontrivial. By Proposition 5.1 any of these properties imply the additivity properties (12), (6).

**5.3. The convex duality formulation.** In [4], tools from convex analysis were applied to study the relation of the additivity problem to superadditivity of entanglement

of formation. Here we apply a similar approach to the conjecture (31). Given a channel $\Phi$, its output entropy $H(\Phi(\rho))$ is a continuous concave function on the state space $\mathfrak{S}(\mathcal{H})$. Consider its modified Legendre transform

$$\begin{aligned} H_\Phi^*(X) &= \min_{\rho\in\mathfrak{S}(\mathcal{H})}\{\operatorname{Tr}\rho X + H(\Phi(\rho))\} \\ &= \min_{\rho\in\mathfrak{S}(\mathcal{H})}\{\operatorname{Tr}\rho X + \hat{H}_\Phi(\rho)\}, \quad X\in\mathfrak{M}_h(\mathcal{H}), \end{aligned} \tag{36}$$

where $\mathfrak{M}_h(\mathcal{H})$ is a real normed space of Hermitian operators in $\mathcal{H}$.

Now let $\Phi_1$, $\Phi_2$ be two channels.

**Lemma 5.4.** *The superadditivity* (31) *of the convex closure $\hat{H}_\Phi(\rho)$ is equivalent to the following additivity property of $H_\Phi^*(X)$:*

$$H^*_{\Phi_1\otimes\Phi_2}(X_1\otimes I_2 + I_1\otimes X_2) = H^*_{\Phi_1}(X_1) + H^*_{\Phi_2}(X_2), \tag{37}$$

*for all $X_1\in\mathfrak{M}_h(\mathcal{H}_1)$, $X_2\in\mathfrak{M}_h(\mathcal{H}_2)$.*

Since $H_\Phi^*(0) = \check{H}(\Phi)$, by letting $X_1 = X_2 = 0$, the relation (37) implies additivity of the minimal output entropy (12).

**5.4. The global equivalence.** A remarkable result was obtained by Shor [48] who showed that different forms of the additivity conjecture become equivalent if one considers their validity for *all* channels. Here we describe a basic construction from [48] which in combination with Proposition 5.1 and Theorem 5.3 suffices for the proof of the following result.

**Theorem 5.5.** *The conjectures* (6), (12), (31), (34) *are globally equivalent in the sense that if one of them holds true for all channels $\Phi_1$, $\Phi_2$, then any of the others is also true for all channels.*

Let us argue that if additivity of the minimal output entropy (12) holds for all channels, then (37) holds for all channels. By Lemma 5.4 this will imply (31) and hence, by Theorem 5.3, all the other properties.

First of all we observe that $H_\Phi^*(X+\lambda I) = H_\Phi^*(X) + \lambda$, which implies that it is sufficient to establish (37) only for $X_1, X_2 \geq 0$. The idea of proof is to build, for any channel $\Phi$ and $X\geq 0$, a sequence of channels $\Phi'_{X,n}$ such that

$$\min_\rho H(\Phi'_{X,n}(\rho)) \equiv \check{H}(\Phi'_{X,n}) = \min_\rho[H(\Phi(\rho)) + \operatorname{Tr}\rho X] + o(1) \equiv H_\Phi^*(X) + o(1).$$

One can then apply the convex duality argument to deduce for the original channels the additivity property (37), which is equivalent to (31), from the additivity of the minimal output entropy for channels $\Phi'_{X,n}$.

Given a channel $\Phi\colon \mathfrak{M}(\mathcal{H}) \to \mathfrak{M}(\mathcal{H}')$ and a positive $X\in\mathcal{H}$, the new channel $\Phi'_{X,n}$ is constructed as follows. Choose a constant $c\geq\|X\|$, then $E = c^{-1}X$ satisfies $0\leq E\leq I$. Let $q_n\in(0,1)$ be such that

$$(1-q_n)\log n = c, \quad n = 2, 3, \ldots.$$

Then $\Phi'_{X,n}\colon \mathfrak{M}(\mathcal{H}) \to \mathfrak{M}(\mathcal{H}'_n)$, where $\mathcal{H}'_n = \mathcal{H}' \oplus \mathcal{H}_n \oplus \mathbb{C}$, acts on $\rho \in \mathfrak{M}(\mathcal{H})$ as follows:

$$\Phi'_{X,n}(\rho) = \begin{bmatrix} q_n\Phi(\rho) & 0 & 0 \\ 0 & (1-q_n)(\operatorname{Tr}\rho E)\frac{I_n}{n} & 0 \\ 0 & 0 & (1-q_n)\operatorname{Tr}\rho(I-E) \end{bmatrix}. \tag{38}$$

This is an orthogonal convex sum of CP maps, preserving trace, and hence is a channel.

The intuition is that the action of $\Phi'_{X,n}(\rho)$ can be described as follows. With probability $q_n$ (which tends to 1 as $n \to \infty$) it acts as the channel $\Phi$, resulting in the state $\Phi(\rho)$. With probability $(1 - q_n)$, however, a quantum measurement described by the resolution of the identity (the quantum observable) $\{E, I - E\}$ is made, so that the first outcome appears with probability $\operatorname{Tr}\rho E$, while the second appears with probability $\operatorname{Tr}\rho(I - E)$. In the first case the output is the chaotic state $\frac{I_n}{n}$ in the $n$-dimensional unitary space $\mathcal{H}_n$; in the second case the output is a pure state orthogonal to $\mathcal{H}' \oplus \mathcal{H}_n$. In this way the channel $\Phi'_{X,n}(\rho)$ with high probability $q_n$ acts as the initial channel, while with a small probability $(1 - q_n)(\operatorname{Tr}\rho E)$ outputs a high dimensional chaotic state $\frac{I_n}{n}$, providing the knowledge about the value of $\operatorname{Tr}\rho E = c^{-1}\operatorname{Tr}\rho X$ involved in the definition of $H^*_\Phi(X)$. This is formalized by proving the uniform estimate

$$H\big((\Phi'_{X,n} \otimes \Phi_2)(\rho_{12})\big) = q_n H\big((\Phi \otimes \Phi_2)(\rho_{12})\big) + \operatorname{Tr}\rho_1 X + o(1),$$

double application of which reduces the property (37) for initial channels to the additivity of the minimal output entropy for the channels $\Phi'_{X,n}$.

A modification of this construction can be also used to show that *if the unconstrained additivity* (6) *holds for all channels, then additivity* (34) *for all channels with arbitrary constraints holds as well* [26]. This completes the global equivalence.

## 6. Infinite-dimensional channels

We have seen that the additivity problem is not completely solved even for the minimal dimension 2. Nevertheless there are several good reasons to consider the problem in *infinite* dimensions.

There is an important and interesting class of Bosonic Gaussian channels, see [28], which act in infinite dimensional Hilbert space. Analysis of continuity properties of the entropic characteristics of an infinite-dimensional channel becomes important since, as is well known, the entropy may then have a rather pathological behavior. It is only lower semicontinuous and "almost everywhere" infinite in the infinite-dimensional case [52]. Another issue is the study of conditions for compactness of subsets of quantum states and ensembles, giving a key for attainability of extrema in expressions for the capacity and the convex closure of the output entropy.

The proof of global equivalence of different forms of the additivity conjecture for finite dimensional channels (Section 5.4), using infinitely growing channel extensions

in fact relies upon the discontinuity of the $\chi$-capacity as a function of the channel in infinite dimensions. This also calls for a study of continuity properties of the entropic quantities related to the classical capacity of infinite dimensional channels. Such a study was undertaken in a series of works [23], [27], [46]. In particular it was shown that in spite of the aforementioned discontinuities, additivity for all finite-dimensional channels implies additivity of the $\chi$-capacity of infinite-dimensional channels with arbitrary constraints [46].

There are two important features essential for channels in infinite dimensions. One is the necessity of the input constraints (such as mean energy constraint for Gaussian channels) to prevent from infinite capacities (although considering input constraints was shown quite useful also in the study of the additivity conjecture for channels in finite dimensions [26]). The other is the natural appearance of infinite, and, in general, "continuous" state ensembles understood as probability measures on the set of all quantum states. By using compactness criteria from probability and operator theory one can show that the set of all such generalized ensembles with the barycenter in a compact set of states is itself weakly compact. With this in hand a sufficient condition for existence of an optimal generalized ensemble for a constrained quantum channel can be given. This condition can be efficiently verified in the case of Bosonic Gaussian channels with constrained mean energy [27].

However apart from mere existence one would like to have an explicit description of the optimal states and ensembles in the case of quantum Gaussian channels. In classical information theory Gaussian channels have Gaussian maximizers, and there is an analytical counterpart of this phenomenon for $(q \to p)$-norms of integral operators with Gaussian kernels, see [39]. Whether a similar description holds true for Bosonic Gaussian channels is another open question (for some partial results in this direction see [28], [17], [18], [55]). We only mention here that a positive solution of this question may also depend on the validity of the multiplicativity/ additivity conjecture [39], [55].

# Complex networks and decentralized search algorithms

Jon Kleinberg*

**Abstract.** The study of complex networks has emerged over the past several years as a theme spanning many disciplines, ranging from mathematics and computer science to the social and biological sciences. A significant amount of recent work in this area has focused on the development of random graph models that capture some of the qualitative properties observed in large-scale network data; such models have the potential to help us reason, at a general level, about the ways in which real-world networks are organized.

We survey one particular line of network research, concerned with small-world phenomena and decentralized search algorithms, that illustrates this style of analysis. We begin by describing a well-known experiment that provided the first empirical basis for the "six degrees of separation" phenomenon in social networks; we then discuss some probabilistic network models motivated by this work, illustrating how these models lead to novel algorithmic and graph-theoretic questions, and how they are supported by recent empirical studies of large social networks.

**Keywords.** Random graphs, complex networks, search algorithms, social network analysis.

## 1. Introduction

Over the past decade, the study of complex networks has emerged as a theme running through research in a wide range of areas. The growth of the Internet and the World Wide Web has led computer scientists to seek ways to manage the complexity of these networks, and to help users navigate their vast information content. Social scientists have been confronted by social network data on a scale previously unimagined: datasets on communication within organizations, on collaboration in professional communities, and on relationships in financial domains. Biologists have delved into the interactions that define the pathways of a cell's metabolism, discovering that the network structure of these interactions can provide insight into fundamental biological processes. The drive to understand all these issues has resulted in what some have called a "new science of networks" – a phenomenological study of networks as they arise in the physical world, in the virtual world, and in society.

At a mathematical level, much of this work has been rooted in the study of *random graphs* [14], an area at the intersection of combinatorics and discrete probability that

*Supported in part by a David and Lucile Packard Foundation Fellowship, a John D. and Catherine T. MacArthur Foundation Fellowship, and NSF grants CCF-0325453, IIS-0329064, CNS-0403340, and BCS-0537606.

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

is concerned with the properties of graphs generated by random processes. While this has been an active topic of study since the work of Erdös and Rényi in the 1950s [26], the appearance of rich, large-scale network data in the 1990s stimulated a tremendous influx of researchers from many different communities. Much of this recent cross-disciplinary work has sought to develop random graph models that more tightly capture the qualitative properties found in large social, technological, and information networks; in many cases, these models are closely related to earlier work in the random graphs literature, but the issues arising in the motivating applications lead to new types of mathematical questions. For surveys covering different aspects of this general area, and in particular reflecting the various techniques of some of the different disciplines that have contributed to it, we refer the reader to recent review papers by Albert and Barabási [4], Bollobás [15], Kleinberg and Lawrence [39], Newman [52], and Strogatz [60], the volume of articles edited by Ben-Naim et al. [10], and the monographs by Dorogovtsev and Mendes [23] and Durrett [25], as well as books by Barabási [8] and Watts [62] aimed at more general audiences.

What does one hope to achieve from a probabilistic model of a complex network arising in the natural or social world? A basic strategy pursued in much of this research is to define a stylized network model, produced by a random mechanism that reflects the processes shaping the real network, and to show that this stylized model reproduces properties observed in the real network. Clearly the full range of factors that contribute to the observed structure will be too intricate to be fully captured by any simple model. But a finding based on a random graph formulation can help argue that the observed properties may have a simple underlying basis, even if their specifics are very complex. While it is crucial to realize the limitations of this type of activity – and not to read too much into the detailed conclusions drawn from a simple model – the development of such models has been a valuable means of proposing concrete, mathematically precise hypotheses about network structure and evolution that can then serve as starting points for further empirical investigation. And at its most effective, this process of modeling via random graphs can suggest novel types of qualitative network features – structures that people had not thought to define previously, and which become patterns to look for in new network datasets.

In the remainder of the present paper, we survey one line of work, motivated by the "small-world phenomenon" and some related search problems, that illustrates this style of analysis. We begin with a striking experiment by the social psychologist Stanley Milgram that frames the empirical issues very clearly [50], [61]; we describe a sequence of models based on random graphs that capture aspects of this phenomenon [64], [36], [37], [38], [63]; and we then discuss recent work that has identified some of the qualitative aspects of these models in large-scale network data [1], [43], [49]. We conclude with some further extensions to these random graph models, discussing the results and questions that they lead to.

## 2. The small-world phenomenon

The small-world phenomenon – the principle that we are all linked by short chains of acquaintances, or "six degrees of separation" [29] – has long been the subject of anecdotal fascination among the general public, and more recently has become the subject of both experimental and theoretical research. At its most basic level, it is a statement about networks, and human social networks in particular; it concerns the graph with one node corresponding to each person in the world, and an edge joining two people if they know each other on a first-name basis. When we say that this graph is a "small world," we mean, informally, that almost every pair of nodes is connected by a path with an extremely small number of steps.

One could worry about whether this graph is precisely specified – for example, what exactly it means to know someone on a first-name basis – but however one fixes a working definition for this, it is clear that the resulting graph encodes an enormous amount of information about society in general. It is also clear that it would be essentially impossible to determine its structure precisely. How then could one hope to test, empirically, the claim that most pairs of nodes in this graph are connected by short paths?

The social psychologist Stanley Milgram [50], [61] took up this challenge in the 1960s, conducting an experiment to test the small-world property by having people explicitly construct paths through the social network defined by acquaintanceship. To this end, he chose a *target person* in the network, a stockbroker living in a suburb of Boston, and asked a collection of randomly chosen "starter" individuals each to forward a letter to the target. He provided the target's name, address, occupation, and some personal information, but stipulated that the participants could not mail the letter directly to the target; rather, each participant could only advance the letter by forwarding it to a single acquaintance that he or she knew on a first-name basis, with the goal of reaching the target as rapidly as possible. Each letter thus passed successively from one acquaintance to another, closing in on the stockbroker outside Boston.

The letters thus acted as virtual "tracers," mapping out paths through the social network. Milgram found that the median length among the completed paths was six, providing the first concrete evidence for the abundance of short paths connecting far-flung pairs of individuals in society, as well as supplying the basis for the number "six" in the resulting pop-cultural mantra. One needs to be careful in interpreting this finding, of course: many of the chains never reached the target, and the target himself was a relatively "high-status" individual who may have been easier to reach than an arbitrary person (see e.g. the recent critique by Kleinfeld [41]). But since Milgram's work, the overall conclusion has been accepted at least at a qualitative level: social networks tend to exhibit very short paths between essentially arbitrary pairs of nodes.

## 3. Basic models of small-world networks

Why should social networks exhibit this type of a small-world property? Earlier we suggested that interesting empirical findings about networks often motivate the development of new random graph models, but we have to be careful in framing the issue here: a simple abundance of short paths is in fact something that most basic models of random graphs already "get right." As a paradigmatic example of such a result, consider the following theorem of Bollobás and de la Vega [14], [17].

**Theorem 3.1** ([17]). *Fix a constant $k \geq 3$. If we choose uniformly at random from the set of all $n$-node graphs in which each node has degree exactly $k$, then with high probability every pair of nodes will be joined by a path of length $O(\log n)$.*

(Following standard notation and terminology, we say that the *degree* of a node is the number of edges incident to it. We say that a function is $O(f(n))$ if there is a constant $c$ so that for all sufficiently large $n$, the function is bounded by $cf(n)$.) In fact, [17] states a much more detailed result concerning the dependence on $n$, but this will not be crucial for our purposes here.

Path lengths that are logarithmic in $n$ – or more generally *polylogarithmic*, bounded by a polynomial function of $\log n$ – will be our "gold standard" in most of this discussion. We will keep the term "small world" itself informal; but we will consider a graph to be a small world, roughly, when all (or most) pairs of nodes are connected by paths of length polylogarithmic in $n$, since in such a case the path lengths are exponentially smaller than the number of nodes.

Watts and Strogatz [64] argued that there is something crucial missing from the picture provided by Theorem 3.1. A standard random graph (for example, as in Theorem 3.1) is locally very sparse; with reasonably high probability, none of the neighbors of a given node $v$ are themselves neighbors of one another. But this is far from true in most naturally occurring networks: in real network data, many of a node's neighbors are joined to each other by edges. (For example, in a social network, many of our friends know each other.) Indeed, at an implicit level, this is a large part of what makes the small-world phenomenon surprising to many people when they first hear it: the social network appears from the local perspective of any one node to be highly "clustered," rather than the kind of branching tree-like structure that would more obviously reach many nodes along very short paths.

Thus, Watts and Strogatz proposed thinking about small-world networks as a kind of superposition: a structured, high-diameter network with a relatively small number of "random" links added in. As a model for social networks, the structured underlying network represents the "typical" social links that we form with the people who live near us, or who work with us; the additional random links are the chance, long-range connections that play a large role in creating short paths through the network as a whole.

This kind of hybrid random graph model had been studied earlier by Bollobás and Chung [16]; they showed that a small density of random links can indeed produce

short paths very effectively. In particular they proved the following, among other results.

**Theorem 3.2** ([16]). *Consider a graph $G$ formed by adding a random matching to an $n$-node cycle.* (*In other words, we assume $n$ is even, pair up the nodes on the cycle uniformly at random, and add edges between each of these node pairs.*) *With high probability, every pair of nodes will be joined by a path of length $O(\log n)$.*

Here too, Bollobás and Chung in fact proved a much more detailed bound on the path lengths; see [16] for further details.

This is quite close to the setting of the Watts-Strogatz work, who also considered cycles with random matchings as a model system for analysis. For our purposes here, we will begin with the following *grid-based model*, which is qualitatively very similar. We start with a two-dimensional $n \times n$ grid graph, and then for each node $v$, we add one extra directed edge to some other node $w$ chosen uniformly at random. (We will refer to $w$ as the *long-range contact* of $v$; to distinguish this, we will refer to the other neighbors of $v$, defined by the edges of the grid, as its *local contacts*.) Following the Watts-Strogatz framework, one can interpret this model as a metaphor for a social network embedded in an underlying physical space – people tend to know their geographic neighbors, as well as having friendships that span long distances. It is also closely related to *long-range percolation models*, though the questions we consider are fairly different; we discuss these connections in Section 7. For the present discussion, though, the essential feature of this model is its superposition of structured and random links, and it is important to note that the results to follow carry over directly to a wide range of variations on the model. Indeed, a significant part of what follows will be focused on a search for the most general framework in which to formulate these results.

## 4. Decentralized search in small-world networks

Thus far we have been discussing purely structural issues; but if one thinks about it, the original Milgram experiment contains a striking algorithmic discovery as well: not only did short paths exist in the social network, but people, using knowledge only of their own acquaintances, were able to collectively construct paths to the target. This was a necessary consequence of the way Milgram formulated the task for his participants; if one really wanted the *shortest* path from a starting person to the target, one should have instructed the starter to forward a letter to *all* of his or her friends, who in turn should have forwarded the letter to all of their friends, and so forth. This "flooding" of the network would have reached the target as rapidly as possible; but for obvious reasons, such an experiment was not a feasible option. As a result, Milgram was forced to embark on the much more interesting experiment of constructing paths by "tunneling" through the network, with the letter advancing just one person at a

time – a process that could well have failed to reach the target, even if a short path existed.

This algorithmic aspect of the small-world phenomenon raises fundamental questions – why should the social network have been structured so as to make this type of decentralized routing so effective? Clearly the network contained some type of "gradient" that helped participants guide messages toward the target, and this is something that we can try to model; the goal would be to see whether decentralized routing can be proved to work in a simple random-graph model, and if so, to try extracting from this model some qualitative properties that distinguish networks in which this type of routing can succeed. It is worth noting that these issues reach far beyond the Milgram experiment or even social networks; routing with limited information is something that takes place in communication networks, in browsing behavior on the World Wide Web, in neurological networks, and in a number of other settings – so an understanding of the structural underpinnings of efficient decentralized routing is a question that spans all these domains.

To begin with, we need to be precise about what we mean by a decentralized algorithm. In the context of the grid-based model in the previous section, we will consider algorithms that seek to pass a message from a starting node $s$ to a target node $t$, by advancing the message along edges. In each step of this process, the current message-holder $v$ has knowledge of the underlying grid structure, the location of the target $t$ on the grid, and its own long-range contact. The crucial point is that it does not know the long-range contacts of any other nodes. (Optionally, we can choose to have $v$ know the path taken by the message thus far, but this will not be crucial in any of the results to follow.) Using this information, $v$ must choose one of its network neighbors $w$ to pass the message to; the process then continues from $w$. We will evaluate decentralized algorithms according to their *delivery time* – the expected number of steps required to reach the target, over a randomly generated set of long-range contacts, and randomly chosen starting and target nodes. Our goal will be to find algorithms with delivery times that are polylogarithmic in $n$.

It is interesting that while Watts and Strogatz proposed their model without the algorithmic aspect in mind, it is remarkably effective as a simple system in which to study the effectiveness of decentralized routing. Indeed, to be able to pose the question in a non-trivial way, one wants a network that is partially known to the algorithm and partially unknown – clearly in the Milgram experiment, as well as in other settings, individual nodes use knowledge not just of their own local connections, but also of certain global "reference frames" (comparable to the grid structure in our setting) in which the network is embedded. Furthermore, for the problem to be interesting, the "known" part of the network should be likely to contain no short path from the source to the target, but there should be a short path in the full network. The Watts-Strogatz model combines all these features in a minimal way, and thus allows us to consider how nodes can use what they know about the network structure to construct short paths.

Despite all this, the first result here is negative.

**Theorem 4.1** ([36], [37]). *The delivery time of any decentralized algorithm in the grid-based model is* $\Omega(n^{2/3})$.

(We say that a function is $\Omega(f(n))$ if there is a constant $c$ so that for infinitely many $n$, the function is at least $cf(n)$.)

This shows that there are simple models in which there can be an exponential separation between the lengths of paths and the delivery times of decentralized algorithms to find these paths. However, it is clearly not the end of the story; rather, it says that the random links in the Watts-Strogatz model are somehow too "unstructured" to support the kind of decentralized routing that one found in the Milgram experiment. It also raises the question of finding a simple extension of the model in which efficient decentralized routing becomes possible.

To extend the model, we introduce one additional parameter $\alpha \geq 0$ that controls the extent to which the long-range links are correlated with the geometry of the underlying grid. First, for two nodes $v$ and $w$, we define their *grid distance* $\rho(v, w)$ to be the number of edges in a shortest path between them on the grid. The idea behind the extended model is to have the long-range contacts favor nodes at smaller grid distance, where the bias is determined by $\alpha$. Specifically, we define the *grid-based model with exponent* $\alpha$ as follows. We start with a two-dimensional $n \times n$ grid graph, and then for each node $v$, we add one extra directed edge to some other long-range contact; we choose $w$ as the long-range contact for $v$ with probability proportional to $\rho(v, w)^{-\alpha}$. Note that $\alpha = 0$ corresponds to the original Watts-Strogatz model, while large values of $\alpha$ produce networks in which essentially no edges span long distances on the grid.

We now have a continuum of models that can be studied, parameterized by $\alpha$. When $\alpha$ is very small, the long-range links are "too random," and can't be used effectively by a decentralized algorithm; when $\alpha$ is large, the long-range links appear to be "not random enough," since they simply don't provide enough of the long-distance jumps that are needed to create a small world. Is there an optimal operating point for the network, where the distribution of long-range links is sufficiently balanced between these extremes to be of use to a decentralized routing algorithm?

In fact there is; as the following theorem shows, there is a unique value of $\alpha$ in the grid-based model for which a polylogarithmic delivery time is achievable.

**Theorem 4.2** ([36], [37]). (a) *For* $0 \leq \alpha < 2$*, the delivery time of any decentralized algorithm in the grid-based model is* $\Omega(n^{(2-\alpha)/3})$.

(b) *For* $\alpha = 2$*, there is a decentralized algorithm with delivery time* $O(\log^2 n)$.

(c) *For* $\alpha > 2$*, the delivery time of any decentralized algorithm in the grid-based model is* $\Omega(n^{(\alpha-2)/(\alpha-1)})$.

(We note that the lower bounds in (a) and (c) hold even if each node has an arbitrary constant number of long-range contacts, rather than just one.)

The decentralized algorithm achieving the bound in (b) is very simple: each node simply forwards the message to a neighbor – long-range or local – whose grid distance to the target is as small as possible. (In other words, each node uses its long-range

contact if this gets the message closer to the target on the grid; otherwise, it uses a local contact in the direction of the target.) The analysis of this algorithm proceeds by showing that, for a constant $\varepsilon > 0$, there is a probability of at least $\varepsilon / \log n$ in every step that the grid distance to the target will be halved. It is also worth noting that the proof can be directly adapted to a grid in any constant number of dimensions; an analogous trichotomy arises, with polylogarithmic delivery time achievable only when $\alpha$ is equal to the dimension.

At a more general level, the proof of Theorem 4.2(b) shows that the crucial property of exponent $\alpha = 2$ is the following: rather than producing long-range contacts that are uniformly distributed over the grid (as one gets from exponent $\alpha = 0$), it produces long-range contacts that are approximately uniformly distributed over "distance scales": the probability that the long-range contact of $v$ is at a grid distance between $2^{j-1}$ and $2^j$ away from $v$ is approximately the same for all values of $j$ from 1 to $\log n$.

From this property, one sees that there is a reasonable chance of halving the message's grid distance to the target, independent of how far away it currently is. The property also has an intuitively natural meaning in the context of the original Milgram experiment; subject to all the other simplifications made in the grid model, it says very roughly that decentralized routing can be effective when people have approximately the same density of acquaintances at many different levels of distance resolution. And finally, this approximate uniformity over distance scales is the type of qualitative property that we mentioned as a goal at the outset. It is something that we can search for in other models and in real network data – tasks that we undertake in the next two sections.

## 5. Decentralized search in other models

**Hierarchical models.** A natural variation on the model of the previous section is to suppose that the network is embedded in a hierarchy rather than a grid – in other words, that the nodes reside at the leaves of a complete $b$-ary tree, and the underlying "distance" between two nodes is based on the height of their lowest common ancestor in this tree.

There are a number of settings where such a model suggests itself. To begin with, follow-up work on the Milgram experiment found that most decisions made by participants on how to forward the letter were based on one of two kinds of cues: geographical and occupational [35]. And if a two-dimensional grid is natural as a simple abstraction for the role of geography, then a hierarchy is a reasonable, also simple, approximation of the way in which people categorize occupations. Another domain in which hierarchies arise naturally is in the relationships among Web pages: for example, a Web page about sequence analysis of the yeast genome could be classified as being about genetics, more generally about biology, and more generally still about science, while a Web page reviewing performances of Verdi's *Aida* could

be classified as being about opera, more generally about music, and more generally still about the arts.

A natural assumption is that the density of links is lower for node pairs that are more widely separated in the underlying hierarchy, and this forms the basis for the following *hierarchical model with exponent* $\beta$. We begin with a complete $b$-ary tree having $n$ leaves (and hence of height $h = \log_b n$). For two leaves $v$ and $w$, let us define their *tree distance* $h(v, w)$ to be the height of their lowest common ancestor in the underlying tree. We now define the following random directed graph $G$ on the set $V$ of leaves: for a value $k$ and for each node $v$ in $V$, we construct $k$ edges out of $v$, choosing $w$ as the endpoint of the $i^{\text{th}}$ edge independently with probability proportional to $b^{-\beta h(v,w)}$. (We will refer to $k$ as the *out-degree* of the model.)

Thus, $\beta$ works much like $\alpha$ did in the grid-based model; when $\beta = 0$, we get uniform random selection, while larger values of $\beta$ bias the selection more toward "nearby" nodes. Now, in this case, a decentralized search algorithm is given the locations of a starting node $s$ and a target node $t$ in the hierarchy, and it must construct a path from $s$ to $t$, knowing only the edges out of nodes that it explicitly visits. Note that in defining the performance metric for a decentralized search algorithm in this model, we face a problem that we didn't encounter in the grid-based model: the graph $G$ may not contain a path from $s$ to $t$. Thus, we say that a decentralized algorithm here has delivery time $f(n)$ if, on a randomly generated $n$-node network, and with $s$ and $t$ chosen uniformly at random, the algorithm produces a path of length $O(f(n))$ with probability at least $1 - \varepsilon(n)$, where $\varepsilon(\cdot)$ is a function going to 0 as $n$ increases.

We now have the following analogue of Theorem 4.2, establishing that there is a unique value of $\beta$ for which polylogarithmic delivery time can be achieved when the network has polylogarithmic out-degree. This is achieved at $\beta = 1$, when the probability that $v$ links to a node at tree distance $h$ is almost uniform over choices of $h$. Also by analogy with the grid-based model, it suffices to use the simple "greedy" algorithm that always seeks to reduce the tree distance to the target by as much as possible.

**Theorem 5.1** ([38]). (a) *In the hierarchical model with exponent* $\beta = 1$ *and out-degree* $k = c \log^2 n$*, for a sufficiently large constant c, there is a decentralized algorithm with polylogarithmic delivery time.*

(b) *For every* $\beta \neq 1$ *and every polylogarithmic function* $k(n)$*, there is no decentralized algorithm in the hierarchical model with exponent* $\beta$ *and out-degree* $k(n)$ *that achieves polylogarithmic delivery time.*

Watts, Dodds, and Newman [63] independently proposed a model in which each node resides in several distinct hierarchies, reflecting the notion that participants in the small-world experiment were simultaneously taking into account several different notions of "proximity" to the target. Concretely, their model constructs a random graph $G$ as follows. We begin with $q$ distinct complete $b$-ary trees, for a constant $q$, and in each of these trees, we independently choose a random one-to-one mapping of the nodes onto the leaves. We then apply a version of the hierarchical model

above, separately in each of the trees; the result is that each node of $G$ acquires edges independently through its participation in each tree. (There are a few minor differences between their procedure within each hierarchy and the hierarchical model described above; in particular, they map multiple nodes to the same leaf in each hierarchy, and they generate each edge by choosing the tail uniformly at random, and then the head according to the hierarchical model. The result is that nodes will not in general all have the same out-degree.)

Precisely characterizing the power of decentralized search in this model, at an analytical level, is an open question, but Watts et al. describe a number of interesting findings obtained through simulation [63]. They study what is perhaps the most natural search algorithm, in which the current message-holder forwards the message to its neighbor who is closest (in the sense of tree distance) to the target in any of the hierarchies. Using an empirical definition of efficiency on networks of several hundred thousand nodes, they examined the set of $(\beta, q)$ pairs for which the search algorithm was efficient; they found that this "searchable region" was centered around values of $\beta \geq 1$ (but relatively close to 1), and on small constant values of $q$. (Setting $q$ equal to 2 or 3 yielded the widest range of $\beta$ for which efficient search was possible.) The resulting claim, at a qualitative level, is that efficient search is facilitated by having a small number of different ways to measure proximity of nodes, and by having a small bias toward nearby nodes in the construction of random edges.

**Models based on set systems.** One can imagine many other ways to construct networks in this general style – for example, placing nodes on both a hierarchy and a lattice simultaneously – and so it becomes natural to consider more general frameworks in which a range of these bounds on searchability might follow simultaneously from a single result. One such approach is based on constructing a random graph from an underlying set system, following the intuition that individuals in a social network often form connections because they are both members of the same small group [38]. In other words, two people might be more likely to form a link because they live in the same town, work in the same profession, have the same religious affiliation, or follow the work of the same obscure novelist.

Concretely, we start with a set of nodes $V$, and a collection of subsets $\mathcal{S} = \{S_1, S_2, \ldots, S_m\}$ of $V$, which we will call the set of *groups*. It is hard to say much of interest for arbitrary set systems, but we would like our framework to include at least the collection of balls or subsquares in a grid, and the collection of rooted sub-trees in a hierarchy. Thus we consider set systems that satisfy some simple combinatorial properties shared by these two types of collections. Specifically, for constants $\lambda < 1$ and $\kappa > 1$, we impose the following three properties.

(i) The full set $V$ is one of the groups.

(ii) If $S_i$ is a group of size $g \geq 2$ containing a node $v$, then there is a group $S_j \subseteq S_i$ containing $v$ that is strictly smaller than $S_i$, but has size at least $\min(\lambda g, g - 1)$.

(iii) If $S_{i_1}, S_{i_2}, S_{i_3}, \ldots$ are groups that all have size at most $g$ and all contain a common node $v$, then their union has size at most $\kappa g$.

The most interesting property here is (iii), which can viewed as a type of "bounded growth" requirement; one can easily verify that it (along with (i) and (ii)) holds for the set of balls in a grid and the set of rooted sub-trees in a hierarchy.

Given a collection of groups, we construct a random graph as follows. For nodes $v$ and $w$, we define $g(v, w)$ to be the size of the smallest group containing both of them – this will serve as a notion of "distance" between $v$ and $w$. For a fixed exponent $\gamma$ and out-degree value $k$, we construct $k$ edges out of each node $v$, choosing $w$ as the endpoint of the $i^{\text{th}}$ edge from $v$ independently with probability proportional to $g(v, w)^{-\gamma}$. We will refer to this as the *group-based model* with set system $\mathcal{S}$, exponent $\gamma$, and out-degree $k$. A decentralized search algorithm in such a random graph is given knowledge of the full set system, and the identity of a target node; but it only learns the links out of a node $v$ when it reaches $v$. We now have the following theorem.

**Theorem 5.2** ([38]). (a) *Given an arbitrary set system $\mathcal{S}$ satisfying properties* (i), (ii), *and* (iii), *there is a decentralized algorithm with polylogarithmic delivery time in the group-based model with set system $\mathcal{S}$, exponent $\gamma = 1$, and out-degree $k = c \log^2 n$, for a sufficiently large constant $c$.*

(b) *For every set system $\mathcal{S}$ satisfying properties* (i), (ii), *and* (iii), *every $\gamma < 1$, and every polylogarithmic function $k(n)$, there is no decentralized algorithm achieving polylogarithmic delivery time in the group-based model with set system $\mathcal{S}$, exponent $\gamma$ and out-degree $k(n)$.*

In other words, efficient decentralized search is possible when nodes link to each other with probability inversely proportional to the size of the smallest group containing both of them. As a simple concrete example, if the groups are the balls in a two-dimensional grid, then the size of the smallest group containing two nodes at distance $\rho$ is proportional to $\rho^2$, and so the link probability indicated by Theorem 5.2 (a) is proportional to $\rho^{-2}$; this yields an analogue of Theorem 4.2 (b), the inverse-square result for grids. (The present setting is not exactly the same as the one there; here, we do not automatically include the edges of the original grid when constructing the graph, but we construct a larger number of edges out of each node.)

Simple examples show that one cannot directly formulate a general negative result in this model for the case of exponents $\gamma > 1$ [38]. At a higher level, the group-based model is clearly not the only way to generalize the results thus far; in the next section we will discuss one other recent approach, and the development of other general models is a natural direction for further research.

## 6. Design principles and network data

In addition to their formulation as basic questions about search algorithms in graphs, the models we have been discussing thus far have been used as design principles in

file-sharing systems; and they have been found to capture some of the large-scale structure of human social networks as reflected in on-line data.

**Peer-to-peer systems and focused web crawling.** A recurring theme in recent work on complex networks is the way in which simple probabilistic models can rapidly become design principles for new types of networked systems. In the case of small-world networks, one observes this phenomenon in the development of protocols for peer-to-peer file sharing. The design of such protocols has become an active topic of research in the area of computer systems, motivated in part by the explosion of popular interest in peer-to-peer applications following the emergence of Napster and music file-sharing in 1999. The goal of such applications was to allow a large collection of users to share the content residing on their personal computers, and in their initial conception, the systems supporting these applications were based on a centralized index that simply stored, in a single place, the files that all users possessed. This way, queries for a particular piece of content could be checked against this index, and routed to the computer containing the appropriate file.

The music-sharing application of these systems, of course, ran into significant legal difficulties; but independent of the economic and intellectual property issues raised by this particular application, it is clear that systems allowing large user communities to share content have a much broader range of potential, less controversial uses, provided they can be structured in a robust and efficient way. This has stimulated much subsequent study in the research community, focusing on *decentralized* approaches in which one seeks file-sharing solutions that do not rely on a single centralized index of all the content.

In this decentralized version of the problem, the crux of the challenge is clear: each user has certain files on his or her own computer, but there is no single place that contains a global list of all these files; if someone poses a query looking for a specific piece of content, how can we efficiently determine which user (if any) possesses a copy of it? Without a central index, we are in a setting very much like that of the Milgram experiment: users must pose the query to a subset of their immediate network neighbors, who in turn can forward the query to some of their neighbors, and so forth. And this is where small-world models have played a role: a number of approaches to this problem have tried to explicitly set up the network on which the protocol operates so that its structure makes efficient decentralized search possible. We refer the reader to the surveys by Aspnes and Shah [6] and Lua et al. [44] for general reviews of this body of work, and the work of Clarke et al. (as described in [32]), Zhang et al. [67], Malkhi et al. [45], and Manku et al. [46] for more specific discussions of the relationship to small-world networks.

A related set of issues comes up in the design of *focused Web crawlers*. Whereas standard Web search engines first compile an enormous index of Web pages, and then answer queries by referring to this index, a focused crawler attempts to locate pages on a specific topic by following hyperlinks from one page to another, without first compiling an index. Again, the underlying issue here is the design of decentralized

search algorithms, in this case for the setting of the Web: when searching for relevant pages without global knowledge of the network, what are the most effective rules for deciding which links to follow? Motivated by these issues, Menczer [49] studied the extent to which the hierarchical model described in the previous section captures the patterns of linkage in large-scale Web data, using the hierarchical organization of topics provided by the Open Directory.

**Social network data.** The previous two applications – peer-to-peer systems and focused Web crawling – are both concerned with the structure of computer and information networks, although in both cases there are obvious social forces underlying their construction. Recent work has also investigated the extent to which the models described in the previous sections are actually reflected in data on human social networks. In other words, these small-world models make very concrete claims about the ways in which networks should be organized to support efficient search, but it is not *a priori* clear whether or not naturally occurring networks are organized in such ways. Two recent studies of this flavor have both focused on social networks that exist in on-line environments – as with the previous applications, we again see an intertwining of social and technological networks, but in these cases the emphasis is on the social component, with the on-line aspect mainly providing an opportune means of performing fine-grained analysis on a large scale.

In one study of this flavor, Adamic and Adar [1] considered the e-mail network of a corporate research lab: they collected data over a period of time, and defined an edge between any two people who exchanged at least a certain number of messages during this period. They overlaid the resulting network on a set system representing the organizational structure, with a set for each subgroup of the lab's organizational hierarchy. Among other findings, they showed that the probability of a link between individuals $v$ and $w$ scaled approximately proportional to $g(v, w)^{-3/4}$, compared with the value $g(v, w)^{-1}$ for efficient search from Theorem 5.2(a). (As above, $g(v, w)$ denotes the size of the smallest group containing both $v$ and $w$.) Thus, interactions in their data spanned large groups at a slightly higher frequency than the optimum for decentralized search. Of course, the e-mail network was not explicitly designed to support decentralized search, although one can speculate about whether there were implicit factors shaping the network into a structure that was easy to search; in any case, it is interesting that the behavior of the links with respect to the collection of groups is approximately aligned with the form predicted by the earlier theorems.

An even closer correlation with the structure predicted for efficient search was found in a large-scale study by Liben-Nowell et al. [43]. They considered LiveJournal, a highly active on-line community with several million participants, in which members communicate with one another, update personal on-line diaries, and post messages to community discussions. LiveJournal is a particularly appealing domain for studying the geographic distribution of links, because members provide explicit links to their friends in the system, and a large subset (roughly half a million at the time of the study in [43]) also provide a hometown in the continental U.S. As a result, one has

the opportunity to investigate, over a very large population, how the density of social network links decays with distance.

A non-trivial technical challenge that must be overcome in order to relate this data to the earlier models is that the population density of the U.S. is extremely non-uniform, and this makes it difficult to interpret predictions based on a model in which nodes are distributed uniformly over a grid. The generalization to group structures in the previous section is one way to handle non-uniformity; Liben-Nowell et al. propose an alternative generalization, *rank-based friendships*, that they argue may be more suitable to the geographic data here [43]. In the rank-based friendship model, one has a set of $n$ people assigned to locations on a two-dimensional grid, where each grid node may have an arbitrary positive number of people assigned to it. By analogy with the grid-based model from Section 4, each person $v$ chooses a *local contact* arbitrarily in each of the four neighboring grid nodes, and then chooses an additional *long-range contact* as follows. First, $v$ ranks all other people in order of their distance to herself (breaking ties in some canonical way); we let $\text{rank}_v(w)$ denote the position of $w$ in $v$'s ordered list, and say that $w$ is at *rank* $r$ with respect to $v$. $v$ then chooses $w$ as her long-range contact with probability proportional to $1/\text{rank}_v(w)$.

Note that this model generalizes the grid-based model of Section 4, in the sense that the grid-based model with the inverse-square distribution corresponds to rank-based friendship in which there is one person resident at each grid node. However, the rank-based friendship construction is well-defined for any population density, and Liben-Nowell et al. prove that it supports efficient decentralized search in general. They analyze a decentralized greedy algorithm that always forwards the message to a grid node as close as possible to the target's; and they define the *delivery time* in this case to be the expected number of steps needed to reach the grid node containing the target. (So we can imagine that the task here is to route the message to the hometown of the target, rather than the target himself; this is also consistent with the data available from LiveJournal, which only localizes people to the level of towns.)

**Theorem 6.1** ([43]). *For an arbitrary population density on a grid, the expected delivery time of the decentralized greedy algorithm in the rank-based friendship model is* $O(\log^3 n)$.

On the LiveJournal data, Liben-Nowell et al. examine the fraction of friendships $(v, w)$ where $w$ is at rank $r$ with respect to $v$. They find that this fraction is very close to inverse linear in $r$, in close alignment with the predictions of the rank-based friendship model.

This finding is notable for several reasons. First, as with the e-mail network considered by Adamic and Adar, there is no *a priori* reason to believe that a large, apparently amorphous social network should correspond so closely to a distribution predicted by a simple model for efficient decentralized search. Second, geography is playing a strong role here despite the fact that LiveJournal is an on-line system in which there are no explicit limitations on forming links with people arbitrarily far away; as a result, one might have (incorrectly) conjectured that it would be difficult

to detect the traces of geographic proximity in such data. And more generally, the analytical results of this section and the previous ones have been based on highly stylized models that nonetheless make very specific predictions about the theoretical "optimum" for search; to see these concrete predictions approximately borne out on real social network data is striking, and it suggests that there may be deeper phenomena yet to be discovered here.

## 7. Further results on small-world networks and decentralized search

**Long-range percolation.** The grid-based models we have been considering are closely related to the problem of *long-range percolation*. In the basic version of long-range percolation, one takes the infinite $d$-dimensional integer lattice $\mathbb{Z}^d$, and for each pair of nodes $(v, w)$ one includes an undirected edge between them independently with probability $\rho(v, w)^{-\alpha}$, where $\rho(v, w)$ is the grid distance between $v$ and $w$ and $\alpha \geq 0$ is a parameter of the model. Note that there are some small differences from the grid-based model described in Section 4: the graph is infinite, it is undirected, its nodes do not all have the same degree, and it does not automatically include edges between nearest neighbors on the lattice. In addition to these, a broader difference is in the nature of the questions investigated, with the initial work on long-range percolation focusing on the range of parameters for which an infinite connected component is likely to exist [3], [51], [57].

Motivated in part by the interest in small-world networks, work on long-range percolation began to investigate diameter issues – the maximum $D$ for which every node is connected by a path of at most $D$ steps. Benjamini and Berger [11] studied this problem in one dimension, modifying the model so that the graph is finite (restricted to the integers $\{1, 2, \ldots, n\}$), and so that edges are guaranteed to exist between adjacent integers. (They also studied the case in which the distance $\rho(\cdot, \cdot)$ is defined by assuming that the integers are "wrapped" into a cycle, so that $\rho(i, j)$ is not $|j - i|$ but $\min(|j - i|, n - |j - i|)$.) Their work was followed by results of Coppersmith et al. [20] and Biskup [13], who obtained sharper bounds in some cases and considered higher-dimensional lattices as well, in which the node set is $\{1, 2, \ldots, n\}^d$. As a result of this work, we know that the diameter of the graph changes qualitatively at the "critical values" $\alpha = d$ and $\alpha = 2d$. In particular, with high probability, the diameter is constant when $\alpha < d$ (due in essence to a result of [12]), is proportional to $\log n / \log \log n$ when $\alpha = d$ [20], is polylogarithmic in $n$ when $d < \alpha < 2d$ (with an essentially tight bound provided in [13]), and is lower-bounded by a polynomial in $n$ when $\alpha > 2d$ [11], [20]. The case $\alpha = 2d$ is largely open, and conjectured to have diameter polynomial in $n$ with high probability [11], [13]. It is also open whether the diameter for $\alpha > 2d$ is in fact linear in $n$; this has been proved for the one-dimensional case [11] and conjectured to hold for higher dimensions as well [11], [13], [20].

This pair of transitions at $\alpha = d$ and $\alpha = 2d$ was observed in a somewhat different setting by Kempe et al. [34], resolving a conjecture of Demers et al. [21] on the behavior of *gossip algorithms*. In this model, there are nodes located on the finite

$d$-dimensional lattice $\{1, 2, \ldots, n\}^d$, and in each time step each node $v$ picks a single other node and tells everything it currently knows to $w$; node $w$ is selected as the recipient of this information with probability proportional to $\rho(v, w)^{-\alpha}$. Information originating at one node thus spreads to other nodes, relayed in an epidemic fashion over time. Now, if a single node $v$ initially possesses a new piece of information at time 0, how long will it take before knowledge of this information has spread to a given node $w$? The main result of [34] is that the time required for this is polylogarithmic in $n$ for $\alpha \leq d$, is polylogarithmic in $\rho(v, w)$ but independent of $n$ for $d < \alpha < 2d$, and is polynomial in $\rho(v, w)$ for $\alpha > 2d$. Here too the case $\alpha = 2d$ is not well understood, which is interesting because this transitional value has particular importance in applications of gossip algorithms to distributed computing systems [54]. (See [34] for partial results concerning $\alpha = 2d$.)

For the specific grid-based model described in Section 4, Martel and Nguyen showed that with high probability the diameter is proportional to $\log n$ for $\alpha \leq d$, in the $d$-dimensional case [48]. They also identified transitions at $\alpha = d$ and $\alpha = 2d$ analogous to the case of long-range percolation [53]. In particular, their results show that while decentralized search can construct a path of length $O(\log^2 n)$ when $\alpha = d$, there in fact exist paths that are shorter by a logarithmic factor. (Note also the contrast with the corresponding results for the long-range percolation model when $\alpha \leq d$; in the grid-based model, the out-degree of each node is bounded by a constant, so a diameter proportional to $\log n$ is the smallest one could hope for; in the case of long-range percolation, on the other hand, the node degrees will be unbounded, allowing for smaller diameters.)

**Decentralized search with additional information.** A number of papers have studied the power of decentralized search algorithms that are provided with small amounts of additional information [28], [42], [47], [48], [66]. Whereas the model of decentralized algorithms in Section 4 charged unit cost to the algorithm for each node visited, the models in these subsequent papers make the following distinction: a node may "consult" a small number of nearby nodes, and then based on what it learns from this consultation, it chooses a node to forward the messages to. In bounding the number of steps taken by the algorithm, only the message-forwarding operations are counted, not the consultation.

In particular, Lebhar and Schabanel [42] consider an algorithm in which the node currently holding the message consults a set $S$ of up to $O(\log n)$ nodes within a small number of steps of it; after this, it forwards the message along a path to the node $w$ in $S$ that is closest to the target in grid distance. They show that, in total, the expected number of nodes consulted by this process is $O(\log^2 n)$ (as in the decentralized algorithm from Section 4), and that the actual path constructed to the target has only $O(\log n(\log\log n)^2)$ steps.

Manku, Naor, and Wieder [47] consider a simpler algorithm in the long-range percolation model on the $d$-dimensional lattice $\{1, 2, \ldots, n\}^d$ with $\alpha = d$. Note that nodes here will have unbounded degrees – proportional to $\log n$ in expectation, rather

than constant as in the grid-based model. Manku et al. analyze a *neighbor-of-neighbor* search algorithm in which the current message-holder $v$ consults each of its neighbors to learn the set $S$ of all of *their* neighbors; $v$ then forwards the message along the two-step path to the node in $S$ that lies closest to the target. They show that with high probability, this algorithm produces a path to the target of at most $O(\log n / \log\log n)$ steps, matching the bound of Coppersmith et al. [20] on the diameter of this network. Moreover, they show that the basic greedy algorithm, which simply forwards the message to the neighbor closest to the target, requires an expected number of steps proportional to $\log n$ to reach the target. Thus, one step of lookahead provides an asymptotic improvement in delivery time; and since one step of lookahead yields path lengths matching the diameter, additional lookahead does not offer any further asymptotic improvements.

Thus, the results of Manku et al. provide a rather sharp characterization of the power of lookahead in the long-range percolation model at the exponent $\alpha = d$ that allows for efficient decentralized search; determining a similarly precise delineation on the power of lookahead in the grid-based model (extending the aforementioned results of Lebhar and Schabanel) is an interesting open question.

**Small-world networks built on arbitrary underlying graphs.** The results in Section 5 describe various methods for constructing searchable networks based on underlying structures other than $d$-dimensional grids. In several recent papers, a number of further structures have been proposed as "scaffolds" for small-world networks [9], [27], [31], [53], [59].

In principle, one can consider adding long-range edges to any underlying graph $G$; Fraigniaud [27] asks whether any $G$ can be converted through such a process into a network that is efficiently searchable by a greedy algorithm. Specifically, suppose we choose a distribution over long-range contacts for each node of $G$, and we use this to generate a random graph $G'$ by adding a single long-range edge out of each node of $G$. We then consider the natural greedy algorithm for forwarding the message to a target $t$: the current message-holder passes the message to a neighbor that has the shortest path to the target as measured in $G$ (not in $G'$). Is it the case that for every graph $G$, there is a distribution over long-range contacts such that this algorithm has a delivery time that is polylogarithmic in $n$?

This question is open in general; note that the challenge in resolving it comes from the fact that a single choice of distribution per node must work (in expectation) over any possible destination, and that even if the graph $G'$ has nicely-structured short paths, the search algorithm is constrained to behave "greedily" in the original graph $G$. Fraigniaud answers the question in the affirmative for graphs of bounded tree-width as well as graphs in which there is no induced cycle of greater than a fixed length [27]; he also discusses some respects in which such underlying graphs are qualitatively consistent with observed properties of social networks. Duchon et al. answer the question in the affirmative for graphs satisfying a certain "bounded growth rate" property [24].

Slivkins [59] considers a different setting, in which nodes are embedded in an underlying metric space. He shows that if the metric is *doubling*, in the sense that every ball can be covered by a constant number of balls of half the radius (see e.g. [7], [30]), then there is a model such that each node generates a polylogarithmic number of long-range contacts from specified distributions, and a decentralized algorithm is then able to achieve a polylogarithmic delivery time. (Some of the logarithmic dependence here is on the *aspect ratio* of the metric – the ratio of the largest to the smallest distance – but it is possible to avoid this dependence in the bound on the delivery time. See [59] for further details on this issue.)

Finally, other work has studied search algorithms that exploit differences in node degrees. There are indications that people navigating social structures, in settings such as small-world experiments, take into account the fact that certain of their acquaintances simply know a large number of people [22]. Similarly, in peer-to-peer networks, it is also the case that certain nodes have an unusually large number of neighbors, and may thus be more useful in helping to forward queries. Adamic et al. [2] formalize these considerations by studying a random graph model in which high-degree nodes are relatively abundant, and decentralized search algorithms only have access to information about degrees of neighboring nodes, not to any embedding of the graph (spatial or otherwise). Through simulation, they find that for certain models, knowledge of degrees provides an improvement in search performance.

Simsek and Jensen [58] consider a model which combines spatial embedding with variable node degrees. Specifically, they study a variant of the grid-based model from Section 4 in which nodes have widely varying degrees, and a decentralized algorithm has access both to the locations of its neighbors and to their degrees. Through simulation, they find that a heuristic taking both these factors into account can perform more efficiently than decentralized algorithms using only one of these sources of information. Finding the optimal way to combine location and degree information in decentralized search, and understanding the range of networks that are searchable under such optimal strategies, is an interesting direction for further research.

## 8. Conclusion

We have followed a particular strand of research running through the topic of complex networks, concerned with short paths and the ability of decentralized algorithms to find them. As suggested initially, the sequence of ideas here is characteristic of the flavor of research in this area: an experiment in the social sciences that highlights a fundamental and non-obvious property of networks (efficient searchability, in this case); a sequence of random graph models and accompanying analysis that seeks to capture this notion in a simple and stylized form; a set of measurements on large-scale network data that parallels the properties of the models, in some cases to a surprising extent; and a range of connections to further results and questions in algorithms, graph theory, and discrete probability.

To indicate some of the further directions in which research on this topic could proceed, we conclude with a list of open questions and issues related to small-world networks and decentralized search. Some of these questions have already come up implicitly in the discussion thus far, so one goal of this list is to collect a number of these questions in a single place. Other questions here, however, bring in issues that reach beyond the context of the earlier sections. And as with any list of open questions, we must mention a few caveats: the questions here take different forms, since some are concretely specified while other are more designed to suggest problems in need of a precise formulation; the questions are not independent, in that the answer to one might well suggest ways of approaching others; and several of the questions may well become more interesting if the underlying model or formulation is slightly varied or tweaked.

**1. Variation in node degrees.** As we discussed at the end of the previous section, decentralized search in models that combine wide variation in node degrees with some kind of spatial embedding is an interesting issue that is not well understood. Simsek and Jensen's study [58] of this issue left open the question of proving bounds on the efficiency of decentralized algorithms. For example, consider the $d$-dimensional grid-based model with exponent $\alpha$, and suppose that rather than constructing a fixed number of long-range contacts for each node, we draw the number of long-range contacts for each node $v$ independently from a given probability distribution. To be concrete, we could consider a distribution in which one selects $k$ long-range contacts with probability proportional to $k^{-\delta}$ for a constant $\delta$.

We now have a family of grid-based models parameterized by $\alpha$ and $\delta$, and we can study the performance of decentralized search algorithms that know not only the long-range contacts out of the current node, but also the degrees of the neighboring nodes. Decentralized selection of a neighbor for forwarding the message has a stochastic optimization aspect here, balancing the goal of forwarding to a node close to the target with the goal of forwarding to a high-degree node. We can now ask the general question of how the delivery time of decentralized algorithms varies in both $\alpha$ and $\delta$. Note that it is quite possible this question becomes more interesting if we vary the model so that long-range links are undirected; this way, a node with a large degree is both easy to find and also very useful once it is found. (In a directed version, a node with large out-degree may be relatively useless simply because it has low in-degree and so is unlikely to be found.)

**2. The case of $\alpha = 2d$.** In both the grid-based model and the related long-range percolation models, very little is known about the diameter of the graph when $\alpha$ is equal to twice the dimension. (It appears that a similar question arises in other versions of the group-based models from Section 5, when nodes form links with probability inversely proportional to the square of the size of the smallest group containing both of them.) Resolving the behavior of the diameter would shed light on this transitional point, which lies at the juncture between "small worlds" and "large worlds." This open

question also manifests itself in the gossip problem discussed in Section 7, where we noted that the transitional value $\alpha = 2d$ arises in distributed computing applications (see the discussion in [34], [54]).

**3. Paths of logarithmic length.** It would be interesting to know whether there is a decentralized algorithm in the $d$-dimensional grid-based model, at the "searchable exponent" $\alpha = d$, that could construct paths of length $O(\log n)$ while visiting only a polylogarithmic number of nodes. This would improve the result of Lebhar and Schabanel [42] to an asymptotically tight bound on path length.

**4. Small-world networks with an arbitrary base graph.** It would also be interesting to resolve the open problem of Fraigniaud [27] described in Section 7, formalizing the question of whether any graph can be turned into an efficiently searchable small world by appropriately adding long-range links[1].

**5. Extending the group-based model.** Theorem 5.2 on the group-based model contained a positive result generalizing the ones for grids and hierarchies, and it contained a general negative result for the case when long-range connection were "too long-range" (i.e. with exponent $\gamma < 1$). However, it does not fully generalize the results for grids and hierarchies, because there are set systems satisfying conditions (i), (ii), and (iii) of the theorem for which efficient decentralized search is possible even for exponents $\gamma > 1$. It would be interesting to find a variation on these three properties that still generalizes grids and hierarchies in a natural way, and for which $\gamma = 1$ is the unique exponent at which efficient decentralized search is possible.

**6. Multiple hierarchies.** Obtaining provable bounds for decentralized search in the "multiple hierarchies" model of Watts, Dodds, and Newman [63] is also an open question. Such results could form an interesting parallel with the findings they discovered through simulation. With some small modifications to the model of Watts et al., one can cast it in the group-based model of Section 5, and so it is entirely possible that progress on this question and the previous could be closely connected.

**7. The evolution of searchable networks.** The remaining questions have a more general flavor, where much of the challenge is the formalization of the underlying issue. To begin with, the current models supporting efficient decentralized search are essentially *static*, in that they describe how the underlying network is organized without suggesting how it might have evolved into this state. What kinds of growth processes or selective pressures might exist to cause networks to become more efficiently searchable? Interesting network evolution models addressing this question have been proposed by Clauset and Moore [19] and by Sandberg [56], both based on feedback mechanisms by which nodes repeatedly perform decentralized searches and

[1] Note added in proof: Fraigniaud, Lebhar, and Lotker have very recently announced a negative resolution of this question, constructing a family of graphs that cannot be turned into efficiently searchable small worlds by this process.

in the process partially "rewire" the network. Obtaining provable guarantees for these models, or variations on them, is an open question. A number of peer-to-peer file-sharing systems include similar feedback mechanisms, achieving good performance in practice. Freenet [18] is a good example of such a system, and the relationship of its feedback mechanism to the evolution of small-world networks is studied by Zhang et al. [67].

Game theory may provide another promising set of techniques for studying the evolution of small-world networks. A growing body of recent work has considered game-theoretic models of network formation, in which agents controlling nodes and edges interact strategically to construct a graph – the basic question is to understand what types of structures emerge when each agent is motivated by self-interest. For surveys of this area, see [5], [33], [65]. In the present case, it would be interesting to understand whether there are ways to define incentives such that the collective outcome of self-interested behavior would be a searchable small-world network.

**8. Decentralized search in the presence of incentives.** Game-theoretic notions can provide insight not just into the growth of a network, but also into the processes that operate on it. A topic of interest in peer-to-peer systems, as well as in the design of on-line communities, is the way in which the incentives offered to the members of the system influence the extent to which they are willing to forward queries and information. In the case of decentralized search, suppose that there is some utility associated with routing the message from the starting node to the target, and intermediate nodes behave strategically, demanding compensation for their participation in the construction of the path. How do results on decentralized path formation change when such behavior is incorporated into the model?

In [40], this question is made precise in a setting where the underlying network is a random tree, constructed via a branching process. It would be interesting to consider analogous issues in richer classes of networks.

**9. Reconstruction.** The networks we have considered here have all been embedded in some underlying "reference frame" – grids, hierarchies, or set systems – and most of our analysis has been predicated on a model in which the network is presented together with this embedding. This makes sense in many contexts; recall, for example, the discussion from Section 6 of network data explicitly embedded in Web topic directories [49], corporate hierarchies [1], or the geography of the U.S. [43]. In some cases, however, we may be presented with just the network itself, and the goal is to determine whether it has a natural embedding into a spatial or hierarchical structure, and to recover this embedding if it exists. For example, we may have data on communication within an organization, and the goal is to reconstruct the hierarchical structure under the assumption that the frequency of communication decreases according to a hierarchical model – or to reconstruct the positions of the nodes under the assumption that the frequency of communication decreases with distance according to a grid-based or rank-based model.

One can formulate many specific questions of this flavor. For example, given a network known to be generated by the grid-based model with a given exponent $\alpha$, can we approximately reconstruct the positions of the nodes on the grid? What if we are not told the exponent? Can we determine whether a given network was more likely to have been generated from a grid-based model with exponent $\alpha$ or $\alpha'$? Or what if there are multiple long-range contacts per node, and we are only shown the long-range edges, not the local edges? A parallel set of questions can be asked for the hierarchical model.

Questions of this type have been considered by Sandberg [55], who reports on the results of computational experiments but leaves open the problem of obtaining provable guarantees. Benjamini and Berger [11] pose related questions, including the problem of reconstructing the dimension $d$ of the underlying lattice when presented with a graph generated by long-range percolation on a finite piece of $\mathbb{Z}^d$.

**10. Comparing network datasets.** As we saw earlier, the models proposed in Sections 4 and 5 suggest a general perspective from which to analyze network datasets, by studying the way in which the density of links decays with increasing distance or increasing group size (e.g. [1], [43]). One could naturally use this style of analysis to compare related network datasets – for example taking the patterns of communication within $k$ different organizations (as Adamic and Adar did for the corporate lab they studied), and determining exponents $\gamma_1, \gamma_2, \ldots, \gamma_k$ for each such that the probability of a link between individuals $v$ and $w$ in a group of size $g$ scales approximately as $g^{-\gamma_i}$ in the $i^{\text{th}}$ organization. Differences among these exponents would suggest structural differences between the organizations at a global level – communication in some is more long-range, while in others it is more clustered at the low levels of the hierarchy. It would be interesting to understand whether these differences in turn were naturally reflected in other aspects of the organizations' behavior and performance.

More generally, large-scale social, technological, and information networks are sufficiently complex objects that the guiding principles provided by simple models seem crucial for our understanding of them. The perspective suggested here has offered one such collection of principles, highlighting in particular the ways in which these networks are intertwined with the spatial and organizational structures that they inhabit. One can hope that as we gather an increasing range of different perspectives, our understanding of complex networks will continue to deepen into a rich and informative theory.

# On expander graphs and connectivity in small space

Omer Reingold*

**Abstract.** This presentation is aimed to communicate a recently found deterministic algorithm for determining connectivity in undirected graphs [40]. This algorithm uses the minimal amount of memory possible, up to a constant factor. Specifically, the algorithm's memory is comparable to that needed to store the name of a *single* vertex of the graph (i.e., it is logarithmic in the size of the graph).

Our algorithm also implies a deterministic, short (i.e. of polynomial length), universal sequence of steps which explores all the edges of every regular undirected graph. Such a sequence will get one out of every maze, and through the streets of every city. More formally we give universal exploration sequences for arbitrary graphs and universal traversal sequences for graphs with some natural restriction on their labelling. Both sequences are constructible with logarithmic memory and are thus only polynomially long.

To obtain this algorithm, we give a method to transform (using small memory), an arbitrary connected undirected graph into an expander graph (which is a sparse but highly connected graph).

**Keywords.** Graph connectivity, expander graphs, randomness in computation, symmetric logspace (SL), pseudorandomness.

## 1. Introduction

An undirected graph is a pair of finite sets $G = (V, E)$ where $V$ is the set of *vertices* and $E$ is the set of *edges*. An edge is simply a pair of vertices (we say that the edge is adjacent to these two vertices and the two vertices are adjacent to it). Special cases of graphs that may be useful to visualize are mazes and road maps where a vertex corresponds to an intersection and an edge directly connects the two vertices adjacent to it.[1] Given as input an undirected graph $G$ and two vertices $s$ and $t$, the undirected st-connectivity (denoted USTCON) problem is to decide whether or not the two vertices are connected by a path (i.e. a sequence of edges) in $G$ . This fundamental combinatorial problem has received a lot of attention in the last few decades and was studied in a large variety of computational models. It is a basic building block for more complex graph algorithms and is complete[2] for an interesting class

[1] In a directed graph an edge is an ordered pair of vertices and we can therefore think of an edge as a unidirectional road going from the first vertex to the second vertex.

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

of computational problems known as SL (these are problems solvable by symmetric, non-deterministic, log-space computations [25]). A few interesting examples of problems in SL are deciding if a graph is bipartite (equivalently if it is 2-colorable), if a bounded degree graph is planar and identifying chordal graphs, interval graphs, split graphs and permutation graphs (see [8] for a recent study of SL and quite a few of its complete problems).

The time complexity of USTCON is well understood as basic search algorithms, particularly breadth-first search (BFS) and depth-first search (DFS), are capable of solving USTCON in linear time. In fact, these algorithms apply to the more complex problem of st-connectivity in directed graphs, denoted STCON (which is complete for the class NL of non-deterministic log-space computations). Unfortunately, the space required to run these algorithms is linear as well. In a recent paper [40] we resolve the space (memory) complexity of USTCON, up to a constant factor, by presenting a log-space (polynomial-time) algorithm for solving it (our algorithm also solves the corresponding search problem, of finding a path from $s$ to $t$ if such a path exists). In this presentation (which is in large part borrowed from [40]) we will discuss this algorithm. We will also discuss the connection of this question to the possible tradeoff between two resources of computation: randomness and memory. Finally, we will discuss explicit (and space efficient) constructions of fascinating combinatorial objects known as universal traversal and universal exploration sequences. Loosely, these are short sequences of simple directions that lead a walk through all of the edges of any graph of an appropriate size. Our main technical tool is borrowed from a combinatorial construction of expander graphs due to Reingold, Vadhan and Wigderson [43]. We will further elaborate on the connection to expander graphs.

**Background.** Given the inefficiency in terms of memory of BFS and DFS, Savitch's [47] introduced an algorithm which solves STCON in space $\log^2(\cdot)$ (and super-polynomial time). Major progress in understanding the space complexity of USTCON was made by Aleliunas, Karp, Lipton, Lovász, and Rackoff [2], who gave a *randomized* log-space algorithm for the problem. Specifically, they showed that a random walk (a path that selects a uniform edge at each step) starting from an arbitrary vertex of any connected undirected graph will visit all the vertices of the graph in polynomial number of steps. Therefore, the algorithm can perform a random walk starting from $s$ and verify that it reaches $t$ within the specified polynomial number of steps. Essentially all that the algorithm needs to remember is the name of the current vertex and a counter for the number of steps already taken. With this result we get the following view of space complexity classes: $\mathrm{L} \subseteq \mathrm{SL} \subseteq \mathrm{RL} \subseteq \mathrm{NL} \subseteq \mathrm{L}^2$ (where RL is the class of problems that can be decided by randomized log-space algorithms with one-sided error and $\mathrm{L}^c$ is the class of problems that can be decided deterministically in space $\log^c(\cdot)$).

[2] A complete problem for a class is such that any other problem "efficiently reduces" to it. Therefore, an algorithm for this problem implies an algorithm (which is almost as efficient) for any other problem in the class.

The existence of a randomized log-space algorithm for USTCON puts this problem in the context of derandomization. Can this randomized algorithm be derandomized without substantial increase in space? Furthermore, the study of the space complexity of USTCON has gained additional motivation as an important test case for understanding the tradeoff between two central resources of computations, namely between memory space and randomness. Particularly, a natural goal on the way to proving RL = L is to prove that USTCON $\in$ L, as USTCON is undoubtedly one of the most interesting problems in RL.

Following [2], most of the progress on the space complexity of USTCON indeed relied on the tools of derandomization. In particular, this line of work greatly benefited from the development of pseudorandom generators that fool space-bounded algorithms [1], [10], [33], [19] and it progressed concurrently with the study of the L vs. RL problem. Another very influential notion, introduced by Stephen Cook in the late 70s, is that of a universal-traversal sequence. Loosely, this is a fixed sequence of directions that guides a *deterministic* walk through all of the vertices of any connected graph of the appropriate size (see further discussion below).

While Nisan's space-bounded generator [33], did not directly imply a more space efficient USTCON algorithm it did imply quasi-polynomially-long, universal-traversal sequences, constructible in space $\log^2(\cdot)$. These were extremely instrumental in the work of Nisan, Szemeredi and Wigderson [34] who showed that USTCON $\in \mathrm{L}^{3/2}$ – The first improvement over Savitch's algorithm in terms of space (limited of course to the case of undirected graphs). Using different methods, but still heavily relying on [33], Saks and Zhou [46] showed that *every* RL *problem* is also in $\mathrm{L}^{3/2}$ (their result in fact generalizes to randomized algorithms with two-sided error). Relying on the techniques of both [34] and [46], Armoni, et. al. [9] showed that USTCON $\in \mathrm{L}^{4/3}$. Their USTCON algorithm was the most space-efficient one previous to this work. We note that the most space-efficient *polynomial-time* algorithm for USTCON previously known was Nisan's [32], which still required space $\log^2(\cdot)$. Independent of our work (and using different techniques), Trifonov [49] has presented an $O(\log n \log\log n)$-space, deterministic algorithm for USTCON.

**Our approach.** The essence of our algorithm is in the following very natural approach: If you want to solve a connectivity problem on your input graph, first *improve its connectivity*. In other words, transform your input graph (or rather, each one of its connected components), into an expander.[3] We will also insist on the final graph being constant degree (i.e., every vertex is adjacent to a constant number of edges). Once the connected component of $s$ is a constant-degree expander, then it is trivial to decide if $s$ and $t$ are connected: Since expander graphs have logarithmic diameter,

[3]The exact definition of expander graphs is less important for now, and the following description could be understood by viewing expanders as graphs with very strong connectivity properties. Still, for the knowledgable reader, the particular measure that seems the most convenient to work with is the second eigenvalue (in absolute value) of the adjacency matrix of the graph (we will only need to work with regular graphs). It may however be that other, more combinatorial, measures will also do (see [41] for a more detailed discussion).

it is enough to enumerate all logarithmically long paths starting with $s$ and to see if one of these paths visits $t$. Since the degree is constant, the number of such paths is polynomial and they can easily be enumerated in log space.

How can we turn an arbitrary graph into an expander? First, we note that every connected, non-bipartite, graph can be thought of as an expander with very small (but non-negligible) expansion. Consider for example an arbitrary connected graph with self-loops added to each one of its vertices. The number of neighbors of every strict subset of the vertices is larger than its size by at least one. In this respect, the graph can be thought of as expanding by a factor $1 + 1/N$ (where $N$ is the total number of vertices in the graph). Now, a very natural operation that improves the expansion of the graph is powering. The $k^{\text{th}}$ power of $G$ contains an edge between two vertices $v$ and $w$ for every path of length $k$ in $G$. Formally, it can be shown that by taking some polynomial power of any connected non-bipartite graph (equivalently, by repeatedly squaring the graph logarithmic number of times), it will indeed turn into an expander.

The down side of powering is of course that it increases the degree of the graph. Taking a polynomial or any non-constant power is prohibited if we want to maintain constant degree. Fortunately, there exist operations that can counter this problem. Consider for example the replacement product of a $D$-regular graph $G$ with a $d$-regular graph $H$ on $D$ vertices (with $d \ll D$). This can be loosely defined as follows: Each vertex $v$ of $G$ is replaced with a "copy" $H_v$ of $H$. Each of the $D$ vertices of $H_v$ is connected to its neighbors in $H_v$ but also to one vertex in $H_w$, where $(v, w)$ is one of the $D$ edges going out of $v$ in $G$. The degree in the product graph is $d + 1$ (which is smaller than $D$). Therefore, this operation can transform a graph $G$ into a new graph (the product of $G$ and $H$) of smaller degree. It turns out that if $H$ is a "good enough" expander, the expansion of the resulting graph is "not worse by much" than the expansion of $G$. Formal statements to this affect were proven by Reingold, Vadhan and Wigderson [43] for both the replacement product and the zig-zag product, introduced there. Independently, Martin and Randall [30], building on previous work of Madras and Randall [27], proved a decomposition theorem for Markov chains that also implies that the replacement product preserves expansion.

Given the discussion above, we are ready to informally describe our USTCON algorithm. First, turn the input graph into a constant-degree, regular graph with each connected component being non-bipartite (this step is very easy). Then, the main transformation turns each connected component of the graph, in logarithmic number of phases, into an expander. Each phase starts by raising the current graph to some constant power and then reducing the degree back via a replacement or a zig-zag product with a constant-size expander. We argue that each phase enhances the expansion at least as well as squaring the graph would, and *without the disadvantage of increasing the degree*. Finally, all that is left is to solve USTCON on the resulting graph (which is easy as the diameter of each connected component is only logarithmic).

To conclude that USTCON $\in$ L, we need to argue that all of the above can be done in logarithmic space, which easily reduces to showing that the main transformation can be carried out in logarithmic space. For that, consider the graph $G_i$ obtained after $i$

phases of the transformation. We note that a step on $G_i$ (i.e., evaluating the $j$'th neighbor of some vertex $v$ in $G_i$) is composed of a constant number of operations that are either a step on the graph $G_{i-1}$ from the previous phase or an operation that only requires a constant amount of memory. As the memory for each of these operations can be freed after it is performed, the memory for carrying out a step on $G_i$ is only larger by an additive constant than the memory for carrying out a step on $G_{i-1}$. This implies that the entire transformation is indeed log space.

**Universal traversal sequences** While universal-traversal sequences were introduced as a way for proving USTCON $\in$ L, these are interesting combinatorial objects in their own right. A universal-traversal sequence for $D$-regular graphs on $N$-vertices, is a sequence of edge labels in $\{1, \ldots, D\}$ such that for every such graph, for every labelling of its edges, and for every start vertex, the *deterministic* walk defined by these labels (where in the $i$'th step we take the edge labeled by the $i$'th element of the sequence), visits all of the vertices of the graph. Aleliunas et. al. [2] showed that polynomial-length universal-traversal sequence exists, and in fact almost every sequence of the appropriate length will do. We are interested in obtaining a polynomially-long, universal-traversal sequence that is *constructible in logarithmic space* (even less explicit sequences may still be very interesting). This is again a derandomization problem. Namely, can we derandomize the probabilistic construction of universal-traversal sequences?

Explicit constructions of polynomially-long universal-traversal sequences are only known for extremely limited classes of graphs. Even for expander graphs, such sequences are only known when the edges are "consistently labelled" [18] (this means that the labels of all edges that lead to any particular vertex are distinct). It is therefore not very surprising that our algorithm on its own does not imply full fledged universal-traversal sequences. Still, our algorithm can be shown to imply a very local, and quite oblivious, deterministic procedure for exploring a graph. We can think of our algorithm as maintaining a single pebble, that is placed on the *edges* of the graph. The pebble is moved either from one side of the edge to another, or between different edges that are adjacent to the same vertex (say to the next or to the previous edge). As with universal-traversal sequences, the fixed sequence of instructions is good for every graph, for every labelling of its edges, and for any starting point on the graph. The only difference from universal-traversal sequences is that the pebble here is placed on the edges rather than on the vertices of the graph. In particular, we get polynomially-long, universal-*exploration* sequences for all undirected graphs. In universal-exploration sequences, introduced by Koucky [23], the elements of the sequence are not interpreted as absolute edge-labels but rather as offsets from the previous edge that was traversed. In terms of traversal sequences, our algorithm implies a polynomially-long, universal-traversal sequence that is *constructible in logarithmic space* under some restrictions on the labelling. These restrictions were relaxed in a subsequent work [41] to be identical to those of [18]. For more details see Section 5.

**More on previous work** Graph connectivity problems and space-bounded derandomization are the focus of a vast and diverse body of research. The scope of this paper only allows for an extremely partial discussion of this area. Some very beautiful and influential research (as many of the papers mentioned above) is only briefly touched upon, other areas will not be discussed at all (examples include, time-space tradeoffs for deterministic and randomized connectivity algorithms, restricted constructions of universal traversal sequences, and analysis of connectivity in many other computational models). Insightful, though somewhat outdated, surveys on these topics were given by Wigderson [50] and by Saks [45]. Useful discussion and pointers were also given by Koucky [24]. We continue here by mentioning a few of the most related previous results (most of which are subsumed by the results of this paper). A more technical comparison with some previous work appears in Section 6.

Following Aleliunas et. al. [2], Borodin et. al. [12] gave a *zero-error*, randomized, log-space algorithm for USTCON. An upper bound of different nature on SL was given by Karchmer and Wigderson [21], who showed $\mathrm{SL} \subseteq \oplus\mathrm{L}$.

Nisan and Ta-Shma [35] showed that SL is closed under complement, thus collapsing the "symmetric log-space hierarchies" of both Reif [39] and Ben Asher et. al. [11], and putting some very interesting problems into SL. To give just one example, the planarity of bounded-degree undirected graphs was placed in SL as a corollary (we refer again to [8] for a list of SL-complete problems).

A research direction initiated by Ajtai et. al. [1], and continued with Nisan and Zuckerman [36] is to fully derandomize (i.e., to put in L) $\log n$-space computations that use fewer than $n$ random bits (poly $\log n$ bits in the case of [36]). Raz and Reingold [38] showed how to derandomize $2^{\sqrt{\log n}}$ bits for subclasses of RL. One of their main applications can be viewed as derandomizing $2^{\sqrt{\log n}}$ bits for SL. It is interesting to note (and personally gratifying to the author) that the techniques of [38] played a major roll in the definition of the zig-zag product and with this work found their way back to the study of space-bounded derandomization.

Goldreich and Wigderson [17] gave an algorithm that on all but a tiny fraction of the graphs, evaluates USTCON correctly (and on the rest of the graphs outputs an error message).

Based on rather relaxed *computational hardness assumptions*, Klivans and van Melkebeek [22] proved both that $\mathrm{RL} = \mathrm{L}$ and that efficiently constructible, polynomial length, universal traversal sequences exist.

## 2. Preliminaries

This section discusses various aspects of graphs: their representation, eigenvalue expansion, graph powering, and two graph products (the replacement product and the zig-zag product). The definitions and notation used here are borrowed directly from [43].

**2.1. Graphs representations.** There are several standard representations of graphs. Fortunately, there exist log-space transformations between natural representations. Thus, the space complexity of USTCON is to a large extent independent of the representation of the input graph.

When discussing the eigenvalue expansion of a graph, we will consider its adjacency matrix. That is, the matrix whose (nonnegative, integral) entry $(u, v)$ equals to the number of edges that go from vertex $u$ to vertex $v$. Note that this representation allows graphs with self loops and parallel edges (and indeed such graphs may be generated by our algorithm). A graph is *undirected* iff its adjacency matrix is symmetric (implying that for every edge from $u$ to $v$ there is an edge from $v$ to $u$). It is *$D$-regular* if the sum of entries in each row (and column) is $D$ (so exactly $D$ edges are incident to every vertex).

Let $G$ be a $D$-regular undirected graph on $N$ vertices. When considering a walk on $G$, we would like to assume that the edges leaving each vertex of $G$ are labeled from 1 to $D$ in some arbitrary, but fixed, way. We can then talk about the $i$'th edge incident to a vertex $v$, and similarly about the $i$'th neighbor of $v$. A central insight of [43] is that when taking a step on a graph from vertex $v$ to vertex $w$, it may be useful to keep track of the edge traversed to get to $w$ (rather than just remembering that we are now at $w$). This gave rise to a new representation of graphs through the following *permutation* on pairs of vertex name and edge label:

**Definition 2.1.** For a $D$-regular undirected graph $G$, the *rotation map* $\mathrm{Rot}_G : [N] \times [D] \to [N] \times [D]$ is defined as follows: $\mathrm{Rot}_G(v, i) = (w, j)$ if the $i$'th edge incident to $v$ leads to $w$, and this edge is the $j$'th edge incident to $w$.

Rotation maps will indeed be the representation of choice for this work. Specifically, the first step of our algorithm will be to transform the input graph into a regular one specified by its rotation map (in particular, this step will give labels to the edges of the graph).

**2.2. Eigenvalue expansion and st-connectivity for expanders.** Expanders are sparse graphs which are nevertheless highly connected. The strong connectivity properties of expanders make them very desirable in our context. Specifically, since the diameter of expander graphs is only logarithmically long, there is a trivial log-space algorithm for finding paths between vertices in constant-degree expanders. The particular formalization of expanders used in this paper is the (algebraic) characterization based on the spectral gap of their adjacency matrix. Namely, the gap between the first and second eigenvalues of the (normalized) adjacency matrix.

The *normalized adjacency matrix* $M$ of a $D$-regular undirected graph $G$, is the adjacency matrix of $G$ divided by $D$. In terms of the rotation map, we have:

$$M_{u,v} = \frac{1}{D} \cdot \left| \{(i, j) \in [D]^2 : \mathrm{Rot}_G(u, i) = (v, j)\} \right|.$$

$M$ is simply the transition probability matrix of a random walk on $G$. By the $D$-regularity of $G$, the all-1's vector $1_N = (1, 1, \ldots, 1) \in \mathbb{R}^N$ is an eigenvector of $M$ of

eigenvalue 1. It turns out that all the other eigenvalues of $M$ have absolute value at most 1. We denote by $\lambda(G)$, the *second largest eigenvalue* (in absolute value) of $G$'s normalized adjacency matrix. We refer to a $D$-regular undirected graph $G$ on $N$ vertices such that $\lambda(G) \leq \lambda$ as an $(N, D, \lambda)$-*graph*. It is well-known that the second largest eigenvalue of $G$ is a good measure of $G$'s expansion properties. In particular, it was shown by Tanner [48] and Alon and Milman [5] that second-eigenvalue expansion implies (and is in fact equivalent [3]) to the standard notion of *vertex expansion*. In particular, for every $\lambda < 1$ there exists $\varepsilon > 0$ such that for every $(N, D, \lambda)$-graph $G$ and for any set $S$ of at most half the vertices in $G$, at least $(1 + \varepsilon) \cdot |S|$ vertices of $G$ are connected by an edge to some vertex in $S$. This immediately implies that $G$ has a logarithmic diameter:

**Proposition 2.2.** *Let $\lambda < 1$ be some constant. Then for every $(N, D, \lambda)$-graph $G$ and any two vertices $s$ and $t$ in $G$, there exists a path of length $O(\log N)$ that connects $s$ to $t$.*

*Proof.* By the vertex expansion of $G$, for some $\ell = O(\log N)$ both s and $t$ have more than $N/2$ vertices of distance at most $\ell$ from them in $G$. Therefore, there exists a vertex $v$ that is of distance at most $\ell$ from both $s$ and $t$. □

We can therefore conclude that st-connectivity in constant-degree expanders can be solved in log-space:

**Proposition 2.3.** *Let $\lambda < 1$ be some constant. Then there exists a space $O(\log D \cdot \log N)$ algorithm $\mathcal{A}$ such that when a $D$-regular undirected graph $G$ on $N$ vertices is given to $\mathcal{A}$ as input, the following hold:*

1. *If $s$ and $t$ are in the same connected component and this component is an $(N', D, \lambda)$-graph then $\mathcal{A}$ outputs 'connected'.*
2. *If $\mathcal{A}$ outputs 'connected' then $s$ and $t$ are indeed in the same connected component.*

*Proof.* The algorithm $\mathcal{A}$ simply enumerates all $D^\ell$ paths of length $\ell = O(\log N)$ from $s$. (Where the leading constant in the big-$O$ notation depends on $\lambda$ as in Proposition 2.2.) The algorithm $\mathcal{A}$ outputs 'connected' if and only if at least one of these paths encounters $t$.

Following any particular path from $s$ of length $\ell$ requires space $O(\log N)$, (when given as input the sequence of $\ell$ edge labels in $[D] = \{1, 2, \ldots D\}$ traversed by this path). Enumerating all these $D^\ell$ paths requires space $O(\log D \cdot \log N)$. By Proposition 2.2, in case (1), $s$ and $t$ are of distance at most $\ell$ of each other and $\mathcal{A}$ will indeed find a path from $s$ to $t$ and will output 'connected'. On the other hand, $\mathcal{A}$ never outputs 'connected' unless it finds a path from $s$ to $t$, implying (2). □

Using the probabilistic method, Pinsker [37] showed that most 3-regular graphs are expanders (in the sense of vertex expansion), and this result was extended to eigenvalue

bounds in [3], [13], [15], [14]. Various *explicit* families of constant-degree expanders, some with optimal tradeoff between degree and expansion, were given in literature (cf. [28], [16], [20], [5], [4], [26], [29], [31], [43]). Our algorithm will employ a single constant size expander with rather weak parameters. This expander can be obtained by exhaustive search or by any of the explicit constructions mentioned above. In fact, one can use simpler explicit constructions than the ones given above, as we can afford a rather large degree (with respect to the number of vertices), rather than a constant degree. An example of a simpler construction that would suffice is the one given by Alon and Roichman [6], (see also related discussions in [43] regarding their "base graph").

**Proposition 2.4.** *There exists some constant $D_e$ and a $((D_e)^{16}, D_e, 1/2)$-graph.*

Finally, a key fact for our algorithm is that every connected, non-bipartite graph has a spectral gap which is at least inverse polynomial in the size of the graph (recall that a graph is non-bipartite if there is no partition of the vertices such that all the edges go between the two sides of the partition).

**Lemma 2.5** ([7]). *For every $D$-regular, connected, non-bipartite graph $G$ on $[N]$ it holds that $\lambda(G) \leq 1 - 1/DN^2$.*

**2.3. Powering.** Our main transformation will take a graph and transform each one of its connected components (that in itself will be a connected, non-bipartite graph), into a constant degree expander. If we ignore the requirement that the graph remains constant degree, a simple way of amplifying the (inverse polynomial) spectral gap of a graph is by powering.

**Definition 2.6.** Let $G$ be a $D$-regular multigraph on $[N]$ given by rotation map $\mathrm{Rot}_G$. The *$t$'th power* of $G$ is the $D^t$-regular graph $G^t$ whose rotation map is given by $\mathrm{Rot}_{G^t}(v_0, (a_1, a_2, \ldots, a_t)) = (v_t, (b_t, b_{t-1}, \ldots, b_1))$, where these values are computed via the rule $(v_i, b_i) = \mathrm{Rot}_G(v_{i-1}, a_i)$.

**Proposition 2.7.** *If $G$ is an $(N, D, \lambda)$-graph, then $G^t$ is an $(N, D^t, \lambda^t)$-graph.*

*Proof.* The normalized adjacency matrix of $G^t$ is the $t$'th power of the normalized adjacency matrix of $G$, so all the eigenvalues also get raised to the $t$'th power. □

**2.4. Two graph products.** While taking a power of a graph reduces its second eigenvalue, it also increases its degree. As we are interested in producing constant-degree graphs, we need a complementing operation that reduces the degree of a graph without harming its expansion by too much. We now discuss two graph products that are capable of doing exactly that.

The first is the very natural product, known as the *replacement product*. Assume that $G$ is a $D$-regular graph on $[N]$ and $H$ is a $d$-regular graph on $[D]$ (where $d$ is significantly smaller than $D$). Very intuitively, the replacement product of the two

graphs is defined as follows: Each vertex $v$ of $G$ is replaced with a "copy" $H_v$ of $H$. Each of the $D$ vertices of $H_v$ is connected to its neighbors in $H_v$ but also to one vertex in $H_w$, where $(v, w)$ is one of the $D$ edges going out of $v$ in $G$. The degree in the product graph is $d + 1$ (which is smaller than $D$).[4] A second, slightly more evolved, product introduced by Reingold, Vadhan and Wigderson [43], is the *zig-zag graph product*. Here too we replace each vertex $v$ of $G$ with a "copy" $H_v$ of $H$. However, the edges of the zig-zag product of $G$ and $H$ correspond to a subset of the paths of length three in the replacement product of these graphs[5] (see formal definition below). The degree of the product graph here is $d^2$ (which should still be thought of as significantly smaller that $D$).

It is immediate from their definition, that both products can transform a graph $G$ to a new graph (the product of $G$ and $H$) of smaller degree. As discussed in the introduction, it was previously shown [43], [30] that if $H$ is a "good enough" expander, then the expansion of the resulting graph is "not worse by much" than the expansion of $G$ (see formal statement below for the zig-zag product). Either one of these products can be used in our USTCON algorithm (with some variation in the parameters). We find it more convenient to work with the zig-zag product (even though it is a bit more involved), hence we proceed by formally defining it.

**Definition 2.8** ([43]). If $G$ is a $D$-regular graph on $[N]$ with rotation map $\mathrm{Rot}_G$ and $H$ is a $d$-regular graph on $[D]$ with rotation map $\mathrm{Rot}_H$, then their *zig-zag product* $G ⓩ H$ is defined to be the $d^2$-regular graph on $[N] \times [D]$ whose rotation map $\mathrm{Rot}_{G ⓩ H}$ is as follows (see Figure 1 for an illustration):

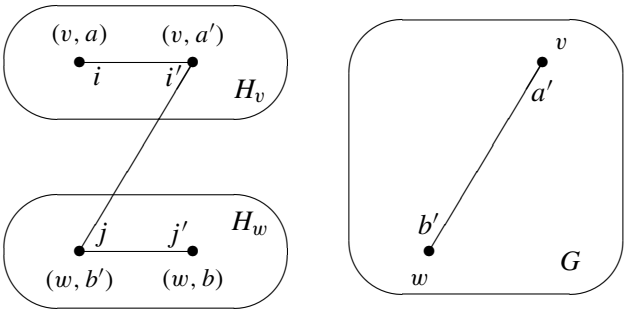

Figure 1. On the left – an edge of the zig-zag product is composed of three steps: a "short step" (in $H_v$), a "big step" (between $H_v$ and $H_w$ which corresponds to an edge of $G$ between $v$ and $w$), and a final "small step" (in $H_w$). The values $i$ ,$i'$, $j$ and $j'$ are labels of edges of $H$ (going out of the $H$ vertices $a$, $a'$, $b'$ and $b$ respectively). On the right – the projection of these steps on the graph $G$ (which corresponds to the middle step specified by $(w, b') = \mathrm{Rot}_G(v, a')$).

[4] Sometimes it is better to consider the *balanced* replacement product, where every edge in $G$ is taken $d$ times in parallel. The degree of the product graph in this case is $2d$ instead of $d + 1$.

[5] Those length three paths that are composed of a "short edge" (an edge inside one of the copies $H_v$), a "long edge" (one that corresponds to an edge of $G$), and finally one additional "short edge".

**$\mathbf{Rot}_{G ⓩ H}((v, a), (i, j))$:**

1. Let $(a', i') = \mathrm{Rot}_H(a, i)$.
2. Let $(w, b') = \mathrm{Rot}_G(v, a')$.
3. Let $(b, j') = \mathrm{Rot}_H(b', j)$.
4. Output $((w, b), (j', i'))$.

In [43], $\lambda(G ⓩ H)$ was bounded as a function of $\lambda(G)$ and $\lambda(H)$. The interesting case there was when both $\lambda(G)$ and $\lambda(H)$ were small constants (and in fact, $\lambda(G)$ is significantly smaller than $\lambda(H)$). In our context, $\lambda(H)$ will indeed be a small constant but $G$ may have an extremely small spectral gap (recall that the spectral gap of $G$ is $1 - \lambda(G)$). In this case, we want the spectral gap of $G ⓩ H$ to be roughly the same as that of $G$ (i.e., smaller by at most a constant factor). It turns out that the stronger bound on $\lambda(G ⓩ H)$, given in [43] implies a useful bound also in this case. We note that a simpler proof for the sort of bound on the zig-zag product we need is given in [41] (in a more general setting than the one considered in [43]).

**Theorem 2.9** ([43]). *If $G$ is an $(N, D, \lambda)$-graph and $H$ is a $(D, d, \alpha)$-graph, then $G ⓩ H$ is a $(N \cdot D, d^2, f(\lambda, \alpha))$-graph, where*

$$f(\lambda, \alpha) = \frac{1}{2}(1 - \alpha^2)\lambda + \frac{1}{2}\sqrt{(1 - \alpha^2)^2\lambda^2 + 4\alpha^2}.$$

As a simple corollary, we have that the spectral gap of $G ⓩ H$ is smaller than that of $G$ by a factor that only depends on $\lambda(H)$.

**Corollary 2.10.** *If $G$ is an $(N, D, \lambda)$-graph and $H$ is a $(D, d, \alpha)$-graph, then*

$$1 - \lambda(G ⓩ H) \geq \frac{1}{2}(1 - \alpha^2) \cdot (1 - \lambda).$$

*Proof.* Since $\lambda \leq 1$ we have that

$$\frac{1}{2}\sqrt{(1 - \alpha^2)^2\lambda^2 + 4\alpha^2} \leq \frac{1}{2}\sqrt{(1 - \alpha^2)^2 + 4\alpha^2} = \frac{1}{2}(1 + \alpha^2) = 1 - \frac{1}{2}(1 - \alpha^2).$$

Therefore, $f(\lambda, \alpha)$ from Theorem 2.9 satisfies $f(\lambda, \alpha) \leq 1 - \frac{1}{2}(1 - \alpha^2)(1 - \lambda)$. □

## 3. Transforming graphs into expanders

This section gives a log-space transformation that essentially turns each one of the connected components of a graph into an expander. This is the main part of our USTCON algorithm.

**Definition 3.1** (Main transformation). On input $G$ and $H$, where $G$ is a $D^{16}$-regular graph on $[N]$ and $H$ is a $D$-regular graph on $[D^{16}]$, both given by their rotation maps, the transformation $\mathcal{T}$ outputs the rotation map of a graph $G_\ell$ defined as follows:

- Set $\ell$ to be the smallest integer such that $(1 - 1/DN^2)^{2^\ell} < 1/2$.
- Set $G_0$ to equal $G$, and for $i > 0$ define $G_i$ recursively by the rule:

$$G_i = (G_{i-1} \textcircled{z} H)^8.$$

Denote by $\mathcal{T}_i(G, H)$ the graph $G_i$, and $\mathcal{T}(G, H) = G_\ell$

Note that by the basic properties of powering and the zig-zag product, it follows inductively that each $G_i$ is a $D^{16}$-regular graph over $[N] \times ([D^{16}])^i$. In particular, the zig-zag product of $G_i$ and $H$ is well defined. In addition, if $D$ is a constant, then $\ell = O(\log N)$ and $G_\ell$ has $poly(N)$ vertices. Our first lemma shows that $\mathcal{T}$ is capable of turning an input graph $G$ into an expander $G_\ell$ (as long as $H$ is in itself an expander).

**Lemma 3.2.** *Let $G$ and $H$ be the inputs of $\mathcal{T}$ as in Definition* 3.1. *If $\lambda(H) \leq 1/2$ and $G$ is connected and non-bipartite then $\lambda(\mathcal{T}(G, H)) \leq 1/2$.*

*Proof.* Since $G = G_0$ is connected and non-bipartite we have by Lemma 2.5 that $\lambda(G_0) \leq 1 - 1/DN^2$. By the choice of $\ell$ it is therefore enough to prove that for every $i > 0$, it holds that $\lambda(G_i) \leq \max\{\lambda(G_{i-1})^2, 1/2\}$. Denote $\lambda = \lambda(G_{i-1})$. Since $\lambda(H) \leq 1/2$, we have by Corollary 2.10 that $\lambda(G_{i-1} \textcircled{z} H) \leq 1 - 3/8(1 - \lambda) < 1 - 1/3(1 - \lambda)$. By the definition of $G_i$ and by Proposition 2.7 we have that $\lambda(G_i) < [1 - 1/3(1 - \lambda)]^8$. We now consider two cases. First, if $\lambda < 1/2$ then $\lambda(G_i) < (5/6)^8 < 1/2$. Otherwise, elementary calculation shows that $[1 - 1/3(1 - \lambda)]^4 \leq \lambda$ and therefore $\lambda(G_i) < \lambda^2$. The lemma follows. □

As we are working our way to solving st-connectivity, rather than solving connectivity (the problem of deciding if the input graph is connected or not), our transformation should be meaningful even for graphs that are not connected (as even in this case the two input vertices $s$ and $t$ may still be in the same connected component). For that, we will argue that $\mathcal{T}$ operates separately on each connected component of $G$. The reason is that $\mathcal{T}$ is composed of two operations (the zig-zag product and powering), that also operate separately on each connected component. We will need some additional notation: For any graph $G$ and subset of its vertices $S$, denote by $G|_S$ the subgraph of $G$ induced by $S$ (i.e., the graph on $S$ which contains all of the edges in $G$ between vertices in $S$). A set $S$ is a connected component of $G$ if $G|_S$ is connected and the set $S$ is disconnected from the rest of $G$ (i.e., there are no edges in $G$ between vertices in $S$ and vertices outside of $S$).

**Lemma 3.3.** *Let $G$ and $H$ be the inputs of $\mathcal{T}$ as in Definition* 3.1. *If $S \subseteq [N]$ is a connected component of $G$ then*

$$\mathcal{T}(G|_S, H) = \mathcal{T}(G, H)|_{S \times ([D^{16}])^\ell}.$$

*Proof.* We will only rely on $S$ being disconnected from the rest of $G$, and will prove inductively that $\mathcal{T}_i(G|_S, H) = \mathcal{T}_i(G, H)|_{S\times([D^{16}])^i}$. Note that for $i > 0$ this directly implies that $S \times ([D^{16}])^i$ is disconnected from the rest of $\mathcal{T}_i(G, H)$ (since both $\mathcal{T}_i(G|_S, H)$ and $\mathcal{T}_i(G, H)$ are $D^{16}$-regular, and thus all of the $D^{16}$ edges incident to a vertex in $S \times ([D^{16}])^i$ reside inside $\mathcal{T}_i(G, H)|_{S\times([D^{16}])^i}$). The base case $i = 0$ is trivial, and here too $S \times ([D^{16}])^i = S$ is disconnected from the rest of $\mathcal{T}_i(G, H) = G$, by assumption.

Assume by induction that $\mathcal{T}_i(G|_S, H) = \mathcal{T}_i(G, H)|_{S\times([D^{16}])^i}$. Set $G_i = \mathcal{T}_i(G, H)$ and $S_i = S \times ([D^{16}])^i$ (and recall that $S_i$ is disconnected from the rest of $G_i$). Then, by the definition of the zig-zag product, $S_i \times [D^{16}]$ is disconnected from the rest of $G_i ⓩ H$ and the edges incident to $S_i \times [D^{16}]$ in $G_i ⓩ H$ are exactly as in $G_i|_{S_i\times[D^{16}]} ⓩ H$. By the definition of powering we now have that $S_i \times [D^{16}]$ is disconnected from the rest of $(G_i ⓩ H)^8$ and the edges incident to $S_i \times [D^{16}]$ in $(G_i ⓩ H)^8$ are exactly as in $(G_i|_{S_i\times[D^{16}]} ⓩ H)^8$. This proves the induction hypothesis for $i + 1$ and completes the proof. □

Finally, we need to argue that $\mathcal{T}$ is a log-space transformation (when $D$ is a constant). The reason is that the evaluation of the rotation map $\mathrm{Rot}_{G_{i+1}}$ of each graph $G_{i+1}$ in the definition of $\mathcal{T}$ requires just a constant additional amount of memory over the evaluation of $\mathrm{Rot}_{G_i}$. Simply, the evaluation of $\mathrm{Rot}_{G_{i+1}}$ is composed of a constant number of operations, where each operation is either an evaluation of $\mathrm{Rot}_{G_i}$ or it requires constant amount of memory (and the same memory can be used for each one of these operations). So the additional memory needed for evaluating $\mathrm{Rot}_{G_{i+1}}$ is essentially a constant size counter (keeping track of which operation we are currently performing).

**Lemma 3.4.** *For every constant $D$ the transformation $\mathcal{T}$ of Definition* 3.1 *can be computed in space $O(\log N)$ on inputs $G$ and $H$, where $G$ is a $D^{16}$-regular graph on $[N]$ and $H$ is a $D$-regular graph on $[D^{16}]$.*

*Proof.* We describe an algorithm $\mathcal{A}$ that on inputs $G$ and $H$ computes the rotation map $\mathrm{Rot}_{G_\ell}$ of $G_\ell = \mathcal{T}(G, H)$. Namely, given $G$ and $H$ (written on the read-only input tape), it enumerates all values $(\bar{v}, \bar{a})$ in the domain of $\mathrm{Rot}_{G_\ell}$ and outputs $[(\bar{v}, \bar{a}), \mathrm{Rot}_{G_\ell}(\bar{v}, \bar{a})]$. Recall that a value $(\bar{v}, \bar{a})$ in the domain of $\mathrm{Rot}_{G_\ell}$ consists of $\bar{v} \in [N] \times ([D^{16}])^\ell$ which is the name of a $G_\ell$ vertex, and $\bar{a} \in [D^{16}]$, which is the label of a $G_\ell$ edge. Since $\ell = O(\log N)$ and $D$ is a constant, the length of each value $(\bar{v}, \bar{a})$ is $O(\log N)$ and therefore enumerating all of these values can be done in space $O(\log N)$. It remains to show that for any particular value $(\bar{v}, \bar{a})$, evaluating $\mathrm{Rot}_{G_\ell}(\bar{v}, \bar{a})$ can also be done in the required space.

The algorithm $\mathcal{A}$ will first allocate the following variables: $v$ which will take value in $[N]$ (specifying a vertex of $G$), and $\ell + 1$ variables $a_0, a_1, \ldots, a_\ell$ each taking value in $[D^{16}]$ (and each specifying a vertex name of $H$; In addition, $a_0$ may specify an edge label of $G$). It is sometimes convenient to view each one of $a_1, \ldots, a_\ell$ as specifying a sequence of 16 edge labels of $H$. In this case we denote $a_i = k_{i,1} \ldots k_{i,16}$. Now, $\mathcal{A}$

will copy the value $(\bar{v}, \bar{a})$ into the above mentioned variables: $\bar{v}$ into $v, a_0, \ldots, a_{\ell-1}$ and $\bar{a}$ into $a_\ell$. Throughout the execution of $\mathcal{A}$, the values of these variables will slowly evolve such that when $\mathcal{A}$ finishes (for this particular $(\bar{v}, \bar{a})$), *the same variables* will contain the desired output $\mathrm{Rot}_{G_\ell}(\bar{v}, \bar{a})$ (which is of the same range as the input $(\bar{v}, \bar{a})$).

We describe the operation of $\mathcal{A}$ in a recursive manner that closely follows the definition of $\mathcal{T}$. Particularly, at each level of the recursion, $\mathcal{A}$ will evaluate $\mathrm{Rot}_{G_i}$ for some $i$ on the appropriate prefix $v, a_0, \ldots, a_i$ of the variables defined above. For the base case $i = 0$, $\mathrm{Rot}_{G_0} = \mathrm{Rot}_G$ is written on the input tape, and can therefore be evaluated in space $O(\log N)$ by simply searching the input tape for the desired entry. For larger $i$, the evaluation of $\mathrm{Rot}_{G_i}$ is as follows:

**For $j = 1$ to 16:**

- Set $a_{i-1}, k_{i,j} \leftarrow \mathrm{Rot}_H(a_{i-1}, k_{i,j})$.
- If $j$ is odd, recursively set $v, a_0 \ldots a_{i-1} \leftarrow \mathrm{Rot}_{G_{i-1}}((v, a_0 \ldots a_{i-2}), a_{i-1})$.
- If $j = 16$, reverse the order of the individual labels in $a_i$: Set $k_{i,1}, \ldots, k_{i,16} \leftarrow k_{i,16}, \ldots, k_{i,1}$.

The correctness of $\mathcal{A}$ immediately follows from the definition of $\mathcal{T}$ and from the operations of which it consists (powering and the zig-zag product). Essentially, going over the operations (in the first two bullets) for any two consecutive values of $j$ corresponds to one step on $(G_{i-1} ⓩ H)$. Repeating eight times implies a path of length eight on $(G_{i-1} ⓩ H)$, or alternatively one step on $(G_{i-1} ⓩ H)^8$. The third bullet reverses the order of labels to fit the definition of zig-zag and powering.

We therefore concentrate on the space complexity of $\mathcal{A}$. Note that each node of the recursion tree performs a constant number of operations and makes a constant number of recursive calls. In addition the depth of the recursion is $\ell + 1 = O(\log N)$. Therefore, maintaining the recursion can be done in space $O(\log N)$. Furthermore, each one of the basic operations (evaluating $\mathrm{Rot}_G$, evaluating $\mathrm{Rot}_H$, and reversing the order of labels in the last step) can be performed in space $O(\log N)$. Finally, the only memory that needs to be kept after a basic operation is performed, is the memory holding the variables $v, a_0, \ldots, a_\ell$ (that are shared by all of these operations), and the memory for maintaining the recursion. We therefore conclude that the space complexity of $\mathcal{A}$ is $O(\log N)$ which completes the proof. □

## 4. A log-space algorithm for USTCON

This section puts together the tools developed above into a deterministic log-space algorithm that decides undirected st-connectivity. As will be discussed in Section 5, the algorithm can also output a path from $s$ to $t$ if such a path exists.

**Theorem 4.1.** USTCON $\in$ L.

As undirected USTCON is complete for SL [25], Theorem 4.1 can be rephrased as follows.

**Theorem 4.2.** SL = L.

*Proof of Theorem* 4.1. We give an algorithm $\mathcal{A}$ that gets as input a graph $G$ over the set of vertices $[N]$, and two vertices $s$ and $t$ in $[N]$. For concreteness, we assume that the graph is given via the adjacency matrix representation. $\mathcal{A}$ will answer 'connected' if and only if there exists a path in $G$ between $s$ and $t$ (i.e., $s$ and $t$ are in the same connected component). Furthermore, $G$ will use space which is logarithmic in its input size.

The algorithm $\mathcal{A}$ will need to evaluate the rotation map of a $((D_e)^{16}, D_e, 1/2)$-graph $H$, where $D_e$ is some constant. By Proposition 2.4, there exists such a graph and therefore $\mathcal{A}$ can obtain it by exhaustive search using constant amount of memory (a more efficient alternative is of course to obtain $H$ by any of the explicit constructions of expanders mentioned in Section 2.2).

Let $\mathcal{T}$ be the transformation given by Definition 3.1. We would like to apply $\mathcal{T}$ to $G$ and $H$ in order to obtain a graph where each connected component is an expander. For such graphs, $st$-connectivity can be solved in logarithmic space by Proposition 2.3. However, we will first need to preprocess $G$ in order to get a new graph $G_{\text{reg}}$ such that $(G_{\text{reg}}, H)$ is a correct input to $\mathcal{T}$. In particular, we need $G_{\text{reg}}$ to be a $D_e^{16}$-regular graph given by its rotation map. There are various ways of transforming $G$ to $G_{\text{reg}}$. The one given here was selected for its simplicity even though it is not the most efficient one possible (in terms of the size of $G_{\text{reg}}$). Essentially, we replace every vertex of $G$ with a cycle of length $N$ and each of the vertices $(v, w)$, where there is an edge between $v$ and $w$ in $G$, is also connected to $(w, v)$ (the rest of the edges are self loops). The rotation map $\text{Rot}_{G_{\text{reg}}}: ([N] \times [N]) \times [D_e^{16}] \mapsto ([N] \times [N]) \times [D_e^{16}]$ of $G_{\text{reg}}$ is formally defined as follows:

- $\text{Rot}_{G_{\text{reg}}}((v, w), 1) = ((v, w'), 2)$, where $w' = w + 1$ if $w < N$ and $w' = 1$ otherwise.
- $\text{Rot}_{G_{\text{reg}}}((v, w), 2) = ((v, w'), 1)$, where $w' = w - 1$ if $w > 1$ and $w' = N$ otherwise.
- In case there is an edge between $v$ and $w$ in $G$ then $\text{Rot}_{G_{\text{reg}}}((v, w), 3) = ((w, v), 3)$. Otherwise, $\text{Rot}_{G_{\text{reg}}}((v, w), 3) = ((v, w), 3)$.
- For $i > 3$, $\text{Rot}_{G_{\text{reg}}}((v, w), i) = ((v, w), i)$.

The transformation from $G$ (given by its adjacency matrix) to $G_{\text{reg}}$ (given by its rotation map) is clearly computable in logarithmic space. Furthermore, $G_{\text{reg}}$ is $D_e^{16}$-regular by definition and all its connected components are non-bipartite (as every vertex in $G_{\text{reg}}$ has self loops). Finally, for every connected component $S \subseteq [N]$ of $G$ we have that $S \times [N]$ is a connected component in $G_{\text{reg}}$. To see that, we first note that for every vertex $v \in [N]$ the set of vertices $v \times [N]$ is in the same connected

component of $G_{\text{reg}}$ (as this set is connected by a cycle). Furthermore, there is an edge in $G_{\text{reg}}$ between some vertex in $v \times [N]$ and some vertex in $w \times [N]$ if and only if $v$ and $w$ are connected by an edge in $G$ (the only possible edge that can connect these subsets is an edge between $(v, w)$ and $(w, v)$ which only exists in $G_{\text{reg}}$ if there is an edge between $v$ and $w$ in $G$).

Now define $G_{\text{exp}} = \mathcal{T}(G_{\text{reg}}, H)$, and $\ell = O(\log N)$ is the corresponding value as in Definition 3.1. Let $S$ be the connected component of $G$, such that $s \in S$. By the arguments above, $S \times [N]$ is a connected component of $G_{\text{reg}}$, and $G_{\text{reg}}|_{S\times[N]}$ is non-bipartite. By Lemma 3.3, $S \times [N] \times ([D^{16}])^{\ell}$ is a connected component of $G_{\text{exp}}$ (as both $G_{\text{exp}}$ and $G_{\text{exp}}|_{S\times[N]\times([D^{16}])^{\ell}}$ are $D_{\text{e}}^{16}$-regular). By Lemma 3.2 and Lemma 3.3, we have that $\lambda(G_{\text{exp}}|_{S\times[N]\times([D^{16}])^{\ell}}) \leq 1/2$.

Let $\mathcal{A}'$ be the algorithm guaranteed by Proposition 2.3 (which decides undirected st-connectivity correctly in graphs where the connected component of the starting vertex is an expanders). The algorithm $\mathcal{A}$ will now invoke $\mathcal{A}'$, on the graph $G_{\text{exp}}$ and the vertices $s' = (s, 1^{\ell+1})$ and $t' = (t, 1^{\ell+1})$. If $\mathcal{A}'$ outputs that $s'$ and $t'$ are connected in $G_{\text{exp}}$ then $\mathcal{A}$ will output that $s$ and $t$ are connected in $G$. Otherwise, $\mathcal{A}$ will output that $s$ and $t$ are not connected.

The algorithm $\mathcal{A}$ is log-space since it is composed of a constant number of log-space procedures: (1) The transformation from $G$ to $G_{\text{reg}}$. (2) The transformation from $G_{\text{reg}}$ to $G_{\text{exp}}$, which is log-space by Lemma 3.4. (3) The algorithm $\mathcal{A}'$ which is log-space by Proposition 2.3. Correctness of $\mathcal{A}$ is argued as follows. First, $s'$ and $t'$ are connected in $G_{\text{exp}}$ if and only if $s$ and $t$ are connected in $G$ (since $S \times [N] \times ([D^{16}])^{\ell}$ is a connected component of $G_{\text{exp}}$, where $S$ is the connected component of $G$ that contains $s$). The correctness of $\mathcal{A}$ now follows since Proposition 2.3 implies that $\mathcal{A}'$ will output 'connected' if and only if $s'$ and $t'$ are indeed connected in $G_{\text{exp}}$ (as $\lambda(G_{\text{exp}}|_{S\times[N]\times([D^{16}])^{\ell}}) \leq 1/2$). □

## 5. Universal traversal and exploration sequences

In this section, we look closer into our USTCON algorithm and conclude that it also solves the corresponding search problem (i.e., finding the path from $s$ to $t$ if such a path exist). In addition, it implies efficiently-constructible universal-traversal sequences for graphs with restricted labelling, and universal exploration sequences for general graphs. The sort of restriction we pose on the labelling of graphs is a strengthening of the "consistent labelling" used in [18]. In a subsequent work [41], our restriction is relaxed to that of [18].

We start by analyzing $\mathcal{T}$, the main transformation of the algorithm, given by Definition 3.1. We show that every edge in $\mathcal{T}(G, H)$ translates to a path in $G$ between the appropriate vertices, and that this path is log-space constructible (as this path is indeed computed during the log-space evaluation of $\mathcal{T}$). Looking ahead to the universal-traversal sequences, we note that if we restrict the labelling of $G$, then the labels of edges, traversed along this path, are independent of $G$.

**Definition 5.1.** Let $\pi$ be a permutation over $[D]$ and $\mathrm{Rot}_G$ the rotation map of a $D$-regular graph $G$. Then $\mathrm{Rot}_G$ is $\pi$-consistent if for every $v, i, w$ and $j$ such that $\mathrm{Rot}_G(v, i) = (w, j)$, it holds that $j = \pi(i)$. In such a case we may also say that the labelling of $G$ is $\pi$-consistent.

An example of a $\pi$-consistent labelling is symmetric labelling where $\pi$ is simply the identity. Namely, every edge is labelled in the same way from both its end points. However, other kinds of $\pi$-consistent labellings come up naturally. An example for that is the labelling of $G_{\mathrm{reg}}$ in the proof of Theorem 4.1. We can now state the appropriate technical lemma regarding the transformation $\mathcal{T}$.

**Lemma 5.2.** *Let $D$ be some constant. Let $G$ be a $D^{16}$-regular graph on $[N]$ and let $H$ be a $D$-regular graph on $[D^{16}]$, both given by their rotation maps. Let $G_\ell = \mathcal{T}(G, H)$, where $\mathcal{T}$ and $\ell$ are given by Definition* 3.1.

*There exists a log-space algorithm such that given $\mathrm{Rot}_G$, $\mathrm{Rot}_H$ and $(\bar{v}, \bar{a})$ in the domain of $\mathrm{Rot}_{G_\ell}$, it outputs a sequence of labels in $[D^{16}]$ with the following property: If the first element of $\bar{v}$ is a vertex $u \in [N]$ and the first element of $\mathrm{Rot}_{G_\ell}(\bar{v}, \bar{a})$ is a vertex $w \in [N]$, then the walk on $G$ from $u$ using the labels that the algorithm outputs leads to $w$.*

*Furthermore, for every fixed permutation $\pi$ on $[D^{16}]$, if the labelling of $G$ is $\pi$-consistent, the log-space algorithm can evaluate the sequence of labels without access to $\mathrm{Rot}_G$.*

*Proof.* Consider the log-space algorithm $\mathcal{A}$ in the proof of Theorem 3.4, as it evaluates $\mathrm{Rot}_{G_\ell}(\bar{v}, \bar{a})$. We enhance it a bit, to define an algorithm $\mathcal{A}'$ as claimed by the lemma. Consider in particular the two variables $v$ and $a_0$ used by $\mathcal{A}$. To begin with, $v$ will be initialized to the value $u$ (the first element of $\bar{v}$). At the end, $v$ will contain the value $w$. Throughout the run of $\mathcal{A}$, the variable $v$ is only updated by the rule $v, a_0 \leftarrow \mathrm{Rot}_G(v, a_0)$ (used at the bottom of the recursion). Therefore, all that $\mathcal{A}'$ needs to do is to output the value of $a_0$ just before each time $\mathcal{A}$ updates $v$.

Regarding the second part of the lemma. We note that the value of $a_0$ is only influenced by $\mathrm{Rot}_G$, through the evaluations $v, a_0 \leftarrow \mathrm{Rot}_G(v, a_0)$. If $G$ is $\pi$-consistent, then $\mathcal{A}'$ can completely ignore the variable $v$ and the rotation map of $G$. To simulate $\mathcal{A}$, it is sufficient that whenever $\mathcal{A}$ evaluates $v, a_0 \leftarrow \mathrm{Rot}_G(v, a_0)$, then $\mathcal{A}'$ will evaluate $a_0 \leftarrow \pi(a_0)$. □

Using Lemma 5.2, it is not hard to obtain the algorithm that finds paths in undirected graphs.

**Theorem 5.3.** *There exists a log-space algorithm that gets as input a graph $G$ over the set of vertices $[N]$, and two vertices $s$ and $t$ in $[N]$, and outputs a path from $s$ to $t$ if such a path exists (otherwise it outputs 'not connected').*

*Proof.* Consider the algorithm $\mathcal{A}$ from the proof of Theorem 4.1. We revise it to an algorithm $\mathcal{A}'$ as required by the theorem. First, we note that it is enough for $\mathcal{A}'$ to

output a path from $(s, 1)$ to $(t, 1)$ in $G_{\text{reg}}$ if such a path exists, as it is easy to transform (in log-space) such a path to a path from $s$ to $t$ in $G$ (and the existence of the two paths is equivalent).

Next we note that $\mathcal{A}$ enumerates all logarithmically-long paths from $s' = (s, 1^{\ell+1})$ in $G_{\text{exp}}$. If it does not find a path that visits $t' = (t, 1^{\ell+1})$, it concludes that $s$ and $t$ are not connected in $G$. Therefore, in such a case, $\mathcal{A}'$ can output 'not connected'. Otherwise $\mathcal{A}$ found a short path from $s'$ to $t'$. Apply the algorithm guaranteed by Lemma 5.2 on each edge on the path from $s'$ to $t'$. Each time the algorithm outputs a sequence of edge-labels in $G_{\text{reg}}$. Let $\vec{a}$ be the concatenation of these sequences. It follows from Lemma 5.2 that the path in $G_{\text{reg}}$ starting from $(s, 1)$ and following the edges according to the labels in $\vec{a}$ leads to $(t, 1)$. The theorem now follows. □

To give our result regarding universal-traversal sequences, we need some notation. Let $\vec{a} = \{a_1, \ldots, a_m\}$ be a sequence of values in $[D]$ (these are interpreted as edge labels). $\vec{a}$ is an $(N, D)$-universal traversal sequence, if for every connected $D$-regular, labelled graph $G$ on $N$ vertices, and every start vertex $s \in [N]$, the walk that starts at $s$ and follows the edges labelled $a_1, \ldots, a_m$, visits every vertex in the graph. For a permutation $\pi$ over $[D]$, we say that $\vec{a}$ is an $(N, D)$ $\pi$-universal traversal sequence, if the above property holds for every connected $D$-regular graph on $N$ vertices, *that has a $\pi$-consistent labelling*, (rather than for all such graphs).

**Theorem 5.4.** *There exists a log-space algorithm that takes as input $1^N$ and a permutation $\pi$ over $[D]$ and outputs an $(N, D)$ $\pi$-universal traversal sequence.*

*Proof.* First we argue that it is enough to construct an $(N \cdot D, D_{\text{e}}^{16})$ $\pi'$-universal sequence for the following simple permutation: $\pi'(1) = 2$, $\pi'(2) = 1$ and for every $i > 2$ $\pi'(i) = i$. Furthermore, all we need is that the sequence will traverse non-bipartite graphs. Consider a (connected) $D$-regular graph $G$ on $N$ vertices that has a $\pi$-consistent labelling. This graph can be transformed into a $D_{\text{e}}^{16}$-regular (connected and non-bipartite) graph $G'$ on $N \cdot D$ vertices that has a $\pi'$-consistent labelling. Each vertex $v \in N$ is transformed into a cycle over $D$ vertices $(v, 1), \ldots, (v, D)$, the edges of the cycle are labelled 1 and 2 (just as in the definition of $G_{\text{reg}}$ in the proof of Theorem 4.1). The edge labelled 3 going out of $(v, i)$ will lead to $\text{Rot}_G(v, i)$ (and will be labelled 3 from that end as well). All other edges are self loops.

Assume that a sequence of labels $a_1, \ldots, a_m$, visits every vertex of $G'$ starting from every vertex $(v, 1)$ (this is even less general than what we obtain). We can translate this (in log space) into a sequence of labels $b_1, \ldots, b_{m'}$ that traverses $G$ from every vertex $v$. To do that, we simulate the walk on $G'$ from an arbitrary vertex $(v, 1)$. As $v$ is unknown and our simulation does not rely on $G$, it will only know at each point the value $b$ such that the walk at this point visits some vertex $(w, b)$ of $G'$ (where $w$ is unknown). First $b$ is set to 1. Then, during the simulation, labels $a_i > 3$ can be ignored (as they are self loops). Given labels 1 and 2, $b$ can easily be updated (these are edges on the cycle). Finally, when encountering $a_i = 3$ the walk moves from a vertex $(w, b)$ to a vertex $(w', \pi(b))$ (as the labelling of $G$ is $\pi$-consistent), and so it is

easy to update the value of $b$ (given access to $\pi$). The projection of the walk on $G$ is exactly the edges labelled 3 that are taken by the walk on $G'$. Therefore, to transform the sequence of $a_i$'s to the sequence of $b_i$'s we can simply output (throughout the simulation) the current value of $b$, whenever we encounter a label $a_i = 3$.

Now we consider a $D_e^{16}$-regular (connected and non-bipartite) graph $G'$ on $N \cdot D$ vertices that has a $\pi'$-consistent labelling. Let $H$ be a $((D_e)^{16}, D_e, 1/2)$-graph. Finally let $G_\ell = \mathcal{T}(G, H)$, where $\mathcal{T}$ and $\ell$ are given by Definition 3.1. By Lemma 3.2, $\lambda(G_\ell) \leq 1/2$ and therefore its diameter is logarithmic. Therefore, for every two vertices $v$ and $u$ of $G'$ one of the polynomially many sequences of labels (of the appropriate logarithmic length) will visit $(u, 1^\ell)$, starting at $(v, 1^\ell)$. Let $B$ be the set of all these sequences of labels. Lemma 5.2 gives a way to translate in log-space each one of the sequences in $B$ into a corresponding sequence of edge-labels of $G'$. Let $B'$ be the set of translated sequences. By Lemma 5.2 and the above argument, for every two vertices $v$ and $u$ of $G'$ one of the sequences in $B'$ will lead a walk in $G'$ that starts in $v$ through the vertex $u$. We should also note that given a sequence $\vec{a} = a_1, \ldots, a_m$ that leads from a vertex $v$ to a vertex $u$, we have that the sequence $\pi'^{-1}(a_m), \ldots, \pi'^{-1}(a_1)$ leads from $u$ to $v$ (this operation simply reverses the walk). We refer to this latter sequence as the reverse of $\vec{a}$. Finally, we can define a sequence that traverses all of the vertices of $G'$ regardless of the starting vertex. Simply, we concatenate for each sequences in $B'$ its reversed sequence and concatenate all of these sequences one after the other. By the arguments above, for every vertex $v$, the sequence we obtain will visit $v$ after every pair of a sequence and its reversed sequence. Furthermore, for every vertex $u$, one of these sequences will lead to $u$. As the log-space construction of this sequence ignores the graph $G'$ (and only relies on $\pi'$), we obtained the desired $(N \cdot D, D_e^{16})$ $\pi'$-universal sequence for non-bipartite graphs. The theorem follows. □

In an $(N, D)$-universal *exploration* sequence, the sequence of labels is interpreted as offsets rather than absolute labels. This means that if we entered a vertex $v$ on an edge labelled $a$ (from $v$'s view point), and we are reading the label $b$, then we will leave $v$ on the edge labelled $a + b$ (or $a + b - D$ if $a + b > D$). In fact this notion can apply to graphs that are not-regular (it then makes sense to allow negative elements in the sequence). Universal-exploration sequences have more flexibility than universal-traversal sequences. For example, it is not clear how to transform a universal-traversal sequence for degree-3 graphs to one for higher-degree graphs. This is easy for universal-exploration sequences (and seems desirable as USTCON can easily be reduced to USTCON for regular-graphs of any degree larger than 2). Koucky [24] showed how to transform a universal-traversal sequence to a universal-exploration sequence. His transformation (which is essentially the same as the one from $G$ to $G'$ in the proof of Theorem 5.4), only needs the universal-sequence to work for graphs with $\pi$-consistent labelling for some simple permutation $\pi$. We can therefore conclude from Theorem 5.4 a log-space construction for general universal-exploration sequences.

**Corollary 5.5.** *There exists a log-space algorithm that takes as input* $(1^N, 1^D)$ *and produces an* $(N, D)$*-universal exploration sequence.*

## 6. Discussion and further research

We start by comparing the techniques of this paper with some previous ones, with the goal of shading some light on the source of our improvements. We continue by discussing some open problems and the results of a subsequent work.

**Comparison with previous techniques** The USTCON algorithms of [47], [34], [9] also operate by transforming, in phases, the input graph into a more accommodating one. In each one of these algorithms, each phase "charges" logarithmic amount to the space complexity of the algorithm. The improvement in the space complexity is directly correlated to reducing the number of phases needed for the transformation. With this approach, the only way to obtain a log-space algorithm is to reduce the number of phases to a constant. We deviate from this direction, as we use a logarithmic number of phases (just as in Savitch's algorithm), to gradually improve the connectivity of the input graph. The space efficiency of our algorithm stems from each transformation being significantly less costly in space.

The parameter being improved by [34], [9], is the size of the graph (each transformation shrinks the graph by collapsing it to a "representative" subset of the vertices). In contrast, our transformation will in fact expand the graph by a polynomial factor (as each phase, enlarges our graph by a constant factor). The parameter Savitch's transformation improves is the diameter of the graph, which is much closer to the parameter we improve (the expansion). In fact, each phase of Savitch's algorithm can be described very similarly to our algorithm. Each one of these phases consists of squaring the graph and then removing parallel edges (which may reduce the degree). Although all that is needed is indeed that the *diameter* of the resulting graph will be small, our analysis relies on bounding the *expansion* of intermediate graphs – a stronger notion of connectivity than the diameter. This allows our transformation to preserve constant degree of the graph (rather than linear degree in Savitch's algorithm), which is crucial for our analysis of the space complexity.

It also seems instructive to compare with the combinatorial construction of expander graphs of [43]. There, an arbitrarily large expander graphs was constructed, starting with a constant size expander. This small expander is made larger and larger, while its degree is kept constant via the zig-zag or the replacement product. Our main transformation shows how to turn *any* connected graph (which is already large) into an expander. This means that the above mentioned products need to be applied when one of the graphs is an extremely weak expander (whereas in [43] both graphs were fairly good expanders). Very fortunately, both products work quite well in this unusual setting of parameters.

**Further Research** There are many open problems and new research directions brought up by this work, we discuss just a few of those. A very natural question is whether the techniques of this paper can be used towards a proof of RL = L. While progress in the context of RL does not seem immediate (as the case of symmetric computations does seem easier), we feel that it is still quite plausible. We also feel that this paper should give an opportunity to reevaluate the common conjecture that Savitch's algorithm is optimal for STCON. While this conjecture may very well be correct, we feel that there is not enough evidence supporting it. Another open problem is to come up with full-fledged, efficiently-constructible, universal-traversal sequences. Interestingly, it seems that this problem shares some of the obstacles that one encounters when trying to generalize the USTCON algorithm to solving RL (this is formalized to some extent in the results of [41] mentioned below).

In a subsequent work, Reingold, Trevisan and Vadhan [41], make some progress on extending our techniques to dealing with the general RL case, obtaining the following results:

1. They exhibit a new complete problem for RL: STCON restricted to directed graphs for which the random walk is promised to have polynomial mixing time.
2. Generalizing our techniques, they present a deterministic, log-space algorithm that given a *regular* directed graph $G$ (i.e., a directed graph where all in-degrees and out-degrees are equal) and two vertices $s$ and $t$, finds a path between $s$ and $t$ if one exists.
3. Using the same techniques as in Item 2, they give a "pseudorandom generator" for random walks on "consistently labelled" regular directed graphs. Roughly speaking, given a random seed of logarithmic length, the generator constructs, in log-space, a "short" pseudorandom walk that ends at an almost-uniformly distributed vertex when taken in any consistently labelled regular directed graph.
4. They prove that if their pseudorandom generator from Item 3 could be generalized to all regular directed graphs (instead of just consistently labelled ones), then their complete problem from Item 1 can be solved in log-space and hence RL = L.

Finally, we have made no attempt to optimize our algorithm in terms of running time (or the constant in the space complexity). Major improvements in efficiency can come about by better analysis of the zig-zag and replacement products. These may also determine which one of these products yields a more efficient algorithm. In a subsequent work Rozenman and Vadhan [44] give a log-space algorithm for USTCON. Their algorithm makes substantial progress in terms of reducing the running time of the algorithm (compared to ours). Their key technical tool is a new operation they introduce and name "derandomized squaring". This operation reduces the second eigenvalue of a graph "similarly" to standard squaring but increases the degree much more moderately. Very loosely, this operation can replace in our algorithm the combination of (standard) powering and zig-zag product. Their analysis for

the new operation is tight (unlike the analysis we currently know for the zig-zag and replacement products) and it is simple and very appealing.[6]

**Acknowledgments.** This work came about during a delightful visit to UC Berkeley. I am most grateful to Irit Dinur and Luca Trevisan for many hours of stimulating discussions on closely related topics and for creating the most conducive research environment possible for me. I would like to thank Moni Naor, Ran Raz, Salil Vadhan and Avi Wigderson for many discussions that helped me form my intuitions on the derandomization of space bounded computations. Among other contributions, I want to thank Moni for steering me towards this topic early on during my PhD studies, and to thank Ran, Salil and Avi for intuitions formed during our joint work on [38], [42].

# Potential functions and the inefficiency of equilibria

Tim Roughgarden*

**Abstract.** We survey one area of the emerging field of algorithmic game theory: the use of approximation measures to quantify the inefficiency of game-theoretic equilibria. Potential functions, which enable the application of optimization theory to the study of equilibria, have been a versatile and powerful tool in this area. We use potential functions to bound the inefficiency of equilibria in three diverse, natural classes of games: selfish routing networks, resource allocation games, and Shapley network design games.

**Mathematics Subject Classification (2000).** 68Q25, 68W25, 90B35, 91A65.

**Keywords.** Game theory, inefficiency of equilibria, Nash equilibrium, network design, potential functions, price of anarchy, price of stability, resource allocation, selfish routing.

## 1. Introduction

The interface between theoretical computer science and microeconomics, often called *algorithmic game theory*, has been an extremely active research area over the past few years. Recent points of contact between the two fields are diverse and include, for example, increased attention to computational complexity and approximation in combinatorial auctions (e.g. [9]); a new focus on worst-case analysis in optimal auction design (e.g. [17]); and a renewed emphasis on the computability and learnability of equilibrium concepts (e.g. [14], [18], [26]). This survey touches on just one connection between theoretical computer science and game theory: the use of approximation measures to quantify the inefficiency of game-theoretic equilibria.

**1.1. Quantifying the inefficiency of equilibria.** Even in very simple settings, selfish behavior can lead to highly inefficient outcomes [11]. A canonical example of this phenomenon is provided by the "Prisoner's Dilemma" [28], in which strategic behavior by two captured and separated prisoners inexorably draws them into the worst-possible outcome. We will see several concrete examples of the inefficiency of selfish behavior in networks later in the survey.

Must more recently, researchers have sought to *quantify* the inefficiency of selfish behavior. Koutsoupias and Papadimitriou [23] proposed a framework to systematically study this issue. The framework presupposes a strategic environment (a *game*), a definition for the outcome of selfish behavior (an *equilibrium concept*), and a real-

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

valued, nonnegative objective function defined on the possible outcomes of the game. The *price of anarchy* [23], [26] is then defined as the ratio between the objective function value of an equilibrium and that of an optimal solution. (For the moment, we ignore the question of whether or not equilibria exist and are unique.) If the price of anarchy of a game is 1, then its equilibria are fully efficient. More generally, bounding the price of anarchy in a class of games provides a guarantee on the worst-possible inefficiency of equilibria in these games.

