# Braids and differential equations

Robert Ghrist*

**Abstract.** Forcing theorems based on topological features of invariant sets have played a fundamental role in dynamics and differential equations. This talk focuses on the recent work of Vandervorst, Van den Berg, and the author using braids to construct a forcing theory for scalar parabolic PDEs, second-order Lagrangian ODEs, and one-dimensional lattice dynamics.

**Mathematics Subject Classification (2000).** Primary 37B30, 35K90; Secondary 34C25, 37L60, 57M25.

**Keywords.** Braids, Conley index, dynamical systems, parabolic PDEs, second order Lagrangian.

This talk covers a particular type of forcing theory for parabolic dynamics which uses the topology of braids in an index theory.

## 1. Topological forcing theorems

Throughout the last century of work in dynamical systems, forcing theorems have played a substantial role in establishing coarse minimal conditions for complicated dynamics. Forcing theorems in dynamics tend to take the following form: given a dynamical system of a specified class, the existence of some invariant set of one topological type implies the existence of invariant sets of other topological types. This forcing is often encoded by some sort of ordering on topological types of invariant sets.

### 1.1. Examples.

Three canonical examples of forcing theorems frame our work.

**Example 1** (*Morse Theory* [43]). The class of systems is that of nondegenerate gradient flows on an oriented manifold $M$. The invariant sets of interest are the fixed points, and the topological type associated to a fixed point is its *Morse index* – the dimension of its unstable manifold. A suitable chain complex generated by fixed points and graded by the Morse index yields a homology which is isomorphic to that

*Research supported by the National Science Foundation, PECASE DMS-0337713. The author wishes to thank Rob Vandervorst, without whom the work described here would not exist.

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

of $M$, allowing one to deduce the existence and indices of additional critical points based on partial knowledge of the invariant sets and the homology of $M$.

Morse theory has blossomed into a powerful array of topological and dynamical theories. One significant extension is the theory of Conley [14] which associates to an 'isolated' invariant set of a finite dimensional dynamical system an index – the *Conley index* – which, like the Morse index, can be used to force the existence of certain invariant sets. Instead of being a number (the dimension of the unstable manifold), the Conley index is a homotopy class of spaces (roughly speaking, the homotopy type of the unstable set). See [44] and the references therein for a sampling of applications to differential equations.

Following on the heels of Conley's index theory is the extension of Floer to infinite-dimensional gradient-like dynamics. This, in turn, has led to an explosion of results in topology and geometry. The recent flurry of activity in contact homology and symplectic field theory [18] is a descendent of these foundational ideas.

**Example 2** (*The Poincaré–Birkhoff Theorem* [5]). This theorem applies to orientation and area preserving homeomorphisms of the annulus whose boundaries are twisted in opposite directions. As with Morse theory, the forcing is in terms of a lower bound (two) on the number of fixed points. The Poincaré–Birkhoff Theorem is the first of many dynamical theorems to exploit the particular features of symplectic manifolds and maps which preserve this symplectic structure. The marriage of this type of theorem with the Morse-type forcing results is the *Arnold Conjecture*, for which Floer theory was first and most strikingly used.

There is a very powerful extension of the Poincaré–Birkhoff Theorem due to Franks [25] (Gambaudo and LeCalvez [39, App.] proved a slightly different version independently at about the same time). Franks' theorem states that if an area and orientation preserving diffeomorphism of the annulus has at least one periodic point, then it has infinitely many periodic orbits. See [26] for this and related results. Franks' Theorem is an excellent example of how a forcing theorem in dynamics often provides a sharp threshold for complicated dynamics: one simple invariant set implies the existence of infinitely many others. This principle finds its clearest exponent in the theorem of Sharkovsky.