The price of anarchy is directly inspired by other popular notions of approximation in theoretical computer science [23]. One example is the *approximation ratio* of a heuristic for a (typically NP-hard) optimization problem, defined as the largest ratio between the objective function value of the solution produced by the heuristic and that of an optimal solution. While the approximation ratio measures the worst-case loss in solution quality due to insufficient computational effort, the price of anarchy measures the worst-case loss arising from insufficient ability (or willingness) to control and coordinate the actions of selfish individuals. Much recent research on the price of anarchy is motivated by optimization problems that naturally occur in the design and management of large networks (like the Internet), in which users act selfishly, but implementing an optimal solution is not practical.

**1.2. Potential functions.** The price of anarchy has been successfully analyzed in a diverse array of game-theoretic models (see e.g. [32], [33] and the references therein). This survey discusses three of these models, with the goal of illustrating a single mathematical tool for bounding the price of anarchy: *potential functions*. The potential function technique is by no means the only one known for bounding the inefficiency of equilibria, but (so far) it has been the most versatile and powerful.

Potential functions enable the application of optimization theory to the study of equilibria. More precisely, a potential function for a game is a real-valued function, defined on the set of possible outcomes of the game, such that the equilibria of the game are precisely the local optima of the potential function. This idea was first used to analyze selfish behavior in networks by Beckmann, McGuire, and Winsten [4], though similar ideas were used earlier in other contexts.

When a game admits a potential function, there are typically consequences for the existence, uniqueness, and inefficiency of equilibria. For example, suppose a game admits a potential function and either: (1) there are a finite number of distinct outcomes; or (2) the set of outcomes is compact and the potential function is continuous. In either case, the potential function achieves a global optimum, which is also a local optimum, and hence the game has at least one equilibrium. This is a much more elementary approach to establishing the existence of equilibria than traditional fixed-point proofs (e.g. [25]). Moreover, if the potential function has a unique local optimum, then the game has a unique equilibrium. Finally, if the potential function is "close to" the true objective function, then the equilibria that are global optima of the potential function have nearly-optimal objective function value, and are thus approximately efficient.

The power of the potential function approach might suggest that its applicability is limited. Fortunately, many important and natural classes of games admit well-behaved potential functions. To suggest what such functions look like, we briefly interpret some classical results about electric networks in terms of potential functions. Consider electrical current in a two-terminal network of resistors. By Kirchhoff's equations and Ohm's law, we can interpret this current as an "equilibrium", in the sense that it equalizes the voltage drop along all paths in the network between the two terminals. (View current as a large population of "selfish particles", each seeking out a path with minimum voltage drop.) On the other hand, Thomson's principle states that electrical current also minimizes the dissipated energy over all flow patterns that achieve the same total current. In other words, energy dissipation serves as a potential function for current in an electrical network. For further details and discussion, see Kelly [21] and Doyle and Snell [10].

**1.3. Survey overview.** Each of the next three sections introduces a model of selfish behavior in networks, and uses a potential function to bound the inefficiency of equilibria in the model. We focus on these three examples because they are simple, natural, and diverse enough to illustrate different aspects of potential function proof techniques. In order to emphasize the most important concepts and provide a number of self-contained proofs, we often discuss only special cases of more general models and results.

Section 2 discusses selfish routing networks, a model that generalizes the electrical networks of Subsection 1.2 and has been extensively studied by the transportation, networking, and theoretical computer science communities. Section 3 analyzes the performance of a well-studied distributed protocol for allocating resources to heterogeneous users. Section 4 bounds the inefficiency of equilibria in a model of selfish network design. Section 5 concludes.

## 2. Selfish routing and the price of anarchy

**2.1. The model.** In this section, we study the inefficiency of equilibria in the following model of noncooperative network routing. A *multicommodity flow network*, or simply a *network*, is a finite directed graph $G = (V, E)$, with vertex set $V$ and (directed) edge set $E$, together with a set $(s_1, t_1), \ldots, (s_k, t_k)$ of source-sink vertex pairs. We also call such pairs *commodities*. We denote the set of simple $s_i$-$t_i$ paths by $\mathcal{P}_i$, and always assume that this set is non-empty for each $i$. We allow the graph $G$ to contain parallel edges, and a vertex can participate in multiple source-sink pairs.

A *flow* in a network $G$ is a nonnegative vector indexed by the set $\mathcal{P} = \bigcup_{i=1}^{k} \mathcal{P}_i$. For a flow $f$ and a path $P \in \mathcal{P}_i$, we interpret $f_P$ as the amount of traffic of commodity $i$ that chooses the path $P$ to travel from $s_i$ to $t_i$. We use $r$ to denote a nonnegative vector of *traffic rates*, indexed by the commodities of $G$. A flow $f$ is *feasible* for $r$ if it routes all of the prescribed traffic: for each $i \in \{1, 2, \ldots, k\}$, $\sum_{P \in \mathcal{P}_i} f_P = r_i$.

We model the negative consequences of network congestion in the following simple way. For a flow $f$ in a network $G$ and an edge $e$ of $G$, let $f_e = \sum_{P \in \mathcal{P} : e \in P} f_P$ denote the total amount of traffic employing edge $e$. Each edge $e$ then has a nonnegative, continuous, and nondecreasing *cost function* $c_e$, which describes the cost incurred by traffic using the edge $e$ as a function of $f_e$. We call a triple of the form $(G, r, c)$ a *selfish routing network* or simply an *instance*.

Next we describe a notion of equilibrium in selfish routing networks – the expected outcome of "selfish routing". Define the cost of a path $P$ with respect to a flow $f$ as the sum of the costs of the constituent edges: $c_P(f) = \sum_{e \in P} c_e(f_e)$. Assuming that selfish traffic attempts to minimize its incurred cost, we obtain the following definition of a *Wardrop equilibrium* [38].

**Definition 2.1** ([38]). Let $f$ be a feasible flow for the instance $(G, r, c)$. The flow $f$ is a *Wardrop equilibrium* if, for every commodity $i \in \{1, 2, \ldots, k\}$ and every pair $P, \tilde{P} \in \mathcal{P}_i$ of $s_i$-$t_i$ paths with $f_P > 0$, $c_P(f) \leq c_{\tilde{P}}(f)$.

In Definition 2.1, we are implicitly assuming that every network user controls a negligible portion of the overall traffic, so that the actions of an individual user have essentially no effect on the network congestion. In the game theory literature, games with this property are called *nonatomic* [35]. Atomic variants of selfish routing have also been extensively studied (see e.g. [32]). We will study other types of atomic games in Sections 3 and 4.

**Example 2.2** (Pigou's example [27]). Consider the two-vertex, two-edge network shown in Figure 1. There is one commodity and the traffic rate is 1. Note that the lower edge is cheaper than the upper edge if and only if less than one unit of traffic uses it. There is thus a unique Wardrop equilibrium, with all traffic routed on the lower edge. In this flow, all traffic incurs one unit of cost.

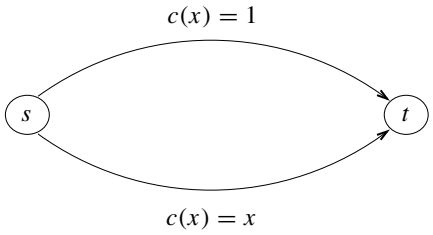

Figure 1. Pigou's example (Example 2.2).

Pigou's example already illustrates that equilibria can be inefficient. More specifically, note that routing half of the traffic on each of the two edges would produce a "better" flow: all of the traffic would incur at most one unit of cost, while half of the traffic would incur only $1/2$ units of cost.

The inefficiency of the Wardrop equilibrium in Example 2.2 arises from what is often called a *congestion externality* – a selfish network user accounts only for its own cost, and not for the costs that its decision imposes on others. The "better" routing of traffic in Example 2.2 is not a Wardrop equilibrium because a selfish network user routed on the upper edge would switch to the lower edge, indifferent to the fact that this switch (slightly) increases the cost incurred by a large portion of the population.

In Example 2.2, there is a unique Wardrop equilibrium. In Subsection 2.2 we will use a potential function to prove the following theorem, which states that Wardrop equilibria exist and are "essentially unique" in all selfish routing networks.

**Theorem 2.3** ([4]). *Let $(G, r, c)$ be an instance.*

(a) *The instance $(G, r, c)$ admits at least one Wardrop equilibrium.*

(b) *If $f$ and $\tilde{f}$ are Wardrop equilibria for $(G, r, c)$, then $c_e(f_e) = c_e(\tilde{f}_e)$ for every edge $e$.*

The Wardrop equilibrium in Example 2.2 is intuitively inefficient; we next quantify this inefficiency. We define our objective function, the *cost* of a flow, as the sum of the path costs incurred by traffic:

$$C(f) = \sum_{P \in \mathcal{P}} c_P(f) f_P = \sum_{e \in E} c_e(f_e) f_e. \tag{1}$$

The first equality in (1) is a definition; the second follows easily from the definitions. An *optimal flow* for an instance $(G, r, c)$ is feasible and minimizes the cost. Since cost functions are continuous and the set of feasible flows is compact, every instance admits an optimal flow. In Pigou's example (Example 2.2), the Wardrop equilibrium has cost 1, while routing half of the traffic on each edge yields an optimal flow with cost $3/4$.

**Definition 2.4** ([23], [26]). The *price of anarchy* $\rho(G, r, c)$ of an instance $(G, r, c)$ is

$$\rho(G, r, c) = \frac{C(f)}{C(f^*)},$$

where $f$ is a Wardrop equilibrium and $f^*$ is an optimal flow. The *price of anarchy* $\rho(\mathcal{I})$ of a non-empty set $\mathcal{I}$ of instances is $\sup_{(G,r,c) \in \mathcal{I}} \rho(G, r, c)$.

Definition 2.1 and Theorem 2.3(b) easily imply that all Wardrop equilibria have equal cost, and thus the price of anarchy of an instance is well defined unless there is a flow with zero cost. In this case, all Wardrop equilibria also have zero cost, and we define the price of anarchy of the instance to be 1.

**Example 2.5** (Nonlinear Pigou's example [34]). The inefficiency of the Wardrop equilibrium in Example 2.2 can be amplified with a seemingly minor modification to the network. Suppose we replace the previously linear cost function $c(x) = x$ on

the lower edge with the highly nonlinear one $c(x) = x^p$ for $p$ large (Figure 2). As in Example 2.2, the cost of the unique Wardrop equilibrium is 1. The optimal flow routes a small $\varepsilon$ fraction of the traffic on the upper edge and has cost $\varepsilon + (1-\varepsilon)^{p+1}$. Since this approaches 0 as $\varepsilon$ tends to 0 and $p$ tends to infinity, the price of anarchy of this selfish routing network grows without bound as $p$ grows large.

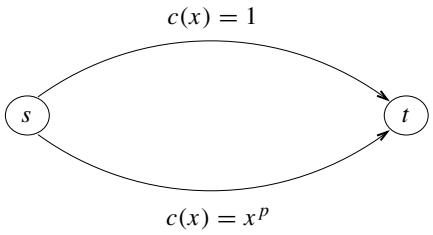

Figure 2. A nonlinear variant of Pigou's example (Example 2.5).

Example 2.5 demonstrates that the price of anarchy can be large in (very simple) networks with nonlinear cost functions. In Subsection 2.2 we use a potential function to show the converse: the price of anarchy is large *only* in networks with "highly nonlinear" cost functions.

**2.2. A potential function for wardrop equilibria.** We now show that Wardrop equilibria can be characterized as the minima of a potential function, and use this characterization to prove both Theorem 2.3 and upper bounds on the price of anarchy of selfish routing. To motivate this potential function, we first characterize the optimal flows of an instance.

Optimal flows for an instance $(G, r, c)$ minimize the cost (1) subject to linear flow feasibility constraints. Assume for the moment that for every edge $e$, the function $x \cdot c_e(x)$ is convex. The cost (1) is then a convex (separable) function, and we can apply the Karush–Kuhn–Tucker conditions (see e.g. [5]) to characterize its global minima. To state this characterization cleanly, assume further that all cost functions are differentiable, and let $c_e^*(x) = (x \cdot c_e(x))' = c_e(x) + x \cdot c_e'(x)$ denote the *marginal cost function* for the edge $e$. The KKT conditions then give the following.

**Proposition 2.6** ([4]). *Let $(G, r, c)$ be an instance such that, for every edge $e$, the function $x \cdot c_e(x)$ is convex and differentiable. Let $c_e^*$ denote the marginal cost function of the edge $e$. Then $f^*$ is an optimal flow for $(G, r, c)$ if and only if, for every commodity $i \in \{1, 2, \ldots, k\}$ and every pair $P, \tilde{P} \in \mathcal{P}_i$ of $s_i$-$t_i$ paths with $f_P > 0$, $c_P^*(f) \leq c_{\tilde{P}}^*(f)$.*

Comparing Definition 2.1 and Proposition 2.6, we discover that Wardrop equilibria and optimal flows are essentially the same thing, just with different sets of cost functions.

**Corollary 2.7.** *Let $(G, r, c)$ be an instance such that, for every edge $e$, the function $x \cdot c_e(x)$ is convex and differentiable. Let $c_e^*$ denote the marginal cost function of the edge $e$. Then $f^*$ is an optimal flow for $(G, r, c)$ if and only if it is a Wardrop equilibrium for $(G, r, c^*)$.*

To construct a potential function for Wardrop equilibria, we need to "invert" Corollary 2.7: of what function do Wardrop equilibria arise as global minima? The answer is simple: to recover Definition 2.1 as an optimality condition, we seek a function $h_e(x)$ for each edge $e$ – playing the previous role of $x \cdot c_e(x)$ – such that $h_e'(x) = c_e(x)$. Setting $h_e(x) = \int_0^x c_e(y)\,dy$ for each edge $e$ thus yields the desired potential function.

Precisely, call

$$\Phi(f) = \sum_{e \in E} \int_0^{f_e} c_e(x)\,dx \tag{2}$$

the *potential function* for an instance $(G, r, c)$. Analogously to Corollary 2.7, the following proposition holds.

**Proposition 2.8** ([4]). *Let $(G, r, c)$ be an instance. A flow feasible for $(G, r, c)$ is a Wardrop equilibrium if and only if it is a global minimum of the corresponding potential function $\Phi$ given in* (2)*.*

**Remark 2.9.** Thomson's principle for electrical networks (Subsection 1.2) can be viewed as the special case of Proposition 2.8 for single-commodity flow networks with linear cost functions (of the form $c_e(x) = a_e x$).

Theorem 2.3 now follows easily.

*Proof of Theorem* 2.3 (Sketch). Since cost functions are continuous and the set of feasible flows is compact, part (a) of the theorem follows immediately from Proposition 2.8 and Weierstrass's Theorem. Since cost functions are nondecreasing, the potential function $\Phi$ in (2) is convex; moreover, the set of feasible flows is convex. Part (b) of the theorem now follows from routine convexity arguments. □

Much more recently, the potential function (2) has been used to upper bound the price of anarchy of selfish routing. The intuition behind this connection is simple: if Wardrop equilibria exactly optimize a potential function (2) that is a good approximation of the objective function (1), then they should also be approximately optimal. Formally, we have the following.

**Theorem 2.10** ([34]). *Let $(G, r, c)$ be an instance, and suppose that $x \cdot c_e(x) \leq \gamma \cdot \int_0^x c_e(y)\,dy$ for all $e \in E$ and $x \geq 0$. Then the price of anarchy $\rho(G, r, c)$ is at most $\gamma$.*

*Proof.* Let $f$ and $f^*$ be a Wardrop equilibrium and an optimal flow for $(G, r, c)$, respectively. Since cost functions are nondecreasing, the cost of a flow (1) is always

at least its potential function value (2). The hypothesis ensures that the cost of a flow is at most $\gamma$ times its potential function value. The theorem follows by writing

$$C(f) \leq \gamma \cdot \Phi(f) \leq \gamma \cdot \Phi(f^*) \leq \gamma \cdot C(f^*),$$

with the second inequality following from Proposition 2.8. □

Theorem 2.10 implies that the price of anarchy of selfish routing is large only in networks with "highly nonlinear" cost functions. For example, if $c_e$ is a polynomial function with degree at most $p$ and nonnegative coefficients, then $x \cdot c_e(x) \leq (p+1)\int_0^x c_e(y)\,dy$ for all $x \geq 0$. Applying Theorem 2.10, we find that the price of anarchy in networks with cost functions that are polynomials with nonnegative coefficients grows at most linearly with the degree bound $p$.

**Corollary 2.11** ([34]). *If $(G, r, c)$ is an instance with cost functions that polynomials with nonnegative coefficients and degree at most $p$, then $\rho(G, r, c) \leq p + 1$.*

This upper bound is nearly matched by Example 2.5. (The upper and lower bounds differ by roughly a $\ln p$ multiplicative factor.) Qualitatively, Example 2.5 and Corollary 2.11 imply that a large price of anarchy can be caused by highly nonlinear cost functions, but not by complex network topologies or by a large number of commodities.

**2.3. An optimal bound on the price of anarchy.** We have established that the price of anarchy of selfish routing depends on the "degree of nonlinearity" of the network cost functions. However, even in the simple case of polynomial cost functions, there is gap between the lower bound on the price of anarchy provided by Example 2.5 and the upper bound of Theorem 2.10. We conclude this section by showing how a different analysis, which can be regarded as a more "global" application of potential function ideas, provides a tight bound on the price of anarchy for essentially every set of allowable cost functions.

We first formalize a natural lower bound on the price of anarchy based on "Pigou-like examples".

**Definition 2.12** ([7], [31]). Let $\mathcal{C}$ be a nonempty set of cost functions. The *Pigou bound* $\alpha(\mathcal{C})$ for $\mathcal{C}$ is

$$\alpha(\mathcal{C}) = \sup_{c \in \mathcal{C}} \sup_{x, r \geq 0} \frac{r \cdot c(r)}{x \cdot c(x) + (r - x)c(r)}, \tag{3}$$

with the understanding that $0/0 = 1$.

The point of the Pigou bound is that it lower bounds the price of anarchy in instances with cost functions in $\mathcal{C}$.

**Proposition 2.13.** *Let $\mathcal{C}$ be a set of cost functions that contains all of the constant cost functions. Then $\rho(\mathcal{C}) \geq \alpha(\mathcal{C})$.*

*Proof.* Fix a choice of $c \in \mathcal{C}$ and $x, r \geq 0$. We can complete the proof by exhibiting a selfish routing network with cost functions in $\mathcal{C}$ and price of anarchy at least $c(r)r/[c(x)x + (r-x)c(r)]$. Since $c$ is nondecreasing, this expression is at least 1 if $x \geq r$; we can therefore assume that $x < r$.

Let $G$ be a two-vertex, two-edge network as in Figure 1. Give the lower edge the cost function $c_1(y) = c(y)$ and the upper edge the constant cost function $c_2(y) = c(r)$. By assumption, both of these cost functions lie in $\mathcal{C}$. Set the traffic rate to $r$. Routing all of the traffic on the lower edge yields a Wardrop equilibrium with cost $c(r)r$. Routing $x$ units of traffic on the lower edge and $r - x$ units of traffic on the upper edge gives a feasible flow with cost $[c(x)x + (r-x)c(r)]$. The price of anarchy in this instance is thus at least $c(r)r/[c(x)x + (r-x)c(r)]$, as desired □

Proposition 2.13 holds more generally for every set $\mathcal{C}$ of cost functions that is *inhomogeneous* in the sense that $c(0) > 0$ for some $c \in \mathcal{C}$ [31].

We next show that, even though the Pigou bound is based only on Pigou-like examples, it is also an upper bound on the price of anarchy in general multicommodity flow networks. The proof requires the following *variational inequality* characterization of Wardrop equilibria, first noted by Smith [36].

**Proposition 2.14** ([36]). *A flow $f$ feasible for $(G, r, c)$ is a Wardrop equilibrium if and only if*

$$\sum_{e \in E} c_e(f_e) f_e \leq \sum_{e \in E} c_e(f_e) f_e^*$$

*for every flow $f^*$ feasible for $(G, r, c)$.*

Proposition 2.14 can be derived as an optimality condition for minimizers of the potential function (2), or can be proved directly using Definition 2.1.

We now show that the Pigou bound is tight.

**Theorem 2.15** ([7], [31]). *Let $\mathcal{C}$ be a set of cost functions and $\alpha(\mathcal{C})$ the Pigou bound for $\mathcal{C}$. If $(G, r, c)$ is an instance with cost functions in $\mathcal{C}$, then*

$$\rho(G, r, c) \leq \alpha(\mathcal{C}).$$

*Proof.* Let $f^*$ and $f$ be an optimal flow and a Wardrop equilibrium, respectively, for an instance $(G, r, c)$ with cost functions in the set $\mathcal{C}$. The theorem follows by writing

$$\begin{aligned} C(f^*) &= \sum_{e \in E} c_e(f_e^*) f_e^* \\ &\geq \frac{1}{\alpha(\mathcal{C})} \sum_{e \in E} c_e(f_e) f_e + \sum_{e \in E} (f_e^* - f_e) c_e(f_e) \\ &\geq \frac{C(f)}{\alpha(\mathcal{C})}, \end{aligned}$$

where the first inequality follows from Definition 2.12 and the second from Proposition 2.14. □

Different, more recent proofs of Theorem 2.15 can be found in [8], [37].

Proposition 2.13 and Theorem 2.15 establish the qualitative statement that, for essentially every fixed restriction on the allowable network cost functions, the price of anarchy is maximized by Pigou-like examples. Determining the largest-possible price of anarchy in Pigou-like examples (i.e., the Pigou bound) is a tractable problem in many cases. For example, it is precisely $4/3$ when $\mathcal{C}$ is the affine functions [34], and more generally is $[1 - p \cdot (p+1)^{-(p+1)/p}]^{-1} \approx p/\ln p$ when $\mathcal{C}$ is the set of polynomials with degree at most $p$ and nonnegative coefficients [31]. In these cases, the maximum price of anarchy (among all multicommodity flow networks) is achieved by the instances in Examples 2.2 and 2.5. For further examples, see [7], [31].

For much more on topics related to the price of anarchy of selfish routing, including many extensions and generalizations of the results described in this section, see [32], [33] and the references therein.

## 3. Efficiency loss in resource allocation protocols

We next study the performance of a protocol for allocating resources to heterogeneous users. While there are a number of conceptual differences between this model and the selfish routing networks of Section 2, the inefficiency of equilibria in these models can be analyzed in a similar way.

**3.1. The model.** We consider a single divisible resource – the capacity of a single network link, say – to be allocated to a finite number $n > 1$ of competing users. These users are *heterogeneous* in the sense that different users can have different values for capacity. We model this by giving each user $i$ a nonnegative real-valued *utility function* $U_i$ that expresses this user's value for a given amount of capacity. We assume that each $U_i$ is concave, strictly increasing, and continuously differentiable. A *resource allocation game* is defined by the $n$ utility functions $U_1, \ldots, U_n$ and the link capacity $C > 0$.

An *allocation* for a resource allocation game is a nonnegative vector $(x_1, \ldots, x_n)$ with $\sum_{i=1}^n x_i = C$. We study the following protocol for allocating capacity. Each user $i$ submits a nonnegative *bid* $b_i$ for capacity. The protocol allocates capacity in proportion to bids, with

$$x_i = \frac{b_i}{\sum_{j=1}^n b_j} \cdot C \tag{4}$$

units of capacity allocated to user $i$. The *payoff* $Q_i$ to a user $i$ is defined as its value for the capacity it receives, minus the bid that it made (and presumably now has to pay):

$$Q_i(b_1, \ldots, b_n) = U_i(x_i) - b_i = U_i\left(\frac{b_i}{\sum_{j=1}^n b_j} \cdot C\right) - b_i.$$

Assume that if all users bid zero, then all users receive zero payoff.

An *equilibrium* is then a bid vector in which each user bids optimally, given the bids of the other users. To state this precisely, we use the notation $b_{-i} = (b_1, b_2, \ldots, b_{i-1}, b_{i+1}, \ldots, b_n)$ to denote the bids of the users other than $i$, and sometimes write $(b_i, b_{-i})$ for a bid vector $(b_1, \ldots, b_n)$.

**Definition 3.1.** A bid vector $(b_1, \ldots, b_n)$ is an *equilibrium* of the resource allocation game $(U_1, \ldots, U_n, C)$ if for every user $i \in \{1, 2, \ldots, n\}$,

$$Q_i(b_i, b_{-i}) = \sup_{\tilde{b}_i \geq 0} Q_i(\tilde{b}_i, b_{-i}). \tag{5}$$

One easily checks that in every equilibrium, at least two users submit strictly positive bids.

While equilibria are most naturally defined for bid vectors, we will be interested in the quality of the corresponding allocations. An *equilibrium allocation* is an allocation $(x_1, \ldots, x_n)$ induced by an equilibrium bid vector – i.e., there is an equilibrium $(b_1, \ldots, b_n)$ such that (4) holds for each user $i$. We next give a characterization of equilibrium allocations that will be crucial for designing a potential function for resource allocation games.

First, a simple calculation shows that concavity of the utility function $U_i$ (in $x_i$) implies strict concavity of the payoff function $Q_i$ (in $b_i$) for every fixed vector $b_{-i}$ with at least one strictly positive component. Similarly, the latter function is continuously differentiable for each such fixed $b_{-i}$. We can therefore characterize solutions to (5) via standard first-order optimality conditions, which yields the following.

**Proposition 3.2** ([16], [20]). *Let $(U_1, \ldots, U_n, C)$ be a resource allocation game and $(b_1, \ldots, b_n)$ a bid vector with at least two strictly positive bids. Let $B = \sum_{j=1}^{n} b_j$ denote the sum of the bids. This bid vector is an equilibrium if and only if*

$$U_i'\left(\frac{b_i}{B} \cdot C\right)\left(1 - \frac{b_i}{B}\right) \leq \frac{B}{C}$$

*for every user $i \in \{1, 2, \ldots, n\}$, with equality holding whenever $b_i > 0$.*

Reformulating Proposition 3.2 in terms of allocations gives the following corollary (cf., Definition 2.1).

**Corollary 3.3** ([16], [20]). *Let $(U_1, \ldots, U_n, C)$ be a resource allocation game. An allocation $(x_1, \ldots, x_n)$ is an equilibrium if and only if for every pair $i$, $j \in \{1, 2, \ldots, n\}$ of users with $x_i > 0$,*

$$U_i'(x_i)\left(1 - \frac{x_i}{C}\right) \geq U_j'(x_j)\left(1 - \frac{x_j}{C}\right).$$

*Proof.* The "only if" direction follows easily from Proposition 3.2 and equation (4). For the "if" direction, suppose $(x_1, \ldots, x_n)$ satisfies the stated condition. There is then a scalar $\lambda \geq 0$ such that $U_i'(x_i)[1 - (x_i/C)] \leq \lambda$ for all users $i$, with equality holding whenever $x_i > 0$. Setting $b_i = \lambda x_i$ for each $i$ yields a bid vector that meets the equilibrium condition in Proposition 3.2. □

**Example 3.4** ([20]). Consider a resource allocation game in which the capacity $C$ is 1, one user has the utility function $U_1(x_1) = 2x_1$, and the other $n-1$ users have the utility function $U_i(x_i) = x_i$. Corollary 3.3 implies that in the unique equilibrium allocation, the first user receives $\frac{1}{2} + \varepsilon$ units of capacity, while each of the other $n-1$ users receive $\delta$ units of capacity (with $\varepsilon, \delta \to 0$ as $n \to \infty$). In this allocation, $U_i'(x_i)(1-x_i)$ is the same for each user $i$, and is slightly less than 1. The corresponding equilibrium bid vector is roughly the same as the equilibrium allocation vector.

In the next subsection, we use a potential function to show that every resource allocation game has a unique equilibrium allocation.

We claim that the equilibrium allocation in Example 3.4 is suboptimal. As in the previous section, we formalize this claim by introducing an objective function and studying the price of anarchy. We define the *efficiency* of an allocation $(x_1, \ldots, x_n)$ of a resource allocation game to be the sum of the users' utilities:

$$\mathcal{E}(x_1, \ldots, x_n) = \sum_{i=1}^{n} U_i(x_i). \tag{6}$$

An *optimal* allocation has the maximum-possible efficiency.

The *price of anarchy* of a resource allocation game is the ratio $\mathcal{E}(x)/\mathcal{E}(x^*)$, where $x$ is the equilibrium allocation and $x^*$ is an optimal allocation. Note that the price of anarchy of such a game is at most 1. In Example 3.4, the optimal allocation gives all of the capacity to the first user and has efficiency 2. The equilibrium allocation has efficiency approaching $3/2$ as $n \to \infty$; the price of anarchy can therefore be arbitrarily close to $3/4$ in this family of examples.

Why does inefficiency arise in Example 3.4? First, note that if the first user is the only one bidding a strictly positive amount (leading to the optimal allocation), then the bid vector cannot be an equilibrium: the first user can bid a smaller positive amount and continue to receive all of the capacity. A similar argument holds whenever the first user's bid comprises a sufficiently large fraction of the sum of the users' bids: if the first user lowers its bid, its allocation diminishes, but the price it pays per unit of bandwidth decreases by a large enough amount to increase its overall payoff. This intuition is mathematically reflected in Corollary 3.3 in the term $U_i'(x_i)(1 - x_i)$ – the marginal benefit of increased capacity to a user becomes increasing tempered as its allocation grows. Inefficiency thus arises in Example 3.4 because of "market power" – the fact that the actions of a single user have significant influence over the effective price of capacity. Indeed, resource allocation games were initially studied by Kelly [22] under the assumption that no users have nontrivial market power. Under this assumption, equilibria are fully efficient – i.e., the price of anarchy is always 1 [22]. See [19, §1.3–1.4] for further discussion.

**Remark 3.5.** Selfish routing networks and resource allocation games differ in a number of ways. In the former, there is a continuum of selfish network users that each have a finite set of strategies (paths); in the latter, there is a finite set of users, each with a

continuum of strategies (bids). In selfish routing, the objective is cost minimization; in resource allocation, it is efficiency maximization. Finally, and perhaps most fundamentally, inefficiency appears to arise for different reasons in the two models. Recall that in selfish routing networks, inefficiency stems from congestion externalities (see the discussion following Example 2.2). Example 3.4 shows that market power is the culprit behind inefficient equilibria in resource allocation games. Despite all of these conceptual differences, the next two subsections show that the inefficiency of equilibria can be quantified in the two models via remarkably similar analyses.

**3.2. A potential function for equilibria.** As in Subsection 2.2, our first step toward constructing a potential function for equilibrium allocations is to characterize optimal allocations. Since efficiency (6) is a separable concave function, a straightforward application of first-order optimality conditions yields the following.

**Proposition 3.6.** *Let $(U_1, \ldots, U_n, C)$ be a resource allocation game. An allocation $(x_1, \ldots, x_n)$ is optimal if and only if for every pair $i, j \in \{1, 2, \ldots, n\}$ of users with $x_i > 0$, $U_i'(x_i) \geq U_j'(x_j)$.*

Given the near-identical characterizations of equilibrium and optimal allocations in Corollary 3.3 and Proposition 3.6, respectively, we again ask: of what function does an equilibrium allocation arise as the global maximum? To recover Corollary 3.3 as an optimality condition, we seek a function $H_i$ for each user $i$ such that $H_i'(x_i) = U_i'(x_i)[1 - (x_i/C)]$ for all $x_i \geq 0$. Setting $H_i(x_i) = U_i(x_i)[1 - (x_i/C)] + \left[\int_0^{x_i} U_i(y)\,dy\right]/C$ thus yields the desired potential function. Precisely, for the resource allocation game $(U_1, \ldots, U_n, C)$, define

$$\Phi_{RA}(x_1, \ldots, x_n) = \sum_{i=1}^{n} \hat{U}_i(x_i), \tag{7}$$

where

$$\hat{U}_i(x_i) = \left(1 - \frac{x_i}{C}\right) \cdot U_i(x_i) + \frac{x_i}{C} \cdot \left(\frac{1}{x_i} \int_0^{x_i} U_i(y)\,dy\right). \tag{8}$$

A simple calculation shows that each function $\hat{U}_i$ is strictly concave, increasing, and continuously differentiable. Regarding $(\hat{U}_1, \ldots, \hat{U}_n, C)$ as a resource allocation game, applying Proposition 2.6 to it, and appealing to Corollary 3.3 formalizes the fact that $\Phi_{RA}$ is a potential function.

**Proposition 3.7** ([16], [20]). *An allocation of the game $(U_1, \ldots, U_n, C)$ is an equilibrium allocation if and only if it is a global maximum of the corresponding potential function $\Phi_{RA}$.*

Existence and uniqueness of equilibrium allocations follow immediately.

**Proposition 3.8** ([16], [20]). *In every resource allocation game, there is a unique equilibrium allocation.*

*Proof.* Existence follows from Proposition 3.7 and the facts that the potential function (7) is continuous and the set of all allocations is compact. Uniqueness follows from Proposition 3.7 and the fact that the potential function (7) is strictly concave. □

Proposition 3.7 also has consequences for the price of anarchy in resource allocation games. To see why, note that the value of $\hat{U}_i(x_i)$ in (8) can be viewed as a weighted average of two quantities – the "true utility" $U_i(x_i)$ and the "average utility" $\left[\int_0^{x_i} U_i(y)\,dy\right]/x_i$. Since $U_i$ is increasing, the latter quantity can only underestimate the utility $U_i(x_i)$, and hence $\hat{U}_i(x_i) \leq U_i(x_i)$ for all $i$ and $x_i \geq 0$. On the other hand, since $U_i$ is nonnegative and concave, the average utility between 0 and $x_i$ is at least half of the utility $U_i(x_i)$ at $x_i$. Thus $\hat{U}_i(x_i) \geq U_i(x_i)/2$ for all $i$ and $x_i \geq 0$. It follows that

$$\mathcal{E}(x_1, \ldots, x_n) \geq \Phi_{RA}(x_1, \ldots, x_n) \geq \mathcal{E}(x_1, \ldots, x_n)/2$$

for every allocation $(x_1, \ldots, x_n)$. Following the proof of Theorem 2.10 now gives a lower bound of $1/2$ on the price of anarchy in resource allocation games.

**Theorem 3.9** ([20]). *In every resource allocation game, the price of anarchy is at least* $1/2$.

**3.3. An optimal bound on the price of anarchy.** There is a gap between the lower bound of $1/2$ on the price of anarchy given in Theorem 3.9 and the upper bound of $3/4$ that is achieved (in the limit) in Example 3.4. As in Subsection 3.3, an optimal (lower) bound can be obtained by leveraging the potential function characterization of equilibria (Proposition 3.7) in a less crude way. Our argument will again be based on a "variational inequality", which can be derived directly from Corollary 3.3 or viewed as a first-order optimality condition for the potential function (7).

**Proposition 3.10.** *Let $(U_1, \ldots, U_n, C)$ be a resource allocation game. For each user $i$, define the modified utility function $\hat{U}_i$ as in* (8)*. An allocation $\hat{x}$ is an equilibrium for $(U_1, \ldots, U_n, C)$ if and only if*

$$\sum_{i=1}^{n} \hat{U}_i'(\hat{x}_i)\hat{x}_i \geq \sum_{i=1}^{n} \hat{U}_i'(\hat{x}_i)x_i$$

*for every feasible allocation $x$.*

Next is the analogue of the Pigou bound (Definition 2.12) for resource allocation games. This definition is primarily motivated by the upper bound on the price of anarchy provided by Example 3.4; we state it in a form that also permits easy application of Proposition 3.10 in the proof of Lemma 3.13 below.

**Definition 3.11.** Let $\mathcal{U}$ denote the set of real-valued, nonnegative, strictly increasing, continuously differentiable, and concave (utility) functions. Define the *JT bound* $\beta$ by

$$\beta = \inf_{U \in \mathcal{U}} \inf_{C > 0} \inf_{0 \leq \hat{x}, x^* \leq C} \frac{U(\hat{x}) + \hat{U}'(\hat{x})(x^* - \hat{x})}{U(x^*)}, \tag{9}$$

where $\hat{U}$ is defined as in (8), as a function of $U$ and $C$.

In the rest of this section, we show that the JT bound is exactly the worst price of anarchy occurring in resource allocation games, and explicitly compute the bound.

**Lemma 3.12.** *For every $\varepsilon > 0$, there is a resource allocation game with price of anarchy at most $\beta + \varepsilon$, where $\beta$ is the JT bound.*

**Lemma 3.13.** *In every resource allocation game, the price of anarchy is at least the JT bound $\beta$.*

**Lemma 3.14.** *The JT bound $\beta$ is exactly $3/4$.*

Lemmas 3.12–3.14 give an explicit optimal bound on the price of anarchy in resource allocation games.

**Theorem 3.15** ([20]). *In every resource allocation game, the price of anarchy is at least $3/4$. Moreover, this bound is tight.*

We now prove Lemmas 3.12–3.14 in turn.

*Proof of Lemma* 3.12. Fix a choice of a utility function $U$, a capacity $C > 0$, and values for $\hat{x}, x^* \in [0, C]$. We aim to exhibit a resource allocation game with price of anarchy (arbitrarily close to)

$$\frac{U(\hat{x}) + \hat{U}'(\hat{x})(x^* - \hat{x})}{U(x^*)}. \tag{10}$$

Recall from (8) that $\hat{U}'(\hat{x}) = U'(\hat{x}) \cdot [1 - (\hat{x}/C)]$. A calculation shows that (10) is at least 1 if $\hat{x} \geq x^*$, so we can assume that $\hat{x} < x^*$. Since (10) is decreasing in $C$, we can assume that $C = x^*$.

Define a resource allocation game in which the capacity is $C$, the first user has the utility function $U_1(x_1) = U(x_1)$, and the other $n - 1$ users each have the linear utility function $U_i(x_i) = \hat{U}'(\hat{x}) \cdot x_i$. Giving all of the capacity to the first user is a feasible allocation with efficiency $U_1(C) = U(x^*)$. Arguing as in Example 3.4, the equilibrium allocation has efficiency approaching $U_1(\hat{x}) + (C - \hat{x}) \cdot \hat{U}'(\hat{x}) = U(\hat{x}) + \hat{U}'(\hat{x})(x^* - \hat{x})$ as the number $n$ of users tends to infinity. The price of anarchy in this family of instances thus tends to (at most) the expression in (10) as $n \to \infty$, completing the proof. □

*Proof of Lemma* 3.13. Let $(U_1, \ldots, U_n, C)$ be a resource allocation game. Let $x^*$ and $\hat{x}$ denote optimal and equilibrium allocations, respectively. Define the modified utility function $\hat{U}_i$ as in (8). The lemma follows by writing

$$\begin{aligned}\sum_{i=1}^{n} U_i(x_i^*) &\leq \sum_{i=1}^{n} \left[\frac{1}{\beta}\big(U_i(\hat{x}_i) + \hat{U}_i'(\hat{x}_i)(x_i^* - \hat{x}_i)\big)\right] \\ &\leq \frac{1}{\beta} \sum_{i=1}^{n} U_i(\hat{x}_i),\end{aligned}$$

where the first inequality follows from Definition 3.11 and the second from Proposition 3.10. □

*Proof of Lemma* 3.14. Setting $U$ to the identity function, $\hat{x} = 1/2$, and $C = x^* = 1$ shows that the JT bound is at most $3/4$. Now fix arbitrary choices of $U$, $C$, and $\hat{x}, x^* \in [0, C]$. We need to show that (10) is at least $3/4$. As in the proof of Lemma 3.12, we can assume that $\hat{x} < x^* = C$. We can then write

$$\begin{aligned}
U(\hat{x}) + \hat{U}'(\hat{x})(x^* - \hat{x}) &= U(\hat{x}) + \left(1 - \frac{\hat{x}}{x^*}\right)U'(\hat{x})(x^* - \hat{x}) \\
&\geq U(\hat{x}) + \left(1 - \frac{\hat{x}}{x^*}\right)\big(U(x^*) - U(\hat{x})\big) \\
&= \left(\frac{\hat{x}}{x^*}\right) \cdot U(\hat{x}) + \left(1 - \frac{\hat{x}}{x^*}\right) \cdot U(x^*) \\
&\geq \left(\frac{\hat{x}}{x^*}\right)^2 \cdot U(x^*) + \left(1 - \frac{\hat{x}}{x^*}\right) \cdot U(x^*) \\
&\geq \frac{3}{4} \cdot U(x^*),
\end{aligned}$$

where the first equality follows from the definition of $\hat{U}$ in (8), the first and second inequalities follow from the concavity and nonnegativity of $U$, and the final inequality follows from the fact that the function $y^2 - y + 1$ is uniquely minimized when $y = 1/2$. The proof is complete. □

**Remark 3.16.** The original proof of Theorem 3.15 is fairly different than the one given here. Specifically, Johari and Tsitsiklis [20] first show that the price of anarchy is minimized in games in which all users have linear utility functions, and then explicitly determine a worst-case example (the same as Example 3.4) by analyzing a linear program. We instead presented the proof above to further highlight the connections between resource allocation games and selfish routing networks.

Despite the numerous common features in our analyses of the price of anarchy in selfish routing networks and in resource allocation games, the precise relationship between the two models is not completely understood. In particular, we lack a unifying analysis of the price of anarchy in the two models.

**Open Question 1.** Find a compelling generalization of selfish routing networks and resource allocation games in which the price of anarchy can be analyzed in a uniform way. Ideally, such a generalization would unify Theorems 2.15 and 3.15, and would also apply to several of the more general classes of games described in [19], [32].

As with selfish routing networks, we have only scratched the surface of the literature on the price of anarchy in resource allocation games. For much more on the subject, including generalizations of these games to general networks, see Johari and Tsitsiklis [20] and Johari [19].

## 4. The price of stability in network design games

Our final class of games is a model of network design with selfish users. These games share some features with selfish routing networks, but also differ in a few fundamental respects.

**4.1. The model.** In this section we study *Shapley network design games*, first proposed by Anshelevich et al. [1]. The game occurs in a directed graph $G = (V, E)$, in which each edge $e \in E$ has a fixed nonnegative cost $c_e$. There is a finite set of $k$ selfish players, and each player $i \in \{1, 2, \ldots, k\}$ is identified with a source-sink vertex pair $(s_i, t_i)$. Let $\mathcal{P}_i$ denote the set of simple $s_i$-$t_i$ paths.

Each player $i$ chooses a path $P_i \in \mathcal{P}_i$ from its source to its destination. This creates a network $\left(V, \bigcup_i P_i\right)$, and we define the *cost* of this outcome as

$$c(P_1, \ldots, P_k) = \sum_{e \in \bigcup_i P_i} c_e. \tag{11}$$

We assume that this cost is shared among the players in the following way. First, if edge $e$ lies in $f_e$ of the chosen paths, then each player choosing such a path pays a proportional share $\pi_e = c_e/f_e$ of the cost. The overall cost $c_i(P_1, \ldots, P_k)$ to player $i$ is then the sum $\sum_{e \in P_i} \pi_e$ of these proportional shares. Selfish players naturally attempt to minimize their incurred cost.

We next define our notion of equilibria for Shapley network design games. In contrast to selfish routing networks and resource allocation games, these network design games are finite games – there is a finite set of players, each with a finite set of strategies. This is the classical setting for *Nash equilibria* [25]. As in Definition 3.1, we use $P_{-i}$ to denote the vector of strategies chosen by the players other than $i$.

**Definition 4.1.** An outcome $(P_1, \ldots, P_k)$ of a Shapley network design game is a (*pure-strategy*) *Nash equilibrium* if for every player $i$,

$$c_i(P_i, P_{-i}) = \min_{\tilde{P}_i \in \mathcal{P}_i} c_i(\tilde{P}_i, P_{-i}).$$

In a pure-strategy Nash equilibrium, every player chooses a single strategy. In a *mixed-strategy* Nash equilibrium, a player can randomize over several strategies. We will not discuss mixed-strategy Nash equilibria in this survey, though the price of anarchy of such equilibria has been studied in different models (see e.g. [3], [23]).

**Example 4.2** ([2]). Consider the network shown in Figure 3. There are $k$ players, each with the same source $s$ and sink $t$. The edge costs are $k$ and $1 + \varepsilon$, where $\varepsilon > 0$ is arbitrarily small. In the minimum-cost outcome, all players choose the lower edge. This outcome is also a Nash equilibrium. On the other hand, suppose all of the players choose the upper edge. Each player $i$ then incurs cost 1, and if player $i$ deviates to the lower edge it pays the full cost of $1 + \varepsilon$. This outcome is thus a second Nash equilibrium, and it has cost $k$.

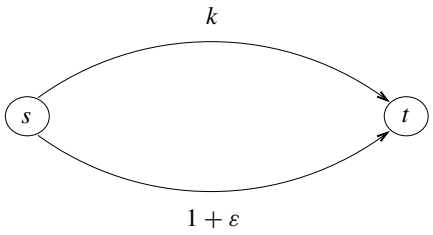

Figure 3. Multiple Nash equilibria in Shapley network design games (Example 4.2).

Example 4.2 shows that Shapley network design games are more ill-behaved than selfish routing networks and resource allocation games in a fundamental respect: there can be multiple equilibria, and different equilibria can have very different objective function values. (Cf., Theorem 2.3 and Proposition 3.8.) The definition of the price of anarchy is ambiguous in games with multiple equilibria – we would like to quantify the inefficiency of an equilibrium, but of which one?

The price of anarchy is historically defined as the ratio between the objective function value of the *worst* equilibrium and that of an optimal solution [23], [26]. This definition is natural from the perspective of worst-case analysis. In Example 4.2, the price of anarchy is (arbitrarily close to) $k$. It is also easy to show that the price of anarchy in every Shapley network design game is at most $k$.

In this section, we instead focus on the ratio between the cost of the *best* Nash equilibrium of a Shapley network design game and that of an optimal solution. This measure is called the *price of stability* [1]. Our motivation is twofold. First, as Example 4.2 shows, the price of anarchy is large and trivial to determine. Second, the price of stability has a reasonably natural interpretation in network design games – if we envision the network as being designed by a central authority for subsequent use by selfish players, then the best Nash equilibrium is an obvious solution to propose. In this sense, the price of stability measures the necessary degradation in solution quality caused by imposing the game-theoretic constraint of stability. See [1], [2], [6], [7] for further discussion and examples of the price of stability.

The price of stability in Example 4.2 is 1. We conclude this subsection with an example showing that this is not always the case.

**Example 4.3** ([1]). Consider the network shown in Figure 4. There are $k$ players, all with the same sink $t$, and $\varepsilon > 0$ is arbitrarily small. For each $i \in \{1, 2, \ldots, k\}$, the edge $(s_i, t)$ has cost $1/i$. In the minimum-cost outcome, each player $i$ chooses the path $s_i \to v \to t$ and the cost is $1 + \varepsilon$. This is not a Nash equilibrium, as player $k$ can decrease its cost from $(1 + \varepsilon)/k$ to $1/k$ by switching to the direct path $s_k \to t$. More generally, this direct path is a *dominant strategy* for the $k$th player – it is the minimum-cost strategy, independent of the paths chosen by the other players. It follows that in every Nash equilibrium, the $k$th player selects its direct path. Arguing inductively

about the players $k-1, k-2, \ldots, 1$, we find that the unique Nash equilibrium is the outcome in which each player $i$ chooses its direct path $s_i \to t$ to the sink. The cost of this outcome is exactly the $k$th harmonic number $\mathcal{H}_k = \sum_{i=1}^{k}(1/i)$, which is roughly $\ln k$. The price of stability can therefore be (arbitrarily close to) $\mathcal{H}_k$ in Shapley network design games.

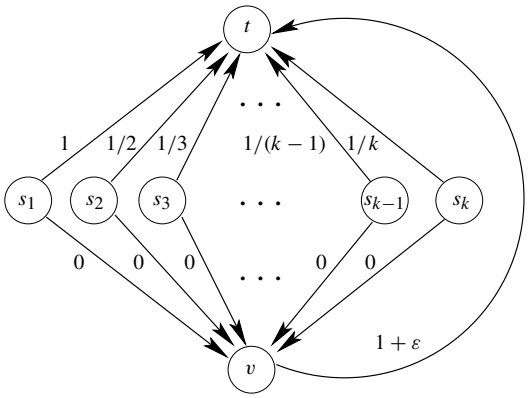

Figure 4. The price of stability in Shapley network design games can be at least $\mathcal{H}_k$ (Example 4.3).

**4.2. A potential function for Nash equilibria.** In this subsection we use a potential function to prove the existence of pure-strategy Nash equilibria and upper bound the price of stability in Shapley network design games. Recall that for both selfish routing networks and resource allocation games, we designed potential functions using a characterization of optimal solutions as a guide (see Propositions 2.6 and 3.6). In Shapley network design games, computing an optimal solution is an NP-hard network design problem [15], and we cannot expect to find an analogous characterization.

There are two ways that Shapley network design games differ from selfish routing networks that prevent the characterization of optimal solutions (Proposition 2.6) from carrying over. First, there are a finite number of players in the former model, and a continuum of players in the latter model. Second, cost functions in selfish routing networks are nondecreasing, whereas Shapley network design games effectively have cost functions that are *decreasing* in the "congestion" – if $x \geq 1$ players use an edge $e$ with fixed cost $c_e$, then the per-player cost on that edge is $c_e/x$.

On the bright side, the potential function (2) for selfish routing networks is easily modified to account for these two differences. First, note that this function $\Phi$ remains well-defined for decreasing cost functions. Second, passing from an infinite player set to a finite one merely involves changing the integrals in (2) to sums. This motivates

the following proposal for a potential function for a Shapley network design game:

$$\Phi_{ND}(P_1, \ldots, P_k) = \sum_{e \in E} \sum_{i=1}^{f_e} \frac{c_e}{i}, \tag{12}$$

where $f_e$ denotes the number of paths $P_i$ that include edge $e$. While equilibria in selfish routing networks and resource allocation games can be characterized as the *global* optima of their respective potential functions (2) and (7), we will see that the Nash equilibria of a Shapley network design game are characterized as the *local* optima of the potential function (12). This idea is originally due to Rosenthal [29], [30], who also considered the broader context of "atomic congestion games".

The next lemma, which is crucial for the rest of this section, states that the potential function "tracks" the change in cost experienced by a deviating player.

**Lemma 4.4** ([1], [30]). *Let $(G, c)$ denote a Shapley network design game with $k$ players and $\Phi_{ND}$ the corresponding potential function* (12)*. Let $i \in \{1, 2, \ldots, k\}$ be a player, and let $(P_i, P_{-i})$ and $(\tilde{P}_i, P_{-i})$ denote two outcomes that differ only in the strategy chosen by the $i$th player. Then*

$$c_i(\tilde{P}_i, P_{-i}) - c_i(P_i, P_{-i}) = \Phi_{ND}(\tilde{P}_i, P_{-i}) - \Phi_{ND}(P_i, P_{-i}). \tag{13}$$

*Proof.* Let $f_e$ denote the number of players that choose a path containing the edge $e$ in the outcome $(P_i, P_{-i})$. Then both sides of (13) are equal to

$$\sum_{e \in \tilde{P}_i \setminus P_i} \frac{c_e}{f_e + 1} - \sum_{e \in P_i \setminus \tilde{P}_i} \frac{c_e}{f_e}.$$

□

In the game theory literature, equation (13) is often taken as the definition of a potential function in the context of finite games. See Monderer and Shapley [24] for a fairly general treatment of potential functions for finite games.

While simple, Lemma 4.4 has a number of non-trivial consequences. First, Nash equilibria of a Shapley network design game are the local minima of the corresponding potential function. Formally, two outcomes of a Shapley network design game are *neighbors* if they differ in at most one component, and an outcome is a *local minimum* of $\Phi_{ND}$ if it has no neighbor with strictly smaller potential function value.

**Corollary 4.5** ([1], [30]). *An outcome of a Shapley network design game is a Nash equilibrium if and only if it is a local minimum of the corresponding potential function $\Phi_{ND}$.*

*Proof.* Immediate from the definitions and Lemma 4.4. □

Since every Shapley network design game has a finite number of outcomes, its corresponding potential function has a global (and hence local) minimum.

**Corollary 4.6** ([1], [30]). *In every Shapley network design game, there is at least one* (*pure-strategy*) *Nash equilibrium.*

We note in passing that several related classes of network games do not always have pure-strategy Nash equilibria [2], [6], [13], [30].

A stronger version of Corollary 4.6 also holds. In a finite game, *better-response dynamics* refers to the following process: start with an arbitrary initial outcome; if the current outcome is not a Nash equilibrium, pick an arbitrary player that can decrease its cost by switching strategies, update its strategy to an arbitrary superior one, and repeat. Better-response dynamics terminate if and only if a Nash equilibrium is reached. Even in extremely simple two-player games, better-response dynamics need not terminate (e.g., in "rock-paper-scissors"). On the other hand, the potential function (12) ensures that such dynamics always converge in Shapley network design games.

**Corollary 4.7** ([1], [30]). *In every Shapley network design game, better-response dynamics always converges to a Nash equilibrium in a finite number of iterations.*

*Proof.* By Lemma 4.4, every iteration of better-response dynamics strictly decreases the value of the potential function $\Phi_{ND}$. Better-response dynamics therefore cannot visit an outcome more than once and eventually terminates, necessarily at a Nash equilibrium. □

Corollary 4.7 does not address the number of iterations required to reach a Nash equilibrium; see [1], [12] for further study of this issue.

Finally, the potential function (12) has direct consequences for the price of stability in Shapley network design games. Comparing the definitions of cost (11) and potential function value (12) of such a game, we have

$$c(P_1, \ldots, P_k) \leq \Phi_{ND}(P_1, \ldots, P_k) \leq \mathcal{H}_k \cdot c(P_1, \ldots, P_k) \tag{14}$$

for every outcome $(P_1, \ldots, P_k)$. As a result, a global minimum of the potential function $\Phi_{ND}$ of a Shapley network design game is both a Nash equilibrium (by Corollary 4.6) and has cost at most $\mathcal{H}_k$ times that of optimal (by the argument in the proof of Theorem 2.10). This gives the following theorem

**Theorem 4.8** ([1]). *In every k-player Shapley network design game, the price of stability is at most* $\mathcal{H}_k$.

A similar argument shows that the bound of $\mathcal{H}_k$ in Theorem 4.8 applies to every Nash equilibrium reachable from an optimal solution via better-response dynamics. The bound also carries over to numerous extensions of Shapley network design games; see [1] for details.

Example 4.3 shows that the bound in Theorem 4.8 is tight for every $k \geq 1$. Thus, unlike for selfish routing networks and resource allocation games, a direct application

of a potential function argument yields an optimal upper bound on the inefficiency of equilibria.

The upper bound in Theorem 4.8 is not optimal for some important special cases of Shapley network design games, however. For example, suppose we insist that the underlying network $G$ is undirected. There is no known analogue of Example 4.3 for undirected Shapley network design games – the best lower bound known on the price of stability in such games is 2. On the other hand, it is not clear how to significantly improve the $\mathcal{H}_k$ bound in Theorem 4.8 for undirected networks.

**Open Question 2.** Determine the largest-possible price of stability in undirected Shapley network design games.

## 5. Conclusion

This survey has discussed three natural types of games: selfish routing networks, resource allocation games, and Shapley network design games. These classes of games differ from each other, both conceptually and technically, in a number of ways. Despite this, the worst-case inefficiency of selfish behavior is fairly well understood in all of these models, and in each case can be determined using a potential function characterization of equilibria.

While the entire field of algorithmic game theory is still in a relatively nascent stage, several broad research agendas are emerging. For the problem of quantifying the inefficiency of noncooperative equilibria, a central research issue is to understand characteristics of games that guarantee approximately optimal equilibria, and to develop flexible mathematical techniques for proving such guarantees. While many research accomplishments from the past few years have improved our understanding of these intertwined goals, there is clearly much left to be done. Perhaps the current state of the art in bounding the inefficiency of equilibria can be compared to the field of approximation algorithms circa twenty-five years ago, when the most fundamental problems and the most powerful algorithmic techniques (such as linear programming) were only beginning to crystallize. Motivated by this analogy, we conclude with the following question: will potential functions be as ubiquitous in bounds on the inefficiency of equilibria as linear programming is in bounds on the performance of approximation algorithms?

**Open Question 3.** We have seen that a potential function characterization of equilibria leads a bound on the inefficiency of equilibria. Under what conditions and to what extent does a converse hold? When does a bound on the inefficiency of the equilibria of a game imply the existence of some form of a potential function for the game?

# Sublinear time algorithms

Ronitt Rubinfeld*

**Abstract.** Sublinear time algorithms represent a new paradigm in computing, where an algorithm must give some sort of an answer after inspecting only a very small portion of the input. We discuss the sorts of answers that one might be able to achieve in this new setting.

**Mathematics Subject Classification (2000).** Primary 68Q25; Secondary 68W20, 68W25.

**Keywords.** Sublinear time algorithms, property testing.

## 1. Introduction

The goal of algorithmic research is to design efficient algorithms, where efficiency is typically measured as a function of the length of the input. For instance, the elementary school algorithm for multiplying two $n$ digit integers takes roughly $n^2$ steps, while more sophisticated algorithms have been devised which run in less than $n \log^2 n$ steps. It is still not known whether a linear time algorithm is achievable for integer multiplication. Obviously any algorithm for this task, as for any other nontrivial task, would need to take at least linear time in $n$, since this is what it would take to read the entire input and write the output. Thus, showing the existence of a linear time algorithm for a problem was traditionally considered to be the gold standard of achievement.

Nevertheless, due to the recent tremendous increase in computational power that is inundating us with a multitude of data, we are now encountering a paradigm shift from traditional computational models. The scale of these data sets, coupled with the typical situation in which there is very little time to perform our computations, raises the issue of whether there is time to consider any more than a miniscule fraction of the data in our computations? Analogous to the reasoning that we used for multiplication, for most natural problems, an algorithm which runs in sublinear time must necessarily use randomization and must give an answer which is in some sense imprecise. Nevertheless, there are many situations in which a fast approximate solution is more useful than a slower exact solution.

A first example of sublinear time computation that comes to mind is the classical result from the theory of sampling that one can, in time independent of the size of the data, determine a good estimate of the average value of a list of numbers of bounded

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

magnitude. But what about more interesting algorithmic questions? For example, given access to all transcripts of trades in the stock exchange, can we determine whether there is a trend change? This is easily detectable after a careful scan of the entire transcript, but by the time the scan is performed, it might be too late to make use of the information. However, it might be feasible to construct much faster algorithms based on random sampling. The recently emerging theory of sublinear time algorithms addresses questions of precisely this nature for problems in various domains.

This paper will describe a number of problems that can be solved in sublinear time, using different types of approximations.

**Outline of the paper.** We begin by giving a motivating example of a sublinear time algorithm in Section 2. In Section 3 we formalize the definitions of approximations that sublinear time algorithms are able to achieve. We then describe various examples of sublinear time algorithms.

## 2. A simple example: monotonicity of a list

Let us begin with a simple example, which will motivate our subsequent definitions of the types of approximations that we will be interested in achieving. A list of integers $\vec{x} = x_1, \ldots, x_n$, is *monotone* (increasing) if $x_i \leq x_j$ for all $1 \leq i < j \leq n$. Given input $\vec{x}$, the task is to determine whether or not $\vec{x}$ is monotone.

In order to construct an algorithm that runs in sublinear time for determining whether $\vec{x}$ is monotone, we first need to make our model of computation precise. For example, if our algorithm must scan $x_1, \ldots, x_{i-1}$ in order to reach $x_i$, then there is no hope for the existence of a sublinear time algorithm. However, it is often natural to assume that our algorithms have *query* (also called *oracle*) access to the input. That is, they can access $x_i$ in one step for any $1 \leq i \leq n$.

Even with this model of computation, it is clear that finding a sublinear time algorithm for the above task is impossible, since any algorithm that does not look at some $x_j$ could be fooled by an input for which all the $x_i$'s are in monotone order for $i \neq j$. Thus, we can only hope to solve an approximate version of this problem, but what is a meaningful notion of an approximation?

One natural approximate version is defined as follows: Say that $x_1, \ldots, x_n$ is *$\varepsilon$-close* to monotone if by changing at most $\varepsilon n$ of the values of the $x_i$'s one can transform $x_1, \ldots, x_n$ into a monotone list. Then, a *property tester for monotonicity* is a randomized algorithm that on input $\vec{x}, \varepsilon$, must output "pass" if $x_1, \ldots, x_n$ is monotone, and "fail" if $x_1, \ldots, x_n$ is not $\varepsilon$-close to monotone. The algorithm is allowed to err with probability at most $1/3$. However, once an algorithm with error probability at most $1/3$ is achieved, it is easy to see that for any $\beta$, a probability of error of at most $\beta$ can be achieved by repeating the algorithm $O\left(\log \frac{1}{\beta}\right)$ times and taking the majority answer. Note that if $x_1, \ldots, x_n$ is, say, $\varepsilon/2$-close to monotone,

the property testing algorithm is allowed to output "pass" or "fail". Indeed, in this case, since the list is close to monotone, it may not be too harmful to pass it. On the other hand, since it is not actually monotone, it is also not a big injustice to fail it.

How do we construct a property tester for monotonicity? On first thought, one might try picking random indices $i$, $j$ and performing tests of the form "is $x_i \leq x_j$?" or "is $x_i \leq x_{i+1}$?". However, these tests do not work very well. It is easy to construct examples showing that there are lists that are not even $\left(1 - \frac{1}{\sqrt{n}}\right)$-close to monotone, yet pass such tests with probability at least $1 - \frac{1}{n^{1/4}}$. This means that at least $n^{1/4}$ such tests must be performed if one is to find a reason to output "fail". Though this does not rule out the possibility of a sublinear time property tester, we will see that one can do much better. In the following, we describe an $O(\log n)$ time algorithm from the work of Ergün et. al. [17] which tests if $\vec{x}$ has a long monotone increasing subsequence. Note that the problem is known to require $\Omega(\log n)$ queries [17], [20].

Let $c$ be a constant that is set appropriately. For simplicity, let us assume that the elements in $\vec{x}$ are distinct. The last assumption is without loss of generality, since one can append the index of an item to the least significant bits of its value in order to break ties.

1. Let $\ell = c/\varepsilon$. Choose indices $i_1, \ldots, i_\ell$ uniformly from $[n]$.
2. For each such chosen index $i_j$, assume the list is monotone and perform a binary search in $\vec{x}$ as if to determine whether $x_{i_j}$ is present in $\vec{x}$ or not.
3. Output "fail" if the binary search fails to find any $x_{i_j}$ in location $i_j$ or finds a pair of out-of-order elements along the search path. Output "pass" if all the $\ell$ binary searches succeed.

The running time of the algorithm is $O((1/\varepsilon)\log n)$. Moreover, if $\vec{x}$ is monotone, then the algorithm will always output "pass" as each of the binary searches will succeed. To show that if $\vec{x}$ is not $\varepsilon$-close to monotone, then the algorithm will output "fail" with probability at least $2/3$, we show the contrapositive. Namely, assume that the input is such that the algorithm outputs "pass" with probability at least $1/3$. To see that $\vec{x}$ has a long increasing subsequence, let $G \subseteq [n]$ denote the set of indices for which the binary search would succeed, i.e., $i \in G$ if and only if $x_i$ can be found by a binary search on $\vec{x}$ that sees no pair of out-of-order elements along the search path. The constant $c$ can be chosen such that if $|G| < (1 - \varepsilon)n$, then the algorithm would pick some $i_j \notin G$ with probability at least $1/3$, causing it to output "fail". Thus, since the algorithm outputs "pass" with probability at least $1/3$, we know that $|G| \geq (1 - \varepsilon)n$. We now argue that the restriction of $\vec{x}$ to the indices in $G$ is an increasing subsequence: Let $i, j \in G$ and $i < j$. Let $k$ be the least common ancestor index where the binary searches for $x_i$ and $x_j$ diverge. Then $x_i < x_k$ and $x_k < x_j$, which implies $x_i < x_j$. Finally, if $\vec{x}$ has an increasing subsequence of size at least $(1 - \varepsilon)n$ then it is easy to see that $\vec{x}$ is $\varepsilon$-close to monotone. Thus we have the following theorem:

**Theorem 2.1** ([17]). *There is an algorithm that, given a sequence $\vec{x} = x_1, \ldots, x_n$ and an $\varepsilon > 0$, runs in $O((1/\varepsilon)\log n)$ time and outputs* (1) "pass"*, if $\vec{x}$ is monotone*

*and* (2) "fail"*, with probability* $2/3$*, if* $\vec{x}$ *does not have an increasing subsequence of length at least* $(1-\varepsilon)n$ (*in particular, if* $\vec{x}$ *is* $\varepsilon$*-far from monotone*).

## 3. What do we mean by an "approximation"?

Now that we have developed some intuition, we present our model and definitions in more detail: We are interested in computing some function $f$ on input $x$ without reading all of $x$. This is an impossible task in general, since a change to a single bit of $x$ could alter the value of $f$. When $f$ is the characteristic function of a property, i.e., $f(x) = 1$ if $x$ has the property and $f(x) = 0$ otherwise, the following notion of approximation has emerged: Given an input, a *property tester* tries to distinguish whether the input has the property from the case where the input is not even close to having the property. We first formalize what it means to be close.

**Definition 3.1.** An input $x$, represented as a function $x\colon \mathcal{D} \to \mathcal{R}$, is $\varepsilon$*-close* to satisfying property $P$ if there is some $y$ satisfying $P$ such that $x$ and $y$ differ on at most $\varepsilon|\mathcal{D}|$ places in their representation. Otherwise, $x$ is said to be $\varepsilon$*-far* from satisfying $P$.

In the monotonicity example of the previous section, $\mathcal{D} = [n]$ and $x(i)$ returns the $i^{\text{th}}$ element of the list.

We now formalize what it means for an algorithm to test a property. As in the previous section, we assume in our model of computation that algorithms have query access to the input.

**Definition 3.2.** Let $P$ be a property. On input $x$ of size $n = |\mathcal{D}|$ and $\varepsilon$, a *property tester* for $P$ must satisfy the following:

- If $x$ satisfies property $P$, the tester must output "pass" with probability at least $2/3$.
- If $x$ is $\varepsilon$-far from satisfying $P$, the tester must output "fail" with probability at least $2/3$.

The probability of error may depend only on the coin tosses of the algorithm and not on any assumptions of the input distribution. The number of queries made by the property tester $q = q(\varepsilon, n)$ is referred to as the query complexity of the property tester. We say that a property tester for $P$ has 1*-sided error* if it outputs "pass" with probability 1 when $x$ satisfies $P$. If the query complexity is independent of $n$, then we say that the property is *easily testable*.

Note that if $x$ does not satisfy $P$ but $x$ is also not $\varepsilon$-far from satisfying $P$, then the output of the property tester can be either "pass" or "fail". We have already seen that it is this gap which allows property testers to be so efficient.

The probability that the property tester errs is arbitrarily set to $1/3$ and may alternatively be defined to be any constant less than 1/2. It is then easy to see that for any $\beta$, a probability of error of at most $\beta$ can be achieved by repeating the algorithm $O\big(\log \frac{1}{\beta}\big)$ times and taking the majority answer.

Property testing was first defined by Rubinfeld and Sudan [37] in the context of program testing. Goldreich, Goldwasser, Ron [23] refined and generalized the definition. Various more general definitions are given in several works, including [17], [25], [31], which mostly differ in terms of the generality of the distance function and natural generalizations as to when the tester should accept and reject.

## 4. Algebraic problems

In this section, we consider property testing algorithms for problems that are algebraic in nature. We begin with the problem of testing whether a function is a homomorphism. We then show that the ideas used to construct property testers for homomorphisms extend to other properties with similar underlying structure.

**4.1. Homomorphism testing.** We begin with an example that was originally motivated by applications in program testing [14] and was later used in the construction of Probabilistically Checkable Proof systems [6]. Suppose you are given oracle access to a function $f : \mathcal{D} \to \mathcal{R}$, that is, you may query the oracle on any input $x \in \mathcal{D}$ and it will reply with $f(x)$. Is $f$ a homomorphism?

In order to determine the answer exactly, it is clear that you need to query $f$ on the entire domain $\mathcal{D}$. However, consider the property testing version of the problem, for which on input $\varepsilon$, the property tester should output "pass" with probability at least $2/3$ if $f$ is a homomorphism and "fail" with probability at least $2/3$ if $f$ is $\varepsilon$-far from a homomorphism (that is, there is no homomorphism $g$ such that $f$ and $g$ agree on at least $(1-\varepsilon)|\mathcal{D}|$ inputs). In order to construct such a property tester, a natural idea would be to test that the function satisfies certain relationships that all homomorphisms satisfy. We next describe two such relationships and discuss their usefulness in constructing property testers.

**Two characterizations of homomorphisms over $\mathbb{Z}_q$.** Consider the case when $f$ is over the domain and range $\mathcal{D} = \mathcal{R} = \mathbb{Z}_q$ for large integer $q$. The set of homomorphisms over $\mathbb{Z}_p$ can be characterized as the set of functions which satisfy $f(x+1) - f(x) = f(1)$ for all $x$. This suggests that a property tester might test that $f(x+1) - f(x) = f(1)$ for most $x$. However, it is easy to see that there are functions $f$ which are very far from any homomorphism, but would pass such a test with overwhelmingly high probability. For example, $g(x) = x \bmod \lceil\sqrt{q}\rceil$ satisfies $g(x+1) - g(x) = g(1)$ for $1 - \frac{1}{\sqrt{q}}$ fraction of the $x \in \mathbb{Z}_q$ but $g(x)$ is $\big(1 - \frac{1}{\sqrt{q}}\big)$-far from a homomorphism.

The set of homomorphisms over $\mathcal{D}$ can alternatively be characterized as the set of functions which satisfy $f(x) + f(y) = f(x + y)$ for all $x, y$. This suggests that one might test that $f(x) + f(y) = f(x + y)$ for most $x, y$. It might be worrisome to note that when $q = 3n$, the function $h(x)$ defined by $h(x) = 0$ if $x \equiv 0 \bmod 3$, $h(x) = 1$ if $x \equiv 1 \bmod 3$ and $h(x) = 3n - 1$ if $x \equiv -1 \bmod 3$ passes the above test for 7/9 fraction of the choices of pairs $x, y \in \mathcal{D}$ and that $h(x)$ is 2/3-far from a homomorphism [16]. However, here the situation is much different: one can show that for any $\delta < 2/9$, if $f(x) + f(y) = f(x + y)$ for at least $1 - \delta$ fraction of the choices of $x, y \in \mathcal{D}$, then there is some homomorphism $g$, such that $f(x) = g(x)$ on at least $1 - \delta/2$ fraction of the $x \in \mathcal{D}$ [13].

Once one has established such a theorem, then one can construct a property tester based on this characterization by sampling $O(1/\varepsilon)$ pairs $x, y$ and ensuring that each pair in the sample satisfies $f(x) + f(y) = f(x + y)$. This property tester clearly passes all homomorphisms. On the other hand, if $f$ is $\varepsilon$-far from a homomorphism then the above statement guarantees that at least $2\varepsilon$ fraction of the choices of $x, y$ pairs do not satisfy $f(x) + f(y) = f(x + y)$, and the property tester is likely to fail.

In both cases, homomorphisms are characterized by a collection of *local* constraints, where by local, we mean that few function values are related within each constraint. What is the difference between the first and the second characterization of a homomorphism that makes the former lead to a bad test and the latter to a much better test? In [37] (see also [36]), the notion of a *robust characterization* was introduced to allow one to quantify the usefulness of a characterization in constructing a property test. Loosely, a robust characterization is one in which the "for all" quantifier can be replaced by a "for most" quantifier while still characterizing essentially the same functions. That is, for a given $\varepsilon, \delta$, a characterization is $(\varepsilon, \delta)$-*robust* if for any function $f$ that satisfies at least $1 - \delta$ fraction of the constraints, $f$ must be $\varepsilon$-close to some function $g$ that satisfies all of the constraints and is thus a solution of the "for all" characterization. As we saw above, once we have an $(\varepsilon, \delta)$-robust characterization for a property, it is a trivial matter to construct a property tester for the property. We are interested in the relationship between $\varepsilon$ and $\delta$ as well as the range of $\delta$ for which the property is $(\varepsilon, \delta)$-robust, since the value of $\delta$ directly influences the running time of the property tester.

**Homomorphism testing, a history.** Let $G, H$ be two finite groups. For an arbitrary map $f: G \to H$, define $\delta$, the probability of group law failure, by

$$1 - \delta = \Pr_{x,y} [f(x) + f(y) = f(x + y)] .$$

Define $\varepsilon$ such that $\varepsilon$ is the minimum $\tau$ for which $f$ is $\tau$-close to a homomorphism. We will be interested in the relationship between $\varepsilon$ and $\delta$.

Blum, Luby and Rubinfeld [14], considered this question and showed that over cyclic groups, there is a constant $\delta_0$, such that if $\delta \leq \delta_0$, then the one can upper bound $\varepsilon$ in terms of a function of $\delta$ that is independent of $|G|$. This yields a homomorphism

tester with query complexity that depends (polynomially) on $1/\varepsilon$, but is independent of $|G|$, and therefore shows that the property of being a homomorphism is easily testable. The final version of [14] contains an improved argument due to Coppersmith [16], which applies to all Abelian groups, shows that $\delta_0 < 2/9$ suffices, and that $\varepsilon$ is upper bounded by the smaller root of $x(1-x) = \delta$ (yielding a homomorphism tester with query complexity linear in $1/\varepsilon$). Furthermore, the bound on $\delta_0$ was shown to be tight for general groups [16]. In [13], it was shown that for general (non-Abelian) groups, for $\delta_0 < 2/9$, then $f$ is $\varepsilon$-close to a homomorphism where $\varepsilon = (3 - \sqrt{9 - 24\delta})/12 \leq \delta/2$ is the smaller root of $3x - 6x^2 = \delta$. The condition on $\delta$, and the bound on $\varepsilon$ as a function of $\delta$, are shown to be tight, and the latter improves that of [14], [16]. Though $\delta_0 < 2/9$ is optimal over general Abelian groups, using Fourier techniques, Bellare et. al. [12] have shown that for groups of the form $(\mathbb{Z}/2)^n$, $\delta_0 \leq 45/128$ suffices.

**A proof of a homomorphism test.** We describe the following proof, essentially due to Coppersmith [14], [16] of the robustness of the homomorphism characterization over Abelian groups. Though this is not the strongest known result, we include this proof to give a flavor of the types of arguments used to show robustness of algebraic properties.

**Theorem 4.1.** *Let $G$ be a finite Abelian group and $f : G \to G$. Let $\delta$ be such that*

$$1 - \delta = \Pr_{x,y}[f(x) + f(y) = f(x+y)].$$

*Then if $\delta < 2/9$, $f$ is $2\delta$-close to a homomorphism.*

*Proof.* Define $\phi(x) = \mathrm{maj}_{y \in G}(f(x+y) - f(y))$, that is, let $\phi(x)$ be the value that occurs with the highest probability when evaluating $f(x+y) - f(y)$ over random $y$ (breaking ties arbitrarily).

The theorem follows immediately from the following two claims showing that $\phi$ is a homomorphism and that $f$ and $\phi$ are $2\delta$-close.

**Claim 4.2.** $|\{y | f(y) = \phi(y)\}| \geq (1 - 2\delta)|G|$.

*Proof of Claim* 4.2. Let $B = \{x \in G : \Pr_y[f(x) \neq f(x+y) - f(y)] > 1/2]\}$. If $x \notin B$, then $\phi(x) = f(x)$. Thus, it suffices to bound $\frac{|B|}{|G|}$. If $x \in B$, then $\Pr_y[f(x) + f(y) \neq f(x+y)] > 1/2$. Thus $\delta = \Pr_{x,y}[f(x) \neq f(x+y) - f(y)] \geq \frac{|B|}{|G|} \cdot \frac{1}{2}$ or equivalently $\frac{|B|}{|G|} \leq 2\delta$. □

**Claim 4.3.** *If $\delta < 2/9$, then $\phi(x) + \phi(z) = \phi(x+z)$ for all $x$, $z$.*

*Proof of Claim* 4.3. Fix $x$, we first show that most pairs $y_1$, $y_2$ agree to vote for the same value of $\phi(x)$. Pick random $y_1, y_2 \in G$, and we have:

$$\begin{aligned}\Pr_{y_1,y_2}[f(x+y_1) - f(y_1) = f(x+y_2) - f(y_2)] &= \Pr_{y_1,y_2}[f(x+y_1) + f(y_2) \\ &= f(x+y_2) + f(y_1)].\end{aligned}$$

$x + y_1$ and $y_2$ are both uniformly distributed elements of $G$. Therefore we have $\Pr_{y_1,y_2}[f(x + y_1) + f(y_2) \neq f(x + y_1 + y_2)] = \delta < 2/9$. Similarly, we have $\Pr_{y_1,y_2}[f(x + y_2) + f(y_1) \neq f(x + y_1 + y_2)] = \delta < 2/9$. If neither of the above events happens, then $f(x + y_1) - f(y_1) = f(x + y_2) - f(y_2)$. Via a union bound we have that

$$\Pr_{y_1,y_2}[f(x + y_1) - f(y_1) = f(x + y_2) - f(y_2)] > 1 - 2\delta \geq 5/9.$$

It is straightforward to show that for any distribution in which the collision probability is at least $5/9$, the maximum probability element must have probability at least $2/3$. Thus,

$$\Pr_y[\phi(x) \neq f(x + y) - f(y)] < 1/3 \quad \text{for all } x \in G. \tag{1}$$

To show that for all $x, z \in G$, $\phi(x) + \phi(z) = \phi(x + z)$, fix $x$ and $z$. Then apply Equation (1) to $x$, $z$ and $x + z$ to get

$$\Pr_y[\phi(x) \neq f(x + (y - x)) - f(y - x)] < 1/3, \tag{2}$$

$$\Pr_y[\phi(z) \neq f(z + y) - f(y)] < 1/3, \tag{3}$$

$$\Pr_y[\phi(x + z) \neq f((x + z) + (y - x)) - f(y - x)] < 1/3. \tag{4}$$

Thus $\Pr_y[\phi(x) = f(y) - f(y - x)$ and $\phi(z) = f(z + y) - f(y)$ and $\phi(x + z) = f(z + y) - f(y - x)] > 0$, and so there exists a $y$ for which

$$\phi(x)+\phi(z) = (f(y)-f(y-x))+(f(z+y)-f(y)) = f(z+y)-f(y-x) = \phi(x+z).$$

The above equality holds for every $x, z \in G$, showing that $\phi$ is a homomorphism and completing the proof of Claim 4.3. □

□

**A word about self-correcting.** In the proof, we note that $\phi$ is defined so that it is the "self-correction" of $f$. Observe that there is a simple randomized algorithm that computes $\phi(x)$ given oracle access to $f$: pick $c \log 1/\beta$ values $y$, compute $f(x + y) - f(y)$ and output the value that you see most often. If $f$ is $\frac{1}{8}$-close to a homomorphism $\phi$, then since both $y$ and $x + y$ are uniformly distributed, we have that for at least $3/4$ of the choices of $y$, $\phi(x + y) = f(x + y)$ *and* $\phi(y) = f(y)$, in which case $f(x + y) - f(y) = \phi(x)$. Thus it is easy to show that there is a constant $c$ such that if $f$ is $\frac{1}{8}$-close to a homomorphism $\phi$, then the above algorithm will output $\phi(x)$ with probability at least $1 - \beta$.

**4.2. Other algebraic functions.** It is natural to wonder what other classes of functions have robust characterizations as in the case of homomorphisms? There are many other classes of functions that are defined via characterizations that are local. The field of functional equations is concerned with the prototypical problem of characterizing the set of functions that satisfy a given set of properties (or functional equations). For

example, the class of functions of the form $f(x) = \tan Ax$ are characterized by the functional equation

$$f(x+y) = \frac{f(x)+f(y)}{1-f(x)f(y)} \quad \text{for all } x, y.$$

D'Alembert's equation

$$f(x+y)+f(x-y) = 2f(x)f(y) \quad \text{for all } x, y$$

characterizes the functions $0, \cos Ax, \cosh Ax$. Multivariate polynomials of total degree $d$ over $\mathbb{Z}_p$ for $p > md$ can be characterized by the equation

$$\sum_{i=0}^{d+1} \alpha_i f(\hat{x} + i\hat{h}) = 0 \quad \text{for all } \hat{x}, \hat{h} \in Z_p^m,$$

where $\alpha_i = (-1)^{i+1}\binom{d+1}{i}$. All of the above characterizations are known to be $(\varepsilon, \delta)$-robust for $\varepsilon$ and $\delta$ independent of the domain size (though for the case of polynomials, there is a polynomial dependence on the total degree $d$) thus showing that the corresponding properties are easily testable [36], [37]. A long series of works have given increasingly robust characterizations of functions that are low total degree polynomials (cf. [6], [32], [7], [34], [3], [29], [27]).

We note that all of these results can be extended to apply over domains that are subsets of infinite cyclic groups. They can further be extended to the case of computation with finite precision, which requires that one address the stability of functional equations [18], [30].

**Convolutions of distributions.** We now turn to a seemingly unrelated question about distributions that are close to their self-convolutions: Let $A = \{a_g \mid g \in G\}$ be a distribution on group $G$. The convolution of distributions $A$, $B$ is

$$C = A * B, \quad c_x = \sum_{\substack{y,z \in G \\ yz = x}} a_y b_z.$$

Let $A'$ be the *self-convolution* of $A$, $A * A$, i.e. $a'_x = \sum_{y,z \in G; yz=x} a_y a_z$. It is known that $A = A'$ exactly when $A$ is the uniform distribution over a subgroup of $G$. Suppose we know that $A$ is close to $A'$, can we say anything about $A$ in this case? Suppose $\text{dist}(A, A') = \frac{1}{2}\sum_{x \in G} |a_x - a'_x| \leq \varepsilon$ for small enough $\varepsilon$. Then [13] show that $A$ must be close to the uniform distribution over a subgroup of $G$. More precisely, in [13] it is shown that for a distribution $A$ over a group $G$, if $\text{dist}(A, A') = \frac{1}{2}\sum_{x \in G} |a_x - a'_x| \leq \varepsilon \leq 0.0273$, then there is a subgroup $H$ of $G$ such that $\text{dist}(A, U_H) \leq 5\varepsilon$, where $U_H$ is the uniform distribution over $H$ [13]. On the other hand, in [13] there is an example of a distribution $A$ such that $\text{dist}(A, A * A) \approx .1504$, but $A$ is not close to uniform on any subgroup of the domain.

A weaker version of this result, was used to prove a preliminary version of the homomorphism testing result in [14]. To give a hint of why one might consider the question on convolutions of distributions when investigating homomorphism testing, consider the distribution $A_f$ achieved by picking $x$ uniformly from $G$ and outputting $f(x)$. It is easy to see that the error probability $\delta$ in the homomorphism test is at least $\text{dist}(A_f, A_f * A_f)$. The other, more useful, direction is less obvious. In [13] it is shown that this question on distributions is "equivalent" in difficulty to homomorphism testing:

**Theorem 4.4.** *Let $G$, $H$ be finite groups. Assume that there is a parameter $\beta_0$ and function $\phi$ such that the following holds:*

> *For all distributions $A$ over group $G$, if $\text{dist}(A * A, A) \leq \beta \leq \beta_0$ then $A$ is $\phi(\beta)$-close to uniform over a subgroup of $G$.*

*Then, for any $f : G \to H$ and $\delta < \beta_0$ such that $1 - \delta = \Pr[f(x) * f(y) = f(x * y)]$, and $\phi(\delta) \leq 1/2$, we have that $f$ is $\phi(\delta)$-close to a homomorphism.*

## 5. Combinatorial objects

In 1996, Goldreich, Goldwasser and Ron [23] focused attention on the problem of testing various properties of graphs and other combinatorial objects. Their work introduced what is now referred to as the *dense graph model* of property testing. In this model, a graph on $n$ nodes is represented via an $n \times n$ adjacency matrix, where the $(i, j)$th entry of the matrix contains a 1 if the edge $(i, j)$ is present in the graph and a 0 otherwise. Two graphs $G$ and $H$ are $\varepsilon$-close if at most $\varepsilon n^2$ edges need to be modified (inserted or deleted) to turn $G$ into $H$. In [23], several graph properties were shown to be easily testable. In fact, as we shall soon see, the question of which graph properties are easily testable has led to a series of intriguing results.

One property that [23] consider is that of $k$-colorability – is it possible to assign one of $k$ colors to each of the nodes so that no pair of nodes that have an edge between them are assigned the same color? The property of $k$-colorability is NP-complete to determine – meaning, that though we know how to verify that a certain coloring is a valid $k$-coloring, we have no idea how to determine whether a graph has a $k$ coloring in time polynomial in the size of the graph. Somewhat surprisingly, $k$-colorability is easily testable, so we can distinguish $k$-colorable graphs from those that are $\varepsilon$-far from $k$-colorable in constant time. Thus we see that the efficiency of a property tester is not directly related to the complexity of deciding the property exactly.

Though the proof of correctness of the property tester for $k$-colorability is involved, the algorithm used to conduct the property test is easy to describe: It simply picks a constant sized random sample of the vertices, queries all the edges among this random sample and then outputs "pass" or "fail", according to whether the sample is

$k$-colorable. Since the sample is of constant size, the determination of whether the sample is $k$-colorable can be made in constant time.

Such algorithms that (1) pick a constant sized random sample of the vertices, (2) query all the edges among this random sample, and then (3) output "pass" or "fail" based on whether the subgraph has the property or not, are referred to as "natural algorithms". Modulo a technicality about how the final output decision is made, Goldreich and Trevisan [26] essentially show that for any graph property that is easily testable, the natural algorithm gives a property tester. Thus, *all* easily testable graph properties provably have easy-to-describe algorithms.

The work of [23] sparked a flurry of results in the dense graph model. A very interesting line of work was initiated in the work of Alon, Fischer, Krivelevich and Szegedy [2], in which they use the Szemerédi Regularity Lemma to show that the property of a graph being $H$-free (that is, the graph does not contain any copy of $H$ as a subgraph) is easily testable for any constant sized graph $H$.

Very recently, the above line of work culminated in the following amazing result: Alon and Shapira [5] have shown that one can *completely* characterize the classes of graph properties that are easily testable with 1-sided error in the dense graph model. Before describing their result, we make two definitions. A graph property $P$ is *hereditary* if it is closed under the removal of vertices (but not necessarily under the removal of edges). A graph property $P$ is *semi-hereditary* if there is a hereditary graph property $H$ such that (1) any graph satisfying $P$ also satisfies $H$ and (2) for any $\varepsilon > 0$, there is an $M(\varepsilon)$, such that any graph $G$ of size at least $M(\varepsilon)$ which is $\varepsilon$-far from satisfying $P$ does not satisfy $H$. The result of Alon and Shapira is then the following:

**Theorem 5.1.** *A graph property $P$ is easily testable with one-sided error if and only if $P$ is semi-hereditary.*

Hereditary graph properties include all monotone graph properties (including $k$-colorability and $H$-freeness), as well as other interesting non-monotone graph properties such as being a perfect, chordal, or interval graph. The techniques used by Alon and Shapira are quite involved, and are based on developing new variants of the Szemerédi Regularity Lemma. Previously in the literature, the "Regularity Lemma type" arguments were used to develop testers for graph properties that were characterized by a finite set of forbidden subgraphs. Here the set of forbidden subgraphs may be infinite, and they are forbidden as *induced* subgraphs.

Several interesting questions regarding easily testable graph properties remain. For example, because of the use of the Szemerédi Regularity Lemma, the upper bounds given by the previously mentioned results have a dependence on $1/\varepsilon$ that is enormous. It would be interesting to characterize which problems have property testers whose dependence on $1/\varepsilon$ is polynomial (cf. [1]).

There are many interesting properties that are not easily testable, but do have sublinear time property testers. For example, the graph isomorphism problem asks whether two graphs are identical under relabeling of the nodes. In [21], it is shown

that the property testing problem requires $\Omega(n)$ queries and that there is a property tester for this problem which uses $O(n^{5/4} \operatorname{polylog} n)$ queries, which is sublinear in the input size $n^2$.

The area of property testing has been very active, with a number of property testers devised for other models of graphs as well as other combinatorial objects. The testability of a problem is very sensitive to the model in which it is being tested. In contrast to the dense graph model, where $k$-colorability is easily testable, it is known that there are no sublinear time property testers for the $k$-colorability problem in models suitable for testing sparse graphs [15]. Property testers have also been studied in models of general graphs, and threshold-like behaviors have been found for the complexity of the testing problems in terms of the average degree of the graph [28], [4].

Property testers for combinatorial properties of matrices, strings, metric spaces and geometric objects have been devised. We refer the reader to the excellent surveys of Goldreich [22], Ron [35] and Fischer [19].

## 6. Testing properties of distributions

In a wide variety of settings, data is most naturally viewed as coming from a probability distribution. In order to effectively make use of such data, one must understand various properties of the underlying probability distribution. Some of these properties are "local" in nature, for example focusing on whether or not a specific domain element appears with large probability. Other properties have a rather "global" feel in the sense that they are a property of the distribution as a whole and not of a small subset of the domain elements. Unlike the case for local properties, it makes sense to characterize a distribution in terms of some meaningful distance measure to the closest distribution that has the global property. This yields a somewhat different model than the property testing model in terms of the assumption on how the data is presented for here we do not assume that an explicit description of the distribution is given.

In the following, we assume that there is an underlying distribution from which the testing algorithm receives independent identically distributed (iid) samples. The complexity of the algorithm is measured in terms of the number of samples required in order to produce a meaningful answer (the sample complexity). As mentioned in the introduction, it is a classical result from the theory of sampling that one can, in time independent of the size of the data, determine a good estimate of the average value of a list of numbers of bounded magnitude. However, more recently, properties such as closeness between two distributions, closeness to an explicitly given distribution, independence, and high entropy, have been studied in this model [24], [10], [9]. For many properties, well-known statistical techniques, such as the $\chi^2$-test or the straightforward use of Chernoff bounds, have sample complexities that are at least linear in the size of the support of the underlying probability distribution. In contrast, there are algorithms whose sample complexity is sublinear in the size of the support

for various properties of distributions.

We mention one illustrative example: Given samples of a distribution $X$ on $[n]$, for example all the previous winners of the lottery, how can one tell whether $X$ is close to uniform? We will measure closeness in terms of the $L_2$ norm, i.e., letting $X(i)$ denote the probability that $X$ assigns to $i$,

$$\|X\|_2 = \sum_{i\in[n]} (X(i) - 1/n)^2.$$

Goldreich and Ron [24] note that since

$$\sum_{i\in[n]} (X(i) - 1/n)^2 = \sum_{i\in[n]} X(i)^2 - 1/n,$$

it is enough to estimate the collision probability. They then show that this can be done by considering only $O(\sqrt{n})$ samples and counting the number of pairs that are the same. By bounding the variance of their estimator, they obtain the following:

**Theorem 6.1** ([24]). *There is an algorithm that, given a distribution $X$ on $[n]$ via a generation oracle, approximates $\|X\|_2$ to within a multiplicative factor of $(1 \pm \varepsilon)$ using $O(\sqrt{n}/\varepsilon^2)$ samples, with constant probability.*

Such techniques are very useful for achieving sublinear time algorithms for testing whether distributions satisfy several other global properties. For example, for the properties of closeness of two arbitrary distributions [10], independence of a joint distribution [9], high entropy [8], and monotonicity of the probability density function (when the distribution is over a totally ordered domain) [11], the testing problem can be reduced to the problem of testing the near-uniformity of the distribution on various subdomains.

## 7. Some final comments

We have seen several contexts in which one can test properties in sublinear time. The study of sublinear time algorithms has led to a new understanding of many problems that had already been well-studied. Though we have mentioned only property testing problems in this survey, other, more traditional, types of approximations are achievable in sublinear time. Such algorithms have been used to design very fast approximation algorithms for graph problems and for string compressibility problems (cf. [23], [10], [33]). Some of these algorithms have even resulted in better linear time approximation algorithms than what was previously known.

Probabilistically Checkable Proof Systems (PCPs) can be thought of as a way to write down a proof so that another person can verify it by viewing only a constant number of locations (cf. [6]). PCPs can thus be viewed as a type of robust characterization and their verification is a sublinear algorithm. More interestingly, property

testers for homomorphisms and low degree polynomials are used as key ingredients in the construction of Probabilistically Checkable Proof Systems.

As we have seen, the study of sublinear algorithms gives a new perspective that has yielded insights to other areas of theoretical computer science. Much still remains to be understood about the scope of sublinear time algorithms, and we expect that this understanding will lead to further insights.

# Pseudorandomness and combinatorial constructions

Luca Trevisan*

**Abstract.** In combinatorics, the probabilistic method is a very powerful tool to prove the existence of combinatorial objects with interesting and useful properties. Explicit constructions of objects with such properties are often very difficult, or unknown. In computer science, probabilistic algorithms are sometimes simpler and more efficient than the best known deterministic algorithms for the same problem.

Despite this evidence for the power of random choices, the computational theory of pseudorandomness shows that, under certain complexity-theoretic assumptions, every probabilistic algorithm has an efficient deterministic simulation and a large class of applications of the probabilistic method can be converted into explicit constructions.

In this survey paper we describe connections between the conditional "derandomization" results of the computational theory of pseudorandomness and unconditional explicit constructions of certain combinatorial objects such as error-correcting codes and "randomness extractors."

**Keywords.** Computational complexity, pseudorandomness, derandomization, randomness extraction.

## 1. Introduction

**1.1. The probabilistic method in combinatorics.** In extremal combinatorics, the *probabilistic method* is the following approach to proving existence of objects with certain properties: prove that a random object has the property with positive probability. This simple idea has been amazingly successful, and it gives the best known bounds for most problems in extremal combinatorics. The idea was introduced (and, later, greatly developed) by Paul Erdős [18], who originally applied it to the following question: define $R(k, k)$ to be the minimum value $n$ such that every graph on $n$ vertices has either an independent set of size at least $k$ or a clique of size at least $k$.[1] It was known that $R(k, k)$ is finite and that it is at most $4^k$, and the question was to prove a lower bound. Erdős proved that a random graph with $2^{k/2}$ vertices has a positive probability of having no clique and no independent set larger than $k$, and so

*The author is supported in part by NSF grant CCF 0515231.

[1] Here by "graph" we mean an undirected graph, that is, a pair $G = (V, E)$ where $V$ is a finite set of *vertices* and $E$ is a set of pairs of elements of $E$, called *edges*. A clique in a graph $G = (V, E)$ is a set $C \subseteq V$ of vertices such that $\{u, v\} \in E$ for every two vertices $u, v \in C$. An independent set is a set $I \subseteq V$ of vertices such that $\{u, v\} \notin E$ for every two vertices $u, v \in I$.

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

$R(k,k) \geq 2^{k/2}$. The method, of course, gives no indication of how to actually construct a large graph with no small clique and no small independent set. Remarkably, in the past 60 years, there has been no asymptotic improvement to Erdős's lower bound and, perhaps more significantly, the best *explicit construction* of a graph without a clique of size $k$ and without an independent set of size $k$ has only about $k^{\log k}$ vertices [20], a bound that has not been improved in 25 years.

Shannon [59] independently applied the same idea to prove the existence of encoding schemes that can optimally correct from errors in a noisy channel and optimally compress data. The entire field of information theory arose from the challenge of turning Shannon's non-constructive results into algorithmic encoding and decoding schemes. We will return to the problem of encodings for noisy channels in Section 2. Around the same time, Shannon [60] applied the probabilistic method to prove the existence of boolean functions of exponential circuit complexity (see Section 4). Proving that certain specific boolean functions (for example, satisfiability of boolean formulae or 3-colorability of graphs) require exponential size circuits is a fundamental open problem in computational complexity theory, and little progress has been made so far.

The probabilistic method has found countless applications in the past 60 years, and many of them are surveyed in the famous book by Alon and Spencer [4].

For most problems in extremal combinatorics, as well as in information theory and complexity theory, probabilistic methods give the best known bound, and explicit constructions either give much worse bounds, or they give comparable bounds but at the cost of technical tours de force.

**1.2. Probabilistic methods in computer science.** In computer science, an important discovery of the late 1970s was the power of *probabilistic algorithms*. The most famous (and useful) of such algorithms are probably the polynomial time probabilistic algorithms for testing primality of integers [65], [47]. In these algorithms one looks for a "certificate" that a given number $n$ is composite; such a certificate could be for example an integer $a$ such that $a^n \not\equiv a \pmod{n}$, or four distinct square roots $\pmod{n}$ of the same integer. Rabin, Solovay and Strassen [65], [47] proved that there is a good chance of finding such certificates just by picking them at random, even though no efficient method to deterministically construct them was known.[2] Two other important and influential algorithms were discovered around the same time: an algorithm to test if two implicitly represented multivariate polynomials are identical [85], [56] (evaluate them at a random point chosen from a domain larger than the degree) and an algorithm to check if two vertices in a graph are connected by a path [2] (start a random walk at the first vertex, and see if the second vertex is reached after a bounded number of steps).[3]

[2] Note the similarity with the probabilistic method.

[3] The algorithm of Aleliunas et al. [2] broke new grounds in terms of *memory* use, not running time. It was already known that the Depth-First-Search algorithm could be used to solve the problem using linear time and a *linear* amount of memory. The random walk algorithm, however, needs only $O(\log |V|)$ bits of memory, and

A different type of probabilistic algorithms was developed starting in the late 1980s with the work of Sinclair and Jerrum [61]. These algorithms solve approximate "counting" problems, where one wants to know the number of solutions that satisfy a given set of combinatorial constraints. For example, given a bipartite graph, one would like to know, at least approximately, how many perfect matchings there are.[4] Sinclair and Jerrum introduced an approach based on a reduction to the problem of approximately sampling from the uniform distribution of all possible solutions. Since the latter problem involves randomness in its very definition, this approach inevitably leads to probabilistic algorithms.

**1.3. The computational theory of pseudorandomness.** In light of such algorithmic results, it was initially conjectured that probabilistic algorithms are strictly more powerful than deterministic ones and that, for example, there exist problems that can be solved probabilistically in polynomial time but that cannot be solved in polynomial time using deterministic algorithms.

This belief has been overturned by developments in the computational theory of pseudorandomness. The theory was initiated by Blum [9], Goldwasser and Micali [22], and Yao [84], with the motivation of providing sound foundations for cryptography. From the very beginning, Yao [84] realized that the theory also provides conditional *derandomization* results, that is, theorems of the form

> "if assumption X is true, then every problem that can be solved by a probabilistic polynomial time algorithm can also be solved by a deterministic algorithm of running time Y."

Yao showed that we can take X to be "there is no polynomial time algorithm that on input a random integer finds its prime factorization"[5] and Y to be "time $2^{n^\varepsilon}$ for every $\varepsilon > 0$."

An important project in complexity theory in the 1980s and 1990s was to strengthen Y to be "polynomial time" with a plausible X. The goal was achieved 1997 in a landmark paper by Impagliazzo and Wigderson [31], building on a considerable body of previous work.

At a very high level, the Impagliazzo–Wigderson result is proved in two steps. The first step (which is the new contribution of [31]) is the proof that an assumption about the worst-case complexity of certain problems implies a seemingly stronger assumption about the average-case complexity of those problems. A result of this kind is called an *amplification of hardness* result, because it "amplifies" a worst-case hardness assumption to an average-case one. The second step, already established

exponential improvement.

[4] A bipartite graph is a triple $G = (U, V, E)$ where $U$, $V$ are disjoint sets of vertices and $E \subseteq U \times V$ is a set of edges. A perfect matching is a subset $M \subseteq E$ such that for every $u \in U$ there is precisely one $v \in V$ such that $(u, v) \in M$, and vice versa.

[5] More generally, Yao showed that X can be "one-way permutations exist," see 5 for more details. The assumption about integer factorization implies the existence of one-way permutations, provided that we restrict ourselves to "Blum integers."

ten years earlier by Nisan and Wigderson [44], is the proof that the average-case assumption suffices to construct a certain very strong pseudorandom generator, and that the pseudorandom generator suffices to simulate deterministically in polynomial time every polynomial time probabilistic algorithm.

In conclusion, assuming the truth of a plausible complexity-theoretic assumption, every polynomial time probabilistic algorithm can be "derandomized," including the approximation algorithms based on the method of Sinclair and Jerrum. Furthermore, under the same assumption, a large class of applications of the probabilistic method in combinatorics can be turned into explicit constructions. We give some more details about the Impagliazzo–Wigderson Theorem in Section 6. The reader is also referred to the excellent survey paper of Impagliazzo [28] in the proceedings of the last ICM.

It is remarkable that many of the "predictions" coming from this theory have been recently validated unconditionally: Agrawal et al. [1] have developed a deterministic polynomial time algorithm for testing primality and Reingold [53] has developed a deterministic $O(\log n)$ memory algorithm for undirected graph connectivity. One can read about such developments elsewhere in these proceedings.

Here is an example of a question that is still open and that has a positive answer under the complexity-theoretic assumption used in the Impagliazzo–Wigderson work:

- Is there a deterministic algorithm that, on input an integer $n$, runs in time polynomial in $\log n$ and return a prime between $n$ and $2n$?

**1.4. When randomness is necessary.** Suppose that, in a distant future, someone proves the assumption used in the Impagliazzo–Wigderson work, so that we finally have an unconditional polynomial time derandomization of all probabilistic algorithms. Would this be the end of the use of randomness in computer science? The answer is no, for at least two reasons.

One reason is that such derandomization would probably not be practical. At a broad qualitative level, we consider polynomial-time algorithms as "efficient" and super-polynomial-time algorithms as "inefficient," and then such a result would establish the deep fact that "efficient" probabilistic algorithms and "efficient" deterministic algorithms have the same power. If the derandomization, however, causes a considerable (albeit polynomial) slow-down, and if it turns a practical probabilistic algorithm into an impractical deterministic one, then the probabilistic algorithm will remain the best choice in applications.

A more fundamental reason is that there are several applications in computer science where the use of randomness is *unavoidable*. For example, consider the task of designing a secure cryptographic protocol in a setting where all parties behave deterministically.

These observations lead us to consider the problem of generating randomness to be used in probabilistic algorithms, cryptographic protocols, and so on. Such generation begins by measuring a physical phenomenon that is assumed to be unpredictable (such as a sequence of physical coin flips) and that will be called a *random source* in

the following. Typically, one has access to random sources of very poor quality, and converting such measurements into a sequence of independent and unbiased random bits is a difficult problem. In Section 8 we discuss various approaches and impossibility results about this problem, leading to the definition of *seeded randomness extractor* due to Nisan and Zuckerman [45], [86].

Seeded randomness extractors have an amazing number of applications in computer science, often completely unrelated to the original motivation of extracting random bits from physical sources. They are related to hash functions, to pseudorandom graphs, to error-correcting codes and they are useful in complexity theory to prove, among other things, negative results for the approximability of optimization problems.

Ironically, the problem of generating high-quality random bits for cryptographic application is not satisfactorily solved by seeded randomness extractors (even though it was the original motivation for the research program that led to their definition). *Seedless* randomness extractors are needed for such application, and their theory is still being developed.

**1.5. Connections.** So far, we have discussed (i) the power of probabilistic methods, (ii) the *conditional* results proving that all probabilistic algorithms have a polynomial-time derandomization under complexity assumption, and (iii) the use of seeded randomness extractors to *unconditionally* run probabilistic algorithms in a setting in which only a weak source of randomness is available.

In Section 8 we describe a recently discovered *connection* between (ii) and (iii) and, more generally, between *conditional* results proved in the computational theory of pseudorandomness and *unconditional* explicit constructions of combinatorial objects.

One connection is between error-correcting codes and "hardness amplification" results. This connection has led to the application of coding-theoretic techniques in the study of average-case complexity. It is also possible to use complexity-theoretic techniques to build error-correcting codes, but so far this approach has not been competitive with previously known coding-theoretic techniques.

The second connection is between pseudorandom generators and seeded randomness extractors. This connection has led to improvements in both settings.

Various impossibility results are known for error-correcting codes and randomness extractors. Via these connections, they imply impossibility results for hardness amplification and conditional derandomization. In Section 7 we discuss approaches to sidestep these negative results.

## 2. Pseudorandom objects: codes and graphs

In this section we introduce two examples of very useful combinatorial objects whose existence easily follows from the probabilistic method: error-correcting codes and expander graphs. Explicit constructions of such objects are also known.

**2.1. Error-correcting codes.** Consider the process of picking a random set $S \subseteq \{0,1\}^n$ of size $2^k$, $k < n$. If, say, $k = n/2$, then it is easy to show that there is an absolute constant $\delta > 0$ such that, with high probability, every two elements $u, v \in S$ differ in at least $\delta n$ coordinates. By a more careful estimate, we can also see that there is an absolute constant $c$ such that, for every $\varepsilon > 0$, it is likely that every two elements of $S$ differ in at least $(1/2 - \varepsilon)n$ coordinates with high probability, provided $k \leq c\varepsilon^2 n$. For reasons that will be clear shortly, let us change our perspective slightly, and consider the (equivalent) process of picking a random injective function $C\colon \{0,1\}^k \to \{0,1\}^n$: clearly the same bounds apply.

For two strings $u, v \in \{0,1\}^n$, the Hamming distance between $u$ and $v$ (denoted $d_H(u,v)$) is the number of coordinates where $u$ and $v$ differ, that is

$$d_H(u,v) := |\{i : u_i \neq v_i\}|. \tag{1}$$

**Definition 2.1** (Error-correcting code). We say that $C\colon \{0,1\}^k \to \{0,1\}^n$ is an $(n,k,d)$-*code* if $d_H(C(x), C(y)) \geq d$ for every two distinct $x, y \in C$.

This concept is due to Hamming [25]. Error-correcting codes are motivated by the following scenario. Suppose we, the *sender*, have a $k$-bit message $M \in \{0,1\}^k$ that we want to transmit to a *receiver* using an unreliable *channel* that introduces errors, and suppose we have an $(n,k,d)$-code $C$. Then we can compute $c = C(M)$ and transmit $c$ over the channel. The receiver gets a string $c'$, which is a corrupted version of $c$, and looks for the message $M'$ that minimizes $d_H(C(M'), c')$. If the channel introduces fewer than $d/2$ errors, then the receiver correctly reconstructs $M$.[6]

Keeping this application in mind, for every given $k$, we would like to construct $(n,k,d)$-codes where $d$ is as large as possible (because then the receiver can tolerate more errors) and $n$ is as small as possible (so that we do not have to communicate a very long encoding). Furthermore, we would like $C$ and the decoding procedure run by the receiver to be computable by efficient algorithms.

One trade-off between the parameters is that $\frac{d}{n} \leq \frac{1}{2} + o_k(1)$. Keeping in mind that the number of errors that can be corrected is at most $d/2$, this means that the receiver can correctly reconstruct the message only if the number of errors is at most $\left(\frac{1}{4} + o_k(1)\right) n$.

It is possible to do better if we are willing to settle for the notion of "list-decodability," introduced by Elias [17].

**Definition 2.2** (List-decodable code). We say that $C\colon \{0,1\}^k \to \{0,1\}^n$ is $(L,\delta)$-*list decodable* if for every $u \in \{0,1\}^n$,

$$|\{x \in \{0,1\}^k : d_H(C(x), u) \leq \delta n\}| \leq L.$$

[6] It is also easy to see that this analysis is tight. If there are two messages $M$, $M'$ such that $d_H(C(M), C(M')) = d$ and we send $M$, then it is possible that even a channel that introduces only $d/2$ errors can fool the receiver into thinking that we sent $M'$.

Here the idea is that we send, as before, the encoding $C(M)$ of a message $M$. The receiver gets a string $u$ and computes the *list* of all possible messages $M'$ such that $d_H(C(x), u) \leq \delta n$. If $C$ is an $(L, \delta)$-code, then the list is guaranteed to be of length at most $L$, and if the channel introduces at most $\delta n$ errors then our message is guaranteed to be in the list.

Using the probabilistic method, it is easy to show the existence of $(L, 1/2-\varepsilon)$-list decodable codes $C\colon \{0,1\}^k \to \{0,1\}^n$ for every $k$ and $\varepsilon$, where $n = O(k\varepsilon^{-2})$ and $L = O(\varepsilon^{-2})$. It was also known how to define *efficiently encodable* codes with good (but not optimal) parameters. It took, however, 40 years until Sudan [66] defined the first *efficient list-decoding* algorithm for such codes. Sudan's algorithm suffices to define $(\varepsilon^{-O(1)}, 1/2-\varepsilon)$-list decodable codes $C\colon \{0,1\}^k \to \{0,1\}^n$ with $n = (k/\varepsilon)^{O(1)}$ for every $k$, $\varepsilon$, and the codes are encodable and list-decodable in time polynomial in $n$. This means that even if the channel introduces close to $n/2$ errors, it is still possible for the receiver to gain considerable information about the message. (Namely, the fact that the message is one out of a small list of possibilities.) Other list-decoding algorithms are now known, but they are beyond the scope of this survey. See Sudan's survey [67], Guruswami's thesis [23] and two recent breakthrough papers [24], [46].

**2.2. Expander graphs.** Consider the process of picking at random a graph according to the $G_{n,\frac{1}{2}}$ distribution.(The $G_{n,\frac{1}{2}}$ distribution is the uniform distribution over the set of $2^{\binom{n}{2}}$ graphs over $n$ vertices.) A simple calculation shows that for every two disjoint sets of vertices $A$, $B$ there are $\left(\frac{1}{2} \pm o_n(1)\right)|A||B|$ edges with one endpoint in $A$ and one endpoint in $B$. Chung, Graham and Wilson [15] call a family of graphs satisfying the above properties a family of *quasi-random* graphs, and prove that six alternative definitions of quasi-randomness are all equivalent. Explicit constructions of quasi-random graphs are known, and the notion has several applications in combinatorics. (See the recent survey paper by Krivelevich and Sudakov [37].) Consider now a process where we randomly generate an $n$-vertex graph where every vertex has degree at most $d$ (think of $d$ as a fixed constant and $n$ as a parameter). For example, consider the process of picking $d$ perfect matchings and then taking their union. Then it is possible to show that for every two disjoint sets of vertices $A$, $B$ there are $(1 \pm o_{n,d}(1))d\frac{|A||B|}{n}$ edges with one endpoint in $A$ and one endpoint in $B$. (Families of) graphs with this property are called *expanders*, and they have several applications in computer science. To gain a sense of their usefulness, imagine that an expander models a communication network and note that if $o(dn)$ edges are deleted, the graph still has a connected component with $(1-o(1))n$ vertices. Furthermore, expander graphs have several other interesting properties: they have small diameter, it is possible to find several short edge-disjoint paths between any two vertices, and so on. There are other possible definitions of expanders, which are related but not equivalent. In one possible (and very useful) definition, expansion is measured in terms of the *eigenvalue gap* of the *adjacency matrix* of the graph (see e.g. the discussion in [37]). For this definition, Lubotzky, Phillips and Sarnak [41] provide an optimal explicit construction. Another possible measure is the *edge expansion* of the graph. Optimal

explicit constructions for this measure are not known, but considerable progress is made in [13], [3].

## 3. Randomness extractor

Randomness extractors are procedures originally designed to solve the problem of generating truly random bits. As we will see, randomness extractors can be seen as a sort of pseudorandom graphs, they can be constructed using techniques from the field of pseudorandomness, and they are tightly related to constructions error-correcting codes, expanders and other random-like combinatorial objects.

**3.1. Generating random bits.** In order to generate random bits in practice, one starts by measuring a physical phenomenon that is assumed to contain randomness.[7] For example, in many computer systems one starts by collecting statistics on the user's keystrokes or mouse movement, or on the latency time of disk access, and so on. This raw data, which is assumed to contain some amount of entropy, is then passed to a "hash function," and the output of the function is assumed to be a sequence of truly random bits. Such systems, widely used in practice, are typically not validated by any rigorous analysis.

In a mathematical modeling of this situation, we have a random variable $X$ representing our physical measurement, ranging, say, over $\{0,1\}^n$. We would like to construct a function $\mathrm{Ext}\colon \{0,1\}^n \to \{0,1\}^m$ such that, by making as little assumptions on $X$ as possible, we can prove that $\mathrm{Ext}(X)$ is distributed uniformly over $\{0,1\}^m$, or at least it is approximately so.

Von Neumann [82] studied a version of this problem where $X$ is a sequence of independent and identically distributed biased coin tosses. The independence assumption is crucially used. The general problem was extensively studied in computer science in the 1980s [55], [80], [79], [78], [14], [16]. Notably, the goal was to define a single function Ext that would work for as large as possible a class of distributions $X$. An early conclusion was that the extraction problem is impossible [55], as defined above, even if just very weak forms of dependencies between different bits are allowed in the distribution of $X$. Two approaches have been considered to circumvent this impossibility.

1. One approach is to consider a model with a *small* number of mutually independent random variables $X_1, \ldots, X_k$, each satisfying weak randomness requirements. This line of work, initiated in [55], [80], [14], saw no progress for a long time, until recent work by Barak et al. [7] made such progress possible by a breakthrough in additive combinatorics [12], [36]. This is now a very active area of research [8], [53], [11], [87], [48] with connections to other areas of combinatorics.

[7] We will not get into the physical and philosophical problems raised by such assumption.

2. The other approach, initiated in [79], is to stick to the model of a single sample $X$ and to consider the following question: suppose we have a randomized algorithm $A$ (that is correct with high probability given the ability to make truly random choices) and suppose we have an input $x$. Can we efficiently find what is the most probable output of $A(x)$?

**3.2. The definition of randomness extractors.** To formalize approach (2) it is convenient to think of a probabilistic algorithm $A(\cdot, \cdot)$ as having two inputs: a "random" input $r$ and a "regular" input $I$. We say that "$A$ computes a function $f$ with high probability" if, for every $I$,

$$\mathbb{P}[A(r, I) = f(I)] \geq .9$$

where the probability is taken with respect to the uniform distribution over bit strings $r$ of the proper length.[8]

Let $U_n$ denote a random variable uniformly distributed over $\{0, 1\}^n$.

Suppose that our algorithm $A$ requires $m$ truly random bits to process a given input $x$. Furthermore, suppose that we can define a function $\mathrm{Ext}\colon \{0, 1\}^n \times \{0, 1\}^d \to \{0, 1\}^m$ such that if $X$ is our physical source and $U_d$ is uniformly distributed over $\{0, 1\}^d$ then $\mathrm{Ext}(X, U_d)$ is uniformly distributed over $\{0, 1\}^m$. Here is a way to simulate $A(\cdot)$ using $X$: (i) get a sample $x \sim X$, (ii) for every $s \in \{0, 1\}^d$, compute $a_s := A(\mathrm{Ext}(x, s), I)$, (iii) output the most common value among the $a_s$.

It is now easy to show that the above algorithm computes $f(I)$ with probability at least .8, over the choice of $X$. This is because $\mathbb{P}[A(\mathrm{Ext}(U_d, X), I) = f(I)] \geq .9$ and so

$$\mathop{\mathbb{P}}_{X}\Big[\mathop{\mathbb{P}}_{U_d}[A(\mathrm{Ext}(U_d, X), I) = f(I)] > \tfrac{1}{2}\Big] \geq .8. \tag{2}$$

The running time of our simulation of $A$ is $2^d$ times the running time of $A$, which is polynomial in the running time of $A$ provided that $d$ is logarithmic.

For this reasoning to work it is not necessary that $\mathrm{Ext}(X, U_d)$ be distributed *exactly* uniformly, but it is enough if it approximates the uniform distribution in an appropriate technical sense. If $X$ and $Y$ are two random variables taking values in $\Omega$, then we define their *variational distance* (also called *statistical distance*) as

$$\|X - Y\|_{\mathrm{SD}} := \max_{T \subseteq \Omega} |\,\mathbb{P}[X \in T] - \mathbb{P}[Y \in T]|. \tag{3}$$

We will sometimes call sets $T \subseteq \Omega$ *statistical tests*. If $\|X - Y\|_{\mathrm{SD}} \leq \varepsilon$ then we say that $X$ is $\varepsilon$-close to $Y$.

We say that $\mathrm{Ext}\colon \{0, 1\}^n \to \{0, 1\}^d \to \{0, 1\}^m$ is a *seeded extractor* for a distribution $X$ with *error parameter* $\varepsilon$ if $\mathrm{Ext}(X, U_d)$ is $\varepsilon$-close to $U_m$.

[8] The reader may find .9 to be a poor formalization of the notion of "with *high* probability," but it is easy to reduce the error probability at the cost of a moderate increase of the running time.

Vazirani and Vazirani [79] provided extractors for a certain class of distributions. (Their terminology was different.) Zuckerman [86] was the first to show that extractors exist for a very general class of distributions. Define the min-entropy of $X$ as $H_\infty(X) := \min_a \log_2 \frac{1}{\mathbb{P}[X=a]}$. If $H_\infty(X) \geq k$, then we say that $X$ is a $k$-source.

**Definition 3.1.** A function $\mathrm{Ext}\colon \{0,1\}^n \to \{0,1\}^d \to \{0,1\}^m$ is a $(k,\varepsilon)$ *seeded extractor* if $\mathrm{Ext}(X, U_d)$ is $\varepsilon$-close to $U_m$ for every $k$-source $X$.

The definition is implicit in [86]. The term extractor was coined in [45]. The term "seeded" refer to the truly random input of length $d$, which is called a *seed*. From now, we will refer to seeded extractors as simply "extractors."

Let $\mathrm{Ext}\colon \{0,1\}^n \times \{0,1\}^d \to \{0,1\}^m$ be a $(k,\varepsilon)$-extractor. Construct a bipartite graph $G = ([N],[M],E)$ with $N = 2^n$ vertices on the left, $M = 2^m$ vertices on the right. Connect two vertices $u, v$ if there is an $s$ that $v = \mathrm{Ext}(u,s)$. Then if we pick any subset $S \subseteq [N]$ on the left and any subset $T \subseteq [M]$ on the right, the number of edges is $|S| \cdot 2^d \cdot |T|/2^m$ plus or minus $\varepsilon|S|2^d$, provided $|S| \geq 2^k$. This is similar to one of the definitions of expander. Zuckerman and Wigderson [83] prove that one can derive expanders with very strong "edge expansion" from extractors.

Radakrishnan and Ta-Shma show that, in every extractor, $d \geq \log(n-k) + 2\log(1/\varepsilon) - O(1)$ and that $m \leq k + d - O(1)$. Non-constructively, one can show that such bounds are achievable up to the additive constant factor, but explicit constructions are difficult. We will discuss explicit constructions later.

**3.3. Applications.** Randomness extractors have several applications, some of which are described below. See the tutorial by Salil Vadhan [76] and the survey by Ronen Shaltiel [57] for more examples and a broader discussion.

**Simulation of randomized algorithms.** Suppose we have a randomized algorithm $A$ that on input $I$ computes $f(I)$ with probability, say, .9, and suppose that Ext is a $(k', 1/4)$-extractor and that $X$ is a $k$-source. As before, let us sample $x \sim X$ and compute $A(\mathrm{Ext}(x,s), I)$ for every $s$ and output the majority value. Let $B$ be the set of $x$ such that the algorithm fails. If $|B| \geq 2^{k'}$, then consider a random variable $Y$ uniformly distributed over $B$. It has entropy $k$, so $\mathrm{Ext}(Y, U_d)$ should be $1/4$-close to uniform. Consider the statistical test $T$ defined as

$$T := \{r : A(r,I)\} = f(I)\}. \tag{4}$$

Then $\mathbb{P}[U_n \in T] \geq .9$ by assumption and $\mathbb{P}[\mathrm{Ext}(Y, U_d) \in T] \leq 1/2$ by construction. This would contradict Ext being an extractor. We then conclude that $|B| \leq 2^{k'}$, and so the probability that our algorithm fails is at most $\mathbb{P}[X \in B] \leq |B|/2^k \leq 2^{k'-k}$.

This is very useful even in a setting in which we assume access to a perfect random source. In such a case, by using $n$ truly random bits we achieve an error probability that is only $2^{k'-n}$. Note that, in order to achieve the same error probability by running the algorithm several times independently we would have used $O((n-k')\cdot m)$ random bits instead of $n$.

**Other applications.** Randomness extractors are also very useful in settings where we assume a fully random distribution, say, over $n$ bits, that is unknown to us, except for some partial information of entropy at most $n - k$ bits.

Then the distribution of the unknown string *conditioned on our knowledge* still has entropy at least $k$. If an extractor is applied to the unknown string, then the output of the extractor will be uniformly distributed even conditioned on our knowledge. In other words, our knowledge in useless in gaining any information about the output of the extractor.

This approach is used in the cryptographic settings of *privacy amplification* and *everlasting security* and in the design of pseudorandom generators for space-bounded algorithms. See [39], [77] and the references therein for the application to everlasting security and [45], [30], [51] for the application to pseudorandom generators.

## 4. Circuit complexity

In order to discuss the computational approach to pseudorandomness we need to define a measure of efficiency for algorithms. We will informally talk about the "running time" of an algorithm on a given input without giving a specific definition. The reader can think of it as the number of elementary operations performed by an implementation of the algorithm on a computer. A more formal definition would be the number of steps in a Turing machine implementation of the algorithm. (See e.g. [64] for a definition of Turing machine.)

We say that a set $L \subseteq \{0,1\}^*$ is *decidable* in time $t(n)$ if there is an algorithm that on input $x \in \{0,1\}^n$ decides in time $\leq t(n)$ whether $x \in L$.

We are also interested in a more "concrete" measure of complexity, called *circuit complexity*. For integers $n$ and $i \leq n$, define the set $P_{i,n} := \{(a_1, \ldots, a_n) \in \{0,1\}^n : a_i = 1\}$. We say that a set $S \subseteq \{0,1\}^n$ has a *circuit of size* $K$ if there is a sequence of sets $S_1, \ldots, S_K$ such that: (i) $S_K = S$ and (ii) each $S_j$ is either a set $P_{i,n}$, or it is the complement of a set $S_h$, $h < j$, or it is the union $S_h \cup S_\ell$ of two sets, with $h, \ell < j$ or it is the intersection $S_h \cap S_\ell$ of two sets, with $h, k < j$. We say that a function $f : \{0,1\}^n \to \{0,1\}$ has a circuit of size $K$ if it is the characteristic function of a set that has a circuit of size $K$.

The *circuit complexity* of a set $S$ is the minimum $K$ such that $S$ has a circuit of size $K$. (Similarly for boolean functions.)

It is easy to see that there are subsets of $\{0,1\}^n$ whose circuit complexity is at least $c\frac{2^n}{n}$ for some constant $c > 0$: if a set has circuit complexity at most $K$, then it can be described by using only $O(K \log K)$ bits, and so there are $2^{O(K \log K)}$ sets of circuit complexity at most $K$. If this number is less than $2^{2^n}$ then there exists a set of circuit complexity larger than $K$. Indeed, by the same argument, a random set has circuit complexity at least $c\frac{2^n}{n}$ with very high probability.

If $L \subseteq \{0,1\}^*$ is a set decidable in time $t(n)$, then for every $n$ there is a circuit

of size $O((t(n))^2)$ for $L \cap \{0,1\}^n$. This implies that in order to prove lower bounds on the running time of algorithms for a given decision problem it is enough to prove lower bounds for the circuit complexity of finite fragments of it.[9]

So far there has been very little success in proving circuit complexity lower bounds for "explicit sets," such as sets in NP. The strongest known lower bound is $5n$ [38], [32], and even an $n \log n$ lower bound is considered hopelessly out of reach of current techniques.

This is perhaps surprising given the simplicity of the definition of circuit complexity. The definition looks like a finite version of the definition of complexity for Borel sets, and one may hope that one could transfer techniques from topology to this setting. Sipser describes this idea in [62], [63], but, unfortunately, so far it has not led to any lower bound for general circuits.

Complexity theorists' failure to prove strong circuit lower bounds is partly explained by a famous paper by Razborov and Rudich [52]. They describe a general class of approaches to lower bounds that they call "natural proofs." Razborov and Rudich show that all known methods to prove lower bounds for restricted classes of circuits yield natural proofs, but that (under certain complexity-theoretic assumptions) natural proofs cannot prove lower bounds for general circuits. The complexity theoretic assumption is itself about circuit lower bounds, and it is used to construct certain pseudorandom generators. The pseudorandom generators, in turn, imply the impossibility result. Somewhat inaccurately, the Razborov–Rudich result can be summarized as:

*Circuit lower bounds are difficult to prove because they are true.*

## 5. Pseudorandom generators and their application to derandomization

Informally, a pseudorandom generator is an efficiently computable map $G\colon \{0,1\}^t \to \{0,1\}^m$, where $m$ is much bigger than $t$, such that, for a uniformly selected $x \in \{0,1\}^t$, the distribution $G(x)$ is pseudorandom, that is, it "looks like" the uniform distribution over $\{0,1\}^m$. We begin by describing how to formalize the notion of a distribution "looking like" the uniform distribution, and, more generally, the notion of two distributions "looking like" one other.

Recall that we use $U_n$ to denote a random variable that is uniformly distributed in $\{0,1\}^n$.

Ideally, we would like to say that $G(\cdot)$ is a good pseudorandom generator if $G(U_t)$ and $U_m$ are close in statistical distance. Then, as we already discussed in Section 3, every application in which $m$ truly random bits are needed could be realized using the output of the generator (with a small increase in the probability of error). Unfortunately, this is too strong a definition: consider the statistical test $T$ defined to be the set of all possible outputs of $G$. Then $\mathbb{P}[G(U_t) \in T] = 1$ but $\mathbb{P}[U_m \in T] \leq 2^{t-m}$.

[9] The converse is not true: one can have undecidable sets of bounded circuit complexity.

The great idea that came from the work of Blum, Goldwasser, Micali and Yao in 1982 ([9], [22], [84]) was to modify the notion of statistical distance by considering only *efficiently computable* statistical tests.

**Definition 5.1** (Computational indistinguishability). Two distributions $\mu_X$ and $\mu_Y$ over $\{0,1\}^m$ are $(K,\varepsilon)$-*indistinguishable* if for every set $T \subseteq \{0,1\}^m$ of circuit complexity at most $K$,

$$\Big| \mathop{\mathbb{P}}_{x\sim\mu_X}[x \in T] - \mathop{\mathbb{P}}_{y\sim\mu_Y}[y \in T]\Big| \leq \varepsilon.$$

**Definition 5.2** (Pseudorandomness). A distribution $\mu_X$ over $\{0,1\}^m$ is $(K,\varepsilon)$-*pseudorandom* if it is $(K,\varepsilon)$-indistinguishable from the uniform distribution. That is, for every $T \subseteq \{0,1\}^m$ of circuit complexity $\leq K$,

$$\Big| \mathop{\mathbb{P}}_{x\sim\mu_X}[x \in T] - \tfrac{|T|}{2^m}\Big| \leq \varepsilon.$$

The following definition is due to Nisan and Wigderson [44].

**Definition 5.3** (Quick pseudorandom generator). Suppose that for every $n$ there is a $G_n\colon \{0,1\}^{t(n)} \to \{0,1\}^n$ that is $(n^2, 1/n)$-pseudorandom, and that there is an algorithm $G$ that, given $n$, $s$, computes $G_n(s)$ in time $2^{O(t(n))}$. Then $G$ is called a $t(n)$-*quick* pseudorandom generator.

Suppose that an $O(\log n)$-quick pseudorandom generator (abbreviated logQPRG) exists, and suppose that $f$ is a function and $A$ is a polynomial time randomized algorithm that computes $f$ with probability at least $3/4$. We now describe a derandomization of the algorithm $A$.

Let $I$ be an input, and let $m$ be the number of random bits used by $A$ on input $I$. Let $K$ be an efficiently computable upper bound for the circuit complexity pf $T := \{r : A(r,I) = f(I)\}$. Choose $n$ to be large enough so that: (i) $n^2 \geq K$, (ii) $n \geq m$, and (iii) $n \geq 5$. Because of our assumption that $A$ runs in polynomial time, $n$ is polynomial in the length of $I$.[10]

Now compute $A(G_n(s), I)$ for each $s$, and output the value that is returned most often. This completes the description of a polynomial time deterministic algorithm.

Regarding correctness, we assumed $\mathbb{P}[A(U_m, I) = f(I)] \geq \frac{3}{4}$, and so

$$\mathbb{P}[A(G_n(U_t(n)), I) = f(I)] \geq \tfrac{3}{4} - \tfrac{1}{n} > \tfrac{1}{2}. \tag{5}$$

Otherwise, the set $T = \{r : A(r,I) = f(I)\}$ contradicts the pseudorandomness of $G_n$. Something similar can be done if $A$ is only guaranteed to *approximate* $f$ with high probability, for example if $f(I)$ is the number of perfect matchings in the graph

[10] It should be noted that we may not know how to construct a circuit for $T$, because it seems that to construct such a circuit we need to know $f(I)$. In order to compute a polynomially bounded upper bound for the circuit complexity of $T$, however, we just need to find out how large the circuit for $T$ is that *we would be able to build if we knew* $f(I)$.

represented by $I$ and $A$ is the Jerrum–Sinclair–Vigoda probabilistic approximation algorithm for this problem [33]. The only difference is that we take the *median* of the outputs instead of the most common one.

The applications of logQPRGs to the probabilistic method is as follows. Suppose that:

- For every $n$, we have a set $\Omega_n$ of "objects of size $n$" (for example, graphs with $n$ vertices and maximum degree $d$, where $d$ is a fixed constant). It is convenient to assume the sets $\Omega_n$ to be disjoint.
- We define $P \subseteq \bigcup_n \Omega_n$ to be the set of *interesting* objects that we would like to construct. (For example, expander graphs.)
- Property $P$ is computable in polynomial time. That is, there is an algorithm that, given $n$ and $x \in \Omega_n$, runs in time polynomial in $n$ and determines whether $x \in P$.
- The probabilistic method proves that such graphs exist and are "abundant." That is, for every $n$, we define a probability distribution $\mu_n$ over $\Omega_n$ and we prove that $\mathbb{P}_{x\sim\Omega_n}[x \in P] \geq 1/2$. (The constant $1/2$ is not important.)
- The distributions $\mu_n$ are polynomial time samplable. That is, there is a probabilistic algorithm $A$ that, given $n$, generates in time polynomial in $n$ a sample from $\mu_n$.

This formalization captures the way the probabilistic method is typically used in practice, with the exception of the efficient computability of $P$, which sometimes is not true. (For example, in the problem of finding lower bounds for $R(k, k)$.) Finally, suppose that a logQPRG exists. Given $n$ here is how we construct an element in $P \cap \Omega_n$. Let $m$ be the number of random bits used by $A$ to sample an element of $\mu_n$, and let $K$ be an upper bound for the size of a circuit for the set $T := \{r : A(n, r) \in P\}$. As before, we can use the assumption that $A$ is computable in polynomial time and $P$ is decidable in polynomial time to conclude that $m$ and $K$ are upper bounded by polynomials in $n$. Let $N$ be large enough so that (i) $N \geq 3$, (ii) $N^2 \geq K$ and (iii) $N \geq m$. Then compute $A(n, G_N(N, s))$ for every $s$, and let $s_0$ be such that $A(n, G_N(N, s_0)) \in P$. Such an $s_0$ must exist, otherwise $T$ contradicts the pseudorandomness of $G_N$. Output $A(n, G_N(N, s_0))$.

## 6. Conditional constructions of pseudorandom generators

Blum and Micali [9] construct $n^{o(1)}$QPRGs, according to a slightly different definition, assuming a specific number-theoretic assumption. Yao [84] proves that the Blum–Micali definition is equivalent to a definition based on indistinguishability and

constructs $n^{o(1)}$QPRGs under the more general assumption that *one-way permutations* exist. Yao [84] also recognizes that $n^{o(1)}$QPRGs imply a $2^{n^{o(1)}}$ derandomization of every probabilistic algorithm.

Blum, Micali and Yao do not use the parametrization that we adopted in the definition of quick pseudorandom generators. In the cryptographic applications that motivate their work, it is important that the generator be computable in time polynomial in the length of the output (rather than exponential in the length of the input), and, if $m$ is the length of the output, one desires $(S(m), \varepsilon(m))$-pseudorandomness where $S(m)$ and $1/\varepsilon(m)$ are super-polynomial in $m$. Their constructions satisfy these stronger requirements.

Håstad et al. [26] show that the weaker assumption that *one-way functions* exist suffices to construct $n^{o(1)}$QPRGs. Their construction satisfies the stronger requirements of [9], [84]. We do not define one-way permutations and one-way functions here and we refer the interested reader to Goldreich's monograph [21], the definitive treatment of these results.

Nisan and Wigderson [44] introduced the definition of quick pseudorandom generator that we gave in the previous section and presented a new construction that works under considerably weaker assumptions than the existence of one-way functions.[11] The Nisan–Wigderson construction also "scales" very well, and it gives more efficient QPRGs if one is willing to start from stronger assumptions. A sufficiently strong assumption implies optimal logQPRGs, and this is the only version of the Nisan–Wigderson results that we will discuss.

We first need to define the notion of *average-case circuit complexity.* We say that a set $S \subseteq \{0,1\}^n$ is $(K, \varepsilon)$-hard on average if for every set $T$ computable by a circuit of size $\leq K$ we have $\mathbb{P}[1_S(x) = 1_T(x)] \leq \frac{1}{2} + \varepsilon$, where we use the notation $1_S$ for the characteristic function of the set $S$. We say that a set $L \subseteq \{0,1\}^*$ is $(K(n), \varepsilon(n))$-hard on average if, for every $n$, $L \cap \{0,1\}^n$ is $(K(n), \varepsilon(n))$-hard on average.

**Theorem 6.1** (Nisan and Wigderson [44]). *Suppose there is a set L such that:* (i) *L can be decided in time* $2^{O(n)}$ *and* (ii) *there is a constant* $\delta > 0$ *such that L is* $(2^{\delta n}, 2^{-\delta n})$*-hard on average. Then a* log*QPRG exists.*

When Theorem 6.1 was announced in 1988, average-case complexity was much less understood than worst-case complexity and it was not even clear if the assumption used in the theorem was plausible.

This motivated a long-term research program on average-case complexity. Building on work by Babai, Fortnow, Impagliazzo, Nisan and Wigderson [6], [27], Impagliazzo and Wigderson finally proved in 1997 that the assumption of Theorem 6.1 is equivalent to a seemingly weaker *worst-case* assumption.

[11] On the other hand, the Nisan–Wigderson generator does not satisfy the stronger properties of the pseudorandom generators of Blum, Micali, Yao, Håstad et al. [9], [84], [26]. This is unavoidable because the existence of such stronger pseudorandom generators is *equivalent* to the existence of one-way functions.

**Theorem 6.2** (Impagliazzo and Wigderson [31]). *Suppose there is a set $L$ such that:* (i) *$L$ can be decided in time $2^{O(n)}$ and* (ii) *there is a constant $\delta > 0$ such that the circuit complexity of $L$ is at least $2^{\delta n}$.*

*Then there is a set $L'$ such that:* (i) *$L'$ can be decided in time $2^{O(n)}$ and* (ii) *there is a constant $\delta' > 0$ such that $L'$ is $(2^{\delta' n}, 2^{-\delta' n})$-hard on average.*

In conclusion, we have optimal logQPRG and polynomial time derandomization of probabilistic algorithms under the assumptions that there are problems of exponential circuit complexity that are computable in exponential time. Such an assumption is considered very plausible.

There are other applications of these techniques that we will not have space to discuss, including extensions to the case of pseudorandomness against "non-deterministic statistical tests," which imply surprising results for the Graph Isomorphism problem [35], [43].

## 7. Average-case complexity and codes

We now come to a connection between the Impagliazzo–Wigderson Theorem and error-correcting codes. Due to space limitations we will only give a short discussion. The interested reader is referred to our survey paper [72] for more details.

Impagliazzo and Wigderson derive Theorem 6.2 from the following "hardness amplification" reduction.

**Theorem 7.1** (Impagliazzo and Wigderson [31]). *For every $\delta > 0$ there are constants $\delta' > 0$, $c > 1$, and an algorithm with the following property.*

*If $S \subseteq \{0,1\}^n$ is a set of circuit complexity at least $2^{\delta n}$, then, on input $S$, the algorithm outputs a set $S' \subseteq \{0,1\}^{cn}$ that is $(2^{\delta' n}, 2^{-\delta' n})$-hard on average.*

Like most results in complexity theory, the proof is by contradiction: suppose we have a set $T$ computable by a circuit of size $2^{\delta' n}$ such that $\mathbb{P}_{x \sim \{0,1\}^n}[1_{S'}(x) = 1_T(x)] \geq 1/2 + 2^{-\delta' n}$; then Impagliazzo and Wigderson show how to use such a circuit for $T$ to construct a circuit for $S$ of size $2^{\delta n}$.

Phrased this way, the result has a strong coding-theoretic flavor: we can think of $S$ as a "message," of $S'$ as the "encoding" of $S$, of $T$ as the "corrupted transmission" that the receiver gets, and of the process of reconstructing (a circuit for) $S$ from (a circuit for) $T$ as a "decoding" process. Given this perspective, introduced in [68], it is natural to try and apply coding-theoretic algorithms to hardness amplification. In doing so, we encounter the following difficulty: viewed as a message, a set $S \subseteq \{0,1\}^n$ is (or can be represented as) a bit-string of length $N = 2^n$, and so a polynomial time coding-theoretic algorithm that reconstructs $S$ from a corrupted encoding of $S$ takes time $N^{O(1)} = 2^{O(n)}$. In Theorem 7.1 however we need to produce a circuit of size $2^{\delta n} = N^{\delta}$, and so the circuit cannot simply be an implementation of the decoding algorithm.

It seems that what we need is the following type of error-correcting code (we use the notation $\mathcal{P}(A)$ to denote the set of all subsets of a set $A$): a map $C\colon \mathcal{P}(\{0,1\}^n) \to \mathcal{P}(\{0,1\}^{n'})$ with $n' = O(n)$ such that there is an algorithm that – given a set $T \in \mathcal{P}(\{0,1\}^{n'})$ close to the encoding $C(S)$ of a message $S \in \mathcal{P}(\{0,1\}^{n'})$ and an element $a \in \{0,1\}^n$ – determines in time at most $2^{\delta n}$ whether $a \in S$ or not. If we think of a set $S \in \mathcal{P}(\{0,1\}^n)$ as simply a bit-string in $\{0,1\}^N$, $N = 2^n$, then we are looking for an error correcting code $C\colon \{0,1\}^N \to \{0,1\}^{N'}$, $N' = N^{O(1)}$, such that there is an algorithm that, given a string $u \in \{0,1\}^{N'}$ close to an encoding $C(x)$ and given an index $i \in \{1,\ldots,N\}$, computes in time at most $N^\delta$ the bit $x_i$. It remains to specify how to "give in input" a string $u$ of length $N' > N$ to an algorithm of running time, say, $N^{.001}$: the algorithm does not even have enough time to *read* the input. This can be handled by modeling the input as an "oracle" for the algorithm, which is a standard notion.

The existence of error-correcting codes with this kind of "sub-linear time decoding algorithms" was well known, but the problem is that this notion is still not sufficient for the application to Theorem 7.1. The reason is that we have described a decoding algorithm that gives a unique answer and, as discussed in Section 2, such algorithms cannot recover from more than a $1/4 + o(1)$ fraction of errors. Theorem 7.1, however, requires us to correct from close to $1/2$ fraction of errors.

In Section 2 we remarked that it is possible to do *list*-decoding even after almost a $1/2$ fraction of errors occur. So we need a definition of *sub-linear time list decoding algorithm*. The definition is too technical to be given here. It was formulated, for a different application, in [5]. A reasonably simple sub-linear time list-decoding algorithm giving a new proof of Theorem 7.1 is presented in [68]. The coding-theoretic proof is considerably simpler than the original one.

The connection between error-correcting and hardness amplification also goes in the other direction: it is possible to view the techniques of [6], [27], [31] as defining list-decodable codes with sub-linear time decoding algorithm. This reverse connection has been used to transfer known coding theoretic impossibility results to the setting of amplification of hardness.

Recall that if we want to correct from $1/2 - \varepsilon$ errors, then unique decoding is impossible. Codes that are $(L, 1/2 - \varepsilon)$-list decodable exist, but it is possible to prove that for such codes we need $L = \Omega(\varepsilon^{-2})$. In our proof [68] of Theorem 6.2, this is not a problem because when we realize the decoding algorithm as a circuit we can "hard-wire" into the circuit the correct choice from the list. Suppose, however, that we want to prove a version of Theorem 6.2 where "algorithm of running time $K$" replaces "circuits of size $K$." Then such a theorem would not follow from [68]: if we try to follow the proof we see that from a good-on-average algorithm for $L' \cap \{0,1\}^{n'}$ we can only construct a *list of algorithms* such that one of them computes $L \cap \{0,1\}^n$ correctly, and it is not clear how to choose one algorithm out of this list.[12] This problem is solved in [74], where we do prove a version of Theorem 6.2 with "probabilistic

[12] This difficulty is discussed in [74].

algorithm" in place of "circuit."

Viola [81] proves that error-correcting codes cannot be computed in certain very low complexity classes, and this means that the exponentially big error-correcting code computations occurring in [68] must add a very strong complexity overhead. This means that coding-theoretic techniques cannot be used to prove a version of Theorem 6.2 where "computable in time $2^{O(n)}$" is replaced by "computable in NP." Indeed, it remains a fundamental open question whether a theorem showing equivalence of worst-case complexity and average-case complexity in NP can be proved. Results of [19], [10] show that this is unlikely.

Impagliazzo [28] wonders about a *positive* use of the fact that amplification of hardness results imply error-correcting codes, and whether the techniques of [6], [27], [31] would lead to practical error-correcting codes. We explore this question in [71], focusing on an optimization of the techniques of [27], but our results are far from being competitive with known constructions and algorithms of list-decodable codes. On the other hand, our work in refining the techniques of [27], while not successful in deriving good coding-theoretic applications, has led to interesting applications within complexity theory [71], [73].

## 8. Extractors and pseudorandom generators

We now come to what is perhaps the most surprising result of this survey, the fact that (the proofs of) Theorems 6.1 and 6.2 directly lead to *unconditional* constructions of extractors.

First, let us give a very high-level description of the pseudorandom generator construction that follows from Theorems 6.1 and 6.2.

Let $L$ be the set of exponential circuit complexity as in the assumption of Theorem 6.2, and let $m$ be a parameter such that we want to construct a generator $G_m\colon \{0,1\}^{O(\log m)} \to \{0,1\}^m$ whose output is $(m^2, 1/m)$-pseudorandom. First, we define $\ell = O(\log m)$ such that $L \cap \{0,1\}^\ell$ has circuit complexity at least $m^c$, for a certain absolute constant $c$. Then we define our generator as $G_m(z) = IW_m(L \cap \{0,1\}^\ell, z)$, where $IW_m(S, z)$ is a procedure that takes as input a set $S \subseteq \{0,1\}^\ell$ and a string $z \in \{0,1\}^{O(\log m)}$, outputs a string in $\{0,1\}^m$, and is such that if $S$ has circuit complexity at least $m^c$ then $IW_m(S, U_{O(\log m)})$ is $(m^2, 1/m)$-pseudorandom. Proving that $IW_m(\cdot,\cdot)$ has this property is of course quite complicated, but the general outline is as follows. As usual we proceed by contradiction and start from a statistical test $T$ of circuit complexity at most $m^2$ such that, supposedly,

$$|\,\mathbb{P}[U_m \in T] - \mathbb{P}[IW_m(S, U_{O(\log m)}) \in T]| > \tfrac{1}{m}.$$

Then we modify the circuit for $T$ and build a new circuit for $S$ of size $< m^c$, thus contradicting the hypothesis.

The analysis, indeed, proves a more general result. We will need some additional definitions before stating this more general result. For sets $T \subseteq \{0,1\}^m$ and $S \subseteq$

$\{0,1\}^\ell$, we say that $S$ has a *circuit with $T$-gates of size $K$* if there is a sequence of sets $S_1, \ldots, S_m$ such that $S_m = S$, and each $S_j$ is either a set of the form $P_{i,n}$, or it is the complement of a set $S_h$ $h < j$, or it is the union or the intersection of two sets $S_h$, $S_{h'}$ with $h, h' < j$, or it is defined as

$$S_j := \{a \in \{0,1\}^\ell : (1_{S_{h_1}}(a), \ldots, 1_{S_{h_m}}(a)) \in T\}$$

for some $h_1, \ldots, h_m < j$. It is not hard to show that if $S$ has a circuit with $T$-gates of size $K_1$, and $T$ has a regular circuit of size $K_2$, then $S$ has a regular circuit of size at most $K_1 \cdot K_2$. With these definitions in place we can be more specific about the analysis in [44], [31]: the analysis shows that if $S \subseteq \{0,1\}^\ell$ and $T \subseteq \{0,1\}^m$ are two *arbitrary* sets such that

$$|\,\mathbb{P}[U_m \in T] - \mathbb{P}[IW_m(S, U_{O(\log m)}) \in T]| > \tfrac{1}{m}$$

then there is a circuit with $T$-gates for $S$ of size $< m^{c-2}$. (Note that this implies our previous statement.)

Here is the main idea in [70]: suppose that we have access to a weak random source, that is, a random variable $X$ taking values in $\{0,1\}^n$ and having min-entropy at least $k$. Suppose that $n = 2^\ell$. Then we can, equivalently, regard $X$ as being distributed over $\mathcal{P}(\{0,1\}^\ell)$, the set of all subsets of $\{0,1\}^\ell$. What can we say about the distribution of $IW_m(X, U_{O(\log m)})$? We claim that, if $k$ is large enough, the distribution $IW_m(X, U_{O(\log m)})$ is close in statistical distance to the uniform distribution; in other words, $IW_m(\cdot,\cdot)$ is an *extractor*.

Let us see how to prove this by contradiction. Let $T$ be a statistical test such that

$$|\,\mathbb{P}[U_m \in T] - \mathbb{P}[IW_m(X, U_{O(\log m)}) \in T]| > \tfrac{1}{m}$$

and call a set $S \in \mathcal{P}(\{0,1\}^\ell)$ *bad* if $|\,\mathbb{P}[U_m \in T] - \mathbb{P}[IW_m(S, U_{O(\log m)}) \in T]| > \frac{2}{m}$.

Let $B$ be the set of all bad sets. Then, by Markov's inequality, $\mathbb{P}[X \in B] \geq \frac{2}{m}$, and since $X$ has min-entropy $k$ we have $|B| \geq 2^{k-\log m-1}$. On the other hand, if $S$ is bad, then there is a circuit with $T$-gates of size at most $m^{c-2}$ that computes $S$. The number of such circuits is at most $2^{O(m^{c-1})}$, and so $|B| \leq 2^{O(m^{c-1})}$. So if $k \geq c' m^{c-1}$, where $c$, $c'$ are absolute constants, we reach a contradiction. Thus, $\|IW_m(X, U_{O(\log m)}) - U_m\|_{\mathrm{SD}} \leq \frac{1}{m}$.

If we look more closely at how $IW_m(S, z)$ is defined, we see that (especially if we use the proof of Theorem 6.2 in [68]) it can be seen as $IW_m(S, z) := NW_m(C(S), z)$, where $C$ is an error-correcting code and $NW_m$ is the relatively simple pseudorandom generator construction of Nisan and Wigderson. For the application to derandomization, it is important that $C$ be a "sub-linear time list-decodable" error-correcting code. However, in order for our argument about randomness extraction to work, it is sufficient that $C$ be an arbitrary list-decodable code, and not even a polynomial time list-decoding algorithm is needed. This means that one can get extractors by using standard error-correcting codes and the simple Nisan–Wigderson generator. The

resulting construction is described and analysed in [70] in about two pages and, at the time, it was the best known extractor construction, improving over very technical previous work.

What makes these calculations work is the intuition that the proofs of Theorems 6.1 and 6.2 prove more than the intended statement. In particular, the proof works if we replace "circuit complexity" with "description complexity" which we exploited in the previous argument. See [70] for further discussion of this point.

The connection with pseudorandomness and the general idea of analysing an extractor by finding short descriptions of the output of the source based on a hypothetical statistical test (the so-called "reconstruction method" to analyse extractors) has led to remarkable advances in extractor constructions in the past five years, together with other ideas. The best distillation of the reconstruction method is in [58], providing a near-optimal and simple construction of extractors.[13] The extractor motivation has also led to improvements in pseudorandom generator constructions, see [58], [75]. Currently, the best known extractor construction [40] uses the notion of "condenser" introduced in [69], [54] and a combination of several components, one of which is analysed with the reconstruction method. The extractors of Lu et al. [40] is almost best possible.

## 9. Conclusions

We have discussed how, starting from worst-case complexity assumptions, it is possible to construct very strong pseudorandom generators and derive conditional derandomization results for *all* probabilistic algorithms.

What about *proving* circuit lower bounds and deriving unconditional derandomization results? The results of Razborov and Rudich [52] show that a significant departure from current techniques will be required to prove such lower bounds. What about deriving derandomization results *without* proving lower bounds? Impagliazzo, Kabanets and Wigderson [29] prove that any general derandomization result implies a circuit lower bound.[14]

Short of proving such elusive circuit lower bounds, we should test the prediction of the theory and look for polynomial time deterministic versions of known probabilistic polynomial time algorithms. The four most important probabilistic algorithms (or collections of algorithms) are: primality testing, graph connectivity using random walks, polynomial identity testing, and algorithms for approximate counting. Primality testing and graph connectivity using random walks have been derandomized [1], [53]. Kabanets and Impagliazzo [34] prove that any derandomized polynomial identity testing algorithms implies circuit lower bounds.[15]

[13] The construction is simple but the analysis is quite non-trivial.

[14] Here is what we mean by "general derandomization": if $f$ is a function and $A$ is randomized algorithm that with high probability achieves a good approximation of $f$, then there is a deterministic algorithm that achieves a good approximation of $f$ and whose running time is polynomial in the running time of $A$.

The possibility of derandomizing approximate counting algorithms with current techniques is quite open. Here is perhaps the simplest question: given an $n$-variable boolean formula in disjunctive normal form and $\varepsilon > 0$, compute in time polynomial in the size of the formula and in $1/\varepsilon$ an approximation to the number of satisfying assignments up to an additive error $\leq 2^n\varepsilon$. See [42] for a nearly polynomial time deterministic algorithm for this problem.

The construction of an optimal (seeded) extractor with parameters matching the known lower bounds remains an elusive open question. It would also be interesting to match the parameters of [40] with a simpler construction.

There has been very exciting recent progress towards constructing good seedless extractors for independent sources, and for the related problem of constructing bipartite Ramsey graphs [8], [11]. The broader area of seedless extractor constructions for general classes of distributions has seen much recent progress. In the long run, we would expect this research to define simple and powerful seedless extractors working for a wide and natural class of distributions. Such extractors would be very useful in practice, giving a principled approach to the production of random bits for cryptographic applications.

# Least-squares finite element methods

Pavel Bochev* and Max Gunzburger†

**Abstract.** Least-squares finite element methods are an attractive class of methods for the numerical solution of partial differential equations. They are motivated by the desire to recover, in general settings, the advantageous features of Rayleigh–Ritz methods such as the avoidance of discrete compatibility conditions and the production of symmetric and positive definite discrete systems. The methods are based on the minimization of convex functionals that are constructed from equation residuals. This paper focuses on theoretical and practical aspects of least-square finite element methods and includes discussions of what issues enter into their construction, analysis, and performance. It also includes a discussion of some open problems.

**Mathematics Subject Classification (2000).** 65N30, 65N99, 65N15.

**Keywords.** Least squares, finite element methods, compatible discretizations.

## 1. Introduction

Finite element methods (FEMs) for the approximate numerical solution of partial differential equations (PDEs) were first developed and analyzed for problems in linear elasticity and other settings for which solutions can be characterized as (unconstrained) minimizers of convex, quadratic functionals on infinite-dimensional Hilbert spaces [46]. A Rayleigh–Ritz approximation of such solutions is defined by minimizing the functional over a family of finite-dimensional subspaces. An FEM results when these spaces consist of piecewise polynomial functions defined with respect to a family of grids. When applied to problems such as linear elasticity or the Poisson equation, the Rayleigh–Ritz setting gives rise to FEMs with several advantageous features that led to their great success and popularity:

1. general regions and boundary conditions are relatively easy to treat in a systematic manner;
2. the conformity[1] of the finite element spaces suffices to guarantee the stability

*Supported by the Applied Mathematical Sciences program, U.S. Department of Energy, Office of Energy Research, and performed at Sandia National Labs, a multiprogram laboratory operated by Sandia Corporation, a Lockheed-Martin Company, for the United States Department of Energy's National Nuclear Security Administration under contract DE-AC-94AL85000.

†Supported in part by CSRI, Sandia National Laboratories, under contract 18407 and by the National Science Foundation under grant number DMS-0240049.

[1]An approximating space is referred to as being *conforming* if it is a subspace of the underlying infinite-dimensional Hilbert space.

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

and optimal accuracy[2] of the approximate solutions;

3. all variables can be approximated using a single type of finite element space, e.g., the same degree piecewise polynomials defined with respect to a same grid;
4. the resulting linear systems are
   a) sparse; b) symmetric; c) positive definite.

The success of FEMs in the Rayleigh–Ritz setting quickly led both engineers and mathematicians to apply and analyze FEMs in other settings, motivated by the fact that properties 1 and 4a are retained for all FEMs.[3] For example, *mixed* FEMs arose from minimization problems constrained by PDEs such as the Stokes problem; the Lagrange multiplier rule was applied to enforce the constraints, resulting in saddle-point problems [19]. In this setting, the only other property retained from the Rayleigh–Ritz setting is 4b. More generally, *Galerkin* FEMs can, in principle, be defined for any PDE by forcing the residual of the PDE (posed in a weak, variational formulation) to be orthogonal to the finite element subspace [3]. In this general setting, one usually loses all the features of the Rayleigh–Ritz setting other than 1 and 4a. Using the same formalisms, Galerkin FEMs were even applied to *nonlinear* problems such as the Navier–Stokes equations [34]. It is a testament to the importance of advantage 1 that despite the loss of other advantages, mixed and Galerkin FEMs are in widespread use and have also been extensively analyzed.[4]

Not surprisingly, despite the success of mixed and Galerkin FEMs in general settings, there has been substantial interest and effort devoted to developing finite element approaches that recover at least some of the advantages of the Rayleigh–Ritz setting. Notable among these efforts have been penalty and stabilized FEMs, e.g., for the Stokes problem, stabilized FEMs [4]–[5], [6], [12], [15], [29], [30], [36], [37], [44] recover advantages 2 and 3 but fail to recover advantage 4c and often lose advantage 4b.

Least-squares finite element methods (LSFEMs) can be viewed as another attempt at retaining the advantages of the Rayleigh–Ritz setting even for much more general problems. In fact, they offer the possibility of, in principle, retaining *all* of the advantages of that setting for practically any PDE problem. In §2, we show how this is possible. However, this is not the whole story. Any FEM, including an LSFEM, must also meet additional practicality criteria:

A. bases for conforming subspaces are easily constructed;

B. linear systems are easily assembled;

C. linear systems are relatively well conditioned.

[2] An approximate solution is referred to as being *optimally accurate* if the corresponding error is bounded by a constant times the error of the best approximation.

[3] These properties follow from the way finite element spaces are constructed, e.g., based on grids and choosing basis functions of compact support.

[4] It should be noted that in the general settings for which FEMs lose many of the advantages they possess in the Rayleigh–Ritz setting, they do not suffer from any disadvantages compared to other discretization methods such as finite difference, finite volume, and spectral methods.

In judging whether or not an LSFEM meets theses criteria, we will measure them up against Galerkin FEMs for the Poisson equation; in particular, we will ask the questions: can we use standard, piecewise polynomial spaces that are merely continuous and for which bases are easily constructed? can the assembly of the linear systems be accomplished by merely applying quadrature rules to integrals? and, are the condition numbers of the linear systems of[5] $O(h^{-2})$? Unfortunately, naively defined LSFEMs often fail to meet one or more of the practicality criteria.

LSFEMs possess two additional advantageous features that other FEMs, even in the Rayleigh–Ritz setting, do not possess. First, least-square functionals provide an easily computable residual error indicator that can be used for adapting grids. Second, the treatment of general boundary conditions, including nonhomogeneous ones, is greatly facilitated because boundary condition residuals can be incorporated into the least-square functional.

## 2. The most straightforward LSFEM

Let $\Omega$ denote a bounded domain in $\Re^d$, $d = 2$ or 3, with boundary $\Gamma$. Consider the problem

$$\mathcal{L}u = f \text{ in } \Omega \quad \text{and} \quad \mathcal{R}u = g \text{ on } \Gamma, \tag{1}$$

where $\mathcal{L}$ is a linear differential operator and $\mathcal{R}$ is a linear boundary operator. We assume that the problem (1) is well posed so that there exists a solution Hilbert space $S$, data Hilbert spaces $H_\Omega$ and $H_\Gamma$, and positive constants $\alpha_1$ and $\alpha_2$ such that

$$\alpha_1 \|u\|_S^2 \le \|\mathcal{L}u\|_{H_\Omega}^2 + \|\mathcal{R}u\|_{H_\Gamma}^2 \le \alpha_2 \|u\|_S^2 \quad \text{for all } u \in S. \tag{2}$$

Then consider the least-squares functional[6]

$$J(u; f, g) = \|\mathcal{L}u - f\|_{H_\Omega}^2 + \|\mathcal{R}u - g\|_{H_\Gamma}^2 \tag{3}$$

and the unconstrained minimization problem

$$\min_{u \in S} J(u; f, g). \tag{4}$$

Note that the functional (3) measures the residuals of the components of the system (1) using the data space norms $H_\Omega$ and $H_\Gamma$ and the minimization problem (4) seeks a solution in the solution space $S$ for which (2) is satisfied. It is clear that the problems (1) and (4) are equivalent in the sense that $u \in S$ is a solution of (4) if and only if it is also a solution, perhaps in a generalized sense, of (1).

An LSFEM can be defined by choosing a family of finite element subspaces $S^h \subset S$ parameterized by $h$ tending to zero and then restricting the minimization problem (4)

[5] Usually, $h$ is a measure of the size of the grid used in the construction of the finite element space.

[6] A least-squares functional may be viewed as an "artificial" energy that plays the same role for LSFEMs as a bona fide physically energy plays for Rayleigh–Ritz FEMs.

to the subspaces. Thus, the LSFEM approximation $u^h \in S^h$ to the solution $u \in S$ of (1) or (4) is the solution of the problem

$$\min_{u^h \in S^h} J(u^h; f, g). \tag{5}$$

The Euler–Lagrange equations corresponding to the minimization problems (4) and (5) are given by

$$\textit{seek } u \in S \quad \textit{such that} \quad B(u, v) = F(v) \quad \textit{for all } v \in S, \tag{6}$$

$$\textit{seek } u^h \in S^h \quad \textit{such that} \quad B(u^h, v^h) = F(v^h) \quad \textit{for all } v^h \in S^h, \tag{7}$$

respectively, where for all $u, v \in S$,

$$B(u, v) = (\mathcal{L}v, \mathcal{L}u)_{H_\Omega} + (\mathcal{R}v, \mathcal{R}u)_{H_\Gamma} \quad \text{and} \quad F(v) = (\mathcal{L}v, f)_{H_\Omega} + (\mathcal{R}v, g)_{H_\Gamma}. \tag{8}$$

If we choose a basis $\{U_j\}_{j=1}^J$, where $J = \dim(S^h)$, then we have that $u^h = \sum_{j=1}^J c_j U_j$ for some constants $\{c_j\}_{j=1}^J$ and then the discretized problem (7) is equivalent to the linear system

$$\mathbb{K}\boldsymbol{c} = \boldsymbol{f}, \tag{9}$$

where the elements of the matrix $\mathbb{K} \in \Re^{J \times J}$ and the vectors $\boldsymbol{f} \in \Re^J$ and $\boldsymbol{c} \in \Re^J$ are given, for $i, j = 1, \ldots, J$, by $\boldsymbol{c}_j = c_j$,

$$\mathbb{K}_{ij} = (\mathcal{L}U_i, \mathcal{L}U_j)_{H_\Omega} + (\mathcal{R}U_i, \mathcal{R}U_j)_{H_\Gamma}, \quad \text{and} \quad \boldsymbol{f}_i = (\mathcal{L}U_i, f)_{H_\Omega} + (\mathcal{R}U_i, g)_{H_\Gamma}.$$

The results of the following theorem follow directly from (2).

**Theorem 2.1.** *Assume that* (2) *holds and that* $S^h \subset S$. *Then,*

*– the bilinear form* $B(\cdot, \cdot)$ *defined in* (8) *is continuous, symmetric, and coercive;*

*– the linear functional* $F(\cdot)$ *defined in* (8) *is continuous;*

*– the problem* (6) *has a unique solution* $u \in S$ *that is also the unique solution of the minimization problem* (4)*;*

*– the problem* (7) *has a unique solution* $u^h \in S^h$ *that is also the unique solution of the minimization problem* (5)*;*

*– for some constant* $C > 0$, *we have that* $\|u\|_S \leq C(\|f\|_{H_\Omega} + \|g\|_{H_\Gamma})$ *and* $\|u^h\|_S \leq C(\|f\|_{H_\Omega} + \|g\|_{H_\Gamma})$;

*– for some constant* $C > 0$, $u$ *and* $u^h$ *satisfy the error estimate*

$$\|u - u^h\|_S \leq C \inf_{v^h \in S^h} \|u - v^h\|_S; \tag{10}$$

*– the matrix* $\mathbb{K}$ *of* (9) *is symmetric and positive definite.*

Note that it is not assumed that the system (1) is self-adjoint or positive as it would have to be in the Rayleigh–Ritz setting; it is only assumed that it is well posed. Despite the generality of the system (1), the LSFEM based on (5) recovers *all* desirable

features of FEMs in the Rayleigh–Ritz setting. Note that (10) shows that least-squares finite element approximations are optimally accurate with respect to solution norm $\|\cdot\|_S$ for which the system (1) is well posed.

In defining the least-squares principle (4), we have not restricted the spaces $S$ and $S^h$ to satisfy the boundary conditions. Instead, we have included the residual $\mathcal{R}u - g$ of the boundary condition in the functional $J(\cdot\,;\cdot,\cdot)$ defined in (3). Thus, we see that LSFEMs possess a desirable feature that is absent even from standard FEMs in the Rayleigh–Ritz setting: the imposition of boundary conditions can be effected through the functional and need not be imposed on the finite element spaces.[7] Notwithstanding this advantage, one can impose essential boundary conditions on the space $S$ in which case all terms in (2)–(8) involving the boundary condition are omitted and we also set $H_\Omega = H$. Note also that since

$$\begin{aligned} J(u_h;\, f, g) &= \|\mathcal{L}u_h - f\|^2_{H_\Omega} + \|\mathcal{R}u_h - g\|^2_{H_\Gamma} \\ &= B(u_h, u_h) - 2F(u_h) + (f,\, f)_{H_\Omega} + (g, g)_{H_\Gamma}, \end{aligned}$$

the least-square functional $J(u_h;\, f, g)$ provides a *computable* indicator for the residual error in the LSFEM approximation $u^h$. Such indicators are in widespread used for grid adaption.

The problems (6) and (7) display the *normal equation* form typical of least-squares systems; see (8). It is important to note that since $\mathcal{L}$ is a differential operator, (6) involves a higher-order differential operator. We shall see that this observation has a profound effect on how practical LSFEMs are defined.

**2.1. The practicality of the straightforward LSFEM.** The complete recovery, in general settings, of all desirable features of the Rayleigh–Ritz setting is what makes LSFEMs intriguing and attractive. But, what about the practicality of the method defined by (5)? We explore this issue using examples.

**2.1.1. An impractical application of the straightforward LSFEM.** Consider the problem

$$-\Delta u = f \text{ in } \Omega \quad \text{and} \quad u = 0 \text{ on } \Gamma, \tag{11}$$

where we assume that $\Omega$ is either a convex, Lipschitz domain or that it has a smooth boundary. Of course, this is a problem which fits into the Rayleigh–Ritz framework so that there is no apparent need[8] to use any other type of FEM. However, let us proceed and use the LSFEM method anyway, and see what happens. Here we have that (2) holds with[9] $S = H^2(\Omega) \cap H^1_0(\Omega)$, $H = L^2(\Omega)$, and $\mathcal{L} = -\Delta$. We then have

[7] This advantage of LSFEM can be useful for imposing inhomogeneous boundary conditions, essential boundary conditions such as Dirichlet boundary conditions for second-order elliptic PDEs, and boundary conditions involving a particular component, e.g., the normal component, of a vector variable.

[8] Inhomogeneous Dirichlet boundary conditions provide a situation in which one might want to use LSFEMs even for the Poisson problem.

[9] We use standard Sobolev space notation throughout the paper. Also, in this and most of our examples, we will be imposing the boundary condition on the solutions space $S$.

that, for all $u, v \in H^2(\Omega) \cap H_0^1(\Omega)$,

$$J(u; f) = \|\Delta u + f\|_0^2, \quad F(v) = \int_\Omega f \Delta v \, d\Omega, \quad \text{and} \quad B(u, v) = \int_\Omega \Delta v \, \Delta u \, d\Omega.$$

Note that minimizing the least-squares functional has turned the second-order Poisson problem into a fourth-order problem.

An LSFEM is defined by choosing a subspace $S^h \subset S = H^2(\Omega) \cap H_0^1(\Omega)$ and then posing the problem (7). It is well known that in this case, the finite element space $S^h$ has to consist of continuously differentiable functions; this requirement greatly complicates the construction of bases and the assembly of the matrix problem. Furthermore, it is also well known that the condition number of the matrix problem is $O(h^{-4})$ which should be contrasted with the $O(h^{-2})$ condition number obtained through a Rayleigh–Ritz discretization of the Poisson equation. Thus, for this problem, the straightforward LSFEM fails all three practicality tests.

Since it is also true that (2) holds with $S = H_0^1(\Omega)$ and $H = H^{-1}(\Omega)$, one could develop an LSFEM based on the functional $J(u; f) = \|\Delta u + f\|_{-1}$ and the solution space $S = H_0^1(\Omega)$. This approach would allow one to use a finite element space $S^h$ consisting of merely continuous functions so that bases may be easily constructed. Moreover, it can be shown that because of the use of the $H^{-1}(\Omega)$ inner product, the condition number of the resulting matrix system is $O(h^{-2})$ which is the same as for a Rayleigh–Ritz discretization. However, the $H^{-1}(\Omega)$ inner product is computed by inverting the Laplacian operator which leads to the loss of property 4a and also makes the assembly of the matrix problem more difficult. So, as it stands, the straightforward LSFEM remains impractical for the second-order Poisson problem.

**2.1.2. A practical application of the straightforward LSFEM.** Consider now the problem

$$-\nabla \cdot \boldsymbol{u} = f \ \text{ and } \ \nabla \times \boldsymbol{u} = \boldsymbol{g} \ \text{ in } \Omega \quad \text{and} \quad \boldsymbol{n} \cdot \boldsymbol{u} = 0 \ \text{ on } \Gamma. \tag{12}$$

Here $\boldsymbol{u} \in S = \boldsymbol{H}_n^1(\Omega) = \{\boldsymbol{v} \in \boldsymbol{H}^1(\Omega) \,|\, \boldsymbol{n} \cdot \boldsymbol{v} = 0 \text{ on } \Gamma\}$ and $\{f, \boldsymbol{g}\} \in H = L_0^2(\Omega) \times \boldsymbol{L}_s^2(\Omega)$, where $L_0^2(\Omega) = \{f \in L^2(\Omega) \,|\, \int_\Omega f \, d\Omega = 0\}$, and $\boldsymbol{L}_s^2(\Omega) = \{\boldsymbol{g} \in \boldsymbol{L}^2(\Omega) \,|\, \nabla \cdot \boldsymbol{g} = 0 \text{ in } \Omega\}$. We then have that (2) holds so that we may define the least-squares functional

$$J(\boldsymbol{u}; f, \boldsymbol{g}) = \|\nabla \cdot \boldsymbol{u} + f\|_0^2 + \|\nabla \times \boldsymbol{u} - \boldsymbol{g}\|_0^2 \quad \text{for all } \boldsymbol{u} \in S = \boldsymbol{H}_n^1(\Omega) \tag{13}$$

that results in

$$B(\boldsymbol{u}, \boldsymbol{v}) = \int_\Omega \big((\nabla \cdot \boldsymbol{u})(\nabla \cdot \boldsymbol{v}) + (\nabla \times \boldsymbol{u}) \cdot (\nabla \times \boldsymbol{v})\big) \, d\Omega \quad \text{for all } \boldsymbol{u}, \boldsymbol{v} \in S = \boldsymbol{H}_n^1(\Omega)$$

and

$$F(\boldsymbol{v}) = \int_\Omega \big( - f \nabla \cdot \boldsymbol{v} + \boldsymbol{g} \cdot \nabla \times \boldsymbol{v}\big) \, d\Omega \quad \text{for all } \boldsymbol{v} \in S = \boldsymbol{H}_n^1(\Omega).$$

An LSFEM is defined by choosing a subspace $S^h \subset S = \boldsymbol{H}_n^1(\Omega)$ and then solving the problem (7).

The LSFEM based on the functional (13) not only recovers all the good properties of the Rayleigh–Ritz setting for the problem (12), but also satisfies all three practicality criteria. Since we merely require that $S^h \subset \boldsymbol{H}_n^1(\Omega)$, we can choose standard finite element spaces for which bases are easily constructed. Furthermore, since the functional (13) only involves $L^2(\Omega)$ inner products, the assembly of the matrix system is accomplished in a standard manner. Finally, it can be shown that the condition number of the matrix system is $O(h^{-2})$.

**2.2. Norm-equivalence vs. practicality.** Since (2) and (3) imply that

$$\alpha_1 \|u\|_S^2 \leq J(u; 0, 0) \leq \alpha_2 \|u\|_S^2, \tag{14}$$

we refer to the functional $J(\,\cdot\,;\,\cdot,\,\cdot)$ as being *norm equivalent.* This property of the functional causes the LSFEM defined by (5) to recover all the desirable properties of the Rayleigh–Ritz setting. However, the norms that enter the definition of the functional $J(\,\cdot\,;\,\cdot,\,\cdot)$ as well as the form of the PDE system (1) can render the resulting LSFEM impractical. Thus, in order to define a practical LSFEM, one may have to define a least-squares functional that is not norm equivalent in the sense of (14). We take up this issue in §3. Here, we examine the examples of §2.1 to see what guidance they give us about what makes an LSFEM practical.

**2.2.1. First-order system form of the PDEs.** Perhaps the most important observation that can be made from the examples of §2.1 is that the example of §2.1.2 involved a first-order system of PDEs and an LSFEM that allowed for the easy construction of finite element bases (because one could work with merely continuous finite element spaces) and resulted in matrix systems with relative good conditioning. As a result, all modern LSFEMs are based on first-order formulations of PDE systems. Of course, many if not most PDEs of practical interest are not usually posed as first-order systems. Thus, *the first step in defining an LSFEM should be recasting a given PDE system into a first-order system.*

Unfortunately, there is no unique way to do this. For example, the three problems

$$\left\{\begin{array}{ll} \boldsymbol{u} + \nabla\phi = \boldsymbol{0} & \text{in } \Omega \\ \nabla \cdot \boldsymbol{u} = f & \text{in } \Omega \\ \phi = 0 & \text{on } \Gamma \end{array}\right\}, \quad \left\{\begin{array}{ll} \boldsymbol{u} + \nabla\phi = \boldsymbol{0} & \text{in } \Omega \\ \nabla \cdot \boldsymbol{u} = f & \text{in } \Omega \\ \nabla \times \boldsymbol{u} = \boldsymbol{0} & \text{in } \Omega \\ \phi = 0 & \text{on } \Gamma \end{array}\right\}, \quad \left\{\begin{array}{ll} \nabla \cdot \boldsymbol{u} = f & \text{in } \Omega \\ \nabla \times \boldsymbol{u} = \boldsymbol{0} & \text{in } \Omega \\ \boldsymbol{n} \times \boldsymbol{u} = \boldsymbol{0} & \text{on } \Gamma \end{array}\right\}$$

are all first-order systems that are equivalent to the Poisson problem (11). Each happens to be norm equivalent, but with respect to different norms. If we assume that in each case the boundary condition is imposed on the solutions space, we have that, for the three problems, the space $S$ in (2) is respectively given by $H_0^1(\Omega) \times H(\Omega, \text{div})$, $H_0^1(\Omega) \times \boldsymbol{H}^1(\Omega)$, and $\boldsymbol{H}_\tau^1(\Omega)$, where $H(\Omega, \text{div}) = \{\boldsymbol{v} \in \boldsymbol{L}^2(\Omega) \mid \nabla \cdot \boldsymbol{v} \in L^2(\Omega)\}$ and $\boldsymbol{H}_\tau^1(\Omega) = \{\boldsymbol{v} \in \boldsymbol{H}^1(\Omega) \mid \boldsymbol{n} \times \boldsymbol{v} = \boldsymbol{0} \text{ on } \Gamma\}$.

**2.2.2. Functionals formed using $L^2$ norms of equation residuals.** Another observation that can be gleaned from the examples of §2.1 is that if one wants to be able to assemble the matrix system using standard finite element techniques, *then one should use $L^2$ norms of equation residuals in the definition of the least-squares functional.* Unfortunately, it is not always the case that the resulting least-squares functional is norm equivalent. Let us explore this issue in more detail.

Consider the Stokes problem

$$-\Delta \boldsymbol{u} + \nabla p = \boldsymbol{f}, \quad \nabla \cdot \boldsymbol{u} = 0 \ \text{ in } \Omega \quad \text{and} \quad \boldsymbol{u} = \boldsymbol{0} \ \text{ on } \Gamma. \tag{15}$$

The most popular LSFEM for this problem is based on the first-order system

$$\nabla \times \boldsymbol{\omega} + \nabla p = \boldsymbol{f}, \quad \boldsymbol{\omega} = \nabla \times \boldsymbol{u}, \quad \nabla \cdot \boldsymbol{u} = 0 \ \text{ in } \Omega \quad \text{and} \quad \boldsymbol{u} = \boldsymbol{0} \ \text{ on } \Gamma \tag{16}$$

that is known for obvious reasons as the *velocity–vorticity–pressure formulation.* One would then be tempted to use the functional

$$J_0(\boldsymbol{u}, \boldsymbol{\omega}, p; \boldsymbol{f}) = \|\nabla \times \boldsymbol{\omega} + \nabla p - \boldsymbol{f}\|_0^2 + \|\nabla \times \boldsymbol{u} - \boldsymbol{\omega}\|_0^2 + \|\nabla \cdot \boldsymbol{u}\|_0^2 \tag{17}$$

that involves only $L^2(\Omega)$ norms of equation residuals. Indeed, this is the most popular approach for defining LSFEM for the Stokes equations. Unfortunately, the functional (17) is not norm equivalent [13]. On the other hand, the functional

$$J_{-1}(\boldsymbol{u}, \boldsymbol{\omega}, p; \boldsymbol{f}) = \|\nabla \times \boldsymbol{\omega} + \nabla p - \boldsymbol{f}\|_{-1}^2 + \|\nabla \times \boldsymbol{u} - \boldsymbol{\omega}\|_0^2 + \|\nabla \cdot \boldsymbol{u}\|_0^2$$

is equivalent to $\|\boldsymbol{u}\|_1^2 + \|\boldsymbol{\omega}\|_0^2 + \|p\|_0^2$ [13]. So, on the one hand, the lack of norm equivalence for the functional $J_0(\cdot\,,\ \cdot\,,\ \cdot\,;\ \cdot)$ results in a loss of accuracy of the LSFEM approximations based on that functional. On the other hand, the appearance of the $\boldsymbol{H}^{-1}(\Omega)$ norm in the functional $J_{-1}(\cdot\,,\ \cdot\,,\ \cdot\,;\ \cdot)$ results in an impractical LSFEM because the matrix systems are not easily assembled.[10]

## 3. More sophisticated LSFEMs

To define the least-squares principle (4), one had to choose the pair $\{S,\ J(\,\cdot\,;\ f,\ g)\}$, where $S$ denotes a solution Hilbert space and $J(\,\cdot\,;\ f,\ g)$ a functional defined over $S$ that satisfies the norm-equivalence relation (14). We refer to the variational principle (4) as the *continuous* least-squares principle.[11] The straightforward LSFEM was defined by choosing a finite element subspace $S^h \subset S$ and then minimizing the functional $J(\,\cdot\,;\ f,\ g)$ over $S^h$; see (5). We refer to the straightforward LSFEM as the *conforming* LSFEM. For such LSFEMs, we obtain the error estimate (10).

[10] A similar dilemma arises when one imposes boundary conditions through the least-squares functional.

[11] Here, "continuous" refers to the fact that solutions of (4) are also solutions of the PDE system (1). Recall also that (14) follows from the well-posedness relation (2) for the PDE system.

Conforming LSFEMs can be generalized so that their applicability and practicality are enhanced. Here, we briefly discuss some of these generalizations. We still have in mind approximating solutions of the continuous least-squares principle (4) or what is equivalent, solutions of the PDE system (1). We again choose a finite element space $S^h$ and a convex, quadratic functional $J_h(\cdot\,;f,g)$ defined over $S^h$. The pair $\{S^h, J_h(\cdot\,;f,g)\}$ gives rise to the *discrete* least-squares principle

$$\min_{u^h \in S^h} J_h(u^h; f, g). \tag{18}$$

Since we only require that the functional $J_h(\cdot\,;f,g)$ be defined for functions in $S^h$, we refer to LSFEMs constructed in this manner as *discrete* LSFEMs.

The functional $J_h(\cdot\,;f,g)$ is required to satisfy the following non-restrictive assumptions.

H1. There exists a *discrete energy inner product* $(\cdot,\cdot)_h : S^h \times S^h \mapsto \Re$ and a *discrete energy norm* $\|\cdot\|_h = (\cdot,\cdot)_h^{1/2}$ such that $J_h(u^h;0,0) = (u^h,u^h)_h = \|u^h\|_h^2$ for all $u^h \in S^h$.

H2. There exist bilinear forms $E(\cdot\,,\cdot)$ and $T(\cdot\,,\cdot)$ such that for all smooth functions $u \in S$ and all $u^h \in S^h$

$$J_h(u^h; \mathcal{L}u, \mathcal{R}u) = \|u - u^h\|_h^2 + E(u, u^h) + T(u,u). \tag{19}$$

The two assumptions are sufficient to prove the following results about solutions of (18).

**Theorem 3.1.** *Assume that hypotheses* H1 *and* H2 *hold for the discrete principle* $\{S^h, J_h(\cdot\,;f,g)\}$ *and let* $u$ *denote a sufficiently smooth solution of* (1). *Then the problem* (18) *has a unique solution* $u^h \in S^h$. *Moreover,* $u^h$ *satisfies*

$$\|u - u^h\|_h \le \inf_{v^h \in S^h} \|u - v^h\|_h + \sup_{v^h \in S^h} \frac{E(u, v^h)}{\|v^h\|_h}. \tag{20}$$

A discrete least-squares functional $J_h(\cdot\,;f,g)$ will be referred to being *order r-consistent* if there exists a positive number $r$ such that for all sufficiently smooth functions $u \in S$, the second term on the right-hand side of (20) can be bounded from above by $C(u)h^r$, where $C(u)$ is a positive number whose value may depend on $u$ but not on $h$. If $J_h(\cdot\,;f,g)$ is order $r$-consistent, then (20) implies that

$$\|u - u^h\|_h \le \inf_{v^h \in S^h} \|u - v^h\|_h + C(u)h^r. \tag{21}$$

Theorem 3.1 shows that discrete LSFEMs can work under a minimal set of assumptions. It also explains why LSFEMs tend to be much more robust than their mixed FEM counterparts; unlike the inf-sup conditions that are required for the latter type of method, defining pairs $\{S^h, J_h(\cdot\,;f,g)\}$ such that the assumptions H1 and H2 are satisfied is not a difficult task.

**Constructing discrete least-squares functionals.** Theorem 3.1 provides estimates for the error with respect to the discrete norm $\|\cdot\|_h$. Of greater interest is estimating errors using the (mesh-independent) solution norm $\|\cdot\|_S$ associated with the PDE problem (1). Since $S^h \subset S$, it is certainly true that $\|\cdot\|_S$ acts as another norm on $S^h$, in addition to $\|\cdot\|_h$. Thus, since $S^h$ is finite dimensional, these two norms are comparable. However, the comparability constants may depend on $h$; if they do, then error estimates analogous to (20) and (21) but in terms of the norm $\|\cdot\|_S$ will surely involve constants that depend on inverse powers of $h$ and, at the least, accuracy may be compromised. We conclude that hypotheses H1 and H2 do not sufficiently connect $J_h(\cdot\,; f, g)$ to the problem (1) for us to determine much about the properties of the error in the discrete LSFEM solution with respect to $\|\cdot\|_S$ norm. Thus, we now discuss how to construct discrete least-squares functionals so that we can get a handle on these properties.

We assume that (2) and (14) hold for the problem (1), the least-squares functional $J(\cdot\,; f, g)$, the solution space $S$, and the data spaces $H_\Omega$ and $H_\Gamma$. Let $\mathcal{D}_S$, $\mathcal{D}_\Omega$, and $\mathcal{D}_\Gamma$ denote *norm-generating* operators that allow us to relate the norms on $S$, $H_\Omega$, and $H_\Gamma$, respectively, to[12] $L^2(\Omega)$ norms, i.e., such that, for all $u \in S$, $f \in H_\Omega$, and $g \in H_\Gamma$, $\|u\|_S = \|\mathcal{D}_S u\|_0$, $\|f\|_{H_\Omega} = \|\mathcal{D}_\Omega f\|_0$, and $\|g\|_{H_\Gamma} = \|\mathcal{D}_\Gamma g\|_{0,\Gamma}$. We then let

$$J_h(u^h; f, g) = \|\mathcal{D}_\Omega^h(\mathcal{L}^h u^h - \mathcal{Q}_\Omega^h f)\|_0^2 + \|\mathcal{D}_\Gamma^h(\mathcal{R}^h u^h - \mathcal{Q}_\Gamma^h g)\|_0^2,$$

where $\mathcal{D}_\Omega^h$, $\mathcal{D}_\Gamma^h$, $\mathcal{L}^h$, and $\mathcal{R}^h$ are approximations of the operators $\mathcal{D}_\Omega$, $\mathcal{D}_\Gamma$, $\mathcal{L}$, and $\mathcal{R}$, respectively, and $\mathcal{Q}_\Omega^h : H_\Omega \mapsto L^2(\Omega)$ and $\mathcal{Q}_\Gamma^h : H_\Gamma \mapsto L^2(\Gamma)$ are projections. It can be shown that $J_h(u^h; f, g)$ satisfies (19) with a specific form for $E(u, v^h)$.

The operators $\mathcal{L}$ and $\mathcal{R}$ define the problem (1) that is being solved so that the main objective in choosing $\mathcal{L}^h$ and $\mathcal{R}^h$ is to make $J_h(u; f, g)$ as small as possible for the exact solutions $u$. An appropriate choice is to use operators that will lead to truncation errors of order $r$ in (19), i.e., $\mathcal{L}^h$ and $\mathcal{R}^h$ should be such that (21) holds. On the other hand, $\mathcal{D}_\Omega$ and $\mathcal{D}_\Gamma$ define the energy balance of (1), i.e., the proper scaling between data and solution spaces. As a result, the main objective in the choice of $\mathcal{D}_\Omega^h$ and $\mathcal{D}_\Gamma^h$ is to ensure that the scaling induced by $J_h(\cdot\,; f, g)$ is as close as possible to (2), i.e., to "bind" $\{S^h, J_h(\cdot\,; f, g)\}$ to the energy balance of $\{S, J(\cdot\,; f, g)\}$.

For *norm-equivalent* discrete least-squares principles, $J_h(\cdot, f, g)$ satisfies

$$\hat{\alpha}_1 \|u^h\|_S \le J_h(\cdot\,; 0, 0) \le \hat{\alpha}_2 \|u^h\|_S \quad \text{for all } u^h \in S^h.$$

If the finite element space satisfies standard inverse assumptions, minimizers of this functional satisfy the error estimate

$$\|u - u^h\|_S \le C\left\{ \inf_{v^h \in S^h} \|u - v^h\|_S + \left( \inf_{v^h \in S^h} \|u - v^h\|_h + \sup_{v^h \in S^h} \frac{E(u, v^h)}{\|v^h\|_h} \right) \right\}.$$

[12] Recall from §2.2 that the use of $L^2(\Omega)$ norms in the definition of the least-squares functional is a key factor to making an LSFEM practical.

For *quasi norm-equivalent* discrete least-squares principles, $J_h(\cdot\,;\, f, g)$ satisfies

$$\hat{\alpha}_1^h \|u^h\|_S \leq J_h(\cdot\,; 0, 0) \leq \hat{\alpha}_2^h \|u^h\|_S,$$

where $\hat{\alpha}_1^h > 0$ and $\hat{\alpha}_2^h > 0$ for all $h > 0$ but may depend on $h$. Under additional assumptions, error estimates can also be derived in this case.

## 4. Compatible LSFEMs

Stable mixed finite element methods (MFEMs) for the Poisson equation[13] based on first-order formulations involving a scalar variable $\phi$ and a vector (or flux) variable $\boldsymbol{u}$ require the use of finite element spaces that satisfy an appropriate inf-sup condition [19], [20]. It is well known that pairs of standard, nodal-based, continuous finite element spaces fail the inf-sup condition and lead to unstable mixed methods. It is also well known that the inf-sup condition is circumvented if one uses such simple element pairs in LSFEMs based on $L^2$ least-squares functionals. Ever since such LSFEMs for first-order formulations of the Poisson equation were first considered in [38], this fact has been deemed as an important advantage of those methods over MFEMs. On the other hand, such LSFEMs suffer from two deficiencies. Computationally-based observations indicate that nodal-based LSFEMs do a poor job, compared to stable MFEMs, of conserving mass, i.e., of locally satisfying $\nabla \cdot \boldsymbol{u} = 0$. In addition, excepting in one special case, such methods produce suboptimally accurate (with respect to $L^2(\Omega)$ norms) flux approximations.[14]

Already in [38], optimal $L^2$ error estimates for LSFEMs were established for the scalar variable; however, there and in all subsequent analyses, optimal $L^2$ error estimates for the flux could not be obtained[15] without the addition of a "redundant" curl equation; see, e.g., [23], [24], [26], [39], [43]. Moreover, computational studies in [32] strongly suggested that optimal $L^2$ convergence for flux approximations may in fact be nearly impossible to obtain if one uses pairs of standard, nodal-based, continuous finite element spaces. A notable exception was a case studied in [32] for which optimal $L^2$ error estimates for both the scalar variable and the flux were obtained when these variables were approximated by continuous nodal spaces corresponding to a criss-cross grid. The key to proving these results was the validity of a grid decomposition property (GDP) which was established for the criss-cross grid in [33]. So far, the criss-cross grid remains the only known case of a continuous, nodal-based

[13] Although we consider only the Poisson problem, much of what we discuss can be easily extended to other systems of elliptic PDEs.

[14] The least-squares functionals in question are norm equivalent so that optimally accurate approximations are obtained with respect to the norms for which the equivalences hold. Here, we are interested in error estimates in weaker $L^2(\Omega)$ norms for which the norm equivalence of the least-square functional does not by itself guarantee optimal accuracy.

[15] A somewhat different situation exists for negative-norm-based LSFEMs for which it is known that the $L^2$ accuracy of the flux is optimal with respect to the spaces used; however, for such methods, no error bound for the divergence of the flux could be established; see [18].

finite element space for which the GDP can be verified. More importantly, it was shown in [33] (see also [17]) that the GDP is necessary and sufficient for the stability of MFEMs.

The correlation between the stability of MFEMs and the optimal accuracy of LSFEMs, established in [32], opens up the intriguing possibility that optimal $L^2$ accuracy for the flux may be obtainable for an LSFEM, provided that this variable is approximated using finite element spaces that are stable for an appropriate MFEM. Today, the stability of MFEMs is well understood, and many examples of stable finite element pairs are known. We will show that the use of some of these spaces in an LSFEM indeed can help improve the $L^2$ accuracy of flux approximations.

What we conclude is that if one gives up the use of nodal-based, continuous finite element spaces for the approximation of the flux, one can obtain optimally accurate approximations of the flux with respect to $L^2(\Omega)$ norms. While this conclusion may disappoint the adherents of equal-order implementations,[16] our results do not void LSFEMs as a viable or even preferable computational alternative to MFEMs. To the contrary, they demonstrate that *an LSFEM can be designed that combines the best computational properties of two dual MFEMs* and at the same time manages to avoid the inf-sup conditions and indefinite linear systems that make the latter more difficult to solve. Although we reach this conclusion in the specific context of MFEMs and LSFEMs for the Poisson problem, the idea of defining the latter type of method so that it inherits the best characteristics of a pair of mixed methods that are related through duality may have considerably wider application.

In the rest of this section, we focus the Poisson equation

$$-\Delta\phi = f \ \text{ in } \Omega, \quad \phi = 0 \ \text{ on } \Gamma_d, \quad \text{and} \quad \partial\phi/\partial n = 0 \ \text{ on } \Gamma_n, \tag{22}$$

where $\Omega$ denotes a bounded region in $\Re^d$, $d = 2, 3$, with a Lipschitz continuous boundary $\Gamma$ that consists of two disjoint parts denoted by $\Gamma_d$ and $\Gamma_n$.

**4.1. MFEMs for the Poisson problem.** So as to provide a background for subsequent discussions concerning LSFEMs, we first consider two[17] (dual) MFEMs for the Poisson problem (22) written in the first-order form

$$\nabla \cdot \boldsymbol{u} = f, \quad \boldsymbol{u} + \nabla\phi = \mathbf{0} \ \text{ in } \Omega, \quad \phi = 0 \ \text{ on } \Gamma_d, \quad \boldsymbol{u} \cdot \boldsymbol{n} = 0 \ \text{ on } \Gamma_n. \tag{23}$$

**4.1.1. Stable MFEMs for the Dirichlet principle.** Continuous, nodal finite element spaces built from $m$th degree polynomials, $m \geq 1$, and whose elements satisfy the boundary condition $\phi = 0$ on $\Gamma_n$ are denoted by $\mathcal{S}_m^0$. Note that $\mathcal{S}_m^0 \subset \{\psi \in H^1(\Omega) \mid \psi = 0 \text{ on } \Gamma_d\}$. We denote by $\mathcal{S}_m^1$ the space $\nabla(\mathcal{S}_m^0)$.[18]

[16] Recall that the ability to approximate all variables using simple nodal finite element spaces was one or the advantages of the FEMs in the Rayleigh–Ritz setting that we set out to recover using LSFEMs.

[17] Because they can be derived from two classical optimization problems, we will refer to the two methods as the discretized Dirichlet and Kelvin principles, respectively.

[18] Except for $m = 1$, $\mathcal{S}_m^1$ is not a complete $(m-1)$st degree polynomial space. However, characterizing $\mathcal{S}_m^1$ is not difficult and turns out to be unnecessary in practice.

A stable MFEM based on the Dirichlet principle is defined as follows: seek $\psi_h \in \mathcal{S}_m^0$ and $\boldsymbol{u}_h \in \mathcal{S}_m^1 = \nabla(\mathcal{S}_m^0)$ such that

$$\begin{cases} \displaystyle\int_\Omega \boldsymbol{u}_h \cdot \boldsymbol{v}_h \, d\Omega + \int_\Omega \nabla\phi_h \cdot \boldsymbol{v}_h \, d\Omega = 0 & \text{for all } \boldsymbol{v}_h \in \mathcal{S}_m^1, \\ \displaystyle\int_\Omega \nabla\psi_h \cdot \boldsymbol{u}_h \, d\Omega = -\int_\Omega f\psi_h \, d\Omega & \text{for all } \psi \in \mathcal{S}_m^0. \end{cases} \tag{24}$$

Note that since $\mathcal{S}_m^1 = \nabla(\mathcal{S}_m^0)$, even at the discrete level, we may eliminate the flux approximation to obtain the equivalent discrete problem for $\phi_h \in \mathcal{S}_m^0$

$$\int_\Omega \nabla\phi_h \cdot \nabla\psi_h \, d\Omega = \int_\Omega f\psi_h \, d\Omega \quad \text{for all } \psi \in \mathcal{S}_m^0 \tag{25}$$

that we recognize as the standard Galerkin discretization of (22). In fact, (24) and (25) are equivalent in that whenever $\phi_h$ is a solution of (25), then $\phi_h$ and $\boldsymbol{u}_h = \nabla\phi_h$ are a solution pair for (24) and conversely. In this way we see that for (24), i.e., the Dirichlet principle, the required inf-sup condition is completely benign in the sense that it can be avoided by eliminating the flux approximation $\boldsymbol{u}_h$ from (24) and solving (25) instead. The required inf-sup condition is implicitly satisfied by the pair of spaces $\mathcal{S}_m^0$ and $\mathcal{S}_m^1 = \nabla(\mathcal{S}_m^0)$. If one insists on solving (24), then one needs to explicitly produce a basis for $\mathcal{S}_m^1$; this is easily accomplished.

From either (24) or (25) one obtains, for the Dirichlet principle, that if $\phi \in H^{m+1}(\Omega) \cap H_d^1(\Omega)$, then

$$\|\phi - \phi_h\|_0 \le h^{m+1}\|\phi\|_{m+1} \quad \text{and} \quad \|\boldsymbol{u} - \boldsymbol{u}_h\|_0 = \|\nabla(\phi - \phi_h)\|_0 \le h^m\|\phi\|_{m+1}. \tag{26}$$

**4.1.2. Stable MFEMs for the Kelvin principle.** The $\mathrm{BDM}_k$ and $\mathrm{RT}_k$ spaces on $\Omega$ are built from the individual element spaces defined with respect to a finite element $\mathcal{K}$ in a partition $\mathcal{T}_h$ of $\Omega$

$$\mathrm{BDM}_k(\mathcal{K}) = (P_k(\mathcal{K}))^n \quad \text{and} \quad \mathrm{RT}_k(\mathcal{K}) = (P_k(\mathcal{K}))^n + \boldsymbol{x}\,P_k(\mathcal{K})$$

in a manner that ensures the continuity of the normal component across element boundaries; see [20] for details and definitions of the corresponding element degrees of freedom. Since $\mathrm{BDM}_k$ and $\mathrm{RT}_k$ both contain complete polynomials of degree $k$, their approximation properties in $L^2$ are the same. Since $\mathrm{RT}_k$ also contains the higher-degree polynomial component $\boldsymbol{x}\,P_k(\mathcal{K})$, it approximates the divergence of the flux with better accuracy than does $\mathrm{BDM}_k$. Note, however, that this additional component does not help to improve the $L^2$ accuracy of $\mathrm{RT}_k$ spaces because it does not increase to $k+1$ the order of the complete polynomials contained in $\mathrm{RT}_k$.

In what follows, we will denote by $\mathcal{S}_k^2$ the RT and BDM spaces having *equal approximation orders with respect to the divergence operator*, i.e., we set $\mathcal{S}_k^2 = \{\boldsymbol{v} \in H_n(\Omega, \mathrm{div}) \mid \boldsymbol{v}|_{\mathcal{K}} \in \mathcal{S}_k^2(\mathcal{K})\}$, where $\mathcal{S}_k^2(\mathcal{K})$ is one of the finite element spaces

$\mathrm{RT}_{k-1}(\mathcal{K})$ or $\mathrm{BDM}_k(\mathcal{K})$ and $H_n(\Omega, \mathrm{div}) = \{\boldsymbol{v} \in H_n(\Omega, \mathrm{div}) \mid \boldsymbol{v} \cdot \boldsymbol{n} = 0 \text{ on } \Gamma_n\}$. We denote by $\mathcal{S}_k^3$ the space $\nabla \cdot (\mathcal{S}_k^2)$. For characterizations of these spaces, see [20].

A stable MFEM based on the Kelvin principle is defined as follows: we seek $\boldsymbol{u}_h \in \mathcal{S}_k^2$ and $\phi_h \in \mathcal{S}_k^3 = \nabla \cdot (\mathcal{S}_k^2)$ such that

$$\begin{cases} \displaystyle\int_\Omega \boldsymbol{u}_h \cdot \boldsymbol{v}_h \, d\Omega - \int_\Omega \phi_h \nabla \cdot \boldsymbol{v}_h \, d\Omega = 0 & \text{for all } \boldsymbol{v}_h \in \mathcal{S}_k^2, \\ \displaystyle\int_\Omega \psi_h \nabla \cdot \boldsymbol{u}_h \, d\Omega = \int_\Omega f \psi_h \, d\Omega & \text{for all } \psi_h \in \mathcal{S}_k^3. \end{cases} \tag{27}$$

For (27), the required inf-sup condition is much more onerous than for (24) in the sense that defining a pair of stable finite element spaces for the scalar variable and the flux is not so straightforward a matter. We refer to [20] for a proof that $(\mathcal{S}_k^3, \mathcal{S}_k^2)$ is a stable pair for the mixed finite element problem (27). Moreover, one can show [20] that for any sufficiently regular exact solution of (23), one has

$$\|\boldsymbol{u} - \boldsymbol{u}_h\|_0 \le C h^r \|\boldsymbol{u}\|_r \quad \begin{cases} \text{for } 1 \le r \le k & \text{if } \mathcal{S}_k^2(\mathcal{K}) = \mathrm{RT}_{k-1}, \\ \text{for } 1 \le r \le k+1 & \text{if } \mathcal{S}_k^2(\mathcal{K}) = \mathrm{BDM}_k, \end{cases} \tag{28}$$

$$\|\nabla \cdot (\boldsymbol{u} - \boldsymbol{u}_h)\|_0 \le C h^r \|\nabla \cdot \boldsymbol{u}\|_r \quad \text{for } 1 \le r \le k \tag{29}$$

and

$$\|\phi - \phi_h\|_0 \le C h^r (\|\phi\|_r + \|\boldsymbol{u}\|_r) \quad \text{for } 1 \le r \le k. \tag{30}$$

It is important to note that if one uses continuous, nodal based finite element spaces for both the scalar variable and the flux, then (24) and (27) are identical discrete systems. It is well known that this leads to unstable approximations, so that one cannot use such pairs of finite element spaces in the MFEMs (24) or (27).

**4.1.3. The grid decomposition property.** The following result establishes the GDP for the spaces $\mathcal{S}_k^2$ used for the discretized Kelvin principle (27);[19] for a proof, see [14].

**Theorem 4.1.** *For every $\boldsymbol{u}_h \in \mathcal{S}_k^2$, there exist $\boldsymbol{w}_h, z_h$ in $\mathcal{S}_k^2$ such that*

$$\begin{aligned} &\boldsymbol{u}_h = \boldsymbol{w}_h + z_h, \quad \nabla \cdot z_h = 0, \quad \int_\Omega \boldsymbol{w}_h \cdot z_h \, d\Omega = 0, \quad \textit{and} \\ &\|\boldsymbol{w}_h\|_0 \le C\big(\|\nabla \cdot \boldsymbol{u}_h\|_{-1} + h\|\nabla \cdot \boldsymbol{u}_h\|_0\big). \end{aligned} \tag{31}$$

It was shown in [33] that the GDP, i.e., (31), along with the relation $\mathcal{S}_k^3 = \nabla \cdot (\mathcal{S}_k^2)$, are necessary and sufficient for the stability of the discretized Kelvin principle (27).

[19] An analogous GDP can be defined in the context of the finite element spaces $\mathcal{S}_m^0$ used for the discretized Dirichlet principle (24) but it is trivially satisfied.

**4.2. LSFEMs for the Poisson problem.** An LSFEM for the Poisson problem (22) can be defined based on the quadratic functional

$$J(\phi, \boldsymbol{u};\, f) = \|\nabla \cdot \boldsymbol{u} - f\|_0^2 + \|\nabla\phi + \boldsymbol{u}\|_0^2 \tag{32}$$

and the least-squares principle

$$\min_{(\phi,\boldsymbol{u})\in H_d^1(\Omega)\times H_n(\Omega,\mathrm{div})} J(\phi, \boldsymbol{u};\, f). \tag{33}$$

Note that we have used the first-order form (23) of the Poisson problem and that we use $L^2(\Omega)$ norms to measure the equation residuals. Also, we require the functions in the spaces $H_d^1(\Omega)$ and $H_n(\Omega, \mathrm{div})$ to satisfy the boundary conditions $\phi = 0$ on $\Gamma_d$ and $\boldsymbol{u} \cdot \boldsymbol{n} = 0$ on $\Gamma_n$, respectively. The Euler–Lagrange equations corresponding to (33) are given by: seek $\{\phi, \boldsymbol{u}\} \in H_d^1(\Omega) \times H_n(\Omega, \mathrm{div})$ such that

$$B(\{\phi, \boldsymbol{u}\}, \{\psi, \boldsymbol{v}\}) = F(\{\psi, \boldsymbol{v}\}) \quad \text{for all } \{\psi, \boldsymbol{v}\} \in H_d^1(\Omega) \times H_n(\Omega, \mathrm{div}), \tag{34}$$

where

$$B(\{\phi, \boldsymbol{u}\}, \{\psi, \boldsymbol{v}\}) = \int_\Omega (\nabla \cdot \boldsymbol{u})(\nabla \cdot \boldsymbol{v})\, d\Omega + \int_\Omega (\nabla\phi + \boldsymbol{u}) \cdot (\nabla\psi + \boldsymbol{v})\, d\Omega \tag{35}$$

and

$$F(\{\psi, \boldsymbol{v}\}) = \int_\Omega f(\nabla \cdot \boldsymbol{v})\, d\Omega. \tag{36}$$

To define an LSFEM, we restrict (33) to the conforming subspace $\mathcal{S}_m^0 \times \mathcal{S}_k^2 \subset H_d^1(\Omega) \times H_n(\Omega, \mathrm{div})$ or, equivalently, restrict (34) to those subspaces to obtain the discrete problem: seek $\{\phi_h, \boldsymbol{u}_h\} \in \mathcal{S}_m^0 \times \mathcal{S}_k^2$ such that

$$B(\{\phi_h, \boldsymbol{u}_h\}, \{\psi_h, \boldsymbol{v}_h\}) = F(\{\psi_h, \boldsymbol{v}_h\}) \quad \text{for all } \{\psi_h, \boldsymbol{v}_h\} \in \mathcal{S}_m^0 \times \mathcal{S}_k^2. \tag{37}$$

The next theorem states that the functional (32) is norm equivalent.[20] For a proof, see any of [21], [23], [24], [43].

**Theorem 4.2.** *There exist positive constants $\alpha_1$ and $\alpha_2$ such that for any $\{\phi, \boldsymbol{u}\} \in H_d^1(\Omega) \times H_n(\Omega, \mathrm{div})$,*

$$\alpha_1\big(\|\phi\|_1^2 + \|\boldsymbol{u}\|_{H(\Omega,\mathrm{div})}^2\big) \le J(\phi, \boldsymbol{u}; 0) \le \alpha_2\big(\|\phi\|_1^2 + \|\boldsymbol{u}\|_{H(\Omega,\mathrm{div})}^2\big). \tag{38}$$

Thus, the LSFEM defined through (37) is an example of an LSFEM that recovers all the desirable properties of the Rayleigh–Ritz setting, except that by using the finite element spaces $\mathcal{S}_m^0$ and $\mathcal{S}_k^2$, we have forced ourselves to not use continuous, nodal-based finite element spaces for the flux approximation.[21] Because we are using finite element spaces that are compatible for the MFEMs (24) and (27), we refer to the LSFEM defined by (37) as a *compatible* LSFEM.

[20] In the theorem, we have that $\|\boldsymbol{u}\|_{H(\Omega,\mathrm{div})} = (\|\boldsymbol{u}\|_0^2 + \|\nabla \cdot \boldsymbol{u}\|_0^2)^{1/2}$.

[21] We could, of course, use such spaces for the flux approximation, but, as indicated previously, we would then not be able to obtain optimal error estimates with respect to $L^2(\Omega)$ norms.

**4.2.1. Error estimates in $H^1(\Omega) \times H(\Omega, \mathrm{div})$.** We now review the convergence properties of LSFEMs for the Poisson equation with respect to the $H^1(\Omega) \times H(\Omega, \mathrm{div})$ norm. For a proof of the following theorem, see [14].

**Theorem 4.3.** *Assume that the solution* $\{\phi, \boldsymbol{u}\}$ *of* (34) *satisfies* $\{\phi, \boldsymbol{u}\} \in H_d^1(\Omega) \cap H^{m+1}(\Omega) \times H_n(\Omega, \mathrm{div}) \cap \boldsymbol{H}^{k+1}(\Omega)$ *for some integers* $k, m \geq 1$. *Let* $\{\phi_h, \boldsymbol{u}_h\} \in \mathcal{S}_m^0 \times \mathcal{S}_k^2$ *be the solution of the least-squares finite element problem* (37). *Then there exists a constant* $C > 0$ *such that*

$$\|\phi - \phi_h\|_1 + \|\boldsymbol{u} - \boldsymbol{u}_h\|_{H(\Omega,\mathrm{div})} \leq C\big(h^k \|\boldsymbol{u}\|_{k+1} + h^m \|\phi\|_{m+1}\big). \tag{39}$$

*The error estimate* (39) *remains valid if* $\boldsymbol{u}$ *is approximated in the continuous, nodal-based finite element space* $(P_k(\Omega))^n$.

Theorem 4.3 shows that the errors in $\boldsymbol{u}_h$ and $\phi_h$ are equilibrated when $k = m$ and that $(\mathcal{S}_k^0, \mathcal{S}_k^2)$ has the same asymptotic accuracy in the norm of $H^1(\Omega) \times H(\Omega, \mathrm{div})$ as the $C^0$ pair $(\mathcal{S}_k^0, (P_k)^n)$. For this reason, in the implementation of the LSFEM, one usually chooses the nodal-based pair $(\mathcal{S}_k^0, (P_k)^n)$ because it is easier to implement. Indeed, the ability to use equal-order interpolation has been often cited as a primary reason for choosing to use LSFEMs. Nevertheless, the pair is not flawless because optimal $L^2$ norm errors for the flux approximation have proven impossible to obtain without using the very restrictive criss-cross grid or augmenting (23) with an additional redundant curl constraint equation.[22] Also, as we have already mentioned, numerical studies in [32] indicate that the $L^2$ convergence of the flux is indeed suboptimal with such finite element spaces.

We will see that if the nodal approximation of the flux is replaced by an approximation in $\mathcal{S}_k^2$, it may be possible to recover optimal $L^2$ convergence rates without adding the curl constraint. As in [32], the key to this is the GDP.

**4.2.2. Error estimates in $L^2$.** We assume that the solution of the problem

$$-\Delta\psi = \eta \ \text{ in } \Omega, \quad \psi = 0 \ \text{ on } \Gamma_d, \quad \frac{\partial \psi}{\partial n} = 0 \ \text{ on } \Gamma_n$$

satisfies the regularity estimate $\|\psi\|_{s+2} \leq C\|\eta\|_s$ for $s = 0, 1$ and for all $\eta \in H^s(\Omega)$. This is needed since $L^2$ error estimates are based on duality arguments.

### $L^2$ error estimates for the scalar variable.

**Theorem 4.4.** *Assume that the regularity assumption is satisfied, and assume that the solution* $(\phi, \boldsymbol{u})$ *of* (34) *satisfies* $(\phi, \boldsymbol{u}) \in H_d^1(\Omega) \cap H^{m+1}(\Omega) \times H_n(\Omega, \mathrm{div}) \cap \boldsymbol{H}^{k+1}(\Omega)$

[22] The redundant curl constraint $\nabla \times \boldsymbol{u} = \boldsymbol{0}$, first introduced in the least-squares finite element setting in [26] and subsequently utilized by many others (see, e.g., [21], [23], [24], [39]), renders the least-squares functional norm-equivalent with respect to the $H^1(\Omega) \times \boldsymbol{H}^1(\Omega)$ norm but, in some situations, may unduly restrict the range of the data and should be avoided.

*for some integers $k, m \geq 1$. Let $(\phi_h, \boldsymbol{u}_h) \in \mathcal{S}_m^0 \times \mathcal{S}_k^2$ be the solution of the least-squares finite element problem* (37). *Then there exists a constant $C > 0$ such that* $\|\phi - \phi_h\|_0 \leq C(h^{k+1}\|\boldsymbol{u}\|_{k+1} + h^{m+1}\|\phi\|_{m+1})$.

For a proof of this theorem, see [14]. The optimal $L^2$ error bound of Theorem 4.4 for the scalar variable does not require that the finite element space for flux approximations satisfy (31), i.e., the GDP. Thus, it remains valid even when continuous, nodal-based finite element spaces are used for the flux approximations, a result first shown in [38]. On the other hand, we will see that the GDP is needed if one wants to improve the $L^2$ accuracy of the flux.

**$L^2$ error estimate for the flux.** The $L^2$ error estimates for approximations to the flux depend on whether $\mathcal{S}_k^2$ represents the $\mathrm{RT}_{k-1}$ or the $\mathrm{BDM}_k$ family. To this end, we have the following result whose proof may be found in [14].

**Theorem 4.5.** *Assume that the hypotheses of Theorem* 4.4 *hold with $k = m = r$. Then there exists a constant $C > 0$ such that*

$$\|\boldsymbol{u} - \boldsymbol{u}_h\|_0 \leq C \begin{cases} h^r(\|\boldsymbol{u}\|_{r+1} + \|\phi\|_{r+1}) & \text{if } \mathcal{S}_r^2(\Omega) = \mathrm{RT}_{r-1}, \\ h^{r+1}(\|\boldsymbol{u}\|_{r+1} + \|\phi\|_{r+1}) & \text{if } \mathcal{S}_r^2(\Omega) = \mathrm{BDM}_r. \end{cases} \tag{40}$$

Consider, for example, the lowest-order case for which $r = 1$, $\mathcal{S}_1^0(\Omega) = P_1$, and $\mathcal{S}_1^2(\Omega)$ is either $\mathrm{RT}_0$ or $\mathrm{BDM}_1$. If the least-squares finite element method is implemented with $\mathrm{RT}_0$ elements, (40) specializes to

$$\|\boldsymbol{u} - \boldsymbol{u}_h\|_0 \leq h(\|\boldsymbol{u}\|_2 + \|\phi\|_2).$$

If instead we use $\mathrm{BDM}_1$ elements, we then obtain the improved error bound

$$\|\boldsymbol{u} - \boldsymbol{u}_h\|_0 \leq h^2(\|\boldsymbol{u}\|_2 + \|\phi\|_2).$$

**4.3. Interpretation of results and mass conservation.** We have seen that an LS-FEM method implemented using equal-order, continuous, nodal-based finite element spaces approximates the scalar variable with the same accuracy (with respect to both $H^1(\Omega)$ and $L^2(\Omega)$ norms) as the Galerkin method (25) (or, equivalently, the mixed method (24) for the Dirichlet principle. However, the approximation properties of the Kelvin principle (27) are only partially inherited in the sense that the accuracy in the approximation to the divergence of the flux is recovered, but the accuracy in the flux approximation itself may be of one order less. This should not be too much of a surprise because continuous, nodal-based finite elements provide stable discretization only for the Dirichlet principle (with the exception of the criss-cross grid; see [32]). While least-squares minimization is stable enough to allow for the approximation of scalar variables and the flux by equal-order, continuous, nodal-based finite element

spaces, it cannot completely recover from the fact that such spaces are unstable for the Kelvin principle.

The key observation from §4.2.2 is that an LSFEM can inherit the best properties of *both* the discretized Dirichlet principle (24) and Kelvin principle (27), provided the scalar variable and the flux are approximated by finite element spaces that are stable with respect to these two principles, respectively. Then least-squares finite element solutions recover the accuracy of the Dirichlet principle for the scalar variable and the accuracy of the Kelvin principle for the flux. In a way, we see that, implemented in this particular manner, the LSFEM represents a balanced mixture of the two principles. In [16], an explanation of this observation using the apparatus of differential form calculus is provided as are the results of several illustrative computational experiments.

Unlike LSFEMs based on the use of continuous, nodal-based finite element spaces for all variables, it can be shown that through a simple local post-processing procedure, the compatible LSFEM inherits the local mass conservation properties of the discretized Kelvin principle (27); see [16] for details.

## 5. Alternative LSFEMs

The LSFEMs considered so far follow variants of the template established in §2: first, spaces $S$, $H_\Omega$, and $H_\Gamma$ that verify (2) are determined, then a least-squares functional (3) is defined by measuring equation residuals in the norms of $H_\Omega$ and $H_\Gamma$ and, finally, an LSFEM is obtained by minimizing (3) over a finite-dimensional subspace $S^h$ of $S$. Here, we provide examples of methods that, while still relying on least-squares notions, deviate in more significant ways from that template.

**5.1. Collocation LSFEMs.** The least-squares optimization steps (3) and (4) precede the discretization step (5). In the broadest sense, *collocation* LSFEM (CLSFEM) are methods [25], [31], [41] that reverse the order of these two steps. They are also known as *point least-squares* or *overdetermined collocation* methods.

Let $\{U_j(\boldsymbol{x})\}_{j=1}^J$ denote a basis for a finite element space. We seek an approximate solution of (1) of the form $u(\boldsymbol{x}) \approx \hat{u}_h(\boldsymbol{x}) = \sum_{j=1}^J c_j U_j(\boldsymbol{x})$, where $\boldsymbol{c} = (c_1, c_2, \ldots, c_J)$ is a vector of unknown coefficients. Then *collocation points* $\{\boldsymbol{x}_i\}_{i=1}^{M_1} \subset \Omega$ and $\{\boldsymbol{x}_i\}_{i=M_1+1}^{M} \subset \Gamma$ are chosen in such a way that the corresponding point residuals $\mathcal{L}\hat{u}_h(\boldsymbol{x}_i) - f(\boldsymbol{x}_i)$ and $\mathcal{R}\hat{u}_h(\boldsymbol{x}_i) - g(\boldsymbol{x}_i)$ are well defined. Then a CLSFEM is defined by minimizing, over $\boldsymbol{c} \in \Re^J$, the discrete functional

$$J_c(\boldsymbol{c}; f, g) = \sum_{i=1}^{M_1} \alpha_i \big(\mathcal{L}\hat{u}_h(\boldsymbol{x}_i) - f(\boldsymbol{x}_i)\big)^2 + \sum_{i=M_1+1}^{M} \beta_i \big(\mathcal{R}\hat{u}_h(\boldsymbol{x}_i) - g(\boldsymbol{x}_i)\big)^2.$$

The weights $\alpha_i$ and $\beta_i$ can be used to adjust the relative importance of the terms in the functional. The necessary condition for the minimization of $J_c(\,\cdot\,; f, g)$ gives rise

to an $M \times J$ linear system $\mathbb{A}\boldsymbol{c} = \boldsymbol{b}$. If $M = J$, then the method reduces to a standard collocation method. If $M > J$, the solution $\boldsymbol{c}$ is obtained in a least-squares sense by solving the normal equations $\mathbb{A}^T\mathbb{A}\boldsymbol{c} = \mathbb{A}^T\boldsymbol{b}$. If the collocation points and weights correspond to a quadrature rule, then the CLSFEM is equivalent to an LSFEM in which integrals are approximated by a quadrature rule.

Since only a finite set of collocation points belonging to the domain $\overline{\Omega}$ need be specified, collocation LSFEMs are attractive for problems posed on irregularly shaped domains; see [41]. On the other hand, since the normal equations tend to become ill-conditioned, such methods require additional techniques such as scaling or orthonormalization in order to obtain a reliable solution; see [31].

**5.2. Discontinuous LSFEMs.** The LSFEMs of §2, 3, and 4 are defined using a conforming finite element subspace $S^h$ of the solution space $S$. Discontinuous LSFEMs (DLSFEMs) are an alternative approach that use finite element subspaces of $L^2(\Omega)$ that consist of piecewise polynomial functions that are not constrained by inter-element continuity requirements. The degrees of freedom on each element can be chosen independently of each other and the elements can have hanging nodes. These features offer great flexibility in implementing adaptive methods because first, resolution on each element can be adjusted as needed and second, new elements can be added by simple subdivisions of existing elements.

In general, the least-squares problem (4) cannot be restricted to a discontinuous space $S^h$ because it is not a proper subspace of $S$. To take advantage of discontinuous spaces, it is necessary to modify (3) so that it is well defined on the "broken" (with respect to a partition $\mathcal{T}_h$ of the domain $\Omega$) data space $\boldsymbol{S} = \{u \in L^2(\Omega) \mid u \in S(\mathcal{K}) \text{ for all } \mathcal{K} \in \mathcal{T}_h\}$. The first DLSFEMs appeared in [2], [22] as least-squares formulations for interface and transmission problems for the Poisson equation. We follow [22], where a DLSFEM is developed for the problem

$$\begin{cases} \nabla \cdot (a_i \boldsymbol{u}_i) = f_i & \text{and} \quad \boldsymbol{u}_i + \nabla\phi_i = \boldsymbol{0} \text{ in } \Omega_i, \quad i = 1, 2, \\ \phi_i = 0 \text{ on } \Gamma_{i,d} & \text{and} \quad \boldsymbol{u}_i \cdot \boldsymbol{n}_i = 0 \text{ on } \Gamma_{i,n}, \quad i = 1, 2, \\ \phi_1 = \phi_2 & \text{and} \quad a_1\boldsymbol{u}_1 \cdot \boldsymbol{n}_1 + a_2\boldsymbol{u}_2 \cdot \boldsymbol{n}_2 = 0 \quad \text{on } \Gamma_{12} \end{cases} \tag{41}$$

that is a first-order formulation of a transmission problem for the Poisson equation.[23] Here, $\Omega_1$ and $\Omega_2$ are two[24] open subsets of $\Omega$ such that $\overline{\Omega}_1 \cup \overline{\Omega}_2 = \overline{\Omega}$ and $\Omega_1 \cap \Omega_2 = \emptyset$. The set $\Gamma_{12} = \overline{\Omega}_1 \cup \overline{\Omega}_2$ is the *interface* between the two subdomains and $\Gamma_{i,d} = \Gamma_d \cap \overline{\Omega}_i$ and $\Gamma_{i,n} = \Gamma_n \cap \overline{\Omega}_i$, $i = 1, 2$.

In the conforming case, an LSFEM for the Poisson equation was defined by using the functional (32) and conforming subspaces of the solution space $S = H^1_d(\Omega) \times H_n(\Omega, \text{div})$. For the problem (41), we instead use the "broken" (with respect to the

[23]The functions $a_1$ and $a_2$ denote a "media property" that is discontinuous across $\Gamma_{12}$.

[24]The generalization to more than two subdomains is straightforward.

partition $\{\Omega_1,\Omega_2\}$) solution space $\boldsymbol{S} = \boldsymbol{H}^1_d(\Omega) \times \boldsymbol{H}_n(\Omega, \mathrm{div})$, where

$$\begin{aligned}
&\boldsymbol{H}^1_d(\Omega) = \{\widetilde{\phi} = \{\phi_1, \phi_2\} \mid \phi_i \in H^1_d(\Omega_i),\ i = 1, 2\} && \text{for the scalar variable,}\\
&\boldsymbol{H}_n(\Omega, \mathrm{div}) = \{\widetilde{\boldsymbol{u}} = \{\boldsymbol{u}_1, \boldsymbol{u}_2\} \mid \boldsymbol{u}_i \in H_n(\Omega_i, \mathrm{div}),\ i = 1, 2\} && \text{for the flux.}
\end{aligned}$$

To define a DLSFEM, we also need to replace (32) by a least-squares functional that can be minimized over $\boldsymbol{S}$. Of course, we also want a functional whose minimizer is a solution of (41). A functional with the desired properties is given by (see [22])

$$\begin{aligned}
J_{12}(\widetilde{\phi}, \widetilde{\boldsymbol{u}};\, f_1,\, f_2) = \sum_{i=1}^{2} \left( \|\nabla \cdot (a_i \boldsymbol{u}_i) - f_i\|^2_{0,\Omega_i^h} + \|\boldsymbol{u}_i + \nabla \phi_i\|^2_{0,\Omega_i^h} \right) \\
+ |\phi_1 - \phi_2|^2_{1/2,\Gamma_{12}} + \|a_1 \boldsymbol{u}_1 \cdot \boldsymbol{n}_1 + a_2 \boldsymbol{u}_2 \cdot \boldsymbol{n}_2\|^2_{-1/2,\Gamma_{12}}.
\end{aligned} \tag{42}$$

Interface terms in (42) are treated in exactly the same way as one would impose weak Dirichlet and Neumann conditions, respectively. To obtain a practical method, they are replaced by weighted $L^2$ norms on $\Gamma_{12}$. Choosing $\boldsymbol{S}^h \subset \boldsymbol{S}$ completes the formulation of the DLSFEM; see [22] for further details.

The Treffetz element least-squares method [42], [45] can be viewed as a variant of the DLSFEM. The term "Treffetz elements" usually refers to methods that use approximation spaces consisting of piecewise analytic solutions of the PDE. Such spaces provide highly accurate approximations of the broken solution space $\boldsymbol{S}$ so that they also require functionals that are well-posed with respect to that space. Given a Treffetz element space, it is a trivial matter to use (42) to define a DLSFEM; see [42], [45] for further details.

## 6. Open problems in LSFEM

We close with a brief discussion of some of the open problems that exist in the theory and application of LSFEMs.

**6.1. Hyperbolic PDEs.** Recovery of the Rayleigh–Ritz properties by LSFEMs relies on the existence of Hilbert spaces that validate the bounds (2) for (1). Such bounds are natural for elliptic PDEs and can be derived for any such PDE by using the Agmon–Douglis–Nirenberg theory [1]. On the other hand, for *hyperbolic* PDEs such bounds are not so natural, partly because they admit data in $L^p$ spaces and their solutions may have contact discontinuities and shock waves.

Recall that (7) can be viewed as a Galerkin method applied to a higher-order PDE. As a result, LSFEMs for hyperbolic equations designed using a Hilbert space setting are equivalent to a Galerkin discretization of a *degenerate* elliptic PDE. The result is an LSFEM that will have excellent stability properties but which will smear shocks and discontinuities; see [11] for numerical examples.

To illustrate some of the pitfalls that can be encountered with hyperbolic PDEs, it suffices to consider the simple linear convection-reaction problem

$$\nabla \cdot (\boldsymbol{b}u) + cu = f \ \text{ in } \Omega \quad \text{and} \quad u = g \ \text{ on } \Gamma_-, \tag{43}$$

where $\boldsymbol{b}$ is a given convection vector, $c(\boldsymbol{x})$ is a bounded measurable function on $\Omega$, and $\Gamma_- = \{\boldsymbol{x} \in \Gamma \mid \boldsymbol{n}(\boldsymbol{x}) \cdot \boldsymbol{b}(\boldsymbol{x}) < 0\}$ is the inflow part of the boundary $\Gamma$. A straightforward $L^2(\Omega)$ norm-based least-squares principle for (43) is defined by minimizing the functional

$$J(v; f, g) = \|\nabla \cdot (\boldsymbol{b}v) + cv - f\|_0^2 + \|v - g\|_{0,\Gamma_-}^2 \tag{44}$$

over the Hilbert space $S = \{u \in L^2(\Omega) \mid \mathcal{L}u = \nabla \cdot (\boldsymbol{b}v) + cv \in L^2(\Omega)\}$. Then the following theorem can be obtained [10].

**Theorem 6.1.** *Assume that $\Gamma_-$ is non-characteristic and $c + \frac{1}{2}\nabla \cdot \boldsymbol{b} \geq \sigma > 0$ for some constant $\sigma$. Then $J(v; 0, 0) = \|\nabla \cdot (\boldsymbol{b}v) + cv\|_0^2 + \|v\|_{0,\Gamma_-}^2$ is equivalent to the graph norm $\|v\|_S^2 = \|v\|_0^2 + \|\mathcal{L}v\|_0^2$. For every $f \in L^2(\Omega)$ and $g \in L^2(\Gamma_-)$, (44) has a unique minimizer $u \in S$ and for that $u$ we have that $J(u; 0, 0) \leq \|f\|_0 + \|g\|_{0,\Gamma_-}^2$.*

This theorem shows that if the data belongs to $L^2$, all the prerequisites needed to define an LSFEM are fulfilled. We can proceed as in §2 and define a method in the most straightforward way by restricting the Euler–Lagrange equation corresponding to the minimization of (44) to a finite dimensional subspace $S^h \subset S$.

However, the convection-reaction problem (43) is meaningful even if the data[25] $f$ belongs only to the Banach space $L^1(\Omega)$. In this case, proper solution and data spaces for (43) are given by $S = \{v \in L^1(\Omega) \mid \nabla \cdot (\boldsymbol{b}v) \in L^1(\Omega)\}$ and $H = L^1(\Omega)$, respectively. One can show [35] that $\mathcal{L}$ is an isomorphism $S \mapsto H$ and so, instead of (2), we have a similar bound but in Banach spaces: $\alpha_1 \|u\|_S \leq \|\mathcal{L}u\|_H$ for all $u \in S$.

Now, consider the unconstrained minimization problem associated with the spaces $S$ and $H$:

$$\min_{u \in S} J_1(u; f), \quad \text{where } J_1(u; f) = \|\mathcal{L}u - f\|_{L^1(\Omega)} = \int_\Omega |\mathcal{L}u - f| \, d\Omega. \tag{45}$$

For our model equation (43), this is the "correct" minimization problem that, restricted to $S^h \subset S$, will have solutions that do not smear discontinuities. This fact has been recognized independently in [40] and more recently in [35]. In [35], it is also shown that under some reasonable assumptions on $S^h$, the discrete problem

$$\min_{u^h \in S^h} J_1(u^h; f) \tag{46}$$

has at least one global minimizer, no local minimizers, and a solution that satisfies the stability bound $\|u^h\|_S \leq C\|f\|_H$.

[25] We assume now that $g = 0$.

We can view (45) as yet another example of the conflict between practicality and optimality. In this case, however, the practicality issue is much more severe because (45) is not differentiable, we cannot write a first-order optimality condition, and the discrete problem (46) does not give rise to a matrix problem. This is the chief reason that so far there are only two examples [35], [40] of FEMs for (43) based on the $L^1$ optimization problem (45). In [35], the minimizer of (46) is approximated by solving a sequence of regularized $L^1$ optimization problems that are differentiable. The method of [40] uses a sequence of more conventional $L^2$ least-squares approaches, but defined using an adaptively weighted $L^2$ inner product. The weights are used to weaken contributions to the least-squares functional from elements that contain solution discontinuities.

At this point, there is very limited experience with solving hyperbolic PDEs by minimizing functionals over Banach spaces. For problems with non-smooth data, computational experiments with the methods of [35] and [40] show that they are superior to LSFEMs defined through the minimization of (44); most notable is their ability to provide sharp discontinuity profiles without over- and under-shooting. A series of experiments in [35] also points strongly towards a possibility that the numerical solutions actually obey a maximum principle on general unstructured grids and that the $L^1$-based algorithm seems to be able to select viscosity solutions. However, at present, there are no mathematical confirmations of these facts, nor is it known whether such algorithms for hyperbolic conservation laws are able to provide accurate shock positions and speeds.

Despite the promise of $L^1$ optimization techniques, the state of LSFEMs for hyperbolic problems is far from satisfactory. Straightforward $L^2$ norm-based LSFEMs are clearly not the most appropriate as they are based on the "wrong" stability estimate for the problem. $L^1$ norm-based techniques give far better results but are more complex and, in the case of [35], require the solution of nonlinear optimization problems. Thus, the jury is still out on whether or not it is possible to define a simple, robust, and efficient LSFEMs for hyperbolic problems that will be competitive with specially designed, upwind schemes employing flux limiters.

**6.2. Mass conservation.** In §4 it was shown that LSFEMs for the Poisson equation can be implemented in a way that allows them to inherit the best computational properties of MFEMs for the same problem. In particular, it is possible to define an LSFEM for (23) so that the approximation *locally conserves mass*.

Currently, the methods in §4 are the only such example. Achieving local mass conservation in LSFEMs for incompressible, viscous flows remains an important open problem. All existing LSFEMs for incompressible, viscous flows conserve mass only approximately so that $\|\nabla \cdot \boldsymbol{u}^h\|_0 = O(h^r)$, where $r$ is the approximation order of the finite element space. For low-order elements, which are among the most popular and easy to use elements, LSFEMs have experienced severe problems with mass conservation. For LSFEMs based on the velocity–vorticity–pressure system (16), these problems were first identified in [27] where also a solution was proposed that

combines least-squares principles *and* Lagrange multipliers to achieve element-wise mass conservation. Then the resulting *restricted* LSFEM treats the continuity equation $\nabla \cdot \boldsymbol{u} = 0$ as an additional constraint that is enforced on each element by a Lagrange multiplier. The method achieves remarkable local conservation but compromises the main motivation underlying LSFEMs: to recover a Rayleigh–Ritz setting for the PDE. In particular, property 4c does not hold.

An alternative to exact local conservation is an LSFEM with *enhanced* total mass conservation. This can be effected by increasing the importance of the continuity residual by using weights. A weighted LSFEM for (16) using the functional

$$J_W(\boldsymbol{\omega}, p, \boldsymbol{u}) = \|\nabla \times \boldsymbol{\omega} + \nabla p - \boldsymbol{f}\|_0^2 + \sum_{\mathcal{K} \in \mathcal{T}_h} h_{\mathcal{K}}^2 \big( W \|\nabla \cdot \boldsymbol{u}\|_{0,\mathcal{K}}^2 + \|\nabla \times \boldsymbol{u} - \boldsymbol{\omega}\|_{0,\mathcal{K}}^2 \big)$$

was studied in [28] where numerical studies showed that fairly a small weight, e.g., $W = 10$, helps to significantly improve total mass conservation.

Thus, for the Stokes problem, at present there are methods that either recover local mass conservation but forfeit some important advantages of the Rayleigh–Ritz settings or retain all those advantages but can at best provide improved global conservation. It is of interest to explore whether or not the ideas of §4 can be extended to develop compatible LSFEMs for viscous flows that retain all the Rayleigh–Ritz advantages and at the same time locally conserve mass.

**6.3. LSFEMs for nonlinear problems.** Consider the nonlinear version of (1)

$$\mathcal{L}u + \mathcal{G}(u) = f \ \text{ in } \Omega \quad \text{and} \quad \mathcal{R}u = g \ \text{ on } \Gamma, \tag{47}$$

where $\mathcal{G}(u)$ is a nonlinear term. Formally, a least-squares principle for (1) can be easily extended to handle (47) by modifying (4) and (3) to

$$\min_{u \in S} J_{\mathcal{G}}(u; f, g), \quad \text{where } J_{\mathcal{G}}(u; f, g) = \|\mathcal{L}u + \mathcal{G}(u) - f\|_{H_\Omega}^2 + \|\mathcal{R}u - g\|_{H_\Gamma}^2 \tag{48}$$

and then define an LSFEM by restricting (48) to a family $S^h \subset S$. While the extension of LSFEMs to (47) is trivial, its analysis is not and remains one of the open problems in LSFEMs. Compared with the well-developed mathematical theory for linear elliptic problems [2], [13], [18], [21], [23], [24], [26], [32], [38], analyses of LSFEMs for nonlinear problems are mostly confined to the Navier–Stokes equations [7]–[9].

It can be shown that the Euler–Lagrange equation associated with the least-squares principle (48) for the Navier–Stokes equations has the abstract form

$$F(\lambda, U) \equiv U + T \cdot G(\lambda, U) = 0, \tag{49}$$

where $\lambda$ is the Reynolds number, $T$ is a least-squares solution operator for the associated Stokes problem, and $G$ is a nonlinear operator. As a result, the corresponding discrete nonlinear problem has the same abstract form

$$F^h(\lambda, U^h) \equiv U^h + T^h \cdot G(\lambda, U^h) = 0, \tag{50}$$

where $T^h$ is an approximation of $T$. The importance of (50) is signified by the fact that discretization in (50) is introduced solely by means of an approximation to the *linear* operator $T$ in (49). As a result, under some assumptions, one can show that the error in the nonlinear approximation defined by (50) is of the same order as the error in the least-squares solution of the linear Stokes problem.

One of the obstacles in extending this approach to a broader class of nonlinear problems is that after the application of a least-squares principle, the (differentiation) order of the nonlinear term may change.

# A posteriori error analysis and adaptive methods for partial differential equations

Zhiming Chen*

**Abstract.** The adaptive finite element method based on a posteriori error estimates provides a systematic way to refine or coarsen the meshes according to the local a posteriori error estimator on the elements. One of the remarkable properties of the method is that for appropriately designed adaptive finite element procedures, the meshes and the associated numerical complexity are quasi-optimal in the sense that in two space dimensions, the finite element discretization error is proportional to $N^{-1/2}$ in terms of the energy norm, where $N$ is the number of elements of the underlying mesh. The purpose of this paper is to report some of the recent advances in the a posteriori error analysis and adaptive finite element methods for partial differential equations. Emphases will be paid on an adaptive perfectly matched layer technique for scattering problems and a sharp $L^1$ a posteriori error analysis for nonlinear convection-diffusion problems.

**Mathematics Subject Classification (2000).** Primary 65N15; Secondary 65N30.

**Keywords.** A posteriori error estimates, adaptivity, quasi-optimality.

## 1. Introduction

The aim of the adaptive finite element method (AFEM) for solving partial differential equations is to find the finite element solution and the corresponding mesh with least possible number of elements in terms of discrete errors. The task to find the mesh with the desired property is highly nontrivial because the solution is a priori unknown. The basic idea of the seminal work [3] is to find the desired mesh under the principle of error equidistribution, that is, the discretization errors should be approximately equal on each element. The errors on the elements which are also unknown can, however, be estimated by a posteriori error estimates. Today AFEM based on a posteriori error estimates attracts increasing interests and becomes one of the central themes of scientific computation. The purpose of this paper is to report some of the recent advances in the a posteriori error analysis and AFEM for partial differential equations.

A posteriori error estimates are computable quantities in terms of the discrete solution and data, which provide information for adaptive mesh refinement (and coarsening), error control, and equidistribution of the computational effort. We describe here briefly the basic idea of AFEM using the example of solving the Possion equation

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

on a polygonal domain $\Omega$ in $\mathbb{R}^2$

$$-\Delta u = f \text{ in } \Omega, \quad u = 0 \text{ on } \partial\Omega. \tag{1.1}$$

Here the source function $f$ is assumed to be in $L^2(\Omega)$. It is well known that the solution of the problem (1.1) may be singular due to the reentrant corners of the domain in which case the standard finite element methods with uniform meshes are not efficient.

Let $\mathcal{M}_h$ be a regular triangulation of the domain $\Omega$ and $\mathcal{B}_h$ be the collection of all inter-element sides of $\mathcal{M}_h$. Denote by $u_h$ the piecewise linear conforming finite element solution over $\mathcal{M}_h$. For any inter-element side $e \in \mathcal{B}_h$, let $\Omega_e$ be the collection of two elements sharing $e$ and define the local error indicator $\eta_e$ as

$$\eta_e^2 := \sum_{K\in\Omega_e} \| h_K f \|^2_{L^2(K)} + \| h_e^{1/2} J_e \|^2_{L^2(e)},$$

where $h_K := \text{diam}(K)$, $h_e := \text{diam}(e)$, and $J_e := [\![ \nabla u_h ]\!]_e \cdot \nu$ stands for the jump of flux across side $e$ which is independent of the orientation of the unit normal $\nu$ to $e$. The following a posteriori error estimate is well known [2]:

$$\| u - u_h \|^2_{H^1(\Omega)} \le C \sum_{e\in\mathcal{B}_h} \eta_e^2.$$

That $\eta_e$ really indicates the error locally is explained by the following local lower bound [39]:

$$\eta_e^2 \le C \sum_{K\in\Omega_e} \| u - u_h \|^2_{L^2(K)} + C \sum_{K\in\Omega_e} \| h_K (f - f_K) \|^2_{L^2(K)},$$

where $f_K = \frac{1}{|K|}\int_K f dx$.

Based on the local error indicator, the usual adaptive algorithm solving the elliptic problem (1.1) reads as follows:

$$\text{Solve} \;\rightarrow\; \text{Estimate} \;\rightarrow\; \text{Refine}.$$

The important convergence property, which guarantees the iterative loop terminates in finite steps starting from any initial coarse mesh, is proved in [23], [30]. It is also widely observed that for appropriately designed adaptive finite element procedures, the meshes and the associated numerical complexity are quasi-optimal in the sense that

$$\| \nabla(u - u_h) \|_{L^2(\Omega)} \approx C N^{-1/2} \tag{1.2}$$

is valid asymptotically, where $N$ is the number of elements of the underlying finite element mesh. Since the nonlinear approximation theory [5] indicates that $N^{-1/2}$ is the highest attainable convergence order for approximating functions in $H^1(\Omega)$ in

two space dimensions over a mesh with $N$ elements, one concludes that AFEM is an *optimal* discretization method for solving the elliptic problem (1.1).

In Section 2 we consider to use AFEM to solve the Helmholtz-type scattering problems with perfectly conducting boundary

$$\Delta u + k^2 u = 0 \qquad \text{in } \mathbb{R}^2 \backslash \bar{D}, \tag{1.3a}$$

$$\frac{\partial u}{\partial \boldsymbol{n}} = -g \qquad \text{on } \Gamma_D, \tag{1.3b}$$

$$\sqrt{r}\left(\frac{\partial u}{\partial r} - \boldsymbol{i}ku\right) \to 0 \qquad \text{as } r = |x| \to \infty. \tag{1.3c}$$

Here $D \subset \mathbb{R}^2$ is a bounded domain with Lipschitz boundary $\Gamma_D$, $g \in H^{-1/2}(\Gamma_D)$ is determined by the incoming wave, and $\boldsymbol{n}$ is the unit outer normal to $\Gamma_D$. We assume the wave number $k \in \mathbb{R}$ is a constant. We study an *adaptive perfectly matched layer* (APML) technique to deal with the Sommerfeld radiation condition (1.3c) in which the PML parameters such as the thickness of the layer and the fictitious medium property are determined through sharp a posteriori error estimates. The APML technique combined with AFEM provides a complete numerical strategy for solving the scattering problem in the framework of finite element which has the nice property that the total computational costs are insensitive to the thickness of the PML absorbing layers. The quasi-optimality of underlying FEM meshes is also observed.

Things become much more complicated when applying AFEM to solve time-dependent partial differential equations. One important question is if one should use the *adaptive method of lines* (AML) in which variable timestep sizes (but constant at each time step) and variable space meshes at different time steps are assumed, or one should consider the *space-time adaptive method* in which space-time domain is considered as a whole and AFEM is used without distinguishing the difference of time and space variables. Our recent studies in [9], [10], [11] reveal that with sharp a posteriori error analysis and carefully designed adaptive algorithms, the AML method produces the very desirable quasi-optimal decay of the error with respect to the computational complexity

$$|\!|\!| u - U |\!|\!|_{\Omega\times(0,T)} \leq C M^{-1/3} \tag{1.4}$$

for a large class of convection-diffusion parabolic problems in two space dimensions using backward Euler scheme in time and conforming piecewise linear finite elements in space. Here $|\!|\!| u - U |\!|\!|_{\Omega\times(0,T)}$ is the energy norm of the error between the exact solution $u$ and the discrete solution $U$, and $M$ is the sum of the number of elements of the space meshes over all time steps. Thus if one takes the quasi-optimality of the computational complexity as the criterion to assess the adaptive methods, then the space-time adaptive method which is less studied in the literature will not have much advantage over the AML method.

A posteriori error analysis for parabolic problems in the framework of AML has been studied intensively in the literature. The main tool in deriving a posteriori error

estimates in [25], [26], [14], [31], [7] is the analysis of linear dual problems of the corresponding *error* equations. The derived a posteriori error estimates, however, depend on the $H^2$ regularity assumption on the underlying elliptic operator. Without using this regularity assumption, energy method is used in [34], [9] to derive an a posteriori error estimate for the total energy error of the approximate solution for linear heat equations. A lower bound for the local error is also derived for the associated a posteriori error indicator in [34], [9]. In [9] an adaptive algorithm is constructed which at each time step, is able to reduce the error indicators (and thus the error) below any given tolerance within finite number of iteration steps. Moreover, the adaptive algorithm is quasi-optimal in terms of energy norm. In [10] an quasi-optimal AML method in terms of the energy norm is constructed for the linear convection-dominated diffusion problems based on $L^1$ a posteriori error estimates.

In Section 3 we study the AML method for the initial boundary value problems of nonlinear convection-diffusion equations of the form

$$\frac{\partial u}{\partial t} + \operatorname{div} f(u) - \Delta A(u) = g.$$

We derive sharp $L^\infty(L^1)$ a posteriori error estimates under the non-degeneracy assumption $A'(s) > 0$ for any $s \in \mathbb{R}$. The problem displays both parabolic and hyperbolic behavior in a way that depends on the solution itself. It is discretized implicitly in time via the method of characteristic and in space via continuous piecewise linear finite elements. The analysis is based on the Kružkov "doubling of variables" device and the recently introduced "boundary layer sequence" technique to derive the entropy error inequality on bounded domains. The derived a posteriori error estimate leads to a quasi-optimal adaptive method in terms of the $L^\infty(L^1)$ norm of the error.

## 2. The APML technique for scattering problems

In this section we consider the APML technique for the scattering problem (1.3a)–(1.3c). Since [4] proposed a PML technique for solving the time dependent Maxwell equations, various constructions of PML absorbing layers have been proposed and studied in the literature [38], [37]. Here we introduce the PML technique for (1.3a)–(1.3c) following the method in [19].

Let $D$ be contained in the interior of the circle $B_R = \{x \in \mathbb{R}^2 : |x| < R\}$. In the domain $\mathbb{R}^2 \backslash \bar{B}_R$, the solution $u$ of (1.3a)–(1.3c) can be written under the polar coordinates as follows:

$$u(r,\theta) = \sum_{n\in\mathbb{Z}} \frac{H_n^{(1)}(kr)}{H_n^{(1)}(kR)} \hat{u}_n e^{in\theta}, \quad \hat{u}_n = \frac{1}{2\pi}\int_0^{2\pi} u(R,\theta) e^{-in\theta}\, d\theta. \tag{2.1}$$

where $H_n^{(1)}$ is the Hankel function of the first kind and order $n$. The series in (2.1) converges uniformly for $r > R$ [20].

The basic idea of PML technique is to surround the fixed domain $\Omega_R = B_R \backslash \bar{D}$ with a PML layer of thickness $\rho - R$ and choose the fictitious medium property so that either the wave never reaches its external boundary or the amplitude of the reflected wave is so small that it does not essentially contaminate the solution in $\Omega_R$.

Let $\alpha = 1 + \boldsymbol{i}\sigma$ be the model medium property satisfying $\sigma \in C(\mathbb{R})$, $\sigma \geq 0$, and $\sigma = 0$ for $r \leq R$. The most widely used model medium property $\sigma$ in the literature is the power function, that is,

$$\sigma = \sigma_0 \left( \frac{r - R}{\rho - R} \right)^m, \quad m \geq 1,\ \sigma_0 > 0 \text{ constant}. \tag{2.2}$$

Denote by $\tilde{r}$ the complex radius defined by

$$\tilde{r} = \tilde{r}(r) = \begin{cases} r & \text{if } r \leq R, \\ \int_0^r \alpha(t)dt = r\beta(r) & \text{if } r \geq R. \end{cases}$$

Since $H_n^{(1)}(z) \sim \sqrt{\frac{2}{\pi z}} e^{\boldsymbol{i}(z - \frac{\pi}{2}n - \frac{\pi}{4})}$ as $|z| \to \infty$, [19] obtained the PML equation by considering the following extension of $u$ in the exterior domain $\mathbb{R}^2 \backslash \bar{B}_R$:

$$w(r, \theta) = \sum_{n \in \mathbb{Z}} \frac{H_n^{(1)}(k\tilde{r})}{H_n^{(1)}(kR)} \hat{u}_n e^{\boldsymbol{i}n\theta}, \quad \hat{u}_n = \frac{1}{2\pi} \int_0^{2\pi} u(R, \theta) e^{-\boldsymbol{i}n\theta}\, d\theta. \tag{2.3}$$

It is easy to check that $w$ satisfies

$$\nabla \cdot (A \nabla w) + \alpha\beta k^2 w = 0 \quad \text{in } \mathbb{R}^2 \backslash \bar{B}_R,$$

where $A = A(x)$ is a matrix which satisfies, in polar coordinates,

$$\nabla \cdot (A\nabla) = \frac{1}{r} \frac{\partial}{\partial r} \left( \frac{\beta r}{\alpha} \frac{\partial}{\partial r} \right) + \frac{\alpha}{\beta} \frac{1}{r^2} \frac{\partial^2}{\partial \theta^2}.$$

The PML problem then becomes

$$\nabla \cdot (A \nabla \hat{u}) + \alpha\beta k^2 \hat{u} = 0 \quad \text{in } B_\rho \backslash \bar{D}, \tag{2.4a}$$

$$\frac{\partial \hat{u}}{\partial \boldsymbol{n}} = -g \quad \text{on } \Gamma_D,\ \hat{u} = 0 \text{ on } \Gamma_\rho. \tag{2.4b}$$

It is proved in [22], [21] that the resultant PML solution converges exponentially to the solution of the original scattering problem as the thickness of the PML layer tends to infinity. We remark that in practical applications involving PML techniques, one cannot afford to use a very thick PML layer if uniform finite element meshes are used because it requires excessive grid points and hence more computer time and more storage. On the other hand, a thin PML layer requires a rapid variation of the artificial material property which deteriorates the accuracy if too coarse mesh is used in the PML layer.

The APML technique was first proposed in [16] for solving scattering by periodic structures (the grating problem) which uses a posteriori error estimates to determine the PML parameters such as the thickness and the medium property $\sigma_0$ in the (2.2). For the scattering problem (1.3a)–(1.3c), the main difficulty of the analysis is that in contrast to the grating problems in which there are only finite number of outgoing modes, now there are infinite number of outgoing modes expressed in terms of Hankel functions. We overcome this difficulty by the by exploiting the following uniform estimate for the Hankel functions $H_\nu^1$, $\nu \in \mathbb{R}$.

**Lemma 2.1.** *For any* $\nu \in \mathbb{R}$, $z \in \mathbb{C}_{++} = \{z \in \mathbb{C} : \Im(z) \geq 0, \Re(z) \geq 0\}$, *and* $\Theta \in \mathbb{R}$ *such that* $0 < \Theta \leq |z|$, *we have*

$$|H_\nu^{(1)}(z)| \leq e^{-\Im(z)\left(1-\frac{\Theta^2}{|z|^2}\right)^{1/2}} |H_\nu^{(1)}(\Theta)|.$$

The proof of the lemma which depends on the Macdonald formula for the modified Bessel functions can be found in [12]. Lemma 2.1 allows us to prove the exponentially decaying property of the PML solution without resorting to the integral equation technique in [22] or the representation formula in [21]. As a corollary of Lemma 2.1, we know that the function $w$ in (2.3) satisfies

$$\| w \|_{H^{1/2}(\Gamma_\rho)} \leq e^{-k\Im(\tilde{\rho})\left(1-\frac{R^2}{|\tilde{\rho}|^2}\right)^{1/2}} \| u \|_{H^{1/2}(\Gamma_R)}.$$

We remark that in [22], [21], it is required that the fictitious absorbing coefficient must be linear after certain distance away from the boundary where the PML layer is placed. We also remark that since (2.5) is valid for all real order $\nu$, the results of [12] can be extended directly to study three dimensional Helmholtz-type scattering problems.

Let $\mathcal{M}_h$ be a regular triangulation of $B_\rho \backslash \bar{D}$ and $u_h$ be the finite element solution of the PML problem (2.4a)–(2.4b). Let $\mathcal{B}_h$ denote the set of all sides that do not lie on $\Gamma_D$ and $\Gamma_\rho^h$. For any $K \in \mathcal{M}_h$, we introduce the residual

$$R_h := \nabla \cdot (A \nabla u_h|_K) + \alpha\beta k^2 u_h|_K.$$

For any interior side $e \in \mathcal{B}_h$ which is the common side of $K_1$ and $K_2 \in \mathcal{M}_h$, we define the jump residual across $e$:

$$J_e := (A \nabla u_h|_{K_1} - A \nabla u_h|_{K_2}) \cdot \nu_e,$$

using the convention that the unit normal vector $\nu_e$ to $e$ points from $K_2$ to $K_1$. If $e = \Gamma_D \cap \partial K$ for some element $K \in \mathcal{M}_h$, then we define the jump residual

$$J_e := 2(\nabla u_h|_K \cdot \boldsymbol{n} + g)$$

For any $K \in \mathcal{M}_h$, denote by $\eta_K$ the local error estimator which is defined by

$$\eta_K = \max_{x \in \tilde{K}} \omega(x) \cdot \left( \|h_K R_h\|_{L^2(K)}^2 + \frac{1}{2} \sum_{e \subset \partial K} h_e \| J_e \|_{L^2(e)}^2 \right)^{1/2},$$

where $\tilde{K}$ is the union of all elements having nonempty intersection with $K$, and

$$\omega(x) = \begin{cases} 1 & \text{if } x \in \bar{B}_R \backslash \bar{D}, \\ |\alpha_0 \alpha| e^{-k\Im(\tilde{r})\left(1-\frac{r^2}{|\tilde{r}|^2}\right)^{1/2}} & \text{if } x \in \bar{B}_\rho \backslash B_R. \end{cases}$$

**Theorem 2.2.** *There exists a constant $C$ depending only on the minimum angle of the mesh $\mathcal{M}_h$ such that the following a posterior error estimate is valid:*

$$\| u - u_h \|_{H^1(\Omega_R)} \le C\Lambda(kR)^{1/2}(1+kR)\Big(\sum_{K\in\mathcal{M}_h} \eta_K^2\Big)^{1/2} + C(1+kR)^2|\alpha_0|^2 e^{-k\Im(\tilde{\rho})\left(1-\frac{R^2}{|\tilde{\rho}|^2}\right)^{1/2}} \| u_h \|_{H^{1/2}(\Gamma_R)}.$$

*Here* $\Lambda(kR) = \max\left(1, \frac{|H_0^{(1)'}(kR)|}{|H_0^{(1)}(kR)|}\right)$.

From Theorem 2.2 we know that the a posteriori error estimate consists of two parts: the PML error and the finite element discretization error. An adaptive algorithm is developed in [12] which uses the a posteriori error estimate to determine the PML parameters. We first choose $\rho$ and $\sigma_0$ such that the exponentially decaying factor

$$\hat{\omega} = e^{-k\Im(\tilde{\rho})(1-\frac{R^2}{|\tilde{\rho}|^2})^{1/2}} \le 10^{-8},$$

which makes the PML error negligible compared with the finite element discretization errors. Once the PML region and the medium property are fixed, we use the standard finite element adaptive strategy to modify the mesh according to the a posteriori error estimate. The extensive numerical experiments reported in [12] show the competitive behavior of the proposed adaptive method. In particular, the quasi-optimality of meshes is observed and the adaptive algorithm is robust with respect to the choice of the thickness of PML layer: the far fields of the scattering solutions are insensitive to the choices of the PML parameters.

## 3. The AML method for nonlinear convection diffusion problems

Let $\Omega$ is a bounded domain in $\mathbb{R}^d$ $(d = 1, 2, 3)$ with Lipschitz boundary and $T > 0$. In this section we consider the following nonlinear convection-diffusion equation:

$$\frac{\partial u}{\partial t} + \operatorname{div} f(u) - \Delta A(u) = g \quad \text{in } Q \tag{3.1}$$

with the initial and boundary conditions

$$u|_{t=0} = u_0, \quad u|_{\partial\Omega\times(0,T)} = 0. \tag{3.2}$$

Here $u = u(x,t) \in \mathbb{R}$, with $(x,t) \in Q = \Omega \times (0,T)$. We assume that the function $f : \mathbb{R} \to \mathbb{R}^d$ is locally Lipschitz continuous, the function $A : \mathbb{R} \to \mathbb{R}$ is nondecreasing and locally Lipschitz continuous, $g \in L^\infty(Q)$ and $u_0 \in L^\infty(\Omega)$.

Problems of the type (3.1) model a wide variety of physical phenomena including porous media flow, flow of glaciers and sedimentation processes, or flow transport through unsaturated porous media which is governed by the so-called Richards equation. For the Richards equation, the existence of weak solutions is considered in [1] and the uniqueness of weak solutions is proved in [33] based on the Kružkov "doubling of variables" technique. Entropy solutions for (3.1) are studied in [6], [29].

The discretization of (3.1) is based on combining continuous piecewise linear finite elements in space with the characteristic finite difference in time. The method of characteristic originally proposed in [24], [35] is widely used to solve convection-diffusion problems in finite element community (cf. e.g. [26], [14]). Given $U_h^{n-1}$ as the finite element approximation of the solution at time $t^{n-1}$, let $\tau_n$ and $V_0^n \subset H_0^1(\Omega)$ be the time step and the conforming linear finite element space at the $n$th time step, then our discrete scheme reads as following: find $U_h^n \in V_0^n$ such that

$$\left\langle \frac{U_h^n - \bar{U}_h^{n-1}}{\tau_n}, v \right\rangle + \langle \nabla A(U_h^n), \nabla v \rangle = \langle \bar{g}^n, v \rangle \quad \text{for all } v \in V_0^n, \tag{3.3}$$

where $\bar{g}^n = \tau_n^{-1} \int_{t^{n-1}}^{t^n} g(x,t)dt$, $\bar{U}_h^{n-1}(x) = U_h^{n-1}(\tilde{X}(t^{n-1}))$, and the approximate characteristic $\tilde{X}(t)$ is defined by

$$d\tilde{X}/dt = f'(U_h^{n-1}(\tilde{X}(t))), \quad \tilde{X}(t^n) = x.$$

The well-known Kružkov "doubling of variables" technique originally appeared in [28] plays a decisive role in the error estimation (both a posteriori and a priori) for numerical schemes solving the Cauchy problems of nonlinear conservation laws (see e.g. [17], [18], [27] and the reference therein). It is also used recently in [32] for the implicit vortex centered finite volume discretization of the Cauchy problems of (3.1) for general non-negative $A'(s) \geq 0$ for all $s \in \mathbb{R}$. The common feature of these studies is that the derived error indicators are of the order $\sqrt{h}$ in the region where the solution is smooth, where $h$ is the local mesh size. We remark that in the region where the diffusion is dominant, the error indicators developed for the parabolic equations (cf. e.g. [34], [9]) are of order $h$. Thus the degeneration of the order of the error indicators used in [32] may cause over-refinements for the solution of (3.1) in the region where the diffusion is dominant.

The basic assumption in this paper is that the diffusion is positive

$$A'(s) > 0, \quad \text{for all } s \in \mathbb{R}.$$

This assumption includes the Richards equation and the viscosity regularization of degenerate parabolic equations, for example, the regularized continuous casting problem which is considered in [14]. The novelty of our analysis with respect to the analysis

for nonlinear conservation laws in [17], [18], [27] or nonlinear degenerate parabolic equations in [32] lies in the following aspects. Firstly, only Cauchy problems are considered in [17], [18], [27], [32]. The difficulty to include boundary condition is essential. Here we use the recently introduced technique of "boundary layer sequence" in [29] to overcome the difficulty. The technique of "boundary layer sequence" allows us to truncate the standard Kružkov test function (see Definition 3.4 below) to obtain the admissible test function in the entropy error identity. Secondly, the nature of the estimators are different: our estimators emphasize the diffusion effect of the problem which requires the assumption $A'(s) > 0$ for any $s \in \mathbb{R}$; the estimates in [32] are valid for any nonlinear function $A$ such that $A'(s) \geq 0$. The nice consequence of the analysis is that our a posteriori error estimates are able to recover the standard sharp a posteriori error estimators in the literature derived for parabolic problem with diffusion coefficients bounded uniformly away from zero.

Now we elaborate the main steps to derive sharp $L^1$ a posteriori error estimate for the discrete scheme (3.3) based on the Kružkov "doubling of variables" device. By testing (3.1) with any function $\varphi \in L^2(0, T; H_0^1(\Omega))$ such that $\phi(\cdot, 0) = \phi(\cdot, T) = 0$, we have

$$\int_0^T \langle \partial_t u, \varphi \rangle \, dt + \int_Q (-f(u) + \nabla A(u)) \cdot \nabla \varphi \, dx dt = \int_Q g\varphi \, dx dt. \tag{3.4}$$

For any $\varepsilon > 0$, let

$$H_\varepsilon(z) = \operatorname{sgn}(z) \min(1, |z|/\varepsilon)$$

be the regularization of the sign function $\operatorname{sgn}(z)$. For any $k \in \mathbb{R}$, define the entropy pair $(U_\varepsilon, F_\varepsilon)$ by

$$U_\varepsilon(z, k) = \int_k^z H_\varepsilon(A(r) - A(k)) \, dr, \quad F_\varepsilon(z, k) = \int_k^z H_\varepsilon(A(r) - A(k)) f'(r) \, dr.$$

The following result is well known (cf. e.g. [6], [29]) by taking $\varphi = H_\varepsilon(A(u) - A(k))\phi$ in (3.4).

**Lemma 3.1.** *For any $\phi \in L^2(0, T; H_0^1(\Omega))$ such that $\phi(\cdot, 0) = \phi(\cdot, T) = 0$, and any $k \in \mathbb{R}$, we have*

$$\begin{aligned} &- \int_Q U_\varepsilon(u, k) \partial_t \phi - \int_Q F_\varepsilon(u, k) \cdot \nabla \phi + \int_Q H_\varepsilon(A(u) - A(k)) \nabla A(u) \cdot \nabla \phi \\ &\qquad + \int_Q H'_\varepsilon(A(u) - A(k)) |\nabla A(u)|^2 \phi \\ &= \int_Q g H_\varepsilon(A(u) - A(k)) \phi. \end{aligned} \tag{3.5}$$

Let $(H^1(\Omega))'$ be the dual space of $H^1(\Omega)$, we define the discrete residual $\mathcal{R} \in L^2(0, T; (H^1(\Omega))')$ through the following relation, for any $\varphi \in H^1(\Omega)$,

$$\langle \partial_t U_h, \varphi \rangle - \langle f(U_h), \nabla \varphi \rangle + \langle \nabla A(U_h), \nabla \varphi \rangle = \langle g, \varphi \rangle - \langle \mathcal{R}, \varphi \rangle. \tag{3.6}$$

For any $k' \in \mathbb{R}$, by taking $\varphi = H_\varepsilon(A(U_h) - A(k'))\phi$ in (3.6), we have the following result.

**Lemma 3.2.** *For any $\phi \in L^2(0, T; H_0^1(\Omega))$ such that $\phi(\cdot, 0) = \phi(\cdot, T) = 0$, and any $k' \in \mathbb{R}$, we have*

$$\begin{aligned} &-\int_Q U_\varepsilon(U_h, k')\partial_t\phi - \int_Q F_\varepsilon(U_h, k')\cdot\nabla\phi \\ &\quad + \int_Q H_\varepsilon(A(U_h) - A(k'))\nabla A(u)\cdot\nabla\phi \\ &\quad + \int_Q H'_\varepsilon(A(U_h) - A(k'))|\nabla A(U_h)|^2\phi \\ &= \int_Q g H_\varepsilon(A(U_h) - A(k'))\phi - \int_0^T \langle \mathcal{R}, H_\varepsilon(A(U_h) - A(k'))\phi\rangle. \end{aligned} \tag{3.7}$$

Now we are going to apply the Kružkov "doubling of variables" technique and will always write $u = u(y, s)$, $U_h = U_h(x, t)$, unless otherwise stated. By taking $k = U_h(x, t)$ in (3.5) and $k' = u(y, s)$ in (3.7), we have the following entropy error identity.

**Lemma 3.3.** *Let $\phi = \phi(x, t; y, s)$ be non-negative function such that*

$$\begin{aligned} &(x, t) \mapsto \phi(x, t; y, s) \in C_c^\infty(Q) \quad \textit{for every } (y, s) \in Q, \\ &(y, s) \mapsto \phi(x, t; y, s) \in C_c^\infty(Q) \quad \textit{for every } (x, t) \in Q. \end{aligned}$$

*Then we have*

$$\begin{aligned} &-\int_{Q\times Q} U_\varepsilon(u, U_h)(\partial_t\phi + \partial_s\phi) - \int_{Q\times Q} F_\varepsilon(u, U_h)(\nabla_x\phi + \nabla_y\phi) \\ &\quad + \int_{Q\times Q} H_\varepsilon(A(u) - A(U_h))\nabla_y A(u)\cdot(\nabla_x\phi + \nabla_y\phi) \\ &\quad + \int_{Q\times Q} H_\varepsilon(A(U_h) - A(u))\nabla_x A(U_h)\cdot(\nabla_x\phi + \nabla_y\phi) \\ &\quad + \int_{Q\times Q} H'_\varepsilon(A(u) - A(U_h))|\nabla_x A(U_h) - \nabla_y A(u)|^2\phi \\ &= -\int_{Q\times Q} \partial_t[U_\varepsilon(U_h, u) - U_\varepsilon(u, U_h))]\phi \\ &\quad - \int_{Q\times Q} \nabla_x[F_\varepsilon(U_h, u) - F_\varepsilon(u, U_h))]\phi \\ &\quad - \int_{Q_{(y,s)}} \int_0^T \langle \mathcal{R}, H_\varepsilon(A(U_h) - A(u))\phi\rangle\, dt. \end{aligned} \tag{3.8}$$

The next objective is to remove the restriction that the test functions in the entropy error identity (3.8) must have vanishing trace. This is achieved by using the technique of boundary layer sequence introduced in [29]. For any $\delta > 0$, the boundary layer sequence $\zeta_\delta$ is defined as the solution of the elliptic problem

$$-\delta^2 \Delta \zeta_\delta + \zeta_\delta = 1 \text{ in } \Omega, \quad \zeta_\delta = 0 \text{ on } \partial\Omega.$$

We specify now the choice of the test function $\phi$ in the entropy error identity (3.8), which is similar to that used in [29].