**Example 3** (*Sharkovsky's Theorem* [48]). For continuous maps of the compact interval to the reals, this theorem gives a total ordering $\lhd$ on the periods of periodic orbits. The theorem states that if a map has an orbit of minimal period $P$ then it has periodic orbits of minimal period $Q$ for all $P \lhd Q$. That the minimal element of $\lhd$ is three has led to the popular coinage *"period three implies chaos."*

The Sharkovsky theorem is remarkable in that there are no assumptions on the systems beyond dimension and continuity. Yet, the topological datum assigned to a periodic orbit is merely the period and nothing more sophisticated. In general, the resolution with which a forcing theorem can act depends on two factors: (1) how narrowly one constrains the class of dynamical systems; and (2) what type of topological data one assigns to the invariant sets.

**1.2. Overview.** This paper motivates and describes a forcing theory developed by R. Vandervorst in collaboration with J.-B. Van den Berg and the author. In this context, the class of dynamics is, roughly speaking, scalar parabolic lattice dynamics. The topological data which drives the forcing theory is a relative Conley index for invariant sets based on the theory of *braids*.

The resulting forcing theory shares features with all three of the above examples. The index we construct – the *homotopy braid index* – is a Conley–Morse index and leads to Morse-type inequalities. The discrete version of the forcing theory is similar in spirit to LeCalvez' work on twist maps for annuli [38], [39], which itself is an elegant descendent of the Poincaré–Birkhoff Theorem. As with the Sharkovsky Theorem, we obtain a (partial) order on invariant sets. This leads to very simple conditions on invariant sets which force an infinite collection of additional invariant sets.

**1.3. Braids and braid types.** The use of braids in forcing theorems is not without precedent. There are various types of topological forcing in dimensions two and three related to braids. In the two-dimensional discrete case, one considers the isotopy class of a map relative to some periodic orbit(s): these are related to braids.

One definition of a *topological braid* on $n$ strands is a loop with basepoint in the configuration space of $n$ distinct unlabeled points in the disc $D^2$. One usually visualizes a braid as an embedding of $n$ intervals $\boldsymbol{u} = \{u^\alpha(t)\}_1^n$ into $D^2 \times [0, 1]$ such that each slice $D^2 \times \{t\}$ is a set of $n$ points and the initial and final configurations the same: $\boldsymbol{u}(0) = \boldsymbol{u}(1)$. See Figure 1 [left]. Given a braid $\boldsymbol{u}$, its *braid class* $\{\boldsymbol{u}\}$ is the equivalence class of braids *isotopic* to $\boldsymbol{u}$, that is, homotopic to $\boldsymbol{u}$ through braids, fixing the endpoints.

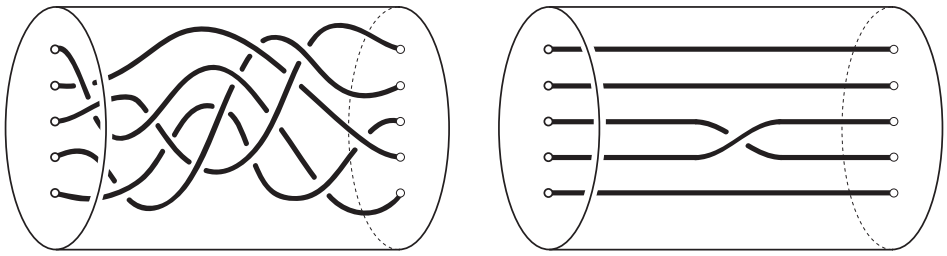

Figure 1. A braid on five strands, illustrated as a collection of embedded arcs in $D^2 \times [0, 1]$ [left]. A typical generator of the braid group has all strands 'straight' with a pair of incident strands crossing [right].

There is an obvious algebraic structure on $n$-strand braid classes by passing to the fundamental group $B_n$ of the configuration space, the group operation being concatenation of the braids in $D^2 \times [0, 1]$. The standard presentation for $B_n$ has $n - 1$ generators, where the $i^{\text{th}}$ generator consists of $n$ parallel strands (the identity braid) except that the $i^{\text{th}}$ strand crosses over the $(i + 1)^{\text{st}}$ strand as in Figure 3 [right]. See [6] for more details on the topology and algebra of braids.