**Definition 3.4.** Let

$$\phi(x, t, y, s) = \zeta_\delta(x)\zeta_\eta(y)\xi(x, t, y, s)\theta(t),$$

where $\theta \in C_c^\infty(0, T)$ such that $\theta \geq 0$, and $\xi$ is defined as follows. Let $\{\varphi_j\}_{0 \leq j \leq J}$ be a partition of unity subordinate to open sets $B_0, B_1, \ldots, B_J$ such that $\bar{\Omega} \subset \cup_{j=0}^J B_j$, $B_0 \subset\subset \Omega$ and $\partial\Omega \subset \cup_{j=1}^J B_j$. Let $\hat{\varphi}_j \in C_c^\infty(\mathbb{R}^d)$, $0 \leq \hat{\varphi}_j \leq 1$, such that $\text{supp}(\hat{\varphi}_j) \subset B_j$ and $\hat{\varphi}_j(x) = 1$ on the support of $\varphi_j$ so that $\varphi_j(x)\hat{\varphi}_j(x) = \varphi_j(x)$. We use $\varphi_j$ as a function of $y$ and $\hat{\varphi}_j$ as a function of $x$, and denote $\hat{\varphi}_j(x)\varphi_j(y) = \psi_j(x, y)$. Define

$$\xi(x, t, y, s) = \sum_{j=0}^{J} \omega_l(t - s)\omega_m(x' - y')\omega_n(x_d - y_d)\psi_j(x, y),$$

where $\omega_l, \omega_n$ are sequences of symmetric mollifiers in $\mathbb{R}$, $\omega_m$ is a sequence of symmetric mollifier in $\mathbb{R}^{d-1}$, and for $j = 1, 2, \ldots, J$, $x = (x', x_d)$, $y = (y', y_d)$ are local coordinates induced by $\psi_j(x, y)$ in $B_j$, that is, $B_j \cap \partial\Omega = \{x \in B_j : x_d = \rho_j(x')\}$, $B \cap \Omega = \{x \in B_j : x_d < \rho_j(x')\}$ for some Lipschitz continuous function $\rho_j : \mathbb{R}^{d-1} \to \mathbb{R}$.

By taking limit $\delta, \eta \to 0$ in the entropy error identity (3.8), we obtain the following entropy error inequality.

**Theorem 3.5.** *Let $\theta$ and $\xi$ be defined in Definition* 3.4. *Then we have the following entropy error inequality:*

$$\begin{aligned}
&-\int_{Q\times Q} U_\varepsilon(u, U_h)\xi\theta_t - \int_{Q\times Q} K_\varepsilon(u, U_h)\cdot(\nabla_x\xi + \nabla_y\xi)\theta \\
&\quad + \int_{Q\times Q} H_\varepsilon'(A(u) - A(U_h))|\nabla_x A(U_h) - \nabla_y A(u)|^2\xi\theta \\
&\leq -\int_{Q\times Q} \partial_t[U_\varepsilon(U_h, u) - U_\varepsilon(u, U_h))]\xi\theta \\
&\quad - \int_{Q\times Q} \nabla_x[F_\varepsilon(u, U_h) - F_\varepsilon(u, U_h))]\xi\theta
\end{aligned} \tag{3.9}$$

$$
\begin{aligned}
&- \int_{Q_{(y,s)}} \int_{\Sigma_{(x,t)}} \Big( F_\varepsilon(u, U_h) - H_\varepsilon(A(u) - A(U_h)) \nabla_y A(u) \Big) \cdot \nu_x \xi \theta \\
&\quad - \int_{Q_{(x,t)}} \int_{\Sigma_{(y,s)}} \Big( F_\varepsilon(u, U_h) - H_\varepsilon(A(U_h) - A(u)) \nabla_x A(U_h) \Big) \cdot \nu_y \xi \theta \\
&\quad\quad - \int_{Q_{(y,s)}} \int_0^T \langle \mathcal{R}, H_\varepsilon(A(U_h) - A(u)) \xi \theta \rangle \, dt,
\end{aligned}
$$

*where* $K_\varepsilon(u, U_h) = F_\varepsilon(u, U_h) - H_\varepsilon(A(u) - A(U_h))(\nabla_y A(u) - \nabla_x A(U_h))$, $\Sigma = \partial\Omega \times (0, T)$, *and* $\Sigma_{(x,t)}$ *or* $\Sigma_{(y,s)}$ *are the domain of integration of* $\Sigma$ *with respect to* $(x, t)$ *or* $(y, s)$ *respectively.*

For any $\varepsilon > 0$ and $z \in \mathbb{R}$, define

$$
\nu(\varepsilon, z) = \min\{A'(s) : |A(s) - A(z)| \le \varepsilon\}.
$$

Assume $A' \circ A^{-1}$ is Lipschitz, then we have the following elementary estimate which extends the result in [18, Corollary 6.4]:

$$
\begin{aligned}
|\partial_z [U_\varepsilon(z, k) - U_\varepsilon(k, z)]| &\le \frac{\varepsilon}{\nu(\varepsilon, z)} \mathcal{K}_1, \\
|\partial_z [F_\varepsilon(z, k) - F_\varepsilon(k, z)]| &\le \frac{\varepsilon}{\nu(\varepsilon, z)} \mathcal{K}_2,
\end{aligned}
\tag{3.10}
$$

where $k, z \in \mathbb{R}$, $\mathcal{K}_1 = \mathrm{L}(A' \circ A^{-1})$, $\mathcal{K}_2 = \mathcal{K}_1 \| f' \|_{L^\infty(\mathbb{R})} + \mathrm{L}(f')$ with $\mathrm{L}(A' \circ A^{-1})$ and $\mathrm{L}(f')$ being the Lipschitz constant of $A' \circ A^{-1}$ and $f'$ respectively.

To complete the Kružkov "doubling of variables" technique, we let first $l, m \to \infty$ then $n \to \infty$ in the entropy error inequality (3.9). The first two terms on the right-hand side of (3.9) can be treated by using (3.10) and the third and fourth terms can be shown to tend to zero. Thus we have

$$
\begin{aligned}
&- \int_Q U_\varepsilon(u, U_h) \theta_t + \int_Q H'_\varepsilon(A(u) - A(U_h)) |\nabla(A(U_h) - A(u))|^2 \theta \\
&\quad \le \mathcal{K} \varepsilon \int_Q \frac{1}{\nu(\varepsilon, U_h)} (|\partial_t U_h| + |\nabla_x U_h|) \theta - \int_0^T \langle \mathcal{R}, H_\varepsilon(A(U_h) - A(u)) \theta \rangle \, dt.
\end{aligned}
$$

where $\mathcal{K} = \max(\mathcal{K}_1, \mathcal{K}_2)$.

To proceed, we introduce the interior residual

$$
R^n := \bar{g}^n - \frac{U_h^n - \bar{U}_h^{n-1}}{\tau_n} + \Delta A(U_h^n) \quad \text{on any } K \in \mathcal{M}^n,
$$

where we recall that $\bar{g}^n = \tau_n^{-1} \int_{t^{n-1}}^{t^n} g(x, t) \, dt$.

**Theorem 3.6.** *Let $\varepsilon_0 = \sum_{i=1}^{3} \mathcal{E}_i$, where $\mathcal{E}_1, \mathcal{E}_2, \mathcal{E}_3$ are the error indicators defined below. For any $m \geq 1$, let $Q_m = \Omega \times (0, t^m)$, and define*

$$\Lambda_m = \max\left(1, \int_{Q_m} \frac{1}{\nu(\varepsilon_0, U_h)}(|\partial_t U_h| + |\nabla U_h|) + \int_{\Omega} \frac{1}{\nu(\varepsilon_0, U_h^m)}\right), \quad (3.11)$$

*where for any $z \in \mathbb{R}$, $\nu(\varepsilon_0, z) = \min\{A'(s) : |A(s) - A(z)| \leq \varepsilon_0\}$. Then there exists a constant $C$ depending only on the minimum angles of the meshes $\mathcal{M}^n$, $n = 1, \ldots, m$, such that the following a posteriori error estimate is valid:*

$$\| u^m - U_h^m \|_{L^1(\Omega)} \leq \mathcal{E}_0 + \mathcal{E}_4 + \mathcal{E}_5 + C\Lambda_m^{1/2}\Big(\sum_{i=1}^{3} \mathcal{E}_i\Big),$$

*where the error indicators $\mathcal{E}_i$, $i = 0, \ldots, 5$, are defined by*

$$\mathcal{E}_0 = \| u_0 - U_h^0 \|_{L^1(\Omega)} \qquad \textit{initial error}$$

$$\mathcal{E}_1 = \Big(\sum_{n=1}^{m} \tau_n \| h_n^{1/2} [\![ \nabla A(U_h^n) ]\!] \|_{L^2(\Omega)}^2\Big)^{1/2} \qquad \textit{jump residual}$$

$$\mathcal{E}_2 = \Big(\sum_{n=1}^{m} \tau_n \| h_n R^n \|_{L^2(\Omega)}^2\Big)^{1/2} \qquad \textit{interior residual}$$

$$\mathcal{E}_3 = \Big(\sum_{n=1}^{m} \tau_n \| \nabla(A(U_h^n) - A(U_h^{n-1})) \|_{L^2(\Omega)}^2\Big)^{1/2} \qquad \textit{time residual}$$

$$\mathcal{E}_4 = \sum_{n=1}^{m} \int_{t^{n-1}}^{t^n} \left\| \frac{U_h^n - \bar{U}_h^{n-1}}{\tau_n} - (\partial_t U_h + \operatorname{div} f(U_h)) \right\|_{L^1(\Omega)} dt \qquad \textit{characteristic and coarsening}$$

$$\mathcal{E}_5 = \sum_{n=1}^{m} \int_{t^{n-1}}^{t^n} \| g - \bar{g}^n \|_{L^1(\Omega)}\, dt \qquad \textit{source.}$$

In the case of strong diffusion $A'(s) \geq \beta > 0$ for any $s \in \mathbb{R}$ and $A'$ is uniformly Lipschitz continuous, then $\Lambda_n$ is bounded by $\beta^{-1} \| U_h \|_{BV(Q_n)}$ which is expected to be bounded in practical computations. The a posteriori error estimator in Theorem 3.6 then recovers the standard a posteriori error estimator derived in the literature for parabolic problems [34], [9]. In particular, the space error indicators $\mathcal{E}_1^n$, $\mathcal{E}_2^n$, which control the adaptation of finite element meshes at each time step, are sharp in the sense that a local lower bound for the error can be established by extending the argument in [9, Theorem 2.2] for linear parabolic equations.

We also remark that the method of the a posteriori error analysis here is different from those for nonlinear conservation laws in [17], [18], [27] or nonlinear degenerate parabolic equations in [32]. Recall that there are several parameters introduced in the analysis:

- The regularizing parameter $\varepsilon$ in $H_\varepsilon(z)$.
- The boundary layer sequence parameters $\delta$ and $\eta$, and the mollifier parameters $l, m$ and $n$.

The analysis for Cauchy problems in [17], [18], [27] is based on letting $\varepsilon \to 0$ and taking finite mollifier parameters $l, m, n$. The analysis in [32] takes both finite $\varepsilon$ and finite mollifier parameters $l, m, n$. Note that there are no boundary layer sequence parameters $\delta, \eta$ for the analysis for Cauchy problems. The analysis in this paper is based on letting $\delta, \eta \to 0$ and $l, m, n \to \infty$ but taking a finite $\varepsilon$. We are not able to use the same technique as that in [17], [18], [27], [32] by choosing finite mollifier parameters $l, m, n$ to treat the problem with boundary conditions.

Based on the a posteriori error estimate in Theorem 3.6, an adaptive algorithm is proposed and implemented in [11]. In particular, the numerical experiments in [11] indicate that the total estimated error is roughly proportional to $M^{-1/3}$, i.e. $\eta \approx CM^{-1/3}$ for some constant $C > 0$. This implies the quasi-optimal decay of the error

$$\| u - U_h \|_{L^\infty(0,T;L^1(\Omega))} + \int_Q H'_\varepsilon(A(u) - A(U_h))|\nabla(A(U_h) - A(u))|^2 \le CM^{-1/3}$$

is valid asymptotically. Here $M$ is the sum of the number of elements of the space meshes over all time steps.

Figure 3.1 shows the meshes and the surface plots of the solutions at time $t = 0.251278$ and $t = 0.500878$ for the Burger's equation with small viscosity

$$\frac{\partial u}{\partial t} + u\partial_x u - \varepsilon \Delta u = 0 \quad \text{in } Q,$$

where $\Omega = (0, 1)^2$, $T = 1.0$, $\varepsilon = 10^{-3}$, and the initial condition and boundary condition

$$u(x, y, t)|_{\partial\Omega} = u_0(x, y) = 0.5 \sin(\pi x) + \sin(2\pi x).$$

The adaptive algorithm is based on the a posteriori error estimate in Theorem 3.6 and is described in [11]. We observe from Figure 3.1 that the method captures the internal and boundary layers of the solution.

# Error estimates for anisotropic finite elements and applications

Ricardo G. Durán*

**Abstract.** The finite element method is one of the most frequently used techniques to approximate the solution of partial differential equations. It consists in approximating the unknown solution by functions which are polynomials on each element of a given partition of the domain, made of triangles or quadrilaterals (or their generalizations to higher dimensions).

A fundamental problem is to estimate the error between the exact solution $u$ and its computable finite element approximation. In many situations this error can be bounded in terms of the best approximation of $u$ by functions in the finite element space of piecewise polynomial functions. A natural way to estimate this best approximation is by means of the Lagrange interpolation or other similar procedures.

Many works have considered the problem of interpolation error estimates. The classical error analysis for interpolations is based on the so-called *regularity assumption*, which excludes elements with different sizes in each direction (called *anisotropic*). The goal of this paper is to present a different approach which has been developed by many authors and can be applied to obtain error estimates for several interpolations under more general hypotheses.

An important case in which anisotropic elements arise naturally is in the approximation of convection-diffusion problems which present boundary layers. We present some applications to these problems.

Finally we consider the finite element approximation of the Stokes equations and present some results for non-conforming methods.

**Keywords.** Finite elements, Mixed methods, anisotropic elements, Stokes equations, convection-diffusion.

## 1. Introduction

The finite element method in its different variants is one of the most frequently used techniques to approximate the solution of partial differential equations. The general idea is to use weak or variational formulations in an infinite dimensional space and to replace that space by a finite dimensional one made of piecewise polynomial functions. In this way, the original differential equation is transformed into an algebraic problem which can be solved by computational methods. Although the main idea goes back

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

to the works of Galerkin and Ritz in the early twentieth-century (or even to previous works, see for example [9] for a discussion of the history of these ideas), the finite element method became more popular since the middle of the twentieth century mainly because of its application by engineers to structural mechanics. On the other hand, the general mathematical analysis started only around forty years ago.

The theory of finite elements can be divided into *a priori* and *a posteriori* error analysis. The main goals of the *a priori* analysis are to prove convergence of the methods, to know the order of convergence (in terms of parameters associated with the finite dimensional problem, such as degree of approximation, mesh-size, size of the discrete problem, geometry of the elements, etc.) and the dependence of the error on properties of the unknown exact solution (such as its smoothness, which in many cases is already known from the theory of partial differential equations). Instead, the goals of the *a posteriori* error analysis are to obtain more quantitative information on the error and to develop self-adaptive methods to improve the approximation iteratively.

In this paper we consider several problems related to *a priori* error estimates. We will deal mainly with the error analysis for flat or anisotropic elements, which arise naturally in several applications.

Let us begin by recalling the basic ideas of weak formulations of differential equations and finite element approximations. A general abstract formulation for linear problems is given by

$$B(u, v) = F(v) \quad \text{for all } v \in V, \tag{1.1}$$

where $u \in V$ is the solution to be found, $V$ is a Hilbert space, $F$ is a continuous linear form and $B$ is a continuous bilinear form, i.e., there exists a constant $M > 0$ such that

$$|B(u, v)| \leq M\|u\|\|v\|$$

where $\|\cdot\|$ is the norm in the Hilbert space $V$.

To approximate the solution, we want to introduce a finite dimensional space $V_h \subset V$. The usual way to do this is to introduce a partition $\mathcal{T}_h$ of the domain $\Omega$ where we want to solve the differential equation usually made of triangular or quadrilateral elements (or their generalizations in 3D). The parameter $h$ is usually related to the mesh size. Then the space $V_h$ consists of functions which restricted to each element of the partition are polynomials.

The approximate solution of our problem is $u_h \in V_h$ that satisfies

$$B(u_h, v) = F(v) \quad \text{for all } v \in V_h.$$

Assume that the form $B$ is coercive, namely, that there exists a constant $\alpha > 0$ such that

$$B(v, v) \geq \alpha\|v\|^2 \quad \text{for all } v \in V. \tag{1.2}$$

Then the classical error analysis is based on Cea's lemma (see [14]), which states that

$$\|u - u_h\| \leq \frac{M}{\alpha}\|u - v\| \quad \text{for all } v \in V_h. \tag{1.3}$$

Notice that (1.2) also guarantees existence and uniqueness of solution in $V$ as well as in $V_h$, thanks to the well-known Lax–Milgram theorem.

If this condition does not hold, but the form $B$ satisfies the so-called *inf-sup conditions*, that is, there exists $\beta > 0$ such that

$$\inf_{u\in V_h} \sup_{v\in V_h} \frac{B(u,v)}{\|u\|\|v\|} \geq \beta, \tag{1.4}$$

$$\inf_{v\in V_h} \sup_{u\in V_h} \frac{B(u,v)}{\|u\|\|v\|} \geq \beta, \tag{1.5}$$

then we also have

$$\|u-u_h\| \leq \frac{M}{\beta}\|u-v\| \quad \text{for all } v\in V_h. \tag{1.6}$$

If the above inf-sup conditions hold in $V$, we also have uniqueness and existence of solution. However, this is not sufficient to obtain (1.6), as the inf-sup conditions are not inherited by subspaces. This is the main difference between error analysis of coercive and non-coercive forms which satisfy (1.4) and (1.5).

The classical example of a form $B$ which satisfies the inf-sup conditions but is not coercive, is the form associated to the Stokes equations of fluid dynamics (see for example [13], [20]).

In view of (1.3) and (1.6), in order to obtain an estimate for $\|u-u_h\|$ it is enough to bound $\|u-v\|$ for a function $v\in V_h$. Therefore this is one of the most important problems in the theory of finite elements. Usually, the function $v$ is taken to be a Lagrange interpolation of $u$. However, in some cases it is more convenient to use different approximations.

In many problems it is convenient to use spaces $V_h$ which are not contained in $V$. These methods are called non-conforming and in this case the right-hand sides of (1.3) and (1.6) are modified by adding the so-called "consistency terms". One of the best-known methods of this type is that of Crouzeix–Raviart, which is closely related to the mixed finite element methods of Raviart–Thomas (see [8], [23]).

The goal of this paper is to present general ideas to obtain error estimates for different interpolations valid under very general hypotheses on the elements, in particular, allowing meshes with flat or anisotropic elements. We consider Lagrange and other kind of interpolations arising in mixed finite element methods and give some applications to the approximation of convection-diffusion equations for which anisotropic elements are needed due to the presence of boundary layers.

Finally we consider the finite element approximation of the Stokes equations and recall some results for non-conforming methods.

## 2. Notation and some basic inequalities

The classical finite element analysis for triangular elements requires the so-called regularity assumption, i.e.,

$$\frac{h_T}{\rho_T} \leq C \tag{2.1}$$

where $h_T$ and $\rho_T$ are the outer and inner diameter, respectively (see Figure 1). In other words, the constants in the error estimates depend on $C$ (see for example [11], [14]).

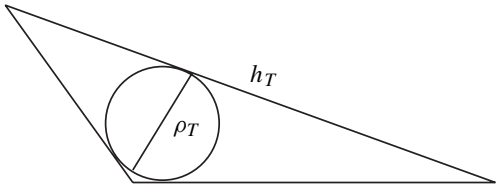

Figure 1

The same hypothesis is also needed for the analysis of mixed and non-conforming methods (see [15] and [24]).

For standard Lagrange interpolation on conforming elements, since the works of Babuska–Azis [10] and Jamet [21] it is well known that the regularity assumption can be relaxed. For example, in the case of triangles it can be replaced by the weaker maximum angle condition (i.e. angles bounded away from $\pi$). For rectangular elements, optimal error estimates can be obtained for arbitrary rectangles (while the regularity assumption requires that the edge sizes be comparable). In the case of general quadrilaterals, the situation is more complicated and several conditions, weaker than regularity, have been introduced to prove the error estimates (see, for example, [3]).

The standard method to prove error estimates is to obtain them first in a reference element and then to make a change of variables (see [14]). A different approach is to work directly in a given element and to use Poincaré type inequalities. The main idea is that the interpolation error usually has some vanishing averages (on the element, or edges, or faces, depending of the kind of interpolation considered). In this approach, the reference element is sometimes used to obtain the Poincaré type inequalities but, since one is bounding an $L^2$-norm, the constants appearing in the estimates are independent of the aspect ratio of the element.

We will use the following notation. By $H^1(\Omega)$ we mean the usual Sobolev space of $L^2$ functions with distributional first derivatives in $L^2$ and by $H_0^1(\Omega)$ the subspace of $H^1(\Omega)$ of functions vanishing on the boundary.

Similarly, $W^{k,p}(\Omega)$, for $1 \leq p \leq \infty$, indicates the Sobolev space of $L^p(\Omega)$ functions with distributional derivatives of order $k$ in $L^p(\Omega)$. When $p = 2$ we set $H^k(\Omega) = W^{k,2}(\Omega)$.

Here $\Omega \subset \mathbb{R}^n$, $n = 2, 3$, is a bounded domain. For a general triangle $T$, $h_T$ is its diameter, $\boldsymbol{p}_0$ is a vertex (arbitrary unless otherwise specified), $\boldsymbol{v}_1$, $\boldsymbol{v}_2$ (with $\|\boldsymbol{v}_i\| = 1$) are the directions of the edges $\ell_1$, $\ell_2$ sharing $\boldsymbol{p}_0$ (see Figure 2), and $\nu_i$ is the exterior unit normal to the side $\ell_i$ (with obvious generalizations to 3D). We also use the standard notation $\mathcal{P}_k$ for polynomials of total degree less than or equal to $k$, and $\mathcal{Q}_k$ for polynomials of degree less than or equal to $k$ in each variable. We call $\hat{T}$ the reference triangle with vertices at $(0, 0)$, $(1, 0)$ and $(0, 1)$, and $F\colon \hat{T} \to T$ the affine transformation $F(\hat{x}) = B\hat{x} + \boldsymbol{p}_0$ with $B\boldsymbol{e}_i = l_i \boldsymbol{v}_i$, where $\boldsymbol{e}_i$ are the canonical vectors.

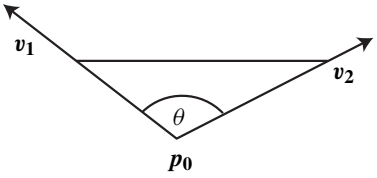

Figure 2

The following two results are the classical Poincaré inequality and a generalization of it (first given in [10]) written in a convenient way for our purposes.

**Lemma 2.1.** *Let $T$ be a triangle (resp. tetrahedron) and let $f \in H^1(T)$ be a function with vanishing average on $T$. Then there exists a constant $C$ independent of $T$ and of $f$ such that*

$$\|f\|_{L^2(T)} \leq C \sum_{j=1}^{n} |\ell_j| \left\| \frac{\partial f}{\partial \boldsymbol{v}_j} \right\|_{L^2(T)}. \tag{2.2}$$

*Proof.* It follows from the Poincaré inequality on $\hat{T}$ and making the change of variables $F$. □

**Lemma 2.2.** *Let $T$ be a triangle (resp. tetrahedron) and $\ell$ be any of its edges (resp. faces). Let $f \in H^1(T)$ be a function with vanishing average on $\ell$. Then there exists a constant $C$ independent of $T$ such that*

$$\|f\|_{L^2(T)} \leq C \sum_{j=1}^{n} |\ell_j| \left\| \frac{\partial f}{\partial \boldsymbol{v}_j} \right\|_{L^2(T)}. \tag{2.3}$$

*Proof.* It is enough to prove that, on the reference element $\hat{T}$,

$$\|f\|_{L^2(\hat{T})} \leq C \|\nabla f\|_{L^2(\hat{T})}. \tag{2.4}$$

Then, for a general triangle, the result follows by making the change of variables $F$.

The estimate (2.4) can be proved by a standard compactness argument (as was done in [10]). A different proof can be given by a using (2.2) and a trace theorem.

Indeed, if $f_{\hat{\ell}}$ and $f_{\hat{T}}$ denote the averages on $\hat{\ell}$ and $\hat{T}$, respectively, and if we assume that $f_{\hat{\ell}} = 0$ we have

$$\|f\|_{L^2(\hat{T})} = \|f - f_{\hat{\ell}}\|_{L^2(\hat{T})} \leq \|f - f_{\hat{T}}\|_{L^2(\hat{T})} + \|f_{\hat{T}} - f_{\hat{\ell}}\|_{L^2(\hat{T})}.$$

But

$$f_{\hat{T}} - f_{\hat{\ell}} = \frac{1}{|\hat{\ell}|}\int_{\hat{\ell}}(f_{\hat{T}} - f),$$

and therefore an application of a standard trace theorem gives

$$\|f_{\hat{T}} - f_{\hat{\ell}}\|_{L^2(\hat{T})} \leq C\{\|f - f_{\hat{T}}\|_{L^2(\hat{T})} + \|\nabla f\|_{L^2(\hat{T})}\}$$

with a constant $C$ which depends only on the reference element. Hence (2.4) follows from (2.2). □

## 3. Error estimates for Lagrange interpolation

**3.1. The two-dimensional case.** To introduce the general idea we present first two simple classical cases: the Lagrange interpolation for lowest degree finite elements in triangles or rectangles. The argument is essentially that given in [10] for triangles. In the case of rectangles, an extra step is required due to the presence of a non-vanishing second derivative of the interpolating function.

Given a triangle $T$ we denote with $I_1 u \in \mathcal{P}_1$ the Lagrange interpolation of $u$, i.e., the affine function which equals $u$ on the vertices of $T$. $D^2 u$ denotes the sum of the absolute values of second derivatives of $u$.

**Theorem 3.1.** *There exists a constant $C$ such that, if $\theta$ is the maximum angle of $T$,*

$$\|\nabla(u - I_1 u)\|_{L^2(T)} \leq \frac{C}{\sin\theta}\, h_T \|D^2 u\|_{L^2(T)}.$$

*Proof.* Observe that, for $i = 1, 2$, $\nabla(u - I_1 u)\cdot \boldsymbol{v}_i$, has vanishing average on one side of $T$. Therefore, applying Lemma 2.2 and using that the second derivatives of $I_1 u$ vanish, we obtain

$$\|\nabla(u - I_1 u)\cdot \boldsymbol{v}_i\|_{L^2(T)} \leq C\left\{|\ell_1|\left\|\frac{\partial \nabla u\cdot \boldsymbol{v}_i}{\partial \boldsymbol{v}_1}\right\|_{L^2(T)} + |\ell_2|\left\|\frac{\partial \nabla u\cdot \boldsymbol{v}_i}{\partial \boldsymbol{v}_2}\right\|_{L^2(T)}\right\}.$$

Then, if we choose $\boldsymbol{p}_0$ as the vertex corresponding to the maximum angle of $T$, we have

$$|\nabla(u - I_1 u)| \leq \frac{C}{\sin\theta}\{|\nabla(u - I_1 u)\cdot \boldsymbol{v}_1| + |\nabla(u - I_1 u)\cdot \boldsymbol{v}_2|\},$$

and hence the theorem is proved. □

We consider now the case of rectangles. We use the same notation, $I_1 u$, for the interpolation which now belongs to $\mathcal{Q}_1$. The proof for this case is analogous to the previous one, with the only difference that $\frac{\partial^2 I_1 u}{\partial x \partial y}$ does not vanish.

Let $R$ be a rectangle and let $\ell_1$, $\ell_2$ be two adjacent sides. Clearly, the result of Lemma 2.2 holds for this case also.

**Theorem 3.2.** *There exists a constant $C$, independent of the relation between $|\ell_1|$ and $|\ell_1|$, such that*

$$\left\| \frac{\partial}{\partial x}(u - I_1 u) \right\|_{L^2(R)} \leq C \left\{ |\ell_1| \left\| \frac{\partial^2 u}{\partial x^2} \right\|_{L^2(R)} + |\ell_2| \left\| \frac{\partial^2 u}{\partial x \partial y} \right\|_{L^2(R)} \right\} \tag{3.1}$$

*and*

$$\left\| \frac{\partial}{\partial y}(u - I_1 u) \right\|_{L^2(R)} \leq C \left\{ |\ell_1| \left\| \frac{\partial^2 u}{\partial x \partial y} \right\|_{L^2(R)} + |\ell_2| \left\| \frac{\partial^2 u}{\partial y^2} \right\|_{L^2(R)} \right\}. \tag{3.2}$$

*Proof.* Proceeding as in the case of triangles, we have

$$\left\| \frac{\partial}{\partial x}(u - I_1 u) \right\|_{L^2(R)} \leq C \left\{ |\ell_1| \left\| \frac{\partial^2 (u - I_1 u)}{\partial x^2} \right\|_{L^2(R)} + |\ell_2| \left\| \frac{\partial^2 (u - I_1 u)}{\partial x \partial y} \right\|_{L^2(R)} \right\}. \tag{3.3}$$

But, $\frac{\partial^2 I_1 u}{\partial x^2} = 0$ and an elementary computation shows that

$$\int_R \frac{\partial^2 I_1 u}{\partial x \partial y} = \int_R \frac{\partial^2 u}{\partial x \partial y},$$

i.e., $\frac{\partial^2 I_1 u}{\partial x \partial y}$ is the average of $\frac{\partial^2 u}{\partial x \partial y}$ on $R$. Then

$$\left\| \frac{\partial^2 I_1 u}{\partial x \partial y} \right\|_{L^2(R)} \leq \left\| \frac{\partial^2 u}{\partial x \partial y} \right\|_{L^2(R)}$$

and therefore (3.1) holds. Obviously, the proof of (3.2) is analogous. □

**Remark 3.3.** If the function $u \in H^3(R)$, then the last term on the right-hand side of (3.3) is of higher order. Indeed, that term is the difference between $\frac{\partial^2 u}{\partial x \partial y}$ and its average. Therefore we have the estimate

$$\left\| \frac{\partial}{\partial x}(u - I_1 u) \right\|_{L^2(R)} \leq C |\ell_1| \left\| \frac{\partial^2 u}{\partial x^2} \right\|_{L^2(R)} + \text{ higher order terms.}$$

**3.2. The three-dimensional case.** Many results on finite elements can be extended almost straightforward from 2D to 3D. However, this is not the case of error estimates for anisotropic elements. Indeed, counterexamples for an estimate analogous to (3.1) in the 3D case have been given in [6] and [26]. They show that the constant in the

estimate blows-up when a rectangular reference tetrahedron (or cube) is compressed in one direction.

Many papers have been published considering the 3D case. For example, in the case of tetrahedra, Krízek [22] introduced a natural generalization of the maximum angle condition: if the angles between faces and the angles in the faces are bounded away from $\pi$, he obtained error estimates for smooth functions, namely, $u \in W^{2,\infty}$. In [16] the results of Krízek were extended to functions in $W^{2,p}$ with $2 < p < \infty$ (and, moreover, to functions in an intermediate Orlicz space between $H^2$ and $W^{2,p}$, $p > 2$). Therefore, although the estimate fails for functions in $H^2$, it is valid for functions only slightly more regular. Let us mention that the reason why the arguments applied in 2D cannot be generalized, is that the estimate given in Lemma 2.2 is not true in 3D if $\ell$ is an edge instead of a face (note that the interpolation error for the Lagrange interpolation has vanishing integral on edges).

On the other hand, many papers have considered error estimates for different interpolations (see for example [1], [5], [16], [17]), namely, different variants of average interpolators. This kind of interpolations have been introduced to approximate non-smooth functions (for which the Lagrange interpolation is not even defined). However, they have as well better approximation properties on anisotropic elements for functions in $H^2$. Indeed, using average interpolations, the 2D results can be generalized to 3D. Observe that, in view of (1.3) and (1.6), error estimates for an average interpolation will give bounds for finite element approximations.

## 4. Applications to convection-diffusion equations

A very important application in which anisotropic elements are needed is the approximation of convection-diffusion problems in which boundary layers arise.

Consider for example the model problem

$$\begin{aligned} -\varepsilon \Delta u + b \cdot \nabla u + cu &= f \quad \text{in } \Omega, \\ u &= 0 \quad \text{on } \partial\Omega, \end{aligned} \tag{4.1}$$

where $\Omega = (0, 1)^2$ and $\varepsilon > 0$ is a small parameter.

It is well known that the numerical approximation of this equation requires some special method in order to obtain good results when the problem is convection dominated, due to the presence of boundary or interior layers. In the case of boundary layers, one possibility is to use appropriate refined meshes near the boundary; this methodology gives rise to anisotropic elements. Using estimates (3.1) and (3.2) it is possible to obtain quasi-optimal order convergence (with respect to the number of nodes) in the $\varepsilon$-norm defined by

$$\|v\|_\varepsilon^2 = \|v\|_{L^2(\Omega)}^2 + \varepsilon \|\nabla v\|_{L^2(\Omega)}^2$$

for the standard $\mathcal{Q}_1$ approximation on appropriate graded meshes.

This problem can be written in the general form (1.1) with $V = H_0^1(\Omega)$,

$$B(u, v) = \int_\Omega (\varepsilon \nabla u \nabla v + b \cdot \nabla u\, v + c\, uv)\ dx$$

and

$$F(v) = \int_\Omega f v\, dx.$$

Assuming that there exists a constant $\mu$ independent of $\varepsilon$ such that

$$c - \frac{\operatorname{div} b}{2} \geq \mu > 0, \tag{4.2}$$

the bilinear form $B$ is coercive in the $\varepsilon$-norm uniformly in $\varepsilon$ (see [25]), i.e., the constant $\alpha$ in (1.2) is independent of $\varepsilon$. However, the continuity of $B$ is not uniform in $\varepsilon$ and this is one of the reasons why it is not possible to apply directly the general result (1.3) to obtain error estimates valid uniformly in $\varepsilon$. Therefore, a special analysis is required and this was the object of [18]. It was proved in that paper that

$$\|u - u_h\|_\varepsilon \leq C \frac{\log^2(1/\varepsilon)}{\sqrt{N}},$$

where $N$ is the number of nodes and $h > 0$ is a parameter associated with the meshes. Observe that this order of convergence is quasi-optimal in the sense that, up to the logarithm factor, it is the same order that one obtains for a smooth solution of a problem with $\varepsilon = O(1)$ using uniform meshes.

Assuming that the coefficient $b$ is such that the boundary layers are close to $x = 0$ and $y = 0$, the meshes $\mathcal{T}_h$ are such that the grading in each direction is given by

$$\begin{cases} \xi_0 = 0, & \\ \xi_i = ih\varepsilon & \text{for } 1 \leq i < \frac{1}{h} + 1, \\ \xi_{i+1} = \xi_i + h\xi_i & \text{for } \frac{1}{h} + 1 \leq i \leq M - 2, \\ \xi_M = 1, & \end{cases} \tag{4.3}$$

where $M$ is such that $\xi_{M-1} < 1$ and $\xi_{M-1} + h\xi_{M-1} \geq 1$. We assume that the last interval $(\xi_{M-1}, 1)$ is not too small in comparison with the previous one $(\xi_{M-2}, \xi_{M-1})$ (if this is not the case, we just eliminate the node $\xi_{M-1}$).

Figure 3 shows the approximate solution of (4.1) for

$$\varepsilon = 10^{-6}, \quad b = (1 - 2\varepsilon)(-1, -1), \quad c = 2(1 - \varepsilon)$$

and

$$f(x, y) = -\left[x - \left(\frac{1 - e^{-\frac{x}{\varepsilon}}}{1 - e^{-\frac{1}{\varepsilon}}}\right) + y - \left(\frac{1 - e^{-\frac{y}{\varepsilon}}}{1 - e^{-\frac{1}{\varepsilon}}}\right)\right] e^{x+y}.$$

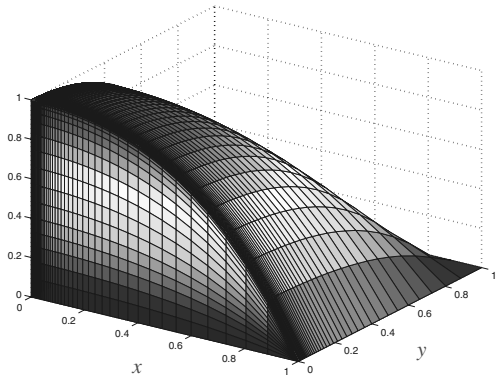

Figure 3

Observe that no oscillations arise although we are using the standard $\mathcal{Q}_1$ finite element method.

The graded meshes are an alternative to the well-known Shishkin meshes which have been widely analyzed for convection-diffusion problems (see for example [25]).

From the error analysis given in [18] one can see that a graded mesh designed for a value of $\varepsilon$ works well also for larger values of $\varepsilon$. This is not the case for Shishkin meshes. Table 1 shows the values of the $\varepsilon$-norm of the error for different values of $\varepsilon$, solving the problem with the mesh corresponding to $\varepsilon = 10^{-6}$, using graded meshes and Shishkin meshes.

Table 1

| $\varepsilon$ | Error |
|---|---|
| $10^{-6}$ | 0.040687 |
| $10^{-5}$ | 0.033103 |
| $10^{-4}$ | 0.028635 |
| $10^{-3}$ | 0.024859 |
| $10^{-2}$ | 0.02247 |
| $10^{-1}$ | 0.027278 |

Graded meshes, $N = 10404$.

| $\varepsilon$ | Error |
|---|---|
| $10^{-6}$ | 0.0404236 |
| $10^{-5}$ | 0.249139 |
| $10^{-4}$ | 0.623650 |
| $10^{-3}$ | 0.718135 |
| $10^{-2}$ | 0.384051 |
| $10^{-1}$ | 0.0331733 |

Shishkin meshes, $N = 10609$.

To see the different structures, we show in Figure 4 a Shishkin mesh (on the right) and one of our graded meshes (on the left) having the same number of nodes. For the sake of clarity, we show only the part of the meshes corresponding to $(0, 1/2) \times (0, 1/2)$ and $\varepsilon = 10^{-\frac{3}{2}}$.

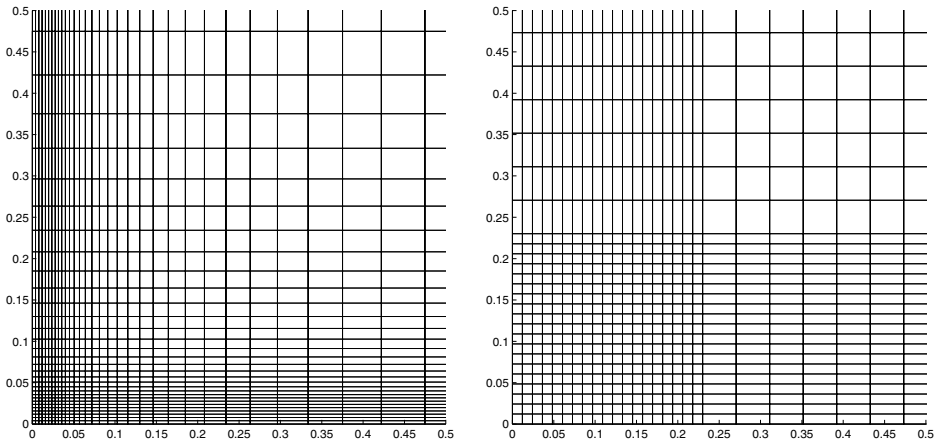

Figure 4

## 5. Error estimates for Raviart–Thomas interpolation

**5.1. The two dimensional case.** The Raviart–Thomas spaces were introduced in [24] to approximate vector fields $\boldsymbol{u} \in H(\mathrm{div}, \Omega)$ where

$$H(\mathrm{div}, \Omega) = \{\boldsymbol{u} \in L^2(\Omega) : \mathrm{div}\, \boldsymbol{u} \in L^2\}.$$

For any integer $k \geq 0$, the space $\mathcal{RT}_k$ on a triangle $T$ is defined by

$$\mathcal{RT}_k(T) = \mathcal{P}_k^2(T) \oplus (x, y)\mathcal{P}_k(T).$$

Calling $P_k$ the $L^2$ orthogonal projection on $\mathcal{P}_k(T)$, it is known (see [24]) that there exists an operator $RT_k \colon H^1(T)^2 \to \mathcal{RT}_k(T)$ satisfying the following commutative diagram property:

$$\begin{array}{ccccc} H^1(T)^2 & \xrightarrow{\mathrm{div}} & L^2(T) & & \\ \Big\downarrow{\scriptstyle RT_k} & & \Big\downarrow{\scriptstyle P_k} & & \\ \mathcal{RT}_k(T) & \xrightarrow[\mathrm{div}]{} & \mathcal{P}_k(T) & \longrightarrow & 0. \end{array} \tag{5.1}$$

For the case of anisotropic elements, only the lowest degree case $\mathcal{RT}_0$ has been considered. Error estimates for this case have been obtained in [2].

Below we will show how the arguments can be generalized to obtain error estimates for the case of $\mathcal{RT}_1$. Higher order approximations can be treated similarly although this extension is not straightforward.

Let us first recall the results for $\mathcal{RT}_0$. Again, the results follow by the generalized Poincaré inequality given in Lemma 2.2 as we show in the next theorem.

**Theorem 5.1.** *There exists a constant $C$ such that, if $\theta$ is the maximum angle of $T$,*

$$\|\boldsymbol{u} - RT_0\boldsymbol{u}\|_{L^2(T)} \leq \frac{C}{\sin\theta} \sum_{k=1}^{2} |\ell_k| \Big( \Big\| \frac{\partial \boldsymbol{u}}{\partial \boldsymbol{v}_k} \Big\|_{L^2(T)} + \|\operatorname{div} \boldsymbol{u}\|_{L^2(T)} \Big).$$

*Proof.* Since $(\boldsymbol{u} - RT_0\boldsymbol{u}) \cdot \nu_i$ has zero mean value on $\ell_i$, it follows from Lemma 2.2 that

$$\|(\boldsymbol{u} - RT_0\boldsymbol{u}) \cdot \nu_i\|_{L^2(T)} \leq C \sum_{k=1}^{2} |\ell_k| \Big\| \frac{\partial (\boldsymbol{u} - RT_0\boldsymbol{u}) \cdot \nu_i}{\partial \boldsymbol{v}_k} \Big\|_{L^2(T)}. \tag{5.2}$$

But it is easy to check that

$$\frac{\partial (RT_0\boldsymbol{u} \cdot \nu_i)}{\partial \boldsymbol{v}_k} = \frac{1}{2} (\operatorname{div} RT_0\boldsymbol{u})\, \boldsymbol{v}_k \cdot \nu_i.$$

On the other hand, using the commutative diagram property (5.1), we have

$$\|\operatorname{div} RT_0\boldsymbol{u}\|_{L^2(T)} \leq \|\operatorname{div} \boldsymbol{u}\|_{L^2(T)}$$

and so it follows from (5.2) that

$$\|(\boldsymbol{u} - RT_0\boldsymbol{u}) \cdot \nu_i\|_{L^2(T)} \leq C \sum_{k=1}^{2} |\ell_k| \Big( \Big\| \frac{\partial \boldsymbol{u}}{\partial \boldsymbol{v}_k} \Big\|_{L^2(T)} + \|\operatorname{div} \boldsymbol{u}\|_{L^2(T)} |\nu_i \cdot \boldsymbol{v}_k| \Big). \tag{5.3}$$

Up to now the constant $C$ is independent of $T$. If we want to bound $\|\boldsymbol{u} - RT_0\boldsymbol{u}\|_{L^2(T)}$, it is natural to expect that the constant will depend on the geometry of the element.

In view of (5.3) it would be enough to control $\boldsymbol{u} - RT\boldsymbol{u}$ in terms of its components in the directions of the normals to the edges. For a fixed triangle the estimate

$$|\boldsymbol{u} - RT_0\boldsymbol{u}| \leq C\{|(\boldsymbol{u} - RT_0\boldsymbol{u}) \cdot \nu_1| + |(\boldsymbol{u} - RT_0\boldsymbol{u}) \cdot \nu_2|\}$$

holds. Moreover, for a family of triangles, the constant $C$ will not degenerate if the angle between $\nu_1$ and $\nu_2$ does not go to 0 or $\pi$ or, equivalently, if the angle between the corresponding edges does not go to 0 or $\pi$. Therefore the constant will be uniformly bounded for a family of elements with maximum angle bounded away from $\pi$. More precisely, we have

$$\|\boldsymbol{u} - RT_0\boldsymbol{u}\|_{L^2(T)} \leq \frac{C}{\sin\theta} \sum_{i=1}^{2} \|(\boldsymbol{u} - RT_0\boldsymbol{u}) \cdot \nu_i\|_{L^2(T)} \tag{5.4}$$

where $\theta$ is the maximum angle of $T$. Indeed, if $N$ is the matrix which has $\nu_1$ and $\nu_2$ as its rows, then

$$\|\boldsymbol{u} - RT_0\boldsymbol{u}\|_{L^2(T)} \leq \|N^{-1}\| \sum_{i=1}^{2} \|(\boldsymbol{u} - RT_0\boldsymbol{u}) \cdot \nu_i\|_{L^2(T)}$$

where $\|\cdot\|$ denotes the matrix norm associated with the euclidean norm. But since the $\nu_i$ are unit vectors it follows that $\|N^{-1}\| \leq \frac{C}{|\det N|}$ and $|\det N| = \sin\theta_1$, where $\theta_1$ is the angle between $\nu_1$ and $\nu_2$. If the vertex $\boldsymbol{p}_0$ is the one corresponding to the maximum angle $\theta_1 = \pi - \theta$, then (5.4) holds and the theorem is proved. □

Similar arguments can be applied for the analysis of higher order elements. However the extension is not straightforward. In what follows we consider the case of $\mathcal{RT}_1$. This case requires the following generalization of the Poincaré inequality.

**Lemma 5.2.** *Let $T$ be a triangle and $\ell$ one of its sides. If $f \in H^2(T)$ satisfies*

$$\int_\ell fp = 0 \quad \textit{for all } p \in \mathcal{P}_1(\ell) \quad \textit{and} \quad \int_T f = 0,$$

*then*

$$\|f\|_{L^2(T)} \leq Ch_T^2 \|D^2 f\|_{L^2(T)}$$

*with a constant $C$ independent of the shape of the triangle.*

*Proof.* Observing that, if $f \in \mathcal{P}_1$ satisfies the three hypotheses of the lemma then $f = 0$, it follows by standard compactness arguments that

$$\|f\|_{L^2(\hat{T})} \leq C\|D^2 f\|_{L^2(\hat{T})}.$$

Then an affine change of variables concludes the proof. □

To obtain the error estimate for the $RT_1$ interpolation we will need to have a bound for the gradient of the $P_1$ projection. This is the goal of the next lemma.

**Lemma 5.3.** *If $f \in H^1(T)$ we have*

$$\|\nabla P_1 f\|_{L^2(T)} \leq C\|\nabla f\|_{L^2(T)}$$

*with a constant $C$ depending only on the maximum angle of $T$.*

*Proof.* We will prove that for the triangle with vertices at $(0, 0)$, $(h, 0)$ and $(0, 1)$ we have

$$\|\nabla P_1 f\|_{L^2(T)} \leq 6\|\nabla f\|_{L^2(T)}.$$

Then the general result follows by an affine change of variables.

Let $M_i, i = 1, 2, 3$ be the mid-side points of $T$. Since the quadrature rule obtained by interpolating at these points is exact for quadratic polynomials, it is easy to see that the functions

$$\phi_1 = \left(\frac{6}{h}\right)^{1/2}(1-2y), \quad \phi_2 = \left(\frac{6}{h}\right)^{1/2}\left(2y+\frac{2x}{h}-1\right) \quad \text{and} \quad \phi_3 = \left(\frac{6}{h}\right)^{1/2}\left(1-\frac{2x}{h}\right)$$

form an orthonormal basis of $\mathcal{P}_1(T)$. Then

$$P_1 f = \sum_{i=1}^{3} c_i \phi_i$$

with $c_i = \int_T f\phi_i$. Therefore,

$$\frac{\partial P_1 f}{\partial x} = \frac{2\sqrt{6}}{h^{\frac{3}{2}}} \int_T f(\phi_2 - \phi_3) = \frac{24}{h^2} \int_T f(x, y)\Big(y + \frac{2x}{h} - 1\Big)\, dxdy.$$

Now observe that, for any $y \in (0, 1)$,

$$\int_0^{h(1-y)} \Big(y + \frac{2x}{h} - 1\Big)\, dx = 0$$

and so, denoting $\bar{f}(y) = \frac{1}{h(1-y)} \int_0^{h(1-y)} f(x, y)\ dx$, we obtain

$$\frac{\partial P_1 f}{\partial x} = \frac{24}{h^2} \int_0^1 \int_0^{h(1-y)} (f(x, y) - \bar{f}(y))\Big(y + \frac{2x}{h} - 1\Big)\, dxdy.$$

But using the one dimensional Poincaré inequality we have

$$\int_0^{h(1-y)} |f(x, y) - \bar{f}(y))|\, dx \le \frac{h}{2} \int_0^{h(1-y)} \Big|\frac{\partial f}{\partial x}(x, y)\Big|\, dx$$

and, since $\big|y + \frac{2x}{h} - 1\big| \le 1$, it follows that

$$\Big|\frac{\partial P_1 f}{\partial x}\Big| \le \frac{12}{h} \int_0^1 \int_0^{h(1-y)} \Big|\frac{\partial f}{\partial x}(x, y)\Big|\, dxdy.$$

Therefore

$$\Big|\frac{\partial P_1 f}{\partial x}\Big| \le \frac{12}{h} \Big\|\frac{\partial f}{\partial x}\Big\|_{L^1(T)} \le \frac{12}{h} |T|^{\frac{1}{2}} \Big\|\frac{\partial f}{\partial x}\Big\|_{L^2(T)}$$

and consequently

$$\Big\|\frac{\partial P_1 f}{\partial x}\Big\|_{L^2(T)} \le 6 \Big\|\frac{\partial f}{\partial x}\Big\|_{L^2(T)}.$$

Clearly, the same arguments can be applied to bound the derivative with respect to $y$. □

**Theorem 5.4.** *There exists a constant $C$ depending only on the maximum angle of $T$ such that*

$$\|\boldsymbol{u} - RT_1\boldsymbol{u}\|_{L^2(T)} \le Ch_T^2 \|D^2\boldsymbol{u}\|_{L^2(T)}.$$

*Proof.* From the definition of $RT_1\boldsymbol{u}$ we know that, for $i = 1, 2, 3$, $(\boldsymbol{u} - RT_1\boldsymbol{u}) \cdot \nu_i$ satisfies the hypotheses of Lemma 5.2 and then

$$\|(\boldsymbol{u} - RT_1\boldsymbol{u}) \cdot \nu_i\|_{L^2(T)} \le Ch_T^2 \|D^2(\boldsymbol{u} - RT_1\boldsymbol{u})\|_{L^2(T)}.$$

So, in order to estimate the component of $\boldsymbol{u} - RT_1\boldsymbol{u}$ in the direction $\nu_i$, we need to bound the second derivatives of $RT_1\boldsymbol{u}$ in terms of $D^2\boldsymbol{u}$.

But an easy computation shows that, for any $\boldsymbol{v} \in \mathcal{RT}_1(T)$,

$$\frac{\partial^2 \boldsymbol{v}}{\partial x^2} = \frac{2}{3}\Big(\frac{\partial(\operatorname{div} \boldsymbol{v})}{\partial x}, 0\Big), \quad \frac{\partial^2 \boldsymbol{v}}{\partial y^2} = \frac{2}{3}\Big(0, \frac{\partial(\operatorname{div} \boldsymbol{v})}{\partial y}\Big)$$

and

$$\frac{\partial^2 \boldsymbol{v}}{\partial x \partial y} = \frac{1}{3}\Big(\frac{\partial(\operatorname{div} \boldsymbol{v})}{\partial y}, \frac{\partial(\operatorname{div} \boldsymbol{v})}{\partial x}\Big).$$

Therefore we have

$$\|(\boldsymbol{u} - RT_1\boldsymbol{u}) \cdot \nu_i\|_{L^2(T)} \le Ch_T^2\big\{\|D^2\boldsymbol{u}\|_{L^2(T)} + \|\nabla(\operatorname{div}\ RT_1\boldsymbol{u})\|_{L^2(T)}\big\}. \tag{5.5}$$

Now from (5.1) we know that

$$\nabla(\operatorname{div} RT_1\boldsymbol{u}) = \nabla(P_1 \operatorname{div} \boldsymbol{u}),$$

hence applying Lemma 5.3 yields

$$\|\nabla(\operatorname{div} RT_1\boldsymbol{u})\|_{L^2(T)} \le C\|\nabla(\operatorname{div} \boldsymbol{u})\|_{L^2(T)}$$

and using this inequality in (5.5) we obtain the estimates for the normal components of $(\boldsymbol{u} - RT_1\boldsymbol{u})$. Then, to conclude the proof of the theorem, we proceed as in the case of $RT_0$. □

**5.2. The three-dimensional case.** As in the case of the Lagrange interpolation, the 3D case presents some important differences with the 2D one. We recall that the definition of $\mathcal{RT}_k$ can be extended straightforwardly to the 3D case. Indeed, for $T$ a tetrahedron we have

$$\mathcal{RT}_k(T) = \mathcal{P}_k^3(T) \oplus (x, y, z)\mathcal{P}_k(T).$$

The *maximum angle condition* can be generalized in different ways. The first one, introduced in [2], is the *regular vertex property*. We say that a tetrahedron satisfies this property with a constant $\bar{c} > 0$ if it has a vertex $\boldsymbol{p}_0$ such that $|\det M| \ge \bar{c} > 0$, where $M$ is the matrix which has $\boldsymbol{v}_i$, $i = 1, 2, 3$ as rows (where we are using the obvious generalization of the notation of the 2D case).

Under this hypothesis, Theorem 5.1 can be generalized almost straightforwardly. Indeed, the basic result given in Lemma 2.2 is valid now for functions with vanishing average on a face of $T$, and using this result we can prove, arguing as in the 2D case, that

$$\|(\boldsymbol{u} - RT_0\boldsymbol{u}) \cdot \nu_i\|_{L^2(T)} \le C \sum_{k=1}^{3} |\ell_k|\Big(\Big\|\frac{\partial \boldsymbol{u}}{\partial \boldsymbol{v}_k}\Big\|_{L^2(T)} + \|\operatorname{div} \boldsymbol{u}\|_{L^2(T)}|\nu_i \cdot \boldsymbol{v}_k|\Big).$$

As a consequence we obtain the following estimate.

**Theorem 5.5.** *Let $T$ be a tetrahedron satisfying the regular vertex property with a constant $\bar{c} > 0$. Then there exists a constant $C$ depending only on $\bar{c}$ such that*

$$\|\boldsymbol{u} - RT_0\boldsymbol{u}\|_{L^2(T)} \leq C \sum_{k=1}^{3} |\ell_k| \left( \left\| \frac{\partial \boldsymbol{u}}{\partial \boldsymbol{v}_k} \right\|_{L^2(T)} + \|\operatorname{div} \boldsymbol{u}\|_{L^2(T)} \right). \tag{5.6}$$

The other "natural" generalization of the 2D maximum angle condition is the condition introduced by Krízek [22]. We say that a family of tetrahedra satisfies the *maximum angle condition* with a constant $\overline{\psi} < \pi$ if the angles inside the faces and the angles between faces are bounded above by $\overline{\psi}$.

It is easy to see that in the 2D case the regular vertex property is equivalent to the maximum angle condition. However, the situation is different in the 3D case. In fact, the family in Figure 5, with arbitrary lengths $h_1, h_2, h_3$, satisfies uniformly the maximum angle condition but not the regular vertex property (take for example $h_1 = h_3 = h^2$, and $h_2 = h$). On the other hand, the regular vertex property implies the maximum angle condition (see [2]). A natural question is whether or not error

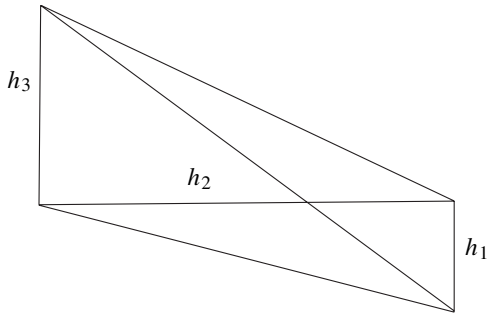

Figure 5

estimates for the $RT_0$ interpolation hold under the maximum angle condition. The answer is positive. In [2] the following result was proved.

**Theorem 5.6.** *If $T$ is a tetrahedron satisfying the maximum angle condition with a constant $\overline{\psi}$. Then there exists a constant $C$ depending only on $\overline{\psi}$ such that*

$$\|\boldsymbol{u} - RT_0\boldsymbol{u}\|_{L^2(T)} \leq Ch_T \|D\boldsymbol{u}\|_{L^2(T)}. \tag{5.7}$$

Again the basic tool to obtain this estimate is the generalization to 3D of Lemma 2.2. Indeed, consider the face mean average interpolator introduced in [15], namely, $\Pi\colon H^1(T) \to \mathcal{P}_1(T)$ given by

$$\int_S \Pi w = \int_S w$$

for any face $S$ of $T$.

**Lemma 5.7.** *The following error estimates hold with a constant $C$ independent of $T$:*

$$\|w - \Pi w\|_{L^2(T)} \le C \sum_{j=1}^{3} |\ell_j| \left\| \frac{\partial w}{\partial \boldsymbol{v}_j} \right\|_{L^2(T)} \tag{5.8}$$

$$\left\| \frac{\partial \Pi w}{\partial \xi} \right\|_{L^2(T)} \le \left\| \frac{\partial w}{\partial \xi} \right\|_{L^2(T)} \tag{5.9}$$

$$\left\| \frac{\partial (w - \Pi w)}{\partial \xi} \right\|_{L^2(T)} \le C \sum_{j=1}^{3} |\ell_j| \left\| \frac{\partial^2 w}{\partial \boldsymbol{v}_j \partial \xi} \right\|_{L^2(T)} \tag{5.10}$$

*where $\frac{\partial}{\partial \xi}$ is a derivative in any direction.*

*Proof.* Since $w - \Pi w$ has vanishing mean value on the faces of $T$, it follows from Lemma 2.2 that

$$\|w - \Pi w\|_{L^2(T)} \le C \sum_{j=1}^{3} |\ell_j| \left\| \frac{\partial (w - \Pi w)}{\partial \boldsymbol{v}_j} \right\|_{L^2(T)}. \tag{5.11}$$

Now, it follows from the definition of $\Pi$ that

$$\int_T \frac{\partial \Pi w}{\partial \xi} = \int_T \frac{\partial w}{\partial \xi}$$

or, in other words, the constant $\frac{\partial \Pi w}{\partial \xi}$ is the average on $T$ of $\frac{\partial w}{\partial \xi}$ and so (5.9) holds and (5.10) follows from Lemma 2.1. Finally, (5.8) is a consequence of (5.11) and (5.9). □

Now it is not difficult to check that, for any $\boldsymbol{u} \in H^1(T)^3$,

$$RT_0 \Pi \boldsymbol{u} = RT_0 \boldsymbol{u}$$

where $\Pi$ is the vector version of $\Pi$. Consequently,

$$\|\boldsymbol{u} - RT_0 \boldsymbol{u}\|_{L^2(T)} \le \|\boldsymbol{u} - \Pi \boldsymbol{u}\|_{L^2(T)} + \|\Pi \boldsymbol{u} - RT_0 \Pi \boldsymbol{u}\|_{L^2(T)}$$

and therefore, in view of (5.8), to prove (5.7) it is enough to prove the error estimate for $\boldsymbol{u} \in \mathcal{P}_1(K)^3$. In this way the problem is reduced to a finite dimensional one and the error estimate (5.7) can be proved under the maximum angle condition (see [2] for details).

## 6. The Stokes equations

The Stokes equations are given by

$$\begin{aligned} -\Delta \boldsymbol{u} + \nabla p &= f \quad \text{in } \Omega, \\ \operatorname{div} \boldsymbol{u} &= 0 \quad \text{in } \Omega, \\ \boldsymbol{u} &= 0 \quad \text{on } \partial\Omega, \end{aligned}$$

where $\boldsymbol{u}$ is the velocity and $p$ the pressure of a fluid contained in $\Omega$.

This problem can be written in the form (1.1) with $V = H_0^1(\Omega)^n \times L_0^2(\Omega)$ where

$$L_0^2(\Omega) = \{f \in L^2(\Omega) \,:\, \textstyle\int_\Omega f = 0\},$$

$$B((\boldsymbol{u}, p), (\boldsymbol{v}, q)) = \sum_{i,j=1}^{n} \int_\Omega \frac{\partial u_i}{\partial x_j}\frac{\partial v_i}{\partial x_j} - \int_\Omega p \ \mathrm{div}\, \boldsymbol{v} - \int_\Omega q \ \mathrm{div}\, \boldsymbol{u}$$

and

$$F(\boldsymbol{v}, q) = \int_\Omega f\boldsymbol{v}.$$

Then to obtain a finite element approximation we need to use a space $W_h$ for the velocity and a space $Q_h$ for the pressure. Note that since in this case the form $B$ is symmetric, the two conditions (1.4) and (1.5) are exactly the same. From the classical theory for mixed finite elements of Brezzi [12] we know that to obtain (1.4) for the space $V_h = W_h \times Q_h$ it is enough to prove that there exists $\gamma > 0$, independent of $h$, such that

$$\inf_{q\in Q_h} \sup_{\boldsymbol{v}\in W_h} \frac{\int_\Omega q \ \mathrm{div}\, \boldsymbol{v}}{\|p\|_{L^2}\|\boldsymbol{v}\|_{H_0^1}} \geq \gamma. \tag{6.1}$$

Equivalently, for any $f \in Q_h$, there exists a solution $\boldsymbol{u} \in W_h$ of

$$\int_\Omega \mathrm{div}\, \boldsymbol{u} \cdot q = \int_\Omega fq \quad \text{for all } q \in Q_h, \tag{6.2}$$

$$\|\boldsymbol{u}\|_{H_0^1} \leq C\|f\|_{L^2} \tag{6.3}$$

with $C$ depending only on the domain $\Omega$.

A lot of work has been done to prove this inf-sup condition for different choices of spaces $W_h$ and $Q_h$. We refer for example to the books [13], [20]. However, most proofs require the regularity assumption (2.1) on the elements although it is not known whether it is essential or not.

One of the main tools to prove (6.1) is the so-called *Fortin operator* introduced in [19], which in the case of the Stokes equations is an operator $\Pi\colon H_0^1(\Omega)^n \to W_h$ such that

$$\int_\Omega q \ \mathrm{div}(\boldsymbol{v} - \Pi\boldsymbol{v}) = 0 \quad \text{for all } q \in Q_h$$

and

$$\|\Pi\boldsymbol{v}\|_{H_0^1} \leq C\|\boldsymbol{v}\|_{H_0^1} \tag{6.4}$$

with a constant $C$ independent of $h$.

Consider for example the non-conforming method of Crouzeix–Raviart, namely, $W_h$ are the $(\mathcal{P}_1)^n$ functions in each element which are also continuous at the midpoints of the edges or faces of the partition, and $Q_h$ are piecewise constant functions. Error estimates for anisotropic elements for this method have been proved in [2], [7].

The Fortin operator for this case is the edge (or face) mean average interpolator $\Pi$ defined in the previous section. In view of (5.9), estimate (6.4) holds with a constant independent of the geometry of the elements which can be taken to be one. However, this is a non-conforming method (because $W_h \not\subset H_0^1(\Omega)^2$) and therefore, to obtain error estimates, some consistency terms have to be bounded. This can be done by using the $RT_0$ interpolation analyzed in the previous section. In this way it is possible to obtain optimal error estimates for this method under the maximum angle condition (see [2]).

# Linear subdivision schemes for the refinement of geometric objects

Nira Dyn

**Abstract.** Subdivision schemes are efficient computational methods for the design, representation and approximation of surfaces of arbitrary topology in $\mathbb{R}^3$. Subdivision schemes generate curves/surfaces from discrete data by repeated refinements. This paper reviews some of the theory of linear stationary subdivision schemes and their applications in geometric modelling. The first part is concerned with "classical" schemes refining control points. The second part reviews linear subdivision schemes refining other objects, such as vectors of Hermite-type data, compact sets in $\mathbb{R}^n$ and nets of curves in $\mathbb{R}^3$. Examples of various schemes are presented.

**Mathematics Subject Classification (2000).** Primary 65D07, 65D17, 65D18; Secondary 41A15, 68U07.

**Keywords.** Subdivision schemes, geometric modelling, curves, surfaces, refinements, smoothness, arbitrary topology, nets of points, nets of curves, compact sets, approximation order.

## 1. Introduction

Subdivision schemes in geometric applications are efficient tools for the generation of curves/surfaces from discrete data, by repeated refinements.

The first subdivision schemes where devised by de Rahm [54] for the generation of functions with a first derivative everywhere and a second derivative nowhere.

In geometric modelling the first schemes were proposed for easy and quick rendering of $B$-spline curves. A $B$-spline curve has the form

$$C(t) = \sum_i P_i B_m(t - i) \tag{1}$$

with $\{P_i\}$ points in $\mathbb{R}^d$ ($d = 2$ or 3) termed control points, and $B_m$ a $B$-spline of degree $m$ with integer knots, namely $B_m|_{[i,i+1]}$ is a polynomial of degree $m$, $B_m \in C^{m-1}(\mathbb{R})$, supp $B_m = [0, m+1]$. Equation (1) is a parametric representation of a $B$-spline curve. By using the refinement equation satisfied by a $B$-spline,

$$B_m(x) = \sum_{i=0}^{m+1} a_i^{[m]} B_m(2x - i), \quad a_i^{[m]} = 2^{-m}\binom{m+1}{i}, \qquad i = 0, \ldots, m+1. \tag{2}$$

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

$C(t)$ in (1) has the parametric representations

$$C(t) = \sum_i P_i^0 B_m(t-i) = \sum_i P_i^1 B_m(2t-i) = \cdots \\ = \sum_i P_i^k B_m(2^k t - i) = \cdots, \tag{3}$$

where

$$P_i^{\ell+1} = \sum_j a_{i-2j}^{[m]} P_j^\ell, \quad \ell = 0, 1, 2, \ldots, \tag{4}$$

with the convention $a_i^{[m]} = 0$, $i \notin \{0, 1, \ldots, m+1\}$.

As is demonstrated in §2.3, the differences $\{P_i^k - P_{i-1}^k\}$ tend to zero as $k$ increases, and since $B_m \geq 0$ and $\sum_i B_m(t-i) \equiv 1$ [6], the polygonal line through the control points $\{P_i^k\}$ is close to $C(t)$ for $k$ large enough, and can be easily rendered.

The relation (4) encompasses the refinement rule for $B$-spline curves. The first scheme of this type was devised by Chaikin [10] for quadratic $B$-spline curves, and the schemes for general $B$-spline curves were investigated in [14]. All other subdivision schemes can be regarded as a generalization of the spline case.

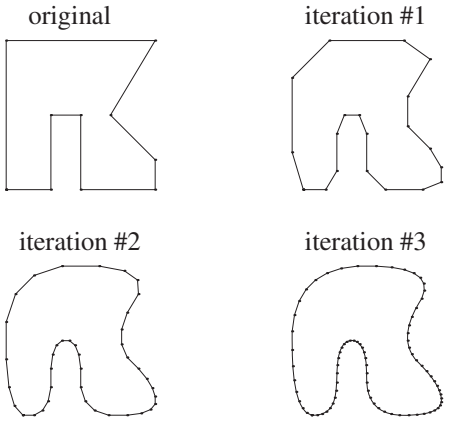

Figure 1. Refinements of a polygon with Chaikin scheme.

In this paper we first review the "classical" subdivision schemes for the refinement of control points. The schemes for the generation of curves are direct generalizations of (4), in the sense that the coefficients, defined in (2), are replaced by other sets of coefficients. The "classical" schemes, and in particular those generating surfaces, are used extensively in Computer Graphics. In §2 we discuss the construction of such schemes, their approximation properties, tools for the analysis of their convergence and smoothness, and their application to the generation of surfaces from general nets of points in $\mathbb{R}^3$. Examples of important schemes are presented.

Subdivision schemes for the refinement of objects other than control points are reviewed in §3. These schemes include subdivision schemes refining vectors, in particular, vectors consisting of values of a function and its consecutive derivatives, schemes refining compact sets in $\mathbb{R}^n$ and a scheme refining nets of curves.

All the schemes reviewed in this paper are linear. Recently, various non-linear schemes were devised and analyzed (see, e.g., [26] and references therein). It seems that this is one of the future directions in the study of subdivision schemes. Applications of "classical" schemes to the numerical solution of special types of PDEs is another direction. (See, e.g., [11]).

New "classical" schemes are still being devised for particular applications. For example, adaptive refinements can be accomplished straightforwardly by refining according to topological rules different from the "classical" ones, therefore, corresponding linear schemes had to be devised (see, e.g. [48] and [59]).

## 2. Stationary linear schemes for the refinement of control points

A subdivision scheme $S_{\boldsymbol{a}}$ for the refinement of control points is defined by a finite set of coefficients called *mask* $\boldsymbol{a} = \{a_i \in \mathbb{R} : i \in \sigma(\boldsymbol{a}) \subset \mathbb{Z}^s\}$. Here $\sigma(\boldsymbol{a})$ denotes the finite support of the mask, $s = 1$ corresponds to curves and $s = 2$ to surfaces. The refinement rule is

$$P_\alpha^{k+1} = \sum_{\beta \in \mathbb{Z}^s} a_{\alpha - 2\beta} P_\beta^k, \quad \alpha \in \mathbb{Z}^s. \tag{5}$$

**Remark.** In most of the paper we consider schemes defined on $\mathbb{Z}^s$, although, in geometric applications the schemes operate on finite sets of data. Due to the finite support of the mask, our considerations apply directly to closed curves/surfaces, and also to "open" ones, except in a finite zone near the boundary.

In the case $s = 1$, a subdivision scheme is termed *uniformly convergent* (or convergent for geometric applications) if the sequence $\{\mathcal{P}^k(t)\}$ of polygonal lines through the control points at refinement levels $k = 0, 1, 2, \ldots$ (with parametric representation as the piecewise linear interpolants to the data $\{(i2^{-k}, P_i^k) : i \in \mathbb{Z}\}$, $k = 0, 1, 2, \ldots$), converges uniformly in bounded intervals. In the case $s = 2$, we require the uniform convergence of the sequence of piecewise bi-linear interpolants to the data $\{(\alpha 2^{-k}, P_\alpha^k) : \alpha \in \mathbb{Z}^2\}$ on bounded squares [9], [33], [24].

The convergence of a scheme $S_{\boldsymbol{a}}$ implies the existence of a *basic-limit-function* $\phi_{\boldsymbol{a}}$, being the limit obtained from the initial data, $f_i^0 = 0$ everywhere on $\mathbb{Z}^s$ except $f_0^0 = 1$.

It follows from the linearity and uniformity of (5) that the limit obtained from any set of initial control points $\boldsymbol{P}^0 = \{P_\alpha^0 \in \mathbb{R}^d : \alpha \in \mathbb{Z}^s\}$, $S_{\boldsymbol{a}}^\infty \boldsymbol{P}^0$, can be written in terms of integer translates of $\phi_{\boldsymbol{a}}$, as

$$S_{\boldsymbol{a}}^\infty \boldsymbol{P}^0(x) = \sum_{\alpha \in \mathbb{Z}^s} P_\alpha^0 \phi_{\boldsymbol{a}}(x - \alpha), \quad x \in \mathbb{R}^s. \tag{6}$$

For $s = 1$ and $d = 2$ or $d = 3$, (6) is a parametric representation of a curve in $\mathbb{R}^d$, while for $s = 2$ and $d = 3$, (6) is a parametric representation of a surface in $\mathbb{R}^3$. Also, by the linearity, uniformity and stationarity of the refinement (5), $\phi_{\boldsymbol{a}}$ satisfies the *refinement equation* (*two-scale relation*)

$$\phi_{\boldsymbol{a}}(x) = \sum_{\alpha \in \mathbb{Z}^s} a_\alpha \phi_{\boldsymbol{a}}(2x - \alpha), \tag{7}$$

analogous to the refinement equation (2) for $B$-splines.

It follows from (5) or from (7) that $\operatorname{supp}(\phi_{\boldsymbol{a}})$ is contained in the convex hull of $\sigma(\boldsymbol{a})$ [9], as is the case for the $B$-spline schemes.

The choice of the mask in the design of good schemes is partly heuristic and partly aims at obtaining specific properties of the scheme as convergence, smoothness, locality, interpolation, shape preservation, and approximation order.

For the case $s = 1$, the topology of $\mathbb{Z}$ is sufficient to describe an ordered set of control points for curve design. For the case $s = 2$, the topology of $\mathbb{Z}^2$, where the point $(i, j)$ is connected to the four points $(i \pm 1, j)$, $(i, j \pm 1)$, is sufficient to describe a set of control points in $\mathbb{R}^3$, connected each to four neighboring points and constituting a *quad-mesh*. The above connectivity of $\mathbb{Z}^2$, with the additional connections of the point $(i, j)$ to the points $(i + 1, j + 1)$, $(i - 1, j - 1)$, forms the *three-direction mesh* which is sufficient to describe a regular triangulation (each vertex is connected to six neighboring vertices). These two types of topologies of $\mathbb{Z}^2$, are also relevant to general topologies of control points, since they are generated by most of the topological refinement rules. This is explained in §2.4.

**2.1. The main construction methods of schemes.** There are two main approaches to the construction of subdivision schemes. The first approach is by repeated averaging. In case $s = 1$, repeated averaging leads to $B$-spline schemes.

In this approach, the refinement rule (5) consists of several simple steps. The first is the trivial refinement

$$P_\alpha^{k+1,0} = P_{\left[\frac{\alpha}{2}\right]}^k, \quad \alpha \in \mathbb{Z}^s \tag{8}$$

with $\left[\frac{\alpha}{2}\right]$ the biggest integer smaller than or equal to $\frac{\alpha}{2}$ for $\alpha \in \mathbb{Z}$, and $\left(\left[\frac{\alpha_1}{2}\right], \left[\frac{\alpha_2}{2}\right]\right)$ for $\alpha = (\alpha_1, \alpha_2) \in \mathbb{Z}^2$.

The trivial refinement is followed by a fixed number $m$ of repeated averaging

$$P_\alpha^{k+1,j} = \frac{P_\alpha^{k+1,j-1} + P_{\alpha - e_j}^{k+1,j-1}}{2}, \quad \alpha \in \mathbb{Z}^s, \ j = 1, \ldots, m,$$

where $\{e_1, \ldots, e_m\}$ are non-zero vectors in $\mathbb{Z}^s$ with components in $\{0, 1\}$.

The case $s = 1$ corresponds to the $B$-spline scheme of degree $m$, while in case $s = 2$ one gets the tensor-product $B$-spline schemes for the choice $e_1 = \cdots = e_r = (1, 0)$, $e_{r+1} = \cdots = e_m = (0, 1)$, $1 \le r < m$, and the three-direction box-spline schemes [7] for the choice $e_1 = \cdots = e_r = (1, 0)$, $e_{r+1} = \cdots = e_\rho = (0, 1)$,

$e_{\rho+1} = \cdots = e_m = (1, 1)$, $1 \le r < \rho < m$. One can get other box-spline schemes for more general choices of $e_1, \ldots, e_m$ [7].

The second construction of subdivision schemes is based on a local approximation operator $A$, approximating on $[0, 1]^s$. $A$ is defined in terms of samples of the approximated function in a set of points $\mathcal{A} \subset \mathbb{Z}^s$,

$$(Af)(x) = \sum_{\alpha \in \mathcal{A}} f(\alpha) w_\alpha(x), \quad x \in [0, 1]^s. \tag{9}$$

For geometrical applications, the set $\mathcal{A}$ contains the set $E_s$ of extreme points of $[0, 1]^s$, and is symmetric relative to $[0, 1]^s$. The operator $A$ has to be scale and shift invariant, so that (9) can be used in any refinement level and at any location. This leads to the choice of a polynomial approximation operator $A$.

The commonly derived refinement rule from (9) is

$$P^{k+1}_{2\alpha+\gamma} = \sum_{\beta \in \mathcal{A}} P^k_{\alpha+\beta} w_\beta \left(\frac{\gamma}{2}\right), \quad \gamma \in E_s. \tag{10}$$

Another possibility is

$$P^{k+1}_{2\alpha+\gamma} = \sum_{\beta \in \mathcal{A}} P^k_{\alpha+\beta} w_\beta \left(g + \frac{\gamma}{2}\right), \quad \gamma \in E_s,\ g = \{1/4\}^s. \tag{11}$$

In case $s = 1$, with $Af$ the interpolation polynomial based on the symmetric set of points relative to $[0, 1]$, $-N+1, \ldots, 0, 1, \ldots, N$, the resulting family of schemes obtained by (10) for $N = 1, 2, \ldots$ consists of the Dubuc–Deslaurier schemes [22]

$$P^{k+1}_{2i} = P^k_i, \quad P^{k+1}_{2i+1} = \sum_{\ell=-N+1}^{N} w_\ell \left(\frac{1}{2}\right) P^k_{i+\ell}, \quad w_i(x) = \prod_{\substack{j=-N+1 \\ j \ne i}}^{N} \frac{x - j}{i - j} \tag{12}$$

The schemes in (12) are interpolatory, since the set of control points after refinement contains the control points before refinement. These schemes are convergent, and the limit curves interpolate the initial control points [22]. Interpolatory schemes in general are discussed in [34].

Recently this construction was extended to non-interpolatory schemes [30], by using (11) instead of (10) with $w_i(x)$ defined in (12).

The refinement rules are

$$P^{k+1}_{2i} = \sum_{\ell=-N+1}^{N} w_\ell \left(\frac{1}{4}\right) P^k_{i+\ell}, \quad P^{k+1}_{2i+1} = \sum_{\ell=-N+1}^{N} w_\ell \left(\frac{3}{4}\right) P^k_{i+\ell}.$$

It is checked in [30] that, for $N \le 10$, the schemes are convergent with limit curves of higher smoothness than the limit curves of the corresponding Dubuc–Deslaurier schemes. Yet, there is no proof that this holds in general.

In fact, (11) can be further extended to

$$P^{k+1}_{2\alpha+\gamma} = \sum_{\beta\in\mathcal{A}} P^k_{\alpha+\beta} w_\beta\big(g + (1-2\mu)\gamma\big), \quad \gamma \in E_s,\ g = \{\mu\}^s$$

with $0 < \mu < \frac{1}{2}$.

This refinement was studied in [33], [40], [4], for $s = 1$ and $A$ a linear interpolation operator at the points $x = 0$, $x = 1$. For $\mu = \frac{1}{4}$, this is the Chaikin scheme for generating quadratic $B$-spline curves [10]. For $\mu \neq \frac{1}{4}$ it is a general *corner cutting* scheme.

**2.2. Approximation order of subdivision schemes.** A convergent subdivision scheme $S$, constructed by the second approach of §2.1 with refinement rule (10), has the property of *reproduction of polynomials*.

Let the operator $A$ map the set $f|_{\mathcal{A}}$ to a unique interpolation polynomial of total degree not exceeding $m$, interpolating the data $\{(x, f(x)) : x \in \mathcal{A}\}$. In the following, we denote by $\Pi_m(\mathbb{R}^s)$ the space of all $s$-variate polynomials of degree up to $m$. It is easy to verify that for $f \in \Pi_m(\mathbb{R}^s)$ and $\boldsymbol{f}^0 = \{f^0_\alpha = f(\alpha h) : \alpha \in \mathbb{Z}^s\}$, $h \in \mathbb{R}_+$, the refinement (10) generates data on $f$, namely $\boldsymbol{f}^k = S^k \boldsymbol{f}^0 = \{f^k_\alpha = f(2^{-k}\alpha h) : \alpha \in \mathbb{Z}^s\}$, and therefore $S^\infty \boldsymbol{f}^0 = f$, and the subdivision scheme reproduces polynomials in $\Pi_m(\mathbb{R}^s)$.

In case of the refinement rule (11), arguments as in [30] lead to $(S^\infty \boldsymbol{f}^0)(x) = f(x + 2hg)$, with $g$ as in (11). This property of the scheme $S$ is termed reproduction *with a fixed shift* of polynomials in $\Pi_m(\mathbb{R}^s)$.

The reproduction of polynomials in $\Pi_m(\mathbb{R}^s)$ (with or without a shift), the representation of $S^\infty \boldsymbol{f}^0$ in terms of the compactly supported basic limit function $\phi$ of $S$,

$$S^\infty \boldsymbol{f}^0(x) = \sum_{\alpha\in\mathbb{Z}^s} f^0_\alpha \phi(x - \alpha), \tag{13}$$

and classical quasi-interpolation arguments [5], lead to the error estimate

$$\sup_{x\in\Omega} \big|(S^\infty \boldsymbol{f}^0)(x) - f(x)\big| \le C h^{m+1}. \tag{14}$$

In (14) $\boldsymbol{f}^0 = \{f^0_\alpha = f(\alpha h) : \alpha \in \mathbb{Z}^s\}$ for the refinement rule (10), while, for the refinement rule (11), $\boldsymbol{f}^0 = \{f^0_\alpha = f(\alpha h - 2gh) : \alpha \in \mathbb{Z}^s\}$, where $f$ is a smooth enough function, $\Omega$ is a bounded domain in $\mathbb{R}^s$, and the constant $C$ may depend on $S$, $f$, $\Omega$ but not on $h$. A subdivision scheme satisfying (14) is said to have *approximation order* $m + 1$.

Subdivision schemes constructed by repeated averaging reproduce constant functions and hence have approximation order 1. If the repeated averaging is done in a symmetric way relative to $[0, 1]^s$, then the resulting scheme reproduces also linear polynomials, and the scheme has approximation order 2. For example, this property is shared by all the symmetric $B$-spline schemes of odd degrees. The mask of the

scheme generating $B$-spline curves, based on the symmetric $B$-spline of degree $2\ell+1$ is

$$\widetilde{a}_i^{[2\ell+1]} = \frac{1}{2^{2\ell+1}}\binom{2\ell+2}{\ell+1+i}, \quad i = -\ell-1, \ldots, 0, \ldots, \ell+1.$$

The repeated averaging for such a symmetric mask takes the symmetric form

$$P_{2i}^{k+1,0} = P_i^k, \quad P_{2i+1}^{k+1,0} = \frac{1}{2}(P_i^k + P_{i+1}^k), \quad i \in \mathbb{Z},$$
$$P_i^{k+1,j} = \frac{1}{4}\big(P_{i-1}^{k+1,j-1} + 2P_i^{k+1,j-1} + P_{i+1}^{k+1,j-1}\big), \quad i \in \mathbb{Z},\ j = 1, \ldots, \ell,$$
$$P_i^{k+1} = P_i^{k+1,\ell}, \quad i \in \mathbb{Z}.$$

**2.3. Convergence and smoothness analysis.** Given the coefficients of the mask of a scheme, one would like to be able to determine if the scheme is convergent, and what is the smoothness of the resulting basic limit function (which is the generic smoothness of the limits generated by the scheme in view of (13)). Such analysis tools are essential for the design of new schemes.

We present one method for convergence analysis of the two cases $s = 1, 2$. The method for smoothness analysis in case $s = 1$ is simpler and is given in full. Its extension to $s = 2$ is omitted, but some special cases are discussed. There are other methods for convergence and smoothness analysis, see, e.g., [18], [19], [20], [42], [45].

An important tool in the analysis of convergence, presented here, is the symbol of a scheme $S_{\boldsymbol{a}}$ with the mask $\boldsymbol{a} = \{a_\alpha : \alpha \in \sigma(\boldsymbol{a})\}$,

$$a(z) = \sum_{\alpha\in\sigma(\boldsymbol{a})} a_\alpha z^\alpha. \tag{15}$$

A first step towards the convergence analysis is the derivation of the necessary condition for uniform convergence,

$$\sum_{\beta\in\mathbb{Z}^s} a_{\alpha-2\beta} = 1, \quad \alpha \in E_s, \tag{16}$$

derived easily from the refinement rule

$$f_\alpha^{k+1} = \sum_{\beta\in\mathbb{Z}^s} a_{\alpha-2\beta} f_\beta^k, \quad \alpha \in \mathbb{Z}^s.$$

with $\boldsymbol{f}^k = \{f_\alpha^k \in \mathbb{R} : \alpha \in \mathbb{Z}^s\}$. The necessary condition (16) implies that we have to consider symbols satisfying

$$a(1) = 2, \quad a(-1) = 0 \quad \text{if } s = 1, \tag{17}$$

or

$$a(1,1) = 4, \quad a(-1,1) = a(1,-1) = a(-1,-1) = 0 \quad \text{if } s = 2. \tag{18}$$

In case $s = 1$, condition (17) is equivalent to

$$a(z) = (1 + z)q(z) \quad \text{with} \quad q(1) = 1. \tag{19}$$

The scheme with symbol $q(z)$, $S_{\boldsymbol{q}}$, satisfies $S_{\boldsymbol{q}}\Delta = \Delta S_{\boldsymbol{a}}$ (see, e.g. [24]), where $\Delta$ is the difference operator

$$\Delta \boldsymbol{f} = \left\{(\Delta \boldsymbol{f})_i = f_i - f_{i-1} : i \in \mathbb{Z}\right\}. \tag{20}$$

A necessary and sufficient condition for the convergence of $S_{\boldsymbol{a}}$ is the contractivity of the scheme $S_{\boldsymbol{q}}$, namely $S_{\boldsymbol{a}}$ is convergent if and only if $S_{\boldsymbol{q}}^{\infty}\boldsymbol{f}^0 = 0$ for any $\boldsymbol{f}^0$ [33]. The contractivity of $S_{\boldsymbol{q}}$ is equivalent to the existence of a positive integer $L$, such that $\|S_{\boldsymbol{q}}^L\|_\infty < 1$. This condition can be checked for a given $L$ by algebraic operations on the symbol $q(z)$ (see, e.g., [24], [25]).

For practical geometrical reasons, only small values of $L$ have to be considered, since a small value of $L$ guarantees "visual convergence" of $\{\mathcal{F}^k(t)\}$ to $S_{\boldsymbol{a}}^{\infty}\boldsymbol{P}^0$, already for small $k$, as the distances between consecutive control points contract to zero fast. A good scheme corresponds to $L = 1$ as the $B$-spline schemes, or to $L = 2$ as many of the schemes constructed by the second method in §2.1 (see the following examples).

For $s = 2$, the necessary condition (18) guarantees the existence of two decompositions of the form

$$(1 - z_i)a(z) = q_{i1}(z)(1 - z_1^2) + q_{i2}(z)(1 - z_2^2), \quad i = 1, 2, \tag{21}$$

where $z = (z_1, z_2)$. The above two decompositions extend to $s = 2$ the factorization (19) written as $(1 - z)a(z) = (1 - z^2)q(z)$. The decompositions (21) guarantee the existence of a matrix subdivision scheme $S_Q$, with a $2 \times 2$ matrix symbol $Q(z) = \{q_{ij}(z)\}_{i,j=1}^2$, satisfying $S_{\boldsymbol{Q}}(\Delta_1, \Delta_2)^T = (\Delta_1, \Delta_2)^T S_{\boldsymbol{a}}$. Here $(\Delta_1, \Delta_2)^T$ is the vector difference operator, extending (20) to $s = 2$,

$$(\Delta_1, \Delta_2)^T \boldsymbol{f} = \left\{((\Delta_1, \Delta_2)^T \boldsymbol{f})_\alpha = (f_\alpha - f_{\alpha-(1,0)}, f_\alpha - f_{\alpha-(0,1)})^T : \alpha \in \mathbb{Z}^2\right\}.$$

A sufficient condition for the convergence of $S_{\boldsymbol{a}}$ is the contractivity of $S_{\boldsymbol{Q}}$, which can be checked by algebraic operations on the symbol $Q(z)$ [9], [24], [44].

Since many of the schemes have symmetries relative to $\mathbb{Z}^2$, their symbols are factorizable and have the form $a(z) = (1 + z_1)(1 + z_2)q(z)$. As a simple extension of the case $s = 1$, we get that $S_{\boldsymbol{a}}$ is convergent if the two schemes with symbols $(1 + z_1)q(z)$, $(1 + z_2)q(z)$ are contractive. If $a(z)$ is symmetric in the sense that $q(z_1, z_2) = q(z_2, z_1)$, then it is sufficient to check the contractivity of $(1 + z_1)q(z)$ (see, e.g., [25]).

The smoothness analysis in the case $s = 1$, relies on the result that if the symbol of a scheme has a factorization

$$a(z) = \left(\frac{1 + z}{2}\right)^{\nu} b(z), \tag{22}$$

such that the scheme $S_{\boldsymbol{b}}$ is convergent, then $S_{\boldsymbol{a}}$ is convergent and its limit functions are related to those $S_{\boldsymbol{b}}$ by

$$D^{\nu}(S_{\boldsymbol{a}}^{\infty}\boldsymbol{f}^{0}) = S_{\boldsymbol{b}}^{\infty}\Delta^{\nu}\boldsymbol{f}^{0}, \tag{23}$$

with $D$ the differentiation operator [33], [24]. Thus, each factor $(1+z)/2$ multiplying a symbol of a convergent scheme adds one order of smoothness. This factor is termed a *smoothing factor*.

The relation between (22) and (23) is a particular instance of the "algebra of symbols" [35]. If $a(z)$, $b(z)$ are two symbols of converging schemes, then $S_c$ with the symbol $c(z) = \frac{1}{2^s}a(z)b(z)$ is convergent, and

$$\phi_{\boldsymbol{c}} = \phi_{\boldsymbol{a}} * \phi_{\boldsymbol{b}}. \tag{24}$$

**Example ($B$-spline schemes).** The smoothness of the limit functions generated by the $m$-th degree $B$-spline scheme, having the symbol $a^{[m]}(z) = 2\left(\frac{1+z}{2}\right)^{m+1}$, can be concluded easily. The factor $b(z) = \frac{(1+z)}{2}^2$ corresponds to $S_{\boldsymbol{b}}$ generating a piecewise linear interpolant to the initial data $\{(i,\, f_i^0)\}$, which is continuous, and the factors $\left(\frac{1+z}{2}\right)^{m-1}$ add smoothness, so that $S_{\boldsymbol{a}^{[m]}}^{\infty} f^0 \in C^{m-1}$. Note that $a^{[m]}(z)$ consists of smoothing factors only. In fact the $B$-spline schemes are optimal, in the sense that for a given support size of the mask, the limit functions generated by the corresponding $B$-spline scheme is of maximal smoothness.

**Example (the four-point scheme).** Here we present the most general univariate interpolatory scheme which is based on four points [31], and describe briefly its convergence and smoothness analysis.

The refinement rule is

$$f_{2i}^{k+1} = f_i^k, \quad f_{2i+1}^{k+1} = -w(f_{i-1}^k + f_{i+2}^k) + \left(\tfrac{1}{2} + w\right)(f_i^k + f_{i+1}^k),$$

with $w$ a parameter controlling the shape of the limit curves. The symbol of the scheme is

$$a_w(z) = \tfrac{1}{2z}(z+1)^2\left[1 - 2wz^{-2}(1-z)^2(z^2+1)\right]. \tag{25}$$

Note that for $w = 0$, $a_0(z)$ is the symbol of the two-point scheme generating the polygonal line through the initial control points, and that for $w = 1/16$ it coincides with the symbol of the Dubuc–Deslauriers scheme based on four points (reproducing cubic polynomials).

The range of $w$ for which $S_{\boldsymbol{a}_w}$ is convergent is the range for which $S_{\boldsymbol{b}_w}$ with symbol $b_w(z) = a_w(z)/(1+z)$ is contractive. The condition $\|S_{\boldsymbol{b}_w}\|_\infty < 1$ holds in the range $-3/8 < w < (-1+\sqrt{13})/8$, while the condition $\|S_{\boldsymbol{b}_w}^2\|_\infty < 1$ holds in the range $-1/4 < w < (-1+\sqrt{17})/8$. Thus $S_{\boldsymbol{a}_w}$ is convergent in the range $-3/8 < w < (-1+\sqrt{17})/8$. To find a range of $w$ where $S_{\boldsymbol{a}_w}$ generates $C^1$ limits,

the contractivity of $S_{\boldsymbol{c}_w}$ with $c_w(z) = 2a_w(z)/(1+z)^2$ has to be investigated. It is easy to check that $\|S_{\boldsymbol{c}_w}\|_\infty \geq 1$, but that $\|S^2_{\boldsymbol{c}_w}\|_\infty < 1$ for $0 < w < (\sqrt{5}-1)/8$.

The limit of $S_{\boldsymbol{a}_w}$ is not $C^2$ even for $w = 1/16$, although for $w = 1/16$ the symbol is divisible by $(1+z)^3$ (see, e.g., [31]). It is shown in [20] by other methods, that the basic limit function for $w = 1/16$, restricted to its support, has a second derivative only at the non-dyadic points.

For the case $s = 2$, the idea of smoothing factors generalizes straightforwardly. Two smoothing factors in two linearly independent directions in $\mathbb{Z}^2$ are sufficient for increasing the smoothness. A smoothing factor in direction $(u, v) \in \mathbb{Z}^2$ is $\frac{1}{2}(1+z_1^u z_2^v)$. Specializing to the coordinate directions in $\mathbb{Z}^2$, $(1, 0)$ and $(0, 1)$, we get for a symbol $a(z) = (1+z_1)^m(1+z_2)^m b(z)$, such that $S_{\boldsymbol{b}}$ is convergent, that

$$\partial_{i,j} S^\infty_{\boldsymbol{a}} f^0 = S^\infty_{\boldsymbol{a}_{i,j}} \Delta_1^i \Delta_2^j f^0, \quad i, j = 0, \ldots, m, \tag{25}$$

with

$$a_{i,j}(z) = \frac{2^{i+j} a(z)}{(1+z_1)^i (1+z_2)^j}, \quad i, j = 0, \ldots, m, \tag{26}$$

and with $\partial_{ij}$ the $(i+j)$-th partial derivative of orders $i, j$ in directions $(1, 0)$ and $(0, 1)$ respectively.

For a symbol with the symmetry of the three direction mesh

$$a(z) = (1+z_1)^m (1+z_2)^m (1+z_1 z_2)^m b(z), \tag{27}$$

such that $S_{\boldsymbol{b}}$ is convergent, we get

$$\partial_{i,j,\ell} S^\infty_{\boldsymbol{a}} f^0 = S^\infty_{\boldsymbol{a}_{i,j,\boldsymbol{\ell}}} \Delta_1^i \Delta_2^j (\Delta_1 + \Delta_2)^\ell f^0, \quad i, j, \ell = 0, \ldots, m, \tag{28}$$

with

$$a_{i,j,\ell}(z) = \frac{2^{i+j+\ell} a(z)}{(1+z_1)^i (1+z^2)^j (1+z_1 z_2)^\ell}, \quad i, j, \ell = 0, \ldots, m, \tag{29}$$

and with $\partial_{i,j,\ell}$ the $(i+j+\ell)$-th partial derivative of orders $i, j, \ell$ in directions $(1, 0)$, $(0, 1)$, $(1, 1)$ respectively.

In particular $S_{\boldsymbol{a}}$ with the symbol $a(z) = (1+z_1)^2(1+z_2)^2 b(z)$ generates $C^1$ limit functions if the three schemes with the symbols

$$2(1+z_1)(1+z_2)b(z), \quad 2(1+z_1)^2 b(z), \quad 2(1+z_2)^2 b(z),$$

are contractive. Similarly for $a(z) = (1+z_1)(1+z_2)(1+z_1 z_2)b(z)$, $\phi_{\boldsymbol{a}} \in C^1$ if two of the three schemes with the symbols $2(1+z_1)b(z)$, $2(1+z_2)b(z)$, $2(1+z_1 z_2)b(z)$ are contractive.

The conditions for smoothness given above are only sufficient. Yet, in the case $s = 1$, there is a large class of convergent schemes for which the factorization in (22) is necessary for generating $C^\nu$ limit functions [39]. The schemes in this class are $L_\infty$-stable, namely, satisfy

$$\|S^\infty_a \boldsymbol{f}^0\| \geq C \|\boldsymbol{f}^0\|_\infty, \quad \boldsymbol{f}^0 \in \ell_\infty(\mathbb{Z}), \tag{31}$$

with constant $C$ dependent on $S_a$ but not on $\boldsymbol{f}^0$. All relevant schemes for geometric applications are $L_\infty$-stable, as the interpolatory schemes and the $B$-spline schemes.

This is not the case for $s = 2$. The symbol of a convergent $L_\infty$-stable scheme, generating smooth limit functions is not necessarily factorizable. Yet, many of the schemes in use have factorizable symbols.

**2.4. Subdivision schemes generating surfaces.** Schemes generating surfaces operate on control nets, and map a control net to a refined one.

A control net $N(V, E, F)$, consists of a set $V$ of points in $\mathbb{R}^3$, termed *vertices*, with two sets of topological relations between them $E$ and $F$, called *edges* and *faces* respectively (see, e.g., [49]). An edge denotes a pair of vertices. A face is a cyclic list of vertices where every pair of consecutive vertices constitutes an edge. The *valency* of a vertex is the number of edges that share it, the *valency* of a face is the number of vertices that belong to it. In Figure 2 we present a schematic net. We consider here

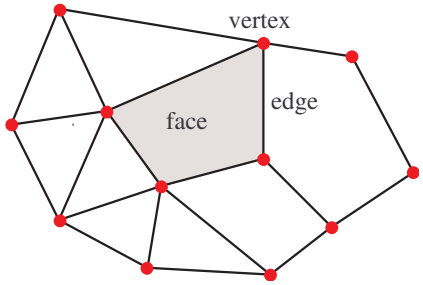

Figure 2. A schematic net.

only closed nets, namely nets in which each edge is shared by two faces.

**2.4.1. Topological refinement of nets.** There are several topological rules for refining a net $N(V, E, F)$. The most common one defines the new set of vertices, as

$$V' = \{u(v) : v \in V\} \cup \{u(e) : e \in E\} \cup \{u(f) : f \in F\} = V'_V \cup V'_E \cup V'_F. \quad (32)$$

Here $V'_V$ denotes all the new vertices, called *v-vertices*, corresponding to the vertices in $V$ (in an interpolatory scheme $V'_V = V$); $E'_V$ denotes all the new vertices, called *e-vertices*, corresponding to the edges in $E$, and $V'_F$ denotes all the new vertices, called *f-vertices*, corresponding to the faces in $F$. The rule for determining the location in $\mathbb{R}^3$ of $u(v)$, $u(e)$ and $u(f)$ is the refinement rule of the subdivision scheme. For example, a new vertex $u(e)$ is a certain linear combination of the vertices in $V$, weighted according to the topological relation between each $v \in V$ and $e$.

The topological relations $E'$, $F'$ in the refined net $N'(V', E', F')$ are independent of the subdivision scheme, but depend only on $E$ and $F$,

$$E' = \{(u(e), u(f)) : e \in f \in F\} \cup \{(u(e), u(v)) : v \in e \in E\} = E'_F \cup E'_E \quad (33)$$

and

$$F' = \{(u(v), u(e), u(f), u(\widetilde{e})) : v = e \cap \widetilde{e} \in f \in F\}. \quad (34)$$

Thus after one refinement step all faces have valency four and similarly all the vertices in the set $V'_E$. The valency of a vertex in $V'_F$ is the same as that of the "parent" face, and the valency of a vertex in $V'_V$ is the same as that of the "parent" vertex. From this observation we conclude that the nets obtained after two or more refinements have the topology of a quad-mesh (of $\mathbb{Z}^2$), except for a finite number of vertices with valency different from four (each equals the valency of an "ancestor" face or vertex in the initial net). The vertices with valency different from four are termed *irregular* (*extra-ordinary*) and a special local analysis of convergence and smoothness is required there [55]. Over the net, except in the vicinity of the irregular vertices, the analysis relative to $\mathbb{Z}^2$ is applicable.

For a net $N(V, E, F)$ with all faces of valency three, the topological refinement which is commonly used is such that the new vertices consist of $v$-vertices and $e$-vertices only, with the topological refinement

$$E' = E'_E \cup E'_V, \quad F' = F'_V \cup F'_F. \quad (35)$$

In (35), $E'_E$ is defined as in (33), and $E'_V = \{(u(e), u(\widetilde{e})) : e \cap \widetilde{e} \in V\}$. The new faces are of two types, $F'_V = \{(u(v), u(e), u(\widetilde{e})) : v \in e \cap \widetilde{e} \in V\}$, and $F'_F = \{(u(e_1), u(e_2), u(e_3)) : e_1, e_2, e_3 \in f \in F\}$. This refinement is presented in a schematic way in Figure 3. As can be observed from Figure 3, every face is replaced

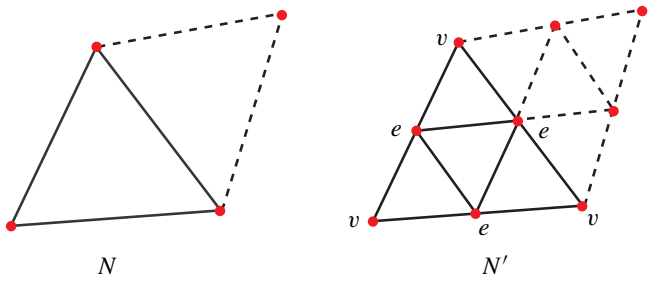

Figure 3. Schematic triangular topological refinement.

by four faces, one determined by the face itself, and three in $F'_V$, each consisting of three new vertices, one corresponding to one vertex of the face and two to the two edges of the face sharing that vertex.

Note that a face with valency three can be realized in $\mathbb{R}^3$ as a planar triangle, and therefore $N(V, E, F)$, with all faces of valency three, can be realized as a triangulation

of the set $V$. According to the topological refinement (35), the $e$-vertices have valency six, while a $v$-vertex has the same valency as that of its "parent" vertex in $V$. Thus, after two or more topological refinements, most of the vertices in the triangulations have valency six. Only a finite set of *irregular* (*extra-ordinary*) vertices have valencies different from six, "inherited" from those in the initial triangulation. Also, each irregular vertex is connected by edges only to regular vertices (of valency six).

Thus for a triangulation refined as above, the analysis of convergence and smoothness relative to the three-direction mesh applies, except in the vicinity of a finite number of isolated points, where a special local analysis is required [55].

While the analysis on regular meshes can handle any order of smoothness, the analysis at irregular vertices is limited to $C^1$ smoothness (see, [52], [46], and references therein). This limitation is the main reason why subdivision schemes are used mainly in computer graphics. In many industrial applications the designed surfaces have to be $C^2$ everywhere.

**2.4.2. Some popular schemes.** The first schemes devised for general nets were the bivariate tensor-product $B$-spline schemes of low degree, with special rules near irregular vertices [8], [23]. A bivariate tensor-product scheme of a univariate scheme with symbol $a(z)$, is a scheme with the symbol $a(z_1, z_2) = a(z_1)a(z_2)$.

The most commonly used scheme of that type for the topological refinement (32)–(34) is the Catmull–Clark scheme, which is an extension of the tensor-product cubic $B$-spline scheme [8]. The weights, up to normalization, of this scheme are given in Figure 4. The points designated by $o$ are the new $f$-vertices, and the weight of a vertex

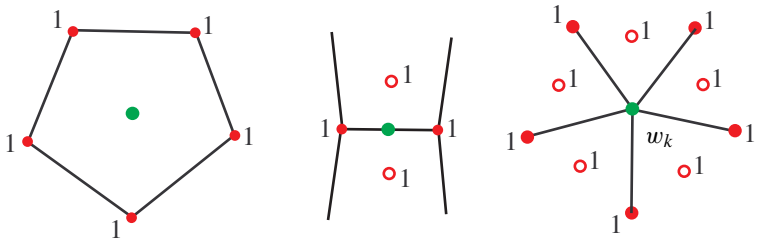

Figure 4. Weights for Catmull–Clark scheme: $f$-vertex (left), $e$-vertex (middle) and $v$-vertex (right).

of valency $k$, in the rule for its "son", is $w_k = k(k-2), k = 3, 4, \ldots$. Note that $w_4 = 8$, which is the weight in the tensor-produce cubic $B$-spline scheme. This scheme is easy to implement as can be inferred from Figure 4. Different choices of $w_k$ were considered in [2], [3] to improve the limit curvature at irregular vertices. Applications of the Catmull–Clark scheme are numerous. Here we refer to two important papers [21], [41].

In [47], the tensor-product four-point scheme is extended to an interpolatory scheme for general nets with the topological refinement (32)–(34).

For triangulations, the box-spline-based scheme of Loop [50] is very popular. Loop scheme is an extension of a box-spline scheme with the symbol

$$a(z_1, z_2) = \frac{1}{16}(1+z_1)^2(1+z_2)^2(1+z_1z_2)^2,$$

generating $C^2$ piecewise quartic box-spline surfaces on the three-direction mesh. The support of the mask of Loop scheme is small, and the refinement rule involves only neighboring vertices. In Figure 5 the weights for defining a new $e$-vertex and a new

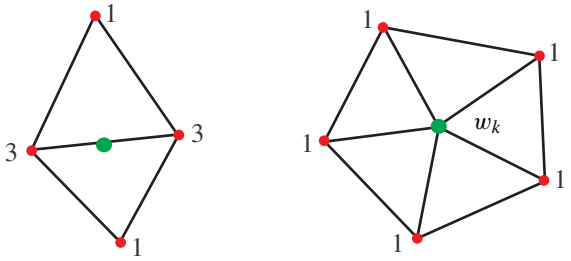

Figure 5. Weights for Loop scheme: $e$-vertex (left) and $v$-vertex (right).

$v$-vertex are given up to normalization. The weight $w_k$ of a vertex of valency $k$, involved in the rule for its "son", is

$$w_k = \frac{64k}{40 - \left(3 + 2\cos\frac{2\pi}{k}\right)}, \quad k = 3, 4, \ldots \tag{36}$$

Figure 6 depicts an initial triangulation of a head, and the triangulations after two refinements with Catmull–Clark scheme and with Loop scheme.

An interpolatory scheme for general closed triangulations with a shape parameter is the butterfly scheme [32]. The weights defining a new $e$-vertex are depicted in the left figure of Figure 7. Since the scheme is interpolatory, the new $v$-vertices coincide with the old vertices. The scheme generates $C^1$ surfaces if all vertices have valencies at least four and at most eight, depending on the value of $w$ [44], [57]. Modified weights for $e$-vertices, corresponding to edges having an irregular vertex of any valency above three are derived in [61] for $w = 1/16$. These weights are depicted in the right figure of Figure 7. The values $\{s_j\}$ are given by a formula depending on the valency $k$ of the irregular vertex,

$$s_j = \frac{1}{k}\left(\frac{1}{4} + \cos\frac{2\pi j}{k} + \frac{1}{2}\cos\frac{4\pi j}{k}\right), \quad j = 0, 1, \ldots, k-1,\ k > 3. \tag{37}$$

With the modified weights, the generated surfaces are $C^1$ for any valency greater than three, and are better looking in the vicinity of irregular vertices of valency between four and eight.

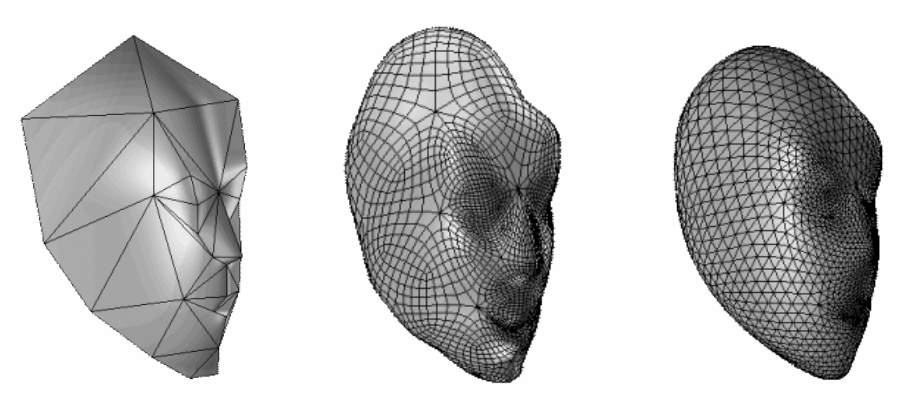

Figure 6. Head. Initial control net (left), after two refinements: with Catmull–Clark scheme (middle) and with Loop scheme (right).

## 3. Linear extensions

In this section, we review several extensions of stationary linear schemes for the refinement of points to stationary linear schemes which refine other objects.

**3.1. Matrix subdivision schemes.** Matrix schemes are defined by matrix masks and refine sequences of vectors. Although, in the geometric setting, the schemes of §2 refine sequences of control points in $\mathbb{R}^2$ or in $\mathbb{R}^3$, the schemes operate on each component of the vectors in the same way, such that the refinement of one component is independent of the other components. This property is very important in geometric applications, since the subdivision schemes commute with affine transformations (the schemes are *affine invariant*). The schemes presented here are not affine invariant, and their main application is in multiwavelets constructions [12], [58] and in the

analysis of multivariate subdivision schemes for control points as indicated in §2.3 (see, e.g., [24]).

A finite set of matrices of order $d \times d$, $\boldsymbol{A} = \{A_\alpha : \alpha \in \sigma(\boldsymbol{A}) \subset \mathbb{Z}^s\}$, defines a matrix subdivision scheme $S_{\boldsymbol{A}}$ with a refinement rule

$$(S_{\boldsymbol{A}} \boldsymbol{v})_\alpha = \sum_{\beta \in \mathbb{Z}^s} A_{\alpha - 2\beta} v_\beta, \quad \boldsymbol{v} = \{v_\alpha \in \mathbb{R}^d : \alpha \in \mathbb{Z}^s\}. \tag{1}$$

Given initial "control vectors" $\boldsymbol{v}^0 = \{v_\alpha^0 \in \mathbb{R}^d : \alpha \in \mathbb{Z}^s\}$, the matrix subdivision scheme $S_{\boldsymbol{A}}$ generates a sequence of control vectors by

$$\boldsymbol{v}^{k+1} = S_{\boldsymbol{A}} \boldsymbol{v}^k, \quad k = 1, 2, \ldots. \tag{2}$$

The notion of uniform convergence from §2 can be extended to this case, by considering the convergence of each of the $d$ components of the vectors. The convergence analysis has a linear algebra component to it, in addition to the analysis component. By considering the matrices

$$B_\gamma = \sum_{\beta \in \mathbb{Z}^s} A_{\gamma - 2\beta}, \quad \gamma \in E_s, \tag{3}$$

one can easily conclude a necessary condition for convergence. This condition is the analogue of condition (2.16), stating that for any initial sequence of control vectors $\boldsymbol{v}^0$, and any $x \in \mathbb{R}^s$,

$$(S_{\boldsymbol{A}}^\infty \boldsymbol{v}^0)(x) \in \operatorname{span}\{u \in \mathbb{R}^d : B_\gamma u = u \text{ for all } \gamma \in E_s\}. \tag{4}$$

In the extreme case of schemes with $B_\gamma = I$, $\gamma \in E_s$, the space in (4) is $\mathbb{R}^d$, and no condition of linear-algebra type is imposed. Such are the schemes used in the analysis of convergence and smoothness of multivariate schemes for points. Schemes for which the space in (4) is $\mathbb{R}^d$, are very similar to schemes with a scalar mask [17]. In the other extreme case, the space in (4) is one dimensional with vectors of equal components, implying that the limit vector function $S_{\boldsymbol{A}}^\infty \boldsymbol{v}^0$, has equal components. An example of this type of schemes is provided by matrix subdivision schemes generating multiple knot $B$-spline curves (see, e.g., [53]). This latter extreme case is the most relevant to the construction of multiwavelets.

In [13] and in [38], univariate ($s = 1$) matrix schemes with the space (4) of dimension $m$, $1 \leq m \leq d$, are studied. An appropriate change of basis, depending on the structure of the space (4), facilitates the extension of the factorization of scalar symbols to a certain factorization of matrix symbols. This factorization is sufficient for convergence and smoothness analysis of matrix schemes, and is also necessary under an extension of the notion of $L_\infty$-stability (see §2.3) to the matrix case. Multivariate matrix schemes with the space (4) of general dimension are considered in [56].

In the next section we discuss a special type of matrix subdivision schemes, which is relevant to curve design from locations and normals, and to the generation of

functions from the point values of the functions and their derivatives. The use of analogous schemes for the generation of surfaces from locations and normals is not straightforward, and leads to non-linear schemes.

**3.2. Hermite subdivision schemes.** The first Hermite schemes to be studied were univariate and interpolatory [51]. Interpolatory Hermite subdivision schemes are matrix schemes, such that the components of the vectors are regarded as the value of a function and its consecutive derivatives up to a certain order at the points of $2^{-k}\mathbb{Z}^s$. Non-interpolatory Hermite subdivision schemes were introduced later [43].

**3.2.1. Univariate interpolatory Hermite schemes.** The most common construction of interpolatory Hermite subdivision schemes is similar to the second construction method presented in §2.1. The approximation operator $A$ is an extension of the one in (2.9). For interpolatory schemes, it is a polynomial interpolation operator of the form

$$(Af)(x) = \sum_{\alpha\in\mathcal{A}} \sum_{i=0}^{d-1} w_{\alpha,i}(x) f^{(i)}(\alpha), \tag{5}$$

satisfying $D^i(Af)(\alpha) = f^{(i)}(\alpha)$, $\alpha \in \mathcal{A}$, $i = 0, 1, \ldots, d-1$.

The refinement is similar to (2.10), namely

$$v_{2\alpha}^{k+1} = v_\alpha^k, \qquad \left(v_{2\alpha+1}^{k+1}\right)_j = \sum_{\beta\in\mathcal{A}} \sum_{i=0}^{d-1} D^j w_{\beta,i}(1/2)(v_{\alpha+\beta}^k)_i, \quad 0 \le j \le d-1. \tag{6}$$

In (6), $(v)_i$ denotes the $i$-th component of the vector $v$. The refinement (6) can be written in terms of a matrix mask as,

$$v_\alpha^{k+1} = \sum_{\beta\in\mathbb{Z}^s} A_{\alpha-2\beta}^{(k)} v_\beta^k, \quad \alpha \in \mathbb{Z}^s, \tag{7}$$

where the matrices with even indices are

$$A_{2\alpha}^{(k)} = \delta_{\alpha,0} I_{d\times d}, \quad \alpha \in \mathbb{Z}, \tag{8}$$

with $\delta_{\alpha,0} = 0$ for $\alpha \neq 0$, and $\delta_{0,0} = 1$. The matrices with odd indices depend on the refinement level $k$, and have the form

$$A_{2\alpha+1}^{(k)} = \Lambda_d(2^k) A_{2\alpha+1}^{(0)} \Lambda_d(2^{-k}), \quad \alpha \in \mathbb{Z}, \tag{9}$$

with $\Lambda_d(h) = \operatorname{diag}(1, h, h^2, \ldots, h^{d-1})$ and

$$A_{1-2\alpha}^{(0)} = \left\{ D^i w_{\alpha,j}\left(\frac{1}{2}\right) \right\}_{i,j,=0}^{d-1}, \quad \alpha \in \mathcal{A}. \tag{10}$$

The powers of 2 in (9) are due to the fact that derivatives of polynomials are not scale invariant. More precisely if $q(x) = p(hx)$, with $p$ a polynomial, then $(D^j q)(hx_0) = h^j (D^j p)(x_0)$.

An interpolatory Hermite scheme is termed *uniformly convergent* if there is a limit vector function $F$ of the form $F = (D^j f,\ 0 \le j \le d-1)^T$, with $f \in C^{d-1}(\mathbb{R})$, satisfying for any closed interval $[a, b]$,

$$\lim_{k\to\infty} \sup_{\alpha\in 2^k[a,b]\cap\mathbb{Z}} \left\| F(2^{-k}\alpha) - v_\alpha^k \right\| = 0,$$

with $\|\cdot\|$ any norm in $\mathbb{R}^d$.

**Example (a two-point Hermite interpolatory scheme).** The scheme is given by the non-zero matrices of its mask:

$$A_0 = I_{2\times 2}, \quad A_1^{(k)} = \begin{pmatrix} \frac{1}{2} & \nu 2^{-k} \\ -\mu 2^k & \frac{1-\mu}{2} \end{pmatrix}, \quad A_{-1}^{(k)} = \begin{pmatrix} \frac{1}{2} & -\nu 2^{-k} \\ \mu 2^k & \frac{1-\mu}{2} \end{pmatrix}.$$

This scheme with $\nu = 1/8$ and $\mu = 3/2$ generates the $C^1$ piecewise Hermite cubic interpolant to the data $\{v_i^0 = (f(i), f'(i))^T : i \in \mathbb{Z}\}$, while for $\nu = 0$, $\mu = 1$, it generates the piecewise linear interpolant to the given function's values at the integers, which is only $C^0$. By the analysis to be reviewed, it can be shown that for $0 < \nu < 1/4$, $\mu = 4\nu + 1$, the limit functions generated by the scheme are $C^1$. (See, e.g. [36].)

One method for the convergence analysis of such schemes is based on deriving an equivalent stationary matrix scheme, refining vectors of $(d-1)$-th order divided differences, obtained from the original control vectors. The limit of such a scheme, if it exists, necessarily consists of equal components, which are the derivative of order $d-1$ of the smooth function $f$ [37].

More precisely, the divided difference vector $u_n^k$ at level $k$ is defined for each $n \in \mathbb{Z}$ by

$$(u_n^k)_j = [\tau_{j+1}, \tau_{j+2}, \ldots, \tau_{j+d}]f, \quad j = 0, \ldots, d-1,$$

with $\tau_1 = \cdots = \tau_{d-1} = (n-1)2^{-k}$, $\tau_d = \tau_{d+1} = \cdots = \tau_{2d-1} = n2^{-k}$. Here we use the definition of divided differences, allowing repeated points for functions with enough derivatives (see, e.g., [6, Chapter 1]). In our setting all integer points have multiplicity $d$. The vector $u_n^k$ can be derived from the vectors $v_{n-1}^k$ and $v_n^k$.

The symbol $D(z)$ of the matrix scheme refining the control vectors $\boldsymbol{u}^k = \{u_n^k : n \in \mathbb{Z}\}$ can be obtained recursively from the symbol $D^{[0]}(z) = \sum_\alpha A_\alpha^{(0)} z^\alpha$, by algebraic manipulations, involving multiplication by certain matrix Laurent polynomials and their inverses.

It is proved in [37] that the matrix symbol $D(z)$ is a matrix Laurent polynomial if the scheme (7) reproduces polynomials of degree $\le d-2$, and that necessarily a scheme of the form (7), which generates $C^{d-1}$ functions, reproduces polynomials of degree $\le d-1$. In (5), the degree of the interpolation polynomial is $d|\mathcal{A}| - 1$,

so the scheme (7), with the mask (8),(9),(10), reproduces polynomials of degree at least $2d-1$, as $\mathcal{A}$ contains at least the points $0, 1$. These arguments lead to the conclusion that the Hermite subdivision scheme $S_{\boldsymbol{A}}$, refining the control vectors $\boldsymbol{v}^k$ can be transformed into the matrix subdivision scheme $S_{\boldsymbol{D}}$ for the control vectors $\boldsymbol{u}^k$.

To determine the convergence of the scheme $S_{\boldsymbol{D}}$, which is equivalent to the convergence of the original Hermite subdivision scheme $S_{\boldsymbol{A}}$ to $C^{d-1}$ functions, we observe that the component $(u_n^k)_j$, in case of convergence, approximates $f^{(d-1)}(2^{-k}n)$ for $j = 1, \ldots, d$. Thus as in the case of control points, a necessary condition for convergence is the contractivity of the scheme which refines the differences $(u_n^k)_j - (u_n^k)_{j-1}$, $j = 2, \ldots, d$, $(u_n^k)_1 - (u_{n-1}^k)_d$, $n \in \mathbb{Z}$. Indeed, such a scheme exists, and its symbol is a matrix Laurent polynomial when (7) reproduces polynomials of degree $\leq d-1$ [37], guaranteeing that the contractivity of this scheme can be checked by algebraic manipulations.

The analysis of higher order smoothness is along the same lines.

**3.3. *B*-spline subdivision schemes for compact sets.** In the last years, the univariate $B$-spline schemes were extended to operate on data consisting of compact sets [27], [28]. The motivation for the study of such schemes is the problem of approximating a 3D object from a discrete set of its 2D parallel cross-sections, and the problem of approximating a 2D shape from a discrete set of its 1D parallel cross-sections. In both problems, either the 3D object or the 2D shape is regarded as a univariate set-valued function, with its parallel cross-sections as images. The $B$-spline subdivision schemes are adapted to this setting, so that the limit set-valued function generated by the subdivision from samples of a continuous set-valued function, approximates it.

For initial data $\boldsymbol{F}^0 = \{F_i^0 \subset \mathbb{R}^n : i \in \mathbb{Z}\}$ consisting of convex compact sets, averages of numbers in the execution of a scheme, can be replaced by Minkowski averages of sets. A *Minkowski average* of sets $B_1, \ldots, B_\ell \subset \mathbb{R}^n$ with weights $\lambda_1, \ldots, \lambda_\ell \in \mathbb{R}$, $\sum_{i=1}^{\ell} \lambda_i = 1$, is the set

$$\sum_{i=1}^{\ell}{}_M \lambda_i B_i = \Big\{ \sum_{i=1}^{\ell} \lambda_i b_i : b_i \in B_i \Big\}.$$

Thus the $m$-th degree $B$-spline subdivision scheme (1.4) can be adapted to convex compact sets by the refinement rule

$$F_i^{k+1} = \sum_j{}_M a_{i-2j}^{[m]} F_j^k, \quad i \in \mathbb{Z}, \tag{11}$$

with $\boldsymbol{a}^{[m]} = \{a_i^{[m]}, i = 0, \ldots, m+1\}$ given in (1.2). Since the coefficients of the mask are positive, the sets $\boldsymbol{F}^k$, $k \geq 1$, generated by the subdivision scheme $S_{M,a^{[m]}}$ with the refinement rule (11) are compact and convex [27]. By the associativity and distributivity of the Minkowski average of convex sets with positive weights, it can

be deduced straightforwardly that the limit generated by $S_{M,a^{[m]}}$ from $\boldsymbol{F}^0$, when $\boldsymbol{F}^0$ consists of convex compact sets, is

$$(S^\infty_{M,\boldsymbol{a}^{[m]}}\boldsymbol{F}^0)(t) = \sum_{i\in\mathbb{Z}_M} F^0_i B_m(t-i). \tag{12}$$

In (12) the convergence is in the Hausdorff metric, defined for two sets $A$, $B$ in $\mathbb{R}^n$, by

$$\text{haus}(A,B) = \max\Big\{\sup_{a\in A}\inf_{b\in B}\|a-b\|,\ \sup_{b\in B}\inf_{a\in A}\|a-b\|\Big\}$$

with $\|\cdot\|$ the Euclidean norm in $\mathbb{R}^n$.

The subdivision scheme $S_{M,a^{[m]}}$ has approximation properties. It is shown in [27] that for a set-valued function $G$ with convex compact images, which is Lipschitz continuous, namely satisfies $\text{haus}(G(t), G(t+\Delta)) = O(\Delta t)$, and for initial data $\boldsymbol{F}^0_h = \{G(ih) : i\in\mathbb{Z}\}$

$$\text{haus}\left((S^\infty_{M,\boldsymbol{a}^{[m]}}\boldsymbol{F}^0_h)(t), G(t)\right) = O(h). \tag{13}$$

The subdivision $S_{M,a^{[m]}}$ fails to approximation set-valued functions with general compact images. As is shown in [29], for initial data $\boldsymbol{F}^0$ consisting of general compact sets,

$$S^\infty_{M,\boldsymbol{a}^{[m]}}\boldsymbol{F}^0 = \sum_{i\in\mathbb{Z}}\langle F^0_i\rangle B_m(\cdot - i)$$

with $\langle F^0_i\rangle$ the convex hull of $F^0_i$. Thus $S^\infty_{M,\boldsymbol{a}^{[m]}}\boldsymbol{F}^0$ is convex even when the initial sets are non-convex, and it cannot approximate set-valued functions with general compact sets as images.

There is another adaptation of the $B$-spline subdivision schemes to compact sets [28], which yields approximation also in case of set-valued functions with general compact sets as images. This adaptation is obtained by using the first construction in §2.1 for $s=1$, and by replacing the average of two numbers by the *metric average* of two compact sets, introduced in [1],

$$A\oplus_t B = \left\{ta + (1-t)b : (a,b)\in\Pi(A,B)\right\}$$

with

$$\Pi(A_0,A_1) = \Big\{(a_0,a_1) : a_i\in A_i,\ i=0,1,\\ \|a_0-a_1\| = \min_{a\in A_j}\|a_i-a\|,\ j=1-i,\ \text{for } i=0 \text{ or } 1\Big\}.$$

The refinement rule of the resulting scheme $S_{MA,m}$ is achieved by the $m+1$ steps,

$$\begin{aligned} F^{k+1,0}_{2i} &= F^k_i, \quad F^{k+1,0}_{2i+1} = F^k_i, \quad i\in\mathbb{Z},\\ F^{k+1,j}_i &= F^{k+1,j-1}_i \oplus_{\frac{1}{2}} F^{k+1,j-1}_{i-1}, \quad i\in\mathbb{Z},\ j=1,\dots,m\\ F^{k+1}_i &= F^{k+1,m}_i, \quad i\in\mathbb{Z} \end{aligned} \tag{14}$$

The refinement rule (14) is denoted formally by $\boldsymbol{F}^{k+1} = S_{MA,m}\boldsymbol{F}^k$.

Two important properties of the metric average, which are central to its application in $B$-spline subdivision schemes are

$$A \oplus_t A = A, \quad \text{haus}(A \oplus_t B, A \oplus_s B) = |s-t|\,\text{haus}(A, B), \tag{15}$$

for $(s, t) \in [0, 1]$.

Let the sequence $\{H^k\}$ consist of the "piecewise linear" set valued functions, interpolating $\{\boldsymbol{F}^k = S^k_{MA,m}\boldsymbol{F}^0\}$,

$$H^k(t) = F^k_i \oplus_{\lambda(t)} F^k_{i+1}, \quad 2^{-k}i \le t < 2^{-k}(i+1),\ i \in \mathbb{Z},\ k = 0, 1, 2, \ldots, \tag{16}$$

with $\lambda(t) = i + 1 - 2^k t$. It is proved in [28], with the aid of the metric property of the metric average (the second equality in (15)) and the completeness of the metric space of compact sets with the Hausdorff metric, that the sequence $\{H^k(t)\}$ converges to a limit set-valued function denoted by $S^\infty_{MA,m}\boldsymbol{F}^0$.

Moreover, for $G$ a Lipschitz continuous set valued function with general compact sets as images, the limit generated by the scheme $S_{MA,m}$ starting from $\boldsymbol{F}^0_h = \{G(ih) : i \in \mathbb{Z}\}$ approximates $G$ with "error" given by

$$\text{haus}\left((S^\infty_{MA,m}\boldsymbol{F}^0_h)(t), G(t)\right) = O(h), \quad t \in \mathbb{R}. \tag{17}$$

**3.4. A blending-based subdivision scheme for nets of curves.** The quadratic $B$-spline scheme (Chaikin algorithm) was extended to the refinement of nets of curves in [15]. A net of curves with parameter $d > 0$ consists of two families of continuous curves

$$\left\{\phi_i(s) : 0 \le i \le n,\ s \in [0, md]\right\}, \quad \left\{\psi_j(t) : 0 \le j \le m,\ t \in [0, nd]\right\}$$

satisfying the compatibility condition

$$\phi_i(jd) = \psi_j(id), \quad i = 0, \ldots, n,\ j = 0, \ldots, m.$$

Such a net is denoted by $\mathcal{N}(d, \{\phi_i\}_{i=0}^n, \{\psi_j\}_{j=0}^m)$. The *blending-based Chaikin-type* scheme refines a net of curves, $\mathcal{N}_0 = \mathcal{N}(d, \{\phi^0_i\}_{i=0}^n, \{\psi^0_j\}_{j=0}^m)$ into a net of curves $\mathcal{N}_1 = \mathcal{N}\left(\frac{d}{2}, \{\phi^1_i\}_{i=0}^{2n-1}, \{\psi^1_j\}_{j=0}^{2m-1}\right)$. A repeated application of such refinements generates a sequence of nets $\left\{\mathcal{N}_k = \mathcal{N}\left(\frac{d}{2^k}, \{\phi^k_i\}_{i=0}^{n_k}, \{\psi^k_j\}_{j=0}^{m_k}\right) : k \in \mathbb{Z}_+\right\}$, with $n_k = 2^k(n-1)+1, m_k = 2^k(m-1)+1$, which converges uniformly to a continuous surface [15].

The construction of the refinement rule is analogous to the second method in §2.1. The approximation operator $A$ maps a net of curves $\mathcal{N}(d, \{\phi_i\}_{i=0}^n, \{\psi_j\}_{j=0}^m)$ into the piecewise Coons patch surface, interpolating the curves of the net,

$$\begin{gathered}\mathcal{C}(\mathcal{N})(s,t) = C(\phi_i, \phi_{i+1}, \psi_j, \psi_{j+1}; d)(s - jd, t - id),\\ (s,t) \in [jd, jd+d] \times [id, id+d], \quad i = 0, \ldots, n-1,\ j = 0, \ldots, m-1,\end{gathered} \tag{18}$$

with $C(\phi_i, \phi_{i+1}, \psi_j, \psi_{j+1}; d)$ a Coons patch [16].

Four continuous curves $\phi_0, \phi_1, \psi_0, \psi_1$ defined on $[0, h]$ and satisfying $\phi_i(jh) = \psi_j(ih)$, $i, j = 0, 1$, define a Coons patch on $[0, h]^2$. For $(s, t) \in [0, h]^2$ the Coons patch is given by

$$\begin{aligned} &C(\phi_0, \phi_1, \psi_0, \psi_1; h)(s, t) \\ &\quad = \left[\left(1 - \frac{t}{h}\right)\phi_0(s) + \frac{t}{h}\phi_1(s)\right] + \left[\left(1 - \frac{s}{h}\right)\psi_0(t) + \frac{s}{h}\psi_1(t)\right] \\ &\qquad - \left[\left(1-\frac{s}{h}\right)\left(\left(1-\frac{t}{h}\right)\phi_0(0)+\frac{t}{h}\phi_1(0)\right)+\frac{s}{h}\left(\left(1-\frac{t}{h}\right)\phi_0(h)+\frac{t}{h}\phi_1(h)\right)\right]. \end{aligned} \tag{19}$$

The Coons patch is blending between two surfaces. One is interpolating linearly between corresponding points of $\phi_0, \phi_1$ and the other between the corresponding points of $\psi_0, \psi_1$. (These two surfaces are the two first terms on the right-hand side of (19)). It is easy to verify that $C(\phi_0, \phi_1, \psi_0, \psi_1; h)$ coincides with the four curves on the boundary of $[0, h]^2$, namely that

$$\begin{aligned} C(\phi_0, \phi_1, \psi_0, \psi_1; h)(jh, t) &= \psi_j(t), \quad j = 0, 1, \\ C(\phi_0, \phi_1, \psi_0, \psi_1; h)(s, ih) &= \phi_i(s), \quad i = 0, 1. \end{aligned}$$

Regarding the Coons patch of four curves as the analogue of a linear segment between two points, the Chaikin scheme for the refinement of control points is "extended" to nets of curves, by sampling each of the Coons patches of $\mathcal{C}(\mathcal{N}_k)$ at $1/4$ and $3/4$ of the corresponding parameters values. Thus the refinement rule analogous to (2.11) is

$$\phi_{2i}^{k+1}(s) = \mathcal{C}(\mathcal{N}_k)\left(s, \left(i + \frac{1}{4}\right)\frac{d}{2^k}\right), \quad \phi_{2i+1}^{k+1} = \mathcal{C}(\mathcal{N}_k)\left(s, \left(i + \frac{3}{4}\right)\frac{d}{2^k}\right), \quad i = 0, \ldots, n_k - 1, \tag{20}$$

$$\psi_{2j}^{k+1}(t) = \mathcal{C}(\mathcal{N}_k)\left(\left(j + \frac{1}{4}\right)\frac{d}{2^k}, t\right), \quad \psi_{2j+1}^{k+1} = \mathcal{C}(\mathcal{N}_k)\left(\left(j + \frac{3}{4}\right)\frac{d}{2^k}, t\right), \quad j = 0, \ldots, m_k - 1. \tag{21}$$

This refinement rule generates a refined net of curves after a simple reparametrization. This is written formally as $\mathcal{N}_{k+1} = S_{BC}\mathcal{N}_k$.

The proof of convergence of the scheme $S_{BC}$ is not an extension of the analysis of §2.3, but is based on the proximity of $S_{BC}$ to a new subdivision scheme $S_{\boldsymbol{a}}$ for points, which is proved to be convergent by the analysis of §2.3.

Convergence proofs by proximity to linear stationary schemes for points are employed, e.g., in [35] for the analysis of linear non-stationary schemes, and in [60] for the analysis of a certain class of non-linear schemes.

Another important ingredient in the convergence proof is a property of a net of curves, which is preserved during the refinements with $S_{BC}$. A net of curves

$\mathcal{N}(d, \{\phi_i\}_{i=0}^n, \{\psi_j\}_{j=0}^m)$ is said to have the *M-property* if the second divided differences of all curves of the net at three points restricted to intervals of the form $\left[\ell d, \left(\ell + \frac{1}{2}\right)d\right]$, $\ell \in (1/2)\mathbb{Z}$ in the domain of definition of the curves, are all bounded by a constant $M$.

The sequence $\{\mathcal{C}(\mathcal{N}_k) : k \in \mathbb{Z}_+\}$ of continuous surfaces is shown to be a Cauchy sequence for $\mathcal{N}_0$ with the $M$-property, by comparison of one refinement of $S_{BC}$ with one refinement of $S_{\boldsymbol{a}}$. The scheme $S_{\boldsymbol{a}}$ is constructed to be in proximity to $S_{BC}$ in the sense that

$$\left\| \mathcal{E}(S_{BC}\mathcal{N}_k) - S_{\boldsymbol{a}}(\mathcal{E}(\mathcal{N}_k)) \right\| \leq \frac{3}{2} M \left( \frac{d}{2^{k+1}} \right)^2, \tag{22}$$

with $\mathcal{E}(\mathcal{N}_k) = \left\{ C(\mathcal{N}_k)\left(i\frac{d}{2}, j\frac{d}{2}\right),\ 0 \leq i \leq 2m_k,\ 0 \leq j \leq 2n_k \right\}$, and with $M$ the constant in the $M$-property satisfied by all the nets $\{\mathcal{N}_k : k \in \mathbb{Z}_+\}$ which are generated by $S_{BC}$.

Although the limit of the Cauchy sequence $\{\mathcal{C}(\mathcal{N}_k) : k \in \mathbb{Z}_+\}$ is only $C^0$, it is conjectured in [15] that $S_{BC}$ generates $C^1$ surfaces from initial curves which are $C^1$. This conjecture is based on simulations.

**Acknowledgement.** The author wishes to thank David Levin and Adi Levin for helping with the figures and the references.

# Wave propagation software, computational science, and reproducible research

Randall J. LeVeque*

*Dedicated to Germund Dahlquist (1925–2005) and Joseph Oliger (1941–2005), two of the influential mentors who have shaped my career. They each inspired generations of students with their interest in the connections between mathematics and computation.*

**Abstract.** Wave propagation algorithms are a class of high-resolution finite volume methods for solving hyperbolic partial differential equations arising in diverse applications. The development and use of the CLAWPACK software implementing these methods serves as a case study for a more general discussion of mathematical aspects of software development and the need for more reproducibility in computational research. Sample applications discussed include medical applications of shock waves and geophysical fluid dynamics modeling volcanoes and tsunamis.

**Mathematics Subject Classification (2000).** Primary 65Y15; Secondary 74S10.

**Keywords.** Hyperbolic partial differential equations, software, numerical analysis, reproducible research, scientific computing, CLAWPACK.

## 1. Introduction

I will ultimately describe a class of numerical methods for solving hyperbolic partial differential equations, software that implements these methods, and some scientific applications. However, for the broad audience that I am honored to address in these proceedings, I would like to first make some more general comments on the topic of software development and its relation to mathematics, and on computational science and reproducible research.

I begin with a quote from a 1995 paper by J. B. Buckheit and D. L. Donoho [13] about wavelet analysis and a software package they developed to aid in studying and applying their methods:

> An article about computational science in a scientific publication is *not* the scholarship itself, it is merely *advertising* of the scholarship. The actual scholarship is the complete software development environment and the complete set of instructions which generated the figures.

*This research was supported in part by several NSF and DOE grants over the past decade, including NSF grants DMS-9803442, DMS-0106511, and CMS-0245206 and DOE grants DE-FG03-96ER25292, DE-FG03-00ER25292, and DE-FC02-01ER25474.

Proceedings of the International Congress of Mathematicians, Madrid, Spain, 2006

They present this as a slogan to distill the insights of Jon Claerbout, an exploration geophysicist who has been a pioneer in this direction since the early 90s (e.g., [59]), and they give many compelling examples to illustrate its truth. I first ran across this quote on the webpage [11] of the book [12], which provides complete codes in several languages for the solutions to each of the 100-digit challenge problems proposed by Trefethen [63]. (This is set of ten computational problems, each easy to state and with a single number as the answer. The challenge was to compute at least 10 digits of each number.) In spite of some progress in the direction of reproducible research, many of the complaints of Buckheit and Donoho still ring true today, as discussed further in the recent paper by Donoho and Huo [24].

Much of my work over the past 10 years has been devoted to trying to make it easier for myself, my students, and other researchers to perform computational scholarship in the field of numerical methods for hyperbolic PDEs, and also I hope in a variety of applications areas in science and engineering where these methods are used. This work has resulted in the CLAWPACK software [40]. This software is apparently being fairly widely used, both in teaching and research. More than 5 000 people have registered to download the code, mentioning all sorts of interesting problems they plan to tackle with it. However, I am not convinced that it is being used to the extent possible in advancing scholarship of the type described above. One goal of this paper is to encourage researchers (myself included) to work harder towards this end, in my field and more generally in computational science.

I will make a distinction between software and computer programs. In my notation, *software* means a package of computer tools that are designed to be applied with some generality to a class of problems that may arise in many different applications. A *computer program* is a code that solves one particular problem. A program may be written entirely from scratch or it may employ one or more software packages as tools. This is an important distinction to make since one has different goals in developing software than in writing a specific computer program. Software is intended to be used by others and to be as general as practically possible. A program is written to solve a problem and often the author does not intend for it to be seen or used by anyone else.

Pure mathematicians search for abstract structures that transcend particular examples and that often unify disparate fields. They produce theorems that apply as generally as possible and that can be used as solid and dependable building blocks for future work. In addition to developing new algorithms, some computational mathematicians also produce theorems, rigorous results guaranteeing that a particular algorithm converges or bounds on the magnitude of the error, for example. Such theorems give us the confidence to apply the algorithm to real world problems.

Other computational mathematicians focus on the development of software that implements an algorithm in a dependable manner. This is perhaps an under-appreciated art in the mathematical world, compared to proving theorems, but I believe it is an analogous mathematical activity in many ways. In both cases the goal is to distill the essence of a set of particular examples into a general result, something that applies as broadly as possible while giving an interesting and nontrivial result that

can be built upon and used as a "subroutine" in future work. In both cases the result is an encapsulation of a set of knowledge that has well defined inputs and outputs and is believed to be proved correct, and that applies in many situations.

The process of developing a novel algorithm and writing software to implement it is also in some ways similar to the process involved in proving a theorem. One needs some mathematical insight to get started, but then working through many technical details is typically required to make everything fit together in a manner that produces the desired result. This part is not very glamorous but is a crucial part of the scholarship. Often frustrations arise when one little detail does not work out quite the way one hoped. Sometimes algorithms, like partially completed proofs, must be shelved for years until someone else makes a breakthrough in a related area that suddenly makes everything come together.

And everything does have to fit together just right; having a nice idea that seems like it should work is not enough. Glossing over the details is not allowed, and is particularly hard to pull off in a computer program. While it may be possible to slip things by the referees in the description of an algorithm in a paper (as also sometimes happens in a shoddy proof), computers will not parse the command "and then a miracle occurs". We are forced to be explicit in every step.

Of course even once a program does work, in the sense of compiling without errors and producing results that seem reasonable, we are faced with the thorny issue of "proving" that it is in fact correct. In computer science there is a whole field devoted to developing methodologies for formally proving the correctness of computer programs. In computational science the programs are often so complex and the problem it is designed to solve so ill-defined that formal correctness proofs are generally impossible. Instead the buzzwords are *Verification and Validation* (V&V for short). These can be summarized by the following mnemonic:

Verification: Are we solving the problem right?
Validation: Are we solving the right problem?

For a physical experiment modeled by partial differential equations, for example, we must verify that the computer program solves the PDEs accurately. A computational scientist must also validate the code by comparing it against experiments to ensure that the PDEs discretized are actually a sufficient model of reality for the situation being modeled. The Euler equations of gas dynamics are sufficient in some situations, but completely inadequate in other cases where viscosity plays a significant role.

Researchers in numerical analysis and scientific computing (as defined in the next section) are generally most concerned with verification, while scientists, engineers, and applied mathematicians focusing on mathematical modeling must also be concerned with validation. Even the relatively simple task of verifying that a code solves the given equations properly can be a real challenge, however, and is often as much an art as a science. A good test problem that captures the essence of some potential difficulty while having a solution that can be checked is often hard to come by, and developing test suites for different classes of algorithms is valuable scholarship in

itself. Numerous papers have been written on the subject of how best to test computer programs or software for scientific computing; see [17], [29], [33], [38], [53], or [56] for just a few approaches.

Elegance is valued in algorithm and software design as it is in other mathematical endeavors. Often the first attempt at an algorithm is not very clean; it is a brute force approach that gets the job done. Later work is often devoted to cleaning things up, perhaps in fundamental ways that greatly reduce the computational complexity, but also often in more subtle ways that simply make it more "elegant", a hard to define property that we recognize when we see.

Perhaps I am straying too far from the topic of reproducible scientific computing, but to make progress in this direction I think it is important to recognize software development as a valid and challenging mathematical activity. It takes a slightly different type of mathematician to develop the necessary intuition and skills to excel at this than is required to prove theorems, just as doing algebra vs. analysis takes different mindsets and these are rarely done equally well by the same mathematician. But no one doubts that algebraists and analysts are both mathematicians, even if they cannot get beyond the first page of each others' papers. Knuth [35] did an interesting study on the connections between algorithmic and mathematical thinking, a topic that he also touched on in an earlier paper [34] on "computer science and its relation to mathematics". This paper was written in 1974, at a time when many computer science departments were just being established, often by mathematicians. It makes interesting reading today, along with similar papers of the same vintage, such as [9], [25]. Software development is a logical conclusion of algorithmic thinking, and the development of software for mathematical algorithms naturally belongs in a mathematics department.

The reason I care about this topic is not for my own mathematical ego. I have been lucky to be at an institution where my work in this direction has been encouraged, or at least tolerated. It may have helped that I did not put much effort into software development until well after I was tenured.[1] The main value of the tenure system is that established people do not need to worry what our colleagues think of our activities or how they choose to label them. But the future depends on bright young people. I think computational science affords a wonderful opportunity to get students involved in a host of mathematical challenges, and making significant progress on these requires computational mathematicians with solid training in a broad range of mathematical

[1] However, many of my attitudes towards software development were shaped by my experiences as a graduate student in the Computer Science Department at Stanford, where students in the numerical analysis group were responsible for maintaining the library of numerical routines [10] available to physicists at the Stanford Linear Accelerator Center (SLAC) and acting as consultants, activities that were encouraged by Gene Golub and Joe Oliger. There I had the pleasure of working directly with an outstanding set of fellow students, most of whom have gone on to make software contributions of their own, including Marsha Berger, Petter Bjorstad, Dan Boley, Tony Chan, Bill Coughran, Bill Gropp, Eric Grosse, Mike Heath, Frank Luk, Stephen Nash, Michael Overton, and Lloyd Trefethen. Many of us were also shaped by Cleve Moler's course on numerical linear algebra, where he tried out his new MATLAB program on us as a front end to the LINPACK and EISPACK routines that were already setting the standard for mathematical software [23], [27], [61]. I think the Computer Science students were more impressed with MATLAB and much more influenced by this experience than Cleve takes credit for in [48].

tools and the ability to apply mathematical abstraction to common problems arising in multiple fields. While there are many talented computational scientists working on specific challenging problems in virtually every science and engineering department, a computational mathematician, centered in a mathematics (or applied mathematics) department, has the best chance of appreciating the common mathematical structure of the problems and producing algorithms and software that are broadly applicable. Doing so not only avoids a lot of wasted effort by scientists whose time is better spent on the peculiarities of their specialty, it also leads to the introduction of techniques into fields where they might not otherwise be invented and the discovery of new connections between existing algorithms and applications.

I once heard Jim Glimm remark that "applied mathematicians are the honey bees of the mathematical world, whose job is to cross-pollinate applications." In addition to providing a service to those in other disciplines, the process of collecting nectar can result in some sweet rewards back in our own hive. This is equally true in algorithm and software development as it is in more classical and theoretical aspects of applied mathematics.

But young mathematicians will feel free to pursue such activities, and to also do the less rewarding but crucial aspects of the scholarship such as documenting their codes and making them presentable to the rest of the world, only if it is accepted as valid mathematical scholarship. If it is seen as non-mathematics, it will only be a waste of time that is best avoided by anyone seeking tenure in a mathematics department.

Applied mathematics in general is becoming much more acceptable in mathematics departments than it once was, at least in the United States. However, I doubt that the careful development of software or computer programs, or the work required to turn research codes into publishable scholarship, has the same level of acceptance.

## 2. Numerical analysis, scientific computing, and computational science & engineering

One can argue at length about the meaning of the terms in this section title. To me, "numerical analysis" has a double meaning: the analysis and solution of real-world problems using numerical methods, and the invention and analysis of the methods themselves using the techniques of mathematics.

When used in the latter sense, numerical analysis belongs firmly in a mathematics (or applied mathematics) department. As just one example, analyzing the stability and convergence properties of finite difference or finite element methods is no less difficult (often more difficult) than analyzing the underlying differential equations, and relies on similar tools of analysis. Specialists in this type of numerical analysis may or may not do much computing themselves, and may be far removed from computational science.

Numerical analysis in the sense of using numerical methods to solve problems, or developing software for general use, is often called "scientific computing" or "com-

putational science & engineering" these days. One can make a further distinction between these two terms: Scientific computing is often used to refer to the development of computational tools useful in science and engineering. This is the main thrust of the *SIAM Journal on Scientific Computing*, for example, which contains few theorems relative to the more theoretical *SIAM Journal on Numerical Analysis*, but still focuses on mathematical and algorithmic developments. Computational science & engineering refers more specifically to the use of computational tools to do real science or engineering in some other field, as a complement to experimental or theoretical science and engineering.

Not everyone would agree with my definitions of these terms. In particular, it can be argued that "computational science" refers to the science of doing computation and "computational engineering" to the implementation of this science in the form of software development, but for my purposes I will lump these two activities under "scientific computing". It is important to be aware of this lack of consistency in nomenclature since, for example, many recently developed academic programs in Computational Science & Engineering stress aspects of scientific computing as well.

I have been arguing that "scientific computing", in the sense just described, is a branch of mathematics (as well as being a branch of other disciplines, such as computer science), and that other mathematicians should be more aware of the intellectual challenges and demands of this field, including the need to document and distribute code. Not only are the activities of many practitioners of scientific computing essentially mathematical, but they (and their students) benefit greatly from frequent contact with more theoretical numerical analysts and mathematicians working in related areas. Other mathematicians may also benefit from having computational experts in the department, particularly as more fields of pure mathematics develop computational sides and realize the benefits of experimental mathematics – there is even a journal (see expmath.org) now devoted to this approach.

## 3. Reproducible research

Within the world of science, computation is now rightly seen as a third vertex of a triangle complementing experiment and theory. However, as it is now often practiced, one can make a good case that computing is the last refuge of the scientific scoundrel. Of course not all computational scientists are scoundrels, any more than all patriots are, but those inclined to be sloppy in their work currently find themselves too much at home in the computational sciences. Buckheit and Donoho [13] refer to the situation in the field of wavelets as "a scandal". The same can be said of many other fields, and I include some of my own work in the category of scandalous.

Where else in science can one get away with publishing observations that are claimed to prove a theory or illustrate the success of a technique without having to give a careful description of the methods used, in sufficient detail that others can attempt to repeat the experiment? In other branches of science it is not only expected

that publications contain such details, it is also standard practice for other labs to attempt to repeat important experiments soon after they are published. Even though this may not lead to significant new publications, it is viewed as a valuable piece of scholarship and a necessary aspect of the scientific method.

Scientific and mathematical journals are filled with pretty pictures these days of computational experiments that the reader has no hope of repeating. Even brilliant and well intentioned computational scientists often do a poor job of presenting their work in a reproducible manner. The methods are often very vaguely defined, and even if they are carefully defined they would normally have to be implemented from scratch by the reader in order to test them. Most modern algorithms are so complicated that there is little hope of doing this properly. Many computer codes have evolved over time to the point where even the person running them and publishing the results knows little about some of the choices made in the implementation. And such poor records are typically kept of exactly what version of the code was used and the parameter values chosen that even the author of a paper often finds it impossible to reproduce the published results at a later time.

The idea of "reproducible research" in scientific computing is to archive and make publicly available all of the codes used to create the figures or tables in a paper in such a way that the reader can download the codes and run them to reproduce the results. The program can then be examined to see exactly what has been done.

The development of very high level programming languages has made it easier to share codes and generate reproducible research. Historically, many papers and text books contained pseudo-code, a high level description of an algorithm that is intended to clearly explain how it works, but that would not run directly on a computer. These days many algorithms can be written in languages such as MATLAB in a way that is both easy for the reader to comprehend and also executable, with all details intact. For example, we make heavy use of this in the recent paper [15]. We present various grid mappings that define logically rectangular grids in smooth domains without corners, such as those shown later in Figure 1, and all of the MATLAB codes needed to describe the various mappings are short enough to fit naturally in the paper. The associated webpage contains the longer CLAWPACK codes used to solve various hyperbolic test problems on these grids.

Trefethen's book on spectral methods [62] is a good example of a textbook along these lines, in which each figure is generated by a 1-page MATLAB program. These are all included in the book and nicely complement the mathematical description the methods discussed. Trefethen makes a plea for more attention to short and elegant computer programs in his recent essay [64].

However, for larger scale computer programs used in scientific publications, there are many possible objections to making them available in the form required to reproduce the research. I will discuss two of these, perhaps the primary stumbling blocks.

One natural objection is that it is a lot of work to clean up a code to the point where someone else can even use it, let alone read it. It certainly is, but it is often well

worth doing, not only in the interest of good science but also for the personal reason of being able to figure out later what you did and perhaps build on it.

Those of us in academia should get in the habit of teaching good programming, documentation, and record keeping practices to our students, and then demand it of them. We owe it to them to teach this set of computational science skills, ones that I hope will be increasingly necessary in academic research environments and that are also highly valued in industrial and government labs. It will also improve the chances that we will be able to build on the work they have done once they graduate, and that future students will be able to make use of it rather than starting from scratch as is too often the case today.

While ideally all published programs would be nicely structured and easily readable with ample comments, as a first step it would be valuable simply to provide and archive the working code that produced the results in a paper. Even this takes more effort than one might think. It is important to begin expecting this as a natural part of the process so that people will feel less like they have to make a choice between finishing off one project properly or going on to another where they can more rapidly produce additional publications. The current system strongly encourages the latter.

As Buckheit and Donoho [13] point out, the scientific method and style of presenting experiments in publications that is currently taken for granted in the experimental sciences was unheard of before the mid-1800s. Now it is a required aspect of respectable research and experimentalists are expected to spend a fair amount of time keeping careful lab books, fully documenting each experiment, and writing their papers to include the details needed to repeat the experiments. A paradigm shift of the same nature may be needed in the computational sciences.

Requiring it of our students may be a good place to start, provided we recognize how much time and effort it takes. Perhaps we should be more willing to accept an elegant and well documented computer program as a substantial part of a thesis, for example.

A second objection to publishing computer code is that a working program for solving a scientific or engineering problem is a valuable piece of intellectual property and there is no way to control its use by others once it is made publicly available. Of course if the research goal is to develop general software then it is desirable to have as many people using it as possible. However, for a scientist or mathematician who is primarily interested in studying some specific class of problems and has developed a computer program as a tool for that purpose, there is little incentive to give this tool away free to other researchers. This is particularly true if the program has taken years to develop and provides a competitive edge that could potentially lead to several additional publications in the future. By making the program globally available once the first publication appears, other researchers can potentially skip years of work and start applying the program to other problems immediately. In this sense providing a program is fundamentally different than carefully describing the materials and techniques of an experiment; it is more like inviting every scientist in the world to come use your carefully constructed lab apparatus free of charge.

This argument undoubtedly has considerable merit in some situations, but on the whole I think it is overblown. It is notoriously difficult to take someone else's code and apply it to a slightly different problem. This is true even when people are trying to collaborate and willing to provide hands-on assistance with the code (though of course this type of collaboration does frequently occur). It is often true even when the author of the code claims it is general software that is easy to adapt to new problems. It is particularly true if the code is obscurely written with few comments and the author is not willing to help out, as would probably be true of many of the research codes people feel the strongest attachment to.

Moreover, my own experience in computational science is that virtually every computational experiment leads to more questions than answers. There is such a wealth of interesting phenomena that can be explored computationally these days that any worthwhile code can probably lead to more publications than its author can possibly produce. If other researchers are able to take the code and apply it in some direction that would not otherwise be pursued, that should be seen as a positive development, both for science and for its original author, provided of course that s/he gets some credit in the process. This is particularly true for computational mathematicians, whose goals are often the development of a new algorithm rather than the solution of specific scientific problems. Even for those not interested in software development *per se*, anything we can do to make it easier for others to use the methods we invent should be viewed as beneficial to our own careers.

Perhaps what is needed is some sort of recognized patent process for scientific codes, so that programs could be made available for inspection and independent execution to verify results, but with the understanding that they cannot be modified and used in new publications without the express permission of the author for some period of years. Permission could be granted in return for co-authorship, for example. In fact such a system already works quite well informally, and greater emphasis on reproducible research would make it function even better. It would be quite easy to determine when people are violating this code of ethics if everyone were expected to "publish" their code along with any paper. If the code is an unauthorized modification of someone else's, this would be hard to hide.

## 4. Wave propagation algorithms and CLAWPACK

As a case study in software development, and its relation to mathematics, scientific computing, and reproducible research, I will briefly review some of the history behind my own work on CLAWPACK (Conservation LAWs PACKage), software for solving hyperbolic systems of partial differential equations.

This software development project began in 1994. I had just taught a graduate course on numerical methods for conservation laws and had distributed some sample computer programs to the students as a starting point for a class project. In the fall I went on sabbatical and decided to spend a few weeks cleaning up the program and

redesigning it as a software package, in large part because I was also planning to spend much of the year revising my lecture notes [42] from a course I taught at ETH-Zürich in 1989 into a longer book, and I wanted to complement the text with programs the students could easily use.

I seriously misjudged the effort involved – I spent most of that year and considerable time since developing software, which grew into something much more that I originally intended. The book [44] took several more years of work and iterations of teaching the course and did not appear until 2002.

Virtually all of the figures in this book are reproducible, in the sense that the programs that generated them can each be downloaded from a website and easily run by the student. Most figure captions contain a link to the corresponding website, in the form [claw/book/chap23/advection/polar], for example, from the caption of Figure 23.3, which is easily translated into the appropriate web address. (Start at http://www.amath.washington.edu/~claw/book.html to browse through all these webpages). Each webpage contains the computer code and many also contain additional material not in the book, for example movies of the solution evolving in time.

All of these examples are based on the CLAWPACK software. This software is described briefly in the book and more completely in the User Guide [41] available on the web. Once the basic software is installed, the problem-specific code for each example in the book is quite small and easy to comprehend and modify. The reader is encouraged to experiment with the programs and observe how changes in parameters or methods affect the results. These programs, along with others on the CLAWPACK website [40], can also form the basis for developing programs to solve similar problems.

This software implements a class of methods I call "wave propagation algorithms" for solving linear or nonlinear hyperbolic problems. Hyperbolic partial differential equations are a broad class of equations that typically model wave propagation or advective transport phenomena. The classic example is the second-order wave equation $p_{tt} = c^2 p_{xx}$ for linear acoustics, modeling the propagation of pressure disturbances in a medium with sound speed $c$. The CLAWPACK software, however, is set up to solve a different form of hyperbolic equations: systems that involve only first order derivatives in space and time.

In the linear case, a first-order system of PDEs (in one space dimension and time) has the form $q_t + Aq_x = 0$, where $q(x, t)$ is a vector of some $m$ conserved quantities, $A$ is an $m \times m$ matrix, and subscripts denote partial derivatives. In the nonlinear case, a system of $m$ conservation laws takes the form $q_t + f(q)_x = 0$, where $f(q)$ is the flux function (in the linear case, $f(q) = Aq$). This system is called *hyperbolic* if the flux Jacobian matrix $f'(q)$ is diagonalizable with real eigenvalues. The system of Euler equations for inviscid compressible gas dynamics has this form, for example, where mass, momentum, and energy are the conserved quantities. The full nonlinear equations can develop shock wave solutions in which these quantities are discontinuous, one of the primary challenges in numerical modeling. Linearizing this system gives the linear acoustics equations in the form of a first-order system of

equations for pressure and velocity. Cross differentiating this system allows one to eliminate velocity and obtain the single second-order wave equation for $p$ mentioned above, but the first-order formulation allows the modeling of a much broader range of phenomena.

First-order hyperbolic systems arise naturally in a multitude of applications, including for example elastodynamics (linear and nonlinear), electromagnetic wave propagation (including nonlinear optics), shallow water equations (important in oceanography and atmospheric modeling), and magnetohydrodynamic and relativistic flow problems in astrophysics.

The wave-propagation algorithms are based on two key ideas: Riemann solvers and limiters. The *Riemann problem* consists of the hyperbolic equation under study with special initial conditions at some time $\bar{t}$: piecewise constant data with left state $q_\ell$ and right state $q_r$ and a jump discontinuity in each conserved quantity at a single point in space, say $\bar{x}$. The solution to this Riemann problem for $t > \bar{t}$ is a similarity solution, a function of $(x-\bar{x})/(t-\bar{t})$ alone that consists of a set of waves propagating at constant speeds away from the initial discontinuity. The definition of hyperbolicity guarantees this, and the eigenvalues of the flux Jacobian are related to the wave speeds. In the linear case the eigenvalues of the matrix $A$ are exactly the wave speeds. In the nonlinear case the eigenvalues vary with $q$. The Riemann solution may then contain shock waves and rarefaction waves, but even in the nonlinear case this special problem has a similarity solution with constant wave speeds.

In 1959, Sergei Godunov [30] proposed a numerical method for solving general shock wave problems in gas dynamics by using the Riemann problem as a building block. If the physical domain is decomposed into a finite number of grid cells and the solution approximated by a piecewise constant function that is constant in each grid cell, then at the start of a time step the initial data consists of a set of Riemann problems, one at each cell interface. By solving each of these Riemann problems the solution can be evolved forward in time by a small increment. The resulting solution is averaged over each grid cell to obtain a new piecewise constant approximation to the solution at the end of the time step. This procedure is repeated in the next time step. This idea of basing the numerical method on Riemann solutions turned out to be a key idea in extending the "method of characteristics" from linear hyperbolic systems to important nonlinear shock propagation problems. This also leads naturally to a software framework: the particular hyperbolic equation being solved is determined by providing a Riemann Solver. This is a subroutine that, given any two states $q_\ell$ and $q_r$, returns the wave speeds of the resulting waves in the similarity solution, along with the corresponding waves themselves (i.e., the jump in $q$ across each wave). The updating formulas for the cell averages based on these waves are very simple and independent of the particular system being solved.

Godunov's method turned out to be very robust and capable of solving problems involving strong shocks where other methods failed. However, it is only first-order accurate on smooth solutions to the PDEs. This means that the error goes to zero only as the first power of the discretization steps $\Delta x$ and $\Delta t$. Moreover, although

complicated solutions involving strong shocks and their interactions could be robustly approximated without the code crashing, the resulting approximations of shock waves are typically smeared out. The process of averaging the solution over grid cells each time step introduces a large amount of "numerical dissipation" or "numerical viscosity".

During the 1970s and 1980s, a tremendous amount of effort was devoted to developing more accurate versions of Godunov's method that better approximated smooth solutions and also captured shock waves more sharply. These methods often go by the general name of "high-resolution shock capturing methods". A wide variety of methods of this type have been proposed and effectively used. Many of these, including the wave-propagation algorithms of CLAWPACK, have the relatively modest goal of achieving something close to second-order accuracy on smooth solutions coupled with sharp resolution of discontinuities. Other approaches have been used that can achieve much better accuracy in certain situations, though for general nonlinear problems involving complicated shock structures, particularly in more than one dimension, it seems hard to improve very much beyond what is obtained using second-order methods.

One standard second-order method for a linear hyperbolic system is the Lax–Wendroff method, first proposed in 1960, which is based on approximating the first few terms of a Taylor series expansion of the solution at time $t + \Delta t$ about the solution at time $t$. This method does not work at all well for problems with discontinuities, however, as it is highly dispersive and nonphysical oscillations arise that destroy all accuracy. In the nonlinear case these oscillations around shock waves can also lead to nonlinear instabilities.

The key feature in many high-resolution methods is to apply a *limiter function* in some manner to suppress these oscillations. In the wave-propagation algorithms this is done in the following way. The Lax–Wendroff method can be rewritten as Godunov's method plus a correction term that again can be expressed solely in terms of the waves and wave speeds in the Riemann solutions arising at each cell interface. Where the solution is smooth, adding in these correction terms improves the accuracy. Where the solution is not smooth, for example near a shock, the Taylor series expansion is not valid and these "correction terms", which approximate higher derivatives in the Taylor expansions, do more harm than good. We can determine how smooth the solution is by comparing the magnitude of a wave with the magnitude of the corresponding wave at the neighboring cell interfaces. If these differ greatly then the solution is not behaving smoothly and the correction terms should be "limited" in some manner.

Many variants of this idea have been used. In some cases it is the Lax–Wendroff expression for the flux at the interface between cells that is limited (in so-called "flux limiter" methods). Another approach is to view the Lax–Wendroff method as a generalization of Godunov's method in which a piecewise linear function in each grid cell is defined and the values at the edges of each cell then used to define Riemann problems. In this case the slope chosen in each cell is based on the averages in nearby cells, with some "slope limiter" applied in regions where it appears the solution is not behaving smoothly. For the special case of a scalar conservation law, a very

nice mathematical theory was developed to guide the choice of limiter functions. The true solution to a scalar problem has its total variation non-increasing over time. By requiring that a numerical method be "total variation diminishing" (TVD) it was possible to derive methods that were essentially second order accurate, or higher, but that could be proved to not introduce spurious oscillations.

The 1980s were an exciting time in this field, as robust high-resolution methods were developed for a variety of challenging applications and as computers became powerful enough that extensions of these methods and the related mathematical theory to more than one space dimension became possible and necessary.

I played a modest role in some of these developments, but I think my main contribution has been in providing a formulation of these methods that lends itself well to software that is very broadly applicable, and in leading the effort to write this software. The wave-propagation formulation that I favor has the advantage that once the Riemann problem has been solved, the limiters and high-resolution correction terms are applied in a general manner that is independent of the equation being solved. Moreover a framework for doing this in two dimensions was proposed in [43] that retains this modularity, separating the process of solving a one-dimensional Riemann problem at each cell interface, along with a related "transverse Riemann problem" in the orthogonal direction, from the process of propagating these waves and correction terms with appropriate limiters. While it had long been recognized that the methods being developed were in principle broadly applicable to all hyperbolic problems, for systems of equations most methods were developed or at least presented in a form that was specific to one particular problem (often the Euler equations of gas dynamics) and a certain amount of work was required to translate them to other problems. Computer programs that I was aware of were all problem-specific, and generally not publicly available.

My original motivation for developing this framework was not software development, but rather the need to teach graduate students, and the desire to write a book that explained how to apply these powerful high-resolution methods to a variety of problems. I had students coming from the Mathematics and Applied Mathematics departments, many of whom knew little about fluid dynamics, and students from several science and engineering departments who had specific interests in very diverse directions.

My subsequent motivation for software development was partly educational, but also partly because I wanted to better publicize the wave-propagation framework I had developed and make it easier for others to use methods in this form. I recognized that these methods, while quite general, were also sufficiently complicated that few would bother to implement them from my descriptions in journal articles. For this research to have any impact beyond a few publications it seemed necessary to provide more than pseudo-code descriptions of the algorithms.

## 5. CLAWPACK as an environment for developing and testing methods

I have provided a few basic sample programs within the CLAWPACK package itself, and some additional test problems in a directory tree labeled applications available at the website. Complete programs also exist for each of the figures in my book. These each consist of a tarred Unix directory containing a small set of subroutines to be used together with the main software. These subroutines specify the specific problem, including the Riemann solver and the initial and boundary conditions. Many standard boundary conditions are already available in the default boundary condition routine, and a variety of Riemann solvers are also provided for many different systems of equations. As a result it is often very easy to adapt one of these examples to a new problem, particularly for some of the standard test problems that often appear in publications.

Although the development of the CLAWPACK software was originally motivated by the desire to make a set of existing methods more broadly accessible, the availability of this software has also encouraged me to pursue new algorithmic advances that I otherwise might not have. I hope that the software will also prove useful to others as a programming environment for developing and testing new algorithms, and for comparing different methods on the same problems. Since the source code is available and the basic CLAWPACK routines are reasonably simple and well documented, it should be easy for users to modify them and try out new ideas. I encourage such use, and I certainly use it this way myself.

As one example, there are many approaches to developing the "approximate Riemann solvers" that are typically used for nonlinear problems. It often is not cost effective, and may not even be possible, to solve the Riemann problem exactly at every cell interface each time step. Different versions of the Riemann solver can easily be swapped in and tested on a set of problems. See Figures 15.5 and 15.6 in [44] and the associated programs for an example of this sort of comparison. The CLAWPACK software also comes with a set of standard limiter functions, and an input parameter specifies which one will be used. The subroutine where these are implemented can be easily modified to test out new approaches.

More extensive modifications could be made to the software as well, for example by replacing the wave-propagation algorithms currently implemented by a different approach. If a new method is formulated so that it depends on a Riemann solver and boundary conditions that are specified in the form already used in CLAWPACK, then it should be easy to test out the new method on all the test problems and applications already developed for CLAWPACK. This would facilitate comparison of a new method with existing methods.

Careful direct comparisons of different methods on the same test problems are too seldom performed in this field, as in many computational fields. One reason for this is the difficulty of implementing other peoples' methods, so the typical paper contains only results obtained with the authors' method. Sometimes (not always) the method has been tested on standard test problems and the results can be compared with

others in the literature, with some work on the reader's part, and assuming the reader is content with comparisons in the "eyeball norm" since many papers only contain contour plots of the computed solution and no quantitative results. Of course there are many exceptions to this, including some papers devoted to careful comparisons of different methods (e.g., [31], [46]), but these papers are still a minority. I hope that CLAWPACK might facilitate this process more in the future, and that new algorithms of this same general type might be provided in a CLAWPACK implementation that allows direct use and comparison by others.

## 6. CLAWPACK extensions and infrastructure

This software effort began about 10 years ago, as recounted above, and has continued in unexpected ways as the software grew beyond my initial intentions in several directions. While originally I viewed it primarily as an educational tool, it was based on my own research codes and I realized that it could perhaps be valuable for other researchers as well, perhaps even as a tool for solving real problems and not just academic test problems. To make it more useful as a general tool required several enhancements.

I originally wrote subroutines for solving systems in one and two space dimensions, but started collaborating with Jan Olav Langseth that same year on the development of three-dimensional generalizations [37]. He took my course as a visiting graduate student from the University of Oslo and went on to write a thesis partly on this topic [36], and wrote the three-dimensional subroutines in CLAWPACK.

I had also been collaborating with Marsha Berger on research related to using cut-cell Cartesian grids to solve the Euler equations in non-rectangular geometries (e.g., [5], [6]) and was familiar with her implementation of adaptive mesh refinement on rectangular grids, using an approach pioneered in her work with Joe Oliger and Phil Colella [4], [8], [7]. While still on sabbatical, in 1995 we started working together to modify her adaptive mesh refinement (AMR) code and make it more generally applicable to any hyperbolic system that can be solved in CLAWPACK. In this approach the rectangular grid is refined by introducing finer grids on rectangular patches. Several levels of refinement are allowed, by an arbitrary refinement factor at each level. The program automatically refines and de-refines as the computation proceeds, based on a standard default or user-specified error criterion, and so fine grids are used only where they are needed. This approach is particularly valuable for problems involving shock waves propagating in three space dimensions. To capture the shock waves as sharp discontinuities, even with high-resolution methods, requires a fairly fine grid around the shock, much finer than is needed in regions where the solution is smooth. Without AMR many three-dimensional problems would be impractical to solve except on the largest supercomputers.

This AMRCLAW software is now a standard part of CLAWPACK, and was extended from two to three space dimensions with programming help from Dave McQueen and

Donna Calhoun. The goal of the AMRCLAW code is primarily to facilitate research and practical problem solving, rather than to teach adaptive refinement techniques. The core library consists of about 9 000 lines of Fortran 77 code that is quite convoluted and not structured or fully documented in a way that others can easily understand. This stems in large part from its history as a merging together of two different codes, with different notation and conventions that have largely been preserved and worked around, and with many new features added over the years as afterthoughts that were not originally designed for. It may not be particularly elegant, but it has proved valuable in solving practical problems and by now has been tested to the point where it is fairly robust and reliable. All of the source code is available for others to inspect and modify, at their own peril perhaps.

The CLAWPACK framework can also be used with other AMR packages. Sorin Mitran is developing BEARCLAW [47], a Fortran 90 version with similar capabilities to AMRCLAW but designed with these capabilities in mind from the beginning. This code is still being developed and has not been tested as extensively as AMRCLAW, but it has been successfully used in astrophysical applications [51], [52]. Ralf Deiterding has developed a general purpose adaptive refinement code AMROC [18], [19] in C++ that also allows the use of the CLAWPACK solvers with adaptive refinement. This is a primary computational tool in the Virtual Shock Physics Test Facility at the Caltech ASC Center for Simulation of Dynamic Response of Materials [1]. Recently Donna Calhoun has written a CHOMBO-CLAW interface [14] between the CLAWPACK solvers and the C++ CHOMBO software package developed by Colella's group at Lawrence Berkeley Lab [16]. These newer packages have various advantages over the AMRCLAW software in CLAWPACK. They are written in more advanced languages that are more suitable for the data structures and dynamic memory allocation needed in AMR codes. They also have more capabilities such as parallel implementations, the ability to handle implicit methods, and/or coupling with elliptic solvers as required in some applications.

Other extensions of CLAWPACK have also been developed, such as the CLAWMAN software [2] that solves hyperbolic systems on curved two-dimensional manifolds. This has been used to solve geophysical flow problems on the sphere and relativistic flow problems in curved space-time near a black hole [3], [54], [55].

The original software was designed for purely Cartesian grids in rectangular regions of space. Some practical problems have this form, but most are posed in more complicated physical domains, e.g., for flows around or through a physical object. There are many approaches to handling complex geometries. The cut-cell Cartesian grid approach has already been mentioned above. At the other extreme lie unstructured grids, typically composed of triangular cells in two dimensions or tetrahedra in three dimensions. These can conform to very general boundaries, but grid generation then becomes a challenging problem in itself, and implementations must deal with special data structures to keep track of what cells are adjacent to one another.

For fairly simple domains, a good compromise is often possible in which the grid is logically rectangular in computational space, but is mapped to a nonrectagular

physical domain. In two dimensions, this means that each grid cell is a quadrilateral and simple $(i, j)$ indexing can be used to denote the cells, with neighboring cells having indices $(i \pm 1, j \pm 1)$. In three dimensions the grid cells are hexahedral but still logically rectangular. It is quite easy to apply CLAWPACK in such situations (as described in Chapter 23 of [44]), with a standard set of additional subroutines used to specify the mapping function. One nice feature of this approach is that the AMR routines work perfectly well on mapped grids – the patches of refinement are still rectangular in computational space. The wave-propagation algorithms turn out to work quite robustly on quadrilateral grids, even if the grid is nonorthogonal and far from smooth. Rather than incorporating the grid mapping directly into the differential equations as "metric terms" that involve derivatives of the mapping function, in the wave-propagation approach one solves one-dimensional Riemann problems orthogonal to each grid interface and transverse Riemann problems based on the adjacent cell interfaces.

Figure 1 shows two grids from some recent work with Calhoun [15] on the use of logically rectangular grids for solving problems in domains with smooth boundaries. The figure on the left shows a quadrilateral grid for a circle, while that on the right is a logically rectangular grid on the sphere. Each grid is simply a rectangle in computational space. Of course polar coordinates also give a logically rectangular grid in a circle, but grid lines coalesce at the center where cells have much smaller area than those near the perimeter. This presents a problem when using explicit

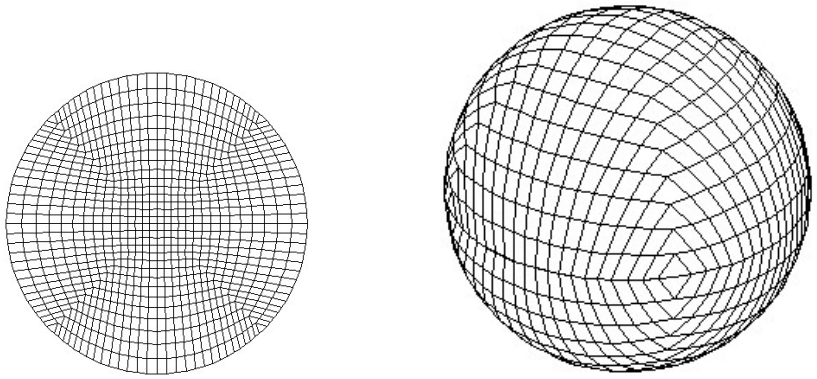

Figure 1. Quadrilateral grids on the circle and the sphere. In each case the computational domain is a rectangular grid. The MATLAB code that generates these grids is available on the webpage [39].

methods for hyperbolic problems: the disparity in cell sizes leads to an undesirable restriction on the time step. The grids in Figure 1 are far from smooth or orthogonal; in fact the images of the two orthogonal cell edges at each corner of the rectangular computational domain are nearly collinear in the physical domain. But the cell areas are nearly uniform, differing by at most a factor of 2. Standard finite difference

methods would presumably not work well on these grids, but applying CLAWPACK yields very nice results, as demonstrated in [15].

Writing new methods in "CLAWPACK form" makes it possible to take advantage of the infrastructure developed for this software, for example to apply the method on a general quadrilateral grid. It may also be possible to apply adaptive mesh refinement quite easily with the new method by taking advantage of one of the AMR wrappers described above. Since implementing AMR effectively is far from trivial, and often has little to do with the particular numerical method used on each grid patch, making use of existing implementations could be worthwhile even if it takes a bit of work to formulate the method in an appropriate form. Extensive graphics routines in MATLAB have been written to plot the results computed by CLAWPACK. These routines (written mostly by Calhoun and myself) deal with adaptive mesh refinement data in two or three space dimensions. This is a not easily done directly with most graphics packages, and again this infrastructure may be useful to developers of new methods. (In fact these graphics routines can take AMR data produced by any program, not just CLAWPACK, provided it is stored in the appropriate form.)

One current research project, with graduate student David Ketcheson, is to implement higher order numerical methods in CLAWPACK, specifically the weighted essentially non-oscillatory (WENO) methods that are based on higher order interpolation in space coupled with Runge–Kutta time stepping (e.g., [31], [60]). Doing so requires reformulating these methods slightly, and in particular we are developing a version that works for linear hyperbolic systems that are not in conservation form. Systems of this form arise in many applications, such as the propagation in heterogeneous media of acoustic, elastic, or electromagnetic waves. In many linear applications the solution is smooth but highly oscillatory, and in this case higher-order methods may be beneficial.

## 7. Applications in computational science

In addition to continuing to work on algorithm development, in the past few years I have become more directly involved in applications of computational science, driven in part by the existence of this software as a starting point. Problems that can be solved easily with the existing software have little interest to me; as a mathematician I consider them solved, though there may be plenty of interesting science to be done by judicious use of the software as a tool. This is best done, however, by scientists who are experts in a particular domain.

A practical problem where CLAWPACK fails to perform well, or where some substantial work is required to apply it, is much more interesting to me. Although the methods implemented in CLAWPACK work well on many classical hyperbolic problems, there are a wealth of more challenging problems that are yet to be solved, and I hope that CLAWPACK might form the basis for approaching some of these problems without the need to rewrite much of the basic infrastructure.

In the remainder of this section I will briefly describe a few topics that are currently occupying me and my students. More details on these and other problems, along with movies, papers, and sometimes computer code, can be found by clicking on the "Research interests" link from my webpage.

**Shock wave therapy and lithotripsy.** Focused shock waves are used in several medical procedures. Extracorporeal shock wave lithotripsy (ESWL) is a standard clinical procedure for pulverizing kidney stones noninvasively. There are several different lithotripter designs. In one model, a spark plug immersed in water generates a cavitating bubble that launches a spherical shock wave. This wave reflects from an ellipsoidal shaped reflector and refocuses at the distal focus of the ellipsoid, where the kidney stone is centered. The shock wave pulse has a jump in pressure of roughly 50 MPa (500 atmospheres) over a few nanoseconds, followed by a more slowly decaying decrease in pressure passing below atmospheric pressure before relaxing to ambient. This tensile portion of the wave is particularly important in kidney stone comminution since stones are composed of brittle material that does not withstand tensile stress well. Typically thousands of pulses are applied clinically (at a rate of 1 to 4 per second). The breakup process is not well understood and better understanding might allow clinical treatment with fewer pulses and less damage to the surrounding kidney.

Together with Kirsten Fagnan and Brian MacConaghy, two graduate students in Applied Mathematics, I have recently been collaborating with researchers at the Applied Physics Laboratory and the medical school at the University of Washington to develop a computational model of nonlinear elastic wave propagation in heterogeneous media that can be used to aid in the study of this process. Preliminary computations have been performed using linear elasticity in two-dimensional axisymmetric configurations in which a cylindrical test stone is aligned with the axis of the lithotripter ellipsoid. We are currently extending these computations to an appropriate nonlinear elasticity model, and also to three dimensional calculations for non-axisymmetric configurations.

We also hope to perform simulations useful in the study of extracorporeal shock wave therapy (ESWT), a relatively new application of lithotripter shock waves to treat medical conditions other than kidney stones, in which the goal is to stimulate tissue or bone without destroying it. For example, several recent clinical studies have shown that treating nonunions (broken bones that fail to heal) with ESWT can lead to rapid healing of the bone [26], [57], perhaps because it stimulates the growth of new vascular structure in regions where there is insufficient blood flow. Conditions such as tennis elbow, plantar fasciitis, and tendinitis have also been successfully treated with ESWL; see for example [32], [58].

In ESWL applications the shock wave is often focusing in a region where there is a complicated mix of bones and tissue. The interfaces between these materials cause significant reflection of wave energy. It is often crucial to insure that the shocks do not accidentally refocus in undesirable locations, such as nearby organs or nerves, which could potentially cause extensive collateral damage. Ideally one would like to be able

to use MRI data from a patient to set material parameters and run 3d simulations of the shock wave propagation in order to adjust the angle of the beam to achieve maximal impact in the desired region with minimal focusing elsewhere. Our current work is a first step in this direction.

**Volcanic flows.** My recent student Marica Pelanti developed a dusty gas model in which the Euler equations for atmospheric gas are coupled to another set of conservation laws for the mass, momentum, and energy of a dispersed dust phase [49], [50]. The two sets of equations are coupled together by source terms modeling viscous drag and heat transfer between the phases. The dust is assumed pressureless and requires special Riemann solvers, based on [45]. This model has been used to study the jets arising from high-velocity volcanic eruptions.

The speed of sound in a dusty gas is considerably less than the sound speed in the atmosphere. As a result, volcanic jets can easily be supersonic relative to the dusty gas sound speed, leading to interesting shock wave structures within an eruption column. Pelanti explored this for 2D axi-symmetric jets for both flat topography and for topography where the jet expands through an idealized conical crater. Similar work has been performed by Augusto Neri and Tomaso Esposti Ongaro in the Earth Sciences Department at the University of Pisa and we are now collaborating with them on some comparisons of our results.

We have also interacted extensively with researchers at the USGS Cascade Volcano Observatory (CVO) near Mount St. Helens (MSH), who study many aspects of volcanic flows and are charged with hazard assessment for MSH. After a long quiescent period, MSH became quite active again in October, 2004, and we worked with these researchers to try to produce a full three-dimensional model of pyroclastic flows over the topography of MSH in order to predict the possible impact of an eruption of various magnitudes. Extension of the dusty gas model to the full three-dimensional topography of MSH is underway, although it turns out there are many numerical and modeling issues still to be tackled.

Considerable data is available from the 1980 eruption that can be used to validate a code. In particular, there is a set of photographs and maps that show the direction in which trees were blown down when the initial pyroclastic blast from the eruption passed over the surrounding ridges. The blown-down trees created a snapshot of the velocity vectors in the leading edge of the flow. These exhibit complex flow patterns, such as recirculation zones on the lee side of ridges where the trees were blown down in the direction pointing towards MSH instead of away. We hope to eventually compare computed velocities from our simulations with these observations.

Richard Iverson and Roger Denlinger at CVO have also done extensive work on modeling debris flows, such as those that arise when water from melting glaciers on a volcano mixes with trees, boulders, and other debris, creating highly damaging and life-threatening flows [20], [21]. Their numerical work is based on equations similar to the shallow water equations but enhanced with more physics within the flow. They use Riemann solver techniques based in part on the wave-propagation framework, with the

additional solution of an elasticity problem within each Riemann solver to compute the local stress tensor within the debris. They encounter difficulties at the edge of the flow similar to the dry-cell problems that arise in tsunami modeling (discussed below) and we have collaborated with them on solving these problems. Denlinger has also recently modeled the great Missoula floods using similar techniques [22].

**Tsunami modeling.** David George and I have been developing a version of AMRCLAW capable of modeling tsunamis, including both their global propagation over large expanses of ocean and the inundation and run-up around small scale features at the level of individual beaches or harbors. We solve the shallow water equations on rectangular grids, in which each grid cell has an elevation value for the earth surface (which is called topography if it is above sea level, or bathymetry when underwater). The components of $q$ are the fluid depth $h$ and momenta $hu$ and $hv$. Grid cells above sea level are dry ($h = 0$) and cells can become wet or dry dynamically as waves move along the shore. This approach avoids the need to model the shoreline as a separate interface, but developing a robust code based on this approach requires a Riemann solver that can deal well with both wet and dry states. The bathymetry comes in as a source term in the conservation laws. Away from shore the bathymetry is varying on a scale of several kilometers (the Indian Ocean is about 4 km deep, for example) whereas a tsunami propagating over the ocean is a few meters high at most. This difference in scales leads to difficulties that I will not describe here, and requires the use of some sort of "well-balanced" scheme in which the source term is incorporated into the Riemann solver. Though of small magnitude in the ocean, a tsunami may have a wavelength of more than 100 km and so the shallow water equations are an appropriate model. The propagation velocity is $\sqrt{gh}$, where $g$ is the gravitational constant, and as they approach shore $h$ decreases and the wave magnitude increases as the wavelength shortens, the same phenomenon observed in breaking waves on a beach. But in a tsunami the entire water column is set in motion by an uplifting of the ocean floor, whereas in wind-driven surface waves only the water very near the surface is moving. The enormous energy tsunamis carry gives them great destructive potential.

Adaptive mesh refinement is essential for this problem. We wish to propagate waves over the ocean, where grid cells several kilometers on a side can be used, and simultaneously predict the run-up around local features, where cell sizes of a few meters are desirable. Developing a well-balanced dry-state Riemann solver that works well in the context of AMR proved to be quite challenging and many difficulties appeared at the boundaries between grids at different levels. These could only be solved by some substantial reworking of the AMRCLAW code. The result is a special-purpose program that incorporates these algorithmic modifications and can now be applied to many tsunami scenarios. It is currently being tested by comparing predictions with measurements made at various places around the Indian Ocean in the wake of the 26 December 2004 Sumatra earthquake.

For this application we are working very closely with tsunami scientists. Our involvement in tsunami modeling arose out of a joint NSF grant with Harry Yeh in

civil engineering at Oregon State University and Joe Hamack at Penn State, who were doing wave tank experiments and related mathematical modeling that they wished to complement with numerical simulations. Since the Sumatra event, our focus has shifted to the larger scale, and the contacts we had already established in the tsunami modeling community proved invaluable. Many Tsunami Survey Teams traveled to the Indian Ocean and surveyed different parts of the coastline, measuring the run-up and inundation observed. Yeh was on a team that mapped the region near Chennai (Madras), India, and our initial validation work is focused on comparing predictions with his observations in this area. Unfortunately fine-scale bathymetry data is hard to come by and we have resorted to digitizing navigational charts to obtain some of the necessary data.

Figure 2 shows part of a simulation of the Indian Ocean tsunami, as described further in the caption. See the webpage [39] for color versions and movies, along with the computer program.

The program we have developed is a research code for this particular problem, but we intend to further improve it and ultimately make it available to the community. There is far more data available than we can compare against ourselves and we hope that other researchers will be able to use it for some of this work and publish the results. If our code does not work well or does not agree well with observations in some cases then we may need to revisit it, or perhaps others will make further improvements to it.

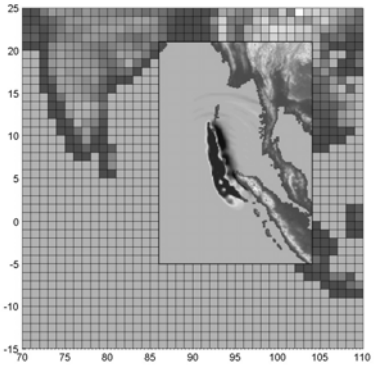
We hope that this code may ultimately be useful as a real-time tsunami prediction tool, and we are working with Vasily Titov and other scientists of the NOAA National Tsunami Hazard Mitigation Program in Seattle to compare our code with theirs and see how we can best complement their efforts (some of which are described in a recent Scientific American article [28]).

## 8. Conclusions

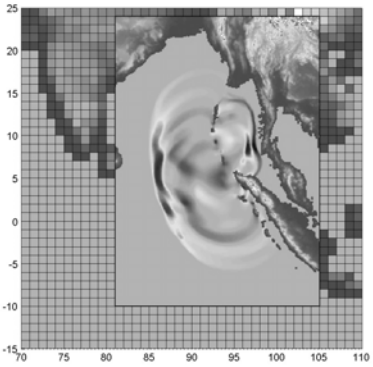
I have made a case that many aspects of scientific computing and software development should be viewed as inherently mathematical, and that mathematicians can play a very important role in computational science. I have also encouraged researchers in this area to produce reproducible research, in particular by making computer programs, not just software, available to others. I have presented some of my own research activities as a case study, though I do not claim it is the best example to follow.

I do hope, however, that the software we have produced will find wider use as one tool in this direction, both as a development environment for testing new methods and as a building block for solving problems in science and engineering. My hope is that others who develop methods or applications using this package will make their full code available on the web, particularly if it has been used to compute results that appear in publications.

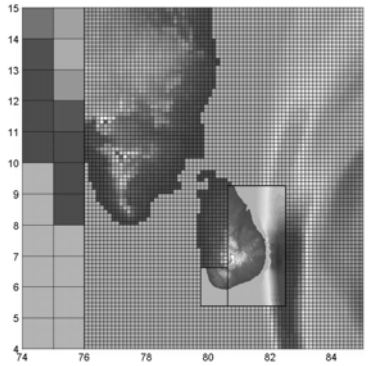
(a) Time 01:06:45 (525 seconds)



(b) Time 02:10:55 (4375 seconds)



(c) Time 02:43:00 (6300 seconds)



(d) Time 3:15:05 (8225 seconds)

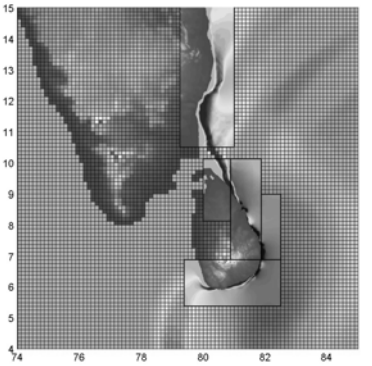


Figure 2. Propagation of the 26 December 2004 tsunami across the Indian Ocean. Units on the axes are longitude and latitude. The top two frames show the Bay of Bengal at two early times. A coarse grid is used where nothing is yet happening and the grid cells are shown on this "Level 1 grid", which has a mesh width of one degree (approximately 111 km). The rectangular region where no grid lines are shown is a Level 2 grid with mesh width 8 times smaller, about 14 km. Red represents water elevation above sea level, dark blue is below the undisturbed surface (see the webpage [39] for color versions of these images). Figure (c) shows a zoomed view of the southern tip of India and Sri Lanka at a later time. The original Level 1 grid is still visible along the left-most edge, but the rest of the region shown has been refined by a Level 2 grid. Part of Sri Lanka has been refined by Level 3 grids. The grid lines on Level 3 are not shown; the mesh width on this level is about 1.7 km, a factor of 8 finer than Level 2. Figure (d) shows a later time, as the wave diffracts around Sri Lanka, moving slowly through the shallow water in this coastal region. The calculation shown here was run on a single-processor 3.2 GHz PC under Linux and took about 40 minutes of wall time for the computation shown here. Movies of this simulation can be viewed on the webpage [39], which also contains pointers to finer grid calculations and more recent work on this problem.

Even for results that are not published, it would be valuable to have more examples and test problems available on-line than what is provided on the CLAWPACK web pages. Please let me know with a brief email if you have created such a page, or published a paper where CLAWPACK was successfully used.

I am also always interested to hear about problems that arise with the software or suggestions for improvements, though as an academic researcher with a small group of graduate students I cannot promise to provide as much technical support as I would like to.

The website [39] contains the codes used to generate the two figures in this paper, two very different examples of what can be provided in conjunction with a publication. The programs for Figure 1 are each less than a page of MATLAB, while the program for Figure 2 is about 13,000 lines of Fortran and also requires a large set of bathymetry and earthquake source data. The webpages also contain movies that illustrate the figures much better than the static versions shown in this paper, and links to other related work.

**Acknowledgments.** Numerous people read drafts of this paper and provided valuable comments and pointers to related work. In particular I would like to thank Marsha Berger, Donna Calhoun, Benjamin LeVeque, William LeVeque, and Nick Trefethen for their extensive comments, and David George for pulling together the necessary pieces for Figure 2.

# Reduced basis method for the rapid and reliable solution of partial differential equations

Yvon Maday*

**Abstract.** Numerical approximation of the solution of partial differential equations plays an important role in many areas such as engineering, mechanics, physics, chemistry, biology – for computer-aided design-analysis, computer-aided decision-making or simply better understanding. The fidelity of the simulations with respect to reality is achieved through the combined efforts to derive: (i) better models, (ii) faster numerical algorithm, (iii) more accurate discretization methods and (iv) improved large scale computing resources. In many situations, including optimization and control, the *same* model, depending on a parameter that is changing, has to be simulated over and over, multiplying by a large factor (up to 100 or 1000) the solution procedure cost of one single simulation. The reduced basis method allows to define a surrogate solution procedure, that, thanks to the complementary design of fidelity certificates on outputs, allows to speed up the computations by two to three orders of magnitude while maintaining a sufficient accuracy. We present here the basics of this approach for linear and non linear elliptic and parabolic PDE's.

**Mathematics Subject Classification (2000).** 65D05, 65M60, 65N15, 65N30, 65N35.

**Keywords.** Reduced-basis, a posteriori error estimation, output bounds, offline-online procedures, Galerkin approximation, parametrized partial differential equations.

## 1. Introduction

Let us consider a class of problems depending on a parameter $\mu \in \mathcal{D}$ set in the form: find $u \equiv u(\mu) \in X$ such that $\mathcal{F}(u;\mu) = 0$ (we do not specify much at this point what $\mathcal{D}$ is, it could be a subset of $\mathbb{R}$, or $\mathbb{R}^p$, or even a subset of functions). Such problems arise in many situations such as e.g. optimization, control or parameter-identification problems, response surface or sensibility analysis. In case $\mathcal{F}$ is written through partial differential equations, the problem may be stationary or time dependent but in all these cases, a solution $u(\mu)$ has to be evaluated or computed for many instances of $\mu \in \mathcal{D}$. Even well optimized, the favorite discretization method of yours

*This paper presents a review of results (on the definition, analysis and solution strategies) most of them first presented elsewhere and that have benefitted from the long-standing collaboration with Anthony T. Patera, Einar M. Rønquist, Gabriel Turinici, and more recently Annalisa Buffa, Emil Løvgren, Ngoc Cuong Nguyen, Georges Pau, Christophe Prud'homme. This paper is not intended to be exhaustive and is an invitation to read more complete papers that treat in depth the features presented here. Due to this, no figures nor tables synthesizing numerical results are provided.

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

will lead to very heavy computations in order to approximate all these solutions and decision may not be taken appropriately due to too large computer time for reliable simulations.

The approach discussed in this paper will not aim at presenting an alternative to your favorite discretization, more the contrary. The idea is that, in many cases, your discretization will help in constructing a surrogate method that will allow to mimic it or at least to do the spadework on the evaluation of the optimal or control solution. The complexity of the equations resulting from this approach will be very low, enabling very fast solution algorithms. No miracle though, the method is based on a learning strategy concept, and, for a new problem, the preliminary *off-line* preparation is much time consuming. It is only after this learning step that the full speed of the method can be appreciated *on-line*, paying off the cost of the *off-line* preparation step. During the first step, we evaluate accurately, based on your preferred solver, a few solutions to $\mathcal{F}(u;\mu) = 0$; actually, any discretization method is good enough here. In the second step, that is involved on request and *on-line*, the discretization method that has been used earlier is somehow forgotten and a new discretization approach is constructed based on a new ad-hoc basis set (named "reduced basis") built out from the previous computations. In many cases the method proves very efficient and – even though the complete understanding of the reasons why it is working so well are not mastered – an *a posteriori* error theory allows to provide fidelity certificates on outputs computed from the reduced-basis-discretized solution. This method is valid in case the set $\mathcal{S}(\mathcal{D}) = \{u(\mu),\ \mu \in \mathcal{D}\}$ has a simple (hidden) structure, the solution $u(\mu)$ has to be regular enough in $\mu$. We provide some explanations on the rational of the reduced basis approximation in Section 2 and present the method in the elliptic case. In Section 3 we give more rigorous explanation on the rapid convergence of the method on a particular case. This is complemented in Section 4 by an analysis of a posteriori tools that provide fidelity certificate for outputs computed from the reduced basis approximation. Section 5 tells more about the track to follow to be convinced that the method will "work" on the particular problem of yours. The efficient implementation of the reduced basis method needs some care, we present in Section 6 some of the required tools. Finally we end this paper by providing in Section 7 some of the new directions we are currently working on.

## 2. Basics and rational of the reduced basis approach

The reduced basis method consists in approximating the solution $u(\mu)$ of a parameter dependent problem $\mathcal{F}(u;\mu) = 0$ by a linear combination of appropriate, preliminary computed, solutions $u(\mu_i)$ for well chosen parameters $\mu_i, i = 1, \ldots, N$. The rational of this approach, stands in the fact that the set $\mathcal{S}(\mathcal{D}) = \{u(\mu)$ of all solutions when $\mu \in \mathcal{D}\}$ behaves well. In order to apprehend in which sense the good behavior of $\mathcal{S}(\mathcal{D})$ should be understood, it is helpful to introduce the notion of $n$-width following Kolmogorov [8] (see also [14]).

**Definition 2.1.** Let $X$ be a normed linear space, $A$ be a subset of $X$ and $X_n$ be a generic $n$-dimensional subspace of $X$. The deviation of $A$ from $X_n$ is

$$E(A; X_n) = \sup_{x \in A} \inf_{y \in X_n} \|x - y\|_X.$$

The *Kolmogorov n-width* of $A$ in $X$ is given by

$$\begin{aligned} d_n(A, X) &= \inf\{E(A; X_n) : X_n \text{ an } n\text{-dimensional subspace of X}\} \\ &= \inf_{X_n} \sup_{x \in A} \inf_{y \in X_n} \|x - y\|_X. \end{aligned} \tag{1}$$

The $n$-width of $A$ thus measures the extent to which $A$ may be approximated by an $n$-dimensional subspace of $X$. There are many reasons why this $n$-width may go rapidly to zero as $n$ goes to infinity. In our case, where $A = \mathcal{S}(\mathcal{D})$, we can refer to regularity of the solutions $u(\mu)$ with respect to the parameter $\mu$, or even to analyticity. Indeed, an upper bound for the asymptotic rate at which the convergence to zero is achieved is provided by this example from Kolmogorov stating that $d_n(\tilde{B}_2^{(r)}; L^2) = \mathcal{O}(n^{-r})$ where $\tilde{B}_2^{(r)}$ is the unit ball in the Sobolev space of all $2\pi$-periodic real valued, $(r-1)$-times differentiable functions whose $(r-1)$st derivative is absolutely continuous and whose $r$th derivative belongs to $L^2$. Actually, exponential convergence is achieved when analyticity exists in the parameter dependency. The knowledge of the rate of convergence is not sufficient: of theoretical interest is the determination of the (or at least one) optimal finite dimensional space $X_n$ that realizes the infimum in $d_n$, provided it exists. For practical reasons, we want to restrict ourselves to finite dimensional spaces that are spanned by elements of $\mathcal{S}(\mathcal{D})$. This might increase the $n$-width in general Banach space, but of course it does not in Hilbert space as it follows easily from the decomposition of $X$ into $X_A \oplus X_A^{\perp}$, where $X_A$ denotes the vectorial space spanned by $A$. We thus have

$$d_n(A, X_A) = d_n(A, X). \tag{2}$$

We derive from this equality that the quantity

$$\inf \left\{ \sup_{u \in \mathcal{S}(\mathcal{D})} \inf_{y \in X_n} \|x - y\|_X : X_n = \text{Span}\{u(\mu_1), \ldots, u(\mu_n),\ \mu_i \in \mathcal{D}\} \right\} \tag{3}$$

converges to zero (almost at the same speed as $d_n(\mathcal{S}(\mathcal{D}); X)$ provided very little regularity exists in the parameter dependency of the solution $u(\mu)$, and an exponential convergence is achieved in many cases since analyticity in the parameter is quite frequent.

This is at the basics of the reduced basis method. Indeed we are led to choose properly a sequence of parameters $\mu_1, \ldots, \mu_n, \ldots \in \mathcal{D}$, then define the vectorial space $X_N = \text{Span}\{u(\mu_1), \ldots, u(\mu_N)\}$ and look for an approximation of $u(\mu)$ in $X_N$.

Let us consider for example an elliptic problem: Find $u(\mu) \in X$ such that

$$a(u(\mu), v; \mu) = f(v) \quad \text{for all } v \in X. \tag{4}$$

Here $X$ is some Hilbert space, and $a$ is a continuous and elliptic, bilinear form in its two first arguments, regular in the parameter dependance and $f$ is some given continuous linear form. We assume for the sake of simplicity that the ellipticity is uniform with respect to $\mu \in \mathcal{D}$: there exists $\alpha > 0$ such that

$$a(u, u; \mu) \geq \alpha \|u\|_X^2 \quad \text{for all } \mu \in \mathcal{D},\ u \in X,$$

and that the continuity of $a$ is uniform with respect to $\mu \in \mathcal{D}$ as well: there exists $\gamma > 0$ such that

$$|a(u, v; \mu)| \leq \gamma \|u\|_X \|v\|_X \quad \text{for all } \mu \in \mathcal{D},\ u, v \in X.$$

It is classical to state that, under the previous hypothesis, problem (4) has a unique solution for any $\mu \in \mathcal{D}$. The Galerkin method is a standard way to approximate the solution to (4) provided that a finite dimensional subspace $X_N$ on $X$ is given. It consists in: Find $u_N(\mu) \in X_N$ such that

$$a(u_N(\mu), v_N; \mu) = f(v_N) \quad \text{for all } v_N \in X_N, \tag{5}$$

which similarly has a unique solution $u_N(\mu)$. Cea's lemma then states that

$$\|u(\mu) - u_N(\mu)\|_X \leq \left(1 + \frac{\gamma}{\alpha}\right) \inf_{v_N \in X_N} \|u(\mu) - v_N\|_X. \tag{6}$$

The best choice for the basis element $u(\mu_1), \ldots, u(\mu_N)$ of $X_N$ would be those that realize the infimum in (3), i.e. the ones that realize the maximum of the volume $V_N(u(\mu_1), \ldots, u(\mu_N))$ of the parallelepiped determined by the vectors $u(\mu_1), \ldots, u(\mu_N)$. Unfortunately, this is not a constructive method and we generally refer to a greedy algorithm such as the following one:

$$\begin{aligned} \mu_1 &= \arg \sup_{\mu \in \mathcal{D}} \|u(\mu)\|_X, \\ \mu_{i+1} &= \arg \sup_{\mu \in D} \|u(\mu) - P_i u(\mu)\|_X, \end{aligned} \tag{7}$$

where $P_i$ is the orthogonal projection onto $X_i = \text{Span}\{u(\mu_1), \ldots, u(\mu_i)\}$ or a variant of it that is explained at the end of Section 4. The convergence proof for the related algorithm is somehow more complex and presented in a quite general settings in [1].

## 3. An example of *a priori* analysis

The previous notion of $n$-width is quite convenient because it is rather general, in spirit, and provides a tool to reflect the rapid convergence of the reduced basis method but it is not much constructive nor qualitatively informative. We are thus going to consider

a particular example where the parametrized "bilinear" form $a\colon X \times X \times \mathcal{D} \to \mathbb{R}$ is defined as follows

$$a(w, v; \mu) \equiv a_0(w, v) + \mu a_1(w, v); \tag{8}$$

here the bilinear forms $a_0\colon X \times X \to \mathbb{R}$ and $a_1\colon X \times X \to \mathbb{R}$ are continuous, symmetric and positive semi-definite, $\mathcal{D} \equiv [0, \mu_{\max}]$, and we assume that $a_0$ is coercive. It follows from our assumptions that there exists a real positive constant $\gamma_1$ such that

$$0 \leq \frac{a_1(v, v)}{a_0(v, v)} \leq \gamma_1 \quad \text{for all } v \in X. \tag{9}$$

For the hypotheses stated above, it is readily demonstrated that the problem (4) satisfies uniformly the Lax–Milgram hypothesis.

Many situations may be modeled by this rather simple problem statement (4), (8). It can be the conduction in thin plates and $\mu$ represents the convective heat transfer coefficient, it can also be a variable-property heat transfer, then $1 + \mu$ is the ratio of thermal conductivities in domains.

The analysis that we did in [12] involves the eigenproblem: Find $(\varphi \in X, \lambda \in \mathbb{R})$, satisfying $a_1(\varphi, v) = \lambda\, a_0(\varphi, v)$ for all $v \in X$. Indeed the solution $u(\mu)$ to problem (4) can be expressed as

$$u(\cdot, \mu) = \int \frac{f(\varphi)\, \varphi(\cdot; \lambda)}{1 + \mu\lambda} d\lambda. \tag{10}$$

The dependency in $\mu$ is thus explicitly expressed and we can propose to approximate $u(\mu)$ by a linear combination of well chosen $u(\mu_i)$. This can be done through interpolation at the $\mu_i$ by polynomials. It is interesting to notice at this point that we have a large choice in the variable in which the polynomial can be expressed. Indeed since we are interested through this interpolation process to evaluate the best fit, a polynomial in $\mu$ may not be the best choice but rather a polynomial in $\frac{1}{\mu}$, $e^{\mu}$ or else; in [12] we have considered a polynomial approximation in the variable $\tau = \ln(\mu + \delta^{-1})$, where $\delta$ is some positive real number. The analysis then involves the interpolation operator at equidistant points (in the variable $\tau$) for which we were able to get an upper bound used, in turn, to qualify the best fit result

**Lemma 3.1.** *There exists a constant $C > 0$ and a positive integer $N_{\text{crit}}$ such that for $N \geq N_{\text{crit}}$*

$$\inf_{w_N \in X_N} \|u(\mu) - w_N\|_X \leq C \exp\left\{\frac{-N}{N_{\text{crit}}}\right\} \quad \textit{for all } \mu \in \mathcal{D},$$

*where $N_{\text{crit}} \equiv c^* e\, \ln(\gamma\, \mu_{\max} + 1)$.*

This analysis of [12] leads to at least three remarks:

**Remark 3.2.** a) The analysis of the best fit done here suggests to use sample points $\mu_i$ that are equidistant when transformed in the $\tau$ variable. We performed some numerical

tests to check whether this sampling gives indeed better results than more conventional ones (of course you should avoid equidistant in the original $\mu$ variable, but we tried e.g. Chebyshev points) and this was actually the case. Unfortunately, in more general situations and especially in higher parameter dimensions, we have no clue of a direct constructive best sampling method.

b) For a given sampling $\mu_i$, one can propose an interpolation procedure to approximate $u(\mu)$ which is more simple than referring to a Galerkin approach. Indeed, an approximation

$$u(\mu) \simeq \sum_{i=1}^{N} \alpha_i(\mu) u(\mu_i),$$

can be proposed by using coefficients that are the Lagrange interpolation basis in the chosen variable (above it was $\tau = \ln(\mu + \delta^{-1})$, i.e. the mapping $\tau \mapsto \alpha_i(\mu(\tau))$ is a polynomial of degree $\leq N$ and $\alpha_i(\mu_j) = \delta_{ij}$). The problem is that the expression of $\alpha_i(\mu)$ depends on the best choice of variable which is unknown and within a set that is quite infinite providing a range of results that are quite different. Since for a given general problem we have no clue of the best interpolation system, the Galerkin approach makes sense, indeed.

c) In opposition, the Galerkin approach does not require any preliminary analysis on guessing the way the solution depends upon the parameter. Its superiority over interpolation process comes from the fact stated in Cea's lemma that the approximation that is obtained, up to some multiplicative constant, gives the optimal best fit, even if we do not know the rate at which the convergence is going.

Finally, as is often the case, we should indicate that the a priori analysis helps to have confidence in developing the method but, at the end of a given computation, a computable a posteriori estimator should be designed in order to qualify the approximation. This is even more true with such new surrogate approximation in order to replace the expertise a user may have in his preferred method, e.g. his intuition on the choice of the discretization parameter to get acceptable discrete solutions. This is the purpose of the next section.

## 4. An example of *a posteriori* analysis

Most of the time, the complete knowledge of the solution of the problem (4) is not required. What is required, is outputs computed from the solution $s = s(u)$, where $s$ is some continuous functional defined over $X$. In order to have a hand over this output, the reduced basis method consists first in computing $u_N \in X_N$ solution of the Galerkin approximation (5), then propose $s_N = s(u_N)$ as an approximation of $s$. Assuming Lipschitz condition (ex. linear case) over $s$, it follows that

$$|s - s_N| \leq c\|u - u_N\|_X. \tag{11}$$

Thus any information over the error in the energy norm will allow to get verification (provided you are able to evaluate $c$). Actually it is well known that the convergence of $s_N$ towards $s$ most often goes faster. This is standard but we go back over it since this will prove useful in the sequel. Let us assume we are in the linear output case where $s \equiv \ell$ is a linear continuous mapping over $X$. It is then standard to introduce the *adjoint state*, solution of the following problem: find $\psi \in X$ such that

$$a(v, \psi; \mu) = -\ell(v) \quad \text{for all } v \in X. \tag{12}$$

The error in the output is then (remember that, for any $\phi_N \in X_N$, $a(u, \phi_N; \mu) = a(u_N, \phi_N; \mu) = (f, \phi_N)$)

$$\begin{aligned} s_N - s &= \ell(u_N) - \ell(u) \\ &= a(u, \psi; \mu) - a(u_N, \psi; \mu) \\ &= a(u, \psi - \phi_N; \mu) - a(u_N, \psi - \phi_N; \mu) \quad (\text{for all } \phi_N \in X_N) \\ &= a(u - u_N, \psi - \phi_N; \mu) \quad (\text{for all } \phi_N \in X_N) \\ &\leq c\|u - u_N\|_X \|\psi - \phi_N\|_X \quad (\text{for all } \phi_N \in X_N), \end{aligned} \tag{13}$$

so that the best fit of $\psi$ in $X_N$ can be chosen in order to improve the first error bound (11) that was proposed for $|s - s_N|$.

For instance if $\psi_N$ is the solution of the Galerkin approximation to $\psi$ in $X_N$, we get

$$|s - s_N| \leq c\|u - u_N\|_X \|\psi - \psi_N\|_X. \tag{14}$$

Actually, the approximation of $\psi$ in $X_N$ may not be very accurate since $X_N$ is well suited for approximating the elements $u(\mu)$ and – except in the case where $\ell = f$ named the compliant case – a separate reduced space $\tilde{X}_N$ should be built which provides an associated approximation $\tilde{\psi}_N$. Then an improved approximation for $\ell(u)$ is given by $\ell_{\text{imp}} = \ell(u_N) - a(u_N, \tilde{\psi}_N) + f(\tilde{\psi}_N)$ since (14) holds with $\|\psi - \tilde{\psi}_N\|_X$ for which a better convergence rate is generally observed.

Even improved, this result is still *a priori* business and it does not allow to qualify the approximation for a given computation. In order to get *a posteriori* information, between $\ell(u)$ and $\ell(u_N)$ (or $\ell_{\text{imp}}$), we have to get a hand on the residuals in the approximations of the primal and dual problems. We introduce for any $v \in X$,

$$\mathcal{R}^{\text{pr}}(v; \mu) = a(u_N, v; \mu) - \langle f, v \rangle, \quad \mathcal{R}^{\text{du}}(v; \mu) = -a(v, \tilde{\psi}_N; \mu) - \ell(v). \tag{15}$$

We then compute the reconstructed errors associated with the previous residuals. These are the solutions of the following problems:

$$2\alpha \int \nabla \hat{e}^{\,\text{pr(du)}} \nabla v = \mathcal{R}^{\text{pr(du)}}(v; \mu) \quad \text{for all } v. \tag{16}$$

We then have

**Theorem 4.1.** *Let* $s^- = \ell_{\rm imp} - \alpha \int [\nabla(\hat{e}^{\,\rm pr} + \hat{e}^{\,\rm du})]^2$ *then* $s^- \le s$. *In addition, there exists two constants* $0 < c \le C$ *such that*

$$c|s - s_N| \le s - s^- \le C|s - s_N|.$$

*Proof.* Let us denote by $e_N$ the difference between the exact solution and the approximated one $e_N = u - u_N$. From (16), we observe that

$$2\alpha \int \nabla \hat{e}^{\rm pr} \nabla e_N = -a(e_N, e_N; \mu)$$

and

$$2\alpha \int \nabla \hat{e}^{\rm du} \nabla e_N = -a(e_N, \tilde{\psi}_N; \mu) - \ell(e_N) = f(\tilde{\psi}_N) - a(u_N, \tilde{\psi}_N) - \ell(e_N).$$

Taking this into account allows to write

$$\begin{aligned} \ell_{\rm imp} - \alpha \int \nabla(\hat{e}^{\rm pr} + \hat{e}^{\rm du})^2 &= \ell(u_N) - a(u_N, \tilde{\psi}_N) + f(\tilde{\psi}_N) - \alpha \int \nabla(\hat{e}^{\rm pr} + \hat{e}^{\rm du})^2 \\ &= \ell(u) - \alpha \int \nabla(e_N + \hat{e}^{\rm pr} + \hat{e}^{\rm du})^2 - a(e_N, e_N; \mu) + \alpha \int [\nabla e_N]^2, \end{aligned} \tag{17}$$

and the proof follows from the uniform ellipticity of $a(\,.\,,.\,;\mu)$. □

Despite the fact that we have avoided to speak about any discretization so far, Theorem 4.1 is already informative in the sense that in order to obtain $s^-$, the problem (16) to be solved, is parameter independent and simpler than the original one, provided that we have a good evaluation of the ellipticity constant. In Section 6 we shall explain how to transform these constructions in a method that can be implemented. Before this we should explain how the previous estimator may help in designing a good choice for the elements of the reduced basis, providing a third alternative to the greedy algorithm presented in (7). Currently indeed, we have two alternative, either a random approach (that generally works not so badly) or select out of a large number of pre-computed solution $\{u_i\}_i$, the best sample from a SVD approach by reducing the matrix of scalar products $(u_i, u_j)$. The former lacks of fiability, the latter is a quite expensive approach and is mostly considered in a pre analysis framework as is explained in the next section. In order to reduce the cost of the off-line stage we can propose a greedy algorithm that combines the reduced approximation and the error evaluation:

- Take a first parameter (randomly).
- Use a (1-dimensional) reduced basis approach over a set of parameter values (chosen randomly) and select, as a second parameter, the one for which the associated predicted error $s^+ - s^-$ is the largest.

This gives now a 2-dimensional reduced basis method.

- Use this (2-dimensional) reduced basis approach over the same set of parameters and select, as a third parameter, the one for which the associated error is the largest.

This gives a 3-dimensional reduced basis method ...

- and proceed ...

Note that we then only compute accurately the solutions corresponding to the parameters that are selected this way.

The a posteriori approach that has been presented above relies on the uniform ellipticity of the bilinear form and the knowledge of the ellipticity constant. For more general problems, where only, nonuniform inf-sup conditions are valid (e.g. the noncoercive Helmholtz acoustics problem which becomes singular as we approach resonance) smarter definitions should be considered. We refer to [18] for improved methods in this direction.

## 5. Some pragmatic considerations

Now that some basics on the reduced basis method have been presented, it is interesting to understand if the problem you have in mind is actually eligible to this type of approximation. We are thus going to propose some pragmatic arguments that may help in the preliminary verification. First of all, let us note that we have illustrated the discretization on linear elliptic problems, of course this is just for the sake of simplicity, non linear problem [11], [19], [20] so as time dependent problems [7], [17] can be solved by these methods. Second, many things can be considered as a valid parameter: this can be the size of some simple geometric domain on which the solution is searched [16] , but it can be the shape itself [13] (the parameter in the former case is a multireal entity while in the latter it is a functional), the parameter can also be the time [7], [17] , or the position of some given singularities [2].

For all these choices, a fair regularity in the parameter is expected and wished so that the $n$-width goes fast to zero. An important remark has to be done here in order the size of the reduced basis be the smallest possible. Indeed, it may be smart to preprocess the precomputed solutions in order they look more similar. An example is given in [2] where quantum problem are considered; the solutions to these problems present some singularities at the position of the nuclei. If the position of the nuclei is the parameter we consider, it is useful to transform each solution in a reference configuration where the singularities/nuclei are at a unique place; the solutions are then much more comparable. Another example is given by the solution of the incompressible Stokes and Navier–Stokes problem where the shape of the computational domain is the parameter; in order to be able to compare them properly, they have to be mapped on a unique (reference) domain. This is generally done through a simple change of variable. In case of the velocity, it is a vector field that is divergence

free and a "standard" change of variable will (generally) not preserve this feature. The Piola transform (that actually corresponds to the classical change of variable over the potential function) allows to have the velocity fields transformed over the reference domain while preserving the divergence free condition as is demonstrated in [9]. These preprocessing steps allow to diminish the $n$-width of $\mathcal{S}(\mathcal{D})$ and it pays to be smart!

In order to sustain the intuition on the potential of the reduced basis concept, a classical way is to use a SVD approach. Let us assume that we have a bunch of solutions $u_i = u(\mu_i)$, snapshots of the space $\mathcal{S}(\mathcal{D})$ of solutions to our problem. Out of these, the correlation matrix $(u_i, u_j)$ which is symmetric can be reduced to its eigen-form, with positive eigenvectors that, ranked in decreasing order, go to zero. The high speed of convergence towards zero of the eigenvalues ranked in decreasing order will sustain the intuition that the reduced basis method will work. Indeed, the $n$-width is directly related to the size of the eigenvalues larger than the $n+1$th. The idea is that if the number of eigenvectors associated with the largest eigenvalues is small, then the method is viable. In order to sustain this, you can also consider, momentarily, the space $X_N$ spanned by the eigenvectors associated with the $N$ largest eigenvalues and analyze the norm of the difference between the snapshots in $\mathcal{S}(\mathcal{D})$ and their best fit in $X_N$. Note that we do not claim that this is a cheap constructive method: this procedure consists in a pre-analysis of the potential of the reduced basis method to approximate the problem you consider. If the norm of the error goes to zero sufficiently fast, you know that a Galerkin approach will provide the same order of convergence and the method is worth trying. We insist on the fact that this pre-analysis is not mandatory, it is only to help in understanding what you should expect, "at best" from the reduced basis approximation. In particular the greedy approach presented in Section 4 has to be preferred to the SVD approach that we discussed above for the determination of the elements that are to be incorporated in the reduced basis space, if you do not want to spend too much time during the off-line stage. Note also that the greedy approach provides solutions, that, when their number becomes large, become more and more linearly dependent (actually this is one of the aspects of the low $n$-width) and thus, for stability purposes it is important, through a Gram–Schmidt process, to extract, from these solutions, orthonormal elements that will be the actual elements of the reduced basis: these will be named $(\zeta_i)_i$. This does not change the potential approximation properties of the reduced basis but improves, to a large extent, the stability of the implementation.

Finally, the preselection may be quite generous in the sense that you may be interested to select more than $N$ basis functions, $N$ being an evaluation of the dimension of the reduced basis for most problems. The reason for this comes from the conclusion of the a posteriori analysis that may tell you to increase the size of the reduced basis, suggesting you to work with $N+2$ (say) instead of $N$ basis functions. This again is a feature of exponentially rapid convergence that lead to a large difference between the accuracy provided by $X_N$ and $X_{N+2}$ (say). It is time now to give some details on the implementation of the method.

## 6. Implementation issues

We start by emphasizing that any reduced basis method necessarily involves the implementation of a more "classical" approximation method. Indeed – except for very particular and uninteresting problems – the knowledge of the solutions, that we named $u_i$, is impossible without referring to a discretization method (e.g. of finite element, spectral type, etc.). This is also the case for the $\zeta$ that are coming out from some shaping of the basis, e.g. Gram–Schmidt, as explained earlier. This is the reason why reduced basis methods should not be considered as competitor to standard approximation methods but only as surrogate approaches.

This implies, though, some difficulties since the elements of the *reduced* basis are only known through a preliminary *computation* basis, which, if we want the solution $u_i$ to be well approximated, has to be *very* large. Knowing this, the rule of the game for the efficient implementation of any reduced basis method is to strictly prohibit any *online* reference to the extended basis. We allow *offline* precomputations of the solutions (that involves the extended basis) and some *offline* cross contribution of these solutions (based on their expression with respect to the extended basis) but this is forbidden *online*. Following [16], we explain in the next subsection how this can be done.

**6.1. Black box approach.** The solution procedure involves the evaluation of the elements of the stiffness matrix $a(\zeta_i, \zeta_j; \mu), 1 \leq i, j \leq N$ that depends on the current parameter $\mu$. This computation involves some derivatives and the evaluation of integrals, that have to be performed and this may be *very* lengthy. It should be stated here that the implementation of the reduced type method has to be much faster than the solution procedure that was used to compute the reduced basis, much means many order of magnitude. The $\mathcal{O}(\dim X_N)^2$ entrees of the stiffness matrix have thus to be evaluated through some smart way.

Let us begin by the easy case that is named *affine parametric dependance* where the entries $a(\zeta_i, \zeta_j; \mu)$ appear to read

$$a(\zeta_i, \zeta_j; \mu) = \sum_p g_p(\mu) a_p(\zeta_n, \zeta_m), \tag{18}$$

where the bilinear forms $a_p$ are parameter independent. Many simple problems where the parameter are local constitutive coefficients or local zooming isotropic or non isotropic factors, enter in this framework. The expensive computation of the $a_{p,n,m} = a_p(\zeta_n, \zeta_m)$ can be done offline, once the reduced basis is constructed; these $a_{p,n,m}$ are stored and, for each new problem, the evaluation of the stiffness matrix is done, online, in $P \times N^2$ operations, and solved in $\mathcal{O}(\dim X_N^3)$ operations. These figures are coherent with the rapid evaluation of the reduced basis method.

**6.2. A posteriori implementation.** Under the same affine dependance hypothesis on $a$, it is easy to explain how the a posteriori analysis can be implemented, re-

sulting in a fast on-line solution procedure, provided some off-line computations are made. First of all the computation of $\tilde{\psi}_N$ can be implemented in the space $\tilde{X}_N = \text{Span}\{\xi_1, \ldots, \xi_N)\}$ exactly as above for the computation of $u_N$. Taking into account (18), together with the expressions obtained from the inversion of problem (5) and (12): $u_N = \sum_{i=1}^N \alpha_i \zeta_i$ and $\tilde{\psi}_N = \sum_{i=1}^N \tilde{\alpha}_i \xi_i$, we can write

$$\mathcal{R}^{\text{pr}}(v, \mu) = \sum_p \sum_i g_p(\mu)\alpha_i a_p(\zeta_i, v) - (f, v),$$

and

$$\mathcal{R}^{\text{du}}(v, \mu) = -\sum_p \sum_j g_p(\mu)\tilde{\alpha}_j a_p(v, \xi_j) - \ell(v),$$

hence by solving *numerically*, off-line, each of the problems

$$2\alpha \int \nabla e^{\text{pr},p,i} \nabla v = a_p(\zeta_i, v), \tag{19}$$

$$2\alpha \int \nabla e^{\text{pr},0} \nabla v = (f, v), \tag{20}$$

$$2\alpha \int \nabla e^{\text{du},p,j} \nabla v = a_p(v, \xi_j), \tag{21}$$

$$2\alpha \int \nabla e^{\text{du},0} \nabla v = \ell(v) \tag{22}$$

allows to write the numerical solutions of (16) as a linear combination of the elements previously computed (e.g. $\hat{e}^{\,\text{pr}} = \sum_p \sum_i g_p(\mu)\alpha_i e^{\text{pr},p,i} - e^{\text{pr},0}$) in $\mathcal{O}(PN)$ operations.

**6.3. Magic points.** The hypothesis of *affine parametric dependency* is rather restrictive, and has to be generalized. In case of quadratic or cubic dependency, this is quite straightforward but even for linear problems such as the Laplace problem, when e.g. geometry is the parameter, this is rarely the case and another approach has to be designed. In order to get a better understanding of the method, let us first indicate that, when the geometry is the parameter, the solutions have to be mapped over a reference domain $\hat{\Omega}$. Let us assume that we want to compute $d(\zeta_i, \zeta_j; \Omega)$ where

$$d(u, v; \Omega) = \int_\Omega uv \, dA = \int_{\hat{\Omega}} uv J_\Phi \, d\hat{A},$$

where $J_\Phi$ is a Jacobian of the transformation that maps $\hat{\Omega}$ onto $\Omega$. There is no reason in the general case that $J_\Phi$ will be affine so that the previous approach will not work. It is nevertheless likely that there exists a sequence of well chosen transformations $\Phi_1^*, \ldots, \Phi_M^*, \ldots$, such that $J_\Phi$ may be well approximated by an expansion $J_\Phi \simeq$

$\sum_{j=1}^{M} \beta_j J_{\Phi_j^*}$. An approximation of $d(\zeta_i, \zeta_j; \Omega)$ will then be given by

$$d(\zeta_i, \zeta_j; \Omega) \simeq \sum_{j=1}^{M} \beta_j \int_{\hat{\Omega}} \hat{\zeta}_i \hat{\zeta}_j J_{\Phi_j^*} \, d\hat{A}, \tag{23}$$

and again, the contributions $\int_{\hat{\Omega}} \hat{\zeta}_i \hat{\zeta}_j J_{\Phi_j^*} d\hat{A}$ will be pre-computed offline. We do not elaborate here on how the $\Phi_j^*$ are selected, and refer to [9], what we want to address is the evaluation of the coefficients $\beta_j = \beta_j(\Omega)$ in the approximation of $J_\Phi$ above. The idea is to use an interpolation procedure as is explained in [6]. Let $\boldsymbol{x}_1$ be the point where $|J_{\Phi_1^*}|$ achieves its maximum value. Assuming then that $\boldsymbol{x}_1, \ldots, \boldsymbol{x}_n$ have been defined, and are such that the $n \times n$ matrix with entries $J_{\Phi_k^*}(\boldsymbol{x}_\ell)$, $1 \leq k, \ell \leq n$ is invertible, we define $\boldsymbol{x}_{n+1}$ as being the point where $r_{n+1} = |J_{\Phi_{n+1}^*} - \sum_{k=1}^{n} \gamma_k J_{\Phi_k^*}|$ achieves it maximum value, here the scalar $\gamma_k$ are defined so that $r_{n+1}$ vanishes at any $(\boldsymbol{x}_\ell)$ for $\ell = 1, \ldots, n$. The definition of the points $\boldsymbol{x}_k$ is possible as long the $\Phi_j$ are chosen such that the $J_{\Phi_k^*}$ are linearly independent (see [6]). The $\beta_j$ are then evaluated also through the interpolation process

$$J_\Phi(\boldsymbol{x}_\ell) = \sum_{k=1}^{M} \beta_k J_{\Phi_k^*}(\boldsymbol{x}_\ell) \quad \text{for all } 1 \leq \ell \leq M. \tag{24}$$

We have not much theory confirming the very good results that we obtain (which makes us call these interpolation point "magic"). An indicator that allows to be quite confident in the interpolation process is the fact that the Lebesgue constant attached to the previously built points is, in all example we have encountered, is rather limited.

Note that the same interpolation approach allows to compute the reconstructed errors with a compatible complexity as in the previous subsection.

The same magic point method has to be used also for the implementation of the reduced basis method for nonlinear problems. Actually, denoting by $z_i = \mathrm{NL}(u_i)$ the nonlinear expression involved in the problem, provided that the set $Z_M = \mathrm{Span}\{z_i, 1 \leq i \leq M\}$ has a small width, the interpolation process presented above allows both to determine a good interpolation set and a good associated interpolation nodes, we refer to [6] for more details on the implementation and to numerical results.

## 7. Some extensions

**7.1. Eigenvalue problems.** We end this paper by noticing that the reduced basis method can actually be found, at least in spirit, in many other approximations. There are indeed many numerical approaches that, in order to tackle a complex problem, use the knowledge of the solution of similar but simpler problems to facilitate the approximation. In this direction, the modal synthesis method provides a method to solve approximately eigenvalue problems on large structures based on the knowledge

of the eigenvalues and eigenfunctions of the same problem on substructures. We refer e.g. to [4], [5] for more details on a high order implementation of these approaches.

Similarly, again, one of the approaches for the resolution of Hartree–Fock problem in quantum chemistry is the L.C.A.O. method that consists in approximating the wave function of a molecule by linear combination of atomic orbitals that are nothing but solutions to the same problem on an atom, instead of a molecule. The atomic orbitals are indeed the approximations of Hydrogenoid functions (the contracted Gaussians have to be seen this way) that are the solutions of the electronic problem of one electron around a nucleus. This similarity is the guideline for the extension that is proposed in [3], [2].

At this level, it is also interesting to note that the reduced basis method, for an eigenvalue problem as the one encountered in the two previous cases, may be very appropriate since it can be proven that, letting $u_i$ denote the set of all first $P$ eigenvectors of an eigenvalue problem depending on a parameter $\mu$, $u_i \equiv (e^1(\mu_i), \ldots, e^p(\mu_i))$, then the approximation of this complete set of eigenvectors can be done with the same linear combination. More precisely it is possible to get an accurate approximation method based on

$$u(\mu) \simeq \sum_{i=1}^{P} \alpha_i u_i, \quad e^j(\mu) \simeq \sum_{i=1}^{P} \alpha_i e^j(\mu_i) \text{ for all } j$$

instead of

$$e^j(\mu) \simeq \sum_{i=1}^{P} \alpha_i^j e^j(\mu_i).$$

Again we refer to [2] for more details on this.

**7.2. The reduced element method.** In the reduced basis element method introduced in [13], we consider the geometry of the computational domain to be the generic parameter. The domain is decomposed into smaller blocks, all of them can be viewed as the deformation of a few reference shapes. Associated with each reference shape are previously computed solutions (typically computed over different deformations of the reference shapes). The precomputed solutions are mapped from the reference shapes to the different blocks of the decomposed domain, and the solution on each block is found as a linear combination of the mapped precomputed solutions. The solutions on the different blocks are glued together using Lagrange multipliers.

To be more precise, we assume that the domain $\Omega$ where the computation should be performed can be written as the *non-overlapping* union of subdomains $\Omega^k$:

$$\overline{\Omega} = \bigcup_{k=1}^{K} \overline{\Omega}^k, \quad \Omega^k \cap \Omega^\ell = \emptyset \text{ for } k \neq \ell. \tag{25}$$

Next, we assume that each subdomain $\Omega^k$ is the deformation of the "reference" domain $\hat{\Omega}$ through a regular enough, and one to one, mapping. In an off-line stage,

this reference geometry has been "filled up" with reference reduced basis solutions $\hat{u}_1, \hat{u}_2, \ldots, \hat{u}_N$ to the problem that is under evaluation. Hence, together with this geometric decomposition, a functional decomposition is proposed since every $\Omega^k$; this allows us to define the finite dimensional space

$$Y_N = \left\{ v \in L^2(\Omega),\ v_{|\Omega^k} = \sum_{i=1}^{N} \alpha_i^k \mathcal{F}_k^{-1}[\hat{u}_i] \right\}, \tag{26}$$

which is a set of uncoupled, element by element, discrete functions, where $\mathcal{F}_k$ allows to transform functions defined over $\hat{\Omega}$ into functions defined over $\Omega^k$. This is generally not yet adequate for the approximation of the problem of interest since some glue at the interfaces $\gamma_{k,\ell}$ between two adjacent domains $\overline{\Omega}^k \cap \overline{\Omega}^\ell$ has to be added to the elements of $Y_N$, the glue depending on the type of equations we are interested to solve (it will be relaxed $C^0$-continuity condition for a Laplace operator, or more generally relaxed $C^1$-continuity condition for a fourth-order operator.

At this stage it should be noticed that, modulo an increase of complexity in the notations, there may exist not only one reference domain $\hat{\Omega}$ filled with its reduced basis functions but a few numbers so that the user can have more flexibilities in the design of the final global shape by assembling deformed basic shapes like a plumber would do for a central heating installation.

The reduced basis element method is then defined as a Galerkin approximation over the space $X_N$ being defined from $Y_N$ by imposing these relaxed continuity constraints. We refer to [9], [10] for more details on the implementation for hierarchical fluid flow systems that can be decomposed into a series of pipes and bifurcations.

# Finite element algorithms for transport-diffusion problems: stability, adaptivity, tractability

Endre Süli

**Abstract.** Partial differential equations with nonnegative characteristic form arise in numerous mathematical models of physical phenomena: stochastic analysis, in particular, is a fertile source of equations of this kind. We survey recent developments concerning the finite element approximation of these equations, focusing on three relevant aspects: (a) stability and stabilisation; (b) *hp*-adaptive algorithms driven by residual-based *a posteriori* error bounds, capable of automatic variation of the granularity $h$ of the finite element partition and of the local polynomial degree $p$; (c) complexity-reduction for high-dimensional transport-diffusion problems by stabilised sparse finite element methods.

**Mathematics Subject Classification (2000).** Primary 65N30; Secondary 65N12, 65N15.

**Keywords.** Transport-dominated diffusion problems, Fokker–Planck equations, finite element methods, stability, a-posteriori error analysis, adaptivity, sparse finite elements.

## 1. Introduction

Let $\Omega$ be a bounded and simply-connected open set in $\mathbb{R}^d$, $d \geq 2$, with Lipschitz continuous boundary $\partial\Omega$. On $\Omega$, we consider the partial differential equation

$$\mathcal{L}u := -\nabla \cdot (a\nabla u) + \nabla \cdot (bu) + cu = f, \tag{1}$$

where $f \in \mathrm{L}_2(\Omega)$ and $c \in \mathrm{L}_\infty(\Omega)$ are real-valued functions, $b = \{b_i\}_{i=1}^d$ is a vector function whose entries $b_i$ are Lipschitz continuous real-valued functions on $\overline{\Omega}$. We shall, further, assume that $a = \{a_{ij}\}_{i,j=1}^d$ is a *symmetric* matrix whose entries $a_{ij}$ are bounded, Lipschitz continuous real-valued functions defined on $\overline{\Omega}$, and that the matrix $a$ is positive semidefinite, almost everywhere on $\overline{\Omega}$, i.e.,

$$\alpha(\xi) := \xi^\top a(x)\xi \geq 0 \quad \text{for all } \xi \in \mathbb{R}^d \text{ and a.e. } x \in \overline{\Omega}. \tag{2}$$

Under hypothesis (2), the equation (1) is referred to as a *partial differential equation with nonnegative characteristic form*. Equations of this kind frequently arise as mathematical models in physics and chemistry [40] (e.g. in the kinetic theory of polymers [7], [44], [49] and coagulation-fragmentation problems [43]). They also appear in molecular biology [21], population genetics (e.g. in mathematical models of random

Proceedings of the International Congress of Mathematicians, Madrid, Spain, 2006

genetic drift) and in mathematical finance. Important special cases of these equations include the following: (a) when the diffusion matrix $a = a^\top$ is positive definite, (1) is an elliptic partial differential equation; (b) when $a \equiv 0$ and the transport direction $b \neq 0$, the partial differential equation (1) is a first-order hyperbolic equation; (c) when $b = (0, \ldots, 0, 1)^\top \in \mathbb{R}^d$ and

$$a = \begin{pmatrix} \alpha & 0 \\ 0 & 0 \end{pmatrix}$$

where $\alpha$ is a $(d-1) \times (d-1)$ symmetric positive definite matrix, (1) is a parabolic partial differential equation, with time-like direction $b$. The family of partial differential equations with nonnegative characteristic form also includes a range of other linear second-order partial differential equations, such as degenerate elliptic and ultra-parabolic equations. Furthermore, by a result of Hörmander [35] (cf. Theorem 11.1.10 on p. 67), second-order hypoelliptic operators with constant coefficients have nonnegative characteristic form, after possible multiplication by $-1$.

For classical types of partial differential equations, such as those under (a), (b) and (c) above, rich families of reliable, stable and accurate numerical techniques have been developed. Yet, there have only been isolated attempts to date to explore computational aspects of the class of partial differential equations with nonnegative characteristic form as a whole (cf. [30] and [33]). In particular, only a limited amount of research has been devoted to the construction and mathematical analysis of adaptive finite element algorithms for these equations; similarly, there has been very little work on the finite element approximation of high-dimensional partial differential equations with nonnegative characteristic form (cf. [57]).

The aim of this paper is to present a brief survey of some recent results in these directions. In Section 2, we state the weak formulation of a boundary-value problem for equation (1). In Sections 3 and 4, we give an overview of stabilised continuous and discontinuous finite element approximations to these equations; we shall also address the question of residual-based a posteriori error estimation for $hp$-version discontinuous Galerkin approximations of these equations, as well as the construction of sparse stabilised finite element methods for *high-dimensional* partial differential equations with nonnegative characteristic form (Section 5).

## 2. Boundary conditions and weak formulation

For the sake of simplicity of presentation, we shall assume that $\Omega$ is a bounded open polytope in $\mathbb{R}^d$ and we denote by $\Gamma$ the union of its $(d-1)$-dimensional open faces; clearly, $\Gamma \subset \partial\Omega$ with strict inclusion. The equation (2) will be supplemented by boundary conditions. For this purpose, let $\nu(x) = \{\nu_i(x)\}_{i=1}^d$ denote the unit outward normal vector to $\Gamma$ at $x \in \Gamma$. On introducing the *Fichera function* (cf. [48])

$x \in \Gamma \mapsto \beta(x) := (b \cdot \nu)(x) \in \mathbb{R}$, we define the following subsets of $\Gamma$:

$$\Gamma_0 = \{x \in \Gamma : \ \alpha(\nu(x)) > 0\},$$
$$\Gamma_- = \{x \in \Gamma \backslash \Gamma_0 : \ \beta(x) < 0\}, \quad \Gamma_+ = \{x \in \Gamma \backslash \Gamma_0 : \ \beta(x) \geq 0\}.$$

The set $\Gamma_0$ is the *elliptic part* of $\Gamma$, while $\Gamma_- \cup \Gamma_+$ represents the *hyperbolic part* of $\Gamma$. The sets $\Gamma_-$ and $\Gamma_+$ will be referred to as the hyperbolic *inflow* and *outflow* boundary, respectively. Clearly, $\Gamma = \Gamma_0 \cup \Gamma_- \cup \Gamma_+$. If $\Gamma_0 \neq \emptyset$ and has positive $(d-1)$-dimensional Hausdorff measure $\mathcal{H}^{d-1}(\Gamma_0)$, we shall further decompose it into disjoint subsets $\Gamma_D$ and $\Gamma_N$ whose union is $\Gamma_0$, with $\mathcal{H}^{d-1}(\Gamma_D) > 0$. We supplement the partial differential equation (1) with the boundary conditions

$$u = g_D \quad \text{on } \Gamma_D \cup \Gamma_-, \qquad \nu \cdot (a \nabla u) = g_N \quad \text{on } \Gamma_N, \tag{3}$$

and adopt the (physically reasonable) hypothesis that $\beta(x) \geq 0$ for a.e. $x \in \Gamma_N$, whenever $\Gamma_N$ is nonempty. In addition, we assume that the following (standard) positivity hypothesis holds: there exists a positive constant $\hat{c}_0$ such that

$$c(x) + \tfrac{1}{2} \nabla \cdot b(x) \geq \hat{c}_0^2 \quad \text{a.e. } x \in \Omega, \tag{4}$$

and define $c_0 = (c + \frac{1}{2} \nabla \cdot b)^{1/2}$ on $\overline{\Omega}$. Now, consider the following boundary-value problem, corresponding to $g_D = 0$ and $g_N = 0$: find $u$ such that

$$\mathcal{L}u \equiv -\nabla \cdot (a \nabla u) + \nabla \cdot (bu) + cu = f \quad \text{in } \Omega, \tag{5}$$
$$u = 0 \quad \text{on } \Gamma_D \cup \Gamma_-, \tag{6}$$
$$\nu \cdot (a \nabla u) = 0 \quad \text{on } \Gamma_N. \tag{7}$$

**Function spaces and weak formulation.** The classical Sobolev space on $\Omega$ of integer order $m$, $m \geq 0$, will be denoted by $W_q^m(\Omega)$ for $q \in [1, \infty]$; in the case $q = 2$ we write $H^m(\Omega)$ for $W_2^m(\Omega)$; $W_q^0(\Omega)$ is simply $L_q(\Omega)$. $W_p^m(\Omega)$ is equipped with the Sobolev norm $\| \cdot \|_{W_q^m(\Omega)}$ and seminorm $| \cdot |_{W_q^m(\Omega)}$. For the sake of simplicity, we shall write $\| \cdot \|$ instead of $\| \cdot \|_{L_2(\Omega)}$, and $\| \cdot \|_\kappa$ will denote $\| \cdot \|_{L_2(\kappa)}$ for an open subset $\kappa$ of $\Omega$. We let $\mathcal{V} = \{v \in H^1(\Omega) : \gamma_{0,\partial\Omega}(v)|_{\Gamma_D} = 0\}$ where $\gamma_{0,\partial\Omega}(v)$ signifies the trace of $v$ on $\partial\Omega$, and define the inner product $(\cdot, \cdot)_{\mathcal{H}}$ by

$$(w, v)_{\mathcal{H}} := (a \nabla w, \nabla v) + (w, v) + \langle w, v \rangle_{\Gamma_N \cup \Gamma_- \cup \Gamma_+}.$$

Here $(\cdot, \cdot)$ denotes the $L_2$ inner product over $\Omega$ and $\langle w, v \rangle_S = \int_S |\beta| wv \, ds$, with $\beta$ denoting the Fichera function $b \cdot \nu$, as before, and $S \subset \Gamma$. We denote by $\mathcal{H}$ the closure of the space $\mathcal{V}$ in the norm $\| \cdot \|_{\mathcal{H}}$ defined by $\|w\|_{\mathcal{H}} := (w, w)_{\mathcal{H}}^{1/2}$. Clearly, $\mathcal{H}$ is a Hilbert space. For $w \in \mathcal{H}$ and $v \in \mathcal{V}$, we now consider the bilinear form $B(\cdot, \cdot) : \mathcal{H} \times \mathcal{V} \to \mathbb{R}$ defined by

$$B(w, v) := (a \nabla w, \nabla v) - (w, \nabla \cdot (bv)) + (cw, v) + \langle w, v \rangle_{\Gamma_N \cup \Gamma_+},$$

and for $v \in \mathcal{V}$ we introduce the linear functional $L\colon \mathcal{V} \to \mathbb{R}$ by $L(v) := (f, v)$. Note, in particular, that by (4),

$$B(v, v) = (a\nabla v, \nabla v) + \|c_0 v\|^2 + \tfrac{1}{2}\langle v, v\rangle_{\Gamma_N \cup \Gamma_- \cup \Gamma_+} \geq K_0 \|v\|^2_{\mathcal{H}} \quad \text{for all } v \in \mathcal{V},$$

where $K_0 = \min\left(\hat{c}_0^2, \frac{1}{2}\right) > 0$. We shall say that $u \in \mathcal{H}$ is a *weak solution* to the boundary-value problem (5), (6) if

$$B(u, v) = L(v) \quad \text{for all } v \in \mathcal{V}. \tag{8}$$

We note that the boundary conditions $u|_{\Gamma_-} = 0$ on the inflow part $\Gamma_-$ of the hyperbolic boundary $\Gamma \setminus \Gamma_0 = \Gamma_- \cup \Gamma_+$ and the boundary condition $\nu \cdot (a\nabla u) = 0$ on the Neumann part $\Gamma_N$ of the elliptic boundary $\Gamma_0$ are imposed weakly, through (8), while the boundary condition $u|_{\Gamma_D} = 0$ on the Dirichlet part, $\Gamma_D$, of $\Gamma_0$ is imposed strongly, through the choice of the function space $\mathcal{H}$. The existence of a unique weak solution is guaranteed by the following theorem (cf. also Theorem 1.4.1 on p. 29 of [48] and [57] for a similar result in the special case of $\Gamma_N = \emptyset$; for $\Gamma_N \neq \emptyset$ the proof is identical to that in [57]).

**Theorem 2.1.** *Suppose that $c_0(x) \geq \hat{c}_0 > 0$ for all $x \in \overline{\Omega}$. Then, for each $f \in L_2(\Omega)$, there is a unique $u$ in a Hilbert subspace $\hat{\mathcal{H}}$ of $\mathcal{H}$ such that* (8) *holds.*

Next, we shall consider the discretisation of the problem (8), first by a stabilised Galerkin method based on continuous piecewise polynomials, and then using discontinuous piecewise polynomials.

## 3. Continuous piecewise polynomial approximation: the streamline-diffusion method

As in the previous section, we suppose that $\Omega$ is a bounded open polytope in $\mathbb{R}^d$, $d \geq 2$. Let $\mathcal{T}_h = \{\kappa\}$ be an admissible subdivision of $\Omega$ into open element domains $\kappa$ which is subordinate to the decomposition of $\Gamma$ into the subsets $\Gamma_D$, $\Gamma_N$, $\Gamma_-$ and $\Gamma_+$; here $h$ is a piecewise constant mesh function with $h(x) = h_\kappa = \mathrm{diam}(\kappa)$ when $x$ is in element $\kappa \in \mathcal{T}_h$. We shall assume that each $\kappa \in \mathcal{T}_h$ is the image, under a bijective affine map $F_\kappa$, of a fixed *master element* $\hat{\kappa}$, where $\hat{\kappa}$ is either an open unit simplex or an axiparallel open unit hypercube in $\mathbb{R}^d$. We shall also suppose that the family of partitions $\{\mathcal{T}_h\}_{h>0}$ is

(a) *regular* (namely, the closures of any two elements in the subdivision are either disjoint or share a common face of dimension $\leq d-1$); and

(b) *shape-regular* (namely, there exists a positive constant $c_1$, independent of $h$, such that $c_1 h_\kappa^d \leq \mathrm{meas}(\kappa)$ for all $\kappa \in \bigcup_h \mathcal{T}_h$).

For $p \geq 1$, we denote by $\mathcal{P}_p(\hat{\kappa})$ the set of polynomials of degree at most $p$ on $\hat{\kappa}$ when $\hat{\kappa}$ is an open unit simplex; when $\hat{\kappa}$ is an axiparallel open unit hypercube, we let $\mathcal{Q}_p(\hat{\kappa})$ denote the set of all tensor-product polynomials of degree at most $p$ in each coordinate direction. We define the *finite element space*

$$\mathcal{H}_{h,p} = \{v \in \mathcal{H} \cap \mathrm{C}(\overline{\Omega}) : v|_\kappa \in \mathcal{R}_p(\kappa) \text{ for all } \kappa \in \mathcal{T}_h\},$$

where $\mathcal{R}_p(\kappa) = \{w \in \mathrm{L}_1(\kappa) \,:\, w \circ F_\kappa \in \mathcal{R}_p(\hat{\kappa})\}$ and $\mathcal{R}_p$ is either $\mathcal{P}_p$ or $\mathcal{Q}_p$.

Next, we formulate the streamline-diffusion finite element approximation of (8). The method was originally introduced by Hughes and Brooks [36] in 1979 for elliptic transport-dominated diffusion equations. Its analysis was pursued by a number of authors (see [38], [39], [54], for example). The definition of the method stems from the empirical observation that standard Galerkin finite element approximations to transport-dominated diffusion problems exhibit nonphysical numerical oscillations which occur predominantly in the direction of subcharacteristic curves (i.e. the characteristic curves of the underlying hyperbolic problem); the standard Galerkin method is therefore supplemented with numerical diffusion/dissipation in the direction of the subcharacteristics through the inclusion of a *streamline-diffusion stabilisation term*. For a survey of recent perspectives on stabilised and multiscale finite element methods for partial differential equations, including transport-dominated diffusion problems, we refer to the survey paper of Brezzi and Marini [14]; see also [13], [15]. Here, we follow the exposition in [33] and consider the bilinear form $B_\delta(\,\cdot\,,\,\cdot\,)$ defined by

$$\begin{aligned} B_\delta(w, v) = (a\nabla w, \nabla v) - (w, \nabla \cdot (bv)) + (cw, v) \\ + \langle w, v\rangle_{\Gamma_\mathrm{N}\cup\Gamma_+} + \sum_{\kappa\in\mathcal{T}_h} (\hat{\mathcal{L}}w, \delta_\kappa\, b\cdot\nabla v)_\kappa \end{aligned}$$

and the linear functional $\ell_\delta(v) = \sum_\kappa (f,\, v+\delta_\kappa\, b\cdot\nabla v)_\kappa$, where, on element $\kappa \in \mathcal{T}_h$, we define $\hat{\mathcal{L}}$ by $\hat{\mathcal{L}}w = -\nabla\cdot(P_\kappa(a\nabla w)) + b\cdot\nabla w + cw$, $w \in \mathrm{H}^1(\kappa)$, and $P_\kappa$ signifies the orthogonal projection in $[\mathrm{L}_2(\kappa)]^d$ onto $[\mathcal{R}_p(\kappa)]^d$. In these definitions $(\cdot,\cdot)_\kappa$ denotes the $\mathrm{L}_2$ inner product over $\kappa$ and the nonnegative piecewise constant function $\delta$, called the *streamline-diffusion stabilisation parameter*, is defined by $\delta|_\kappa = \delta_\kappa$ for $\kappa \in \mathcal{T}_h$, where $\delta_\kappa$ is a nonnegative constant on element $\kappa$. The precise choice of $\delta$ will be discussed below.

Now, the streamline-diffusion finite element method is defined as follows: find $u_\mathrm{SD} \in \mathcal{H}_{h,p}$ such that

$$B_\delta(u_\mathrm{SD}, v) = \ell_\delta(v) \quad \text{for all } v \in \mathcal{H}_{h,p}. \tag{9}$$

Here, we shall focus on the stability and error analysis of this method. A key property is the following: from (8) and (9) we deduce that if $u \in \mathcal{H} \cap \mathrm{H}^2(\Omega)$ then

$$B_\delta((u - u_\mathrm{SD}), v) = \sum_{\kappa\in\mathcal{T}_h} (\nabla\cdot(a\nabla u - P_\kappa(a\nabla u)), \delta_\kappa b\cdot\nabla v)_\kappa \quad \text{for all } v \in \mathcal{H}_{h,p}. \tag{10}$$

In particular, if $a$ is a constant matrix, then the projection operator $P_\kappa$ can be replaced by the identity operator. In this case the right-hand side in (10) is zero and this identity is then referred to as the *Galerkin orthogonality* property of the streamline-diffusion finite element method (9).

Next we show the stability of the method (9) and state an optimal order *a priori* error bound. The bound will be expressed in terms of the so-called streamline-diffusion norm $|||\cdot|||_{\mathrm{SD}}$ defined by

$$|||v|||_{\mathrm{SD}}^2 = \|\nabla v\|_a^2 + \hat{c}_0^2\|v\|^2 + \|v\|_{\Gamma_{\mathrm{N}}\cup\Gamma_-\cup\Gamma_+}^2 + \|\sqrt{\delta}\, b\cdot\nabla v\|^2,$$

where $\|\nabla v\|_a^2 = (a\nabla v, \nabla v)$. The analysis requires the following results; cf. [33].

**Lemma 3.1** (Inverse inequality). *There exists a positive constant $C_{\mathrm{inv}} = C_{\mathrm{inv}}(c_1)$, independent of $a$, $h_\kappa$ and $p$ such that*

$$\|\nabla\cdot(P_\kappa(a\nabla v))\|_{\mathrm{L}_2(\kappa)} \le C_{\mathrm{inv}}\,\frac{p^2}{h_\kappa}\,\|a\nabla v\|_{\mathrm{L}_2(\kappa)} \quad \textit{for all } v\in\mathcal{H}_{h,p},\ \kappa\in\mathcal{T}_h.$$

**Lemma 3.2.** *Suppose that $M$ is a real $d\times d$ symmetric positive semidefinite matrix and let $|\cdot|$ denote the Euclidean norm on $\mathbb{R}^d$; then $|M\xi|^2 \le \rho(M)(M\xi,\xi)$ for all $\xi\in\mathbb{R}^d$, where $\rho(M)=\max_{1\le i\le d}\lambda_i$ is the spectral radius of $M$ and $\lambda_i$, $i=1,\dots,d$, are the (real, nonnegative) eigenvalues of $M$.*

Now we are ready to discuss the coercivity of the bilinear form $B_\delta(\cdot,\cdot)$ over $\mathcal{H}_{h,p}\times\mathcal{H}_{h,p}$. To this end we define $\mathcal{T}_h' = \{\kappa\in\mathcal{T}_h : \|b\|_{\mathrm{L}_\infty(\kappa)}\neq 0\}$.

**Proposition 3.3.** *Suppose that the streamline-diffusion parameter $\delta_\kappa$ on element $\kappa$ is selected, with the convention $1/0=\infty$, so that*

$$0\le\delta_\kappa\le\tfrac{1}{2}\min\left(\frac{h_\kappa^2}{(C_{\mathrm{inv}})^2\,\|\rho(a)\|_{\mathrm{L}_\infty(\kappa)}\,p^4},\ \frac{\hat{c}_0^2}{\|c\|_{\mathrm{L}_\infty(\kappa)}^2}\right) \quad \textit{for all } \kappa\in\mathcal{T}_h'. \tag{11}$$

*Then, the bilinear form $B_\delta(\cdot,\cdot)$ is coercive on $\mathcal{H}_{h,p}\times\mathcal{H}_{h,p}$, i.e.*

$$B_\delta(v,v)\ge\tfrac{1}{2}|||v|||_{\mathrm{SD}}^2 \quad \textit{for all } v\in\mathcal{H}_{h,p}.$$

*Proof.* Integrating by parts gives

$$\begin{aligned} B_\delta(v,v) \ge{}& (a\nabla v,\nabla v) + \int_\Omega c_0^2 v^2\,\mathrm{d}x + \tfrac{1}{2}\|v\|_{\Gamma_{\mathrm{N}}\cup\Gamma_-\cup\Gamma_+}^2 + \|\sqrt{\delta}\,b\cdot\nabla v\|^2 \\ &- \sum_{\kappa\in\mathcal{T}_h'}\delta_\kappa\left(\|\nabla\cdot(P_\kappa(a\nabla v))\|_\kappa + \|cv\|_\kappa\right)\|b\cdot\nabla v\|_\kappa, \end{aligned} \tag{12}$$

for $v\in\mathcal{H}_{h,p}$. Now, using Lemma 3.1 and Lemma 3.2 with $M=a$ and $\xi=\nabla v$,

$$\|\nabla\cdot(P_\kappa(a\nabla v))\|_\kappa + \|cv\|_\kappa \le C_{\mathrm{inv}}\,\frac{p^2}{h_\kappa}\,\|\rho(a)\|_{\mathrm{L}_\infty(\kappa)}^{1/2}\|\nabla v\|_{a,\kappa} + \|c\|_{\mathrm{L}_\infty(\kappa)}\|v\|_\kappa,$$

with the notation $\|\nabla v\|_{a,\kappa} = (a\nabla v, \nabla v)_\kappa^{1/2}$. Thus, for any real number $\gamma > 0$,

$$\sum_{\kappa\in\mathcal{T}_h'} \delta_\kappa \left(\|\nabla\cdot(P_\kappa(a\nabla v))\|_\kappa + \|cv\|_\kappa\right)\|b\cdot\nabla v\|_\kappa \le \gamma \sum_{\kappa\in\mathcal{T}_h'} \delta_\kappa \|b\cdot\nabla v\|_\kappa^2$$
$$+ \frac{1}{2\gamma}\sum_{\kappa\in\mathcal{T}_h'} \delta_\kappa \|c\|_{\mathrm{L}_\infty(\kappa)}^2 \|v\|_\kappa^2 + \frac{1}{2\gamma}\sum_{\kappa\in\mathcal{T}_h'} \delta_\kappa \,(C_{\mathrm{inv}})^2 \,\|\rho(a)\|_{\mathrm{L}_\infty(\kappa)} \frac{p^4}{h_\kappa^2}\,\|\nabla v\|_{a,\kappa}^2.$$

Choosing $\gamma = 1/2$, we deduce from (12) and the definition of $c_0$ that

$$B_\delta(v,v) \ge \|\nabla v\|_a^2 + \hat{c}_0^2\|v\|^2 + \tfrac{1}{2}\|v\|_{\Gamma_{\mathrm{N}}\cup\Gamma_-\cup\Gamma_+}^2 + \tfrac{1}{2}\|\sqrt{\delta}\; b\cdot\nabla v\|^2$$
$$- \sum_{\kappa\in\mathcal{T}_h'} \delta_\kappa \|c\|_{\mathrm{L}_\infty(\kappa)}^2\|v\|_\kappa^2 - \sum_{\kappa\in\mathcal{T}_h'} \delta_\kappa \,(C_{\mathrm{inv}})^2 \,\|\rho(a)\|_{\mathrm{L}_\infty(\kappa)} \frac{p^4}{h_\kappa^2}\,\|\nabla v\|_{a,\kappa}^2.$$

Selecting the streamline-diffusion parameter as in (11), the result follows. □

**Corollary 3.4** (Stability). *Under the hypotheses of Proposition* 3.3,

$$|||u_{\mathrm{SD}}|||_{\mathrm{SD}}^2 \le 4\hat{c}_0^{-2}\|f\|^2 + 4\sum_{\kappa\in\mathcal{T}_h'} \delta_\kappa \|f\|_\kappa^2.$$

In particular, if $f = 0$ then $u_{\mathrm{SD}} = 0$; since $\mathcal{H}_{h,p}$ is a finite-dimensional linear space, it follows that (9) has a unique solution $u_{\mathrm{SD}} \in \mathcal{H}_{h,p}$ for any $f \in \mathrm{L}_2(\Omega)$. The next result concerns the accuracy of the method (9).

**Theorem 3.5.** *Let the streamline-diffusion parameter $\delta_\kappa$ be chosen so that*

$$0 < \delta_\kappa \le \frac{1}{2}\min\left(\frac{h_\kappa^2}{(C_{\mathrm{inv}})^2\,\|\rho(a)\|_{\mathrm{L}_\infty(\kappa)}\,p^4}\,,\ \frac{\hat{c}_0^2}{\|c\|_{\mathrm{L}_\infty(\kappa)}^2}\right) \quad \textit{for all } \kappa \in \mathcal{T}_h',$$

*with the convention $1/0 = \infty$. Then, assuming that $u \in \mathcal{H}\cap \mathrm{H}^k(\Omega)\cap \mathrm{C}(\overline{\Omega})$, with a positive integer $k$ and $a \in [\mathrm{W}_\infty^{k-1}(\kappa)]^{d\times d}$, $\kappa \in \mathcal{T}_h$, the following error bound holds:*

$$|||u - u_{\mathrm{SD}}|||_{\mathrm{SD}} \le C\Big(\sum_{\kappa\in\mathcal{T}_h} \frac{h_\kappa^{2\tau-1}}{p^{2k-1}} M_\kappa(a,b,c,h_\kappa,p)\|u\|_{\mathrm{H}^k(\kappa)}^2\Big)^{1/2},$$

*where $\tau = \min(p+1,k)$, $C$ is a positive constant which depends only on $c_1$ and $k$, $M_\kappa(a,b,c,h_\kappa,p) = A_\kappa(p/h_\kappa) + B_\kappa + C_\kappa(h_\kappa/p)$, with*

$$A_\kappa = \begin{cases} \|a\|_{\mathrm{L}_\infty(\kappa)} + \dfrac{\|a\|_{\mathrm{L}_\infty(\kappa)}^2 + \|a\|_{\mathrm{W}_\infty^{k-1}(\kappa)}^2}{\|\rho(a)\|_{\mathrm{L}_\infty(\kappa)}}, & \textit{when } \|\rho(a)\|_{\mathrm{L}_\infty(\kappa)} \ne 0,\\ 0, & \textit{otherwise},\end{cases}$$

$$B_\kappa = \begin{cases} \|b\|_{\mathrm{L}_\infty(\kappa)}(1 + D_\kappa + D_\kappa^{-1}), & \textit{when } \|b\|_{\mathrm{L}_\infty(\kappa)} \ne 0,\\ 0, & \textit{otherwise},\end{cases}$$

$$C_\kappa = 1 + c_0 + c_0^{-2}\,\|c - \nabla\cdot b\|_{\mathrm{L}_\infty(\kappa)}^2, \quad D_\kappa = \delta_\kappa\|b\|_{\mathrm{L}_\infty(\kappa)}p/h_\kappa.$$

Theorem 3.5 is an extension of classical *a priori* error bounds for the streamline-diffusion discretisation of a first-order hyperbolic problem and a second-order elliptic transport-diffusion problem with $a$ isotropic and constant; see, for example, [37], [54] ($h$-version) and [29] ($hp$-version), and [33] for a proof in the case of $\Gamma_N = \emptyset$.

## 4. Discontinuous piecewise polynomial approximation: the discontinuous Galerkin method

Discontinuous Galerkin finite element methods (DGFEMs, for short) date back to the early 1970s; they were simultaneously proposed by Reed & Hill [52] in 1973 for the numerical solution of the neutron transport equation and by Nitsche [45] in 1971 as a nonstandard scheme for the approximation of second-order elliptic equations. Since the early 1970s there has been extensive work on the development of these methods for a wide range of applications; for an excellent historical survey of DGFEMs up until 2000 we refer to the paper of Cockburn, Karniadakis and Shu in the volume [19].

One of the key advantages of the DGFEM in comparison with standard Galerkin finite element methods based on continuous piecewise polynomials, such as the streamline-diffusion finite method discussed in the previous section, is their high degree of locality: the computational stencil of the DGFEM remains very compact even as the degree of the approximating polynomial is increased. Hence, high-order adaptive $hp$- and spectral element approximations may be handled in a particularly flexible and simple manner. Indeed, $hp$-adaptive DGFEMs offer tremendous gains in terms of computational efficiency in comparison with standard mesh refinement algorithms which only incorporate local $h$-refinement with a given (fixed) polynomial degree. For discussions concerning various $hp$-refinement strategies see [1], [8], [32], [34], [53], [58]. A further attractive property of the discontinuous Galerkin finite element method for a transport-dominated diffusion problem is that, unlike its counterpart based on continuous piecewise polynomials, the method is stable even in the absence of streamline-diffusion stabilisation.

In this section, we survey *a priori* and *a posteriori* error bounds for discontinuous Galerkin finite element approximations of second-order partial differential equations with nonnegative characteristic form. We shall then show how the *a posteriori* error bound can be used to drive an $hp$-adaptive finite element algorithm. The presentation in this section is based on the paper [25].

We consider shape-regular meshes $\mathcal{T}_h = \{\kappa\}$ that partition the domain $\Omega$ into open element domains $\kappa$, with possible *hanging nodes*. We shall suppose that the mesh is 1-irregular in the sense that there is at most one hanging node per $(d-1)$-dimensional element-face, e.g. the barycenter of the face. We denote by $h$ the piecewise constant mesh function with $h(x) \equiv h_\kappa = \mathrm{diam}(\kappa)$ when $x$ is in element $\kappa$. Let each $\kappa \in \mathcal{T}_h$ be a smooth bijective image of a fixed master element $\hat{\kappa}$, that is, $\kappa = F_\kappa(\hat{\kappa})$ for all $\kappa \in \mathcal{T}_h$, where $\hat{\kappa}$ is either the open unit simplex $\hat{\kappa}_S = \{\hat{x} = (\hat{x}_1, \ldots, \hat{x}_d) \in \mathbb{R}^d : 0 < x_1 + \cdots + x_d < 1,\ x_i > 0,\ i = 1, \ldots, d\}$, or the open hypercube

$\hat{\kappa}_{\mathrm{C}} = (-1, 1)^d$ in $\mathbb{R}^d$. On $\hat{\kappa}$ we define spaces of polynomials of degree $p \geq 1$ as follows: $\mathcal{Q}_p = \mathrm{span}\{\hat{x}^\alpha : 0 \leq \alpha_i \leq p,\ 1 \leq i \leq d\}$, $\mathcal{P}_p = \mathrm{span}\{\hat{x}^\alpha : 0 \leq |\alpha| \leq p\}$. To each $\kappa \in \mathcal{T}_h$ we assign an integer $p_\kappa \geq 1$; collecting the $p_\kappa$ and $F_\kappa$ in the vectors $\boldsymbol{p} = \{p_\kappa : \kappa \in \mathcal{T}_h\}$ and $\boldsymbol{F} = \{F_\kappa : \kappa \in \mathcal{T}_h\}$, respectively, we introduce the finite element space

$$S^{\boldsymbol{p}}(\Omega, \mathcal{T}_h, \boldsymbol{F}) = \{u \in \mathrm{L}_2(\Omega) : u|_\kappa \circ F_\kappa \in \mathcal{Q}_{p_\kappa} \text{ if } F_\kappa^{-1}(\kappa) = \hat{\kappa}_{\mathrm{C}} \\ \text{and } u|_\kappa \circ F_\kappa \in \mathcal{P}_{p_\kappa} \text{ if } F_\kappa^{-1}(\kappa) = \hat{\kappa}_{\mathrm{S}};\ \kappa \in \mathcal{T}_h\}.$$

We assign to $\mathcal{T}_h$ the *broken Sobolev space* of composite order $\boldsymbol{s} = \{s_\kappa : \kappa \in \mathcal{T}_h\}$ defined by $\mathrm{H}^{\boldsymbol{s}}(\Omega, \mathcal{T}_h) = \{u \in \mathrm{L}_2(\Omega) : u|_\kappa \in \mathrm{H}^{s_\kappa}(\kappa) \text{ for all } \kappa \in \mathcal{T}_h\}$, equipped with the *broken Sobolev norm*

$$\|u\|_{\boldsymbol{s}, \mathcal{T}_h} = \Big( \sum_{\kappa \in \mathcal{T}_h} \|u\|^2_{\mathrm{H}^{s_\kappa}(\kappa)} \Big)^{1/2}.$$

When $s_\kappa = s$ for all $\kappa \in \mathcal{T}_h$, we write $\mathrm{H}^s(\Omega, \mathcal{T}_h)$ and $\|u\|_{s, \mathcal{T}_h}$.

An *interior face* of $\mathcal{T}_h$ is defined as the (non-empty) $(d-1)$-dimensional interior of $\partial\kappa_i \cap \partial\kappa_j$, where $\kappa_i$ and $\kappa_j$ are two adjacent elements of $\mathcal{T}_h$, not necessarily matching. A *boundary face* of $\mathcal{T}_h$ is defined as the (non-empty) $(d-1)$-dimensional interior of $\partial\kappa \cap \Gamma$, where $\kappa$ is a boundary element of $\mathcal{T}_h$. We denote by $\Gamma_{\mathrm{int}}$ the union of all interior faces of $\mathcal{T}_h$. Given a face $e \subset \Gamma_{\mathrm{int}}$, shared by the two elements $\kappa_i$ and $\kappa_j$, where the indices $i$ and $j$ satisfy $i > j$, we write $\nu_e$ to denote the (numbering-dependent) unit normal vector which points from $\kappa_i$ to $\kappa_j$; on boundary faces we put $\nu_e = \nu$. Further, for $v \in \mathrm{H}^1(\Omega, \mathcal{T}_h)$ we define the jump of $v$ across $e$ and the mean value of $v$ on $e$, respectively, by $[v] = v|_{\partial\kappa_i \cap e} - v|_{\partial\kappa_j \cap e}$ and $\langle v \rangle = \frac{1}{2}(v|_{\partial\kappa_i \cap e} + v|_{\partial\kappa_j \cap e})$. On a boundary face $e \subset \partial\kappa$, we set $[v] = v|_{\partial\kappa \cap e}$ and $\langle v \rangle = v|_{\partial\kappa \cap e}$. Finally, given a function $v \in \mathrm{H}^1(\Omega, \mathcal{T}_h)$ and an element $\kappa \in \mathcal{T}_h$, we denote by $v_\kappa^+$ (respectively, $v_\kappa^-$) the interior (respectively, exterior) trace of $v$ defined on $\partial\kappa$ (respectively, $\partial\kappa \backslash \Gamma$). Since below it will always be clear from the context which element $\kappa$ in the subdivision $\mathcal{T}_h$ the quantities $v_\kappa^+$ and $v_\kappa^-$ correspond to, for the sake of notational simplicity we shall suppress the letter $\kappa$ in the subscript and write, respectively, $v^+$ and $v^-$ instead. Given that $\kappa$ is an element in the subdivision $\mathcal{T}_h$, we denote by $\partial\kappa$ the union of $(d-1)$-dimensional open faces of $\kappa$. Let $x \in \partial\kappa$ and suppose that $\nu_\kappa(x)$ denotes the unit outward normal vector to $\partial\kappa$ at $x$. With these conventions, we define the inflow and outflow parts of $\partial\kappa$, respectively, by $\partial_-\kappa = \{x \in \partial\kappa : b(x) \cdot \nu_\kappa(x) < 0\}$, $\partial_+\kappa = \{x \in \partial\kappa : b(x) \cdot \nu_\kappa(x) \geq 0\}$.

For simplicity of presentation, we suppose that each entry of the matrix $a$ is piecewise continuous on $\mathcal{T}_h$ and belongs to $S^{\boldsymbol{0}}(\Omega, \mathcal{T}_h, \boldsymbol{F})$. With minor changes only, our results can easily be extended to the case when each entry of $\sqrt{a}$ belongs to $S^{\boldsymbol{q}}(\Omega, \mathcal{T}_h, \boldsymbol{F})$, where the composite polynomial degree vector $\boldsymbol{q}$ has nonnegative entries; for more general $a$, see [23]. In the following, we write $\bar{a} = |\sqrt{a}\,|_2^2$, where $|\cdot|_2$ denotes the matrix norm subordinate to the $l_2$-vector norm on $\mathbb{R}^d$ and $\bar{a}_\kappa = \bar{a}|_\kappa$; by $\bar{a}_{\tilde{\kappa}}$ we denote the arithmetic mean of the values $\bar{a}_{\kappa'}$ over those elements $\kappa'$ (including $\kappa$ itself) that share a $(d-1)$-dimensional face with $\kappa$.

The $hp$-DGFEM approximation of (1), (3) is defined as follows: find $u_{\mathrm{DG}}$ in $S^{\boldsymbol{p}}(\Omega, \mathcal{T}_h, \boldsymbol{F})$ such that

$$B_{\mathrm{DG}}(u_{\mathrm{DG}}, v) = \ell_{\mathrm{DG}}(v) \quad \text{for all } v \in S^{\boldsymbol{p}}(\Omega, \mathcal{T}_h, \boldsymbol{F}). \tag{13}$$

Here, the bilinear form $B_{\mathrm{DG}}(\,\cdot\,,\cdot\,)$ is defined by

$$B_{\mathrm{DG}}(w, v) = B_a(w, v) + B_b(w, v) + \theta B_e(v, w) - B_e(w, v) + B_\sigma(w, v)\,,$$

where

$$\begin{aligned}
B_a(w, v) &= \sum_{\kappa\in\mathcal{T}_h} \int_\kappa a\nabla w \cdot \nabla v \,\mathrm{d}x,\\
B_b(w, v) &= \sum_{\kappa\in\mathcal{T}_h} \Big\{ -\int_\kappa (w\, b\cdot\nabla v - cwv)\,\mathrm{d}x + \int_{\partial_+\kappa} (b\cdot\nu_\kappa)\, w^+ v^+ \,\mathrm{d}s\\
&\qquad\qquad + \int_{\partial_-\kappa\setminus\Gamma} (b\cdot\nu_\kappa)\, w^- v^+ \,\mathrm{d}s\Big\},\\
B_e(w, v) &= \int_{\Gamma_{\mathrm{int}}\cup\Gamma_{\mathrm{D}}} \langle (a\nabla w)\cdot\nu_e\rangle [v]\,\mathrm{d}s,\\
B_\sigma(w, v) &= \int_{\Gamma_{\mathrm{int}}\cup\Gamma_{\mathrm{D}}} \sigma [w][v]\,\mathrm{d}s,
\end{aligned}$$

and the linear functional $\ell_{\mathrm{DG}}(\,\cdot\,)$ is given by

$$\begin{aligned}
\ell_{\mathrm{DG}}(v) = \sum_{\kappa\in\mathcal{T}_h} \Big\{ &\int_\kappa f v\,\mathrm{d}x - \int_{\partial_-\kappa\cap(\Gamma_{\mathrm{D}}\cup\Gamma_-)} (b\cdot\nu_\kappa)\, g_{\mathrm{D}}\, v^+ \,\mathrm{d}s\\
&+ \int_{\partial\kappa\cap\Gamma_{\mathrm{D}}} \theta\, g_{\mathrm{D}}((a\nabla v^+)\cdot\nu_\kappa)\,\mathrm{d}s + \int_{\partial\kappa\cap\Gamma_{\mathrm{N}}} g_{\mathrm{N}} v^+ \,\mathrm{d}s\\
&+ \int_{\partial\kappa\cap\Gamma_{\mathrm{D}}} \sigma g_{\mathrm{D}} v^+ \,\mathrm{d}s\Big\}.
\end{aligned}$$

Here, $\sigma$ is defined by

$$\sigma|_e = C_\sigma \frac{\langle \bar{a} p^2\rangle}{\langle h\rangle} \quad \text{for } e \subset \Gamma_{\mathrm{int}}\cup\Gamma_{\mathrm{D}}, \tag{14}$$

where $C_\sigma$ is a positive constant, called the *discontinuity-penalisation* parameter; cf. [30]. We shall adopt the convention that edges $e \subset \Gamma_{\mathrm{int}}\cup\Gamma_{\mathrm{D}}$ with $\sigma|_e = 0$ are omitted from the integrals appearing in the definition of $B_\sigma(w, v)$ and $\ell_{\mathrm{DG}}(v)$, although we shall not highlight this explicitly in our notation; the same convention is adopted in the case of integrals where the integrand contains the factor $1/\sigma$. Thus, in particular, the definition of the DG-norm, cf. (15) below, is meaningful even if $\sigma|_e$ happens to be equal to zero on certain edges $e \subset \Gamma_{\mathrm{int}}\cup\Gamma_{\mathrm{D}}$, given that such edges are understood to be excluded from the region of integration.

Selecting the parameter $\theta = 1$ gives rise to the so-called *Nonsymmetric Interior Penalty* (*NIP*) *method*, while setting $\theta = -1$ yields the *Symmetric Interior Penalty* (*SIP*) *scheme*; in the following we write SIP/NIP to denote the symmetric/nonsymmetric versions of the interior penalty method.

While a symmetric discretisation of a symmetric differential operator seems quite natural, the NIP scheme is often preferred, especially for transport-dominated problems where the underlying discretisation matrix is nonsymmetric anyway, as it is stable for any choice of the parameter $C_\sigma > 0$; see, for example, [2], [30], [51], and Theorem 4.1 below. On the other hand, the SIP scheme is only stable when $C_\sigma > 0$ is chosen sufficiently large. In terms of accuracy, both schemes converge at the optimal rate when the error is measured in terms of the DG-norm (cf. (15) below), but the lack of adjoint consistency (see, [2]) of the NIP method leads to suboptimal convergence of the error when measured in terms of the $L_2$ norm. In this case, the SIP scheme is still optimally convergent, while the NIP method is suboptimal by a full order; however, numerical experiments indicate that in practice the $L_2$ norm of the error arising from the NIP scheme converges to zero at the optimal rate when the polynomial degree $p$ is odd, cf. [30]. Thereby, in practice the loss of optimality of the NIP scheme when the error is measured in terms of the $L_2$ norm only arises for even $p$. However, we showed in [25] that, for $p \geq 2$, the lack of adjoint consistency of the NIP scheme leads to an even more dramatic deterioration of its convergence rate when the error is measured in terms of a certain (linear) target functional $J(\cdot)$, such as $J: v \mapsto \int_\Omega v(x)\psi(x)\,\mathrm{d}x$, for example, where $\psi$ is a given weight-function: for fixed $p$ the error measured in terms of $J(\cdot)$ behaves like $\mathcal{O}(h^{2p})$ when the SIP scheme is employed, while for the NIP scheme, in general we only have the rate of convergence $\mathcal{O}(h^p)$ as $h$ tends to zero. For related work on *a posteriori* error estimation for DGFEMs with interior penalty, see e.g. Becker *et al.* [9], [10] and Rivière & Wheeler [53]. For further perspectives on the construction and postprocessing of DGFEMs, see [12], [18].

Before embarking on the analysis of the discontinuous Galerkin method (13), we define the DG-norm $|||\cdot|||_{\mathrm{DG}}$ by

$$
\begin{aligned}
|||w|||_{\mathrm{DG}}^2 = \sum_{\kappa\in\mathcal{T}_h} \Big( & \|\nabla w\|_{a,\kappa}^2 + \|c_0 w\|_\kappa^2 + \frac{1}{2}\|w^+\|_{\partial_-\kappa\cap(\Gamma_{\mathrm{D}}\cup\Gamma_-)}^2 \\
& + \frac{1}{2}\|w^+\|_{\partial_+\kappa\cap\Gamma}^2 + \frac{1}{2}\|w^+ - w^-\|_{\partial_-\kappa\setminus\Gamma}^2 \Big) \\
& + \int_{\Gamma_{\mathrm{int}}\cup\Gamma_{\mathrm{D}}} \sigma[w]^2\,\mathrm{d}s + \int_{\Gamma_{\mathrm{int}}\cup\Gamma_{\mathrm{D}}} \frac{1}{\sigma}\langle (a\,\nabla w)\cdot \nu_e\rangle^2\,\mathrm{d}s,
\end{aligned}
\tag{15}
$$

where $\|\nabla w\|_{a,\kappa}^2 = (a\nabla w, \nabla w)_\kappa$, $\|\cdot\|_\tau$, $\tau \subset \partial\kappa$, denotes the (semi)norm induced by the (semi)inner-product $(v, w)_\tau = \int_\tau |b\cdot\nu_\kappa| v w\,\mathrm{d}s$, and $c_0$ is as defined in (4). The above definition of $|||\cdot|||_{\mathrm{DG}}$ represents a slight modification of the norm considered in [30]; for $a > 0$, $b \equiv 0$, (15) corresponds to the norm proposed by Baumann *et al.* [8], [47] and Baker *et al.* [5], cf. [51]. With this notation, we state the following coercivity result for the bilinear form $B_{\mathrm{DG}}(\cdot,\cdot)$ over $S^p(\Omega, \mathcal{T}_h, \boldsymbol{F}) \times S^p(\Omega, \mathcal{T}_h, \boldsymbol{F})$.

**Theorem 4.1.** *With $\sigma$ defined as in* (14)*, there exists a positive constant $C$, which depends only on the dimension $d$ and the shape-regularity of $\mathcal{T}_h$, such that*

$$B_{\mathrm{DG}}(v, v) \geq C|||v|||_{\mathrm{DG}}^2 \quad \textit{for all } v \in S^{\boldsymbol{p}}(\Omega, \mathcal{T}_h, \boldsymbol{F}),$$

*provided that the constant $C_\sigma$ arising in the definition of the discontinuity penalisation parameter $\sigma$ is chosen so that $C_\sigma > 0$ arbitrary when $\theta = 1$, and $C_\sigma \geq C'_\sigma$ with $C'_\sigma$ sufficiently large when $\theta \neq 1$.*

This result is an extension of the coercivity result derived by Prudhomme *et al.* [51] with $b \equiv 0$; see also [30] for the proof in the case when $\theta = 1$. For the case of $a \equiv 0$, the connection of stabilisation to upwinding has been discussed in [16]. In particular, Theorem 4.1 implies that (13) has a unique solution for any $f \in \mathrm{L}_2(\Omega)$, any $g_{\mathrm{D}} \in \mathrm{L}_2(\Gamma_{\mathrm{D}})$ and any $g_{\mathrm{N}} \in \mathrm{L}_2(\Gamma_{\mathrm{N}})$. Theorem 4.1 also indicates that while the NIP scheme is coercive over $S^{\boldsymbol{p}}(\Omega, \mathcal{T}_h, \boldsymbol{F}) \times S^{\boldsymbol{p}}(\Omega, \mathcal{T}_h, \boldsymbol{F})$ for any choice of the constant $C_\sigma > 0$ arising in the definition of the discontinuity-penalisation parameter $\sigma$, the SIP scheme (corresponding to $\theta = -1$) is only coercive if $C_\sigma$ is chosen sufficiently large; see [25] for details about the minimum size of $C_\sigma$.

Henceforth, we shall assume that the solution $u$ to the boundary value problem (1), (3) is sufficiently smooth: namely, $u \in \mathrm{H}^2(\Omega, \mathcal{T}_h)$ and that $u$ and $(a\nabla u) \cdot \nu_e$ are continuous across each face $e \subset \partial\kappa \backslash \Gamma$ that intersects the subdomain of ellipticity, $\Omega_a = \{x \in \overline{\Omega} : \boldsymbol{\zeta}^\top a(x)\boldsymbol{\zeta} > 0 \text{ for all } \boldsymbol{\zeta} \in \mathbb{R}^d\}$. If this smoothness requirement is violated, the discretisation method has to be modified accordingly, cf. [30]. We note that under these assumptions, the following Galerkin orthogonality property holds:

$$B_{\mathrm{DG}}(u - u_{\mathrm{DG}}, v) = 0 \quad \text{for all } v \in S^{\boldsymbol{p}}(\Omega, \mathcal{T}_h, \boldsymbol{F}). \tag{16}$$

We shall assume that $b \in [\mathrm{W}^1_\infty(\Omega)]^d$ is such that

$$b \cdot \nabla_{\mathcal{T}_h} v \in S^{\boldsymbol{p}}(\Omega, \mathcal{T}, \boldsymbol{F}) \quad \text{for all } v \in S^{\boldsymbol{p}}(\Omega, \mathcal{T}, \boldsymbol{F}). \tag{17}$$

Let us denote by $\Pi_p$ the orthogonal projector in $\mathrm{L}_2(\Omega)$ onto the finite element space $S^{\boldsymbol{p}}(\Omega, \mathcal{T}, \boldsymbol{F})$. We remark that this choice of projector is essential in the following *a priori* error analysis, in order to ensure that $(u - \Pi_p u, b \cdot \nabla_{\mathcal{T}_h} v) = 0$ for all $v$ in $S^{\boldsymbol{p}}(\Omega, \mathcal{T}, \boldsymbol{F})$. If, on the other hand, the scheme (13) is supplemented by streamline-diffusion stabilisation, then alternative choices of $\Pi_p$ may be employed (see [29], [59], for example); in that case, hypothesis (17) is redundant. We now decompose the global error $u - u_{\mathrm{DG}}$ as

$$u - u_{\mathrm{DG}} = (u - \Pi_p u) + (\Pi_p u - u_{\mathrm{DG}}) \equiv \eta + \xi. \tag{18}$$

**Lemma 4.2.** *Assume that* (4) *and* (17) *hold and let $\beta_1|_\kappa = \|c/c_0^2\|_{\mathrm{L}_\infty(\kappa)}$; then there exists a positive constant $C$ that depends only on $d$ and the shape-regularity of $\mathcal{T}_h$*

*such that the functions $\xi$ and $\eta$ defined by* (18) *satisfy the following inequality*

$$|||\xi|||_{\mathrm{DG}}^2 \le C\Big\{ \sum_{\kappa\in\mathcal{T}_h} \big(\|\sqrt{a}\,\nabla\eta\|_\kappa^2 + \beta_1^2\|c_0\eta\|_\kappa^2 + \|\eta^+\|_{\partial_+\kappa\cap\Gamma}^2 + \|\eta^-\|_{\partial_-\kappa\setminus\Gamma}^2\big) + \int_{\Gamma_{\mathrm{int}}\cup\Gamma_{\mathrm{D}}} \frac{1}{\sigma}\langle(a\nabla\eta)\cdot\nu_e\rangle^2\,\mathrm{d}s + \int_{\Gamma_{\mathrm{int}}\cup\Gamma_{\mathrm{D}}} \sigma[\eta]^2\,\mathrm{d}s\Big\}.$$

The proof is given in [25]. We also need the following result concerning the approximation properties of the projector $\Pi_p$; for simplicity, we restrict ourselves to 1-irregular, shape-regular meshes consisting of affine equivalent $d$-parallelepiped elements (cf. [4], [30], and also [24] for similar results in augmented Sobolev spaces).

**Lemma 4.3.** *Suppose that $\kappa \in \mathcal{T}_h$ is a $d$-parallelepiped of diameter $h_\kappa$ and that $u|_\kappa \in \mathrm{H}^{k_\kappa}(\kappa)$, $k_\kappa \ge 0$, for $\kappa \in \mathcal{T}_h$. Then, the following approximation results hold:*

$$\|u-\Pi_p u\|_{\mathrm{L}_2(\kappa)} \le C\frac{h_\kappa^{s_\kappa}}{p_\kappa^{k_\kappa}}\|u\|_{\mathrm{H}^{k_\kappa}(\kappa)}, \quad \|u-\Pi_p u\|_{\mathrm{L}_2(\partial\kappa)} \le C\frac{h_\kappa^{s_\kappa-1/2}}{p_\kappa^{k_\kappa-1/2}}\|u\|_{\mathrm{H}^{k_\kappa}(\kappa)},$$

$$|u-\Pi_p u|_{\mathrm{H}^1(\kappa)} \le C\frac{h_\kappa^{s_\kappa-1}}{p_\kappa^{k_\kappa-3/2}}\|u\|_{\mathrm{H}^{k_\kappa}(\kappa)}, \quad |u-\Pi_p u|_{\mathrm{H}^1(\partial\kappa)} \le C\frac{h_\kappa^{s_\kappa-3/2}}{p_\kappa^{k_\kappa-5/2}}\|u\|_{\mathrm{H}^{k_\kappa}(\kappa)},$$

*where $1 \le s_\kappa \le \min(p_\kappa+1, k_\kappa)$ and $C$ is a constant independent of $u$, $h_\kappa$ and $p_\kappa$, but dependent on the dimension $d$ and the shape-regularity of $\mathcal{T}_h$.*

For the rest of this section, we assume that the polynomial degree vector $\boldsymbol{p}$, with $p_\kappa \ge 1$, $\kappa \in \mathcal{T}_h$, has *bounded local variation*; *i.e.*, there exists a constant $\rho \ge 1$ such that, for any pair of elements $\kappa$ and $\kappa'$ which share a $(d-1)$-dimensional face,

$$\rho^{-1} \le p_\kappa/p_{\kappa'} \le \rho. \tag{19}$$

On noting that $\eta = u - \Pi_p u$ and combining Lemmas 4.2 and 4.3, we deduce that

$$|||\xi|||_{\mathrm{DG}}^2 \le C\sum_{\kappa\in\mathcal{T}_h}\left(\alpha\frac{h_\kappa^{2(s_\kappa-1)}}{p_\kappa^{2(k_\kappa-3/2)}} + \beta_2\frac{h_\kappa^{2s_\kappa}}{p_\kappa^{2k_\kappa}} + \gamma\frac{h_\kappa^{2(s_\kappa-1/2)}}{p_\kappa^{2(k_\kappa-1/2)}}\right)\|u\|_{\mathrm{H}^{k_\kappa}(\kappa)}^2,$$

where $\alpha|_\kappa = \bar{a}_{\tilde{\kappa}}$, $\beta_2|_\kappa = (\beta_1|_\kappa)^2\,\|c_0\|_{\mathrm{L}_\infty(\kappa)}^2$, $(\beta_1|_\kappa = \|c/(c_0)^2\|_{\mathrm{L}_\infty(\kappa)}$, cf. Lemma 4.2), $\gamma|_\kappa = \|b\|_{\mathrm{L}_\infty(\kappa)}$ and $C$ is a positive constant that depends only on $d$, the parameter $\rho$ in (19) and the shape-regularity of $\mathcal{T}_h$. The DG-norm $|||\eta|||_{\mathrm{DG}}$ of $\eta = u - \Pi_p u$ can be estimated directly using Lemma 4.3 to show that a bound analogous to that on $|||\xi|||_{\mathrm{DG}}$ above holds. Hence, a bound on the discretisation error $u - u_{\mathrm{DG}} = \xi + \eta$ in the DG-norm $|||\cdot|||_{\mathrm{DG}}$ is obtained via the triangle inequality (see [30] for details).

Very often in practice the objective of the computation is not the approximation of the analytical solution $u$ in a given norm, but controlling the error in an output/target-functional $J(\cdot)$ of the solution. Relevant examples of output functionals include the lift and drag coefficients of a body immersed into a viscous fluid, the local mean value

of the field, or its flux through the outflow boundary of the computational domain. Here we give a brief survey of *a posteriori* and *a priori* error bounds for general linear target functionals $J(\cdot)$ of the solution; for related work, we refer to [11], [26], [28], [31], [32], [34], [42], [58], [59], for example, and to the recent monograph of Bangerth & Rannacher [6]. We shall confine ourselves to Type I (dual-weighted) *a posteriori* bounds; the computationally simpler, but cruder, Type II error bounds will not be discussed here (see Giles & Süli [22]).

**Type I *a posteriori* error analysis.** We proceed as in [34], [58] and begin by considering the following *dual* or *adjoint* problem: find $z \in \mathrm{H}^2(\Omega, \mathcal{T}_h)$ such that

$$B_{\mathrm{DG}}(w, z) = J(w) \quad \text{for all } w \in \mathrm{H}^2(\Omega, \mathcal{T}_h). \tag{20}$$

Let us assume that (20) possesses a unique solution. Clearly, the validity of this assumption depends, *inter alia*, on the choice of the linear functional under consideration. We shall return to this issue below; see also [25], [28], [34].

For a given linear functional $J(\cdot)$ the *a posteriori* error bound will be expressed in terms of the finite element residual $R_{\mathrm{int}}$ defined on $\kappa \in \mathcal{T}_h$ by $R_{\mathrm{int}}|_\kappa = (f - \mathcal{L}u_{\mathrm{DG}})|_\kappa$, which measures the extent to which $u_{\mathrm{DG}}$ fails to satisfy the differential equation on the union of the elements $\kappa$ in the mesh $\mathcal{T}_h$; thus we refer to $R_{\mathrm{int}}$ as the *internal residual*. Also, since $u_{\mathrm{DG}}$ only satisfies the boundary conditions approximately, the differences $g_{\mathrm{D}} - u_{\mathrm{DG}}$ and $g_{\mathrm{N}} - (a\nabla u_{\mathrm{DG}}) \cdot \nu$ are not necessarily zero on $\Gamma_{\mathrm{D}} \cup \Gamma_-$ and $\Gamma_{\mathrm{N}}$, respectively; thus we define the *boundary residuals* $R_{\mathrm{D}}$ and $R_{\mathrm{N}}$ by $R_{\mathrm{D}}|_{\partial\kappa\cap(\Gamma_{\mathrm{D}}\cup\Gamma_-)} = (g_{\mathrm{D}} - u^+_{\mathrm{DG}})|_{\partial\kappa\cap(\Gamma_{\mathrm{D}}\cup\Gamma_-)}$ and $R_{\mathrm{N}}|_{\partial\kappa\cap\Gamma_{\mathrm{N}}} = (g_{\mathrm{N}} - (a\nabla u^+_{\mathrm{DG}}) \cdot \nu)|_{\partial\kappa\cap\Gamma_{\mathrm{N}}}$, respectively. By using the divergence theorem, the Galerkin orthogonality property (16) may be rewritten as follows:

$$\begin{aligned}
0 = B_{\mathrm{DG}}(u - u_{\mathrm{DG}}, v) &= \ell_{\mathrm{DG}}(v) - B_{\mathrm{DG}}(u_{\mathrm{DG}}, v) \\
&= \sum_{\kappa\in\mathcal{T}_h} \Bigg\{ \int_\kappa R_{\mathrm{int}} v \,\mathrm{d}x - \int_{\partial_-\kappa\cap\Gamma} (b\cdot\nu_\kappa)\, R_{\mathrm{D}} v^+ \,\mathrm{d}s \\
&\qquad + \int_{\partial_-\kappa\setminus\Gamma} (b\cdot\nu_\kappa)\,[u_{\mathrm{DG}}]v^+ \,\mathrm{d}s + \int_{\partial\kappa\cap\Gamma_{\mathrm{D}}} \theta\, R_{\mathrm{D}}((a\nabla v^+)\cdot\nu_\kappa)\,\mathrm{d}s \\
&\qquad + \int_{\partial\kappa\cap\Gamma_{\mathrm{D}}} \sigma R_{\mathrm{D}} v^+ \,\mathrm{d}s + \int_{\partial\kappa\cap\Gamma_{\mathrm{N}}} R_{\mathrm{N}} v^+ \,\mathrm{d}s \\
&\qquad - \int_{\partial\kappa\setminus\Gamma} \left( \frac{\theta}{2}\,[u_{\mathrm{DG}}](a\nabla v^+)\cdot\nu_\kappa + \frac{1}{2}[(a\nabla u_{\mathrm{DG}})\cdot\nu_\kappa]v^+ \right) \mathrm{d}s \\
&\qquad - \int_{\partial\kappa\setminus\Gamma} \sigma [u_{\mathrm{DG}}] v^+ \,\mathrm{d}s \Bigg\}
\end{aligned} \tag{21}$$

for all $v \in S^{\boldsymbol{p}}(\Omega, \mathcal{T}_h, \boldsymbol{F})$. The starting point is the following result from [25].

**Theorem 4.4.** *Let $u$ and $u_{\mathrm{DG}}$ denote the solutions of* (1), (3) *and* (13), *respectively, and suppose that the dual solution $z$ is defined by* (20). *Then, the following error*

*representation formula holds:*

$$J(u) - J(u_{\mathrm{DG}}) = \mathcal{E}_{\Omega}(u_{\mathrm{DG}}, h, p, z - z_{h,p}) \equiv \sum_{\kappa \in \mathcal{T}_h} \eta_{\kappa}, \tag{22}$$

*where*

$$\begin{aligned}
\eta_{\kappa} = & \int_{\kappa} R_{\mathrm{int}}(z - z_{h,p})\,\mathrm{d}x - \int_{\partial_{-}\kappa \cap \Gamma} (b \cdot \nu_{\kappa})\, R_{\mathrm{D}}(z - z_{h,p})^{+}\,\mathrm{d}s \\
& + \int_{\partial_{-}\kappa \setminus \Gamma} (b \cdot \nu_{\kappa})\, [u_{\mathrm{DG}}](z - z_{h,p})^{+}\,\mathrm{d}s \\
& + \int_{\partial\kappa \cap \Gamma_{\mathrm{D}}} \theta\, R_{\mathrm{D}}((a\nabla(z - z_{h,p})^{+}) \cdot \nu_{\kappa})\,\mathrm{d}s \\
& + \int_{\partial\kappa \cap \Gamma_{\mathrm{D}}} \sigma\, R_{\mathrm{D}}(z - z_{h,p})^{+}\,\mathrm{d}s + \int_{\partial\kappa \cap \Gamma_{\mathrm{N}}} R_{\mathrm{N}}(z - z_{h,p})^{+}\,\mathrm{d}s \\
& - \int_{\partial\kappa \setminus \Gamma} \left\{ \frac{\theta}{2}\, [u_{\mathrm{DG}}](a\nabla(z - z_{h,p})^{+}) \cdot \nu_{\kappa} + \frac{1}{2}[(a\nabla u_{\mathrm{DG}}) \cdot \nu_{\kappa}](z - z_{h,p})^{+} \right\} \mathrm{d}s \\
& - \int_{\partial\kappa \setminus \Gamma} \sigma [u_{\mathrm{DG}}](z - z_{h,p})^{+}\,\mathrm{d}s
\end{aligned} \tag{23}$$

*for all* $z_{h,p} \in S^{\boldsymbol{p}}(\Omega, \mathcal{T}_h, \boldsymbol{F})$.

*Proof.* On choosing $w = u - u_{\mathrm{DG}}$ in (20) and recalling the linearity of $J(\cdot)$ and the Galerkin orthogonality property (21), we deduce that

$$\begin{aligned}
J(u) - J(u_{\mathrm{DG}}) &= J(u - u_{\mathrm{DG}}) = B_{\mathrm{DG}}(u - u_{\mathrm{DG}}, z) \\
&= B_{\mathrm{DG}}(u - u_{\mathrm{DG}}, z - z_{h,p}),
\end{aligned} \tag{24}$$

and hence (22), with $\eta_{\kappa}$ defined by (23), using the definitions of the residuals. □

**Corollary 4.5.** *Under the assumptions of Theorem* 4.4*, and with* $\eta_{\kappa}$ *defined as in* (23)*, the following Type I* a posteriori *error bound holds:*

$$|J(u) - J(u_{\mathrm{DG}})| \leq \mathcal{E}_{|\Omega|}(u_{\mathrm{DG}}, h, p, z - z_{h,p}) \equiv \sum_{\kappa \in \mathcal{T}_h} |\eta_{\kappa}|\,. \tag{25}$$

As discussed in [6], [11], [26], [58], the local *weighting terms* involving the difference between the dual solution $z$ and its projection/interpolant $z_{h,p}$ onto $S^{\boldsymbol{p}}(\Omega, \mathcal{T}_h, \boldsymbol{F})$ appearing in the Type I bound (25) contain useful information concerning the global transport of the error. Therefore, we shall retain the weighting terms involving the (unknown) dual solution $z$ in our bound and approximate them numerically, — instead of eliminating $z$, as one would in the derivation of a structurally simpler, but cruder, Type II *a posteriori* bound. However, before proceeding any further, we need to consider more carefully the dual problem defined by (20). Let us suppose, for example,

that the aim of the computation is to approximate the (weighted) mean value of the solution $u$; *i.e.*, $J(\cdot) \equiv M_\psi(\cdot)$, where $M_\psi(w) = \int_\Omega w\psi \, \mathrm{d}x$ and $\psi \in \mathrm{L}_2(\Omega)$. When $\theta = -1$, performing integration by parts, we find that the corresponding dual solution $z = z^{\mathrm{SIP}}$ is the solution of the following mesh-dependent problem: find $z$ such that

$$\begin{aligned} \mathcal{L}^* z \equiv -\nabla \cdot (a\nabla z) - b \cdot \nabla z + cz = \psi \quad & \text{in } \Omega, \\ z = 0 \quad & \text{on } \Gamma_{\mathrm{D}} \cup \Gamma_+, \\ (b \cdot \nu)z + (a\nabla z) \cdot \nu = 0 \quad & \text{on } \Gamma_{\mathrm{N}}. \end{aligned}$$

Thus, for $\theta = -1$ the dual problem is well-posed for this choice of target functional. We remark that, since in this case the dual problem formed by transposing the arguments in the bilinear form $B_{\mathrm{DG}}(\cdot,\cdot) = B^{\mathrm{SIP}}_{\mathrm{DG}}(\cdot,\cdot)$ involves the formal adjoint of the partial differential operator $\mathcal{L}$, $B^{\mathrm{SIP}}_{\mathrm{DG}}(\cdot,\cdot)$ is said to be *adjoint consistent*, cf. Arnold *et al.* [2]; in particular, when $\theta = -1$ and the primal and dual solutions are sufficiently smooth, the error in the functional will be seen to exhibit an optimal order of convergence. As we shall explain below by means of *a priori* error analysis, the situation is dramatically different when $\theta \neq -1$: then, the bilinear form $B_{\mathrm{DG}}(\cdot,\cdot)$ is *not* adjoint consistent; this, in turn, leads to degradation of the convergence rate of the error in the computed functional $J(\cdot)$ as the finite element space $S^{\boldsymbol{p}}(\Omega, \mathcal{T}_h, \boldsymbol{F})$ is enriched (by reducing $h$ or by increasing the polynomial degree vector $\boldsymbol{p}$). Once again, we refer to [25] for technical details.

***A priori* error bounds.** We continue to use the superscripts SIP and NIP to distinguish between the two methods and write $B^{\mathrm{SIP}}_{\mathrm{DG}}(\cdot,\cdot) \equiv B_{\mathrm{DG}}(\cdot,\cdot)$ when $\theta = -1$ and $B^{\mathrm{NIP}}_{\mathrm{DG}}(\cdot,\cdot) \equiv B_{\mathrm{DG}}(\cdot,\cdot)$ when $\theta = 1$. The corresponding numerical solutions $u^{\mathrm{SIP}}_{\mathrm{DG}}$ and $u^{\mathrm{NIP}}_{\mathrm{DG}}$ satisfy the following problems: find $u^{\mathrm{SIP}}_{\mathrm{DG}}$ in $S^{\boldsymbol{p}}(\Omega, \mathcal{T}_h, \boldsymbol{F})$ such that

$$B^{\mathrm{SIP}}_{\mathrm{DG}}(u^{\mathrm{SIP}}_{\mathrm{DG}}, v) = \ell_{\mathrm{DG}}(v) \quad \text{for all } v \in S^{\boldsymbol{p}}(\Omega, \mathcal{T}_h, \boldsymbol{F});$$

and find $u^{\mathrm{NIP}}_{\mathrm{DG}}$ in $S^{\boldsymbol{p}}(\Omega, \mathcal{T}_h, \boldsymbol{F})$ such that

$$B^{\mathrm{NIP}}_{\mathrm{DG}}(u^{\mathrm{NIP}}_{\mathrm{DG}}, v) = \ell_{\mathrm{DG}}(v) \quad \text{for all } v \in S^{\boldsymbol{p}}(\Omega, \mathcal{T}_h, \boldsymbol{F}),$$

respectively. The starting point for the *a priori* error analysis is the identity (24) in the proof of Theorem 4.4. Again, using the above notation, we see that

$$J(u) - J(u^{\mathrm{SIP}}_{\mathrm{DG}}) = B^{\mathrm{SIP}}_{\mathrm{DG}}(u - u^{\mathrm{SIP}}_{\mathrm{DG}}, z^{\mathrm{SIP}} - z_{h,p})$$

when the SIP scheme is employed, while for the NIP scheme, we have

$$J(u) - J(u^{\mathrm{NIP}}_{\mathrm{DG}}) = B^{\mathrm{NIP}}_{\mathrm{DG}}(u - u^{\mathrm{NIP}}_{\mathrm{DG}}, z^{\mathrm{NIP}} - z_{h,p})$$

for all $z_{h,p}$ in $S^{\boldsymbol{p}}(\Omega, \mathcal{T}_h, \boldsymbol{F})$. Here, $z^{\mathrm{SIP}}$ and $z^{\mathrm{NIP}}$ are the analytical solutions to the following dual problems: find $z^{\mathrm{SIP}} \in \mathrm{H}^2(\Omega, \mathcal{T}_h)$ such that

$$B^{\mathrm{SIP}}_{\mathrm{DG}}(w, z^{\mathrm{SIP}}) = J(w) \quad \text{for all } w \in \mathrm{H}^2(\Omega, \mathcal{T}_h);$$

and find $z^{\text{NIP}} \in \mathrm{H}^2(\Omega, \mathcal{T}_h)$ such that

$$B_{\text{DG}}^{\text{NIP}}(w, z^{\text{NIP}}) = J(w) \quad \text{for all } w \in \mathrm{H}^2(\Omega, \mathcal{T}_h).$$

Hence, for all $z_{h,p} \in S^{\boldsymbol{p}}(\Omega, \mathcal{T}_h, \boldsymbol{F})$,

$$J(u) - J(u_{\text{DG}}) = B_{\text{DG}}(u - u_{\text{DG}}, z^{\text{SIP}} - z_{h,p}) - (1+\theta) B_e(z^{\text{SIP}}, u - u_{\text{DG}}^{\text{NIP}}), \quad (26)$$

where $u_{\text{DG}}$ is either $u_{\text{DG}}^{\text{SIP}}$ or $u_{\text{DG}}^{\text{NIP}}$, depending on whether $\theta = -1$ or $\theta = 1$, respectively. In particular, the second term on the right-hand side of (26) is absent for the SIP scheme, i.e. when $\theta = -1$, but it is present when the NIP scheme is employed, *i.e.*, when $\theta = 1$. Since this second term is of lower order than the first term in (26), it will lead to suboptimal rates of convergence as the finite element space $S^{\boldsymbol{p}}(\Omega, \mathcal{T}_h, \boldsymbol{F})$ is enriched in the case of $\theta \neq -1$.

**Theorem 4.6.** *Let $\Omega \subset \mathbb{R}^d$ be a bounded polyhedral domain, $\mathcal{T}_h = \{\kappa\}$ a shape-regular subdivision of $\Omega$ into $d$-parallelepipeds and $\boldsymbol{p}$ a polynomial degree vector of bounded local variation. Let* (4) *and* (17) *hold, let the entries of $a$ be piecewise constant on $\mathcal{T}_h$, and $u|_\kappa \in \mathrm{H}^{k_\kappa}(\kappa)$, $k_\kappa \geq 2$, for $\kappa \in \mathcal{T}_h$, $z^{\text{SIP}}|_\kappa \in \mathrm{H}^{l_\kappa}(\kappa)$, $l_\kappa \geq 2$, for $\kappa \in \mathcal{T}_h$; then, the solution $u_{\text{DG}} \in S^{\boldsymbol{p}}(\Omega, \mathcal{T}_h, \boldsymbol{F})$ of* (13) *satisfies the error bound*

$$|J(u) - J(u_{\text{DG}})|^2 \leq C \left\{ \sum_{\kappa \in \mathcal{T}_h} \left( \alpha \frac{h_\kappa^{2(s_\kappa - 1)}}{p_\kappa^{2(k_\kappa - 3/2)}} + \beta_3 \frac{h_\kappa^{2s_\kappa}}{p_\kappa^{2k_\kappa}} + \gamma \frac{h_\kappa^{2(s_\kappa - 1/2)}}{p_\kappa^{2(k_\kappa - 1/2)}} \right) \|u\|^2_{\mathrm{H}^{k_\kappa}(\kappa)} \right\}$$

$$\times \left\{ \sum_{\kappa \in \mathcal{T}_h} \left( \alpha \frac{h_\kappa^{2(t_\kappa - 1)}}{p_\kappa^{2(l_\kappa - 3/2)}} + \beta_4 \frac{h_\kappa^{2t_\kappa}}{p_\kappa^{2l_\kappa}} + \gamma \frac{h_\kappa^{2(t_\kappa - 1/2)}}{p_\kappa^{2(l_\kappa - 1)}} \right) \|z^{\text{SIP}}\|^2_{\mathrm{H}^{l_\kappa}(\kappa)} + (1+\theta) \|z^{\text{SIP}}\|^2_{2,\mathcal{T}_h} \right\}$$

*for $1 \leq s_\kappa \leq \min(p_\kappa + 1, k_\kappa)$, $1 \leq t_\kappa \leq \min(p_\kappa + 1, l_\kappa)$, $p_\kappa \geq 1$, $\kappa \in \mathcal{T}_h$, where $\alpha|_\kappa = \bar{a}_{\tilde{\kappa}}$, $\beta_3|_\kappa = (1 + (\beta_1|_\kappa)^2)\|c_0\|^2_{\mathrm{L}_\infty(\kappa)}$, $(\beta_1|_\kappa = \|c(x)/(c_0(x))^2\|_{\mathrm{L}_\infty(\kappa)})$, $\beta_4|_\kappa = \|(c + \nabla \cdot b)/c_0\|^2_{\mathrm{L}_\infty(\kappa)}$, $\gamma|_\kappa = \|b\|_{\mathrm{L}_\infty(\kappa)}$ and $C$ is a constant depending on the dimension $d$, the parameter $\rho$ from* (19) *and the shape-regularity of $\mathcal{T}_h$.*

If we assume uniform orders $p_\kappa = p$, $s_\kappa = s$, $t_\kappa = t$, $k_\kappa = k$, $l_\kappa = l$, where $s$, $t$, $k$ and $l$ are positive integers, and $h = \max_{\kappa \in \mathcal{T}_h} h_\kappa$, then, in the diffusion-dominated case (viz. $b \approx 0$), Theorem 4.6, with $\theta = -1$ implies that for the SIP scheme

$$|J(u) - J(u_{\text{DG}})| \leq C\, (h^{s+t-2}/p^{k+l-2})\, p\, \|u\|_{\mathrm{H}^k(\Omega)} \|z^{\text{SIP}}\|_{\mathrm{H}^l(\Omega)}, \quad (27)$$

where $1 \leq s \leq \min(p+1, k)$ and $1 \leq t \leq \min(p+1, l)$. This error bound is optimal with respect to $h$ and suboptimal in $p$ by a full order. We note, however, that 'order-doubling' of the rate of convergence in $|J(u) - J(u_{\text{DG}})|$ observed when the SIP scheme is employed, as expressed by (27), is lost when the NIP method is used. In the hyperbolic case ($a \equiv 0$), the bound in Theorem 4.6 becomes

$$|J(u) - J(u_{\text{DG}})| \quad \leq \quad C\, (h^{s+t-1}/p^{k+l-1})\, p^{1/2}\, \|u\|_{\mathrm{H}^k(\Omega)} \|z^{\text{SIP}}\|_{\mathrm{H}^l(\Omega)}.$$

This error bound is optimal in $h$ and suboptimal in $p$ by $p^{1/2}$ (cf. also [34]).

**Adaptive algorithm.** In the light of Theorem 4.6, we now confine ourselves to the SIP scheme ($\theta = -1$). For a user-defined tolerance TOL, we consider the problem of designing an $hp$-finite element space $S^{\boldsymbol{p}}(\Omega, \mathcal{T}_h, \boldsymbol{F})$ such that the inequality $|J(u) - J(u_{\mathrm{DG}})| \leq \mathtt{TOL}$ holds, subject to the constraint that the number of degrees of freedom in $S^{\boldsymbol{p}}(\Omega, \mathcal{T}_h, \boldsymbol{F})$ is minimized. Following [34], we use the *a posteriori* error bound (25) with $z$ replaced by a discontinuous Galerkin approximation $\hat{z}$ computed on the same mesh $\mathcal{T}_h$ as for the primal solution $u_{\mathrm{DG}}$, but with a higher degree polynomial, *i.e.*, $\hat{z} \in S^{\hat{\boldsymbol{p}}}(\Omega, \mathcal{T}_h, \boldsymbol{F})$ , $\hat{\boldsymbol{p}} = \boldsymbol{p} + \boldsymbol{p}_{\mathrm{inc}}$; in our experiments we set $\boldsymbol{p}_{\mathrm{inc}} = \mathbf{1}$, cf. [26], [32], [58]. Thereby, in practice we enforce the stopping criterion

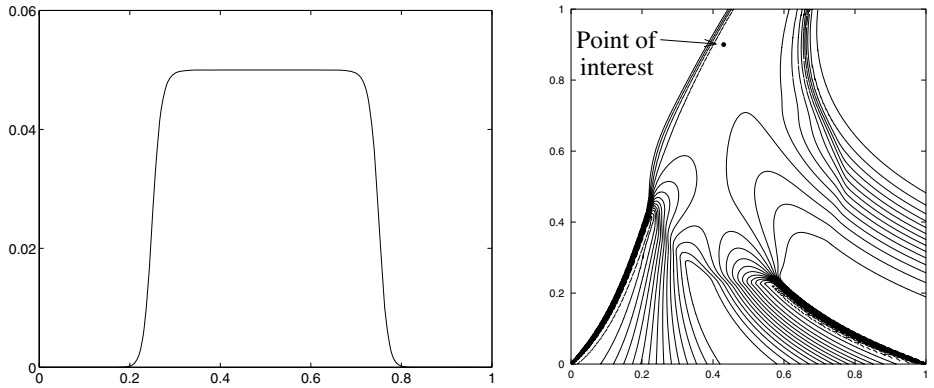
$$\hat{\mathcal{E}}_{|\Omega|} \equiv \mathcal{E}_{|\Omega|}(u_{\mathrm{DG}}, h, p, \hat{z} - z_{h,p}) \leq \mathtt{TOL}\,. \tag{28}$$

If (28) is not satisfied, then the elements are marked for refinement/derefinement according to the size of the (approximate) error indicators $|\hat{\eta}_\kappa|$; these are defined analogously to $|\eta_\kappa|$ in (23) with $z$ replaced by $\hat{z}$. In our experiments we use the fixed fraction mesh refinement algorithm, with refinement and derefinement fractions set to 20% and 10%, respectively.

Once an element $\kappa \in \mathcal{T}_h$ has been flagged for refinement or derefinement, a decision must be made whether the local mesh size $h_\kappa$ or the local degree $p_\kappa$ of the approximating polynomial should be altered. The choice to perform either $h$-refinement/derefinement or $p$-refinement/derefinement is based on the local smoothness of the primal and dual solutions $u$ and $z$, respectively; cf. [32], [34]. Let us first consider the case when an element has been flagged for *refinement*. If $u$ or $z$ are locally smooth, then $p$-refinement will be more effective than $h$-refinement, since the error will be expected to decay quickly within the current element $\kappa$ as $p_\kappa$ is increased. On the other hand, if both $u$ and $z$ have low regularity within the element $\kappa$, then $h$-refinement will be performed. To ensure that the desired level of accuracy is achieved efficiently, in [34] an automatic procedure was developed for deciding when to $h$- or $p$-refine, based on the smoothness-estimation strategy proposed by Ainsworth & Senior [1]. For a review of various $hp$-adaptive strategies as well as descriptions of new algorithms based on Sobolev index estimation *via* local Legendre expansions, we refer to [31], [32]. If an element has been flagged for *derefinement*, then the strategy implemented here is to coarsen the mesh in low-error-regions where either the primal or dual solutions $u$ and $z$, respectively, are smooth and decrease the degree of the approximating polynomial in low-error-regions when both $u$ and $z$ are insufficiently regular, cf. [34].

**Numerical experiments.** We explore the performance of the $hp$-adaptive strategy outlined above for the symmetric version of the interior penalty method, applied to a mixed hyperbolic-elliptic problem with discontinuous boundary data (cf. [25]). We let $a = \varepsilon(x)I$, where $\varepsilon = \frac{1}{2}\delta(1 - \tanh((r - 1/4)(r + 1/4)/\gamma))$, $r^2 = (x - 1/2)^2 + (y - 1/2)^2$ and $\delta \geq 0$ and $\gamma > 0$ are constants. Let $b = (2y^2 - 4x + 1, 1 + y)$, $c = -\nabla \cdot b$ and $f = 0$. With $\delta > 0$ and $0 < \gamma \ll 1$, the diffusion parameter $\varepsilon$

is approximately equal to $\delta$ in the circular region defined by $r < 1/4$, where the underlying partial differential equation is uniformly elliptic. In this example, we set $\delta = 0.05$ and $\gamma = 0.01$; a cross-section of $\varepsilon$ along $0 \le x \le 1$, $y = 1/2$ is shown in Figure 1. As the value of $r$ is increased beyond $1/4$, the function $\varepsilon$ rapidly decreases through a layer of width $\mathcal{O}(\gamma)$; for example, when $r > 0.336$ we have $\varepsilon < 10^{-15}$, so from the computational point of view $\varepsilon$ is zero to within rounding error; in this



(a) (b)

Figure 1. (a) Profile of $\varepsilon$ along $y = 0.5$, $0 \le x \le 1$; (b) DGFEM approximation to the primal problem on a $129 \times 129$ mesh with piecewise bilinear elements ($\boldsymbol{p} = \mathbf{1}$); from [25].

region, the partial differential equation undergoes a change of type becoming, in effect, hyperbolic. Thus we shall refer to the part of $\Omega$ with $r > 1/4 + \mathcal{O}(\gamma)$ as the *hyperbolic region*, while the set of points in $\Omega$ with $r \le 1/4$ will be called the *elliptic region*; of course, strictly speaking, the partial differential equation is elliptic in the whole of $\overline{\Omega}$. The characteristics associated with the hyperbolic part of the operator enter the computational domain $\Omega$ from three sides of $\Gamma$, namely through the vertical edges placed along $x = 0$ and $x = 1$ and the horizontal edge along $y = 0$; the characteristics exit $\Omega$ through the horizontal edge along $y = 1$. On the union of these three faces we prescribe the following boundary condition:

$$u(x, y) = \begin{cases} 1 & \text{for } x = 0 \ , \ 0 < y \le 1, \\ \sin^2(\pi x) & \text{for } 0 \le x \le 1 \ , \ y = 0, \\ \mathrm{e}^{-50y^4} & \text{for } x = 1 \, , \ 0 < y \le 1. \end{cases}$$

Figure 1 shows the numerical approximation to (1) using the SIP method on a uniform $129 \times 129$ uniform square mesh with $\boldsymbol{p} = \mathbf{1}$. Let us suppose that the objective of the computation is to calculate the value of the analytical solution $u$ at a certain point of interest, $x = (0.43, 0.9)$, *i.e.*, $J(u) = u(0.43, 0.9)$; cf. Figure 1. The true value of the functional is given by $J(u) = 0.704611313375$.

In Table 1 we show the performance of our adaptive finite element algorithm using $hp$-refinement. Clearly, the computed Type I *a posteriori* error bound (25) is very sharp in the sense that it overestimates the true error in the computed functional by a factor of about 1–8 only, and by a factor of only 3.34 on average on the meshes that arise in the course of our adaptive $hp$-refinement.

Table 1. History of the adaptive $hp$-refinement. The effectivity index is defined as the ratio of the *a posteriori* error bound $\sum_\kappa |\hat{\eta}_\kappa|$ and the error $|J(u) - J(u_{\mathrm{DG}})|$; from [25].

| Nodes | Elements | Degrees of freedom | $\lvert J(u) - J(u_{\mathrm{DG}})\rvert$ | $\sum_\kappa \lvert\hat{\eta}_\kappa\rvert$ | Effectivity index |
|---|---|---|---|---|---|
| 81 | 64 | 576 | 1.924e-02 | 3.330e-02 | 1.73 |
| 99 | 76 | 740 | 1.056e-02 | 1.085e-02 | 1.03 |

| 1313 | 1132 | 47406 | 6.531e-10 | 2.154e-09 | 3.30 |

Figure 2 shows $|J(u) - J(u_{\mathrm{DG}})|$, using both $h$- and $hp$-refinement, against the square-root of the number of degrees of freedom on a linear-log scale. After the initial transient, the error in the computed functional using $hp$-refinement is seen to become (on average) a straight line, which indicates exponential convergence of $J(u_{\mathrm{DG}})$ to $J(u)$; this occurs since $z^{\mathrm{SIP}}$ is a real analytic function in the regions of the computational domain where $u$ is not smooth and *vice versa*. Figure 2 also demonstrates the superiority of the adaptive $hp$-refinement strategy over the standard adaptive $h$-refinement algorithm when $\mathtt{TOL} \lessapprox 10^{-3}$.

On the final mesh the error between $J(u)$ and $J(u_{\mathrm{DG}})$ using $hp$-refinement is over 4 orders of magnitude smaller than the corresponding quantity when $h$-refinement is used alone.

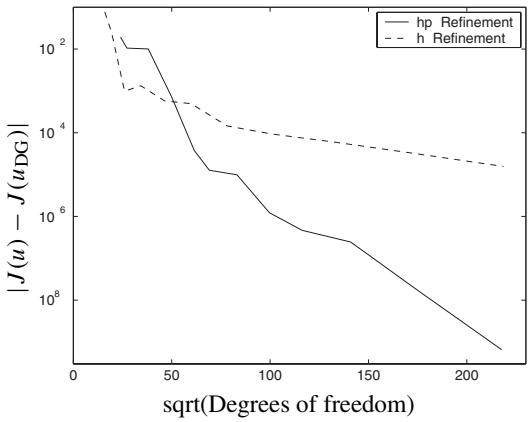

Figure 2. Comparison between $h$- and $hp$-adaptive mesh refinement; from [25].

Figure 3 depicts the primal mesh after 11 adaptive mesh refinement steps. We display the $h$-mesh alone, as well as the corresponding distribution of the polynomial degree on this mesh and the percentage of elements with that degree. We see that some $h$-refinement of the primal mesh has taken place in the region of the computational

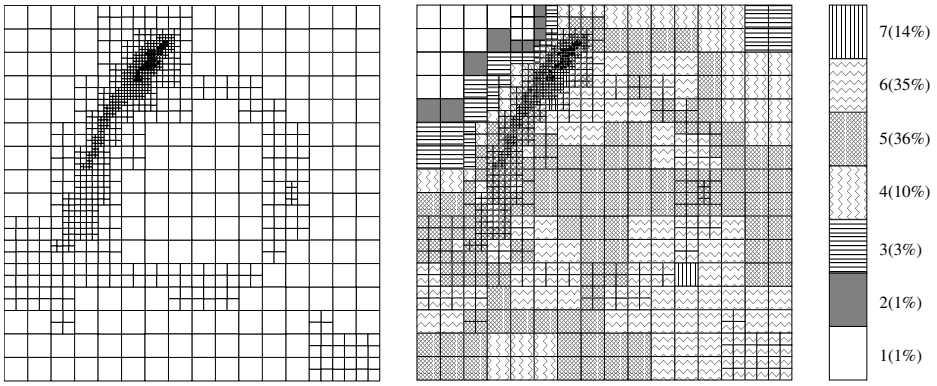

Figure 3. $h$- and $hp$-meshes after 11 refinements, with 1313 nodes, 1132 elements and 47406 degrees of freedom: here, $|J(u) - J(u_{\mathrm{DG}})| = 6.531 \times 10^{-10}$; from [25].

domain upstream of the point of interest, as well as in the circular region where the underlying partial differential equation changes type. Once the $h$-mesh has adequately captured the structure of the primal and dual solutions, the $hp$-adaptive algorithm performs $p$-refinement elsewhere in the domain of dependence of the point of interest.

## 5. High-dimensional transport-diffusion problems

We conclude by giving some pointers to recent results on stabilised sparse finite element methods for high-dimensional partial differential equations (1) with nonnegative characteristic form (cf. [57]). Such high-dimensional equations arise from a number of important applications in physics, chemistry, biology and finance. The origins of sparse tensor-product constructions and hyperbolic cross spaces can be traced back to Babenko [3] and Smolyak [56]; we refer to the papers of Temlyakov [61], DeVore, Konyagin & Temlyakov [20] for the study of high-dimensional approximation problems, to the works of Wasilkowski & Woźniakowski [62] and Novak & Ritter [46] for high-dimensional integration problems and associated complexity questions, to the paper of Zenger [63] for an early contribution to the numerical solution of high-dimensional elliptic equations, to the articles by von Petersdorff & Schwab [50] and Hoang & Schwab [27] for the analysis of sparse-grid methods for high-dimensional elliptic multiscale problems and parabolic equations, respectively, and to the recent survey article of Bungartz & Griebel [17].

Suppose that $\Omega = (0,1)^d$, $\Gamma_{\rm N} = \emptyset$ and $g_{\rm D} = 0$ in (3), and that the operator $\mathcal{L}$ in (1) has constant coefficients. In the simplest case, the construction of the finite element space $\hat{V}_0^L \subset \mathcal{H}$ begins by taking the tensor product of $d$ copies of a finite element space of univariate hierarchical continuous piecewise linear functions ($p = 1$) on a uniform mesh of size $h_L = 2^{-L}$, $L \geq 1$. The resulting tensor-product space $V_0^L$ has dimension $\dim(V_0^L) = \mathcal{O}(h_L^{-d})$. Clearly, the use of this space would lead to exponential growth of computational complexity for fixed $h_L$, as $d$ increases. Thus, the idea is to reduce the complexity of the computation for large $d$ by sparsifying the space $V_0^L$; the resulting sparse finite element space is denoted $\hat{V}_0^L$ and has only $\dim(\hat{V}_0^L) = \mathcal{O}(h_L^{-1}|\log h_L|^{d-1})$ degrees of freedom. The relevant result from [57], stated in the theorem below, is that, with a careful choice of the streamline-diffusion stabilisation parameter $\delta_L$ and assuming that $u \in \mathcal{H}^2(\Omega) \cap \mathcal{H}$, where $\mathcal{H}^2(\Omega) = \{v : D^\alpha v \in {\rm L}_2(\Omega),\ |\alpha|_\infty \leq 2\}$ is the space of functions with $\rm L_2$-bounded mixed second derivatives, one can ensure that this reduction of computational complexity is achieved at essentially no loss in accuracy in the streamline-diffusion finite element method compared to the case when the full tensor-product space $V_0^L$ is used instead of the sparse space $\hat{V}_0^L$.

**Theorem 5.1.** *Let $f \in {\rm L}_2(\Omega)$, $c > 0$ and $u \in \mathcal{H}^2(\Omega) \cap \mathcal{H}$. Then, the following bound holds for the error $u - u_{\rm SD}$ between the analytical solution $u$ of* (8) *and its sparse finite element approximation $u_{\rm SD} \in \hat{V}_0^L$, with $L \geq 1$ and $h = h_L = 2^{-L}$:*

$$
\begin{aligned}
&|||u - u_{\rm SD}|||_{\rm SD}^2 \\
&\qquad \leq C(u)\left\{|a|h_L^2 + h_L^4|\log_2 h_L|^{2(d-1)}\max\left(\frac{|a|}{h_L^2},\ \frac{d|b|}{h_L|\log_2 h_L|^{d-1}},\ c\right)\right\}
\end{aligned}
$$

*with the streamline-diffusion parameter $\delta_L$ defined by the formula*

$$\delta_L := K_\delta \min\left(\frac{h_L^2}{|a|}, \frac{h_L|\log_2 h_L|^{d-1}}{d|b|}, \frac{1}{c}\right),$$

*with $K_\delta \in \mathbb{R}_{>0}$ a constant, independent of $h_L$ and $d$, and $C(u) = \text{Const.}\|u\|^2_{\mathcal{H}^2(\Omega)}$ where* Const. *is a positive constant independent of the discretisation parameter $h_L$.*

We refer to [57] for further technical details, including the proof of this result.

## 6. Concluding remarks

We surveyed continuous stabilised and discontinuous Galerkin finite element methods for the numerical solution of second-order partial differential equations with nonnegative characteristic form. We stated *a priori* and residual-based *a posteriori* error bounds, and in the case of the discontinuous Galerkin method we showed how the *a posteriori* bound may be used to drive an *hp*-adaptive finite element algorithm. We also commented on the use of sparse stabilised finite element methods for high-dimensional transport-dominated diffusion equations: stochastic analysis and kinetic theory are particularly fertile sources of Fokker–Planck equations of this kind [41]. The numerical solution of high-dimensional partial differential equations has been an active area of research in recent years [17], though the bulk of the research has been confined to self-adjoint elliptic and parabolic equations. As we have briefly indicated, extensions of these results to the, vastly richer, class of partial differential equations with nonnegative characteristic form are feasible, and we expect that activities in this direction will continue to flourish.

**Acknowledgments.** I am grateful to Franco Brezzi, Bernardo Cockburn, Kathryn Gillow, Paul Houston, Donatella Marini, Rolf Rannacher and Christoph Schwab for numerous stimulating discussions on the ideas presented in this paper. The computational experiments in Section 4 were performed by Paul Houston.

# Ergodic control of diffusion processes

Vivek S. Borkar*

**Abstract.** Results concerning existence and characterization of optimal controls for ergodic control of nondegenerate diffusion processes are described. Extensions to the general 'controlled martingale problem' are indicated, which cover in particular degenerate diffusions and some infinite dimensional problems. In conclusion, some related problems and open issues are discussed.

**Mathematics Subject Classification (2000).** Primary 93E20; Secondary 60H20.

**Keywords.** Controlled diffusions, ergodic control, stationary Markov control, controlled martingale problems, dynamic programming.

## 1. Introduction

Ergodic or 'long run average' control of Markov processes considers the minimization of a time-averaged cost over admissible controls. This stands apart from the usual 'integral' cost criteria such as finite horizon or infinite horizon discounted cost criteria because neither the dynamic programming principle nor the usual 'tightness' arguments for existence of optima common to these set-ups carry over easily to the ergodic problem. Thus entirely new proof techniques have to be employed. The situation gets more complicated for continuous time continuous state space processes, of which diffusion processes are a prime example, because of the additional technicalities involved. This article describes first the reasonably well-understood case of non-degenerate diffusions, and then the partly resolved case of the more general 'controlled martingale problem' which covers degenerate diffusions and partially observed diffusions, among others.

An extended account of this topic will appear in [2].

## 2. Ergodic control of non-degenerate diffusions

**2.1. Preliminaries.** The $d$-dimensional ($d \geq 1$) controlled diffusion process $X(\cdot) = [X_1(\cdot), \ldots, X_d(\cdot)]^T$ is described by the stochastic differential equation

$$X(t) = X_0 + \int_0^t m(X(s), u(s))\, ds + \int_0^t \sigma(X(s))\, dW(s), \tag{1}$$

*The work is supported in part by a grant from the Department of Science and Technology, Government of India

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

for $t \geq 0$. Here:

1. for a compact metric 'control space' $U$, $m(\cdot,\cdot) = [m_1(\cdot,\cdot), \ldots, m_d(\cdot,\cdot)]^T : \mathcal{R}^d \times U \to \mathcal{R}^d$ is continuous and Lipschitz in the first argument uniformly with respect to the second,
2. $\sigma(\cdot) = [[\sigma_{ij}(\cdot)]]_{1 \leq i,j \leq d} : \mathcal{R}^d \to \mathcal{R}^{d \times d}$ is Lipschitz,
3. $X_0$ is an $\mathcal{R}^d$-valued random variable with a prescribed law $\pi_0$,
4. $W(\cdot) = [W_1(\cdot), \ldots, W_d(\cdot)]^T$ is a $d$-dimensional standard Brownian motion independent of $X_0$,
5. $u(\cdot) : \mathcal{R}^+ \to U$ is the 'control process' with measurable paths, satisfying the *non-anticipativity condition*: for $t > s \geq 0$, $W(t) - W(s)$ is independent of $\{X_0, W(y), u(y), y \leq s\}$. (In other words, $u(\cdot)$ does not anticipate the future increments of $W(\cdot)$.)

This class of $u(\cdot)$ is referred to as *admissible* controls. It is known that without loss of generality, one may take these to be adapted to the natural filtration of $X(\cdot)$, given by $\mathcal{F}_t$ = the completion of $\bigcap_{s>t} \sigma(X(y), y \leq s)$. We shall say that it is a *stationary Markov* control if in addition $u(t) = v(X(t)), t \geq 0$, for a measurable $v : \mathcal{R}^d \to U$. By a standard abuse of terminology, we identify this control with the map $v(\cdot)$. We shall say that (1) is *non-degenerate* if the least eigenvalue of $\sigma(\cdot)\sigma^T(\cdot)$ is uniformly bounded away from zero, *degenerate* otherwise. We use the 'weak solution' framework, i.e., only the law of the pair $(X(\cdot), u(\cdot))$ is prescribed and 'uniqueness' is interpreted as uniqueness in law. For this section, we assume non-degeneracy. This in particular implies existence of a unique *strong* solution for stationary Markov controls.

We shall also need the relaxation of the notion of control process $u(\cdot)$ above to that of a *relaxed* control process. That is, we assume that $U = \mathcal{P}(U_0)$, the space of probability measures on $U_0$ with Prohorov topology, where $U_0$ is compact metrizable (whence so is $U$) and $m_i(\cdot,\cdot)$, $1 \leq i \leq d$, are of the form

$$m_i(x,u) = \int \bar{m}_i(x,y)u(dy), \quad 1 \leq i \leq d,$$

for some $\bar{m}_i : \mathcal{R}^d \times U_0 \to \mathcal{R}$ that are continuous and Lipschitz in the first argument uniformly w.r.t. the second. We may write $u(t) = u(t, dy)$ to underscore the fact that it is a measure-valued process. Likewise for stationary Markov controls, write $v(\cdot) = v(\cdot, dy)$. Then the original notion of $U_0$-valued control $u_0(\cdot)$ (say) corresponds to $u(t, dy) = \delta_{u_0(t)}(dy)$, the Dirac measure at $u_0(t)$, for all $t$. We call such controls as *precise* controls. Precise stationary Markov controls may be defined accordingly.

The objective of ergodic control is to minimize

$$\limsup_{T \to \infty} \frac{1}{T} \int_0^T E[k(X(t), u(t))]\, dt \tag{2}$$

(the average version), or to a.s. minimize

$$\limsup_{T\to\infty} \frac{1}{T}\int_0^T k(X(t), u(t))\,dt \tag{3}$$

(the 'almost sure' version). Here $k : \mathcal{R}^d \times U \to \mathcal{R}$ is continuous. In view of our relaxed control framework, we take it to be of the form $k(x,u) = \int \bar{k}(x,y)u(dy)$ for a continuous $\bar{k} : \mathcal{R}^d \times U_0 \to \mathcal{R}$. This cost criterion is popular in applications where transients are fast, hence negligible, and one is choosing essentially from among the attainable 'steady states'. As mentioned above, we consider the non-degenerate case first. Most of the results presented in the remainder of this section have been established for bounded coefficients in the original sources, but the extension to the Lipschitz coefficients (implying linear growth) is not difficult and appears in [2]. One usually assumes (and we do) that $k$ is bounded from below.

**2.2. Existence results.** Let $v(\cdot)$ be a stationary Markov control such that the corresponding $X(\cdot)$ is positive recurrent and therefore has a unique stationary distribution $\eta^v \in \mathcal{P}(\mathcal{R}^d)$. Define the corresponding ergodic occupation measure as $\mu^v(dx,dy) = \eta^v(dx)v(x,dy)$. Costs (2), (3) will then equal ('a.s.' in the latter case) $\int \bar{k}d\mu^v$. A key result is:

**Theorem 2.1** ([18]). *The set $\mathcal{G} = \{\mu^v : v(\cdot)$ stationary Markov$\}$ is closed convex in total variation norm topology, with its extreme points corresponding to precise stationary Markov controls.*

We can say much more: define the empirical measures $\{\nu_t\}$ by:

$$\int f\,d\nu_t = \frac{1}{t}\int_0^t \int f(X(s), y)u(s,dy)\,ds, \quad f \in C_b(\mathcal{R}^d \times U_0),\ t > 0.$$

Let $\overline{\mathcal{R}} = \mathcal{R}^d \cup \{\infty\}$ = the one point compactification of $\mathcal{R}^d$ and view $\nu_t$ as a random variable in $\mathcal{P}(\overline{\mathcal{R}} \times U_0)$ that assigns zero mass to $\{\infty\} \times U_0$.

**Theorem 2.2** ([16]). *As $t \to \infty$, almost surely*

$$\nu_t \to \{\nu : \nu(A) = a\nu'(A \cap (\{\infty\} \times U_0)) + (1-a)\nu''(A \cap (\mathcal{R}^d \times U_0)) \text{ for all } A \text{ Borel in } \overline{\mathcal{R}} \times U_0,\ \text{with } a \in [0,1],\ \nu' \in \mathcal{P}(\{\infty\} \times U_0),\ \nu'' \in \mathcal{G}\}.$$

There are two important special cases for which Theorem 2.1 allows us to reduce the control problem to the infinite dimensional linear programming problem of minimizing $\int \bar{k}d\mu$ over $\mathcal{G}$ and thereby deduce the existence of an optimal precise stationary Markov control for the 'a.s.' version of the ergodic control problem [16]:

1. under a suitable 'stability condition' (such as a convenient 'stochastic Liapunov condition') that ensures compactness of $\mathcal{G}$ and a.s. tightness of $\{\nu_t\}$, or,

2. under a condition that penalizes escape of probability mass to infinity, such as the 'near-monotonicity condition':

$$\liminf_{||x||\to\infty} \min_u k(x,u) > \beta,$$

where $\beta =$ the optimal cost.

The latter condition is often satisfied in practice. The 'average' version of the ergodic cost can be handled similarly, using the average empirical measures $\{\bar{\nu}_t\}$ defined via

$$\int f\, d\bar{\nu}_t = \frac{1}{t}\int_0^t E\left[\int f(X(s),y)u(s,dy)\right] ds, \quad f \in C_b(\mathcal{R}^d \times U_0),\ t > 0,$$

in place of $\{\nu_t\}$.

**2.3. Dynamic programming.** The standard approach to dynamic programming for ergodic control, inherited from earlier developments in the discrete time and state problems, is to treat it as a limiting case of the infinite horizon discounted cost problem as the discount vanishes. Hence we begin with the infinite horizon discounted cost

$$E\left[\int_0^\infty e^{-\alpha t} k(X(t),u(t))\, dt\right],$$

where $\alpha > 0$ is the discount factor. Define

$$Lf(x,u) = \langle \nabla f(x), m(x,u)\rangle + \frac{1}{2}\mathrm{tr}\big(\sigma(x)\sigma^T(x)\nabla^2 f(x)\big)$$

for $f \in C^2(\mathcal{R}^d)$. We may write $L_u f(x)$ for $Lf(u,x)$, treating $u$ as a parameter. The Hamilton–Jacobi–Bellman (HJB) equation for the 'value function'

$$V^\alpha(x) = \inf E\left[\int_0^\infty e^{-\alpha t} k(X(t),u(t))\, dt | X(0) = x\right]$$

(where the infimum is over all admissible controls) can be arrived at by standard dynamic programming heuristic and is

$$\min_u (k(x,u) - \alpha V^\alpha(x) + LV^\alpha(x,u)) = 0$$

on the whole space. For $k$ bounded from below, $V^\alpha$ is its least solution in $C^2(\mathcal{R}^d)$. Define $\overline{V}^\alpha = V^\alpha - V^\alpha(0)$. Then $\overline{V}^\alpha$ satisfies

$$\min_u (k(x,u) - \alpha \overline{V}^\alpha(x) - \alpha V^\alpha(0) + L\overline{V}^\alpha(x,u)) = 0. \tag{4}$$

Under suitable technical conditions (such as near-monotonicity or stability conditions mentioned above) one can show that as $\alpha \downarrow 0$, $\overline{V}^\alpha(\cdot)$ and $\alpha V^\alpha(0)$ converge along

a subsequence to some $V, \beta$ in an appropriate Sobolev space and $\mathcal{R}$, respectively. Letting $\alpha \downarrow 0$ along this subsequence in (4), these are seen to satisfy

$$\min_u (k(x,u) - \beta + LV(x,u)) = 0.$$

This is the HJB equation of ergodic control. One can show uniqueness of $\beta$ as being the optimal ergodic cost and of $V$ up to an additive scalar in an appropriate function class depending on the set of assumptions one is working with. A verification theorem holds, i.e., the optimal stationary Markov control $v(\cdot)$ is characterized by the condition

$$v(x) \in \text{Argmin}\,(k(x,\cdot) + \langle \nabla V(x), m(x,\cdot)\rangle)\,, \text{ a.e.}$$

See [6], [17]. Note that the minimum will be attained in particular at a precise stationary Markov control, establishing the existence of an optimal precise stationary Markov control.

One also has the following stochastic representations for the ergodic value function $V$ (modulo an additive constant):

$$V(x) = \lim_{r \downarrow 0} \left( \inf E\left[ \int_0^{\tau_r} (k(X(s), u(s)) - \beta)\, ds | X(0) = x \right] \right),$$

where $\tau_r = \min\{t > 0 : ||X(t)|| = r\}$ for $r > 0$ [17] and the infimum is over all admissible controls. Alternatively,

$$V(x) = \inf \left( \inf_\tau E\left[ \int_0^{\tau} (k(X(s), u(s)) - \beta)\, ds | X(0) = x \right] \right),$$

where the inner infimum is over all bounded stopping times w.r.t. the natural filtration $\{\mathcal{F}_t\}$ of $X(\cdot)$, and the outer infimum is over all $\{\mathcal{F}_t\}$-adapted controls [21].

## 3. Controlled martingale problems

**3.1. Preliminaries.** Such explicit results are not as forthcoming in the more general scenario we discuss next. We shall denote by $E$ the Polish space that will serve as the state space of the controlled Markov process $X(\cdot)$, and by $U_0$ the compact metric 'control' space. $\mathcal{U}$ will denote the space of measurable maps $[0, \infty) \to U = \mathcal{P}(U_0)$ with the coarsest topology that renders continuous each of the maps

$$\mu(\cdot) = \mu(\cdot, du) \in \mathcal{U} \mapsto \int_0^T g(t) \int_{U_0} h(u) \mu(t, du)\, dt,$$

for all $T > 0$, $g \in L_2[0, T]$, $h \in C_b(U_0)$. This is compact metrizable (see, e.g., [9]). The control process $u(\cdot)$ can then be viewed as a $\mathcal{U}$-valued random variable.

For $\{f_k\}$, $f \in B(E) \stackrel{\text{def}}{=}$ the space of bounded measurable maps $E \to \mathcal{R}$, say that $f_k \xrightarrow{\text{bp}} f$ (where 'bp' stands for '*bounded pointwise*') if $\sup_{x,k} |f_k(x)| < \infty$ and

$f_k(x) \to f(x)$ for all $x$. $Q \subset B(E)$ is *bp-closed* if $f_k \in Q$ for all $k$ and $f_k \xrightarrow{\text{bp}} f$ together imply $f \in Q$. For $Q \subset B(E)$, define bp-closure$(Q)$ = the smallest bp-closed subset of $B(E)$ containing $Q$.

Let $A$ be an operator with domain $\mathcal{D}(A) \subset C_b(E)$ and range $\mathcal{R}(A) \subset C_b(E \times U_0)$. Let $\nu \in \mathcal{P}(E)$.

**Definition 3.1.** *An $E \times U$-valued process $(X(\cdot), \pi(\cdot) = \pi(\cdot, du))$ defined on a probability space $(\Omega, \mathcal{F}, P)$ is said to be a solution to the relaxed controlled martingale problem for $(A, \nu)$ with respect to a filtration $\{\mathcal{F}_t, t \geq 0\}$ if:*

- *$(X(\cdot), \pi(\cdot))$ is $\{\mathcal{F}_t\}$-progressive;*
- *$\mathcal{L}(X(0)) = \nu$;*
- *for $f \in \mathcal{D}(A)$,*

$$f(X(t)) - \int_0^t \int_{U_0} Af(X(s), u)\pi(s, du)\, ds, \quad t \geq 0, \tag{5}$$

*is an $\{\mathcal{F}_t\}$-martingale.*

We omit explicit mention of $\{\mathcal{F}_t\}$ or $\nu$ when they are apparent from the context. The operator $A$ is assumed to satisfy the following conditions:

1. (C1) There exists a countable subset $\{g_k\} \subset \mathcal{D}(A)$ such that

$$\{(g, Ag) : g \in \mathcal{D}(A)\} \subset \text{bp-closure}(\{(g_k, Ag_k) : k \geq 1\}).$$

2. (C2) $\mathcal{D}(A)$ is an algebra that separates points in $E$ and contains constant functions. Also, $A\mathbf{1} = 0$, where $\mathbf{1}$ is the constant function identically equal to 1.
3. (C3) For each $u \in U_0$, let $A^u f(\cdot) = Af(\cdot, u)$. Then there exists an r.c.l.l. solution to the martingale problem for $(A^u, \delta_x)$ for all $u \in U_0$, $x \in E$.

For example, the following can be shown to fit this framework:

1. $X(\cdot)$ as in (1) with or without the non-degeneracy condition.
2. An important instance of the above is the 'separated control problem' for control of diffusions with partial observations, which we describe in some detail next. Append to (1) the 'observation equation'

$$Y(t) = \int_0^t h(X(s))\, ds + W'(t),$$

where $h : \mathcal{R}^d \to \mathcal{R}^s$ $(s \geq 1)$ is a Lipschitz observation map and $W'(\cdot)$ is an $s$-dimensional standard Brownian motion independent of $(X_0, W(\cdot))$, representing the (integrated) observation noise. The control $u(\cdot)$ is ideally

required to be adapted to the natural filtration of $Y(\cdot)$, but a standard relaxation allows for somewhat more general 'wide sense admissible' controls. These require merely that under a locally (in time) absolutely continuous change of measure that retains (1) but renders $Y(\cdot)$ itself an $s$-dimensional standard Brownian motion independent of $(X_0, W(\cdot))$, the future increments $Y(t+\cdot) - Y(t)$ should be independent of $\{X_0, W(\cdot), u(s), Y(s), s \le t\}$ for all $t > 0$. The correct state variable for this problem (to be precise, one choice thereof) turns out to be the $\mathcal{P}(\mathcal{R}^d)$-valued process $\{\mu_t\}$ of regular conditional laws of $X(t)$ given $\{Y(s), u(s), s \le t\}$ for $t \ge 0$. This evolves according to the equations of nonlinear filtering:

$$\mu_t(f) = \mu_0(f) + \int_0^t \mu_s(L_{u(s)}f)\,ds + \int_0^t \langle \mu_s(fh) - \mu_s(f)\mu_s(h), d\hat{Y}(s)\rangle \tag{6}$$

for $f \in C_b^2(\mathcal{R}^d)$, where we follow the notation $\nu(f) = \int f d\nu$. The products in the integrand of the stochastic integral in (6) are componentwise, and the process $\hat{Y}(t) = Y(t) - \int_0^t \mu_s(h)ds$, $t \ge 0$, is the so called 'innovations process' which is an $s$-dimensional standard Brownian motion that generates the same natural filtration as $Y(\cdot)$ [1]. The well-posedness of (6) can be established under additional regularity conditions on $h$ [24]. In terms of $\{\mu_t\}$, the ergodic cost can be rewritten as

$$\limsup_{t\to\infty} \frac{1}{t} \int_0^t E[\mu_s(\bar{k}(\cdot, u(s)))]\,ds.$$

The $\mathcal{P}(\mathcal{R}^d)$-valued controlled Markov process $\{\mu_t\}$ with this cost functional can be shown to fit the above framework. This is called the 'separated control problem' because it separates the issues of estimation and control.

3. Certain Hilbert-space valued controlled stochastic evolution equations can also be shown to fit the above framework [7].

**3.2. The control problem.** Let $k : E \times U_0 \to [0, \infty]$ be a continuous *running cost* function. The ergodic control problem is to minimize the *ergodic cost*

$$\limsup_{t\to\infty} \frac{1}{t} \int_0^t E\left[\int_{U_0} k(X(s), u)\pi(s, du)\right] ds. \tag{7}$$

We assume that the set of laws of $(X(\cdot), \pi(\cdot))$ for which this is finite is nonempty.

For a stationary $(X(\cdot), \pi(\cdot))$, define the associated *ergodic occupation measure* $\varphi \in \mathcal{P}(E \times U_0)$ by:

$$\int f(x, u)\varphi(dxdu) = E\left[\int_{U_0} f(X(t), u)\pi(t, du)\right].$$

Note that (7) then becomes $\int k d\varphi$. Let $\mathcal{G}$ denote the set of all ergodic occupation measures. From [7], we then have (see [27], [33], [34] for related results):

**Theorem 3.2.** *$\mathcal{G}$ is closed convex and is characterized as*

$$\mathcal{G} = \left\{\mu \in \mathcal{P}(E \times U_0) : \int Af \, d\mu = 0 \text{ for all } f \in \mathcal{D}(A)\right\}.$$

*In particular, for each $\mu \in \mathcal{G}$, there exists a stationary pair $(X(\cdot), \pi(\cdot))$ whose marginal at each time is $\mu$. Furthermore, $\pi(\cdot)$ may be taken to be stationary Markov.*

This can be made a starting point for existence results in specific cases. For example, for degenerate diffusions and the separated control problem for partially observed diffusions, somewhat stronger variants of the 'stability' and 'near-monotonicity' conditions described earlier suffice for the existence of an optimal stationary pair $(X(\cdot), \pi(\cdot))$. By considering the ergodic decomposition thereof, 'stationary' here may be improved to 'ergodic' [7]. Also, in view of the above theorem, the control therein may be taken to be stationary Markov.

This, however, does not imply that the process $X(\cdot)$ itself is time-homogeneous Markov, or even Markov. To establish the existence of an optimal Markov solution, we assume the following:

*For a fixed initial law $\nu$ of $X_0$, the attainable laws of $(X(\cdot), \pi(\cdot))$ form a tight set*

$$\bar{\mathcal{M}}(\nu) \subset \mathcal{P}(D([0, \infty); E) \times \mathcal{U}).$$

Simple sufficient conditions for this can be given in specific cases mentioned above. An immediate consequence of this is that $\bar{\mathcal{M}}(\nu)$ is in fact a compact convex set. Consider the equivalence relation on $\bar{\mathcal{M}}(\nu)$ that equates two laws when the corresponding one dimensional marginals agree for a.e. $t$. The set of equivalence classes, called the 'marginal classes', then forms a convex compact set in the quotient topology.

**Theorem 3.3.** *Every representative of an extremal marginal class corresponds to a Markov process.*

This is proved for degenerate diffusions in [10] and for the separated control problem in [20], but the same arguments carry over to the general case. This can be combined with the above to deduce the existence of an optimal pair $(X(\cdot), \pi(\cdot))$ such that $\pi(\cdot)$ is stationary Markov and $X(\cdot)$ Markov, though not necessarily time-homogeneous Markov [7]. Also, $(X(\cdot), \pi(\cdot))$ need not be stationary. Our experience with the non-degenerate case, however, suggests the existence of a stationary ergodic time-homogeneous Markov solution that is optimal. Under additional technical conditions, such a result has been proved in [8] by stretching the 'vanishing discount' argument, but there is scope for improvement.

As for dynamic programming, scattered results are available in specific cases. The degenerate problem has been approached in the viscosity solution framework [3], [4], [5]. For the separated control problem under partial observations, a martingale

dynamic programming principle has been derived [12], [13]. Dualizing the linear programme above yields the following dual linear programme that can be interpreted as 'dynamic programming inequalities' [7]:

*Maximize* $z \in \mathcal{R}$ *subject to* $Lf(x,u) + k(x,u) \geq z$, *for all* $x \in E$, $u \in U_0$, $f \in \mathcal{D}(L)$.

## 4. Some related problems and open issues

1. 'Ergodic control with constraints' seeks to minimize one ergodic cost functional while imposing bounds on one or more additional ergodic cost functionals. In the linear programming formulation alluded to above, this amounts to a few additional constraints. Existence of optimal precise stationary Markov controls has been proved in the non-degenerate case under suitable stability or near-monotonicity hypotheses [11], [18]. A Lagrange multiplier formulation can be used to aggregate the costs into a single cost.

2. We did not include control in the diffusion matrix $\sigma(\cdot)$. The reason for this is that, for stationary Markov controls $u(\cdot) = v(X(\cdot))$, one is in general obliged to consider at best measurable $v(\cdot)$. For a merely measurable diffusion matrix, even in the non-degenerate case only the existence of a weak solution is available, the uniqueness may not hold [26] (except in one and two dimensions – see [35], pp. 192–194). It may, however, be possible to work with 'the set of all weak solutions' in place of '*the*' solution, but this is not very appealing unless one has a good selection criterion that prescribes a unique choice from among the many.

3. Singularly perturbed ergodic control concerns ergodic control of diffusions wherein some components move on a much faster time scale, characterized by a perturbation parameter $\epsilon > 0$. One can show that as $\epsilon \downarrow 0$, the slower components satisfy an 'averaged' dynamics wherein the coefficients in their dynamics are averaged over the stationary distribution of the fast components when the latter is derived by 'freezing' the slower components to constant values. The ergodic control problem for this limiting case is then a valid approximation for the original problem for small $\epsilon > 0$. See [15] for a precise statement and proofs.

4. We have not considered several related problems with a similar flavor, such as ergodic control of reflected [14] or switching diffusions [23], [30], ergodic impulse control [32], singular ergodic control [31], and stochastic differential games with ergodic payoffs [19]. The latter in particular are also of interest in risk-sensitive control problems on infinite time horizon, which effectively get converted to two person zero sum stochastic differential games with ergodic payoffs after the celebrated 'log-transform' of the value function [22].

5. We have also not addressed the computational issues here. Two major strands therein are Markov chain approximations [28] and approximations of the infinite dimensional linear programmes [25].

# Convex optimization of graph Laplacian eigenvalues

Stephen Boyd*

**Abstract.** We consider the problem of choosing the edge weights of an undirected graph so as to maximize or minimize some function of the eigenvalues of the associated Laplacian matrix, subject to some constraints on the weights, such as nonnegativity, or a given total value. In many interesting cases this problem is convex, *i.e.*, it involves minimizing a convex function (or maximizing a concave function) over a convex set. This allows us to give simple necessary and sufficient optimality conditions, derive interesting dual problems, find analytical solutions in some cases, and efficiently compute numerical solutions in all cases.

In this overview we briefly describe some more specific cases of this general problem, which have been addressed in a series of recent papers.

- *Fastest mixing Markov chain.* Find edge transition probabilities that give the fastest mixing (symmetric, discrete-time) Markov chain on the graph.
- *Fastest mixing Markov process.* Find the edge transition rates that give the fastest mixing (symmetric, continuous-time) Markov process on the graph.
- *Absolute algebraic connectivity.* Find edge weights that maximize the algebraic connectivity of the graph (*i.e.*, the smallest positive eigenvalue of its Laplacian matrix). The optimal value is called the *absolute algebraic connectivity* by Fiedler.
- *Minimum total effective resistance.* Find edge weights that minimize the total effective resistance of the graph. This is same as minimizing the average commute time from any node to any other, in the associated Markov chain.
- *Fastest linear averaging.* Find weights in a distributed averaging network that yield fastest convergence.
- *Least steady-state mean-square deviation.* Find weights in a distributed averaging network, driven by random noise, that minimizes the steady-state mean-square deviation of the node values.

## 1. Introduction

Let $G = (V, E)$ be an undirected graph with $n = |V|$ nodes and $m = |E|$ edges, with weights $w_1, \ldots, w_m \in \mathbb{R}$ on the edges. Suppose edge $l$ connects vertices (or nodes) $i$ and $j$. We define $a_l \in \mathbb{R}^n$ as $(a_l)_i = 1$, $(a_l)_j = -1$, with other entries 0. The *weighted Laplacian* (matrix) is the $n \times n$ matrix defined as

$$L = \sum_{l=1}^{m} w_l a_l a_l^T = A \operatorname{diag}(w) A^T,$$

where $\operatorname{diag}(w) \in \mathbb{R}^{m \times m}$ is the diagonal matrix formed from $w = (w_1, \ldots, w_m) \in \mathbb{R}^m$, and $A \in \mathbb{R}^{n \times m}$ is the *incidence matrix* of the graph, $A = [a_1 \ \cdots \ a_m]$.

We assume that the weights are such that $L$ is positive semidefinite, which we write as $L \succeq 0$. This is always the case when the weights are nonnegative. Since $L\mathbf{1} = 0$, where $\mathbf{1}$ is the vector with all components one, $L$ has smallest eigenvalue 0, corresponding to the eigenvector $\mathbf{1}$. We denote the eigenvalues of the Laplacian matrix $L$ as

$$0 = \lambda_1 \leq \lambda_2 \leq \cdots \leq \lambda_n.$$

Let $\phi$ be a symmetric closed convex function defined on a convex subset of $\mathbb{R}^{n-1}$. Then

$$\psi(w) = \phi(\lambda_2, \ldots, \lambda_n) \tag{1}$$

is a convex function of $w$ [2, §5.2]. Thus, a symmetric convex function of the positive Laplacian eigenvalues yields a convex function of the edge weights. As a simple example, consider $\phi(u_1, \ldots, u_{n-1}) = \sum_{i=1}^{n-1} u_i$, *i.e.*, the sum. In this case we have

$$\psi(w) = \sum_{i=2}^{n} \lambda_i = \sum_{i=1}^{n} \lambda_i = \operatorname{Tr} L = 2\mathbf{1}^T w,$$

twice the sum of the edge weights, which is linear and therefore also convex. As another example, the function $\phi(u_1, \ldots, u_{n-1}) = \max_{i=1}^{n-1} u_i$ (which is convex and symmetric) yields the function $\psi(w) = \lambda_n$, the largest eigenvalue (or spectral radius) of the Laplacian matrix (and a convex function of the edge weights).

We consider optimization problems with the general form

$$\begin{array}{ll} \text{minimize} & \psi(w) \\ \text{subject to} & w \in \mathcal{W}, \end{array} \tag{2}$$

where $\mathcal{W}$ is a closed convex set, and the optimization variable here is $w \in \mathbb{R}^m$. The problem (2) is to choose edge weights on a graph, subject to some constraints, in order to minimize a convex function of the positive eigenvalues of the associated Laplacian matrix. We can also handle the case of maximizing a concave function $\phi$ of the positive Laplacian eigenvalues, by minimizing $-\psi$ over $w \in \mathcal{W}$.

The problem (2) is a *convex optimization problem*. Roughly speaking, this means that the analysis of the problem is fairly straightforward, and that the problem is easily solved numerically; see, *e.g.*, [6]. In the cases we will consider, the problem (2) can be formulated even more specifically as a *semidefinite program* (SDP), which has the form

$$\begin{array}{ll} \text{minimize} & c^T x \\ \text{subject to} & \sum_{i=1}^n x_i A_i \preceq B. \end{array} \tag{3}$$

Here $x \in \mathbb{R}^n$ is the variable, and the problem data are $c \in \mathbb{R}^n$ and the symmetric matrices $A_1, \ldots, A_n, B \in \mathbb{R}^{k\times k}$. The inequality symbol $\preceq$ between symmetric matrices refers to inequality with respect to the cone of positive semidefinite matrices. The constraint $\sum_{i=1}^n x_i A_i \preceq B$ is called a *linear matrix inequality* (LMI). The SDP (3) can be thought of as a generalization of a linear program (LP),

$$\begin{array}{ll} \text{minimize} & c^T x \\ \text{subject to} & \sum_{i=1}^n x_i a_i \leq b, \end{array}$$

where here, $a_1, \ldots, a_n, b$ are vectors, and the inequality symbol between vectors means componentwise. Many results for LPs have analogs for SDPs; moreover, in the last 15 years or so, effective algorithms for numerically solving SDPs have been developed, and are now widely used in many application areas.

## 2. Fastest mixing Markov chain

In this section we briefly describe the problem of finding the fastest mixing symmetric Markov chain on a given graph. Many more details (and additional references) can be found in [4, 5].

We consider a symmetric Markov chain on the graph $G$, with transition matrix $P \in \mathbb{R}^{n\times n}$, where $P_{ij} = P_{ji}$ is the probability of a transition from vertex $i$ to vertex $j$. Since $P$ is symmetric, the uniform distribution $\pi_{\text{unif}} = (1/n)\mathbf{1}^T$ is an equilibrium distribution. The rate of convergence of the distribution $\pi(t)$ to uniform is governed by $\mu(P)$, the *second largest eigenvalue magnitude* (SLEM) of $P$, with smaller $\mu(P)$ meaning faster asymptotic convergence. To find the fastest mixing symmetric Markov chain on the graph, we must choose the transition matrix $P$ to minimize $\mu(P)$, subject to the following conditions:

$$P = P^T, \quad P\mathbf{1} = \mathbf{1}, \quad P_{ij} \geq 0, \;\; i, j = 1, \ldots, n, \quad P_{ij} = 0 \;\; \text{for } (i, j) \notin E.$$

The first three conditions state that $P$ is a symmetric stochastic matrix; the last states that transitions can only occur over the graph edges.

Identifying the graph edge weights with edge transition probabilities, we find that $P$ can be expressed as $P = I - L$. The conditions above are equivalent to the conditions

$$w \geq 0, \quad \text{diag}(L) \leq \mathbf{1}$$

imposed on the edge weight vector $w$. (Here $\mathrm{diag}(L)$ is the vector consisting of the diagonal entries of $L$, and both inequalities above are vector inequalities, *i.e.*, componentwise.)

The eigenvalues of $P$ are $1-\lambda_1, \ldots, 1-\lambda_n$. Since $1-\lambda_1 = 1$, and $|1-\lambda_i| \leq 1$ (since $P$ is stochastic), its SLEM is given by

$$\mu(P) = \max\{|1-\lambda_2|, \ldots, |1-\lambda_n|\} = \max\{1-\lambda_2, \lambda_n - 1\}. \tag{4}$$

This has the general form (1), with $\phi(u_1, \ldots, u_{n-1}) = \max_{i=1}^{n-1} |1-u_i|$. In particular, the SLEM $\mu(P)$ is a convex function of the edge transition probabilities. Thus, the fastest mixing symmetric Markov chain problem can be expressed as our general problem (2), with $\mathcal{W} = \{w \mid w \geq 0,\ \mathrm{diag}(L) \leq \mathbf{1}\}$, a polyhedron.

The semidefinite programming formulation of the problem is

$$\begin{array}{ll} \text{minimize} & \gamma \\ \text{subject to} & -\gamma I \preceq I - L - (1/n)\mathbf{1}\mathbf{1}^T \preceq \gamma I, \quad w \geq 0, \quad \mathrm{diag}(L) \leq \mathbf{1}, \end{array}$$

with variables $w \in \mathbb{R}^m$ and $\gamma \in \mathbb{R}$.

Since the fastest mixing symmetric Markov chain problem is convex, indeed, equivalent to an SDP, it can be solved effectively. Generic methods can be used for problems with only a few thousand edges; far larger problems, with millions of edges, can be solved using subgradient optimization techniques, exploiting Lanczos methods to efficiently compute a few extreme eigenvalues and eigenvectors of $I - L - (1/n)\mathbf{1}\mathbf{1}^T$; see [5].

The optimal transition probabilities can be quite interesting; for example, a graph can have many edges with optimal transition probability zero. This means (roughly) that those edges are not needed to achieve fastest mixing on the given graph. We also note that the optimal transition probabilities can yield a mixing rate that is unboundedly better than some simple standard schemes for assigning transition probabilities for fast mixing, such as the maximum-degree method, or the Metropolis–Hastings method [5].

Standard methods can be used to construct various dual problems for the fastest mixing symmetric Markov chain problem. One such dual is

$$\begin{array}{ll} \text{maximize} & \mathbf{1}^T z \\ \text{subject to} & Y\mathbf{1} = 0, \quad Y = Y^T, \quad \|Y\|_* \leq 1 \\ & (z_i + z_j)/2 \leq Y_{ij}, \quad (i,j) \in E, \end{array} \tag{5}$$

with variables $z \in \mathbb{R}^n$ and $Y \in \mathbb{R}^{n\times n}$. Here $\|Y\|_* = \sum_{i=1}^n |\lambda_i(Y)|$, the sum of the singular values of $Y$, which is the dual norm of the spectral norm. This dual problem is convex, since the objective, which is maximized, is linear, hence concave, and the constraints are all convex. We have the following:

- *Weak duality.* If $Y$, $z$ are feasible for the dual problem (5), then we have $\mathbf{1}^T z \leq \mu^\star$, where $\mu^\star$ is the optimal value of the fastest mixing symmetric Markov chain problem.

- *Strong duality.* There exist $Y^\star$, $z^\star$ that are optimal for the dual problem, and satisfy $\mathbf{1}^T z^\star = \mu^\star$. This means that the optimal values of the primal and dual problems are the same, and that the dual problem yields a sharp lower bound on the optimal SLEM.

Both of these conclusions follow from general results for convex optimization problems (see, *e.g.*, [10, 1, 6]). We can conclude strong duality using (a refined form of) Slater's condition (see, *e.g.*, [1, §3.3] and [6, §5.2]), since the constraints are all linear equalities and inequalities.

## 3. Fastest mixing Markov process

Here we briefly describe the problem of finding the fastest mixing continuous-time symmetric Markov process on a given graph [11].

Consider a continuous-time Markov process on the graph $G$, with transition rate (or intensity) $w_l$ across edge $l$. The probability density $\pi(t) \in \mathbb{R}^{1\times n}$ at time $t \geq 0$ is given by $\pi(t) = \pi(0)e^{-tL}$. It follows that the asymptotic rate of convergence to the uniform distribution is governed by $\lambda_2$, the smallest positive eigenvalue of the Laplacian matrix. The deviation from uniform distribution decays, in the worst case, as $e^{-\lambda_2 t}$. We can express $\lambda_2$ as

$$\lambda_2 = \min\{\lambda_2, \ldots, \lambda_n\},$$

which has the standard form (1), with $\phi(u_1, \ldots, u_{n-1}) = \min_{i=1}^{n-1} u_i$. Since the minimum function is concave, we see that $\lambda_2$ is a concave function of the edge weights $w$. It is evidently homogeneous in $w$, so to get a sensible problem we must normalize the weights in some way, for example, as $\mathbf{1}^T w = 1$.

To find the transition rates that give fastest convergence (among weights that sum to one), we pose the problem

$$\begin{array}{ll} \text{maximize} & \lambda_2 \\ \text{subject to} & w \geq 0, \quad \mathbf{1}^T w = 1, \end{array}$$

with variable $w \in \mathbb{R}^m$. This is a convex optimization problem, which can be formulated as the SDP

$$\begin{array}{ll} \text{maximize} & \gamma \\ \text{subject to} & \gamma I \preceq L + \beta \mathbf{1}\mathbf{1}^T, \quad w \geq 0, \quad \mathbf{1}^T w = 1, \end{array}$$

with variables $\gamma, \beta \in \mathbb{R}$, $w \in \mathbb{R}^m$.

The same problem, allocating a fixed total edge weight across the graph edges so as to maximize the smallest positive Laplacian eigenvalue, arises in other areas. For example, $\lambda_2$ arises in graph theory, and is called the *algebraic connectivity* of the graph. Fiedler refers to the maximum value of $\lambda_2$ that can be obtained by allocating a fixed total weight to the edges of a graph, as its *absolute algebraic connectivity* [7].

The dual of the fastest mixing Markov process problem can be given a very interesting interpretation. It is equivalent to the following problem. We are given some distances $d_1, \ldots, d_m$ on the graph edges. The goal is find a configuration of points $x_1, \ldots, x_n \in \mathbb{R}^n$ that satisfy $\|x_i - x_j\|_2 \leq d_l$, whenever edge $l$ connects vertices $i$ and $j$, and in addition maximizes the total variance, given by $\sum_{i \neq j} \|x_i - x_j\|^2$. This problem was recently formulated in the machine learning literature as a method for identifying low dimensional structure in data; see, *e.g.*, [12].

## 4. Minimum total effective resistance

Here we describe the problem of choosing the edge weights to minimize the total effective resistance of a graph, subject to some given total weight [8]. We consider the graph as an electrical circuit or network, with the edge weight representing the conductance (inverse of resistance) of the associated electrical branch. We define $R_{ij}$ as the resistance in the network seen between nodes $i$ and $j$. The total effective resistance is defined as $R = \sum_{i<j} R_{ij}$.

The total effective resistance comes up in several applications beyond circuit theory. For example, it is proportional to the average commute time, over all pairs of vertices, in the random walk on the graph defined by the weights $w_l$ [8]. (The probability of a transition from vertex $i$ to vertex $j$ is $w_l$, the associated edge weight, divided by the total weight of all edges adjacent to vertex $i$.)

It can be shown that

$$R = \frac{1}{n} \sum_{i=2}^{n} 1/\lambda_i,$$

*i.e.*, it is proportional to the sum of the inverses of the positive Laplacian eigenvalues. This follows our general form (1), with $\phi(u_1, \ldots, u_{n-1}) = \sum_{i=1}^{n-1} 1/u_i$, with domain $\mathbb{R}^{n-1}_{++}$. ($\mathbb{R}_{++}$ is the set of positive reals.) In particular, the total effective resistance is a convex function of the weight vector $w$. Minimizing total effective resistance, subject to $w \geq 0$ and $\mathbf{1}^T w = 1$, is thus a convex optimization problem.

The problem can be formulated as the SDP

$$\begin{array}{ll} \text{minimize} & n \operatorname{Tr} Y \\ \text{subject to} & \mathbf{1}^T w = 1, \quad w \geq 0, \\ & \begin{bmatrix} L + (1/n)\mathbf{1}\mathbf{1}^T & I \\ I & Y \end{bmatrix} \succeq 0, \end{array}$$

with variables $w \in \mathbb{R}^m$ and the (slack) matrix $Y = Y^T \in \mathbb{R}^{n \times n}$ (see [8]).

## 5. Fast averaging

Here we describe the problem of choosing edge weights that give fastest averaging, using a classical linear iteration [13]. The nodes start with value $x(0) \in \mathbb{R}^n$, and at each iteration we update the node values as $x(t+1) = (I - L)x(t)$. The goal is to choose the edge weights so that $x_i(t)$ converges, as rapidly as possible, to the average value, *i.e.*, $x(t) \to (1/n)\mathbf{1}\mathbf{1}^T x(0)$.

This iteration can be given a very simple interpretation. At each step, we replace each node value with a weighted average of its previous value and its neighbors' previous values. The weights used to form the average are taken from the graph edge weights, with the self-weight chosen so that the sum of the adjacent edge weights, plus the self-weight, equals one. The weights used to carry out this local averaging sum to one at each node, but can be negative.

When the weights are symmetric (which we assume here), the convergence rate of this averaging process is determined by the SLEM of $I - L$, *i.e.*, (4), exactly as in the Markov chain problem. The difference here is that the weights can be negative; in the Markov chain, of course, the weights (transition probabilities) must be nonnegative. The optimal weights can be found by solving the unconstrained problem

$$\text{minimize} \quad \max_{i=2}^{n} |1 - \lambda_i|,$$

which evidently is a convex optimization problem. It can be posed as the SDP

$$\begin{array}{ll} \text{minimize} & \gamma \\ \text{subject to} & -\gamma I \preceq L - (1/n)\mathbf{1}\mathbf{1}^T \preceq \gamma I, \end{array}$$

with variables $\gamma \in \mathbb{R}$, $w \in \mathbb{R}^m$. Without loss of generality, we can assume that $L \succeq 0$. The problem is the same as the fastest mixing symmetric Markov chain problem, but without the nonnegativity requirement on $w$. It often happens that some of the optimal weights are negative [13].

## 6. Minimum RMS consensus error

Here we describe a variation on the fastest linear averaging problem described above, in which an additive random noise perturbs the node values [15]. The iteration is $x(t+1) = (I - L)x(t) + v(t)$, where $v(t) \in \mathbb{R}^n$ are uncorrelated zero mean unit variance random variables, *i.e.*,

$$\mathbf{E}\, v(t) = 0, \quad \mathbf{E}\, v(t)v(t)^T = I, \quad \mathbf{E}\, v(t)v(s)^T = 0, \quad t \neq s.$$

This iteration arises in noisy averaging, distributed data fusion, and load balancing applications; see the references in [15].

We can measure the effectiveness of the averaging iteration at countering the effects of the additive noises by the steady-state mean-square deviation, defined as

$$\delta_{\mathrm{ss}} = \lim_{t\to\infty} \mathbf{E}\left(\frac{1}{n}\sum_{i<j}(x_i(t) - x_j(t))^2\right).$$

The steady-state mean-square deviation can be expressed as

$$\delta_{\mathrm{ss}} = \sum_{i=2}^{n} \frac{1}{\lambda_i(2-\lambda_i)},$$

provided $0 < \lambda_i < 2$ for $i = 2, \ldots, n$, and is infinite otherwise. (The condition $0 < \lambda_i < 2$ for $i = 2, \ldots, n$ is the same as $\max\{1-\lambda_2, \lambda_n - 1\} < 1$, which is the condition that the linear iteration for averaging, without the additive noise, converges.) Once again, this has the standard form (1), with $\phi(u_1, \ldots, u_{n-1}) = \sum_{i=1}^{n-1} 1/(u_i(2-u_i))$, with domain $(0,2)^{n-1}$. In particular, we see that $\delta_{\mathrm{ss}}$ is a convex function of the edge weights. To find the weights that yield the smallest steady-state mean-square deviation, we simply minimize the convex function $\delta_{\mathrm{ss}}$ over $w \in \mathbb{R}^m$.

## 7. Methods

All the problems described above can be effectively solved numerically, by a variety of standard methods for convex optimization, including interior-point methods for modest sized problems (with a few thousand weights) and subgradient-based methods for larger problems. We can exploit structure in the problems (such as sparsity of the underlying graph) to increase the efficiency of these methods.

We can also exploit symmetry in solving the problems. Two edges are symmetric if there exists an automorphism of the graph that maps one edge to the other. Whenever two edges are symmetric, we can assume without loss of generality that the corresponding edge weights are equal. (This follows from a basic result in convex optimization: there is always a solution that is invariant under the group of permutations that leave the objective function and constraint set fixed.) If the symmetry group of the graph is large, this can considerably reduce the size of the optimization problem that needs to be solved. As an extreme example, consider an edge-transitive graph, *i.e.*, one in which any two edges are symmetric. For such a graph, we can assume that all edge weights are equal, *i.e.*, there is only one common edge weight to be determined. This reduces the problem to one with at most one scalar variable (the common edge weight); if there is an equality constraint, such as $\mathbf{1}^T w = 1$, we conclude that an optimal solution is given by uniform edge weights, $w = (1/m)\mathbf{1}$ [3]. This idea is used in [9] to reduce some specific weight optimization problems to ones with a handful of variables, which can be solved analytically.

# Controllability of evolution equations of fluid dynamics

Oleg Yu. Emanouilov (Imanuvilov)

**Abstract.** In this paper we will discuss recent developments in controllability of evolution equations of fluid mechanics. The control is assumed to be distributed either on a part of the boundary or locally distributed in some subdomain. We will present some ideas of proof of main theorems. Special attention will be paid to the technique based on Carleman estimates.

**Mathematics Subject Classification (2000).** 93C20, 35B37.

**Keywords.** Carleman estimates, exact controllability, Navier–Stokes system.

## 1. Introduction

This paper is concerned with the problem of exact controllability of partial differential equations with control concentrated either on the part of the boundary or locally distributed inside of the boundary in some subdomain. The typical statement of general controllability problem, which we are going to discuss in this paper, can be formulated as follows: let a function $y(t, x)$, which describes the state of a system, satisfy a semilinear partial differential equation

$$\partial_t y + A(x, D)y + F(x, y, \nabla y) = \chi_\omega u \quad \text{in } (0, T) \times \Omega, \tag{1.1}$$

$$B(x, D)y = 0 \quad \text{on } (0, T) \times \partial\Omega, \quad y(0, \cdot) = y_0, \tag{1.2}$$

where $A(x, D)$ is a linear operator, $F$ is a nonlinear term, $B(x, D)$ is a boundary operator, $\chi_\omega$ is the characteristic function of the domain $\omega \subset \Omega$ where the control function $u(t, x)$ is supported.

The initial conditions, the function $y_0(x)$ and another function $y_1(x)$ called target function, are given. Let us choose some time moment $T$. Then the exact controllability problem may be formulated as follows: Find the control $u$ and the state function $y$ such that

$$y(T, \cdot) = y_1. \tag{1.3}$$

The solvability properties of the controllability problem (1.1)–(1.3) are completely different from the properties of the initial boundary value problem (1.1)–(1.2) with fixed $u$. For initial value problems with a reasonable choice of boundary conditions and for smooth initial conditions we usually expect the uniqueness of the solution. Moreover, if a priori estimates are obtained, this solution typically may be extended

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

globally in time. On the other hand, for most boundary/locally distributed controllability problems of equations of mathematical physics, solutions are not unique and a priori estimates typically are absent. In case of control of linear equations these difficulties do not produce a huge problem, since the controllability problem typically can be reduced to an *observability* problem which can be formulated as follows. Suppose two Banach spaces $X$ and $Y$ are given. For the solution of the adjoint linear equation

$$-\partial_t z + A^*(x, D)z = 0 \quad \text{in } (0, T) \times \Omega, \tag{1.4}$$

$$B^*(x, D)z = 0 \quad \text{on } (0, T) \times \partial\Omega \tag{1.5}$$

one needs to obtain the a priori estimate

$$\|z\|_X \le C\|\chi_\omega z\|_Y. \tag{1.6}$$

The initial conditions at $t = T$ for problem (1.4), (1.5) are not assumed to be known. This creates the main difficulty in proving estimate (1.6). There are several methods to deal with such observability problems:

1. The method based on the theorem on propagation of singularities (see Bardos–Lebeau–Rauch [2]);

2. Multipliers method (see [31], [28], [27], [29], [39]);

3. Carleman estimates (see [21], [22], [25], [26], [37], [38]).

The first two methods are effective for the wave and Schrödinger equations. As for the equations of parabolic type and the generalized Stokes system, the Carleman type estimates with the singular weight functions appears to be more effective method compared to methods 1 and 2.

## 2. Controllability of parabolic equations and the Burgers equation

In a bounded domain $\Omega \in \mathbb{R}^N$ with $\partial\Omega \in C^2$ we consider the semilinear parabolic equation

$$G(y) = \partial_t y - \Delta y + f(t, x, y) = \chi_\omega u + g \tag{2.7}$$

with given initial condition and zero Dirichlet boundary conditions

$$y|_{(0,T)\times\partial\Omega} = 0, \quad y(0, \cdot) = y_0. \tag{2.8}$$

Here $\omega$ is an arbitrary but fixed subdomain, $\chi_\omega$ is the characteristic function of the domain $\omega$ and $u(t, x)$ is the control locally distributed in $\omega$. Suppose that the target function $y_1(x)$ is given and some moment of time $T$ is fixed. We are looking for control $u$ such that

$$y(T, \cdot) = y_1. \tag{2.9}$$

Since the solution $y(t, x)$ of the heat equation with zero right-hand side is analytic as a function of $x$ for any positive $t$, we cannot solve in general problem (2.7)–(2.9) for an arbitrary smooth target function $y_1$.

Let us assume that

$$f \in C^1([0,T]\times\bar{\Omega}\times\mathbb{R}^1), \quad f(t,x,0)=0 \quad \text{for all } (t,x)\in(0,T)\times\Omega, \tag{2.10}$$

and that the function $f(t,x,y)$ satisfies the Lipschitz condition

$$|f(t,x,\zeta_1)-f(t,x,\zeta_2)|\le K|\zeta_1-\zeta_2| \quad \text{for all } (t,x)\in(0,T)\times\Omega,\ \zeta_1,\zeta_2\times\mathbb{R}^1, \tag{2.11}$$

where the constant $K$ is independent of $t, x, \zeta$.

We have

**Theorem 2.1** ([22]). *Let $y_1\equiv 0$ and conditions* (2.10), (2.11) *hold true. Suppose that there exists $\delta>0$ such that $e^{\frac{1}{(T-t)^{1+\delta}}}g\in L^2((0,T)\times\Omega)$. Then for any $y_0\in \mathring{W}_2^1(\Omega)$, there exists a solution $(y,u)\in W_2^{1,2}((0,T)\times\Omega)\times L^2((0,T)\times\omega)$ to problem* (2.7)–(2.9).

Here $W^{1,2}((0,T)\times\Omega)=\{y(t,x)\mid \partial_t y, \partial_x^\beta y\in L^2((0,T)\times\Omega) \text{ for all } |\beta|\le 2\}$.

Thanks to assumption (2.11) by standard methods of functional analysis the proof of Theorem 2.1 may be reduced to the question of solvability of the controllability problem for the linear parabolic equation

$$\begin{aligned} &\partial_t v-\Delta v+c(t,x)v=\chi_\omega\tilde{u}+\tilde{g} \quad \text{in } (0,T)\times\Omega,\\ &v|_{(0,T)\times\partial\Omega}=0, \quad v(0,\cdot)=v_0, \quad v(T,\cdot)=0, \end{aligned} \tag{2.12}$$

where $c\in L^\infty((0,T)\times\Omega)$. The solvability of problem (2.12) is equivalent to obtaining the observability estimate for the adjoint parabolic equation:

$$-\partial_t z-\Delta z+c(t,x)z=q \quad \text{in } [0,T]\times\Omega, \tag{2.13}$$

$$z|_{(0,T)\times\partial\Omega}=0. \tag{2.14}$$

The observability estimate for (2.13)–(2.14) can be proved using the technique of Carleman estimates. First we need to introduce some weight functions. Let $\psi\in C^2(\overline{\Omega})$ be such that

$$\psi(x)>0 \ \text{ for all } x\in\Omega, \quad \psi|_{\partial\Omega}=0, \quad |\nabla\psi(x)|>0 \ \text{ for all } x\in\Omega\setminus\omega_0, \tag{2.15}$$

where $\omega_0\subset\subset\omega$ is some open set. Using the function $\psi$ we construct three more functions: $\varphi(t,x)=e^{\lambda\psi(x)}/(t(T-t))$, $\alpha(t,x)=(e^{\lambda\psi}-e^{2\lambda||\psi||_{C(\overline{\Omega})}})/(t(T-t))$, and $\eta(t,x)=(e^{\lambda\psi}-e^{2\lambda||\psi||_{C(\overline{\Omega})}})/(\ell(t)(T-t))$ where $\ell\in C^\infty[0,T]$, $\ell(t)>0$ for any $t\in[0,T]$ and $\ell(t)=t$ for $t\in\left[\frac{3T}{4},T\right]$.

The following holds:

**Lemma 2.1** ([22]). *There exists a number $\hat{\lambda}>0$ such that for an arbitrary $\lambda\ge\hat{\lambda}$ there exists $s_0(\lambda)$ such that for each $s\ge s_0(\lambda)$ solutions to problem* (2.13)–(2.14)

*satisfy the following inequality:*

$$\int_{(0,T)\times\Omega}\left(\frac{1}{s\varphi}\left(\left|\frac{\partial z}{\partial t}\right|^2+|\Delta z|^2\right)+s\varphi|\nabla z|^2+s^3\varphi^3z^2\right)e^{2s\alpha}dx\,dt \\ \leq C\left(\int_{(0,T)\times\Omega}|q|^2e^{2s\alpha}dxdt+\int_{[0,T]\times\omega}s^3\varphi^3z^2e^{2s\alpha}dxdt\right), \tag{2.16}$$

*where the constant $C$ is independent of $s$.*

This estimate, combined with the standard energy estimate for equation (2.13), implies that for any $v_0\in\overset{\circ}{W}{}_2^1(\Omega)$ and $e^{-s_0\eta}\tilde{g}\in L^2((0,T)\times\Omega)$ there exists a solution to problem (2.12): a pair $(y,u)\in W^{1,2}((0,T)\times\Omega)\times L^2((0,T)\times\omega)$ such that $e^{-s_0\eta}\tilde{u}\in L^2((0,T)\times\Omega)$, $e^{-s_0\eta}v/(T-t)^{\frac{3}{2}}\in L^2((0,T)\times\Omega)$.

A different approach, still based on Carleman estimates, was proposed by G. Lebeau and L. Robbiano in [30] for linear parabolic equations with time independent coefficients. In [8], [11], [35] solutions for the controllability problem of the linear heat equation were constructed directly by solving a moment problem. In [36] the solution to the controllability problem for the heat equation was obtained from a solution of the corresponding problem for the wave equation. In [34] another method was proposed, essentially based on the solvability of the Cauchy problem for the one dimensional heat equation. Later this method was applied to the semilinear parabolic equation in [33]. The approximate controllability for equation (2.7) was proved in [9].

Next we consider the problem of exact controllability of equation (2.7) with boundary control. Let $\Gamma_0$ be an arbitrary subdomain of $\partial\Omega$. Suppose that the control $u$ is distributed over $\Gamma_0$:

$$G(y)=g,\quad y|_{(0,T)\times\Gamma_0}=u,\quad y|_{(0,T)\times\partial\Omega\setminus\Gamma_0}=0,\quad y(0,\cdot)=y_0,\quad y(T,\cdot)=y_1. \tag{2.17}$$

We have

**Theorem 2.2** ([22]). *Let $y_1\equiv 0$ and conditions* (2.10), (2.11) *hold true. Suppose that there exists $\delta>0$ such that $e^{\frac{1}{(T-t)^{1+\delta}}}g\in L^2((0,T)\times\Omega)$. Then for any $y_0\in\overset{\circ}{W}{}_2^1(\Omega)$ there exists a solution $(y,u)\in W_2^{1,2}((0,T)\times\Omega)\times L^2(0,T;H^{\frac{1}{2}}(\Gamma_0))$ to problem* (2.17).

Theorem 2.2 will easily follow from Theorem 2.1 if we enlarge the domain $\Omega$ up to $\tilde{\Omega}$ in such a way that

$$\omega\subset\tilde{\Omega},\quad \omega=\tilde{\Omega}\setminus\Omega,\quad \partial\omega\cup\partial\Omega\subset\Gamma_0.$$

Then we consider problem (2.7)–(2.9) in $\tilde{\Omega}$ with the control locally distributed in $\omega$. Since the existence of the solution $y$ is guaranteed by Theorem 2.1 we consider the restriction of $y$ on $\Omega$ and put $u=y|_{\Gamma_0}$.

Next we consider the situation when the target function is not zero. In order to solve the controllability problem we need some conditions on the functions $y_1$ and $g$.

**Condition 2.1.** There exists a constant $\tau > 0$ and a function $\tilde{u} \in L^2((0,T)\times\omega)$ such that the boundary value problem

$$G(\tilde{y}) = \chi_\omega \tilde{u} + g \quad \text{in } [T-\tau, T]\times\Omega, \quad \tilde{y}|_{[T-\tau,T]\times\partial\Omega} = 0, \quad \tilde{y}(T,\cdot) = y_1$$

has a solution $\tilde{y} \in W^{1,2}((0,T)\times\Omega)$.

We have

**Theorem 2.3** ([22]). *Let $y_0 \in \mathring{W}_2^1(\Omega)$ and $g \in L^2((0,T)\times\Omega)$. Suppose that* (2.10), (2.11) *hold true. Let the functions $y_1$ and $g$ satisfy Condition* 2.1. *Then there exists a solution $(y,u) \in W^{1,2}((0,T)\times\Omega)\times L^2((0,T)\times\omega)$ of problem* (2.7)–(2.9).

Theorem 2.3 provides necessary and sufficient conditions for solvability of problem (2.7)–(2.9).

A similar result holds true for the situation when the control is locally distributed over the boundary.

**Condition 2.2.** There exists a constant $\tau > 0$ and a function $\tilde{u} \in L^2((0,T)\times\omega)$ such that the boundary value problem

$$\begin{aligned} &G(\tilde{y}) = g \quad \text{in } [T-\tau, T]\times\Omega, \\ &\tilde{y}|_{[T-\tau,T]\times\Gamma_0} = \tilde{u}, \quad \tilde{y}|_{[T-\tau,T]\times\partial\Omega\setminus\Gamma_0} = 0, \quad \tilde{y}(T,\cdot) = y_1 \end{aligned}$$

has a solution $\tilde{y} \in W^{1,2}((0,T)\times\Omega)$.

The following holds:

**Theorem 2.4** ([22]). *Let $y_0 \in \mathring{W}_2^1(\Omega)$ and $g \in L^2((0,T)\times\Omega)$. Suppose that* (2.10), (2.11) *hold true. Let the functions $y_1$ and $g$ satisfy Condition* 2.2. *Then there exists a solution $(y,u) \in W^{1,2}((0,T)\times\Omega)\times L^2(0,T; H^{\frac{1}{2}}(\partial\Omega))$ of problem* (2.17).

In case when the nonlinear term of the parabolic equation is superlinear the situation is different. For example, there exists $y_0 \in C^\infty(\bar{\Omega})$ and a time moment $\hat{T}$ which depends on $\Omega$ only, such that any solution for the initial value problem

$$\partial_t y - \Delta y + y^2 = 0 \quad \text{in } \Omega, \quad y(0,\cdot) = y_0, \quad y|_{(0,T)\times\partial\Omega} = u$$

will blow up at some time $\tau(u) < \hat{T}$. Hence we even cannot prevent a blowup by the boundary control. The similar question for the nonlinearity $f(t,x,y) = -y^3$ is open. If the nonlinear term has the form $f(t,x,y) = y^3$ for any $y_0 \in W_2^1(\Omega)\cap L^6(\Omega)$ and sufficiently regular $u$ (which satisfies the compatibility condition) a solution to the initial value problem

$$\partial_t y - \Delta y + y^3 = 0 \quad \text{in } \Omega, \quad y(0,\cdot) = y_0, \quad y|_{(0,T)\times\partial\Omega} = u$$

exists and satisfies the a priori estimate

$$\frac{d}{dt}\int_\Omega \rho^7(x) y^2(t,x)dx + \frac{1}{8}\int_\Omega \rho^7(x) y^4(t,x)dx \le C,$$

where $\rho \in C^2(\bar{\Omega})$ is an arbitrary function such that $\rho(x) > 0$ for each $x \in \Omega$, $\rho|_{\partial\Omega} = 0$, $|\nabla\rho|_{\partial\Omega} \neq 0$ and the constant $C$ depends on $\rho$ only. This estimate immediately implies that for some open set of target functions $y_1(x)$ in $L^2(\Omega)$ there is no solution to problem (2.17).

Let us consider the Burgers equation

$$\partial_t y - \partial_x^2 y + \partial_x y^2 = \chi_\omega u(t,x), \quad (t,x) \in [0,T] \times [0,L], \tag{2.18}$$

with zero Dirichlet boundary conditions and the initial condition

$$y(t,0) = y(t,L) = 0, \quad y(0,\cdot) = y_0. \tag{2.19}$$

Here $\omega \subset [0,L]$ is an arbitrary but fixed open set. We are looking for a control $u$ such that

$$y(T,\cdot) = y_1 \tag{2.20}$$

The following holds:

**Theorem 2.5** ([16]). *Let $y_1 \in \overset{\circ}{W}{}_2^1(0,L)$ be a steady-state solution to the Burgers equation and $y_0 \in \overset{\circ}{W}{}_2^1(0,L)$. Then there exists a time moment $T(y_1)$ such that the controllability problem* (2.18)–(2.20) *has a solution $(y,u) \in W^{1,2}((0,T)\times[0,L]) \times L^2((0,T)\times[0,L])$.*

Suppose that $\omega$ satisfies the following condition:

$$\text{there exists } b > 0 \text{ such that } \omega \subset (b,L). \tag{2.21}$$

We have

**Lemma 2.2** ([16]). *Let $y(t,x)$ be a solution to problem* (2.18), (2.19). *Denote $y_+(t,x) = \max(y(t,x),0)$. Then for arbitrary $N > 5$ the following estimate holds true:*

$$\frac{d}{dt}\int_0^b (b-x)^N y_+^4(t,x)dx < \gamma(N) b^{N-5}. \tag{2.22}$$

*Here $\gamma(N) > 0$ is a constant depending on $N$ only.*

The immediate consequence of (2.22) is the existence of an open set of target functions which is unreachable by means of the locally distributed control satisfying (2.21) or by means of the boundary control concentrated at $x = L$.

If condition (2.21) fails, we of course do not have the a priori estimate (2.22). In terms of the boundary control this situation corresponds to the case when the control is located at both endpoints of the segment $[0,L]$. By Hopf's transformation this problem might be reduced to the controllability problem of the one-dimensional heat equation with control located at both endpoints of the segment $[0,L]$ but with one additional constraint: control functions are nonnegative. Then from results of [1] it follows that for some initial condition $y_0$ the set of all reachable functions is not dense in $L^2(0,L)$. Later we will see that the controllability properties of the Burgers equation and the Navier–Stokes system are completely different.

## 3. Local controllability of the Navier–Stokes system

In [32] J.-L. Lions conjectured that the Navier–Stokes system with boundary or locally distributed control is globally approximately controllable. This paper inspired intensive research in the area. In this section we discuss the local controllability results for the Navier–Stokes system and the Boussinesq system.

Let us consider the Navier–Stokes system defined on the bounded domain $\Omega \subset \mathbb{R}^N$ $(N = 2, 3)$ with boundary $\partial\Omega \in C^2$

$$\partial_t y(t,x) - \Delta y(t,x) + (y, \nabla)\, y + \nabla p = f + \chi_\omega u \quad \text{in } \Omega, \quad \operatorname{div} y = 0, \tag{3.23}$$

$$y|_{(0,T)\times\partial\Omega} = 0, \quad y(0,\cdot) = y_0, \tag{3.24}$$

where $y(t,x) = (y_1(t,x), \dots, y_N(t,x))$ is the velocity of fluid, $p$ is the pressure. The density of external forces $f(t,x) = (f_1(t,x), \dots, f_N(t,x))$ and the initial velocity $y_0$ are given, $u(t,x)$ is a control distributed in some arbitrary but fixed subdomain $\omega$ of the domain $\Omega$.

Let $(\hat{y}(t,x), \hat{p}(t,x))$ be a solution of the Navier–Stokes equations with the right-hand side $f$ exactly the same as in (3.23):

$$\partial_t \hat{y} - \Delta\hat{y} + (\hat{y}, \nabla)\hat{y} + \nabla\hat{p} = f \quad \text{in } (0,T)\times\Omega, \quad \operatorname{div}\hat{y} = 0, \quad \hat{y}|_{(0,T)\times\partial\Omega} = 0 \tag{3.25}$$

close enough to the initial condition $y_0$ at the moment $t = 0$

$$\|y_0 - \hat{y}(0,\cdot)\|_V \le \varepsilon, \quad \text{(the parameter } \varepsilon \text{ is sufficiently small)} \tag{3.26}$$

where $V = \{y(x) = (y_1, \dots, y_N) \in (W_2^1(\Omega))^N : \operatorname{div} y = 0 \text{ in } \Omega,\ y|_{\partial\Omega} = 0\}$.

We are looking for a control $u$ such that, for a given $T > 0$, the following equality holds

$$y(T,\cdot) = \hat{y}(T,\cdot). \tag{3.27}$$

In order to formulate our results, we introduce the following functional spaces:

$$H = \{y(x) = (y_1, \dots, y_N) \in (L^2(\Omega))^N : \operatorname{div} y = 0,\ \text{in } \Omega,\ (y, \vec{n})|_{\partial\Omega} = 0\},$$

$$V^{1,2}((0,T)\times\Omega) = \{y(t,x) \in (W_2^{1,2}((0,T)\times\Omega))^N : \operatorname{div} y = 0 \text{ in } \Omega,\ y|_{\partial\Omega} = 0\},$$

where $\vec{n} = \vec{n}(x) = (n_1(x), \dots, n_N(x))$ is the outward unit normal to $\partial\Omega$.

Suppose that the function $\hat{y}$ has the following regularity properties:

$$\begin{aligned} &\hat{y} \in L^\infty((0,T)\times\Omega), \\ &\partial_t\hat{y} \in L^2(0,T; L^\sigma(\Omega)), \quad \sigma > 6/5 \text{ for } N = 3, \sigma > 1 \text{ for } N = 2. \end{aligned} \tag{3.28}$$

The following result in particular gives us a positive answer to the question of the possibility of stabilization of the flow near an unstable steady state solution by means of locally distributed control.

**Theorem 3.1** ([12]). *Let $y_0 \in V$, $f \in L^2(0,T;H)$ and suppose that the pair $(\hat{y},\hat{p})$ solves* (3.25) *and satisfies condition* (3.28). *Then for sufficiently small $\varepsilon > 0$ there exists a solution $(y,p,u) \in V^{1,2}((0,T)\times\Omega)\times L^2(0,T;W_2^1(\Omega))\times(L^2((0,T)\times\omega)))^N$ to problem* (3.23), (3.24), (3.26), (3.27).

This result first has been proved in [15] for the control distributed over the whole boundary $\partial\Omega$. In [21] the case of control distributed over an arbitrary small subdomain $\omega$, but with some assumptions on the geometry of $\Omega$ was considered. Finally, in [23], these assumptions on $\Omega$ were removed under the regularity condition on the function $\hat{y}$ which is stronger then (3.28).

Since the existence theorem 3.1 is local, in order to prove this existence result one first proves the solvability of the controllability problem for the Navier–Stokes equation linearized at trajectory $\hat{y}$:

$$\begin{cases} \partial_t\tilde{y} - \Delta\tilde{y} + (\hat{y},\nabla)\tilde{y} + (y,\nabla)\hat{y} + \nabla\tilde{p} = f + \chi_\omega\tilde{u},\ \operatorname{div}\tilde{y} = 0 & \text{in } (0,T)\times\Omega,\\ \tilde{y} = 0 & \text{on } (0,T)\times\partial\Omega,\\ \tilde{y}(0,\cdot) = y_0,\ \ \tilde{y}(T,\cdot) = 0 & \text{in } \Omega. \end{cases} \tag{3.29}$$

After the solvability of (3.29) is established in appropriate functional spaces the conclusion of the Theorem 3.1 follows from the standard implicit function theorem.

The typical way to solve (3.29) is to reduce it to the observability problem for the operator adjoint to the operator of the linearization of the Navier–Stokes system at trajectory $\hat{y}$. More precisely, let the function $z \in L^2(0,T;H)$ satisfy the equations

$$-\partial_t z - \Delta z - Dz\hat{y} = \nabla\pi + g \text{ in } (0,T)\times\Omega, \tag{3.30}$$

$$\operatorname{div} z = 0, \quad z|_{(0,T)\times\partial\Omega} = 0, \tag{3.31}$$

where the function $Dz = \nabla z + \nabla z^t$.

Denote $\alpha(t,x) = \frac{e^{\lambda\psi(x)+8\|\psi\|_{L^\infty(\Omega)}} - e^{10\lambda\|\psi\|_{L^\infty(\Omega)}}}{(t(T-t))^4}$, $\alpha^*(t) = \min_{x\in\Omega}\alpha(t,x)$, $\hat{\alpha}(t) = \max_{x\in\Omega}\alpha(t,x)$, $\hat{\varphi}(t,x) = \frac{e^{8\lambda\|\psi\|_{L^\infty(\Omega)}}}{(t(T-t))^4}$, $\varphi(t,x) = \frac{e^{8\lambda\|\psi\|_{L^\infty(\Omega)}+\psi(x)}}{(t(T-t))^4}$. The function $\psi$ is introduced in (2.15). For the system (3.30)–(3.31), we have the following observability estimate:

**Theorem 3.2** ([12]). *There exist three positive constants $\hat{s}$, $\hat{\lambda}$, $C$ depending on $\Omega$ and $\omega$ such that for every $z_0 \in H$, $g \in L^2((0,T)\times\Omega)$ the corresponding solution to* (3.30), (3.31) *verifies:*

$$\begin{aligned} &\int_{(0,T)\times\Omega}\left(\frac{1}{s\varphi}\left(\left|\frac{\partial z}{\partial t}\right|^2 + \sum_{i,j=1}^n\left|\frac{\partial^2 z}{\partial x_i\partial x_j}\right|^2\right) + s\lambda^2\varphi|\nabla z|^2 + s^3\lambda^4\varphi^3|z|^2\right)e^{2s\alpha}dxdt\\ &\quad\le C(1+T^2)\left(s^{\frac{15}{2}}\lambda^{20}\int_{(0,T)\times\Omega}|g|^2\hat{\varphi}^{\frac{15}{2}}e^{4s\hat{\alpha}-2s\alpha^*}dxdt\right.\\ &\qquad\left.+\int_{(0,T)\times\omega}s^{16}\lambda^{40}\hat{\varphi}^{16}|z|^2e^{8s\hat{\alpha}-6s\alpha^*}dxdt\right) \quad \text{for all } s \ge s_0, \end{aligned} \tag{3.32}$$

*for all* $\lambda \geq \hat{\lambda}(1 + \|\hat{y}\|^2_{L^\infty((0,T)\times\Omega)} + \|\partial_t \hat{y}\|^2_{L^2(0,T;L^\sigma(\Omega))} + e^{\hat{\lambda}T\|\hat{y}\|^2_{L^\infty((0,T)\times\Omega)}})$ *and* $s \geq \hat{s}(T^4 + T^8)$.

The strategy of the proof of (3.32) is as follows. First we apply the Carleman estimate (2.16) to equations (3.31). Next we need to eliminate the norm of the function $\nabla\pi$ on the right-hand side. In order to do that we observe that the pressure $\pi$ for each $t \in [0, T]$ satisfies the Laplace equation

$$-\Delta\pi = \operatorname{div}(Dz\hat{y}) + \operatorname{div} g \quad \text{in } \Omega. \tag{3.33}$$

Since the velocity field $z$ satisfies the zero Dirichlet boundary conditions, there are no explicit boundary conditions for the pressure $\pi$. Therefore to equation (3.33) we apply the Carleman estimates for elliptic equations obtained in [24] with weights which minimize the contribution of the boundary terms. Finally we eliminate the norms of the functions $\pi|_{\partial\Omega}$ and $\chi_\omega\pi$ using some a priori estimates for the initial value problems for the Stokes system and the heat equation.

In many controllability problems in addition to be locally distributed in a subdomain, the control $u$ is required to satisfy some additional constraints. Below we discuss the situation when in problems (3.23), (3.24), (3.27) the control satisfies the following constraint: one of the components of the vector function $u(t, x)$ is identically equal zero on $(0, T) \times \Omega$. Suppose that $\omega$ satisfies the following condition:

$$\text{there exists } x^0 \in \partial\Omega,\ \tilde{\delta} > 0 \text{ such that } \overline{\omega} \cap \partial\Omega \supset B(x^0; \tilde{\delta}) \cap \partial\Omega. \tag{3.34}$$

($B(x^0; \tilde{\delta})$ is the ball centered at $x^0$ of radius $\tilde{\delta}$.)

Let $E = H$ for $N = 2$ and $E = H \cap L^4(\Omega)$ for $N = 3$. Assume that the initial condition $y_0$ is close to $\hat{y}(0, \cdot)$ in the norm of the space $E$:

$$\|y_0 - \hat{y}(0, \cdot)\|_E \leq \varepsilon. \tag{3.35}$$

We have

**Theorem 3.3.** *Assume that* $\omega$ *satisfies* (3.34). *Let* $y_0 \in E$, $f \equiv 0$ *and suppose that the pair* $(\hat{y}, \hat{p})$ *solves* (3.25) *and satisfies condition* (3.28). *Then for sufficiently small* $\varepsilon > 0$ *there exists a solution* $(y, p, u)$ *to problem* (3.23), (3.24), (3.35), (3.27) *with control* $u \in (L^2((0, T) \times \omega))^N$ *having one component identically zero.*

In the case of locally distributed control with zero component $u_k$ for the corresponding observability problem, associated with (3.30),(3.31) we do not have any information on the $k$-th component of the function $z$ in $(0, T) \times \omega$. This means that the function $z_k$ should not appear in the right-hand side of the inequality (3.32). This difficulty can be overcome if we recall that $z$ is divergence free function and therefore its $k$-th component satisfies the equation $\partial_{x_k} z_k = \sum_{j=1, j\neq k}^{N} \partial_{x_j} z_j$. From this ordinary differential equation, thanks to zero Dirichlet boundary conditions and assumption (3.34), in some subdomain of $\omega$ we can estimate $z_k$ by the remaining components of the function $z$ and then apply (3.32).

Next we consider the similar controllability problem of the Boussinesq system.

$$\begin{cases} \partial_t y - \Delta y + (y, \nabla) y + \nabla p = \chi_\omega u + \theta\, e_N, \ \ \operatorname{div} y = 0 & \text{in } (0,T)\times\Omega, \\ \partial_t \theta - \Delta\theta + (y, \nabla\theta) = \chi_\omega h & \text{in } (0,T)\times\Omega, \\ y = 0,\ \theta = 0 & \text{on } (0,T)\times\partial\Omega, \\ y(0,\cdot) = y_0,\ \theta(0,\cdot) = \theta_0 & \text{in } \Omega. \end{cases} \tag{3.36}$$

In the domain $(0,T)\times\omega$ we control both the density of external forces $u$ and the density of external heat sources $h$.

Let $(\hat y, \hat p, \hat\theta)$ be a sufficiently regular solution to the Boussinesq system:

$$\partial_t \hat y - \Delta \hat y + (\hat y, \nabla)\hat y + \nabla \hat p = \hat\theta\, e_N, \ \ \operatorname{div} \hat y = 0 \quad \text{in } (0,T)\times\Omega, \tag{3.37}$$

$$\partial_t \hat\theta - \Delta\hat\theta + (\hat y, \nabla\hat\theta) = 0 \quad \text{in } (0,T)\times\Omega, \tag{3.38}$$

$$\hat y = 0,\ \hat\theta = 0 \quad \text{on } (0,T)\times\partial\Omega, \tag{3.39}$$

$$\hat y(0,\cdot) = \hat y_0,\ \hat\theta(0,\cdot) = \hat\theta_0 \quad \text{in } \Omega. \tag{3.40}$$

Assume that $\hat y$ satisfies (3.28) and the temperature $\hat\theta$ has the following regularity

$$\begin{aligned} &\hat\theta \in L^\infty((0,T)\times\Omega), \\ &\partial_t\hat\theta \in L^2(0,T; L^\sigma(\Omega)), \quad \sigma > 1 \text{ if } N = 2, \sigma > 6/5 \text{ if } N = 3. \end{aligned} \tag{3.41}$$

In addition to condition (3.34) we assume that

$$\text{there exists } k < N, \text{ such that } n_k(x^0) \neq 0. \tag{3.42}$$

Our goal is to prove that for some $\varepsilon > 0$ , whenever $(y_0, \theta_0) \in E \times L^2(\Omega)$ and

$$\|(y_0,\theta_0) - (\hat y_0, \hat\theta_0)\|_{E\times L^2(\Omega)} \le \varepsilon, \tag{3.43}$$

we can find $L^2$ controls $u$ and $h$ with $u_k \equiv u_N \equiv 0$ such that

$$y(T,\cdot) = \hat y(T,\cdot) \text{ and } \theta(T,\cdot) = \hat\theta(T,\cdot) \text{ in } \Omega. \tag{3.44}$$

We note that for dimension $N = 2$ we are trying to control both the velocity field and the temperature by choosing the density of external heat sources in the subdomain $\omega$. The following holds:

**Theorem 3.4.** *Assume that $\omega$ satisfies* (3.34) *and* (3.42). *Let $y_0 \in E$, $\theta_0 \in L^2(\Omega)$ and suppose that the pair $(\hat y, \hat\theta, \hat p)$ solves* (3.37)–(3.40) *and satisfies conditions* (3.28), (3.41). *Then for sufficiently small $\varepsilon > 0$ there exists a solution $(y, \theta, p, u, h)$ to problem* (3.36), (3.43), (3.44) *such that $(u, h) \in (L^2((0,T)\times\Omega))^{N+1}$ and $u_k \equiv u_N \equiv 0$. In particular, if $N = 2$, we have local exact controllability with controls $u \equiv 0$ and $h \in L^2((0,T)\times\omega)$.*

## 4. Global controllability of the Navier–Stokes and the Boussinesq system

In this section we will discuss the global controllability of the Boussinesq and the Navier–Stokes systems. We start with the controllability problem for the Boussinesq system with periodic boundary conditions:

$$\partial_t y - \Delta y + (y, \nabla)y + \nabla p = f + \theta e_N + \chi_\omega u \quad \text{in } K = \Pi_{j=1}^N [0, 2\pi], \quad \operatorname{div} y = 0, \tag{4.45}$$

$$\partial_t \theta - \Delta\theta + (y, \nabla\theta) = g + \chi_\omega h \quad \text{in } K, \tag{4.46}$$

$$y(t, \dots x_i + 2\pi, \dots) = y(t, x), \quad \theta(t, \dots x_i + 2\pi, \dots) = \theta(t, x) \quad \text{for all } i \in \{1, \dots, N\}, \tag{4.47}$$

$$y(0, \cdot) = y_0, \quad \theta(0, \cdot) = \theta_0, \quad y(T, \cdot) = \hat{y}(T, \cdot), \quad \theta(T, \cdot) = \hat{\theta}(T, \cdot). \tag{4.48}$$

Here $\hat{\theta}$, $\hat{y}$ is some solution to the Boussinesq system with the same right-hand side:

$$\partial_t \hat{y} - \Delta\hat{y} + (\hat{y}, \nabla)\hat{y} + \nabla\hat{p} = f + \hat{\theta} e_N \quad \text{in } (0, T) \times K, \quad \operatorname{div} \hat{y} = 0, \tag{4.49}$$

$$\partial_t \hat{\theta} - \Delta\hat{\theta} + (\hat{y}, \nabla\hat{\theta}) = g \quad \text{in } (0, T) \times K, \tag{4.50}$$

$$\hat{y}(t, \dots x_i + 2\pi, \dots) = \hat{y}(t, x), \quad \hat{\theta}(t, \dots x_i + 2\pi, \dots) = \hat{\theta}(t, x) \quad \text{for all } i \in \{1, \dots, N\}. \tag{4.51}$$

A very essential role in controllability problems for the Navier–Stokes system and the Boussinesq system is played by the type of boundary conditions.

For the case of periodic boundary conditions the situation is understood much better than for the case of Dirichlet boundary conditions. One reason for this striking difference is that for the periodic case we can construct explicitly a set of nonzero solutions of the Boussinesq system

$$\partial_t \tilde{y} - \Delta\tilde{y} + (\tilde{y}, \nabla)\tilde{y} = \nabla\tilde{p} + \tilde{\theta} e_N + \chi_\omega \tilde{u} \quad \text{in } K, \ \operatorname{div} \tilde{y} = 0, \quad \tilde{y}(0, \cdot) = \tilde{y}(T, \cdot) = 0, \tag{4.52}$$

$$\tilde{y}(t, \dots x_i + 2\pi, \dots) = \tilde{y}(t, x), \quad \tilde{\theta}(t, \dots x_i + 2\pi, \dots) = \tilde{\theta}(t, x) \quad \text{for all } i \in \{1, \dots, N\}, \tag{4.53}$$

$$\partial_t \tilde{\theta} - \Delta\tilde{\theta} + (\tilde{y}, \nabla\tilde{\theta}) = 0 \quad \text{in } K, \quad \tilde{\theta}(0, \cdot) = \tilde{\theta}(T, \cdot) = 0 \tag{4.54}$$

in the form

$$\begin{aligned} &\tilde{y}(t, x) = m(t, x), \quad \tilde{\theta}(t, x) \equiv 0, \\ &m(t, \dots, x_i + 2\pi, \dots) = m(t, x) \quad \text{for all } i \in \{1, \dots, N\}, \end{aligned} \tag{4.55}$$

where $m(t, x) = \nabla\gamma(t, x)$ and $\Delta\gamma(t, \cdot) = 0$ in $K \setminus \omega$ for all $t \in [0, T]$ and $\gamma(0, \cdot) = \gamma(T, \cdot) = 0$. (Obviously for the Dirichlet boundary conditions the function $\gamma \equiv 0$ is the only possible choice!) Note that for any $\tilde{N}$ the functions $(\tilde{N}\tilde{y}, \tilde{N}\tilde{\theta}, \tilde{N}\tilde{p})$ also

solve (4.52)–(4.54) with some $\tilde{u}_{\tilde{N}}$. If we are looking for a solution of the problem (4.45), (4.46), (4.47), (4.48) in the form $(y, \theta) = (Y + \tilde{N}\tilde{m}, \theta)$ then in new equations for $(Y, \theta)$ the large parameter $\tilde{N}$ will appear. Therefore the next logical step in finding $(Y, \theta)$ is to solve a controllability problem associated to the transport equation. In order to do that we need to make a special choice of the vector field $m$. The following holds:

**Lemma 4.1** ([17]). *There exists a vector field* $m(t, x) = (m_1(t, x), \dots, m_N(t, x)) \in C^\infty([0, T] \times K)$ *such that*

$$\operatorname{div} m = 0 \text{ in } [0, T] \times K, \quad m(t, x) = \nabla\gamma(t, x) \quad \text{and} \quad \Delta\gamma = 0 \text{ in } [0, T] \times (K \setminus \omega),$$

*for arbitrary* $k \in \mathbb{N}$

$$m(0, x) \equiv m(T, x) \equiv 0, \quad \frac{\partial^k m(t, x)}{\partial t^k}|_{t=0} = \frac{\partial^k m(t, x)}{\partial t^k}|_{t=T} = 0,$$

*and the relation*

$$\{(t, x(t, x_0), t \in (0, T)\} \cap [0, T] \times \omega \neq \emptyset$$

*is valid for every* $x_0 \in K$, *where* $x(t, x_0)$ *is solution to the Cauchy problem*

$$\frac{d}{dt}x(t, x_0) = m(t, x(t, x_0)), \quad x(t, x_0)|_{t=0} = x_0.$$

*Moreover,* $x(T, x_0) = x_0$ *for each* $x \in K$. *Furthermore there exist a finite cover* $\{\mathcal{O}_j \ j = 1, \dots, J\}$ *of* $K$ *by open sets* $\mathcal{O}_j$ *and a number* $\hat{\delta} > 0$ *such that for each* $j$ *all the curves* $x(t, x_0)$, $x_0 \in \mathcal{O}_j$ *lie in* $\omega$ *for some time interval* $\hat{\delta}$.

In case we choose the vector field $m$ as in Lemma 4.1 the following controllability problem may be solved for all regular initial data $y_0, \theta_0$:

$$\partial_t r + (m, \nabla)r + (r, \nabla)m - \nabla q_1 = \chi_\omega \bar{u}, \ \operatorname{div} r = 0,$$

$$\partial_t z + (m, \nabla z) = \chi_\omega \bar{h},$$

$$r(t, \dots, x_i + 2\pi, \dots) = r(t, x), \ z(t, \dots, x_i + 2\pi, \dots) = z(t, x), \ \ i \in \{1, \dots, N\},$$

$$r(0, \cdot) = y_0, \quad z(0, \cdot) = z_0, \quad r(T, \cdot) = \hat{y}(\varepsilon T, \cdot), \quad z(T, \cdot) = \hat{\theta}(\varepsilon T, \cdot).$$

Finally one can construct an approximation for the solution to problem (4.45)–(4.48) in the form

$$y(t, x) = \frac{1}{\varepsilon} m\Big(\frac{t}{\varepsilon}, x\Big) + r\Big(\frac{t}{\varepsilon}, x\Big) + y_\varepsilon, \quad \theta(t, x) = z\Big(\frac{t}{\varepsilon}, x\Big) + \theta_\varepsilon, \tag{4.56}$$

$$u(t, x) = \frac{1}{\varepsilon}\bar{u}\Big(\frac{t}{\varepsilon}, x\Big) - \chi_\omega \Delta \frac{1}{\varepsilon} m\Big(\frac{t}{\varepsilon}, x\Big), \quad h = \frac{1}{\varepsilon}\bar{h}\Big(\frac{t}{\varepsilon}, x\Big). \tag{4.57}$$

Here the terms $y_\varepsilon$, $\theta_\varepsilon$ are small provided that $\varepsilon > 0$ is small. Of course, we do not have the exact equality $y(\varepsilon T, \cdot) = \hat{y}(\varepsilon T, \cdot)$ but the difference $y(\varepsilon T, \cdot) - \hat{y}(\varepsilon T, \cdot)$

can be made arbitrarily small.( This proves Lions global controllability conjecture for the Boussinesq and the Navier–Stokes system with control distributed on the whole boundary.) Then the local controllability result similar to Theorem 3.4 could be applied in order to switch to the trajectory $(\hat{y}, \hat{\theta})$.

The idea to construct a solution to the controllability problem in the form (4.56), (4.57) was proposed by J. M. Coron in [3], [4] for the two dimensional Navier–Stokes system and Euler equation. In particular, Coron proved that if the control acts on an arbitrary open subset of the boundary which meets any connected component of this boundary, then the 2-D Euler equations are exactly controllable. Later the proof was extended to 3-D Euler equation by Glass [18], [19]. In [6], Coron constructed explicitly the feedback laws which globally asymptotically stabilize the fluid flow described by the Euler equation. The global exact controllability of the Navier–Stokes system on a manifold without boundary was studied in [7].

In order to formulate controllability results for the Boussinesq system rigorously we introduce the functional spaces

$$V^0(K) = \{y(x) \in (L^2(K))^N : \operatorname{div} y = 0,\ y(t, \dots x_i + 2\pi, \dots) = y(t, x) \quad \text{for all } i \in \{1, \dots, N\}\},$$

$$V^1(K) = \{y \in V^0(K) \cap (W_2^1(K))^N\},$$

$$V^{1,2} = \{y(t, x) \in (W_2^{1,2}((0, T)\times K))^N : \operatorname{div} y = 0,\ y(t, \dots x_i + 2\pi, \dots) = y(t, x)\}.$$

We have the following result:

**Theorem 4.1** ([17]). *Let* $y_0 \in V^1(K)$, $\theta_0 \in W_2^1(K)$, $f \in L^2(0, T; V^0(K))$, $g \in L^2((0, T) \times K)$ *and suppose that for some* $\beta \in (0, 1)$ *the function* $(\hat{y}, \hat{\theta}, \hat{p}) \in C^1(0, T; V^0(K) \cap (C^{2,\beta}(K))^N) \times C^1(0, T; C^{2,\beta}(K)) \times L^2(0, T; W_2^1(K))$ *is a given solution of the Boussinesq system* (4.49)–(4.51). *Then there exists a solution* $(y, \theta, p, u, h) \in V^{1,2} \times W^{1,2}((0, T)\times K) \times L^2(0, T; W_2^1(K)) \times (L^2((0, T)\times\omega))^{N+1}$ *to problem* (4.45), (4.46), (4.47), (4.48).

Now we consider the problem of global controllability for the 2-D Navier–Stokes system with zero Dirichlet boundary conditions and control distributed over a part of the boundary. We need to introduce a "large parameter" in this problem but the analog of (4.55) for a general domain is hard to find. Therefore below we consider the Navier–Stokes system in the special domain $\Omega = \{(x_1, x_2) : x_1 \in (0, 1),\ x_2 \in (0, 1)\}$. Let us consider the following controllability problem:

$$\begin{cases} \partial_t y - \Delta y + (y, \nabla)y = \nabla p + f, \ \operatorname{div} y = 0 & (t, x) \in (0, T) \times \Omega, \\ y(t, 0, x_2) = 0 & (t, x_2) \in (0, T) \times (0, 1), \\ y(0, \cdot) = y_0, \ \ y(T, \cdot) = 0 & x = (x_1, x_2) \in \Omega. \end{cases} \tag{4.58}$$

The initial condition $y_0$ satisfies

$$\operatorname{div} y_0 = 0, \quad x \in \Omega, \qquad \text{and} \qquad y_0(0, x_2) = 0, \quad x_2 \in (0, 1). \tag{4.59}$$

Observe that in system (4.58) we did not fix traces of $y$ on $(\{1\} \times (0,1)) \cup ((0,1) \times \{0,1\})$. They can be chosen arbitrarily and considered as a boundary control.

Next we construct an analog of the vector field $m$. Let the function $U(t,x)$ have the form $U(t,x) = (0, z(t,x_1))$ where $z = z(t,x_1)$ solves the following problem associated to a linear heat equation:

$$\begin{cases} \partial_t z - \partial^2_{x_1 x_1} z = c(t) & (t,x_1) \in (0,T) \times (0,2), \\ z(t,0) = 0, \quad z(t,1) = w(t) & t \in (0,T), \\ z(0,x_1) = 0 & x_1 \in (0,2). \end{cases} \tag{4.60}$$

Here $c(t)$ is a constant for each $t$ such that

$$c(0) \neq 0, \quad w(t) \in C^\infty[0,T], \quad w(0) = 0,\ w'(0) = c(0),\ w''(0) = c'(0).$$

Using this function, we construct $U(t,x) = (0, z(t,x_1))$ and $q = x_2 c(t)$ for $t \in (0,T)$, $x \in \tilde{K} = [0,1] \times [0,2]$, which for an arbitrary $\tilde{N} \in \mathbb{R}^1$ solves

$$\begin{cases} \partial_t(\tilde{N}U) - \Delta \tilde{N}U + (\tilde{N}U, \nabla)(\tilde{N}U) = \nabla(\tilde{N}q), \\ \operatorname{div}(\tilde{N}U) = 0 & (t,x) \in (0,T) \times \tilde{K}, \\ \tilde{N}U(t,0,x_2) = 0 & (t,x_2) \in (0,T) \times \mathbb{R}^1, \\ \tilde{N}U(0,x) = 0 & x \in \tilde{K}. \end{cases} \tag{4.61}$$

We have

**Theorem 4.2** ([20]). *Let $f \in L^2((0,T) \times \Omega)$ and let $y_0 \in W^1_2(\Omega)$ satisfy* (4.59). *Then there exists a sequence of functions $f_\varepsilon$ such that*

$$f_\varepsilon \to f \ \text{ in } \ L^{p_0}(0,T;V'), \quad p_0 \in (1, 8/7),$$

*and there exists at least one solution to the controllability problem*

$$\begin{cases} \partial_t y_\varepsilon - \Delta y_\varepsilon + (y_\varepsilon, \nabla) y_\varepsilon + \nabla p_\varepsilon = f_\varepsilon, \ \operatorname{div} y_\varepsilon = 0 & (t,x) \in (0,T) \times \Omega, \\ y_\varepsilon(t,0,x_2) = 0 & (t,x_2) \in (0,T) \times (0,1), \\ y_\varepsilon(0,x) = y_0, \quad y_\varepsilon(T,x) = 0 & x \in \Omega. \end{cases} \tag{4.62}$$

The sequence of the functions $y_\varepsilon$ can be constructed in the following way: First let us choose a sufficiently small number $\delta = \delta(\varepsilon) > 0$ such that

$$\|f\|_{L^{p_0}(T-3\delta,T;V')} \leq \varepsilon/10.$$

• On the interval between $t = 0$ and $t = T - 3\delta$, we do not exert any control. So in this interval our function $y_\varepsilon$ is given by the solution to the Navier–Stokes system with homogeneous Dirichlet boundary conditions.

• Next, on the interval $[T-3\delta, T-2\delta]$, we consider a function $\tilde{y}_{0,\varepsilon} \in V \cap C_0^\infty(\Omega)$ close to $y(T-3\delta, x)$ in $V$. In particular,

$$\|\tilde{y}_{0,\varepsilon} - y(T-3\delta, \cdot)\|_V \le \delta^3.$$

On the interval $[T-3\delta, T-2\delta]$ we set

$$y_\varepsilon(t,x) = \frac{(t-T+3\delta)}{\delta}\tilde{y}_{0,\varepsilon}(x) - \frac{(t-T+2\delta)}{\delta}y(T-3\delta, x),$$
$$(t,x) \in [T-3\delta, T-2\delta] \times \Omega.$$

• As the next step, on the segment $[T-2\delta, T-2\delta+2/\tilde{N}]$, we look for the solution $u_\varepsilon$ in the form

$$y_\varepsilon(t,x) = \tilde{N}^2\tilde{U}(t,x) + \boldsymbol{y}(t,x) - \tilde{V}(t,x), \quad p_\varepsilon(t,x) = \tilde{r}(t,x),$$

where $\tilde{U}(t,x) = U(t-T+2\delta, x)$, $\boldsymbol{y}(t,x) = \tilde{y}(t-T+2\delta, x)$, $\tilde{V}(t,x) = \theta(t-T+2\delta)V(t-T+2\delta, x)$, $\tilde{r}(t,x) = \theta(t)r(t-T+2\delta, x)$.

The function $\tilde{y}$ solves the following controllability problem for the transport equation:

$$\begin{cases} \partial_t\tilde{y} + \tilde{N}^2(U,\nabla)\tilde{y} + \tilde{N}^2(\tilde{y},\nabla)U = 0 & (t,x) \in (0,T)\times\tilde{K}, \\ \tilde{y}(t,0,x_2) = 0 & (t,x_2) \in (0,T)\times\mathbb{R}^1, \\ \tilde{y}(0,x) = \tilde{y}_{0,\varepsilon}, \ \ \tilde{y}(1/\tilde{N},x) = 0 & x \in \tilde{K}. \end{cases} \tag{4.63}$$

The function $\tilde{V}$ is a correction term, which ensure that the vector field $y_\varepsilon$ is divergence free:

$$\begin{cases} \partial_t V - \Delta V = \nabla r, \ \ \operatorname{div} V = \operatorname{div}\tilde{y} & (t,x) \in (0,T)\times\tilde{K}, \\ V(t,0,x_2) = V(t,1,x_2) = 0 & (t,x_2) \in (0,T)\times\mathbb{R}^1, \\ V(t,x_1,x_2) = V(t,x_1,x_2+2) & (t,x_1,x_2) \in (0,T)\times(0,2)\times\mathbb{R}^1, \\ V(0,x) = 0 & x \in \tilde{K}. \end{cases} \tag{4.64}$$

There exists a positive constant $C > 0$ independent of $\tilde{N}$ such that

$$\|V\|_{C([0,2/\tilde{N}];L^2(\tilde{K}))} + \|V_{x_2}\|_{C([0,2/\tilde{N}];L^2(\tilde{K}))} \le \frac{C}{\tilde{N}^{\frac{1}{8}}}. \tag{4.65}$$

This estimate is the consequence of the global version of sharp regularity result for the pressure obtained in [10]. Finally $\theta = \theta(t) \in C^2([0, 2/\tilde{N}])$ is an arbitrary function such that

$$\theta(t) = 1, \ \ t \in [0, 1/\tilde{N}], \quad \text{and} \quad \theta(t) = 0 \ \text{ in a neighborhood of } 2/\tilde{N}.$$

Let $\boldsymbol{y}_\varepsilon = 0$ for $(t, x) \in (T - 2\delta, T - 2\delta + 2/\tilde{N}) \times \Omega$. We set $f_\varepsilon = \partial_t y_\varepsilon - \Delta y_\varepsilon + (y_\varepsilon, \nabla) y_\varepsilon$ for all $(t, x) \in [T - 2\delta, T - 2\delta + 2/\tilde{N}] \times \Omega$.

A short computation and (4.65) imply

$$\|\tilde{f}_\varepsilon\|_{L^{p_0}(T-2\delta, T-2\delta+2/\tilde{N}; V')} \leq C\tilde{N}^{7/8-1/p_0}.$$

Thanks to our choice of $p_0$, this constant tends to zero as $\tilde{N} \to +\infty$.

• Finally, on the interval $[T - 2\delta + 1/\tilde{N}, T]$, we take $f_\varepsilon \equiv 0$ and we try to find a boundary control which drives the associated solution of (4.62) which starts at time $t = T - 2\delta + 2/\tilde{N}$ from the initial condition $\tilde{N}^2 U(2/\tilde{N}, x)$ to zero at time $t = T$.

Observe that we have $y_\varepsilon(T - 2\delta + 2/\tilde{N}, x) = \tilde{N}^2 U(2/\tilde{N}, x)$ since $\theta(2/\tilde{N}) = 0$.

By Theorem 2.1 for any $\overline{z}_0 \in L^2(0, 1)$, there exists a boundary control $\rho = \rho(t) \in L^2(0, 2/\tilde{N} - 2\delta)$ such that the solution of

$$\begin{cases} \partial_t \overline{z} - \partial^2_{x_1 x_1} \overline{z} = 0 & (t, x_1) \in (0, T) \times (0, 1), \\ \overline{z}(t, 0) = 0, \ \ \overline{z}(t, 1) = \rho(t) & t \in (0, T), \\ \overline{z}(0, x_1) = \overline{z}_0 & x_1 \in (0, 1). \end{cases}$$

satisfies

$$\overline{z}(2\delta - 2/\tilde{N}, x_1) = 0, \quad x_1 \in (0, 1).$$

Then it suffices to take

$$y_\varepsilon(t, x) = (0, \overline{z}(t - T + 2\delta - 2/\tilde{N}, x_1)), \quad (t, x) \in (T - 2\delta + 2/\tilde{N}, T) \times \Omega,$$

with $\overline{z}$ the solution of the previous null controllability problem with initial condition

$$\overline{z}_0(x_1) = z(2/\tilde{N}, x_1) \quad x_1 \in (0, 1).$$

The construction of the function $y_\varepsilon$ is finished.

# Port-Hamiltonian systems: an introductory survey

Arjan van der Schaft

**Abstract.** The theory of port-Hamiltonian systems provides a framework for the geometric description of network models of physical systems. It turns out that port-based network models of physical systems immediately lend themselves to a Hamiltonian description. While the usual geometric approach to Hamiltonian systems is based on the canonical symplectic structure of the phase space or on a Poisson structure that is obtained by (symmetry) reduction of the phase space, in the case of a port-Hamiltonian system the geometric structure derives from the *interconnection* of its sub-systems. This motivates to consider Dirac structures instead of Poisson structures, since this notion enables one to define Hamiltonian systems with algebraic constraints. As a result, any power-conserving interconnection of port-Hamiltonian systems again defines a port-Hamiltonian system.

The port-Hamiltonian description offers a systematic framework for analysis, control and simulation of complex physical systems, for lumped-parameter as well as for distributed-parameter models.

**Keywords.** Interconnection, Dirac structures, constrained systems, Hamiltonian DAEs, stabilization, boundary control, conservation laws.

## 1. Introduction

Historically, the Hamiltonian approach has its roots in analytical mechanics and starts from the principle of least action, and proceeds, via the Euler-Lagrange equations and the Legendre transform, towards the Hamiltonian equations of motion. On the other hand, the *network* approach stems from electrical engineering, and constitutes a cornerstone of mathematical systems theory. While most of the *analysis* of physical systems has been performed within the Lagrangian and Hamiltonian framework, the network point of view is prevailing in *modelling* and *simulation* of (complex) physical engineering systems.

The framework of port-Hamiltonian systems *combines* both points of view, by associating with the interconnection structure of the network model a *geometric structure* given by a (pseudo-) *Poisson structure*, or more generally a *Dirac structure*. The Hamiltonian dynamics is then defined with respect to this Dirac structure *and* the Hamiltonian given by the total stored energy. Furthermore, port-Hamiltonian systems are *open* dynamical systems, which interact with their environment through ports. Re-

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

sistive effects are included by terminating some of these ports on energy-dissipating elements.

Dirac structures encompass the geometric structures which are classically being used in the geometrization of mechanics (that is, Poisson structures and pre-symplectic structures), and allow to describe the geometric structure of dynamical systems with algebraic *constraints*. Furthermore, Dirac structures allow to extend the Hamiltonian description of *distributed-parameter systems* to include variable boundary conditions, leading to distributed-parameter port-Hamiltonian systems with boundary ports.

**Acknowledgements.** This survey is based on joint work with several co-authors. In particular I thank Bernhard Maschke and Romeo Ortega for fruitful collaborations.

## 2. Finite-dimensional port-Hamiltonian systems

In this section we recapitulate the basics of finite-dimensional port-Hamiltonian systems. For more details we refer e.g. to [19], [17], [20], [33], [34], [30], [36], [12], [5].

**2.1. From classical Hamiltonian equations to port-Hamiltonian systems.** The standard *Hamiltonian equations* for a mechanical system are given as

$$\begin{aligned} \dot{q} &= \frac{\partial H}{\partial p}(q, p), \\ \dot{p} &= -\frac{\partial H}{\partial q}(q, p) + F \end{aligned} \tag{1}$$

where the *Hamiltonian* $H(q, p)$ is the total energy of the system, $q = (q_1, \ldots, q_k)^T$ are generalized configuration coordinates for the mechanical system with $k$ degrees of freedom, $p = (p_1, \ldots, p_k)^T$ is the vector of generalized momenta, and the input $F$ is the vector of external generalized forces. The state space of (1) with local coordinates $(q, p)$ is called the *phase space*.

One immediately derives the following *energy balance*:

$$\frac{d}{dt}H = \frac{\partial^T H}{\partial q}(q, p)\dot{q} + \frac{\partial^T H}{\partial p}(q, p)\dot{p} = \frac{\partial^T H}{\partial p}(q, p)F = \dot{q}^T F, \tag{2}$$

expressing that the increase in energy of the system is equal to the supplied work (*conservation of energy*). This motivates to define the *output* of the system as $e = \dot{q}$ (the vector of generalized velocities).

System (1) is more generally given in the following form

$$\begin{aligned} \dot{q} &= \frac{\partial H}{\partial p}(q,p), \quad (q,p) = (q_1,\dots,q_k,p_1,\dots,p_k), \\ \dot{p} &= -\frac{\partial H}{\partial q}(q,p) + B(q)f, \qquad f \in \mathbb{R}^m, \\ e &= B^T(q)\frac{\partial H}{\partial p}(q,p) \quad (= B^T(q)\dot{q}), \quad e \in \mathbb{R}^m, \end{aligned} \tag{3}$$

with $B(q)f$ denoting the generalized forces resulting from the input $f \in \mathbb{R}^m$. In case $m < k$ we speak of an *underactuated* system. Similarly to (2) we obtain the energy balance

$$\frac{dH}{dt}(q(t),p(t)) = e^T(t)f(t). \tag{4}$$

A further generalization is to consider systems which are described in local coordinates as

$$\begin{aligned} \dot{x} &= J(x)\frac{\partial H}{\partial x}(x) + g(x)f, \qquad x \in \mathcal{X},\ f \in \mathbb{R}^m, \\ e &= g^T(x)\frac{\partial H}{\partial x}(x), \qquad e \in \mathbb{R}^m, \end{aligned} \tag{5}$$

where $J(x)$ is an $n \times n$ matrix with entries depending smoothly on $x$, which is assumed to be *skew-symmetric*, that is $J(x) = -J^T(x)$, and $x = (x_1,\dots,x_n)$ are local coordinates for an $n$-dimensional state space manifold $\mathcal{X}$ (not necessarily even-dimensional as above). Because of skew-symmetry of $J$ we easily recover the energy-balance $\frac{dH}{dt}(x(t)) = e^T(t)f(t)$. We call (5) a *port-Hamiltonian system* with *structure matrix* $J(x)$, input matrix $g(x)$, and *Hamiltonian* $H$ ([17], [19], [18]).

**Remark 2.1.** In many examples the structure matrix $J$ will additionally satisfy an *integrability* condition (the Jacobi-identity) allowing us to find by Darboux's theorem "canonical coordinates". In this case $J$ is the structure matrix of a *Poisson structure* on $\mathcal{X}$.

**Example 2.2.** An important class of systems that naturally can be written as port-Hamiltonian systems, is constituted by mechanical systems with *kinematic constraints* [22]. Consider a mechanical system locally described by $k$ configuration variables $q = (q_1,\dots,q_k)$. Suppose that there are constraints on the generalized velocities $\dot{q}$, described as

$$A^T(q)\dot{q} = 0, \tag{6}$$

with $A(q)$ an $r \times k$ matrix of rank $r$ everywhere. The constraints (6) are called *holonomic* if it is possible to find new configuration coordinates $\bar{q} = (\bar{q}_1,\dots,\bar{q}_k)$ such that the constraints are equivalently expressed as $\dot{\bar{q}}_{k-r+1} = \dot{\bar{q}}_{n-r+2} = \cdots = \dot{\bar{q}}_k = 0$, in which case the kinematic constraints integrate to the *geometric* constraints

$$\bar{q}_{k-r+1} = c_{k-r+1},\dots,\bar{q}_k = c_k \tag{7}$$

for certain constants $c_{k-r+1}, \ldots, c_k$ determined by the initial conditions. Then the system reduces to an *unconstrained* system in the remaining configuration coordinates $(\bar{q}_1, \ldots, \bar{q}_{k-r})$. If it is *not* possible to integrate the kinematic constraints as above, then the constraints are called *nonholonomic*. The equations of motion for the mechanical system with constraints (6) are given by the *constrained Hamiltonian equations*

$$\begin{aligned} \dot{q} &= \frac{\partial H}{\partial p}(q, p), \\ \dot{p} &= -\frac{\partial H}{\partial q}(q, p) + A(q)\lambda + B(q) f, \\ e &= B^T(q)\frac{\partial H}{\partial p}(q, p), \\ 0 &= A^T(q)\frac{\partial H}{\partial p}(q, p). \end{aligned} \tag{8}$$

The *constrained* state space is therefore given as the following subset of the phase space:

$$\mathcal{X}_c = \left\{(q, p) \mid A^T(q)\frac{\partial H}{\partial p}(q, p) = 0\right\}. \tag{9}$$

One way of proceeding is to *eliminate* the constraint forces, and to *reduce* the equations of motion to the constrained state space, leading (see [32] for details) to a port-Hamiltonian system (5). The structure matrix of this reduced port-Hamiltonian system satisfies the Jacobi identity if and only if the constraints (6) are *holonomic* [32]. An alternative way of approaching the system (8) is to formalize it directly as an *implicit* port-Hamiltonian system (with respect to a Dirac structure), as will be the topic of Section 2.3.

**2.2. From port-based network modelling to port-Hamiltonian systems.** In this subsection we take a different point of view by emphasizing how port-Hamiltonian systems directly arise from *port-based network models* of physical systems.

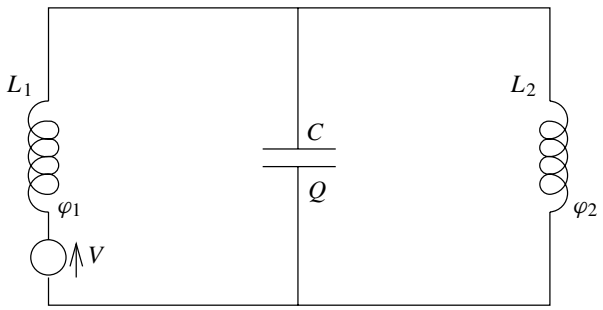

Figure 1. Controlled LC-circuit.

In network models of complex physical systems the overall system is regarded as the *interconnection* of energy-storing elements via basic interconnection (balance) laws such as Newton's third law or Kirchhoff's laws, as well as power-conserving elements like transformers, kinematic pairs and ideal constraints, together with energy-dissipating elements [3], [14], [13]. The basic point of departure for the theory of port-Hamiltonian systems is to formalize the basic interconnection laws together with the power-conserving elements by a *geometric structure*, and to define the Hamiltonian as the total energy stored in the system. This is already illustrated by the following simple example.

**Example 2.3** (LCTG circuits). Consider a controlled LC-circuit (see Figure 1) consisting of two inductors with magnetic energies $H_1(\varphi_1)$, $H_2(\varphi_2)$ ($\varphi_1$ and $\varphi_2$ being the magnetic flux linkages), and a capacitor with electric energy $H_3(Q)$ ($Q$ being the charge). If the elements are linear then $H_1(\varphi_1) = \frac{1}{2L_1}\varphi_1^2$, $H_2(\varphi_2) = \frac{1}{2L_2}\varphi_2^2$ and $H_3(Q) = \frac{1}{2C}Q^2$. Furthermore let $V = u$ denote a voltage source. Using Kirchhoff's laws one obtains the dynamical equations

$$\begin{aligned} \begin{bmatrix} \dot{Q} \\ \dot{\varphi}_1 \\ \dot{\varphi}_2 \end{bmatrix} &= \underbrace{\begin{bmatrix} 0 & 1 & -1 \\ -1 & 0 & 0 \\ 1 & 0 & 0 \end{bmatrix}}_{J} \begin{bmatrix} \frac{\partial H}{\partial Q} \\ \frac{\partial H}{\partial \varphi_1} \\ \frac{\partial H}{\partial \varphi_2} \end{bmatrix} + \begin{bmatrix} 0 \\ 1 \\ 0 \end{bmatrix} u, \\ y &= \frac{\partial H}{\partial \varphi_1} \qquad (= \text{current through voltage source}) \end{aligned} \tag{10}$$

with $H(Q, \varphi_1, \varphi_2) := H_1(\varphi_1) + H_2(\varphi_2) + H_3(Q)$ the total energy. Clearly (by Tellegen's theorem) the matrix $J$ is skew-symmetric.

In this way every LC-circuit with independent elements can be modelled as a port-Hamiltonian system. Similarly any LCTG-circuit with independent elements can be modelled as a port-Hamiltonian system, with $J$ now being determined by Kirchhoff's laws *and* the constitutive relations of the transformers $T$ and gyrators $G$.

**2.3. Dirac structures and implicit port-Hamiltonian systems.** From a general modeling point of view physical systems are, at least in first instance, often described as DAE's, that is, a mixed set of differential and *algebraic* equations. This stems from the fact that in network modeling the system under consideration is regarded as obtained from interconnecting simpler sub-systems. These interconnections usually give rise to algebraic constraints between the state space variables of the sub-systems; thus leading to implicit systems. Therefore it is important to extend the framework of port-Hamiltonian systems to the context of *implicit systems*; that is, systems with algebraic constraints.

**2.3.1. Dirac structures.** In order to give the definition of an implicit port-Hamiltonian system we introduce the notion of a Dirac structure, formalizing the concept of

a power-conserving interconnection, and generalizing the notion of a structure matrix $J(x)$ as encountered before.

Let $\mathcal{F}$ be an $\ell$-dimensional linear space, and denote its dual (the space of linear functions on $\mathcal{F}$) by $\mathcal{F}^*$. The product space $\mathcal{F} \times \mathcal{F}^*$ is considered to be the space of power variables, with power defined by

$$P = \langle f^* | f \rangle, \quad (f, f^*) \in \mathcal{F} \times \mathcal{F}^*, \tag{11}$$

where $\langle f^* | f \rangle$ denotes the duality product. Often we call $\mathcal{F}$ the space of *flows* $f$, and $\mathcal{F}^*$ the space of *efforts* $e$, with the power of an element $(f, e) \in \mathcal{F} \times \mathcal{F}^*$ denoted as $\langle e | f \rangle$.

**Example 2.4.** Let $\mathcal{F}$ be the space of generalized *velocities*, and $\mathcal{F}^*$ be the space of generalized *forces*, then $\langle e | f \rangle$ is mechanical power. Similarly, let $\mathcal{F}$ be the space of *currents*, and $\mathcal{F}^*$ be the space of *voltages*, then $\langle e | f \rangle$ is electrical power.

There exists on $\mathcal{F} \times \mathcal{F}^*$ the canonically defined symmetric bilinear form

$$\langle (f_1, e_1), (f_2, e_2) \rangle_{\mathcal{F} \times \mathcal{F}^*} := \langle e_1 | f_2 \rangle + \langle e_2 | f_1 \rangle \tag{12}$$

for $f_i \in \mathcal{F}$, $e_i \in \mathcal{F}^*$, $i = 1, 2$.

**Definition 2.5** ([6], [8], [7]). A constant Dirac structure on $\mathcal{F}$ is a linear subspace $\mathcal{D} \subset \mathcal{F} \times \mathcal{F}^*$ such that

$$\mathcal{D} = \mathcal{D}^{\perp} \tag{13}$$

where $^{\perp}$ denotes the orthogonal complement with respect to the bilinear form $\langle \, , \rangle_{\mathcal{F} \times \mathcal{F}^*}$.

It immediately follows that the dimension of any Dirac structure $\mathcal{D}$ on an $\ell$-dimensional linear space is equal to $\ell$. Furthermore, let $(f, e) \in \mathcal{D} = \mathcal{D}^{\perp}$. Then by (12)

$$0 = \langle (f, e), (f, e) \rangle_{\mathcal{F} \times \mathcal{F}^*} = 2 \langle e \mid f \rangle. \tag{14}$$

Thus for all $(f, e) \in \mathcal{D}$ we obtain $\langle e \mid f \rangle = 0$. Hence a Dirac structure $\mathcal{D}$ on $\mathcal{F}$ defines a power-conserving relation between the power variables $(f, e) \in \mathcal{F} \times \mathcal{F}^*$, which moreover has maximal dimension.

**Remark 2.6.** For many systems, especially those with 3-D mechanical components, the Dirac structure is actually *modulated* by the energy or geometric variables. Furthermore, the state space $\mathcal{X}$ is a *manifold* and the flows $f_S = -\dot{x}$ corresponding to energy-storage are elements of the tangent space $T_x\mathcal{X}$ at the state $x \in \mathcal{X}$, while the efforts $e_S$ are elements of the co-tangent space $T_x^*\mathcal{X}$.

Modulated Dirac structures often arise as a result of *kinematic constraints*. In many cases, these constraints will be configuration dependent, causing the Dirac structure to be modulated by the configuration variables, cf. Section 2.2.

In general, a port-Hamiltonian system can be represented as in Figure 2. The port variables entering the Dirac structure $\mathcal{D}$ have been split in different parts. First, there are two *internal* ports. One, denoted by $\mathcal{S}$, is corresponding to energy-storage and the other one, denoted by $\mathcal{R}$, is corresponding to internal energy-dissipation (resistive elements). Second, two *external* ports are distinguished. The external port denoted by $\mathcal{C}$ is the port that is accessible for controller action. Also the presence of *sources* may be included in this port. Finally, the external port denoted by $\mathcal{I}$ is the interaction port, defining the interaction of the system with (the rest of) its environment.

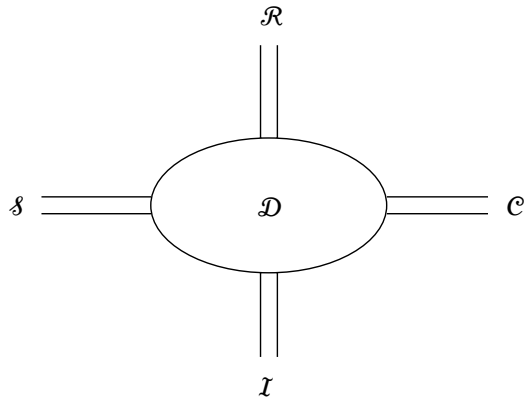

Figure 2. Port-Hamiltonian system.

**2.3.2. Energy storage port.** The port variables associated with the internal storage port will be denoted by $(f_S, e_S)$. They are interconnected to the energy storage of the system which is defined by a finite-dimensional state space manifold $\mathcal{X}$ with coordinates $x$, together with a Hamiltonian function $H\colon \mathcal{X} \to \mathbb{R}$ denoting the energy. The flow variables of the energy storage are given by the *rate* $\dot{x}$ of the energy variables $x$. Furthermore, the effort variables of the energy storage are given by the *co-energy* variables $\frac{\partial H}{\partial x}(x)$, resulting in the energy balance

$$\frac{d}{dt}H = \left\langle \frac{\partial H}{\partial x}(x) \;\middle|\; \dot{x} \right\rangle = \frac{\partial^T H}{\partial x}(x)\dot{x}. \tag{15}$$

(Here we adopt the convention that $\frac{\partial H}{\partial x}(x)$ denotes the *column* vector of partial derivatives of $H$.)

The interconnection of the energy storing elements to the storage port of the Dirac structure is accomplished by setting

$$\begin{aligned} f_S &= -\dot{x}, \\ e_S &= \frac{\partial H}{\partial x}(x). \end{aligned} \tag{16}$$

Hence the energy balance (15) can be also written as

$$\frac{d}{dt}H = \frac{\partial^T H}{\partial x}(x)\dot{x} = -e_S^T f_S. \tag{17}$$

**2.3.3. Resistive port.** The second internal port corresponds to internal energy dissipation (due to friction, resistance, etc.), and its port variables are denoted by $(f_R, e_R)$. These port variables are terminated on a static resistive relation $\mathcal{R}$. In general, a static resistive relation will be of the form

$$R(f_R, e_R) = 0, \tag{18}$$

with the property that for all $(f_R, e_R)$ satisfying (18)

$$\langle e_R \mid f_R \rangle \leq 0. \tag{19}$$

In many cases we may restrict ourselves to *linear* resistive relations. This means that the resistive port variables $(f_R, e_R)$ satisfy linear relations of the form

$$R_f f_R + R_e e_R = 0. \tag{20}$$

The inequality (19) corresponds to the square matrices $R_f$ and $R_e$ satisfying the properties of symmetry and semi-positive definiteness

$$R_f R_e^T = R_e R_f^T \geq 0, \tag{21}$$

together with the dimensionality condition $\text{rank}[R_f | R_e] = \dim f_R$.

Without the presence of additional external ports, the Dirac structure of the port-Hamiltonian system satisfies the power-balance $e_S^T f_S + e_R^T f_R = 0$ which leads to

$$\frac{d}{dt}H = -e_S^T f_S = e_R^T f_R \leq 0. \tag{22}$$

An important special case of resistive relations between $f_R$ and $e_R$ occurs when the resistive relations can be expressed as an *input-output* mapping $f_R = -F(e_R)$, where the resistive characteristic $F: \mathbb{R}^{m_r} \to \mathbb{R}^{m_r}$ satisfies

$$e_R^T F(e_R) \geq 0, \quad e_R \in \mathbb{R}^{m_r}. \tag{23}$$

For *linear* resistive elements this specializes to $f_R = -\tilde{R} e_R$, for some positive semi-definite symmetric matric $\tilde{R} = \tilde{R}^T \geq 0$.

**2.3.4. External ports.** Now, let us consider in more detail the *external* ports to the system. We distinguish between two types of external ports. One is the *control port* $\mathcal{C}$, with port variables $(f_C, e_C)$, which are the port variables which are accessible for controller action. Other type of external port is the *interaction port* $\mathcal{I}$, which denotes the interaction of the port-Hamiltonian system with its environment. The

port variables corresponding to the interaction port are denoted by $(f_I, e_I)$. By taking both the external ports into account the power-balance extends to

$$e_S^T f_S + e_R^T f_R + e_C^T f_C + e_I^T f_I = 0 \tag{24}$$

whereby (22) extends to

$$\frac{d}{dt}H = e_R^T f_R + e_C^T f_C + e_I^T f_I. \tag{25}$$

**2.3.5. Port-Hamiltonian dynamics.** The port-Hamiltonian system with state space $\mathcal{X}$, Hamiltonian $H$ corresponding to the energy storage port $\mathcal{S}$, resistive port $\mathcal{R}$, control port $\mathcal{C}$, interconnection port $\mathcal{I}$, and total Dirac structure $\mathcal{D}$ will be succinctly denoted by $\Sigma = (\mathcal{X}, H, \mathcal{R}, \mathcal{C}, \mathcal{I}, \mathcal{D})$. The dynamics of the port-Hamiltonian system is specified by considering the constraints on the various port variables imposed by the Dirac structure, that is

$$(f_S, e_S, f_R, e_R, f_C, e_C, f_I, e_I) \in \mathcal{D},$$

and to substitute in these relations the equalities $f_S = -\dot{x}$, $e_S = \frac{\partial H}{\partial x}(x)$. This leads to the implicitly defined dynamics

$$\Big( -\dot{x}(t), \frac{\partial H}{\partial x}(x(t)), f_R(t), e_R(t), f_C, (t), e_C(t), f_I(t), e_I(t) \Big) \in \mathcal{D} \tag{26}$$

with $f_R(t), e_R(t)$ satisfying for all $t$ the resistive relation (18):

$$R(f_R, e_R) = 0. \tag{27}$$

In many cases of interest the dynamics (26) will constrain the allowed states $x$, depending on the values of the external port variables $(f_C, e_C)$ and $(f_I, e_I)$. Thus in an equational representation port-Hamiltonian systems generally will consist of a mixed set of *differential* and *algebraic* equations (DAEs).

**Example 2.7** (General LC- circuits). Consider an LC-circuit with general network topology. Kirchhoff's current and voltage laws take the general form

$$A_L{}^T I_L + A_C{}^T I_C + A_P{}^T I_P = 0,$$

$$V_L = A_L \lambda, \quad V_C = A_C \lambda, \quad V_P = A_P \lambda$$

for some matrices $A_L$, $A_C$, $A_S$. Here $I_L$, $I_C$, $I_P$ denote the currents, respectively through the inductors, capacitors and external ports. Likewise, $V_L$, $V_C$, $V_P$ denote the voltages over the inductors, capacitors and external ports. Kirchhoff's current and voltage laws define a Dirac structure between the flows and efforts:

$$f = (I_C, V_L, I_P) = (-\dot{Q}, -\dot{\phi}, I_P),$$
$$e = (V_C, I_L, V_P) = \left( \frac{\partial H}{\partial Q}, \frac{\partial H}{\partial \phi}, V_P \right)$$

with Hamiltonian $H(\phi, Q)$ the total energy. This leads the to port-Hamiltonian system in implicit form

$$\begin{aligned} -\dot{\phi} &= A_L \lambda, \\ \frac{\partial H}{\partial Q} &= A_C \lambda, \\ V_P &= A_P \lambda, \\ 0 &= {A_L}^T \frac{\partial H}{\partial \phi} - {A_C}^T \dot{Q} + {A_P}^T I_P. \end{aligned}$$

**Example 2.8** (Electro-mechanical system). Consider the dynamics of an iron ball in the magnetic field of a controlled inductor: The port-Hamiltonian description of this

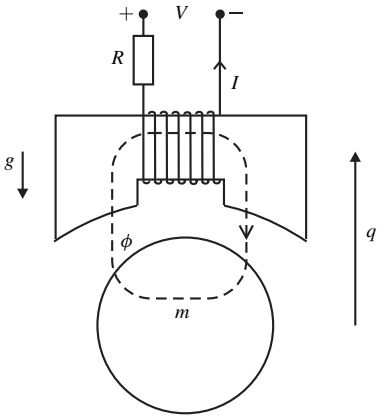

Figure 3. Magnetically levitated ball.

system (with $q$ the height of the ball, $p$ the vertical momentum, and $\varphi$ the magnetic flux of the inductor) is given as

$$\begin{aligned} \begin{bmatrix} \dot{q} \\ \dot{p} \\ \dot{\varphi} \end{bmatrix} &= \begin{bmatrix} 0 & 1 & 0 \\ -1 & 0 & 0 \\ 0 & 0 & -\frac{1}{R} \end{bmatrix} \begin{bmatrix} \frac{\partial H}{\partial q} \\ \frac{\partial H}{\partial p} \\ \frac{\partial H}{\partial \varphi} \end{bmatrix} + \begin{bmatrix} 0 \\ 0 \\ 1 \end{bmatrix} V, \\ I &= \frac{\partial H}{\partial \varphi}. \end{aligned} \tag{28}$$

This is a typical example of a system where the *coupling* between two different physical domains (mechanical and magnetic) takes place via the Hamiltonian

$$H(q, p, \varphi) = mgq + \frac{p^2}{2m} + \frac{\varphi^2}{2k_1(1 - \frac{q}{k_2})}$$

where the last term depends both on a magnetic variable (in this case $\varphi$) and a mechanical variable (in this case the height $q$).

**2.4. Input-state-output port-Hamiltonian systems.** An important special case of port-Hamiltonian systems is the class of *input-state-output port-Hamiltonian systems*, where there are no algebraic constraints on the state space variables, and the flow and effort variables of the resistive, control and interaction port are split into conjugated input–output pairs. Input–state–output port-Hamiltonian systems without interaction port are of the form

$$\begin{aligned} \dot{x} &= [J(x) - R(x)]\frac{\partial H}{\partial x}(x) + g(x)u, \\ y &= g^T(x)\frac{\partial H}{\partial x}(x) \end{aligned} \tag{29}$$

where $u$, $y$ are the input–output pairs corresponding to the control port $\mathcal{C}$. Here the matrix $J(x)$ is skew-symmetric, while the matrix $R(x) = R^T(x) \geq 0$ specifies the resistive structure, and is given as $R(x) = g_R^T(x)\tilde{R}g_R(x)$ for some linear resistive relation $f_R = -\tilde{R}e_R$, $\tilde{R} = \tilde{R}^T \geq 0$, with $g_R$ representing the input matrix corresponding to the resistive port. The underlying Dirac structure of the system is then given by the graph of the skew-symmetric linear map

$$\begin{pmatrix} -J(x) & -g_R(x) & -g(x) \\ g_R^T(x) & 0 & 0 \\ g^T(x) & 0 & 0 \end{pmatrix}. \tag{30}$$

## 3. Control by interconnection of port-Hamiltonian systems

The basic property of port-Hamiltonian systems is that the power-conserving interconnection of any number of port-Hamiltonian systems is again a port-Hamiltonian system.

To be explicit, consider two port-Hamiltonian systems $\Sigma_A$ and $\Sigma_B$ with Dirac structures $\mathcal{D}_A$ and $\mathcal{D}_B$ and Hamiltonians $H_A$ and $H_B$, defined on state spaces $\mathcal{X}_A$, respectively $\mathcal{X}_B$. For convenience, split the ports of the Dirac structures $\mathcal{D}_A$ and $\mathcal{D}_B$ into the internal energy storage ports and all remaining external ports whose port-variables are denoted respectively by $f_A$, $e_A$ and $f_B$, $e_B$. Now, consider any *interconnection* Dirac structure $\mathcal{D}_I$ involving the port-variables $f_A$, $e_A$, $f_B$, $e_B$ possibly together with additional port-variables $f_I$, $e_I$. Then the interconnection of the systems $\Sigma_A$ and $\Sigma_B$ via $\mathcal{D}_I$ is again a port-Hamiltonian system with respect to the composed Dirac structure $\mathcal{D}_A \circ \mathcal{D}_I \circ \mathcal{D}_B$, involving as port-variables the internal storage port-variables of $\mathcal{D}_A$ and $\mathcal{D}_B$ together with the additional port-variables $F_I$, $e_I$. For details we refer to [5], [34], [30].

Furthermore, the state space of the interconnected port-Hamiltonian system is the product of the two state spaces $\mathcal{X}_A \times \mathcal{X}_B$, while its Hamiltonian is simply the sum $H_A + H_B$ of the two Hamiltonians.

This basic statement naturally extends to the interconnection of any number of port-Hamiltonian systems via an interconnection Dirac structure.

*Control by port-interconnection* is based on designing a controller system which is *interconnected* to the control port with port-variables $(f_C, e_C)$. *In principle* this implies that we only consider *collocated* control, where the controller will only use the information about the plant port-Hamiltonian system that is contained in the conjugated pairs $(f_C, e_C)$ of port variables of the control port, without using additional information about the plant (e.g. corresponding to observation on other parts of the plant system). In the second place, we will restrict attention to controller systems which are themselves *also* port-Hamiltonian systems. There are two main reasons for this. One is that by doing so the closed-loop system is *again* a port-Hamiltonian system, allowing to easily ensure some desired properties. Furthermore, it will turn out that the port-Hamiltonian framework suggests useful ways to construct port-Hamiltonian controller systems. Second reason is that port-Hamiltonian controller systems allow in principle for a physical system realization (thus linking to passive control and systems design) and physical *interpretation* of the controller action.

Since we do not know the environment (or only have very limited information about it), but on the other hand, the system *will* interact with this unknown environment, the task of the controller is often two-fold: 1) to achieve a desired control goal (e.g. set-point regulation or tracking) if the interaction with the environment is marginal or can be compensated, 2) to make sure that the controlled system has a desired interaction behavior with its environment. It is fair to say that up to now the development of the theory of control of port-Hamiltonian systems has mostly concentrated on the second aspect (which at the same time, is often underdeveloped in other control theories).

Most successful approaches to deal with the second aspect of the control goal are those based on the concept of "*passivity*", such as *dissipativity theory* [38], *impedance control* [13] and *Intrinsically Passive Control* (IPC) [36]. In fact, the port-Hamiltonian control theory can be regarded as an enhancement to the theory of passivity, making a much closer link with complex physical systems modeling at one hand and with the theory of dynamical systems (in particular, Hamiltonian dynamics) at the other hand.

As said above, we will throughout consider controller systems which are again port-Hamiltonian systems. We will use the same symbols as above for the internal and external ports and port-variables of the controller port-Hamiltonian system, with an added overbar $\bar{}$ or a superscript $^c$ in order to distinguish it from the plant system. (The interaction port of the controller system may be thought of as an extra possibility for additional controller action (outer-loop control).) In order to further distinguish the plant system and the controller we denote the state space of the plant system by $\mathcal{X}_p$ with coordinates $x_p$, the Dirac structure by $\mathcal{D}_p$ and its Hamiltonian by $H_p$, while we will denote the state space manifold of the controller system by $\mathcal{X}_c$ with coordinates $x_c$, its Dirac structure by $\mathcal{D}_c$ and its Hamiltonian by $H_c \colon \mathcal{X}_c \to \mathbb{R}$. The interconnection

of the plant port-Hamiltonian system with the controller port-Hamiltonian system is obtained by equalizing the port variables at the control port by

$$\begin{aligned} f_C &= -\bar{f}_C, \\ e_C &= \bar{e}_C \end{aligned} \tag{31}$$

where $\bar{f}_C$, $\bar{e}_C$ denote the control port variables of the controller system. Here, the minus sign is inserted to have a uniform notion of direction of power flow. Clearly, this 'synchronizing' interconnection is power-conserving, that is $e_C^T f_C + \bar{e}_C^T \bar{f}_C = 0$.

**Remark 3.1.** A sometimes useful alternative is the *gyrating* power-conserving interconnection

$$\begin{aligned} f_C &= -\bar{e}_C, \\ e_C &= \bar{f}_C. \end{aligned} \tag{32}$$

In fact, the standard feedback interconnection can be regarded to be of this type.

For both interconnection constraints it directly follows from the theory of composition of Dirac structures that the interconnected (closed-loop) system is again a port-Hamiltonian system with Dirac structure determined by the Dirac structures of the plant PH system and the controller PH system.

The resulting interconnected PH system has state space $\mathcal{X}_p \times \mathcal{X}_c$, Hamiltonian $H_p + H_c$, resistive ports $(f_R, e_R, \bar{f}_R, \bar{e}_R)$ and interaction ports $(f_I, e_I, \bar{f}_I, \bar{e}_I)$, satisfying the power-balance

$$\frac{d}{dt}(H_p + H_c) = e_R^T f_R + \bar{e}_R^T \bar{f}_R + e_I^T f_I + \bar{e}_I^T \bar{f}_I \leq e_I^T f_I + \bar{e}_I^T \bar{f}_I \tag{33}$$

since both $e_R^T f_R \leq 0$ and $\bar{e}_R^T \bar{f}_R \leq 0$. Hence we immediately recover the state space formulation of the passivity theorem, see e.g. [31], if $H_p$ and $H_c$ are both non-negative, implying that the plant and the controller system are passive (with respect to their controller and interaction ports and storage functions $H_p$ and $H_c$), then also the closed -loop system is passive (with respect to the interaction ports and storage function $H_p + H_c$.)

Furthermore, due to the Hamiltonian structure, we can go *beyond* the passivity theorem, and we can derive conditions which ensure that we can passify and/or stabilize plant port-Hamiltonian systems for which the Hamiltonian $H_p$ does *not* have a minimum at the desired equilibrium.

**3.1. Stabilization by Casimir generation.** What does the power-balance (33)mean for the stability properties of the closed-loop system, and how can we design the controller port-Hamiltonian system in such a way that the closed-loop system has desired stability properties? Let us first consider the stability of an arbitrary port-Hamiltonian system $\Sigma = (\mathcal{X}, H, \mathcal{R}, \mathcal{C}, \mathcal{I}, \mathcal{D})$ *without* control or interaction ports,

that is, an autonomous port-Hamiltonian system $\Sigma = (\mathcal{X}, H, \mathcal{R}, \mathcal{D})$. Clearly, the power-balance (33) reduces to

$$\frac{d}{dt}H = e_R^T f_R \leq 0. \tag{34}$$

Hence we immediately infer by standard Lyapunov theory that if $x^*$ is a minimum of the Hamiltonian $H$ then it will be a *stable* equilibrium of the autonomous port-Hamiltonian system $\Sigma = (\mathcal{X}, H, \mathcal{R}, \mathcal{D})$, which is actually *asymptotically stable* if the dissipation term $e_R^T f_R$ is negative *definite* outside $x^*$, or alternatively if some sort of detectability condition is satisfied, guaranteeing asymptotic stability by the use of LaSalle's Invariance principle (see for details e.g. [31]).

However, what can we say if $x^*$ is *not* a minimum of $H$, and thus we cannot directly use $H$ as a Lyapunov function?

A well-known method in Hamiltonian systems, sometimes called the Energy-Casimir method, is to use in the Lyapunov analysis next to the Hamiltonian *other* conserved quantities (dynamical invariants) which may be present in the system. Indeed, if we may find other conserved quantities then candidate Lyapunov functions can be sought within the class of *combinations* of the Hamiltonian $H$ and those conserved quantities. In particular, if we can find a conserved quantity $C\colon \mathcal{X} \to \mathbb{R}$ such that $V := H + C$ has a minimum at the desired equilibrium $x^*$ then we can still infer stability or asymptotic stability by replacing (34) by

$$\frac{d}{dt}V = e_R^T f_R \leq 0 \tag{35}$$

and thus using $V$ as a Lyapunov function.

For the application of the Energy-Casimir method one may distinguish between two main cases. First situation occurs if the desired equilibrium $x^*$ is not a stationary point of $H$, and one looks for a conserved quantity $C$ such that $H + C$ has a minimum at $x^*$. This for example happens in the case that the desired set-point $x^*$ is *not* an equilibrium of the uncontrolled system, but only a controlled equilibrium of the system. Second situation occurs when $x^*$ *is* a stationary point of $H$, but not a minimum.

Functions that are conserved quantities of the system for *every* Hamiltonian are called *Casimir functions* or simply Casimirs. Casimirs are completely characterized by the Dirac structure of the port-Hamiltonian system. Indeed, a function $C\colon \mathcal{X} \to \mathbb{R}$ is a Casimir function of the autonomous port-Hamiltonian system (without energy dissipation) $\Sigma = (\mathcal{X}, H, \mathcal{D})$ if and only if the gradient vector $e = \frac{\partial^T C}{\partial x}$ satisfies

$$e^T f_S = 0 \quad \text{for all } f_S \text{ for which there exists } e_S \text{ such that } (f_S, e_S) \in \mathcal{D}. \tag{36}$$

Indeed, (36) is equivalent to

$$\frac{d}{dt}C = \frac{\partial^T C}{\partial x}(x(t))\dot{x}(t) = \frac{\partial^T C}{\partial x}(x(t))\, f_S = e^T f_S = 0 \tag{37}$$

for every port-Hamiltonian system $(\mathcal{X}, H, \mathcal{D})$ with the same Dirac structure $\mathcal{D}$. By the generalized skew-symmetry of the Dirac structure (36) is equivalent to the requirement that $e = \frac{\partial^T C}{\partial x}$ satisfies

$$(0, e) \in \mathcal{D}.$$

Similarly, we define a Casimir function for a port-Hamiltonian system with dissipation $\Sigma = (\mathcal{X}, H, \mathcal{R}, \mathcal{D})$ to be any function $C\colon \mathcal{X} \to \mathbb{R}$ satisfying

$$(0, e, 0, 0) \in \mathcal{D}. \tag{38}$$

Indeed, this will imply that

$$\frac{d}{dt}C = \frac{\partial^T C}{\partial x}(x(t))\dot{x}(t) = \frac{\partial^T C}{\partial x}(x(t))\, f_p = e^T f_p = 0 \tag{39}$$

for every port-Hamiltonian system $(\mathcal{X}, H, \mathcal{R}, \mathcal{D})$ with the same Dirac structure $\mathcal{D}$. (In fact by definiteness of the resistive structures the satisfaction of (39) for a particular resistive structure $\mathcal{R}$ *implies* the satisfaction for *all* resistive structures $\mathcal{R}$.)

Now let us come back to the design of a controller port-Hamiltonian system such that the closed-loop system has desired stability properties. Suppose we want to stabilize the plant port-Hamiltonian system $(\mathcal{X}_p, H_p, \mathcal{R}, \mathcal{C}, \mathcal{D}_p)$ around a desired equilibrium $x_p^*$. We know that for every controller port-Hamiltonian system the closed-loop system satisfies

$$\frac{d}{dt}(H_p + H_c) = e_R^T f_R + \bar{e}_R^T \bar{f}_R \leq 0. \tag{40}$$

What if $x^*$ is not a minimum for $H_p$? A possible strategy is to *generate* Casimir functions $C(x_p, x_c)$ for the closed-loop system by choosing the controller port-Hamiltonian system in an appropriate way. Thereby we generate candidate Lyapunov functions for the closed-loop system of the form

$$V(x_p, x_c) := H_p(x_p) + H_c(x_c) + C(x_p, x_c)$$

where the controller Hamiltonian function $H_c\colon \mathcal{X}_c \to \mathbb{R}$ still has to be designed. The goal is thus to construct a function $V$ as above in such a way that $V$ has a minimum at $(x_p^*, x_c^*)$ where $x_c^*$ still remains to be chosen. This strategy thus is based on finding all the achievable closed-loop Casimirs. Furthermore, since the closed-loop Casimirs are based on the closed-loop Dirac structures, this reduces to finding all the achievable closed-loop Dirac structures $\mathcal{D} \circ \bar{\mathcal{D}}$.

*Another* way to interpret the generation of Casimirs for the closed-loop system is to look at the level sets of the Casimirs as *invariant submanifolds* of the combined plant and controller state space $\mathcal{X}_p \times \mathcal{X}_c$. Restricted to every such invariant submanifold (part of) the controller state can be expressed as a function of the plant state, whence the closed-loop Hamiltonian restricted to such an invariant manifold can be seen as a

*shaped* version of the plant Hamiltonian. To be explicit (see e.g. [31], [24], [25] for details) suppose that we have found Casimirs of the form

$$x_{ci} - F_i(x_p), \quad i = 1, \ldots, n_p$$

where $n_p$ is the dimension of the controller state space, then on every invariant manifold $x_{ci} - F_i(x_p) = \alpha_i$, $i = 1, \ldots, n_p$, where $\alpha = (\alpha_1, \ldots, \alpha_{n_p})$ is a vector of constants depending on the initial plant and controller state, the closed-loop Hamiltonian can be written as

$$H_s(x_p) := H_p(x_p) + H_c(F(x_p) + \alpha),$$

where, as before, the controller Hamiltonian $H_c$ still can be assigned. This can be regarded as *shaping* the original plant Hamiltonian $H_p$ to a new Hamiltonian $H_s$.

**3.2. Port Control.** In broad terms, the *Port Control* problem is to design, given the plant port-Hamiltonian system, a controller port-Hamiltonian system such that the *behavior* at the interaction port of the plant port-Hamiltonian system is a desired one, or close to a desired one. This means that by adding the controller system we seek to shape the external behavior at the interaction port of the plant system. If the desired external behavior at this interaction port is given in input–output form as a desired (dynamic) impedance, then this amounts to the Impedance Control problem as introduced and studied by Hogan and co-workers [13]; see also [36] for subsequent developments.

The Port Control problem, as stated in this generality, immediately leads to two fundamental questions: 1). Given the plant PH system, and the controller PH system to be arbitrarily designed, what are the achievable behaviors of the closed-loop system at the interaction port of the plant? 2). If the desired behavior at the interaction port of the plant is not achievable, then what is the closest achievable behavior? Of course, the second question leaves much room for interpretation, since there is no obvious interpretation of what we mean by 'closest behavior'. Also the first question in its full generality is not easy to answer, and we shall only address an important subproblem.

An obvious observation is that the desired behavior, in order to be achievable, needs to be the port behavior of a PH system. This leads already to the problem of characterizing those external behaviors which are port behaviors of port-Hamiltonian systems. Secondly, the Port Control problem can be split into a number of subproblems. Indeed, we know that the closed-loop system arising from interconnection of the plant PH system with the controller PH system is specified by a Hamiltonian which is just the sum of the plant Hamiltonian and the controller Hamiltonian, and a resistive structure which is the "product" of the resistive structure of the plant and of the controller system, together with a Dirac structure which is the *composition* of the plant Dirac structure and the controller Dirac structure. Therefore an important subproblem is again to characterize the *achievable closed-loop Dirac structures.* On the other hand, a fundamental problem in addressing the Port Control problem in general theoretical terms is the lack of a systematic way to specify 'desired behavior'.

The problem of Port Control is to determine the controller system in such a way that the port behavior in the port variables $f_I, e_I$ is a desired one. In this particular (simple and linear) example the desired behavior can be quantified e.g. in terms of a desired stiffness and damping of the closed-loop system, which is easily expressed in terms of the closed-loop transfer function from $f_I$ to $e_I$. Of course, on top of the requirements on the closed-loop transfer function we would also require internal stability of the closed-loop system. For an appealing example of port control of port-Hamiltonian systems within a context of hydraulic systems we refer to [15].

**3.3. Energy Control.** Consider two port-Hamiltonian systems $\Sigma_i$ (without internal dissipation) in input–state–output form

$$\begin{aligned} \dot{x}_i &= J_i(x_i)\frac{\partial H_i}{\partial x_i} + g_i(x_i)u_i, \\ y_i &= g_i^T(x_i)\frac{\partial H_i}{\partial x_i}, \qquad i = 1, 2, \end{aligned} \tag{41}$$

both satisfying the power-balance $\frac{d}{dt}H_i = y_i^T u_i$. Suppose now that we want to transfer the energy from the port-Hamiltonian system $\Sigma_1$ to the port-Hamiltonian system $\Sigma_2$, while keeping the total energy $H_1 + H_2$ constant. This can be done by using the following output feedback

$$\begin{bmatrix} u_1 \\ u_2 \end{bmatrix} = \begin{bmatrix} 0 & -y_1 y_2^T \\ y_2 y_1^T & 0 \end{bmatrix} \begin{bmatrix} y_1 \\ y_2 \end{bmatrix}. \tag{42}$$

Since the matrix in (42) is skew-symmetric it immediately follows that the closed-loop system composed of systems $\Sigma_1$ and $\Sigma_2$ linked by the power-conserving feedback is energy-preserving, that is $\frac{d}{dt}(H_1 + H_2) = 0$. However, if we consider the individual energies then we notice that

$$\frac{d}{dt}H_1 = -y_1^T y_1 y_2^T y_2 = -\|y_1\|^2\|y_2\|^2 \leq 0 \tag{43}$$

implying that $H_1$ is decreasing as long as $\|y_1\|$ and $\|y_2\|$ are different from 0. Conversely, as expected since the total energy is constant,

$$\frac{d}{dt}H_2 = y_2^T y_2 y_1^T y_1 = \|y_2\|^2\|y_1\|^2 \geq 0 \tag{44}$$

implying that $H_2$ is increasing at the same rate. In particular, if $H_1$ has a minimum at the zero equilibrium, and $\Sigma_1$ is zero-state observable, then all the energy $H_1$ of $\Sigma_1$ will be transferred to $\Sigma_2$, provided that $\|y_2\|$ is not identically zero (which again can be guaranteed by assuming that $H_2$ has a minimum at the zero equilibrium, and that $\Sigma_2$ is zero-state observable).

If there is internal energy dissipation, then this energy transfer mechanism still works. However, the fact that $H_2$ grows or not will depend on the balance between the energy delivered by $\Sigma_1$ to $\Sigma_2$ and the internal loss of energy in $\Sigma_2$ due to dissipation.

We conclude that this particular scheme of power-conserving energy transfer is accomplished by a skew-symmetric output feedback, which is *modulated* by the values of the output vectors of both systems. Of course this raises, among others, the question of the efficiency of the proposed energy-transfer scheme, and the need for a systematic quest of similar power-conserving energy-transfer schemes. We refer to [9] for a similar but different energy-transfer scheme directly motivated by the structure of the example (control of a snakeboard).

**3.4. Achievable closed-loop Dirac structures.** In all the control problems discussed above the basic question comes up what are the achievable closed-loop Dirac structures based on a given plant Dirac structure and a controller Dirac structure, which still is to be determined.

**Theorem 3.2** ([5]). *Given any plant Dirac structure $\mathcal{D}_p$, a certain interconnected $\mathcal{D} = \mathcal{D}_p \circ \mathcal{D}_c$ can be achieved by a proper choice of the controller Dirac structure $\mathcal{D}_c$ if and only if the following two equivalent conditions are satisfied:*

$$\mathcal{D}_p^0 \subset \mathcal{D}^0,$$
$$\mathcal{D}^\pi \subset \mathcal{D}_p^\pi$$

*where*

$$\mathcal{D}_p^0 := \{f_1, e_1) \mid (f_1, e_1, 0, 0) \in \mathcal{D}_p\},$$
$$\mathcal{D}_p^\pi := \{(f_1, e_1) \mid \textit{there exists } (f_2^P, e_2^P) \textit{ with } (f_1, e_1, f_2^P, e_2^P) \in \mathcal{D}_p\},$$
$$\mathcal{D}^0 := \{(f_1, e_1) \mid (f_1, e_1, 0, 0) \in \mathcal{D}\},$$
$$\mathcal{D}^\pi := \{(f_1, e_1) \mid \textit{there exists } (f_3, e_3) \textit{ with } (f_1, e_1, f_3, e_3) \in \mathcal{D}\}.$$

An important application of the above theorem concerns the characterization of Casimir functions which can be achieved by interconnecting a given plant port-Hamiltonian system with a controller port-Hamiltonian system.

## 4. Distributed-parameter port-Hamiltonian systems

The treatment of infinite-dimensional Hamiltonian systems in the literature is mostly confined to systems with boundary conditions such that the energy exchange through the boundary is *zero*. On the other hand, in many applications the interaction with the environment (e.g. actuation or measurement) will actually take place through the boundary of the system. In [35] a framework has been developed to represent classes of physical distributed-parameter systems with boundary energy flow as *infinite-dimensional port-Hamiltonian systems*. It turns out that in order to allow the inclusion of boundary variables in distributed-parameter systems the concept of (an

infinite-dimensional) Dirac structure provides again the right type of generalization with respect to the existing framework [23] using Poisson structures.

As we will discuss in the next three examples, the port-Hamiltonian formulation of distributed-parameter systems is closely related to the general framework for describing basic distributed-parameter systems as systems of conservation laws, see e.g. [11], [37].

**Example 4.1** (Inviscid Burger's equation). The viscous *Burger's equation* is a scalar parabolic equation defined on a one-dimensional spatial domain (interval) $Z = [a, b] \subset \mathbb{R}$, with the state variable $\alpha(t, z) \in \mathbb{R}$, $z \in Z$, $t \in I$, where $I$ is an interval of $\mathbb{R}$, satisfying the partial differential equation

$$\frac{\partial \alpha}{\partial t} + \alpha \frac{\partial \alpha}{\partial z} - \nu \frac{\partial^2 \alpha}{\partial z^2} = 0. \tag{45}$$

The *inviscid* ($\nu = 0$) Burger's equations may be alternatively expressed as

$$\frac{\partial \alpha}{\partial t} + \frac{\partial}{\partial z} \beta = 0 \tag{46}$$

where the state variable $\alpha(t, z)$ is called the *conserved quantity* and the function $\beta := \frac{\alpha^2}{2}$ the *flux* variable. Eq. (46) is called a *conservation law*, since by integration one obtains the *balance equation*

$$\frac{d}{dt} \int_a^b \alpha \, dz = \beta(a) - \beta(b). \tag{47}$$

Furthermore, according to the framework of Irreversible Thermodynamics [27], one may express the flux $\beta$ as a function of the *generating force* which is the *variational derivative* of some functional $H(\alpha)$ of the state variable. The variational derivative $\frac{\delta H}{\delta \alpha}$ of a functional $H(\alpha)$ is uniquely defined by the requirement

$$H(\alpha + \varepsilon \eta) = H(\alpha) + \varepsilon \int_a^b \frac{\delta H}{\delta \alpha} \eta \, dz + O(\varepsilon^2) \tag{48}$$

for any $\varepsilon \in \mathbb{R}$ and any smooth function $\eta(z, t)$ such that $\alpha + \varepsilon \eta$ satisfies the same boundary conditions as $\alpha$ [23]. For the inviscid Burger's equation one has $\beta = \frac{\delta H}{\delta \alpha}$, where

$$H(\alpha) = \int_a^b \frac{\alpha^3}{6} \, dz. \tag{49}$$

Hence the inviscid Burger's equation may be also expressed as

$$\frac{\partial \alpha}{\partial t} = -\frac{\partial}{\partial z} \frac{\delta H}{\delta \alpha}. \tag{50}$$

This defines an infinite-dimensional Hamiltonian system in the sense of [23] with respect to the skew-symmetric operator $\frac{\partial}{\partial z}$ that is defined on the functions with support contained in the interior of the interval $Z$.

From this formulation one derives that the Hamiltonian $H(\alpha)$ is *another* conserved quantity. Indeed, by integration by parts

$$\frac{d}{dt}H = \int_a^b \frac{\delta H}{\delta \alpha} \cdot -\frac{\partial}{\partial z}\frac{\delta H}{\delta \alpha} dz = \frac{1}{2}\left(\beta^2(a) - \beta^2(b)\right). \tag{51}$$

We note that the right-hand side is a *function of the flux variables* evaluated at the boundary of the spatial domain $Z$.

The second example consists of a system of *two* conservations laws, corresponding to the case of two physical domains in interaction.

**Example 4.2** (The p-system, cf. [11], [37]). The p-system is a model for e.g. a one-dimensional gas dynamics. Again, the spatial variable $z$ belongs to an interval $Z \subset \mathbb{R}$, while the dependent variables are the specific volume $v(t, z) \in \mathbb{R}^+$, the velocity $u(t, z)$ and the pressure functional $p(v)$ (which for instance in the case of an ideal gas with constant entropy is given by $p(v) = Av^{-\gamma}$ where $\gamma \geq 1$). The *p-system* is then defined by the following system of partial differential equations

$$\begin{aligned} \frac{\partial v}{\partial t} - \frac{\partial u}{\partial z} &= 0, \\ \frac{\partial u}{\partial t} + \frac{\partial\, p(v)}{\partial z} &= 0 \end{aligned} \tag{52}$$

representing respectively conservation of mass and of momentum. By defining the state vector as $\alpha(t, z) = (v, u)^T$, and the vector-valued flux $\beta(t, z) = (-u, p(v))^T$ the p-system is rewritten as

$$\frac{\partial \alpha}{\partial t} + \frac{\partial}{\partial z}\beta = 0. \tag{53}$$

Again, according to the framework of Irreversible Thermodynamics, the flux vector may be written as function of the variational derivatives of some functional. Indeed, consider the energy functional $H(\alpha) = \int_a^b \mathcal{H}(v, u)dz$ where the energy density $\mathcal{H}(v, u)$ is given as the sum of the internal energy and the kinetic energy densities

$$\mathcal{H}(v, u) = \mathcal{U}(v) + \frac{u^2}{2} \tag{54}$$

with $-\mathcal{U}(v)$ a primitive function of the pressure. (Note that for simplicity the mass density has been set equal to 1, and hence no difference is made between the velocity and the momentum.) The flux vector $\beta$ may be expressed in terms of the variational derivatives of $H$ as

$$\beta = \begin{pmatrix} 0 & -1 \\ -1 & 0 \end{pmatrix} \begin{pmatrix} \frac{\delta H}{\delta v} \\ \frac{\delta H}{\delta u} \end{pmatrix}. \tag{55}$$

The anti-diagonal matrix represents the canonical coupling between two physical domains: the kinetic and the potential (internal) domain. Thus the variational derivative

of the total energy with respect to the state variable of one domain generates the flux variable for the other domain. Combining eqns. (53) and (55), the p-system may thus be written as the Hamiltonian system

$$\begin{pmatrix} \frac{\partial \alpha_1}{\partial t} \\ \frac{\partial \alpha_2}{\partial t} \end{pmatrix} = \begin{pmatrix} 0 & -\frac{\partial}{\partial z} \\ -\frac{\partial}{\partial z} & 0 \end{pmatrix} \begin{pmatrix} \frac{\delta H}{\delta \alpha_1} \\ \frac{\delta H}{\delta \alpha_2} \end{pmatrix}. \tag{56}$$

Using again integration by parts, one may derive the following *energy balance equation*:

$$\frac{d}{dt} H = \beta_1(a)\beta_2(a) - \beta_1(b)\beta_2(b). \tag{57}$$

Notice again that the right-hand side of this power-balance equation is a quadratic function of the fluxes at the boundary of the spatial domain.

The last example is the *vibrating string*. It is again a system of two conservation laws representing the canonical interdomain coupling between the kinetic energy and the elastic potential energy. However in this example the *classical* choice of the state variables leads to express the total energy as a function of some of the *spatial derivatives* of the state variables.

**Example 4.3** (Vibrating string). Consider an elastic string subject to traction forces at its ends, with spatial variable $z \in Z = [a, b] \subset \mathbb{R}$. Denote by $u(t, z)$ the displacement of the string and the velocity by $v(t, z) = \frac{\partial u}{\partial t}$. Using the vector of state variables $x(t, z) = (u, v)^T$, the dynamics of the vibrating string is described by the system of partial differential equations

$$\frac{\partial x}{\partial t} = \begin{pmatrix} v \\ \frac{1}{\mu}\frac{\partial}{\partial z}\left(T\frac{\partial u}{\partial z}\right) \end{pmatrix} \tag{58}$$

where the first equation is simply the definition of the velocity and the second one is Newton's second law. Here $T$ denotes the elasticity modulus, and $\mu$ the mass density. The total energy is $H(x) = U(u) + K(v)$, where the elastic potential energy $U$ is a function of the *strain* $\frac{\partial u}{\partial z}(t, z)$

$$U(u) = \int_a^b \frac{1}{2}\, T \left(\frac{\partial u}{\partial z}\right)^2 dz \tag{59}$$

and the kinetic energy $K$ depends on the velocity $v(t, z) = \frac{\partial u}{\partial t}$ as

$$K(v) = \int_a^b \frac{1}{2}\, \mu v(t, z)^2\, dz. \tag{60}$$

Thus the total system (58) may be expressed as

$$\frac{\partial x}{\partial t} = \begin{pmatrix} 0 & \frac{1}{\mu} \\ -\frac{1}{\mu} & 0 \end{pmatrix} \begin{pmatrix} \frac{\delta H}{\delta u} \\ \frac{\delta H}{\delta v} \end{pmatrix} \tag{61}$$

where $\frac{\delta H}{\delta u} = \frac{\delta U}{\delta u} = -\frac{\partial}{\partial z}\left(T\,\frac{\partial u}{\partial z}\right)$ is the elastic force and $\frac{\delta H}{\delta v} = \frac{\delta K}{\delta v} = \mu v$ is the momentum.

In this formulation, the system is *not* anymore expressed as a system of conservation laws since the time-derivative of the state variables is a function of the variational derivatives of the energy *directly*, and *not* the spatial derivative of a function of the variational derivatives as before. Instead of being a simplification, this reveals a drawback for the case of non-zero energy flow through the boundary of the spatial domain. Indeed, in this case the *variational derivative has to be completed by a boundary term* since the Hamiltonian functional depends on the *spatial derivatives of the state*. For example, in the computation of the variational derivative of the elastic potential energy $U$ one obtains by integration by parts that $U(u+\varepsilon\eta) - U(u)$ equals

$$-\varepsilon \int_a^b \frac{\partial}{\partial z}\left(T\frac{\partial u}{\partial z}\right)\eta\, dz + \varepsilon\left[\eta\left(T\frac{\partial u}{\partial z}\right)\right]_a^b + O(\varepsilon^2) \tag{62}$$

and the second term in this expression constitutes an extra boundary term.

Alternatively we now formulate the vibrating string as a system of two conservation laws. Take as alternative vector of state variables $\alpha(t,z) = (\varepsilon,\, p)^T$, where $\varepsilon$ denotes the *strain* $\alpha_1 = \varepsilon = \frac{\partial u}{\partial z}$ and $p$ denotes the *momentum* $\alpha_2 = p = \mu v$. Recall that in these variables the total energy is written as

$$H_0 = \int_a^b \frac{1}{2}\left(T\alpha_1^2 + \frac{1}{\mu}\alpha_2^2\right) dz \tag{63}$$

and directly depends on the state variables and *not* on their spatial derivatives. Furthermore, one defines the flux variables to be the *stress* $\beta_1 = \frac{\delta H_0}{\delta \alpha_1} = T\alpha_1$ and the *velocity* $\beta_2 = \frac{\delta H_0}{\delta \alpha_1} = \frac{\alpha_2}{\mu}$. In matrix notation, the flux vector $\beta$ is thus expressed as a function of the variational derivatives $\frac{\delta H_0}{\delta \alpha}$ by

$$\beta = \begin{pmatrix} 0 & -1 \\ -1 & 0 \end{pmatrix} \frac{\delta H_0}{\delta \alpha}. \tag{64}$$

Hence the vibrating string may be alternatively expressed by the system of two conservation laws

$$\frac{\partial \alpha}{\partial t} = \begin{pmatrix} 0 & \frac{\partial}{\partial z} \\ \frac{\partial}{\partial z} & 0 \end{pmatrix} \frac{\delta H_0}{\delta \alpha} \tag{65}$$

satisfying the power balance equation (57).

**4.1. Systems of two conservation laws in interaction.** Let us now consider the *general class* of distributed-parameter systems consisting of two conservation laws with the canonical coupling as in the above examples of the p-system and the vibrating string. Let the spatial domain $Z \subset \mathbb{R}^n$ be an $n$-dimensional smooth manifold with smooth $(n-1)$-dimensional boundary $\partial Z$. Denote by $\Omega^k(Z)$ the vector space of (differential) $k$-forms on $Z$ (respectively by $\Omega^k(\partial Z)$ the vector space of $k$-forms on $\partial Z$).

Denote furthermore by $\Omega = \bigoplus_{k\geq 0} \Omega^k(Z)$ the algebra of differential forms over $Z$ and recall that it is endowed with an exterior product $\wedge$ and an exterior derivation d.

**Definition 4.4.** A *system of conservation laws* is defined by a set of *conserved quantities* $\alpha_i \in \Omega^{k_i}(Z)$, $i \in \{1, \ldots, N\}$ where $N \in \mathbb{N}, k_i \in \mathbb{N}$, defining the state space $\mathcal{X} = \bigotimes_{i=1,\ldots,N} \Omega^{k_i}(Z)$, and satisfying a set of *conservation laws*

$$\frac{\partial \alpha_i}{\partial t} + \mathrm{d}\beta_i = g_i \tag{66}$$

where $\beta_i \in \Omega^{k_i-1}(Z)$ denote the set of *fluxes* and $g_i \in \Omega^{k_i}(Z)$ denote the set of *distributed interaction forms*. In general, the fluxes $\beta_i$ are defined by so-called *closure equations*

$$\beta_i = J(\alpha_i, z), \quad i = 1, \ldots, N \tag{67}$$

leading to a closed form for the dynamics of the conserved quantities $\alpha_i$. The integral form of the conservation laws yields the following *balance equations*

$$\frac{d}{dt}\int_S \alpha_i + \int_{\partial S} \beta_i = \int_S g_i \tag{68}$$

for any surface $S \subset Z$ of dimension equal to the degree of $\alpha_i$.

**Remark 4.5.** A common case is that $Z = \mathbb{R}^3$ and that the conserved quantities are 3-forms, that is, the balance equation is evaluated on volumes of the 3-dimensional space. In this case () takes in vector calculus notation the familiar form

$$\frac{\partial \alpha_i}{\partial t}(z,t) + \mathrm{div}_z \beta_i = g_i, \quad i = 1, \ldots, n. \tag{69}$$

However, systems of conservation laws may correspond to differential forms of any degree. Maxwell's equations are an example where the conserved quantities are differential forms of degree 2.

In the sequel, as in our examples sofar, we consider a particular class of systems of conservation laws where the closure equations are such that fluxes are linear functions of the variational derivatives of the Hamiltonian functional. First recall the general definition of the *variational derivative* of a functional $H(\alpha)$ with respect to the differential form $\alpha \in \Omega^p(Z)$ (generalizing the definition given before).

**Definition 4.6.** Consider a density function $\mathcal{H}\colon \Omega^p(Z) \times Z \to \Omega^n(Z)$ where $p \in \{1, \ldots, n\}$, and denote by $H := \int_Z \mathcal{H} \in \mathbb{R}$ the associated functional. Then the uniquely defined differential form $\frac{\delta H}{\delta \alpha} \in \Omega^{n-p}(Z)$ which satisfies for all $\Delta\alpha \in \Omega^p(Z)$ and $\varepsilon \in \mathbb{R}$

$$H(\alpha + \varepsilon\Delta\alpha) = \int_Z \mathcal{H}(\alpha) + \varepsilon \int_Z \left[\frac{\delta H}{\delta \alpha} \wedge \Delta\alpha\right] + \mathrm{O}\left(\varepsilon^2\right)$$

is called the *variational derivative* of $H$ with respect to $\alpha \in \Omega^p(Z)$.

**Definition 4.7.** *Systems of two conservation laws with canonical interdomain coupling* are systems involving a pair of conserved quantities $\alpha_p \in \Omega^p(Z)$ and $\alpha_q \in \Omega^q(Z)$, differential forms on the $n$-dimensional spatial domain $Z$ of degree $p$ and $q$ respectively, satisfying $p+q = n+1$ ('complementarity of degrees'). The closure equations generated by a *Hamiltonian density function* $\mathcal{H}: \Omega^p(Z) \times \Omega^q(Z) \times Z \to \Omega^n(Z)$ resulting in the Hamiltonian $H := \int_Z \mathcal{H} \in \mathbb{R}$ are given by

$$\begin{pmatrix} \beta_p \\ \beta_q \end{pmatrix} = \varepsilon \begin{pmatrix} 0 & (-1)^r \\ 1 & 0 \end{pmatrix} \begin{pmatrix} \frac{\delta H}{\delta \alpha_p} \\ \frac{\delta H}{\delta \alpha_q} \end{pmatrix} \tag{70}$$

where $r = pq+1$, $\varepsilon \in \{-1, +1\}$, depending on the sign convention of the considered physical domain.

Define the vector of *flow variables* to be the time-variation of the state, and the *effort variables* to be the variational derivatives

$$\begin{pmatrix} f_p \\ f_q \end{pmatrix} = \begin{pmatrix} \frac{\partial \alpha_p}{\partial t} \\ \frac{\partial \alpha_q}{\partial t} \end{pmatrix}, \quad \begin{pmatrix} e_p \\ e_q \end{pmatrix} = \begin{pmatrix} \frac{\delta H}{\delta \alpha_p} \\ \frac{\delta H}{\delta \alpha_q} \end{pmatrix}. \tag{71}$$

Their product equals again the time-variation of the Hamiltonian

$$\frac{dH}{dt} = \int_Z (e_p \wedge f_p + e_q \wedge f_q). \tag{72}$$

Using the conservation laws (4.5) for $g_i = 0$, the closure relations (70) and the properties of the exterior derivative $d$ and Stokes' theorem, one obtains

$$\begin{aligned} \frac{dH}{dt} &= \int_Z \varepsilon \beta_q \wedge (-d\beta_p) + (-1)^r \beta_p \wedge \varepsilon(-d\beta_q) \\ &= -\varepsilon \int_Z \beta_q \wedge d\beta_p + (-1)^q \beta_q \wedge d\beta_p = -\varepsilon \int_{\partial Z} \beta_q \wedge \beta_p. \end{aligned} \tag{73}$$

Finally, as before we define the power-conjugated pair of *flow and effort variables on the boundary* as the *restriction* of the flux variables to the boundary $\partial Z$ of the domain $Z$:

$$\begin{pmatrix} f_\partial \\ e_\partial \end{pmatrix} = \begin{pmatrix} \beta_q|_{\partial Z} \\ \beta_p|_{\partial Z} \end{pmatrix}. \tag{74}$$

On the total space of power-conjugated variables, that is, the differential forms $(f_p, e_p)$ and $(f_q, e_q)$ on the domain $Z$ and the differential forms $(f_\partial, e_\partial)$ defined on the boundary $\partial Z$, one defines an *interconnection structure* by Eqn. (74) together with

$$\begin{pmatrix} f_q \\ f_p \end{pmatrix} = \varepsilon \begin{pmatrix} 0 & (-1)^r d \\ d & 0 \end{pmatrix} \begin{pmatrix} e_q \\ e_p \end{pmatrix}. \tag{75}$$

This interconnection can be formalized as a special type of Dirac structure, called Stokes–Dirac structure, leading to the definition of distributed-parameter port-Hamiltonian systems [35].

## 5. Concluding remarks

We have surveyed some of the recently developed theory of port-Hamiltonian systems; for further applications towards modeling, analysis, simulation and control we refer to the literature cited below.

From the geometric point of view many questions regarding port-Hamiltonian systems are waiting to be investigated. A theory of symmetry and reduction of port-Hamiltonian systems has been explored in [29], [1], while some questions concerning integrability of Dirac structures have been studied in [7]. A main question for distributed-parameter port-Hamiltonian systems concerns the relation with variational calculus.

# Passive linear discrete time-invariant systems

Olof J. Staffans*

**Abstract.** We begin by discussing linear discrete time-invariant i/s/o (input/state/output) systems that satisfy certain 'energy' inequalities. These inequalities involve a quadratic storage function in the state space induced by a positive self-adjoint operator $H$ that may be unbounded and have an unbounded inverse, and also a quadratic supply rate in the combined i/o (input/output) space. The three most commonly studied classes of supply rates are called scattering, impedance, and transmission. Although these three classes resemble each other, we show that there are still significant differences. We then present a new class of s/s (state/signal) systems which have a Hilbert state space and a Kreĭn signal space. The state space is used to store relevant information about the past evolution of the system, and the signal space is used to describe interactions with the surrounding world. A s/s system resembles an i/s/o system apart from the fact that inputs and outputs are not separated from each other. By decomposing the signal space into a direct sum of an input space and an output space one gets a standard i/s/o system, provided the decomposition is *admissible*, and different i/o decompositions lead to different i/o supply rates (for example of scattering, impedance, or transmission type). In the case of non-admissible decompositions we obtain right and left affine representations, both of the s/s system itself, and of the corresponding transfer function. In particular, in the case of a passive system we obtain right and left coprime representations of the generalized transfer functions corresponding to nonadmissible decompositions of the signal space, and we end up with transfer functions which are, e.g., generalized Potapov or Nevanlinna class functions.

**Keywords.** Passive, storage function, supply rate, scattering, impedance, transmission, input/state/output, state/signal, Schur function, Carathéodory function, Nevanlinna function, Potapov function, behavior.

## 1. $H$-passive discrete time i/s/o systems

The evolution of a *linear discrete time-invariant i/s/o* (*input/state/output*) *system* $\Sigma_{\mathrm{i/s/o}}$ with a Hilbert *input space* $\mathcal{U}$, a Hilbert *state space* $\mathcal{X}$, and a Hilbert *output space* $\mathcal{Y}$ is described by the system of equations

$$\begin{aligned} x(n+1) &= Ax(n) + Bu(n), \\ y(n) &= Cx(n) + Du(n), \quad n \in \mathbb{Z}^+ = \{0, 1, 2, \ldots\}, \\ x(0) &= x_0, \end{aligned} \tag{1.1}$$

*This article is based on recent joint work with Prof. Damir Arov [AS05], [AS06a], [AS06b], [AS06c]. Thank you, Dima, for everything that I have learned from you!

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

where the initial state $x_0 \in \mathcal{X}$ may be chosen arbitrarily and $A\colon \mathcal{X} \to \mathcal{X}$, $B\colon \mathcal{U} \to \mathcal{X}$, $C\colon \mathcal{X} \to \mathcal{Y}$, and $D\colon \mathcal{U} \to \mathcal{Y}$ are bounded linear operators. Equivalently,

$$\begin{bmatrix} x(n+1) \\ y(n) \end{bmatrix} = \begin{bmatrix} A & B \\ C & D \end{bmatrix} \begin{bmatrix} x(n) \\ u(n) \end{bmatrix}, \quad n \in \mathbb{Z}^+,\ x(0) = x_0, \tag{1.2}$$

where $\left[\begin{smallmatrix} A & B \\ C & D \end{smallmatrix}\right] \in \mathcal{B}\left(\left[\begin{smallmatrix} \mathcal{X} \\ \mathcal{U} \end{smallmatrix}\right]; \left[\begin{smallmatrix} \mathcal{X} \\ \mathcal{Y} \end{smallmatrix}\right]\right)$.[1] We call $u = \{u(n)\}_{n=0}^{\infty}$ the *input sequence*, $x = \{x(n)\}_{n=0}^{\infty}$ the *state trajectory*, and $y = \{y(n)\}_{n=0}^{\infty}$ the *output sequence*, and we refer to the triple $(u, x, y)$ as a *trajectory of* $\Sigma_{\mathrm{i/s/o}}$. The operators appearing in (1.1) and (1.2) are usually called as follows: $A$ is the *main operator*, $B$ is the *control operator*, $C$ is the *observation operator*, and $D$ is the *feedthrough operator*. The *transfer function* or *characteristic function* $\mathfrak{D}$ of this system is given by[2]

$$\mathfrak{D}(z) = zC(1_{\mathcal{X}} - zA)^{-1}B + D, \quad z \in \Lambda(A),$$

where $\Lambda(A)$ is the set of points $z \in \mathbb{C}$ for which $1_{\mathcal{X}} - zA$ has a bounded inverse, plus the point at infinity if $A$ has a bounded inverse. Note that $\mathfrak{D}$ is analytic on $\Lambda(A)$, and that $D = \mathfrak{D}(0)$. We shall denote the above system by $\Sigma_{\mathrm{i/s/o}} = \left(\left[\begin{smallmatrix} A & B \\ C & D \end{smallmatrix}\right]; \mathcal{U}, \mathcal{X}, \mathcal{Y}\right)$. Since all the systems in this paper will be linear and time-invariant and have a discrete time variable we shall in the sequel omit the words "linear discrete time-invariant" and refer to a system of the above type by simply calling it an *i/s/o system*.

The i/s/o system $\Sigma_{\mathrm{i/s/o}}$ is *controllable* if the sets of all states $x(n)$, $n \geq 1$, which appear in some trajectory $(u, x, y)$ of $\Sigma_{\mathrm{i/s/o}}$ with $x_0 = 0$ (i.e., an *externally generated trajectory*) is dense in $\mathcal{X}$. The system $\Sigma_{\mathrm{i/s/o}}$ is *observable* if there do not exist any nontrivial trajectories $(u, x, y)$ where both $u$ and $y$ are identically zero. Finally, $\Sigma_{\mathrm{i/s/o}}$ is *minimal* if $\Sigma_{\mathrm{i/s/o}}$ is both controllable and observable.

In this work we shall primarily be concerned with i/s/o systems which are passive or even conservative. To define these notions we first introduce the notions of a storage function $E_H$ which represents the (internal) energy of the state, and a supply rate $j$ which describes the interchange of energy between the system and its surroundings. In the classical case the *storage* (or *Lyapunov*) *function* $E_H$ is bounded, and it is given by $E_H(x) = \langle x, Hx\rangle_{\mathcal{X}}$, where $H$ is a bounded positive self-adjoint operator on $\mathcal{X}$ (positivity of $H$ means that $\langle x, Hx\rangle_{\mathcal{X}} > 0$ for all $x \neq 0$). However, we shall also consider unbounded storage functions induced by some (possibly unbounded) positive self-adjoint operator $H$ on $\mathcal{X}$. In this case we let $\sqrt{H}$ be the positive self-adjoint square root of $H$, and define the storage function $E_H$ by

$$E_H(x) = \|\sqrt{H}x\|_{\mathcal{X}}^2, \quad x \in \mathcal{D}(\sqrt{H}). \tag{1.3}$$

Clearly, this is equivalent to the earlier definition of $E_H$ if $H$ is bounded. The *supply rate* $j$ will always be a bounded (indefinite) self-adjoint quadratic form on $\mathcal{Y} \oplus \mathcal{U}$,

[1] Here $\left[\begin{smallmatrix} \mathcal{X} \\ \mathcal{U} \end{smallmatrix}\right]$ is the cartesian product of $\mathcal{X}$ and $\mathcal{U}$, and $\mathcal{B}(\mathcal{U}; \mathcal{Y})$ is the set of bounded linear operators from $\mathcal{U}$ to $\mathcal{Y}$.

[2] $1_{\mathcal{X}}$ is the identity operator in $\mathcal{X}$.

i.e., it can be written in the form

$$j(u, y) = \left\langle \begin{bmatrix} y \\ u \end{bmatrix}, J \begin{bmatrix} y \\ u \end{bmatrix} \right\rangle_{\mathcal{Y} \oplus \mathcal{U}}, \tag{1.4}$$

where $J = \left[\begin{smallmatrix} J_{11} & J_{12} \\ J_{21} & J_{22} \end{smallmatrix}\right]$ is a bounded self-adjoint operator in $\mathcal{Y} \oplus \mathcal{U}$. For simplicity we throughout require $J$ to have a bounded inverse. Often $J$ is taken to be a signature operator (both self-adjoint and unitary), so that $J = J^* = J^{-1}$. In the sequel we shall always use *one and the same supply rate* $j$ for a given system $\Sigma_{\mathrm{i/s/o}}$ and include this supply rate in the notation of the system, thus denoting the system by $\Sigma_{\mathrm{i/s/o}} = \left(\left[\begin{smallmatrix} A & B \\ C & D \end{smallmatrix}\right]; \mathcal{U}, \mathcal{X}, \mathcal{Y}; j\right)$ whenever the supply rate is important.

**Definition 1.1.** The i/s/o system $\Sigma_{\mathrm{i/s/o}} = \left(\left[\begin{smallmatrix} A & B \\ C & D \end{smallmatrix}\right]; \mathcal{U}, \mathcal{X}, \mathcal{Y}; j\right)$ is *forward $H$-passive*, where $H$ is a positive self-adjoint operator in $\mathcal{X}$, if $x(n) \in \mathcal{D}(\sqrt{H})$ and

$$\|\sqrt{H}x(n+1)\|_{\mathcal{X}}^2 - \|\sqrt{H}x(n)\|_{\mathcal{X}}^2 \le j(u(n), y(n)), \quad n \in \mathbb{Z}^+, \tag{1.5}$$

for every trajectory $(u, x, y)$ of $\Sigma_{\mathrm{i/s/o}}$ with $x_0 \in \mathcal{D}(\sqrt{H})$. If the above inequality holds as an equality then $\Sigma_{\mathrm{i/s/o}}$ is *forward $H$-conservative*.

It is not difficult to see that $\Sigma_{\mathrm{i/s/o}}$ is forward $H$-passive if and only if[3] $H > 0$ is a solution of the (forward) generalized i/s/o *KYP* (*Kalman–Yakubovich–Popov*) inequality[4]

$$\|\sqrt{H}(Ax + Bu)\|_{\mathcal{X}}^2 - \|\sqrt{H}x\|_{\mathcal{X}}^2 \le j(u, Cx + Du), \quad x \in \mathcal{D}(\sqrt{H}),\ u \in \mathcal{U}, \tag{1.6}$$

and that $\Sigma_{\mathrm{i/s/o}}$ is forward $H$-conservative if and only if $H > 0$ is a solution of the corresponding equality. This inequality is named after *Kalman* [Kal63], *Yakubovich* [Yak62], and *Popov* [Pop61] (who at that time restricted themselves to the finite-dimensional case). There is a rich literature on the finite-dimensional version of the KYP inequality and the corresponding equality; see, e.g., [PAJ91], [IW93] and [LR95], and the references mentioned there. In the seventies the classical results on the KYP inequalities were extended to infinite-dimensional systems by V. A. Yakubovich and his students and collaborators (see [Yak74], [Yak75], and [LY76] and the references listed there). There is now also a rich literature on this infinite-dimensional case; see, e.g., the discussion in [Pan99] and the references cited there. However, until recently it was assumed throughout that *either $H$ itself is bounded or $H^{-1}$ is bounded*. The first study of this inequality which permits both $H$ and $H^{-1}$ to be unbounded was done by Arov, Kaashoek and Pik in [AKP05].

Above we have defined *forward $H$-passivity* and forward $H$-conservativity. The corresponding *backward* notions are defined by means of the adjoint i/s/o system

[3] The notation $H > 0$ means that $H$ is a (possibly unbounded) self-adjoint operator satisfying $\langle x, Hx\rangle_{\mathcal{X}} > 0$ for all nonzero $x \in \mathcal{D}(H)$.

[4] In particular, in order for the first term in this inequality to be well-defined we require $A$ to map $\mathcal{D}(\sqrt{H})$ into itself and $B$ to map $\mathcal{U}$ into $\mathcal{D}(\sqrt{H})$.

$\Sigma^*_{\mathrm{i/s/o}} = \left(\left[\begin{smallmatrix} A^* & C^* \\ B^* & D^* \end{smallmatrix}\right]; \mathcal{Y}, \mathcal{X}, \mathcal{U}; j_*\right)$ whose trajectories $(y_*, x_*, u_*)$ satisfy the system of equations

$$\begin{aligned} x_*(n+1) &= A^* x_*(n) + C^* y_*(n), \\ u_*(n) &= B^* x_*(n) + D^* y_*(n), \quad n \in \mathbb{Z}^+, \\ x_*(0) &= x_{*0}. \end{aligned} \tag{1.7}$$

Note that this system has the same state space $\mathcal{X}$, but the input and output have been interchanged, so that $\mathcal{Y}$ is the input space and $\mathcal{U}$ is the output space. The appropriate storage function and supply rates for the adjoint system $\Sigma^*_{\mathrm{i/s/o}}$ differ from those of the primal system $\Sigma_{\mathrm{i/s/o}}$: $H$ is replaced by $H^{-1}$, and the primal supply rate $j$ is replaced by the dual supply rate

$$j_*(y_*, u_*) = \left\langle \begin{bmatrix} u_* \\ y_* \end{bmatrix}, J_* \begin{bmatrix} u_* \\ y_* \end{bmatrix} \right\rangle_{\mathcal{U}\oplus\mathcal{Y}}, \tag{1.8}$$

where

$$J_* = \begin{bmatrix} 0 & -1_{\mathcal{U}} \\ 1_{\mathcal{Y}} & 0 \end{bmatrix} J^{-1} \begin{bmatrix} 0 & -1_{\mathcal{Y}} \\ 1_{\mathcal{U}} & 0 \end{bmatrix}. \tag{1.9}$$

**Definition 1.2.** Let $\Sigma_{\mathrm{i/s/o}} = \left(\left[\begin{smallmatrix} A & B \\ C & D \end{smallmatrix}\right]; \mathcal{U}, \mathcal{X}, \mathcal{Y}; j\right)$ be an i/s/o system, and let $H$ be a positive self-adjoint operator in $\mathcal{X}$.

(i) $\Sigma_{\mathrm{i/s/o}}$ is *backward $H$-passive* if the adjoint system $\Sigma^*_{\mathrm{i/s/o}}$ is forward $H^{-1}$-passive.

(ii) $\Sigma_{\mathrm{i/s/o}}$ is *backward $H$-conservative* if the adjoint system $\Sigma^*_{\mathrm{i/s/o}}$ is forward $H^{-1}$-conservative.

(iii) $\Sigma_{\mathrm{i/s/o}}$ is $H$-passive if it is both forward and backward $H$-passive.

(iv) $\Sigma_{\mathrm{i/s/o}}$ is $H$-conservative if it is both forward and backward $H$-conservative.

(v) By *passive* or *conservative* (with or without the attributes "forward" or "backward") we mean $1_{\mathcal{X}}$-passive or $1_{\mathcal{X}}$-conservative, respectively.

The generalized KYP inequality for the adjoint i/s/o system $\Sigma^*_{\mathrm{i/s/o}}$ with storage function $E_{H^{-1}}$ is given by[5]

$$\begin{aligned} \|H^{-1/2}(A^* x_* + C^* y_*)\|^2_{\mathcal{X}} - \|H^{-1/2} x_*\|^2_{\mathcal{X}} \le j_*(y_*, B^* x_* + D^* y_*), \\ x_* \in \left(\sqrt{H}\right),\ y_* \in \mathcal{Y}. \end{aligned} \tag{1.10}$$

Thus, $\Sigma_{\mathrm{i/s/o}}$ is backward $H$-passive if and only if $H$ is a solution of (1.10), and $\Sigma_{\mathrm{i/s/o}}$ is backward $H$-conservative if and only if $H$ is a solution of the corresponding equality.

[5] In particular, in order for the first term in this inequality to be well-defined we require $A^*$ to map $\mathcal{R}(\sqrt{H})$ into itself and $C^*$ to map $\mathcal{Y}$ into $\mathcal{R}(\sqrt{H})$.

## 2. Scattering, impedance and transmission supply rates

The three most common supply rates are the following:

(i) The *scattering* supply rate $j_{\mathrm{sca}}(u, y) = -\langle y, y\rangle_{\mathcal{Y}} + \langle u, u\rangle_{\mathcal{U}}$ with signature operator $J_{\mathrm{sca}} = \left[\begin{smallmatrix} -1_{\mathcal{Y}} & 0 \\ 0 & 1_{\mathcal{U}} \end{smallmatrix}\right]$. The signature operator of the dual supply rate is $J_{\mathrm{sca}*} = \left[\begin{smallmatrix} -1_{\mathcal{U}} & 0 \\ 0 & 1_{\mathcal{Y}} \end{smallmatrix}\right]$.

(ii) The *impedance* supply rate $j_{\mathrm{imp}}(u, y) = 2\Re\langle y, \Psi u\rangle_{\mathcal{U}}$ with signature operator $J_{\mathrm{imp}} = \left[\begin{smallmatrix} 0 & \Psi \\ \Psi^* & 0 \end{smallmatrix}\right]$, where $\Psi$ is a unitary operator $\mathcal{U} \to \mathcal{Y}$. The signature operator of the dual supply rate is $J_{\mathrm{imp}*} = \left[\begin{smallmatrix} 0 & \Psi^* \\ \Psi & 0 \end{smallmatrix}\right]$.

(iii) The *transmission* supply rate $j_{\mathrm{tra}}(u, y) = -\langle y, J_{\mathcal{Y}} y\rangle_{\mathcal{Y}} + \langle u, J_{\mathcal{U}} u\rangle_{\mathcal{U}}$ with signature operator $J_{\mathrm{tra}} = \left[\begin{smallmatrix} -J_{\mathcal{Y}} & 0 \\ 0 & J_{\mathcal{U}} \end{smallmatrix}\right]$, where $J_{\mathcal{Y}}$ and $J_{\mathcal{U}}$ are signature operators in $\mathcal{Y}$ and $\mathcal{U}$, respectively. The signature operator of the dual supply rate is $J_{\mathrm{tra}*} = \left[\begin{smallmatrix} -J_{\mathcal{U}} & 0 \\ 0 & J_{\mathcal{Y}} \end{smallmatrix}\right]$.

In the sequel when we talk about *scattering $H$-passive* or *impedance $H$-conservative*, etc., we mean that the supply rate is of the corresponding type. It turns out that although Definition 1.1 and 1.2 can be applied to all three types of supply rates, these three cases still differ significantly from each other.

**2.1. Scattering supply rate.** In the case of scattering supply rate *forward $H$-passivity is equivalent to backward $H$-passivity, hence to passivity*. This is easy to see in the case where $H = 1_{\mathcal{X}}$: the system $\Sigma_{\mathrm{i/s/o}} = \left(\left[\begin{smallmatrix} A & B \\ C & D \end{smallmatrix}\right]; \mathcal{U}, \mathcal{X}, \mathcal{Y}; j_{\mathrm{sca}}\right)$ is forward passive if and only if the operator $\left[\begin{smallmatrix} A & B \\ C & D \end{smallmatrix}\right]$ is a contraction, which is true if and only if its adjoint $\left[\begin{smallmatrix} A^* & C^* \\ B^* & D^* \end{smallmatrix}\right]$ is a contraction, which is true if and only if the adjoint system $\Sigma^*_{\mathrm{i/s/o}} = \left(\left[\begin{smallmatrix} A^* & C^* \\ B^* & D^* \end{smallmatrix}\right]; \mathcal{U}, \mathcal{X}, \mathcal{Y}; j_{\mathrm{sca}*}\right)$ is forward passive. The case where $H$ is bounded and has a bounded inverse is almost as easy, and the general case is proved in [AKP05, Proposition 4.6].

The existence of an operator $H > 0$ such that $\Sigma_{\mathrm{i/s/o}}$ is scattering $H$-passive is related to the properties of the transfer function $\Sigma_{\mathrm{i/s/o}}$. To formulate this result we first recall some definitions. The *Schur class* $\mathcal{S}(\mathcal{U}, \mathcal{Y}; \mathbb{D})$ is the unit ball in $H^\infty(\mathcal{U}, \mathcal{Y}, \mathbb{D})$, i.e., each function in $\mathcal{S}(\mathcal{U}, \mathcal{Y}; \mathbb{D})$ is an analytic function on the open unit disk $\mathbb{D} = \{z \in \mathbb{C} \mid |z| < 1\}$ whose values are contractions in $\mathcal{B}(\mathcal{U}, \mathcal{Y})$. The *restricted Schur class* $\mathcal{S}(\mathcal{U}, \mathcal{Y}; \Omega)$, where $\Omega \subset \mathbb{D}$, contains all functions $\theta$ which are restrictions to $\Omega$ of some function in $\mathcal{S}(\mathcal{U}, \mathcal{Y}; \mathbb{D})$. In other words, $\theta \in \mathcal{S}(\mathcal{U}, \mathcal{Y}; \Omega)$ if the (Nevanlinna–Pick) extension (or interpolation) problem with the (possibly infinite) set of data points $(z, \theta(z))$, $z \in \Omega$, has a solution in $\mathcal{S}(\mathcal{U}, \mathcal{Y}; \mathbb{D})$. It is known that this problem has a solution if and only if the kernel

$$K^\theta_{\mathrm{sca}}(z, \zeta) = \frac{1_{\mathcal{Y}} - \theta(z)\theta(\zeta)^*}{1 - z\overline{\zeta}}, \quad z, \zeta \in \Omega,$$

is nonnegative definite on $\Omega \times \Omega$, or equivalently, if and only if the kernel

$$K_{\text{sca}}^{\theta *}(z, \zeta) = \frac{1_{\mathcal{U}} - \theta(\zeta)^* \theta(z)}{1 - \overline{\zeta} z}, \quad z, \zeta \in \Omega,$$

is nonnegative definite on $\Omega \times \Omega$ (see [RR82]). We shall here be interested in the case where $\Omega$ is an *open* subset of $\mathbb{D}$, which implies that the solution of this Nevanlinna–Pick extension problem is unique (if it exists).

**Theorem 2.1.** *Let* $\Sigma_{\text{i/s/o}} = \left( \left[ \begin{smallmatrix} A & B \\ C & D \end{smallmatrix} \right]; \mathcal{U}, \mathcal{X}, \mathcal{Y}; j_{\text{sca}} \right)$ *be an i/s/o system with scattering supply rate and transfer function* $\mathfrak{D}$*, and let* $\Lambda_0(A)$ *be the connected component of* $\Lambda(A) \cap \mathbb{D}$ *which contains the origin.*

(i) *If* $\Sigma_{\text{i/s/o}}$ *is forward* $H$*-passive for some* $H > 0$*, then* $\Sigma_{\text{i/s/o}}$ *is* $H$*-passive and* $\mathfrak{D}|_{\Lambda_0(A)} \in \mathcal{S}(\mathcal{U}, \mathcal{Y}; \Lambda_0(A))$.

(ii) *Conversely, if* $\Sigma_{\text{i/s/o}}$ *is minimal and* $\mathfrak{D}|_{\Lambda_0(A)} \in \mathcal{S}(\mathcal{U}, \mathcal{Y}; \Lambda_0(A))$*, then* $\Sigma_{\text{i/s/o}}$ *is* $H$*-passive for some* $H > 0$.

In statement (ii) it is actually possible to choose the operator $H$ to satisfy an additional minimality requirement. We shall return to this question in Theorem 3.5.

**2.2. Impedance supply rate.** Also in the case of impedance supply rate *forward* $H$*-passivity is equivalent to backward* $H$*-passivity, hence to passivity*. This is well known in the case where $H = 1_{\mathcal{X}}$ (see, e.g., [Aro79a]). One way to prove this is to reduce the impedance case to the scattering case by means of the following simple transformation.

Suppose that $\Sigma_{\text{i/s/o}} = \left( \left[ \begin{smallmatrix} A & B \\ C & D \end{smallmatrix} \right]; \mathcal{U}, \mathcal{X}, \mathcal{Y}; j_{\text{imp}} \right)$ is a forward impedance $H$-passive system with signature operator $J_{\text{imp}} = \left[ \begin{smallmatrix} 0 & \Psi \\ \Psi^* & 0 \end{smallmatrix} \right]$. Let $(u, x, y)$ be a trajectory of $\Sigma_{\text{i/s/o}}$. We define a new input $u^\times$ by $u^\times = \frac{1}{\sqrt{2}}(u + \Psi^* y)$ and a new output $y^\times$ by $y^\times = \frac{1}{\sqrt{2}}(\Psi u - y)$, after which we solve (1.2) for $x$ and $y^\times$ in terms of $x_0$ and $u^\times$. It turns out that for this to be possible we need $\Psi + D$ to have a bounded inverse. However, this is always the case, since (1.6) (with $x = 0$) implies that $\Psi^* D + D^* \Psi \geq 0$. A direct computation shows that $(y^\times, x, u^\times)$ is a trajectory of another system $\Sigma_{\text{i/s/o}}^\times = \left( \left[ \begin{smallmatrix} A^\times & B^\times \\ C^\times & D^\times \end{smallmatrix} \right]; \mathcal{U}, \mathcal{X}, \mathcal{Y} \right)$, called the *external Cayley transform of* $\Sigma_{\text{i/s/o}}$, whose coefficients are given by

$$\begin{aligned} A^\times &= A - B(\Psi + D)^{-1} C, & B^\times &= \sqrt{2}\, B(\Psi + D)^{-1} \Psi, \\ C^\times &= -\sqrt{2}\, \Psi(\Psi + D)^{-1} C, & D^\times &= (\Psi - D)(\Psi + D)^{-1} \Psi. \end{aligned} \tag{2.1}$$

The transfer functions of the two systems are connected by

$$\mathfrak{D}^\times(z) = (\Psi - \mathfrak{D}(z))(\Psi + \mathfrak{D}(z))^{-1} \Psi, \quad z \in \Lambda(A) \cap \Lambda(A^\times). \tag{2.2}$$

The external Cayley transform is its own inverse in the sense that $\Psi + D^\times = 2\Psi(\Psi + D)^{-1}\Psi$ always has a bounded inverse, and if we apply the external Cayley transform to the system $\Sigma^\times_{\mathrm{i/s/o}}$, then we recover the original system $\Sigma_{\mathrm{i/s/o}}$.

The main reason for defining the external Cayley transform in the way that we did above is that it 'preserves the energy exchange' in the sense that $j_{\mathrm{imp}}(u, y) = j_{\mathrm{sca}}(y^\times, u^\times)$. This immediately implies that $\Sigma^\times_{\mathrm{i/s/o}}$ is forward scattering $H$-passive whenever $\Sigma_{\mathrm{i/s/o}}$ is forward impedance $H$-passive.[6] According to the discussion in Section 2.1, forward scattering $H$-passivity of $\Sigma^\times_{\mathrm{i/s/o}}$ is equivalent to backward scattering $H$-passivity of $\Sigma^\times_{\mathrm{i/s/o}}$, and this in turn is equivalent to the backward (impedance) $H$-passivity of $\Sigma_{\mathrm{i/s/o}}$. Thus, we get the desired conclusion, namely that forward impedance $H$-passivity implies backward impedance $H$-passivity, hence impedance $H$-passivity.

The same argument can be used to convert all the results mentioned in Section 2.1 into an impedance setting. For simplicity we below take $\mathcal{Y} = \mathcal{U}$ and $\Psi = 1_{\mathcal{U}}$ (this amounts to replacing the output sequence $y$ with values in $\mathcal{Y}$ by the new output sequence $\Psi^* y$ with values in $\mathcal{U}$)). The *Carathéodory class* $\mathcal{C}(\mathcal{U}; \mathbb{D})$ (also called the Carathéodory–Nevanlinna class, or Nevanlinna class, or Weyl class, or Titchmarsh–Weyl class, etc.) consists of all analytic $\mathcal{B}(\mathcal{U})$-valued functions $\psi$ on $\mathbb{D}$ with nonnegative 'real part', i.e., $\psi(z) + \psi(z)^* \geq 0$ for all $z \in \mathbb{D}$. The *restricted Carathéodory class* $\mathcal{C}(\mathcal{U}; \Omega)$, where $\Omega \subset \mathbb{D}$, contains all functions $\theta$ which are restrictions to $\Omega$ of some function in $\mathcal{C}(\mathcal{U}; \mathbb{D})$. In other words, $\theta \in \mathcal{C}(\mathcal{U}; \Omega)$ if the extension problem with the set of data points $(z, \theta(z))$, $z \in \Omega$, has a solution in $\mathcal{C}(\mathcal{U}; \Omega)$. This is equivalent to the requirement that the kernel

$$K^{\psi}_{\mathrm{imp}}(z, \zeta) = \frac{\psi(z) + \psi(\zeta)^*}{1 - z\overline{\zeta}}, \quad z, \zeta \in \Omega,$$

is nonnegative definite on $\Omega \times \Omega$ (this can be proved by reducing the impedance case to the scattering case as explained above).

**Theorem 2.2.** *Let* $\Sigma_{\mathrm{i/s/o}} = \left(\left[\begin{smallmatrix} A & B \\ C & D \end{smallmatrix}\right]; \mathcal{U}, \mathcal{X}, \mathcal{U}; j_{\mathrm{imp}}\right)$ *be an i/s/o system with impedance supply rate, signature operator* $J_{\mathrm{imp}} = \left[\begin{smallmatrix} 0 & 1_{\mathcal{U}} \\ 1_{\mathcal{U}} & 0 \end{smallmatrix}\right]$, *and transfer function* $\mathfrak{D}$. *Let* $\Lambda_0(A)$ *be the connected component of* $\Lambda(A) \cap \mathbb{D}$ *which contains the origin.*

(i) *If* $\Sigma_{\mathrm{i/s/o}}$ *is forward* $H$*-passive for some* $H > 0$, *then* $\Sigma_{\mathrm{i/s/o}}$ *is* $H$*-passive and* $\mathfrak{D}|_{\Lambda_0(A)} \in \mathcal{C}(\mathcal{U}, \mathcal{Y}; \Lambda_0(A))$.

(ii) *Conversely, if* $\Sigma_{\mathrm{i/s/o}}$ *is minimal and* $\mathfrak{D}|_{\Lambda_0(A)} \in \mathcal{C}(\mathcal{U}, \mathcal{Y}; \Lambda_0(A))$, *then* $\Sigma_{\mathrm{i/s/o}}$ *is* $H$*-passive for some* $H > 0$.

This theorem follows from Theorem 2.1 as explained above.

[6] It is also true that $\Sigma^\times_{\mathrm{i/s/o}}$ is forward impedance $H$-passive if $\Sigma_{\mathrm{i/s/o}}$ is forward scattering $H$-passive, provided $(\Psi + D)$ has a bounded inverse so that $\Sigma^\times_{\mathrm{i/s/o}}$ exists.

Above we have reduced the impedance passive case to the scattering passive case. Historically the development went in the opposite direction: the impedance version is older than the scattering version. It is related to Neumark's dilation theorem for positive operator-valued measures (see [Bro71, Appendix 1]). In many classical and also in some recent works (especially those where the functions are defined on a half-plane instead of the unit disk) the impedance version is used as 'reference system' from which scattering and other results are derived (see, e.g., [Bro78]). Thus, one easily arrives at the (in my opinion incorrect) conclusion that it does not really matter which one of the two classes is used as the basic corner stone on which the theory is built. However, there is a significant difference between the two classes: the *external Cayley transformation* that converts one of the classes into the other *is well-defined for every impedance $H$-passive system, but not for every scattering $H$-passive system*. In other words, the external Cayley transform maps the class of impedance $H$-passive systems *into but not onto* the class of scattering $H$-passive systems (even if we restrict the input and output dimensions of the scattering system to be the same).

What happens if we try to apply the external Cayley transform to a scattering $H$-passive system for which this transform is not defined (i.e., $\Psi + D$ is not invertible)? In this case the formal transfer function of the resulting system may take its values in the space of closed unbounded operators in $\mathcal{U}$, and it may even be multi-valued. To be able to study this class of 'generalized Carathéodory functions' we need some other more general type of linear systems than the i/s/o systems we have considered so far. This was one of the motivations for the introduction of the notion of a state/signal system in [AS05], to be discussed in Section 3.

**2.3. Transmission supply rate.** In the case of transmission supply rate *forward $H$-passivity is no longer equivalent to backward $H$-passivity*. For simplicity, let us take $H$ to be the identity. Arguing in the same way as in the scattering case we find that $\Sigma_{\mathrm{i/s/o}} = \left(\left[\begin{smallmatrix} A & B \\ C & D \end{smallmatrix}\right]; \mathcal{U}, \mathcal{X}, \mathcal{Y}; j_{\mathrm{tra}}\right)$ is forward (transmission) passive if and only if the operator $\left[\begin{smallmatrix} A & B \\ C & D \end{smallmatrix}\right]$ is a contraction[7] between two Kreĭn spaces, namely from the space $\left[\begin{smallmatrix} \mathcal{X} \\ \mathcal{U} \end{smallmatrix}\right]$ with the signature operator $\left[\begin{smallmatrix} 1_{\mathcal{X}} & 0 \\ 0 & J_{\mathcal{U}} \end{smallmatrix}\right]$ to the space $\left[\begin{smallmatrix} \mathcal{X} \\ \mathcal{Y} \end{smallmatrix}\right]$ with the signature operator $\left[\begin{smallmatrix} 1_{\mathcal{X}} & 0 \\ 0 & J_{\mathcal{Y}} \end{smallmatrix}\right]$. In the same way we find that $\Sigma_{\mathrm{i/s/o}}$ is backward (transmission) passive if $\left[\begin{smallmatrix} A & B \\ C & D \end{smallmatrix}\right]^*$ is a contraction from the space $\left[\begin{smallmatrix} \mathcal{X} \\ \mathcal{Y} \end{smallmatrix}\right]$ with the signature operator $\left[\begin{smallmatrix} 1_{\mathcal{X}} & 0 \\ 0 & J_{\mathcal{Y}} \end{smallmatrix}\right]$ to the space $\left[\begin{smallmatrix} \mathcal{X} \\ \mathcal{U} \end{smallmatrix}\right]$ with the signature operator $\left[\begin{smallmatrix} 1_{\mathcal{X}} & 0 \\ 0 & J_{\mathcal{U}} \end{smallmatrix}\right]$. However, *in a Kreĭn space setting the contractivity of an operator does not imply that the adjoint of this operator is contractive*, and hence forward transmission passivity does not imply backward transmission passivity without any further restrictions on the system. One necessary condition for the system $\Sigma_{\mathrm{i/s/o}}$ to be both forward and backward (transmission) $H$-passive is that the *dimensions of the negative eigenspaces of $J_{\mathcal{U}}$ and $J_{\mathcal{Y}}$ are the*

[7] An operator $A \in \mathcal{B}(\mathcal{U}; \mathcal{Y})$, where $\mathcal{U}$ and $\mathcal{Y}$ are Kreĭn spaces, is a contraction if $[Au, Au]_{\mathcal{Y}} \le [u, u]_{\mathcal{U}}$ for all $u \in \mathcal{U}$.

*same*. If these dimensions are the same *and finite*, then it is true that forward $H$-passivity is equivalent to backward $H$-passivity, hence to passivity. To prove these statements one can use the following transformation that maps the transmission supply rate into a scattering supply rate.

Suppose that $\Sigma_{\mathrm{i/s/o}} = \left(\left[\begin{smallmatrix} A & B \\ C & D \end{smallmatrix}\right]; \mathcal{U}, \mathcal{X}, \mathcal{Y}; j_{\mathrm{tra}}\right)$ is a forward transmission $H$-passive system with signature operator $J_{\mathrm{tra}} = \left[\begin{smallmatrix} J_{\mathcal{Y}} & 0 \\ 0 & J_{\mathcal{Y}} \end{smallmatrix}\right]$. We begin by splitting the output space $\mathcal{Y}$ into the orthogonal direct sum $\mathcal{Y} = -\mathcal{Y}_- \,[\dot{+}]\, \mathcal{Y}_+$, where $\mathcal{Y}_-$ is the negative and $\mathcal{Y}_+$ is the positive eigenspace of $J_{\mathcal{Y}}$. In the same way we split the input space $\mathcal{U}$ into $\mathcal{U} = -\mathcal{U}_- \,[\dot{+}]\, \mathcal{U}_+$, and we split the operator $\left[\begin{smallmatrix} A & B \\ C & D \end{smallmatrix}\right]$ accordingly into

$$\left[\begin{array}{c|c} A & B \\ \hline C & D \end{array}\right] = \left[\begin{array}{c|cc} A & B_1 & B_1 \\ \hline C_1 & D_{11} & D_{12} \\ C_2 & D_{21} & D_{22} \end{array}\right].$$

Let $(u, x, y)$ be a trajectory of $\Sigma_{\mathrm{i/s/o}}$, and split $y$ and $u$ into $y = \left[\begin{smallmatrix} y_- \\ y_+ \end{smallmatrix}\right]$ and $u = \left[\begin{smallmatrix} u_- \\ u_+ \end{smallmatrix}\right]$, so that $y_-$ is a sequence in $\mathcal{Y}_-$, etc. We define a new input $u^{\curvearrowleft}$ by $u^{\curvearrowleft} = \left[\begin{smallmatrix} y_- \\ u_+ \end{smallmatrix}\right]$ and a new output $y^{\curvearrowleft}$ by $y^{\curvearrowleft} = \left[\begin{smallmatrix} u_- \\ y_+ \end{smallmatrix}\right]$, so that $u^{\curvearrowleft}$ is a sequence in $\mathcal{U}^{\curvearrowleft} = \mathcal{Y}_- \oplus \mathcal{U}_+$ and $y^{\curvearrowleft}$ is a sequence in $\mathcal{Y}^{\curvearrowleft} = \mathcal{U}_- \oplus \mathcal{Y}_+$. We then solve (1.2) for $x$ and $y^{\curvearrowleft}$ in terms of $x_0$ and $u^{\curvearrowleft}$. It turns out that for this to be possible we need $D_{11}$ to have a bounded inverse. The forward $H$-passivity of $\Sigma_{\mathrm{i/s/o}}$ implies that $D_{11}$ is injective and has a closed range, but it need not be surjective. However, let us suppose that $D_{11}$ has a bounded inverse. Then a direct computation shows that $(u^{\curvearrowleft}, x, y^{\curvearrowleft})$ is a trajectory of another system $\Sigma^{\curvearrowleft}_{\mathrm{i/s/o}} = \left(\left[\begin{smallmatrix} A^{\curvearrowleft} & B^{\curvearrowleft} \\ C^{\curvearrowleft} & D^{\curvearrowleft} \end{smallmatrix}\right]; \mathcal{U}^{\curvearrowleft}, \mathcal{X}, \mathcal{Y}^{\curvearrowleft}\right)$, called the *Potapov–Ginzburg* (or *chain scattering*) *transform of* $\Sigma_{\mathrm{i/s/o}}$, whose coefficients are given by

$$\begin{aligned} \begin{bmatrix} A^{\curvearrowleft} & B^{\curvearrowleft} \\ C^{\curvearrowleft} & D^{\curvearrowleft} \end{bmatrix} &= \left[\begin{array}{c|cc} A & B_1 & B_2 \\ \hline 0 & 1_{\mathcal{Y}_-} & 0 \\ C_2 & D_{21} & D_{22} \end{array}\right] \left[\begin{array}{c|cc} 1_{\mathcal{X}} & 0 & 0 \\ \hline C_1 & D_{11} & D_{12} \\ 0 & 0 & 1_{\mathcal{U}_+} \end{array}\right]^{-1} \\ &= \left[\begin{array}{c|cc} 1_{\mathcal{X}} & -B_1 & 0 \\ \hline 0 & -D_{11} & 0 \\ 0 & -D_{21} & 1_{\mathcal{Y}_+} \end{array}\right]^{-1} \left[\begin{array}{c|cc} A & 0 & B_2 \\ \hline C_1 & -1_{\mathcal{U}_-} & D_{12} \\ C_2 & 0 & D_{22} \end{array}\right]. \end{aligned} \tag{2.3}$$

The transfer functions of the two systems are connected by

$$\begin{bmatrix} \mathfrak{D}^{\curvearrowleft}_{11}(z) & \mathfrak{D}^{\curvearrowleft}_{12}(z) \\ \mathfrak{D}^{\curvearrowleft}_{21}(z) & \mathfrak{D}^{\curvearrowleft}_{22}(z) \end{bmatrix} = \begin{bmatrix} (\mathfrak{D}_{11}(z))^{-1} & -(\mathfrak{D}_{11}(z))^{-1}\mathfrak{D}_{12}(z) \\ \mathfrak{D}_{21}(z)(\mathfrak{D}_{11}(z))^{-1} & \mathfrak{D}_{22}(z) - \mathfrak{D}_{21}(z)(\mathfrak{D}_{11}(z))^{-1}\mathfrak{D}_{12}(z) \end{bmatrix}, \quad z \in \Lambda(A) \cap \Lambda\big(A^{\curvearrowleft}\big). \tag{2.4}$$

The Potapov–Ginzburg transform is its own inverse in the sense that $D^{\curvearrowleft}_{11} = D_{11}^{-1}$ always has a bounded inverse, and if we apply the Potapov–Ginzburg transform to the system $\Sigma^{\curvearrowleft}_{\mathrm{i/s/o}}$, then we recover the original system $\Sigma_{\mathrm{i/s/o}}$.

The Potapov–Ginzburg transform has been designed to 'preserve the energy exchange' in the sense that $j_{\text{tra}}(u, y) = j_{\text{sca}}(u^{\curvearrowleft}, y^{\curvearrowleft})$. This immediately implies that $\Sigma_{\text{i/s/o}}^{\curvearrowleft}$ is forward scattering $H$-passive whenever $\Sigma_{\text{i/s/o}}$ is forward transmission $H$-passive, provided that $D_{11}$ is invertible so that the transform is defined. As in the impedance case we conclude that the forward transmission $H$-passive system $\Sigma_{\text{i/s/o}}$ is also backward $H$-passive, i.e., $H$-passive, if $D_{11}$ has a bounded inverse (where $D_{11}$ is the part of the feedthrough operator $D$ that maps the negative part of the input space $\mathcal{U}$ into the negative part of the output space $\mathcal{Y}$). The converse is also true: if $\Sigma_{\text{i/s/o}}$ is (transmission) $H$-passive, then $D_{11}$ has a bounded inverse. Thus, a forward transmission $H$-passive system $\Sigma_{\text{i/s/o}}$ is $H$-passive if and only if $D_{11}$ has a bounded inverse, or equivalently, if and only if the Potapov–Ginzburg transform of $\Sigma_{\text{i/s/o}}$ is defined.

The analogue of Theorems 2.1 and 2.2 is more complicated to formulate than in the scattering and impedance cases. In particular, it is not immediately clear how to define the appropriate class of transfer functions. Above we first defined the Schur class $\mathcal{S}(\mathcal{U}, \mathcal{Y}; \mathbb{D})$ and the Carathéodory class $\mathcal{C}(\mathcal{U}; \mathbb{D})$ in the full unit disk, and then restricted these classes of functions to some subset $\Omega \subset \mathbb{D}$. Here it is easier to proceed in the opposite direction, and to directly define the *restricted Potapov class* $\mathcal{P}(\mathcal{U}, \mathcal{Y}; \Omega)$ for some $\Omega \subset \mathbb{D}$. We now *interpret $\mathcal{U}$ and $\mathcal{Y}$ as Kreĭn spaces*, i.e., we replace the original Hilbert space inner products in $\mathcal{Y}$ and $\mathcal{U}$ by the Kreĭn space inner products

$$[y, y']_{\mathcal{Y}} = \langle y, J_{\mathcal{Y}} y' \rangle_{\mathcal{Y}}, \quad [u, u']_{\mathcal{U}} = \langle u, J_{\mathcal{U}} u' \rangle_{\mathcal{U}}.$$

In the sequel *we compute all adjoints with respect to these Kreĭn space inner products*, and we also *interpret positivity with respect to these inner products* (so that, e.g., an operator $D$ is nonnegative definite in $\mathcal{U}$ if $[u, Du]_{\mathcal{U}} \geq 0$ for all $u \in \mathcal{U}$). A function $\varphi\colon \Omega \to \mathcal{B}(\mathcal{U}; \mathcal{Y})$ belongs to $\mathcal{P}(\mathcal{U}, \mathcal{Y}; \Omega)$ if both the kernels

$$\begin{aligned} K_{\text{tra}}^{\varphi}(z, \zeta) &= \frac{1_{\mathcal{Y}} - \varphi(z)\varphi(\zeta)^*}{1 - z\overline{\zeta}}, \quad z, \zeta \in \Omega, \\ K_{\text{tra}}^{\varphi *}(z, \zeta) &= \frac{1_{\mathcal{U}} - \varphi^*(\zeta)\varphi(z)}{1 - \overline{\zeta} z}, \quad z, \zeta \in \Omega, \end{aligned} \tag{2.5}$$

are nonnegative definite on $\Omega \times \Omega$.

**Theorem 2.3.** *Let $\Sigma_{\text{i/s/o}} = \left( \left[ \begin{smallmatrix} A & B \\ C & D \end{smallmatrix} \right]; \mathcal{U}, \mathcal{X}, \mathcal{Y}; j_{\text{tra}} \right)$ be an i/s/o system with transmission supply rate, signature operator $J_{\text{tra}} = \left[ \begin{smallmatrix} J_{\mathcal{Y}} & 0 \\ 0 & J_{\mathcal{U}} \end{smallmatrix} \right]$, and transfer function $\mathfrak{D}$. Let $\Lambda_0(A)$ be the connected component of $\Lambda(A) \cap \mathbb{D}$ which contains the origin.*

(i) *If $\Sigma_{\text{i/s/o}}$ is $H$-passive for some $H > 0$, then $\mathfrak{D}|_{\Lambda_0(A)} \in \mathcal{P}(\mathcal{U}, \mathcal{Y}; \Lambda_0(A))$.*

(ii) *Conversely, if $\Sigma_{\text{i/s/o}}$ is minimal and $\mathfrak{D}|_{\Lambda_0(A)} \in \mathcal{P}(\mathcal{U}, \mathcal{Y}; \Lambda_0(A))$, then $\Sigma_{\text{i/s/o}}$ is $H$-passive for some $H > 0$.*

This theorem follows from Theorem 2.1 via the Potapov–Ginzburg transformation. Note that (2.5) with $z = \zeta = 0$ implies that both $D$ and $D^*$ are Kreĭn space contractions, so that $D_{11}$ is invertible and the Potapov–Ginzburg transform is defined.

From what we have said so far it seems to follow that the transmission case is not that different from the scattering and impedances cases. However, this impression is not correct. One significant difference is that the Potapov–Ginzburg transformation is not always defined for a forward transmission $H$-passive i/s/o system. Another even more serious problem is that a function in the Potapov class may have singularities inside the unit disk $\mathbb{D}$, which means that in the definition of the (full) Potapov class $\mathcal{P}(\mathcal{U}, \mathcal{Y}; \mathbb{D})$ we must take into account that the function in this class need not be defined everywhere on $\mathbb{D}$. If the negative dimensions of $\mathcal{U}$ and $\mathcal{Y}$ are the same and finite, then this is not a serious problem, because in this case it is possible to define the Potapov class $\mathcal{P}(\mathcal{U}, \mathcal{Y}; \mathbb{D})$ to be the set of all meromorphic functions on $\mathbb{D}$ whose values in $\mathcal{B}(\mathcal{U}; \mathcal{Y})$ are contractive with respect to the Kreĭn space inner products in $\mathcal{U}$ and $\mathcal{Y}$ at all points where the functions are defined. However, in the general case the set of singularities of a function in $\mathcal{P}(\mathcal{U}, \mathcal{Y}; \mathbb{D})$ may be uncountable, and the domain of definition of a function in $\mathcal{P}(\mathcal{U}, \mathcal{Y}; \mathbb{D})$ need not even be connected. For this reason we prefer to define $\mathcal{P}(\mathcal{U}, \mathcal{Y}; \mathbb{D})$ in a different way. We say that a function $\varphi$ belongs to the (full) Potapov class $\mathcal{P}(\mathcal{U}, \mathcal{Y}; \mathbb{D})$ if it belongs to $\mathcal{P}(\mathcal{U}, \mathcal{Y}; \Omega)$ where *the domain* $\Omega$ *is maximal* in the sense that the function $\varphi$ does not have an extension to any larger domain $\Omega' \subset \mathbb{D}$ with the property that the two kernels in (2.5) are still nonnegative on $\Omega' \times \Omega'$. The existence of such a maximal domain is proved in [AS06b]. This maximal domain need not be connected, but it is still true that if we start from an open set $\Omega \subset \mathbb{D}$, then the values of $\varphi$ on $\Omega$ define the extension of $\varphi$ to its maximal domain uniquely. Moreover, as shown in [AS06b], if $\varphi \in \mathcal{P}(\mathcal{U}, \mathcal{Y}; \mathbb{D})$, then $\varphi$ does not have an analytic extension to any boundary point of its domain contained in the open unit disk $\mathbb{D}$.

Taking a closer look at Theorem 2.3 we observe that it puts one artificial restriction on the transfer function $\mathfrak{D}$, namely that the domain of definition must contain the origin. Not every function in the Potapov class is defined at the origin, so the class of transfer functions covered by Theorem 2.3 is not the full Potapov class. In addition it is possible to extend the Potapov class so that the values of the functions in this class may be unbounded, even multivalued, operators (as in the impedance case) by taking the formal Potapov transforms of functions in $\mathcal{S}(\mathcal{U}, \mathcal{Y}, \mathbb{D})$. Thus, we again see the need of a more general class of systems than the i/s/o class that we have discussed up to now.

## 3. State/signal systems

It is possible to develop a linear systems theory where the differences between the three different types of supply rates, namely scattering, impedance, and transmission, more or less disappear. Both the basic transforms that we have presented above,

namely the external Cayley transform which is used to pass from an impedance $H$-passive system to a scattering $H$-passive system and back, and the Potapov–Ginzburg transform that is used to pass from a transmission $H$-passive system to a scattering $H$-passive system and back, can be regarded as simple 'changes of coordinates in the signal space $\mathcal{W} = \left[\begin{smallmatrix} \mathcal{Y} \\ \mathcal{U} \end{smallmatrix}\right]$'. The main idea is *not to distinguish between the input sequence $u$ and the output sequence $y$*, but to simply regard these as components of the general 'signal sequence' $w = \left[\begin{smallmatrix} y \\ u \end{smallmatrix}\right]$.

We start by combining the input space $\mathcal{U}$ and the output space $\mathcal{Y}$ into one signal space $\mathcal{W} = \left[\begin{smallmatrix} \mathcal{Y} \\ \mathcal{U} \end{smallmatrix}\right]$. This signal space has a natural Kreĭn space[8] inner product obtained from the supply rate $j$ in (1.4), namely

$$\left[\begin{bmatrix} y \\ u \end{bmatrix}, \begin{bmatrix} y' \\ u' \end{bmatrix}\right]_{\mathcal{W}} = \left\langle \begin{bmatrix} y \\ u \end{bmatrix}, J \begin{bmatrix} y' \\ u' \end{bmatrix} \right\rangle_{\mathcal{Y}\oplus\mathcal{U}}.$$

If we combine the input sequence $u$ and the output sequence $y$ into one *signal sequence* $w = \left[\begin{smallmatrix} y \\ u \end{smallmatrix}\right]$, then the basic i/s/o relation (1.1) can be rewritten in the form

$$\begin{bmatrix} x(n+1) \\ x(n) \\ w(n) \end{bmatrix} \in V, \quad n \in \mathbb{Z}^+ = \{0, 1, 2, \ldots\},\ x(0) = x_0, \tag{3.1}$$

where $V$ is the subspace of $\mathfrak{K} := \left[\begin{smallmatrix} \mathcal{X} \\ \mathcal{X} \\ \mathcal{W} \end{smallmatrix}\right]$ given by

$$V = \left\{ \begin{bmatrix} z \\ x \\ w \end{bmatrix} \in \begin{bmatrix} \mathcal{X} \\ \mathcal{X} \\ \mathcal{W} \end{bmatrix} \;\middle|\; \begin{array}{l} z = Ax + Bu, \\ y = Cx + Du, \end{array} \quad w = \left[\begin{smallmatrix} y \\ u \end{smallmatrix}\right],\ x \in \mathcal{X},\ u \in \mathcal{U} \right\}. \tag{3.2}$$

It is not difficult to show that the subspace $V$ obtained in this way has the following four properties:

(i) $V$ is closed in $\mathfrak{K}$.

(ii) For every $x \in \mathcal{X}$ there is some $\left[\begin{smallmatrix} z \\ w \end{smallmatrix}\right] \in \left[\begin{smallmatrix} X \\ \mathcal{W} \end{smallmatrix}\right]$ such that $\left[\begin{smallmatrix} z \\ x \\ w \end{smallmatrix}\right] \in V$.

(iii) If $\left[\begin{smallmatrix} z \\ 0 \\ 0 \end{smallmatrix}\right] \in V$, then $z = 0$.

(iv) The set $\left\{ \left[\begin{smallmatrix} x \\ w \end{smallmatrix}\right] \in \left[\begin{smallmatrix} \mathcal{X} \\ \mathcal{W} \end{smallmatrix}\right] \mid \left[\begin{smallmatrix} z \\ x \\ w \end{smallmatrix}\right] \in V \text{ for some } z \in \mathcal{X} \right\}$ is closed in $\left[\begin{smallmatrix} \mathcal{X} \\ \mathcal{W} \end{smallmatrix}\right]$.

**Definition 3.1.** A triple $\Sigma = (V; \mathcal{X}, \mathcal{W})$, where the (*internal*) *state space* $\mathcal{X}$ is a Hilbert space and the (*external*) *signal space* $\mathcal{W}$ is a Kreĭn space and $V$ is a subspace

[8] Both [BS05] and [AS06a] contain short sections on the geometry of a Kreĭn space. For more detailed treatments we refer the reader to one of the books [ADRdS97], [AI89] and [Bog74].

of the product space $\mathfrak{K} := \left[\begin{smallmatrix}\mathcal{Z}\\ \mathcal{X}\\ \mathcal{W}\end{smallmatrix}\right]$ is called a *s/s* (*state/signal*) *node* if it has properties (i)–(iv) listed above. We interpret $\mathfrak{K}$ as a Kreĭn space with the inner product

$$\left[\begin{bmatrix} z\\ x\\ w\end{bmatrix}, \begin{bmatrix} z'\\ x'\\ w'\end{bmatrix}\right]_{\mathfrak{K}} = -\langle z, z'\rangle_{\mathcal{Z}} + \langle x, x'\rangle_{\mathcal{X}} + [w, w']_{\mathcal{W}}, \quad \begin{bmatrix} z\\ x\\ w\end{bmatrix}, \begin{bmatrix} z'\\ x'\\ w'\end{bmatrix} \in \mathfrak{K}, \quad (3.3)$$

and we call $\mathfrak{K}$ the *node space* and $V$ the *generating subspace*.

By a *trajectory* of $\Sigma$ we mean a pair of sequences $(x, w)$ satisfying (3.1). We call $x$ the *state component* and $w$ the *signal component* of this trajectory. By the *s/s system* $\Sigma$ we mean the s/s node $\Sigma$ together with all its trajectories.

The conditions (i)–(iv) above have natural interpretations in terms of the trajectories of $\Sigma$: for each $x_0 \in \mathcal{X}$ condition (ii) gives forward existence of at least one trajectory $(x, w)$ of $\Sigma$ with $x(0) = x_0$. Condition (iii) implies that a trajectory $(x, w)$ is determined uniquely by $x_0$ and $w$, and conditions (i) and (iv) imply that the signal part $x$ depends continuously in $\mathcal{X}^{\mathbb{Z}^+}$ on $x_0 \in \mathcal{X}$ and $w \in \mathcal{W}^{\mathbb{Z}^+}$.

A s/s system $\Sigma$ is *controllable* if the set of all states $x(n)$, $n \geq 1$, which appear in some trajectory $(x, w)$ of $\Sigma$ with $x(0) = 0$ (i.e., an *externally generated trajectory*) is dense in $\mathcal{X}$. The system $\Sigma$ is *observable* if there do not exist any nontrivial trajectories $(x, w)$ where the signal component $w$ is identically zero. Finally, $\Sigma$ is *minimal* if $\Sigma$ is both controllable and observable.

Above we explained how to interpret an i/s/o system $\Sigma_{\mathrm{i/s/o}}$ as a s/s system. Conversely, *from every s/s system* $\Sigma$ *it is possible to create not only one, but infinitely many i/s/o systems*. The representation (3.2) is characterized by the fact that it is a *graph representation of* $V$ *over* $\left[\begin{smallmatrix}\mathcal{X}\\ \mathcal{U}\end{smallmatrix}\right]$ where $\mathcal{U}$ is one of the two components in a direct sum decomposition of $\mathcal{W} = \mathcal{Y} \dotplus \mathcal{U}$ (not necessarily orthogonal) of $\mathcal{W}$. Indeed, splitting $w$ into $w = \left[\begin{smallmatrix} y\\ u\end{smallmatrix}\right]$ and reordering the components we find that (3.2) is equivalent to

$$V = \left\{ \begin{bmatrix} z\\ y\\ x\\ u\end{bmatrix} \in \begin{bmatrix}\mathcal{Z}\\ \mathcal{Y}\\ \mathcal{X}\\ \mathcal{U}\end{bmatrix} \;\middle|\; \begin{bmatrix} z\\ y\end{bmatrix} = \begin{bmatrix} A & B\\ C & D\end{bmatrix}\begin{bmatrix} x\\ u\end{bmatrix}, \begin{bmatrix} x\\ u\end{bmatrix} \in \begin{bmatrix}\mathcal{X}\\ \mathcal{U}\end{bmatrix} \right\}. \quad (3.4)$$

As shown in [AS05], *the generating subspace of every s/s system* $\Sigma$ *has at least one* (*hence infinitely many*) *graph representation of this type*. A direct sum decomposition $\mathcal{W} = \mathcal{Y} \dotplus \mathcal{U}$ of $\mathcal{W}$ is called an *admissible i/o* (*input/output*) *decomposition of* $\mathcal{W}$ *for* $\Sigma$, or simply an admissible decomposition, if it leads to a graph representation of the generating subspace of $\Sigma$ described above. From each such graph representation of $V$ we get an i/s/o system $\Sigma_{\mathrm{i/s/o}} = \left(\left[\begin{smallmatrix} A & B\\ C & D\end{smallmatrix}\right]; \mathcal{U}, \mathcal{X}, \mathcal{Y}\right)$ of $\Sigma$, which we call an *i/s/o representation* of $\Sigma$.

The above definitions are taken from [AS05], [AS06a], and [AS06b]. It turns out that a very large part of the proof of the $H$-passivity theory covered in Section 2 can be carried out directly in the s/s setting, rather than applying the same arguments separately with the scattering, impedance, and transmission supply rates. This leads to both a simplification and to a unification of the whole theory. Below we present the

most basic parts of the $H$-passive s/s theory, and refer the reader to [AS05]–[AS06c] for details.

Let $\Sigma = (V; \mathcal{X}, \mathcal{W})$ be a s/s node. The *adjoint* $\Sigma_* = (V_*; \mathcal{X}, \mathcal{W}_*)$ of $\Sigma$ (introduced in [AS06a, Section 4]) is another s/s node, with the same state space $\mathcal{X}$ as $\Sigma$, and with the signal space $\mathcal{W}_* = -\mathcal{W}$.[9] The generating subspace $V_*$ of $\Sigma_*$ is given by

$$V_* = \left\{ \begin{bmatrix} x_* \\ z_* \\ w_* \end{bmatrix} \,\middle|\, \begin{bmatrix} z_* \\ x_* \\ w_* \end{bmatrix} \in V^{[\perp]} \right\},$$

where $V^{[\perp]}$ is the orthogonal companion to $V$ with respect to the Kreĭn space inner product of $\mathfrak{K}$.[10] The adjoint system $\Sigma_*$ is determined by the property that

$$-\langle x(n+1), x_*(0)\rangle_{\mathcal{X}} + \langle x(0), x_*(n+1)\rangle_{\mathcal{X}} + \sum_{k=0}^{n} [w(k), w_*(n-k)]_{\mathcal{W}} = 0, \quad n \in \mathbb{Z}^+,$$

for all trajectories $(x, w)$ of $\Sigma$.

The following definition is the s/s version of Definitions 1.1 and 1.2.

**Definition 3.2.** Let $H$ be a positive self-adjoint operator in the Hilbert space $\mathcal{X}$. A s/s system $\Sigma$ is

(i) *forward $H$-passive* if $x(n) \in \mathcal{D}(\sqrt{H})$ and

$$\|\sqrt{H}x(n+1)\|_{\mathcal{X}}^2 - \|\sqrt{H}x(n)\|_{\mathcal{X}}^2 \le [w(n), w(n)]_{\mathcal{W}}, \quad n \in \mathbb{Z}^+,$$

for every trajectory $(x, w)$ of $\Sigma$ with $x(0) \in \mathcal{D}(\sqrt{H})$,

(ii) *forward $H$-conservative* if the above inequality holds as an equality,

(iii) *backward $H$-passive* or *$H$-conservative* if $\Sigma_*$ is forward $H^{-1}$-passive or $H^{-1}$-conservative, respectively,

(iv) *$H$-passive* or *$H$-conservative* if it is both forward and backward $H$-passive or $H$-conservative, respectively,

(v) *passive* or *conservative* if it is $1_{\mathcal{X}}$-passive or $1_{\mathcal{X}}$-conservative.

To formulate a s/s version of Theorems 2.1, 2.2 and 2.3 we need a s/s analogue of the transfer function of an i/s/o system. Such an analogue is most easily obtained in the time domain (as opposed to the frequency domain), and it amounts to the introduction of a *behavior*[11] *on the signal space* $\mathcal{W}$. By this we mean a closed right-shift invariant subspace of the Fréchet space $\mathcal{W}^{\mathbb{Z}^+}$. Thus, in particular, the set $\mathfrak{W}$ of all sequences $w$

[9] Algebraically $-\mathcal{W}$ is the same space as $\mathcal{W}$, but the inner product in $-\mathcal{W}$ is obtained from the one in $\mathcal{W}$ by multiplication by the constant factor $-1$.

[10] Thus, $V^{[\perp]} = \{k_* \in \mathfrak{K} \mid [k, k_*]_{\mathfrak{K}} = 0 \text{ for all } k \in V\}$. Note that $V_*$ differs from $V^{[\perp]}$ only by the order of the first two components.

[11] Our behaviors are what Polderman and Willems call *linear time-invariant mainfest behaviors* in [PW98, Definitions 1.3.4, 1.4.1, and 1.4.2]. We refer the reader to this book for further details on behaviors induced by systems with a finite-dimensional state space and for an account of the extensive literature on this subject.

that are the signal parts of externally generated trajectories of a given s/s system $\Sigma$ is a behavior. We call this the *behavior induced by* $\Sigma$, and refer to $\Sigma$ as a *s/s realization of* $\mathfrak{W}$, or, in the case where $\Sigma$ is minimal, as a *minimal s/s realization of* $\mathfrak{W}$. A behavior is *realizable* if it has a s/s realization.

Two s/s systems $\Sigma_1$ and $\Sigma_2$ with the same signal space are *externally equivalent* if they induce the same behavior. This property is related to the notion of *pseudo-similarity*. Two s/s systems $\Sigma = (V; \mathcal{X}, \mathcal{W})$ and $\Sigma_1 = (V_1; \mathcal{X}_1, \mathcal{W})$ are called *pseudo-similar* if there exists an injective densely defined closed linear operator $R\colon \mathcal{X} \to \mathcal{X}_1$ with dense range such that the following conditions hold:

> If $(x(\cdot), w(\cdot))$ is a trajectory of $\Sigma$ on $\mathbb{Z}^+$ with $x(0) \in \mathcal{D}(R)$, then $x(n) \in \mathcal{D}(R)$ for all $n \in \mathbb{Z}^+$ and $(Rx(\cdot), w(\cdot))$ is a trajectory of $\Sigma_1$ on $\mathbb{Z}^+$, and conversely, if $(x_1(\cdot), w(\cdot))$ is a trajectory of $\Sigma_1$ on $\mathbb{Z}^+$ with $x_1(0) \in \mathcal{R}(R)$, then $x_1(n) \in \mathcal{R}(R)$ for all $n \in \mathbb{Z}^+$ and $(R^{-1}x_1(\cdot), w(\cdot))$ is a trajectory of $\Sigma$ on $\mathbb{Z}^+$.

In particular, if $\Sigma_1$ and $\Sigma_2$ are pseudo-similar, then they are externally equivalent. Conversely, if $\Sigma_1$ and $\Sigma_2$ are minimal and externally equivalent, then they are necessarily pseudo-similar. Moreover, a realizable behavior $\mathfrak{W}$ on the signal space $\mathcal{W}$ has a minimal s/s realization, which is determined uniquely by $\mathfrak{W}$ up to pseudo-similarity. (See [AS05, Section 7] for details.)

The *adjoint* of the behavior $\mathfrak{W}$ on $\mathcal{W}$ is a behavior $\mathfrak{W}_*$ on $\mathcal{W}_*$ defined as the set of sequences $w_*$ satisfying

$$\sum_{k=0}^{n} [w(k), w_*(n-k)]_{\mathcal{W}} = 0, \quad n \in \mathbb{Z}^+,$$

for all $w \in \mathfrak{W}$. If $\mathfrak{W}$ is induced by $\Sigma$, then $\mathfrak{W}_*$ is (realizable and) induced by $\Sigma_*$, and the adjoint of $\mathfrak{W}_*$ is the original behavior $\mathfrak{W}$.

The following definition is a s/s analogue of our earlier definitions of the Schur, Carathéodory, and Potapov classes of transfer functions.

**Definition 3.3.** A behavior $\mathfrak{W}$ on $\mathcal{W}$ is

(i) *forward passive* if

$$\sum_{k=0}^{n} [w(k), w(k)]_{\mathcal{W}} \geq 0, \quad w \in \mathfrak{W},\ n \in \mathbb{Z}^+,$$

(ii) *backward passive* if $\mathfrak{W}_*$ is forward passive,

(iii) *passive* if it is realizable[12] and both forward and backward passive.

It is not difficult to see that a s/s system $\Sigma = (V; \mathcal{X}, \mathcal{W})$ is forward $H$-passive if and only if $H > 0$ is a solution of the generalized s/s KYP (Kalman–Yakubovich–

[12] We do not know if the realizability assumption is redundant or not.

Popov) inequality[13]

$$\|\sqrt{H}z\|_{\mathcal{X}}^2 - \|\sqrt{H}x\|_{\mathcal{X}}^2 \le [w, w]_{\mathcal{W}}, \quad \begin{bmatrix} z \\ x \\ w \end{bmatrix} \in V, \ x \in \mathcal{D}(\sqrt{H}), \tag{3.5}$$

and that it is forward $H$-conservative if and only if the above inequality holds as an equality.

The following proposition is a s/s version of parts (i) of Theorems 2.1, 2.2, and 2.3.

**Proposition 3.4.** *Let $\mathfrak{W}$ be the behavior induced by a s/s system $\Sigma$.*

(i) *If $\Sigma$ is forward $H$-passive for some $H > 0$, then $\mathfrak{W}$ is forward passive.*

(ii) *If $\Sigma$ is backward $H$-passive for some $H > 0$, then $\mathfrak{W}$ is backward passive.*

(iii) *If $\Sigma$ is forward $H_1$-passive for some $H_1 > 0$ and backward $H_2$-passive for some $H_2 > 0$, then $\Sigma$ is both $H_1$-passive and $H_2$-passive, and $\mathfrak{W}$ is passive.*

The following theorem generalizes parts (ii) of Theorems 2.1, 2.2, and 2.3.

**Theorem 3.5.** *Let $\mathfrak{W}$ be a passive behavior on $\mathcal{W}$. Then*

(i) *$\mathfrak{W}$ has a minimal passive s/s realization.*

(ii) *Every $H$-passive realization $\Sigma$ of $\mathfrak{W}$ is pseudo-similar to a passive realization $\Sigma_H$ with pseudo-similarity operator $\sqrt{H}$. The system $\Sigma_H$ is determined uniquely by $\Sigma$ and $H$.*

(iii) *Every minimal realization of $\mathfrak{W}$ is $H$-passive for some $H > 0$, and it is possible to choose $H$ in such a way that the system $\Sigma_H$ in* (ii) *is minimal.*

Assertion (ii) can be interpreted in the following way: we can always convert an $H$-passive s/s system into a passive one by simply replacing the original norm $\|\cdot\|_{\mathcal{X}}$ in the state space by the new norm $\|x\|_H = \|\sqrt{H}x\|_{\mathcal{X}}$, which is finite for all $x \in \mathcal{D}(\sqrt{H})$, and then completing $\mathcal{D}(\sqrt{H})$ with respect to this new norm.

We shall end this section with a result that says that a suitable subclass of all operators $H > 0$ for which a s/s system $\Sigma$ is $H$-passive can be partially ordered. Here we use the following partial ordering of nonnegative self-adjoint operators on $\mathcal{X}$: if $H_1$ and $H_2$ are two nonnegative self-adjoint operators on the Hilbert space $\mathcal{X}$, then we write $H_1 \preceq H_2$ whenever $\mathcal{D}(H_2^{1/2}) \subset \mathcal{D}(H_1^{1/2})$ and $\|H_1^{1/2}x\| \le \|H_2^{1/2}x\|$ for all $x \in \mathcal{D}(H_2^{1/2})$. For *bounded* nonnegative operators $H_1$ and $H_2$ with $\mathcal{D}(H_2) = \mathcal{D}(H_1) = \mathcal{X}$ this ordering coincides with the standard ordering of bounded self-adjoint operators.

For each s/s system $\Sigma$ we denote the set of operators $H > 0$ for which $\Sigma$ is $H$-passive by $M_\Sigma$, and we let $M_\Sigma^{\min}$ be the set of $H \in M_\Sigma$ for which the system $\Sigma_H$ in assertion (ii) of Theorem 3.5 is minimal.

[13] In particular, in order for the first term in this inequality to be well-defined we require $z \in \mathcal{D}(\sqrt{H})$ whenever $\begin{bmatrix} z \\ x \\ w \end{bmatrix} \in V$ and $x \in \mathcal{D}(\sqrt{H})$.

**Theorem 3.6.** *Let $\Sigma$ be a minimal s/s system with a passive behavior. Then $M_\Sigma^{\min}$ contains a minimal element $H_\circ$ and a maximal element $H_\bullet$, i.e., $H_\circ \preceq H \preceq H_\bullet$ for every $H \in M_\Sigma^{\min}$.*

The two extremal storage functions $E_{H_\circ}$ and $E_{H_\bullet}$ correspond to Willems' [Wil72a], [Wil72b] *available storage* and *required supply*, respectively (there presented in an i/s/o setting). In the terminology of Arov [Aro79b], [Aro95], [Aro99] (likewise in an i/s/o setting), $\Sigma_{H_\circ}$ is the *optimal* and $\Sigma_{H_\bullet}$ is the $*$-*optimal* realization of $\mathfrak{W}$.

## 4. Scattering, impedance and transmission representations of s/s systems

The results presented in Section 2 can be recovered from those in Section 3, together with a number of additional results. This is done by studying different i/s/o representations of a s/s system. Depending on the admissible i/o decomposition of the signal space $\mathcal{W}$ into an input space $\mathcal{U}$ and an output space $\mathcal{Y}$ we get different supply rates (inherited from the Kreĭn space inner product in $\mathcal{W}$).

Let $\Sigma = (V; \mathcal{X}, \mathcal{W})$ be a s/s system, and decompose $\mathcal{W}$ into the direct sum of an input space $\mathcal{U}$ and an output space $\mathcal{Y}$. Furthermore, suppose that this decomposition is admissible, so that it gives rise to an i/s/o representation $\Sigma_{\mathrm{i/s/o}}$ of $\Sigma$. In the case of a *fundamental decomposition* $\mathcal{W} = -\mathcal{Y}\,[\dot{+}]\,\mathcal{U}$, where $\mathcal{Y}$ and $\mathcal{U}$ are Hilbert spaces (i.e., $-\mathcal{Y}$ is an anti-Hilbert space) and $-\mathcal{Y}$ and $\mathcal{U}$ are orthogonal in $\mathcal{W}$, the inner product in $\mathcal{W}$ is given by

$$\left[\begin{bmatrix} y \\ u \end{bmatrix}, \begin{bmatrix} y' \\ u' \end{bmatrix}\right]_{\mathcal{W}} = -\langle y, y'\rangle_{\mathcal{Y}} + \langle u, u'\rangle_{\mathcal{U}},$$

which leads to a *scattering supply rate* for the i/s/o representation $\Sigma_{\mathrm{i/s/o}}$. In this case we call $\Sigma_{\mathrm{i/s/o}}$ an *admissible scattering representation* of $\Sigma$. In the case of a (nonorthogonal) *Lagrangian decomposition*, where both $\mathcal{Y}$ and $\mathcal{U}$ are Lagrangian[14] subspaces of $\mathcal{W}$ we get an *impedance supply rate* and an *admissible impedance representation* of $\Sigma$. Finally, if $\mathcal{W} = -\mathcal{Y}\,[\dot{+}]\,\mathcal{U}$ is an arbitrary *orthogonal decomposition* of $\mathcal{W}$ (not necessarily fundamental), then we get a *transmission supply rate* and an *admissible transmission representation* of $\Sigma$. Thus, in the s/s setting the external Cayley transform and the Potapov–Ginzburg transform that we presented in Section 2 are simply two different ways at looking at the same s/s system, via different i/o decompositions of the signal space $\mathcal{W}$ into an input space $\mathcal{U}$ and an output space $\mathcal{Y}$.

The following proposition is related to the discussions at the beginning of Sections 2.1 and 2.2.

**Proposition 4.1.** *Let $\Sigma = (V; \mathcal{X}, \mathcal{W})$ be a forward $H$-passive s/s system for some $H > 0$. Then the following claims hold.*

[14] A subspace of a Kreĭn space is Lagrangian if it coincides with its own orthogonal companion.

(i) $\Sigma$ *is $H$-passive if and only if* $\Sigma$ *has an admissible scattering representation, in which case* every *fundamental decomposition of* $\mathcal{W}$ *is admissible.*

(ii) *If* $\Sigma$ *has an admissible impedance representation, then* $\Sigma$ *is $H$-passive.*

The converse of (ii) is not true: there do exist passive s/s systems which do not have any admissible impedance representation, even if we require the positive and negative dimensions of $\mathcal{W}$ to be the same. Every $H$-passive s/s system does have some admissible transmission representations (for example, every scattering representation can be interpreted as a transmission representation), but in general there also exist orthogonal decompositions of the signal space that are not admissible.

One way to prove many of the results listed above is to pass to some particular i/s/o representation $\Sigma_{\mathrm{i/s/o}}$ of the s/s system $\Sigma$, to prove the corresponding result for $\Sigma_{\mathrm{i/s/o}}$, and to reinterpret the result for the s/s system $\Sigma$. In many cases the most convenient choice is to use a scattering representation, corresponding to some admissible fundamental decomposition of the signal space. We recall from Proposition 4.1 that if $\Sigma$ is $H$-passive for some $H > 0$, then every fundamental decomposition is admissible. However, this is not the only possible choice. If $\mathcal{W} = \mathcal{Y} \dot{+} \mathcal{U}$ is an arbitrary admissible i/o decomposition for $\Sigma$, then $\Sigma$ is forward or backward $H$-passive if and only if the corresponding i/s/o system $\Sigma_{\mathrm{i/s/o}}$ is forward or backward $H$-passive with respect to the supply rate on $\mathcal{Y} \dot{+} \mathcal{U}$ inherited from the inner product $[\,\cdot\,,\,\cdot\,]_{\mathcal{W}}$. Thus, in the family of i/s/o systems $\Sigma_{\mathrm{i/s/o}} = \left(\left[\begin{smallmatrix} A & B \\ C & D \end{smallmatrix}\right]; \mathcal{U}, \mathcal{X}, \mathcal{Y}\right)$ that we get from $\Sigma$ by varying the i/o decomposition $\mathcal{W} = \mathcal{Y} \dot{+} \mathcal{U}$ the coefficients $\left[\begin{smallmatrix} A & B \\ C & D \end{smallmatrix}\right]$ vary, and so do the supply rates $j(u, y)$, but *the set of solutions of the generalized KYP inequalities* (1.6) *and* (1.10) *stay the same*.

Up to now we have only considered *admissible* i/o decompositions of the signal space $\mathcal{W}$ of a s/s system $\Sigma$. As we commented earlier, not every Lagrangian or orthogonal decomposition need be admissible for $\Sigma$, even if $\Sigma$ is $H$-passive for some $H > 0$. However, it is still possible to study also these non-admissible decompositions by replacing the i/s/o representations by *left or right affine representations* of $\Sigma$. These are defined for arbitrary decompositions $\mathcal{W} = \mathcal{Y} \dot{+} \mathcal{U}$ (not only for the admissible ones). By a *right affine i/s/o representation of* $\Sigma$ we mean an i/s/o system[15]

$$\Sigma^r_{\mathrm{i/s/o}} = \left(\left[\begin{array}{c|c} A' & B' \\ \hline C'_{\mathcal{Y}} & D'_{\mathcal{Y}} \\ C'_{\mathcal{U}} & D'_{\mathcal{U}} \end{array}\right]; \mathcal{L}, \mathcal{X}, \left[\begin{smallmatrix} \mathcal{Y} \\ \mathcal{U} \end{smallmatrix}\right]\right)$$

with the following two properties: 1) $D' = \left[\begin{smallmatrix} D'_{\mathcal{Y}} \\ D'_{\mathcal{U}} \end{smallmatrix}\right]$ has a bounded left-inverse, and 2) $\left(x, \left[\begin{smallmatrix} y \\ u \end{smallmatrix}\right]\right)$ is a trajectory of $\Sigma$ if and only if $\left(\ell, x, \left[\begin{smallmatrix} y \\ u \end{smallmatrix}\right]\right)$ is a trajectory of $\Sigma^r_{\mathrm{i/s/o}}$ for some sequence $\ell$ with values in $\mathcal{L}$. By a *left affine i/s/o representation of* $\Sigma$ we mean

[15] Here the new input space $\mathcal{L}$ is an auxiliary Hilbert space called the *driving variable* space.

an i/s/o system[16]

$$\Sigma^l_{\mathrm{i/s/o}} = \left( \left[\begin{array}{c|cc} A'' & B''_{\mathcal{Y}} & B''_{\mathcal{U}} \\ \hline C'' & D''_{\mathcal{Y}} & D''_{\mathcal{U}} \end{array}\right]; \left[\begin{smallmatrix} \mathcal{Y} \\ \mathcal{U} \end{smallmatrix}\right], \mathcal{X}, \mathcal{K} \right)$$

with the following two properties: 1) $D'' = \left[\begin{array}{cc} \mathfrak{D}''_{\mathcal{Y}} & \mathfrak{D}''_{\mathcal{U}} \end{array}\right]$ has a bounded right-inverse, and 2) $\left(x, \left[\begin{smallmatrix} y \\ u \end{smallmatrix}\right]\right)$ is a trajectory of $\Sigma$ if and only if $\left(\left[\begin{smallmatrix} y \\ u \end{smallmatrix}\right], x, 0\right)$ is a trajectory of $\Sigma^l_{\mathrm{i/s/o}}$ (i.e., the output is identically zero in $\mathcal{K}$). The transfer functions of these systems are called the right, respectively left, affine transfer functions of $\Sigma$ corresponding to the i/o decomposition $\mathcal{W} = \mathcal{Y} \dotplus \mathcal{U}$. Note, in particular, that the right and left affine transfer functions are now decomposed into $\mathfrak{D}' = \left[\begin{smallmatrix} \mathfrak{D}'_{\mathcal{Y}} \\ \mathfrak{D}'_{\mathcal{U}} \end{smallmatrix}\right]$ and $\mathfrak{D}'' = \left[\begin{array}{cc} \mathfrak{D}''_{\mathcal{Y}} & \mathfrak{D}''_{\mathcal{U}} \end{array}\right]$, respectively.

Let

$$\Omega(\Sigma^r_{\mathrm{i/s/o}}) = \{z \in \Lambda_{A'} \mid \mathfrak{D}'_{\mathcal{U}}(z) \text{ has a bounded inverse}\},$$
$$\Omega(\Sigma^l_{\mathrm{i/s/o}}) = \{z \in \Lambda_{A''} \mid \mathfrak{D}''_{\mathcal{Y}}(z) \text{ has a bounded inverse}\},$$

and let

$\Omega^r(\Sigma; \mathcal{U}, \mathcal{Y})$ be the union of the above sets $\Omega(\Sigma^r_{\mathrm{i/s/o}})$,

$\Omega^l(\Sigma; \mathcal{U}, \mathcal{Y})$ be the union of the above sets $\Omega(\Sigma^l_{\mathrm{i/s/o}})$.

We can now define the notions of right and left generalized transfer functions of $\Sigma$ with input space $\mathcal{U}$ and output space $\mathcal{Y}$ on the sets $\Omega^r(\Sigma; \mathcal{U}, \mathcal{Y})$ and $\Omega^l(\Sigma; \mathcal{U}, \mathcal{Y})$, respectively, by the formulas

$$\mathfrak{D}_r(z) = \mathfrak{D}'_{\mathcal{Y}}(z)\mathfrak{D}'_{\mathcal{U}}(z)^{-1}, \tag{4.1}$$
$$\mathfrak{D}_l(z) = -\mathfrak{D}''_{\mathcal{Y}}(z)^{-1}\mathfrak{D}''_{\mathcal{U}}(z), \tag{4.2}$$

respectively.

**Theorem 4.2.** *The right-hand side of* (4.1) *does not depend on the choice of* $\Sigma^r_{\mathrm{i/s/o}}$ *as long as* $\Omega(\Sigma^r_{\mathrm{i/s/o}}) \ni z$, *and the right-hand side of* (4.2) *does not depend on the choice of* $\Sigma^l_{\mathrm{i/s/o}}$ *as long as* $\Omega(\Sigma^l_{\mathrm{i/s/o}}) \ni z$.

**Theorem 4.3.** *The right and left generalized transfer functions defined by* (4.1) *and* (4.2), *respectively, coincide on*

$$\Omega(\Sigma; \mathcal{U}, \mathcal{Y}) = \Omega^r(\Sigma; \mathcal{U}, \mathcal{Y}) \cap \Omega^l(\Sigma; \mathcal{U}, \mathcal{Y})$$

(*whenever this set is nonempty*). *If the i/o decomposition* $\mathcal{W} = \mathcal{Y} \dotplus \mathcal{U}$ *is admissible, and if* $A$ *is the main operator of the corresponding i/s/o representation of* $\Sigma$, *then*

$$\Omega^r(\Sigma; \mathcal{U}, \mathcal{Y}) = \Omega^l(\Sigma; \mathcal{U}, \mathcal{Y}) = \Lambda_A,$$

*and the left and right generalized transfer functions coincide with the ordinary transfer function corresponding to the decomposition* $\mathcal{W} = \mathcal{Y} \dotplus \mathcal{U}$

[16]Here the new output space $\mathcal{K}$ is an auxiliary Hilbert space called the *error variable* space.

In the case where the s/s system $\Sigma$ is $H$-passive for some $H > 0$ we can say more. In this case it is possible to choose the different affine representations of $\Sigma$ in such a way that the right and left transfer functions are defined in the whole unit disk $\mathbb{D}$ and belong to $H^\infty$, and they will even be *right and left coprime in* $H^\infty$, respectively. In this way we obtain right and left coprime transmission representations of $\Sigma$, and in the case that the positive and negative dimensions of the signal space $\mathcal{W}$ are the same we also obtain right and left coprime impedance representations. The corresponding right and left coprime affine transfer functions will be generalized Potapov and Carathéodory class functions, respectively.

## 5. Further extensions

The results of Sections 3 and 4 are taken primarily from [AS05], [AS06a]–[AS06c]. At present they do not yet make up a complete theory that would be ready to replace the classical i/s/o theory. However, the following additional *discrete part* ingredients of the s/s theory are presently under active development:

- The study of the *interconnection* of two s/s systems (this is the s/s analogue of feedback).
- *Lossless behaviors* and *bi-lossless extensions* of passive behaviors (including the s/s analogue of Darlington synthesis).
- Additional *representations* of generalized Carathéodory and Potapov class functions.
- External and internal *symmetry* of s/s systems (including reciprocal systems).
- Further studies of the *stability properties* of passive s/s systems.
- Conditions for *ordinary similarity* (as opposed to pseudo-similarity) of minimal passive realizations.

An even larger project is still in its infancy, namely the *extension of the s/s theory to continuous time systems*. Some preliminary results in this direction have been obtained in [BS05] and [MS06a], [MS06b].

# Control and numerical approximation of the wave and heat equations

Enrique Zuazua*

*Ama, Magaly, Oihane eta Ainarari.*

**Abstract.** In recent years important progress have been done in the context of numerical approximation of controllability problems for PDEs. It is by now well known that, often, numerical approximation schemes that are stable for solving initial-boundary value problems, develop instabilities when applied to controllability problems. This is due to the presence of spurious high frequency numerical solutions that the control mechanisms are not able to control uniformly as the mesh-size tends to zero. However, the theory is far from being complete. In this article we present some new results in this framework for the wave and the heat equations, which also raise a number of open questions and future directions of research. We first prove that a two-grid method, introduced by R. Glowinski, that is by now well-known to guarantee convergence for the $1-d$ wave equation, also converges in the semilinear setting for globally Lipschitz nonlinearities. This result provides a further evidence of the robustness of the two-grid method. We then show that boundary controls for finite-difference space semi-discretizations of the heat equation converge when applied all along the boundary of the domain, a fact that does not hold for wave-like equations. This confirms that the strong irreversibility of the heat equation enhances the control properties of its numerical approximation schemes. This result fails when the control is restricted to some subsets of the boundary because of the lack of unique continuation of some high frequency eigenvectors of the underlying discrete eigenvalue problem.

## 1. Introduction

In recent years important progresses have been done in the context of numerical approximation of controllability problems for PDEs. It is by now well known that, often, numerical approximation schemes that are stable for solving an initial-boundary value problem, develop instabilities when applied to controllability problems. This is due to the presence of spurious high frequency numerical solutions that the control mechanisms are not able to control uniformly as the mesh-size tends to zero.

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

To cure these instabilities a number of methods have been introduced in the literature. We refer to [30] for a recent survey article on the topic.

In this context and in an effort to build a general theory, there are two prototypical equations that need to be understood first of all: the *wave equation* and the *heat equation*.

In the framework of the linear wave equation, R. Glowinski [6] introduced a two-grid control mechanism that allows filtering the high frequency numerical spurious solutions and guarantee the convergence of controls. There are clear numerical evidences of the convergence of the method whose proof has been successfully carried out in [17] in the $1-d$ case by using discrete multipliers. More recently the same result has been proved, with a better estimate on the minimal control time, in [16] by using Ingham type inequalities. Other methods have also been developed for avoiding these instabilities to occur: Tychonoff regularization, Fourier filtering, mixed finite elements,…(see [30]). But most of the existing theory is devoted to linear problems. The first part of this article is devoted to show how the convergence result of the two-grid algorithm can be extended to semilinear systems too, with globally Lipschitz nonlinearities. This result adds one more evidence of the robustness and efficiency of the two-grid algorithm for the control of wave problems.

The high frequency spurious numerical solutions for the wave equation are due to the existence of wave-packets that travel with a vanishing group velocity (see [21], [30]). This can be understood by analyzing the symbol of the operator and the dynamics of the Hamiltonian system generating the bicharacteristic rays. However, one expects that the heat equation, because of its intrinsic time-irreversibility and strong damping should escape to those pathologies and that most common numerical approximation schemes should be controllable, uniformly with respect to the mesh-size. This holds indeed in the $1-d$ setting (see [14]). But, surprisingly enough, this property may fail to hold in $2-d$ even for the simplest finite-difference semi-discretization scheme for the heat equation in the square. This is due to the fact that there are some high-frequency numerical solutions that do not fulfill the classical property of unique continuation of the continuous heat equation. Thus, at the control level, the numerical approximation schemes may generate some solutions which are insensitive to the action of controls. Strictly speaking this happens when the control acts on some (small enough) subsets of the boundary where the equation holds. However, this fact clearly indicates a major difference in the control theoretical behavior of the continuous and the semi-discrete heat equation since the first one is controllable from any open and non-empty subset of the boundary while the second one is not. Characterizing completely the subsets of the boundary for which these pathologies arise is probably a difficult problem. In this article we prove that convergence occurs when the controls act everywhere on the boundary of the domain. This confirms that heat equations are better behaved than wave ones. Indeed, for the wave equation, even if controls act everywhere on the boundary of the domain, the uniform controllability property for numerical approximation schemes may fail because of the existence of spurious numerical solutions that are trapped in the interior of the mesh without reaching the

boundary in an uniform time. Our positive result for the heat equation shows that this kind of spurious solutions are ruled out due to the strong dissipativity of the heat equation and its numerical approximation schemes but, so far, only when the control is distributed everywhere on the boundary.

The lack of unique continuation for semi-discrete heat equations is due to the fact that the property fails to hold for the spectrum of the discrete Laplacian. Indeed, for the Dirichlet spectrum of the continuous Laplacian, unique continuation holds in the sense that, when the normal derivative of an eigenfunction vanishes in a subset of the boundary, the eigenfunction vanishes everywhere. This property fails to hold for the eigenvectors of the discrete Laplacian. The main method to prove unique continuation properties in the continuous framework are the so-called Carleman inequalities. But the discrete analogue is still to be developed. An alternate natural way of addressing this issue, in the spirit of the classical theory of numerical analysis, would consist in viewing the solutions of the discrete problem as a perturbation of those of the continuous one and applying the continuous Carleman inequalities. This approach has been successfully applied in [31] to elliptic equations with irregular coefficients in the principal part. Developing this program in the context of discrete elliptic equations is an interesting open problem.

The two topics we address in this article also raise a number of interesting open problems and future directions of research that we mention briefly. Some of them, in our opinion, are deep and will require important research efforts. The interest of these problems goes much beyond Control Theory since they mainly concern the way classical numerical analysis and the existing theory of partial differential equations have to be melt to address subtle qualitative aspects of numerical solutions. We hope that this article will serve to stimulate research in this area.

## 2. Controllability of the two-grid approximation scheme for the $1-d$ semilinear wave equation

One of the main drawbacks of the existing theory to analyze the controllability of numerical approximation schemes for PDE is that it often relies on Fourier analysis. This makes it of little use for nonlinear problems. However there is by now an extensive literature on the controllability of semilinear PDE and, in particular, of wave and heat equations. Therefore, it is natural to develop numerical methods allowing to address these nonlinear models and to build convergent numerical schemes for their control.

In this section we consider the $1-d$ semilinear wave equation with boundary control:

$$\begin{cases} y_{tt} - y_{xx} + f(y) = 0, & x \in (0,\,1),\ 0 < t < T, \\ y(0,\,t) = 0, \quad y(1,\,t) = v(t), & 0 < t < T, \\ y(x,\,0) = y^0(x),\ y_t(x,\,0) = y^1(x), & x \in (0,\,1). \end{cases} \tag{2.1}$$

Here the control $v = v(t)$ enters into the system through the extreme $x = 1$ of the boundary.

This semilinear wave equation is known to be controllable under sharp growth conditions on the nonlinearity. Namely, if

$$|f'(s)| \leq C \log^2(1 + |s|) \quad \text{for all } s \in \mathbb{R} \tag{2.2}$$

for some $C > 0$, system (2.1) is exactly controllable in any time $T > 2$. This means that for all $(y^0,\ y^1) \in L^2(0,\ 1) \times H^{-1}(0,\ 1)$ and $(z^0,\ z^1) \in L^2(0,\ 1) \times H^{-1}(0,\ 1)$ there exists a control $v \in L^2(0,\ T)$ such that the solution $y$ of (2.1) satisfies

$$y(x,\ T) = z^0(x), \quad y_t(x,\ T) = z^1(x) \quad \text{in } (0,\ 1). \tag{2.3}$$

This result was proved in [26] for $C > 0$ sufficiently small in (2.2) and, without restrictions on the size of the constant $C$, in [1].

This growth condition is sharp since blow-up phenomena may occur for nonlinearities growing faster at infinity and, due to the finite speed of propagation, boundary controls are unable to avoid blow-up to occur. In that case controllability fails.

The most common method to derive the exact controllability property of semilinear equations is based on the following ingredients:

- a fixed point argument;
- sharp estimates on the dependence of controls for the underlying linear equation perturbed by a potential.

We refer to [25] where this method was introduced in the context of the wave equation (see also [22] for further developments, and [23] for an updated survey on this problem) and to [4] where the same technique was applied to semilinear heat equations.

Knowing that the semilinear wave equation (2.1) is controllable under the growth condition (2.2) it is natural to analyze whether the controls can be obtained as limits of controls of numerical approximation schemes. As we have explained in the introduction this issue is delicate even for linear problems, and it is necessarily more complex for nonlinear ones.

Among the possible remedies to the lack of convergence of the standard conservative schemes the two-grid method introduced in [6] seems to be the one that is better adapted to semilinear problems. In this section we confirm this assertion by proving its convergence in this nonlinear setting for globally Lipschitz nonlinearities.

The two-grid scheme is, roughly, as follows.

Given an integer $N \in \mathbb{N}$ we introduce the partition $\{x_j = jh\}_{j=0,\ldots,N+1}$ of the interval $(0,\ 1)$ with $h = 1/(N + 1)$ so that $x_0 = 0$ and $x_{N+1} = 1$.

We then consider the conservative finite-difference semi-discretization of the semilinear wave equation (2.1) as follows:

$$\begin{cases} y_j'' + \frac{2y_j - y_{j+1} - y_{j-1}}{h^2} + f(y_j) = 0, & j = 1, \ldots,\ N,\ 0 < t < T, \\ y_0(t) = 0,\ y_{N+1}(t) = v(t), & 0 < t < T, \\ y_j(0) = y_j^0,\ y_j'(0) = y_j^1, & j = 0, \ldots,\ N + 1. \end{cases} \tag{2.4}$$

The scheme is conservative in the sense that, in the absence of control (i.e. for $v \equiv 0$) the energy of solutions is conserved. The same property holds for the continuous version (2.1). In that case the energy is given by

$$E(t) = \frac{1}{2}\int_0^1 \left[y_t^2(x,t) + y_x^2(x,t)\right] dx + \int_0^1 F(y(x,t))\, dx,$$

where $F$ is a primitive of $f$, i.e. $F(z) = \int_0^z f(s)ds$. In the semi-discrete case the corresponding energy is

$$E_h(t) = \frac{h}{2}\sum_{j=0}^{N}\left[|y_j'|^2 + \left|\frac{y_{j+1}-y_j}{h}\right|^2\right] + h\sum_{j=0}^{N} F(y_j).$$

The goal of this section is to analyze the controllability of (2.4) and whether, as $h \to 0$, the controls of (2.4) converge to those of (2.1). The controls being, in general, non unique, one has to be precise when discussing their convergence. Here, in the linear context, we shall always refer to the controls of minimal $L^2(0,T)$-norm which are given by the so called Hilbert Uniqueness Method (HUM) ([13]). As we mentioned above, in the nonlinear case, the controls we shall deal with are obtained by fixed point methods on the basis of the HUM controls for the linearized problems.

But, even in the linear case, to guarantee convergence as $h \to 0$, the final control requirement has to be relaxed, or the numerical scheme modified.

In [29] it was proved that, if the exact controllability condition is relaxed to the approximate controllability one (in which the state is required to reach an $\varepsilon$-neighborhood of the target), then convergence occurs in the linear framework. But it is convenient to deal with other relaxation criteria that do not introduce extra parameters since the controls may depend on them in a very sensitive way.

The two-grid method is a very natural way of introducing such relaxation. It is based on the idea of relaxing the final condition to avoid the divergence of controls due to the need of controlling high frequency spurious oscillations. To be more precise, the semi-discrete analogue of the exact controllability final condition (2.3) is

$$y_j(T) = z_j^0, \quad y_j'(T) = z_j^1, \quad j = 0, \ldots, N+1. \tag{2.5}$$

But, as it is by now well-known (see [30]), under the final requirement (2.5), controls diverge as $h \to 0$ even for the linear wave equation.

In the two-grid algorithm, the final condition (2.5) is relaxed to

$$\Pi_h\big(Y(T)\big) = \Pi_h(Z^0), \quad \Pi_h\big(Y'(T)\big) = \Pi_h(Z^1), \tag{2.6}$$

where $Y(t)$ and $Y'(t)$ stand for the vector-valued unknowns

$$Y(t) = \big(y_0(t), \ldots, y_{N+1}(t)\big), \quad Y'(t) = \big(y_0'(t), \ldots, y_{N+1}'(t)\big).$$

We shall also use the notation $Y_h$ for $Y$ when passing to the limit to better underline the dependence on the parameter $h$. $\Pi_h$ is the projection operator so that

$$\Pi_h(G) = \left(\frac{1}{2}\left(g_{2j+1} + \frac{1}{2}g_{2j} + \frac{1}{2}g_{2j+2}\right)\right)_{j=0,\dots,\frac{N+1}{2}-1}, \tag{2.7}$$

with $G = (g_0, g_1, \dots, g_N, g_{N+1})$. Note that the projection $\Pi_h(G)$ is a vector of dimension $(N+1)/2$. Thus, roughly speaking, the relaxed final requirement (2.6) only guarantees that half of the state of the numerical scheme is controlled. Despite this fact, the formal limit of (2.6) as $h \to 0$ is still the exact controllability condition (2.3) on the continuous wave equation.

The main result of this section is as follows:

**Theorem 2.1.** *Assume that the nonlinearity $f : \mathbb{R} \to \mathbb{R}$ is such that*

$$f \text{ is globally Lipschitz.} \tag{2.8}$$

*Let $T_0 > 0$ be such that the two-grid algorithm for the control of the linear wave equation converges for all $T > T_0$.*

*Then, the algorithm converges for the semilinear system* (2.1) *too for all $T > T_0$. More precisely, for all $(y^0,\ y^1) \in H^s(0,\ 1) \times H^{s-1}(0,\ 1)$ with $s > 0$, there exists a family of controls $\{v_h\}_{h>0}$ for the semi-discrete system* (2.4) *such that the solutions of* (2.4) *satisfy the relaxed controllability condition* (2.6) *and*

$$v_h(t) \to v(t) \qquad \text{in } L^2(0,\ T),\ h \to 0 \tag{2.9}$$

$$(Y_h,\ Y_h') \to (y,\ y_t) \quad \text{in } L^2(0,\ T;\ L^2(0,\ 1) \times H^{-1}(0,\ 1)) \tag{2.10}$$

*where $y$ is the solution of the semilinear wave equation* (2.1) *and $v$ is a control such that the state $y$ satisfies the final requirement* (2.3).

**Remark 2.2.** Several remarks are in order.

• The controllability of the semilinear wave equation (2.1) under the globally Lipschitz assumption (2.8) on the nonlinearity was proved in [25] in $1-d$ and in the multi-dimensional case. The proof of Theorem 2.1 is based on an adaptation of the arguments in [25] to the two-grid approximation scheme.

Whether the two-grid algorithm applies under the weaker and sharp growth condition (2.2) is an open problem. The difficulty for doing that is that the two existing proofs allowing to deal with the semilinear wave equation under the weaker growth condition (2.2) are based, on a way or another, on the sidewise solvability of the wave equation, a property that the semi-discrete scheme fails to have.

• Theorem 2.1 holds for a sufficiently large time $T_0$. The requirement on $T_0$ is that, in the linear case ($f \equiv 0$), the two-grid algorithm converges for all $T > T_0$. This was proved to hold for $T > 4$ in [17]. The proof in [17] is based on the obtention of the corresponding observability inequality for the solutions of the adjoint semi-discrete wave equation by multiplier techniques. Later on this result was improved in [16]

using a variant of the classical Ingham inequality obtaining the sharp minimal control time $T_0 = 2\sqrt{2}$.

Note that the minimal time for controllability of the continuous wave equation (2.1) is $T = 2$.[1] However this minimal time may not be achieved by the two-grid algorithm as described here since, despite it filters the spurious high frequency numerical solutions, it is compatible with the existence of wave packets travelling with velocity smaller than 1, and this excludes the controllability in the minimal time $T = 2$. The two-grid algorithm can be further improved to get smaller minimal times by considering other projection operators $\Pi_h$, obtained by means of the two-grid approach we shall describe below but with ratio $1/2^\ell$, for some $\ell \geq 2$, instead of the ratio $1/2$. This idea has been used successfully in [7] when proving dispersive estimates for conservative semi-discrete approximation schemes of the Schrödinger equation. When diminishing the ratio between grids, the filtering that the two-grid algorithm introduces concentrates the solutions of the numerical problem on lower and lower frequencies for which the velocity of propagation becomes closer and closer to that of the continuous wave equation. In that way the minimal controllability time may be made arbitrarily close to that of the wave equation $T = 2$ by means of the two-grid approach.

• In the statement of Theorem 2.1 we have chosen initial data for (2.1) in the space $(y^0,\ y^1) \in H^s(0,\ 1) \times H^{s-1}(0,\ 1)$, but we have not explained how the initial data for the semi-discrete system (2.4) have to be taken. The simplest way for doing that is taking as initial data for (2.4) the truncated Fourier series of the continuous initial data $(y^0,\ y^1)$, involving only the first $N$ Fourier modes. One can also define the discrete initial data by taking averages of the continuous ones on the intervals $[x_j - h/2, x_j + h/2]$ around the mesh-points.

• The meaning of the convergence property (2.10) needs also to be made precise. This may be done by extending the semi-discrete state $(Y_h(t),\ Y_h'(t))$ into a continuous one $(y_h(x,\ t),\ y_h'(x,\ t))$ and then proving convergence (2.10) for the extended one. This extension may be defined at least in two different ways. Either by extending the Fourier representation of $Y_h$ or rather by using a standard piecewise linear and continuous extension. We refer to [28] and [19] where these two extensions have been used in similar limit processes.

• In the statement of Theorem 2.1 the initial data are assumed to be in $H^s(0,\ 1) \times H^{-1+s}(0,\ 1)$ for some $s > 0$, which is a slightly stronger regularity assumption than the one needed for the semilinear wave equation (2.1) to be controllable ($L^2(0,\ 1) \times H^{-1}(0,\ 1)$). This is probably a purely technical assumption but it is needed for the method we develop here to apply. The same difficulty arises in the context of the continuous semilinear wave equation [25]. This extra regularity condition for the continuous wave equation was avoided in [1] and [26] but using the very special property of the $1-d$ wave equation of being well-posed in the sidewise sense.

[1] By minimimal control time we mean that the controllability property holds for all time $T$ which is greater than 2. Thus, this does not necessarily mean that controllability occurs for time $T = 2$.

In the context of the problem of numerical approximation we are working this difficulty seems hard to avoid even at the level of passing to the limit as $h \to 0$ on the state equations. Indeed, this requires passing to the limit, in particular, on the nonlinear terms and this seems hard to achieve in the $L^2(0,\ 1) \times H^{-1}(0,\ 1)$-setting because the corresponding states $Y_h$ would then be merely bounded in $C([0,\ T];\ L^2(0,\ 1)) \cap C^1([0,\ T];\ H^{-1}(0,\ 1))$, which seems to be insufficient to guarantee compactness and the convergence of the nonlinear term.

**Proof of Theorem 2.1.** To simplify the presentation we assume that the final target is the null trivial state $z^0 \equiv z^1 \equiv 0$, although the same proof applies in the general case. We proceed in several steps.

*Step* 1. *Two-grid controllability of the semi-discrete system* (2.4). First of all, following the standard fixed point argument ([25]), we prove that, for $h > 0$ fixed, the semilinear system (2.4) is controllable. In fact this argument allows proving that (2.4) is exactly controllable for all $T > 0$. But, as we mentioned above (see [30]), the controls fail to be bounded as $h \to 0$. It is precisely to guarantee that the controls are bounded that we need to relax the final condition to the weaker two-grid one (2.6) and the time $T$ is needed to be large enough as in the statement of Theorem 2.1.

To simplify the presentation we assume that $f \in C^1(\mathbb{R};\ \mathbb{R})$ and $f(0) = 0$, although the proof can be easily adapted to globally Lipschitz nonlinearities. We then introduce the continuous function

$$g(z) = \begin{cases} f(z)/z, & z \neq 0, \\ f'(0), & z = 0. \end{cases} \tag{2.11}$$

Given any semi-discrete function $Z = Z(t) \in C([0,\ T];\ \mathbb{R}^{N+2})$ we consider the linearized wave equation

$$\begin{cases} y_j'' + \frac{2y_j - y_{j+1} - y_{j-1}}{h^2} + g(z_j)y_j = 0, & j = 1, \dots, N;\ 0 < t < T, \\ y_0(t) = y_j^0,\ y_{N+1}(t) = v(t), & 0 < t < T, \\ y_j(0) = y_j'(0) = y_j^1, & j = 0, \dots, N+1. \end{cases} \tag{2.12}$$

We proceed by a classical fixed point argument (see [25]). This requires essentially proving that:

a) For all $Z = Z(t)$ as above (2.12) is two-grid controllable in the sense of (2.6);

b) The mapping $\mathcal{N}(Z) = Y$ has a fixed point.

To be more precise, we shall identify uniquely a control of minimal $L^2(0,\ T)$-norm $v$ (which, obviously, depends on $Z$. Thus, in some cases we shall also denote it as $v_Z$). In this way the controlled trajectory $Y = Y_Z$ will also be uniquely determined and the nonlinear map $\mathcal{N}$ well defined. The problem is then reduced to proving that the

map $\mathcal{N}$ has a fixed point. Indeed, if $Z = Y$, and, consequently, $g(z_j)y_j = f(y_j)$ for all $j = 1, \dots, N$, then $Y$ is also solution of the semilinear semi-discrete equation (2.1) and, of course, satisfies the two-grid relaxed final requirement (2.6).

The existence of the fixed point of $\mathcal{N}$ is consequence of Schauder's fixed point Theorem. The key point to apply it is to show a bound on the two-grid control for the linearized equation (2.12) which is independent of $Z$, i.e. the existence of $C > 0$ such that

$$\|v_Z\|_{L^2(0,T)} \leq C \quad \text{for all } Z \in C([0,\ T];\ \mathbb{R}^{N+2}). \tag{2.13}$$

Here and in the sequel we denote by $v_Z$ the control of the linearized system (2.12) to underline the fact that the control depends on the potential $g(Z)$ and thus on $Z$.

To do that we argue as in [17], reducing the problem to the obtention of a suitable observability inequality for the adjoint system:

$$\begin{cases} \varphi_j'' + \frac{2\varphi_j - \varphi_{j+1} - \varphi_{j-1}}{h^2} + g(z_j)\varphi_j = 0, & j = 1, \dots, N,\ 0 < t < T, \\ \varphi_0 = \varphi_{N+1} = 0, & 0 < t < T, \\ \varphi_j(T) = \varphi_j^0,\ \varphi_j'(T) = \varphi_j^1, & j = 1, \dots, N. \end{cases} \tag{2.14}$$

For doing that, however, system (2.14) has to be considered only in the class of slowly oscillating data obtained as extensions to the fine grid (the original one, of size $h$) of data defined on a coarse grid of size $2h$. In other words, we consider the class of data

$$\mathcal{V}_h = \left\{ \Phi = (\varphi_0, \dots, \varphi_{N+1}) : \varphi_{2j+1} = \frac{\varphi_{2j} + \varphi_{2j+2}}{2},\ j = 0, \dots, \frac{N-1}{2} \right\}. \tag{2.15}$$

Note that any vector in $\mathcal{V}_h$ is completely determined by its values on the grid of mesh-size $2h$. Implicitly we are assuming that $1/2h$ is an integer number so that $(N-1)/2 = 1/2h - 1$ is an integer too.

In [17] and [16] it was proved that for $T > T_0$, where $T_0$ is as in Remark 2.2, the following observability inequality holds:

$$E_0 \leq C \int_0^T \left| \frac{\varphi_N}{h} \right|^2 dt, \tag{2.16}$$

with $C > 0$ independent of $h > 0$ and for all solution $\Phi = (\varphi_0, \dots, \varphi_{N+1})$ of (2.14) with data $(\Phi^0,\ \Phi^1) \in \mathcal{V}_h \times \mathcal{V}_h$ when $g \equiv 0$. Here $E_0$ stands for the total energy of solutions at time $t = T$, which is constant in time when $g \equiv 0$:

$$E(t) = \frac{h}{2} \sum_{j=0}^{N} \left[ |\varphi_j'|^2 + \left| \frac{\varphi_{j+1} - \varphi_j}{h} \right|^2 \right]. \tag{2.17}$$

At this point it is important to emphasize that the key ingredient of the proof of convergence for the two-grid algorithm for the linear wave equation is precisely that the observability constant $C$ in (2.16) is uniform, independent of $h$.

Let us now address the perturbed problem (2.14). We first observe that, because of the globally Lipschitz assumption on $f$, the function $g$ is uniformly bounded, i.e.

$$\|g\|_{L^\infty(\mathbb{R})} \leq L, \tag{2.18}$$

$L$ being the Lipschitz constant of $f$. Therefore for all $Z \in C([0,\ T];\ \mathbb{R}^{N+2})$ it follows that

$$\|g(Z)\|_{L^\infty(0,\ T;\ \mathbb{R}^{N+2})} \leq L. \tag{2.19}$$

System (2.14) can then be viewed as a family of perturbed semi-discrete wave equations, the perturbations with respect to the conservative wave equation being a family of zero order bounded potentials. Then a standard perturbation argument allows showing that (2.16) holds for system (2.14) too, with, possibly, a larger observability constant, depending on $L$, but independent of $Z$. In fact, arguing by contradiction, since $h > 0$ is fixed and we are therefore dealing with finite-dimensional dynamical systems, the problem is reduced to show that the following unique continuation property holds for all $Z$:

$$\text{If } \varphi_N(t) = 0,\ 0 < t < T,\ \text{ then } \Phi \equiv 0. \tag{2.20}$$

This property is easy to prove by induction. Indeed, using the boundary condition $\varphi_{N+1} \equiv 0$ and the fact that $\varphi_N \equiv 0$, and writing the equation (2.14) for $j = N$ we deduce that

$$\frac{\varphi_{N-1}}{h^2} = \varphi_N'' + \frac{2\varphi_N - \varphi_{N-1}}{h^2} + g(z_N)\varphi_N = 0. \tag{2.21}$$

This implies that $\varphi_{N-1} = 0$. Repeating this argument we deduce that $\Phi \equiv 0$.

Once (2.16) holds for the solutions of (2.14) with initial data in $\mathcal{V}_h \times \mathcal{V}_h$, uniformly on $Z$, system (2.14) turns out to be controllable in the sense of (2.6) with an uniform bound on the control, independent of $Z$, i.e.

$$\|v\|_{L^2(0,\ T)} \leq C(h,\ \|(Y^0,\ Y^1)\|,\ L,\ T) \quad \text{for all } Z. \tag{2.22}$$

We emphasize that the bound (2.22), in principle, depends on the time of control $T$, the mesh-size $h$, the Lipschitz constant $L$ of the nonlinearity $f$ and the norm of the initial data to be controlled, but is independent of $Z$.

As a consequence of (2.22) a similar estimate can be obtained for the state $Y$ solution of (2.12), i.e.

$$\|Y\|_{C^1([0,\ T];\ \mathbb{R}^{N+2})} \leq C \quad \text{for all } Z. \tag{2.23}$$

This allows applying the Schauder's fixed point theorem to the map $\mathcal{N}$, which turns out also to be compact from $L^2(0,\ T;\ \mathbb{R}^{N+2})$ into itself, thanks to (2.23). In this way we conclude that, for all $h > 0$, system (2.4) is controllable in the sense of (2.6).

*Step* 2. *Uniform controllability with respect to h.* In the previous step we have proved the controllability of (2.4) but with estimates on controls and states depending on $h$.

In order to pass to the limit as $h \to 0$ we need to get a bound on controls and states which is independent of $h$. For doing that we need to assume that $T > T_0$ (so that the linear unperturbed numerical schemes are uniformly, with respect to $h > 0$, two-grid controllable) and that the initial data $(y^0,\ y^1)$ belong to $H^s(0,\ 1) \times H^{s-1}(0,\ 1)$.

The last requirement is important to get the compactness of the nonlinear term. Indeed, in that setting the control for the continuous wave equation (2.1) belongs to $H^s(0,\ T)$ rather than $L^2(0, T)$ and the controlled trajectory $y$ then belongs to $C([0,\ T];\ H^s(0,\ 1)) \cap C^1([0,\ T];\ H^{s-1}(0,\ 1))$. This guarantees the required compactness properties to deal with the nonlinear term $f(y)$ in (2.1). Indeed, when passing to the limit, the pointwise convergence of the state in $(0,\ 1) \times (0,\ T)$ is needed and this is achieved by means of the extra $H^s$ regularity imposed on the initial data (see [25]). This is necessary both when treating the continuous equation (2.1) by fixed point arguments and also when dealing with numerical approximation issues and limit processes as $h \to 0$.

To analyze the controllability of the systems under consideration in $H^s(0,\ 1) \times H^{s-1}(0,\ 1)$, we first need to analyze the $H^{-s}$-version of the observability inequality (2.16), namely:

$$E_{0,\ -s} \leq C_s \left\| \frac{\varphi_N}{h} \right\|^2_{H^{-s}(0,\ T)}. \tag{2.24}$$

Inequality (2.24) may be proved for the adjoint system (2.14) in the absence of the potential induced by the nonlinearity, i.e. for

$$\begin{cases} \psi_j'' + \frac{2\psi_j - \psi_{j+1} - \psi_{j-1}}{h^2} = 0, & j = 1, \dots, N,\ 0 < t < T, \\ \psi_0 = \psi_{N+1} = 0, & 0 < t < T, \\ \psi_j(T) = \psi_j^0,\ \psi_j(T) = \psi_j^1, & j = 1, \dots, N. \end{cases} \tag{2.25}$$

More precisely, for $0 < s < 1/2$ and $T > T_0$ as in Theorem 2.1, there exists a constant $C_s$ such that (2.24) holds for all solution $\psi$ of (2.25) with initial data in $\mathcal{V}_h \times \mathcal{V}_h$ and all $h > 0$. We emphasize that the constant $C_s$ is independent of $h$.

In (2.24) $E_{0,\ -s}$ stands for the $H^{-s}$ version of the energy of system (2.25), which is constant in time. It can be defined easily by means of the Fourier expansion of solutions and it is then the discrete analogue of the continuous energy

$$E_{0,\ -s} = \frac{1}{2}\left[ \left\| \psi^0 \right\|^2_{H^{1-s}(0,\ 1)} + \left\| \psi^1 \right\|^2_{H^{-s}(0,\ 1)} \right] \tag{2.26}$$

which is constant in time for the solutions of the unperturbed adjoint wave equation

$$\begin{cases} \psi'' - \psi_{xx} = 0, & 0 < x < 1, 0 < t < T, \\ \psi(0,\ t) = \psi(1,\ t) = 0, & 0 < t < T, \\ \psi(x,\ T) = \psi^0(x),\ \psi_t(x,\ T) = \psi^1(x), & 0 < x < 1. \end{cases} \tag{2.27}$$

The inequality (2.24) may be obtained, as (2.16), by the two methods mentioned above:

- It can be proved as a consequence of (2.16) directly using interpolation arguments (see, for instance, [25]);
- It can also be obtained by the variant of the Ingham inequality in [16].

Once (2.24) is proved for the unperturbed system (2.25), uniformly on $h > 0$, we are in conditions to prove it for the perturbed system (2.14) uniformly on $h > 0$ and $Z$ too. To do it we use a classical perturbation and compactness argument (see [25]).

We decompose the solution $\Phi$ of (2.14) as $\Phi = \Psi + \Sigma$ where $\Psi$ solves the unperturbed system (2.25) with the same data $(\Phi^0,\ \Phi^1)$ as $\Phi$ itself and where the remainder $\Sigma = (\sigma_0, \dots, \sigma_{N+1})$ solves

$$\begin{cases} \sigma_j'' + \frac{2\sigma_j - \sigma_{j+1} - \sigma_{j-1}}{h^2} = -g(z_j)\varphi_j, & j = 1, \dots, N,\ 0 < t < T, \\ \sigma_0 = \sigma_{N+1} = 0, & 0 < t < T, \\ \sigma_j(T) = \sigma_j'(T) = 0, & j = 1, \dots, N. \end{cases} \tag{2.28}$$

In view of (2.24), which is valid for $\Psi$, we deduce that

$$E_{0,\,-s} \leq 2C_s \Big[ \Big\| \frac{\varphi_N}{h} \Big\|^2_{H^{-s}(0,\,T)} + \Big\| \frac{\sigma_N}{h} \Big\|^2_{H^{-s}(0,\,T)} \Big]. \tag{2.29}$$

Using discrete multipliers (see [8]) it follows that

$$\Big\| \frac{\sigma_N}{h} \Big\|_{L^2(0,\,T)} \leq C \| \{ g(z_j)\varphi_j \} \|_{L^2(0,\,T;\,\ell^2_h)} \tag{2.30}$$

with a constant $C$ which depends on $T$ but is independent of $h$.

In (2.30) we use the notation

$$\| \{p_j\} \|_{L^2(0,\,T;\,\ell^2_h)} = \Big[ h \int_0^T \sum_{j=1}^N p_j^2(t)\, dt \Big]^{1/2} \tag{2.31}$$

which is simply the $L^2$-norm, scaled to the mesh-size $h > 0$.

Combining (2.30)–(2.31) and using that the nonlinearity $g$ is uniformly bounded we deduce that

$$E_{0,\,-s} \leq C \Big[ \Big\| \frac{\varphi_N}{h} \Big\|^2_{H^{-s}(0,\,T)} + \| \Phi \|^2_{L^2(0,\,T;\,\ell^2_h)} \Big], \tag{2.32}$$

for every solution $\Phi$ of (2.14) with data $(\Phi^0,\ \Phi^1)$ in $\mathcal{V}_h \times \mathcal{V}_h$, every $h > 0$ and $Z$.

To conclude we can apply a compactness-uniqueness argument whose details may be found in [28] where it was fully developed in the context of the $2-d$ semi-discrete wave equation. It consists simply in showing, by contradiction, that there exists an uniform constant $C > 0$ such that

$$\| \Phi \|_{L^2(0,\,T;\,\ell^2_h)} \leq C \Big\| \frac{\varphi_N}{h} \Big\|_{H^{-s}(0,\,T)} \tag{2.33}$$

for every solution $\Phi$ of (2.14), every $h > 0$ and $Z$. To do it we assume that there exists a sequence $h \to 0$, potentials of the form $g(Z_h)$ and initial data in $\mathcal{V}_h \times \mathcal{V}_h$ for which (2.33) fails and, consequently,

$$\left\| \frac{\varphi_N}{h} \right\|_{H^{-s}(0,\,T)} \to 0, \quad h \to 0 \tag{2.34}$$

$$\|\Phi\|_{L^2(0,\,T;\,\ell^2_h)} = 1. \tag{2.35}$$

Combining (2.32), (2.34) and (2.35), the corresponding sequence of data $(\Phi^0_h,\ \Phi^1_h)$ turns out to be bounded in $H^{1-s}(0,\,1) \times H^{-s}(0,\,1)$ (at this point we are implicitly working with the piecewise linear extension of the data). By the well-posedness of (2.14) in these spaces the corresponding solutions $\Phi_h$ turn out to be bounded in $L^\infty(0,\ T;\ H^{s-1}(0,\,1)) \cap W^{1,\,\infty}(0,\ T;\, H^{-s}(0,\,1))$. Therefore, they are relatively compact in $L^2(0,\ T;\ L^2(0,\,1))$. Passing to the limit as $h \to 0$ we obtain a solution $\varphi$ of an adjoint wave equation of the form

$$\begin{cases} \varphi'' - \varphi_{xx} + a(x,\,t)\varphi = 0, & 0 < x < 1,\ 0 < t < T, \\ \varphi(0,\,t) = \varphi(1,\,t) = 0, & 0 < t < T, \\ \varphi(x,\,T) = \varphi^0(x),\ \varphi_t(x,\,0) = \varphi^1(x), & 0 < x < 1, \end{cases} \tag{2.36}$$

such that

$$\partial_x \varphi(1,\,t) = 0, \quad 0 < t < T \tag{2.37}$$

and

$$\|\varphi\|_{L^2(0,\,T;\,L^2(0,\,1))} = 1. \tag{2.38}$$

This is clearly a contradiction since, in view of the unique continuation property of the solutions of the wave equation (2.36), (2.37) implies that $\varphi \equiv 0$, which is incompatible with (2.38). This is true because $T > T_0$ and, in particular $T > 2$.

In this argument the bounded limit potential $a = a(x,\,t)$ in (2.36) arises as weak-$*$ limit of the discrete ones $g\,(Z_h)$, (of its piecewise linear extension to $0 < x < 1,\ 0 < t < T$, to be more precise). Therefore $a$ also fulfills the bound $\|a\|_\infty \leq L$, $L$ being the Lipschitz constant of $f$.

For this argument to apply one needs to pass to the limit in the potential perturbation $g\,(Z_h)\,\Phi_h$ in (2.14). This can be done because of the strong convergence of $\Phi_h$ (of its extension to $0 < x < 1$) in $L^2((0,\ 1) \times (0,\ T))$.

Once (2.24) is known to hold for all $h > 0$ and all data in $\mathcal{V}_h \times \mathcal{V}_h$ this allows proving the uniform controllability of (2.4) in the spaces $H^s(0,\,1) \times H^{-1+s}(0,\,1)$, in the two-grid sense (2.6). This can be done applying the fixed point argument in Step 1. More precisely, it follows that there exists a family of controls $v_h \in H^s(0,\ T)$, with an uniform bound

$$\|v_h\|_{H^s(0,\,T)} \leq C \left\| \left(Y^0_h,\ Y^1_h\right) \right\|_{H^s(0,1) \times H^{s-1}(0,1)} \tag{2.39}$$

such that the solutions $Y_h$ of (2.4) satisfy (2.6).

*Step* 3. *Two-grid observability* $\Longrightarrow$ *Two-grid controllability.* For the sake of completeness, let us show how the two-grid control of (2.12) can be obtained as a consequence of the observability inequality (2.24) for the solutions of the adjoint wave equation (2.14) with initial data in the class $\mathcal{V}_h \times \mathcal{V}_h$ in (2.15) of slowly oscillating data.

We introduce the functional

$$J_h\left(\Phi^0,\ \Phi^1\right) = \frac{1}{2}\left\| \frac{\varphi_N}{h} \right\|^2_{H^{-s}(0,\,T)} + h\sum_{j=1}^{N}\left[y_j^0\varphi_j'(0) - y_j^1\varphi_j(0)\right], \tag{2.40}$$

which is continuous and convex. Moreover, in view of (2.24), the functional $J_h\colon \mathcal{V}_h \times \mathcal{V}_h \to \mathbb{R}$ is uniformly coercive. Let us denote by $(\Phi_h^{0,*},\ \Phi_h^{1,*})$ the minimizer of $J_h$ over $\mathcal{V}_h \times \mathcal{V}_h$. Then,

$$\left\langle DJ_h\left(\Phi_h^{0,*},\ \Phi_h^{1,*}\right),\ \left(\Phi^0,\ \Phi^1\right)\right\rangle = 0 \tag{2.41}$$

for all $(\Phi^0,\ \Phi^1) \in \mathcal{V}_h \times \mathcal{V}_h$. This implies that

$$\left(\frac{\varphi_N^*}{h},\ \frac{\varphi_N}{h}\right)_{H^{-s}(0,\,T)} + h\sum_{j=1}^{N}\left[y_j^0\varphi_j'(0) - y_j^1\varphi_j(0)\right] = 0 \tag{2.42}$$

where $\Phi_h^*$ stands for the solution of (2.14) with the minimizer $(\Phi_h^{0,*},\ \Phi_h^{1,*})$ as data and $\Phi$ the solution with data $(\Phi^0,\ \Phi^1)$.

We now choose the control

$$v_h = I_s\frac{\varphi_N^*}{h}, \tag{2.43}$$

where $I_s\colon H^{-s}(0,\ T) \to H^s(0,\ T)$ is the canonical duality isomorphism.

Equation (2.42) then reads

$$\int_0^T v_h\frac{\varphi_N}{h}dt + h\sum_{j=0}^{N}\left[y_j^0\varphi_j'(0) - y_j^1\varphi_j(0)\right] = 0. \tag{2.44}$$

On the other hand, using (2.43) as control in (2.12), multiplying by $\Phi$ the solution of the adjoint system (2.14), adding on $j = 1, \ldots,\ N$ and integrating by parts with respect to $t \in (0,\ T)$, we deduce that

$$\int_0^T v\frac{\varphi_N}{h}dt + h\sum_{j=1}^{N}\left[y_j^0\varphi_j'(0) - y_j^1\varphi_j(0)\right] - h\sum_{j=1}^{N}\left[y_j(T)\varphi_j^1 - y_j'(T)\varphi_j^0\right] = 0. \tag{2.45}$$

Combining (2.44)–(2.45) we deduce that the solution $Y_h$ of (2.12) satisfies

$$h\sum_{j=1}^{N}\left[y_j(T)\varphi_j^1 - y_j'(T)\varphi_j^0\right] = 0 \quad \text{for all } (\varphi^0,\ \varphi^1) \in \mathcal{V}_h \times \mathcal{V}_h. \tag{2.46}$$

This means that both $Y_h(T)$ and $Y_h'(T)$ are perpendicular to $\mathcal{V}_h$. This is equivalent to the two-grid control requirement (2.6) with $z^0 \equiv z^1 \equiv 0$.

In view of this construction and using the observability inequality (2.24), which is uniform with respect to $h > 0$ and $Z$, we can obtain uniform bounds on the controls. Indeed, by (2.43) we have

$$\|v_h\|_{H^s(0,\,T)} = \left\| \frac{\varphi_N^*}{h} \right\|_{H^{-s}(0,\,T)}. \tag{2.47}$$

On the other hand, the minimizer $(\Phi_h^{0,*},\ \Phi_h^{1,*})$ is such that

$$J\left(\Phi_h^{0,*},\ \Phi_h^{1,*}\right) \leq 0 \tag{2.48}$$

and this implies

$$\begin{aligned} \frac{1}{2}\|\frac{\varphi_N^*}{h}\|^2_{H^{-s}(0,\,T)} &\leq \left| h \sum_{j=1}^{N} \left[ y_j^0 \varphi_j^{*'}(0) - y_j^1 \varphi_j^*(0) \right] \right| \\ &\leq \|(Y^0,\ Y^1)\|_{H^s(0,1)\times H^{s-1}(0,1)} \sqrt{E^*_{0,\,-s}} \end{aligned} \tag{2.49}$$

where $E^*_{0,\,-s}$ denotes the $E_{0,\,-s}$ energy of the minimizer $(\Phi_h^{0,*},\ \Phi_h^{1,*})$.

Combining (2.48), (2.49) and the observability inequality (2.24) we deduce that

$$\|v_h\|_{H^s(0,\,T)} \leq 2\sqrt{C_s}\|(Y^0,\ Y^1)\|_{H^s(0,1)\times H^{s-1}(0,1)}, \tag{2.50}$$

where $C_s$ is the same constant as in (2.24). In particular, the bound (2.50) on the control is independent of $h > 0$ and $Z$.

*Step* 4. *Passing to the limit.* Using the uniform bound (2.39) it is easy to pass to the limit and get the null-controllability of the semilinear wave equation (2.1).

Indeed, as a consequence of (2.39) and by the well-posedness of (2.4) we deduce that the controlled state $Y_h$ is uniformly bounded in $L^\infty(0,\ T;\ H^s(0,\ 1)) \cap W^{1,\infty}(0,\ T;\ H^{s-1}(0,\ 1))$.

By extracting subsequences we have

$$v_h \rightharpoonup v \text{ weakly in } H^s(0,\ T) \tag{2.51}$$

$$Y_h \rightharpoonup y \text{ weakly in } L^2(0,\ T;\ H^s(0,\ 1)) \cap H^1(0,\ T;\ H^{s-1}(0,\ 1)). \tag{2.52}$$

Consequently, in particular,

$$v_h \to v \text{ strongly in } L^2(0,\ T) \tag{2.53}$$

$$Y_h \to y \text{ strongly in } L^2((0,\ 1) \times (0,\ T)). \tag{2.54}$$

These convergences suffice to pass to the limit in (2.4) and to get (2.1). The strong convergence (2.54) is particularly relevant when doing that since it allows passing to the limit in the nonlinearity.

Here the convergence of the states $Y_h$ may be understood in the sense that its extensions to functions defined for all $0 < x < 1$ converge.

One can also check that the limit state $y = y(x, t)$ satisfies the final exact controllability requirement (2.3) as a consequence of the two-grid relaxed version (2.6) that the semi-discrete state $Y_h$ satisfies. This can be done either by transposition or by compactness.

This concludes the sketch of the proof of Theorem 2.1.

**Remark 2.3.** Several remarks are in order:

- The proof we have given can be adapted to other equations and schemes. In particular it applies to the two-grid finite element approximation of (2.1).
- In [2] a mixed finite-element discretization scheme has been introduced for which the uniform controllability property holds without requiring any filtering or two-grid adaptation. The arguments we have developed here can also be adapted to prove convergence of that method in the semilinear case under the globally Lipschitz assumption on the nonlinearity $f$.
- In [12] it was proved that the standard finite-difference semi-discretization for the exact controllability of the following beam equation converges without filtering or two-grid adaptation:

  $$y_{tt} + y_{xxxx} = 0.$$

  The method of proof of Theorem 2.1 allows showing that the same is true in the semilinear context too.
- The proof of convergence of the two-grid control algorithm is still to be developed for numerical approximations of the wave equation in the multi-dimensional case. But, in view of the proof of Theorem 2.1, which can be easily adapted to the multi-dimensional framework, we can say that, if convergence is proved in the linear case, the same will hold in the semilinear one too, for globally Lipschitz nonlinearities.
- For the semilinear wave equation (2.1) the *local* null-controllability can be proved in wider classes of nonlinearities satisfying $f'(0) = 0$. Here by local null-controllability we refer to the property that sufficiently small initial data can be driven to the null state, i.e. to the existence of $\delta > 0$ such that the control driving the solution to the final equilibrium $\{0, 0\}$ exists for all initial data $\{y^0, y^1\}$ such that

  $$\|y^0\|_{L^2(0,1)} + \|y^1\|_{H^{-1}(0,1)} \leq \delta.$$

  It can be proved as a consequence of the controllability of the linear wave equation applying the inverse function theorem around the null state. In order to guarantee the well-posedness of the semilinear wave equation (2.1) in

$L^2(0,\,1) \times H^{-1}(0,\,1)$ one also needs to impose a growth condition on the nonlinearity of the form

$$|f'(s)| \leq C|s| \quad \text{for all } s \in \mathbb{R}.$$

But this allows proving local controllability for quadratic nonlinearities, for instance (see [24]).

The method of proof of Theorem 2.1 can be used to prove the convergence of the two-grid method in that context of local controllability too.

- In [24] it was also observed that for nonlinearities with the good sign property, for instance, for
$$f(s) = |s|^{p-1}s \quad \text{for all } s \in \mathbb{R}$$
with $1 < p \leq 2$, every initial datum may be driven to zero for a sufficiently large time. For doing that one first uses the exponential decay of solutions with boundary feedback ([9]) to later apply the local controllability property when the solution becomes small enough.

  To adapt that result to the framework of the two-grid scheme one could need a uniform (with respect to $h$) stabilization result for the numerical schemes with boundary feedback. However it is well known that, due to the lack of uniform boundary observability as $h \to 0$, the uniform stabilization property fails. In [19] and [20] (see also [18]) the uniform (with respect to $h$) exponential decay property was proved but by adding a viscous damping term distributed all along the mesh. In view of the efficiency of the two-grid approach at the level of controllability, one would expect the uniform (with respect to $h > 0$) exponential decay property to hold for initial data in the space $\mathcal{V}_h \times \mathcal{V}_h$ without the extra viscous damping term. But this property does not seem to happen. Indeed, when trying to obtain the uniform exponential decay from the uniform observability inequality a technical difficulty appears since the space $\mathcal{V}_h \times \mathcal{V}_h$ is not invariant under the flow of the semi-discrete wave equation. Thus, the observability inequality we have obtained in the time interval $[0,\,T]$ with $T > T_0$ can not be extended for all $t \geq 0$, a fact that would be needed for proving the exponential decay. But in fact, the situation is much worse and the uniform exponential decay fails to hold since, despite of the fact that the two-grid initial data have a distribution of energy so that most of it is concentrated on the low frequencies, as time evolves, this partition of energy is lost because, precisely, high frequency components are weakly dissipated. The apparently purely technical difficulty for proving the uniform decay turns out to be in fact the reason for the lack of uniform decay.

- Recently it has also been proved that $1 - d$ semilinear wave equations are controllable in the sense that two different equilibria can be connected by a controlled trajectory provided they belong to the same connected component of

the set of stationary solutions (see [3]). This holds without any sign restriction on the nonlinearity and therefore without excluding blow-up phenomena to occur. Proving the convergence of the two-grid algorithm in what concerns that result is an open problem too.

- The main drawback of the arguments we have used in the proof of Theorem 2.1 is that they do not provide any explicit estimate on the cost of controlling the system with respect to the Lipschitz constant $L$ of the nonlinearity. This is due to the use of compactness-uniqueness arguments in the obtention of the uniform (with respect to $h$) observability estimates (2.24) in the class of initial data $\mathcal{V}_h \times \mathcal{V}_h$. Therefore we may not recover by this method the property of controllability of the semilinear wave equation under the sharp superlinear growth condition (2.2).

- The existence of the convergent controls of the semi-discrete semilinear system has been proved by means of a fixed point method. This adds extra technical difficulties for its efficient computation. The most common tool to deal with such problem, for $h$ fixed and after a suitable time discretization, is the Newton method with variable step. It is applicable in the present situation since the nonlinear map $\mathcal{N}$ under consideration is differentiable when the nonlinearity $f$ in the equation is $C^1$. In each iteration of the Newton method, one is lead to solve a linearized control problem. But this one is solvable by means of a standard conjugate gradient algorithm ([6]) because of the uniform observability properties that are guaranteed to hold, as we have seen, due to the two-grid relaxation we have introduced. A complete numerical study of these issues is yet to be developed.

- The limit control $v$ we have obtained can be proved to be a fixed point of the nonlinear map $\mathcal{N}$ that corresponds to the controllability of the semilinear continuous wave equation, based on the HUM controls of minimal $L^2(0, T)$-norm for the linearized wave equations. Thus, the controls we are dealing with both, for the continuous and the semi-discrete equation, belong to the same category.

## 3. Boundary control of the finite-difference space semi-discretizations of the heat equation

**3.1. Problem formulation.** This section is devoted to analyze the null controllability of the space semi-discretizations, by means of finite differences, of the heat equation in multi-dimensional domains. To simplify the presentation we focus on the $2 - d$ case although the same results, with similar proofs, apply in any dimension $d \geq 2$.

The heat equation in bounded domains is known to be null-controllable from any open, non-empty subset of the domain or its boundary [5]. Thus, it is natural to

analyze whether the control is the limit of the controls of the semi-discrete systems as the mesh-size tends to zero. But this turns out not to be the case even for the heat equation in the square when the control is applied on a strict subset of one of the segments constituting its boundary (see [30]).

In this section we prove a positive counterpart of that result. More precisely, we prove that convergence holds when the control acts on a whole side of the boundary. The proof uses the Fourier series development of solutions, which allows reducing the problem to a one-parameter family of controllable $1-d$ heat equations. As a consequence of that result we can prove convergence for general domains when the control is applied on the whole boundary. For that it is sufficient to extend the initial data in the original domain to data in a square containing it and then obtaining the controls on the boundary of the original domain as restrictions to the boundary of the states defined in the extended square.

The same results hold in any space dimension.

To be more precise, let $\Omega$ be the square $\Omega = (0,\pi)\times(0,\pi)$ of $\mathbb{R}^2$. Let $\Gamma_0$ be one side of its boundary, say $\Gamma_0 = \{(x_1,0) : 0 < x_1 < \pi\}$.

Consider the heat equation with control on $\Gamma_0$:

$$\begin{cases} y_t - \Delta y = 0 & \text{in } \Omega\times(0,T), \\ y = 0 & \text{on } [\partial\Omega\setminus\Gamma_0]\times(0,T), \\ y = v & \text{on } \Gamma_0\times(0,T), \\ y(x,0) = y^0(x) & \text{in } \Omega. \end{cases} \tag{3.1}$$

Here $y = y(x,t)$, with $x = (x_1,x_2)$, is the *state* and $v = v(x_1,t)$ is the *control*.

System (3.1) is well-known to be null-controllable in any time $T > 0$ (see Fursikov and Imanuvilov [5] and Lebeau and Robbiano [11]). More precisely, the following holds: *For any $T > 0$ and any $y^0 \in L^2(\Omega)$ there exists $v \in L^2(\Gamma_0\times(0,T))$ such that the solution $y = y(x,t)$ of* (3.1) *satisfies*

$$y(x,T) \equiv 0. \tag{3.2}$$

*Moreover, there exists a constant $C > 0$ depending on $T$ but independent of the initial datum $y^0$ such that*

$$\|v\|_{L^2(\Gamma_0\times(0,T))} \le C\|y^0\|_{L^2(\Omega)} \quad \text{for all } y^0 \in L^2(\Omega). \tag{3.3}$$

In fact the same result holds in a general smooth bounded domain $\Omega$ and with controls in any open non-empty subset $\Gamma_0$ of its boundary.

In the present setting, this result is equivalent to an observability inequality for the *adjoint heat equation*:

$$\begin{cases} \varphi_t + \Delta\varphi = 0 & \text{in } \Omega\times(0,T), \\ \varphi = 0 & \text{on } \partial\Omega\times(0,T), \\ \varphi(x,T) = \varphi^0(x) & \text{in } \Omega. \end{cases} \tag{3.4}$$

More precisely, it is equivalent to the existence of a positive constant $C > 0$ such that

$$\|\varphi(0)\|^2_{L^2(\Omega)} \leq C \int_0^T \int_{\Gamma_0} \left| \frac{\partial \varphi}{\partial n} \right|^2 d\sigma dt \quad \text{for all } \varphi^0 \in L^2(\Omega). \tag{3.5}$$

Here and in the sequel by $n$ we denote the unit exterior normal vector field and by $\partial \cdot / \partial n$ the normal derivative. In this case, over $\Gamma_0$, $\partial \cdot / \partial n = -\partial \cdot / \partial_{x_2}$.

Let us now consider the finite-difference space semi-discretizations of (3.1) and (3.4).

Given $N \in \mathbb{N}$ we set $h = \pi/(N+1)$ and we consider the mesh

$$x_{i,j} = (ih, jh), \quad i, j = 0, \ldots, N+1. \tag{3.6}$$

We now introduce the finite-difference semi-discretizations:

$$\begin{cases} y'_{j,k} + \frac{1}{h^2}(4y_{j,k} - y_{j+1,k} - y_{j-1,k} - y_{j,k+1} - y_{j,k-1}) = 0, \ (j,k) \in \Omega_h, \ 0 < t < T, \\ y_{j,k} = 0, \ (j,k) \in [\partial\Omega \setminus \Gamma_0]_h, \quad 0 < t < T, \\ y_{j,0} = v_j, \ j = 0, \ldots, N+1, \quad 0 < t < T, \\ y_{j,k}(0) = y^0_{j,k}, \qquad\qquad (j,k) \in \Omega_h, \end{cases} \tag{3.7}$$

and

$$\begin{cases} \varphi'_{j,k} - \frac{1}{h^2}(4\varphi_{j,k} - \varphi_{j+1,k} - \varphi_{j-1,k} - \varphi_{j,k+1} - \varphi_{j,k-1}) = 0, \ (j,k) \in \Omega_h, \ 0 < t < T, \\ \varphi_{j,k} = 0, \qquad (j,k) \in [\partial\Omega]_h, \ 0 < t < T, \\ \varphi_{j,k}(T) = \varphi^0_{j,k}, \quad (j,k) \in \Omega_h. \end{cases} \tag{3.8}$$

To simplify the notations, we have denoted by $\Omega_h$ (resp. $\partial\Omega_h$) the set of interior (resp. boundary) nodes, and by $[\partial\Omega \setminus \Gamma_0]_h$ the set of indices $(j,k)$ so that the corresponding nodes belong to $\partial\Omega \setminus \Gamma_0$. Here and in the sequel $y_{j,k} = y_{j,k}(t)$ (resp. $\varphi_{j,k} = \varphi_{j,k}(t)$) stands for an approximation of the solution $y$ of (3.1) (resp. $\varphi$ of (3.4)) at the mesh-points $x_{i,j}$. On the other hand, $v_j$ denotes the control that acts on the semi-discrete system (3.7) through the subset $[\Gamma_0]_h$ of the boundary. Note that the control does not depend of the index $k$ since the subset of the boundary $[\Gamma_0]_h$ where the control is being applied corresponds to $k = 0$.

In order to simplify the notation we introduce the vector unknowns and control

$$Y_h = (y_{j,k})_{0 \leq j,k \leq N+1}, \quad \Phi_h = (\phi_{j,k})_{0 \leq j,k \leq N+1}, \quad V_h = (v_j)_{1 \leq j \leq N}, \tag{3.9}$$

that we shall often denote simply by $Y$, $\Phi$ and $V$.

Accordingly, systems (3.7) and (3.8) read as follows:

$$\begin{cases} Y'_h + A_h Y_h = B_h V_h, \\ Y_h(0) = Y^0_h, \end{cases} \tag{3.10}$$

$$\begin{cases} \Phi_h' - A_h \Phi_h = 0, \\ \Phi_h(T) = \Phi_h^0. \end{cases} \tag{3.11}$$

We denote by $A_h$ the usual positive-definite symmetric matrix associated with the five-point finite-different scheme we have employed in the discretization of the Laplacian so that

$$(A_h W)_{j,k} = \frac{1}{h^2}(4w_{j,k} - w_{j+1,k} - w_{j-1,k} - w_{j,k+1} - w_{j,k-1}), \tag{3.12}$$

for the inner nodes. In (3.11) the homogenous boundary conditions have been integrated by assuming simply that their values in the expression (3.12) have been replaced by the zero one. On the other hand the linear operator $B_h$ in (3.10) is such that the action of the control $v_j$ enters on those nodes which are neighbors to those of $[\Gamma_0]_h$, i.e. for $k = 1$, so that $[B_h V]_{j,k} = 0$ whenever $2 \leq k \leq N$ but $[B_h V]_{j,1} = -v_j/h^2$.

The null-controllability problem for system (3.10) reads as follows: Given $Y^0 \in \mathbb{R}^{N+2\times N+2}$ to find $V \in L^2(0, T;\ \mathbb{R}^N)$ such that the solution $Y$ of (3.10) satisfies

$$Y(T) = 0. \tag{3.13}$$

On the other hand, the problem of observability for system (3.11) consists in proving the existence of $C > 0$ such that

$$\|\Phi(0)\|_h^2 \leq Ch \int_0^T \sum_{j=1}^{N} \left| \frac{\phi_{j,1}}{h} \right|^2 dt \tag{3.14}$$

for every solution $\Phi$ of (3.11).

In (3.14) $\|\cdot\|_h$ stands for the scaled Euclidean norm

$$\|\Phi\|_h = \left[ h^2 \sum_{j,k=0}^{N+1} |\phi_{j,k}|^2 \right]^{1/2} \tag{3.15}$$

and the right hand side term of inequality (3.14) represents the discrete version of the $L^2$-norm of the normal derivative in (3.5).

A similar problem can be formulated in general bounded smooth domains $\Omega$. In that case, obviously, the domain $\Omega$ needs to be approximated by domains $\Omega_h$ whose boundaries are constituted by mesh-points. We first address the case of the square domain by Fourier series to later derive some consequences for general domains.

All this section is devoted to the problem of null control. Obviously the situation is different if the final requirement is relaxed to an approximate controllability condition. In that context, as a consequence of the null controllability of the limit heat equation and the convergence of the numerical algorithm it can be proved that the state $Y_h$ at time $t = T$ can be driven to a final state of norm $\varepsilon_h$ such that $\varepsilon_h \to 0$ as $h \to 0$. But, as mentioned above, this property fails in general in the framework of null controllability. At this point the work in [10] is also worth mentioning. There it was proved that, in the context of analytic semigroups, one can also get uniform bounds on the number of iterations needed for computing controls using conjugate gradient algorithms.

**3.2. The square domain.** The goal of this subsection is to prove that, as $h \to 0$, the controls $V_h$ of (3.10) are uniformly bounded and converge in $L^2(\Gamma_0 \times (0, T))$ to the control of (3.1). All along this section we deal with controls of minimal $L^2$-norm, the so-called HUM controls.

In order to make this convergence result more precise it is convenient to take the following facts into account:

- To state and analyze the convergence of the discrete states $Y_h$ it is convenient to extend them to continuous functions $y_h(x, t)$ with respect to the space variable $x = (x_1, x_2)$. This can be done, as in the previous section, in two different ways either by considering a piecewise linear and continuous extension or extending the discrete Fourier expansion of solutions by keeping exactly the same analytic expression. The control $V_h$ has to be extended as well to a function depending on the continuous variable $0 < x_1 < \pi$. This can be done in the same two ways.

- To state the convergence of controls as $h \to 0$ the initial data $Y_h^0$ in (3.10) have to be chosen in connection with the initial data $y^0$ of the PDE (3.1). This may be done in several ways. When $y^0$ is continuous, $Y_h^0$ can be taken to be the restriction of $y^0$ to the mesh-points. Otherwise, one can take average values over cells, or simply truncate the Fourier expansion of the continuous initial datum $y^0$ by taking the first $N \times N$ terms.

This being made precise, the following result holds:

**Theorem 3.1.** *Let $T > 0$ be any positive control time. Let $y^0 \in L^2(\Omega)$ and $Y_h^0$ be as above. Then, the null controls $V_h$ for the semi-discrete problem* (3.10) *are uniformly bounded, with respect to h and converge in $L^2(\Gamma_0 \times (0, T))$ towards the null control of the heat equation* (3.1). *The semi-discrete controlled states $Y_h$ also converge to the controlled state y of the heat equation in $L^2(0, T; H^{-1}(\Omega))$ satisfying the null final condition* (3.2).

**Remark 3.2.** The result is sharp in what concerns the support $\Gamma_0$ of the control. Indeed, as pointed out in [30] this result fails when $[\Gamma_0]_h$ is replaced by the set of indices $[\Gamma_0^*]_h$ in which the first node corresponding to the index $j = 1$ is removed. In that case the observability inequality (3.14) fails because of the existence of a non-trivial solution (3.11) such that $\Phi$ vanishes on $[\Gamma_0^*]_h$. This is so in fact because of the existence of a non-trivial eigenvector of the discrete Laplacian $A_h$ with eigenvalue $\lambda_h = 4/h^2$, taking alternating values $\pm 1$ along the diagonal and vanishing out of it.

The main elements of the proof of this result are the following. The key point is precisely proving that the observability inequality (3.14) is uniform with respect to the mesh-size $h > 0$. Once this is done standard variational methods allow proving that the controls are uniformly bounded and then passing to the limit as $h \to 0$. We refer to [27] where the same issue was addressed for the heat equation in thin cylindrical

domains by similar tools and to [14] where the limit process was described in detail in the context of the finite-difference semi-discrete approximation of the $1-d$ heat equation.

The method of proof of the uniform estimate (3.14) depends heavily on the Fourier decomposition of solutions. To develop it we need some basic facts about the Fourier decomposition of the discrete Laplacian.

The eigenvalue problem associated with the semi-discrete system (3.11) is as follows:

$$\begin{cases} \frac{1}{h^2}\left[4w_{j,k} - w_{j+1,k} - w_{j-1,k} - w_{j,k+1} - w_{j,k-1}\right] = \lambda w_{j,k}, & (j,k) \in \Omega_h, \\ w_{j,k} = 0, & (j,k) \in [\partial\Omega]_h. \end{cases} \tag{3.16}$$

Its spectrum may be computed explicitly:

$$\lambda^{\ell,m}(h) = \frac{4}{h^2}\left[\sin^2\left(\frac{\ell h}{2}\right) + \sin^2\left(\frac{mh}{2}\right)\right] \tag{3.17}$$

$$W^{\ell,m}(h) = w^{\ell,m}(x)\big|_{x=(jh,kh),\, j,k=0,\cdots,N+1} \tag{3.18}$$

for $\ell, m = 1, \ldots, N$, where $w^{\ell,m}(x)$ are the eigenfunctions of the continuous Laplacian:

$$w^{\ell,m}(x) = \frac{2}{\pi}\sin(\ell x_1)\sin(m x_2).$$

In particular, in view of (3.18) the eigenvectors of the discrete system (3.16) are simply the restrictions of the eigenfunctions of the continuous Laplacian to the mesh points. Of course, this is a very particular fact that is not true for general domains $\Omega$.

It is also easy to check that

$$\lambda^{\ell,m}(h) \to \lambda^{\ell,m} = \ell^2 + m^2 \quad \text{as } h \to 0 \tag{3.19}$$

for all $\ell, m \geq 1$, where $\lambda^{\ell,m}$ stand for the eigenvalues of the continuous Laplacian. This confirms that the 5-point finite-difference scheme provides a convergent numerical scheme.

The eigenvectors $\{W^{\ell,m}\}_{\ell,m=1,\ldots,N}$ constitute an orthonormal basis of $\mathbb{R}^{N\times N}$ with respect to the scalar product

$$\langle f, \widetilde{f}\rangle_h = \left[h^2 \sum_{j,k=1}^{N} f_{j,k}\widetilde{f}_{j,k}\right]^{1/2}, \tag{3.20}$$

associated with the norm (3.15).

The solution of the semi-discrete adjoint system (3.11) can also be easily developed in this basis:

$$\Phi_h(t) = \sum_{\ell,m=1}^{N} a^{\ell,m} e^{-\lambda^{\ell,m}(h)(T-t)} W^{\ell,m} \tag{3.21}$$

where $\{a^{\ell,m}\}$ are the Fourier coefficients of the datum at time $t = T$:

$$\Phi_h^0 = \sum_{\ell,m=1}^{N} a^{\ell,m} W^{\ell,m}, \quad a^{\ell,m} = \langle \Phi_h^0,\ W^{\ell,m} \rangle_h. \tag{3.22}$$

Solutions may also be rewritten in the form

$$\Phi_h(t) = \sum_{\ell=1}^{N} \psi^m(t) \otimes \sigma^m, \tag{3.23}$$

where

$$\sigma^m = \left( \frac{\sqrt{2}}{\sqrt{\pi}} \sin(mkh) \right)_{k=0,\dots,N+1},$$

so that $W^{\ell,m} = \sigma^\ell \otimes \sigma^m$, and each vector-valued function $\psi^m(t) = (\psi_j^m(t))_{j=0,\dots,N+1}$ is a solution of the $1-d$ semi-discrete problem:

$$\begin{cases} \psi_j' - \left[2\psi_j - \psi_{j+1} - \psi_{j-1}\right]/h^2 + \mu^m \psi_j = 0, & j = 1, \dots, N,\ 0 < t < T, \\ \psi_0 = \psi_{N+1} = 0, & 0 < t < T, \\ \psi_j(T) = \psi_j^0, & j = 1, \dots, N, \end{cases} \tag{3.24}$$

where $\mu^m = \frac{4}{h^2} \sin^2\left(\frac{mh}{2}\right)$.

The observability inequality (3.14) is equivalent to proving the $1-d$ analogue for (3.24), uniformly with respect to the index $m \geq 1$, i.e.

$$\|\psi(0)\|_h^2 \leq C \int_0^T \left| \frac{\psi_1}{h} \right|^2 dt, \tag{3.25}$$

for all $\psi^0$, $\psi$ being the solution of (3.24), with a constant $C > 0$ which is independent of $m$.

The proof of this $1-d$ uniform estimate can be developed easily following the arguments in [14]. In fact that inequality is an immediate consequence of the explicit form of the spectrum together with a technical result on series of real exponentials that we recall for the sake of completeness. Consider the class $\mathcal{L}(\xi, M)$ constituted by increasing sequences of positive real numbers $\{\nu_j\}_{j\geq 1}$ such that

$$\nu_{j+1} - \nu_j \geq \xi > 0 \quad \text{for all } j \geq 1, \tag{3.26}$$

$$\sum_{k \geq M(\delta)} \frac{1}{\nu_k} \leq \delta \qquad \text{for all } \delta > 0. \tag{3.27}$$

Here $\xi$ is any positive number and $M\colon (0, \infty) \to \mathbb{N}$ is a function such that $M(\delta) \to \infty$ as $\delta \to 0$. Obviously, different values of $\xi$ and $M$ determine different classes of sequences $\mathcal{L}(\xi, M)$. The following holds (see [14]):

**Proposition 3.3.** *Given a class of sequences $\mathcal{L}(\xi, M)$ and $T > 0$, there exists a positive constant $C > 0$ such that*

$$\int_0^T \Big| \sum_{k=1}^{\infty} a_k e^{-\nu_k t} \Big|^2 dt \geq \frac{C}{\left[\sum_{k\geq 1} 1/\nu_k\right]} \sum_{k\geq 1} \frac{|a_k|^2 e^{-2\nu_k T}}{\nu_k}, \tag{3.28}$$

*for all $\{\nu_k\}_{k\geq 1} \in \mathcal{L}(\xi, M)$ and all bounded sequence $\{a_k\}_{k\geq 1}$.*

Note that the sequences of eigenvalues of problems (3.24) belong to the same class $\mathcal{L}(\xi, M)$ for all $h > 0$ and $m \geq 1$. Thus, the constant $C$ in (3.28) is uniform and, consequently, (3.24) holds, with an observability constant independent of $h > 0$ and $m \geq 1$ as well.

**Remark 3.4.** The same result holds for the case in which the control acts as a right hand side external force applied on a band, i.e. on a set of the form $\omega = \{(x_1, x_2) : 0 < x_1 < \gamma, 0 < x_2 < \pi\}$ with $0 < \gamma < \pi$. The corresponding continuous model reads

$$\begin{cases} y_t - \Delta y = f 1_\omega & \text{in } \Omega \times (0, T), \\ y = 0 & \text{on } \partial\Omega \times (0, T), \\ y(x, 0) = y^0(x) & \text{in } \Omega, \end{cases} \tag{3.29}$$

where $f = f(x_1, x_2, t)$ is the control and $1_\omega$ is the characteristic function of the set $\omega$ where the control is applied.

The corresponding observability inequality is

$$\|\varphi(0)\|^2_{L^2(\Omega)} \leq C \int_0^T \int_\omega \varphi^2 \, dx dt \quad \text{for all } \varphi^0 \in L^2(\Omega). \tag{3.30}$$

The problems can be formulated similarly for the semi-discrete scheme we have considered.

The observability inequality (3.30) and the corresponding semi-discrete versions hold uniformly with respect to the mesh-size parameter $h > 0$. Consequently the heat equation (3.29) and the corresponding semi-discretizations are uniformly (with respect to $h > 0$) null controllable. Convergence of controls and states holds as well.

In this case the most natural functional setting is the following one. The initial data $y^0$ belongs to $L^2(\Omega)$, the control $f$ lies in $L^2(\omega \times (0, T))$ and the solutions then belong to $C([0, T]; L^2(\Omega)) \cap L^2(0, T; H_0^1(\Omega))$. Convergences hold in these classes as well.

**3.3. General domains.** The methods of proof of the previous section, based on Fourier series expansions, do not apply to general domains. In fact, even in the context of the continuous heat equation, the existing proofs of null controllability require obtaining the observability estimates by Carleman inequalities (see [5] and [11]). So far the discrete or semi-discrete version of these Carleman inequalities

and its possible applications to observability estimates for numerical approximation schemes for the heat equation is a completely open subject of research.

However, in view of the results of the previous section, and using a classical argument, based on extending the control domain and then getting the controls as restrictions to the original boundary of the controlled states, one can derive similar results for general domains but provided *the controls are supported everywhere on the boundary of the domain.* The problem of determining sharp conditions on the subsets of the boundary so that the semi-discrete systems are uniformly controllable is completely open. As we have mentioned above, even in the simplest geometry of the square domain of the previous subsection, the result fails to hold without some restrictions on the support of the control that are not needed for the continuous heat equation.

The following holds:

**Theorem 3.5.** *For all bounded smooth domain $\Omega$, all time $T > 0$ and all initial data $y^0 \in L^2(\Omega)$, there exists a uniformly bounded sequence of discrete controls $V_h \in L^2(\partial\Omega_h \times (0,T))$ ensuring the null controllability of the finite-difference semi-discrete approximation in $\Omega_h$. These controls can be chosen so that the solutions $Y_h$ converge weakly in $L^2(0,T;H^1(\Omega))$ to the solution $y$ of the heat equation satisfying the null final condition* (3.2).

*Proof.* Let us briefly explain how this classical extension-restriction method can be implemented in this framework.

Without loss of generality we can assume that $\Omega$ is contained in the square domain $\tilde{\Omega} = (0,\pi) \times (0,\pi)$. We discretize the square as in the previous sections, and define the approximating domains $\Omega_h$ as those that, having their boundary constituted by mesh-points, better approximate the domain $\Omega$. For the sake of simplicity we assume that $\Omega_h$ contains $\Omega$. We also consider a band-like control subdomain $\omega$ in the square $\tilde{\Omega}$ so that the results of the previous sections apply and $\Omega_h \cap \omega = \emptyset$ for all $h > 0$.

Given initial data $y^0 \in L^2(\Omega)$ for the continuous heat equation we define approximating discrete data $Y_h^0$ in $\Omega_h$ in a standard way, for instance, by simply taking on each mesh-point the average of $y^0$ on the neighboring square of sides of size $h$. This data can be easily extended by zero to discrete data $\tilde{Y}_h^0$ defined in the whole mesh of the square. In view of the results of the previous section (Remark 3.4 ) this generates controls $F_h$ with support in $\omega$, which are uniformly bounded in $L^2(\omega \times (0,T))$ and converging, as $h \to 0$, to the control of the heat equation (3.29) in the square $\tilde{\Omega}$. This yields also uniformly bounded states $\tilde{Y}_h$ in the space $C([0,T];L^2(\tilde{\Omega})) \cap L^2(0,T;H_0^1(\tilde{\Omega}))$. Obviously, here, as in previous sections, these bounds hold in fact for the piecewise linear continuous extensions of the discrete solutions.

More precisely, the corresponding solutions $\tilde{Y}_h$ converge to the solution $y$ of the heat equation in the space $L^2(0,T;H_0^1(\tilde{\Omega}))$. We can then restrict these solutions to the domains $\Omega_h$ and obtain the solutions $Y_h$ of the semi-discrete system in $\Omega_h$, which, by construction, satisfy the final null condition (3.13) and converge to the solution of the heat equation. These solutions satisfy non-homogeneous boundary conditions.

We read their trace as the boundary controls $V_h$ in $\partial\Omega_h$ (resp. $\partial\Omega$) for the semi-discrete (resp. continuous) heat equations. These controls are bounded in $L^2(\partial\Omega_h \times (0,T))$ because they are traces of solutions of bounded energy in $L^2(0,T;H_0^1(\tilde{\Omega}))$. Their weak convergence can also be proved. However, at this point one has to be careful since the controls are defined on boundaries $\partial\Omega_h$ that depend on $h$. A possible way of stating that convergence rigorously is considering smooth test functions $\theta(x)$ defined everywhere in the square and ensuring that $\int_{\partial\Omega_h} V_h\theta d\sigma$ tends to $\int_{\partial\Omega} v\theta d\sigma$, as $h \to 0$ for all smooth test functions $\theta$. This convergence property of controls holds as well. □

**Remark 3.6.** The method of proof we have presented based on the extension of the domains and using the previously proved results on the square has two main drawbacks:

- The first one is that the control is required to be supported everywhere on the boundary of the domain. We emphasize however that, despite the fact that no geometric restrictions are needed for the continuous heat equation, in the sense that null controllability holds from an arbitrarily small open subset of the boundary, that is not the case for the semi-discrete one. Thus, the class of subsets of the boundary for which passing to limit on the null-controllability property is possible is still to be clarified, and the result above showing that the whole boundary always suffices is the first positive one in this direction.

- The second one is that it is based on the results obtained in the square by Fourier series techniques. As we have mentioned above, the main tool to deal with continuous heat equations are the Carleman inequalities. As far as we know there is no discrete counterpart of those inequalities and this would be essential to deal with more general heat equations with variable coefficients, or semilinear perturbations. The methods described in Section 2 showing the two-grid controllability of the semilinear wave equation by compactness-uniqueness arguments do not apply for heat-like equations because of their very strong time-irreversibility. Thus, the Carleman approach seems to be the most promising one. However, the fact that observability fails for the semi-discrete system for some observation subdomains indicates that the problem is complex in the sense that the discrete version of the continuous Carleman inequality does not hold. This is a widely open subject of research.

**Remark 3.7.** Similar results hold for a semi-discrete regular finite-element approximation of the heat equation, as long as solutions can be developed in Fourier series, allowing to reduce the problem in the square to a one-parameter family of $1-d$ problems, and then apply the extension-restriction method to address general domains.

**Acknowledgements.** I am grateful to E. Trélat and X. Zhang for fruitful comments that contributed to improve the first version of this article. My thanks also go to

C. Simó for his valuable comments on the use of Newton's method for efficiently computing the controls obtained in Section 2 by means of fixed point techniques.