There is a wonderful analogue of the Sharkovsky Theorem for forcing periodic orbits in surface homeomorphisms. In this setting, the period is not a sufficiently fine datum – one must use what Boyland [7] coined the *braid type* of a periodic orbit. Consider, for the sake of simplicity, an orientation preserving homeomorphism $f\colon D^2 \to D^2$ of the closed disc with a periodic orbit $P$ of period $n$. The braid type $\mathrm{BT}(P)$ is, roughly speaking, the isotopy class of $f$ relative to $P$. Using the relationship between braid groups and mapping class groups [6], it is possible to formally identify $\mathrm{BT}(P)$ with a conjugacy class in the braid group $B_n$ modulo its center. This is best seen by suspending the disc map to a flow on $D^2 \times S^1$. When embedded in $\mathbb{R}^3$, the periodic orbit is a braid. The choice of how many meridional twists to employ in the embedding is the genesis of modding out by the center of $B_n$.

Boyland defined the following *forcing order* on braid types: one says that $\gamma \leq \beta$ if and only if for any homeomorphism $f\colon D^2 \to D^2$ with $\gamma$ a braid type for some periodic orbit of $f$, then $\beta$ must also be a braid type for some (perhaps distinct) periodic orbit of $f$ as well. Boyland showed that this is a partial order on braid types [8], which, though weaker than the total order of the Sharkovsky theory, is nevertheless efficacious in forcing complicated dynamics.

Boyland's theory, when generalized to surfaces, entwines with the Nielsen–Thurston theory for surface homeomorphisms. This combination of braid types together with Nielsen–Thurston theory has matured to yield numerous strong results, not only in the dynamics of horseshoe and Hénon maps [11], [13], but also in problems of fluid mixing [9], [33].

**1.4. Knots and links.** In the case of flows in dimension three, embedding and isotopy data is likewise crucial. Since each periodic orbit is an embedded loop, it is a *knot*, and the set of periodic orbits forms a (perhaps infinite) *link*. The relationship between the link of periodic orbits and the dynamics of the flow is very subtle.

A forcing theory for flows in not straightforward. Roughly speaking, the counterexamples to the Seifert Conjecture constructed by K. Kuperberg [37] imply that there cannot be a forcing theorem for general smooth nonsingular 3-d flows – one can always insert a Kuperberg plug and destroy any isolated periodic orbit. At one extreme, Kuperberg's work implies that there exist smooth nonsingular flows on $S^3$ without any periodic orbits whatsoever. At the other extreme, it is possible to have a smooth, nonsingular, structurally stable flow on $S^3$ which displays all possible knots and links as periodic orbits [29]. These phenomena do not bode well for a forcing theory based on knots and links.

However, upon restriction to the correct subclass of flows, it is often possible to retain some vestige of forcing based on knot and link types. One principle which persists is that simple dynamics implicate simple types of knots. For example, in the class of nonsingular Morse–Smale flows on $S^3$, only certain knot types and link types can appear, a complete classification being given by Wada [54]. This result has a nearly dual counterpart in the class of integrable Hamiltonian dynamics on an invariant 3-sphere, as shown by Fomenko and Nguyen [24] and explained best by Casasayas et

al. [12]. Other instantiations of this principle appear in smooth, integrable fluid flows on Riemannian 3-spheres [20] and in gradient fields on $S^3$ kinematically constrained by a plane field distribution [19].

A complementary principle also holds, that complex dynamics implicate complex knot types in a flow on a 3-sphere. The best example of this type of result is the theorem of Franks and Williams [27], which states that any $C^2$ flow with positive topological entropy has a link of periodic orbits which has an infinite number of distinct knot types represented. Other results on knotting and linking for suspensions of Smale horseshoes have been proved by Holmes and Williams [35] and used to force bifurcations in Hénon maps. These results all employ the relationship between knots, links, and *closed braids* – conjugacy classes of braids in the braid group which are visualized by identifying the left and right endpoints of a braid.

**1.5. Toward higher dimensions.** Forcing theorems based on knots, links, or braids in higher dimensional dynamics seem hopeless at first: these objects fall apart in dimension higher than three. One possibility is to try to work with embedding data associated to higher-dimensional invariant sets, say spheres or tori, which can be knotted and linked in the appropriate codimension. At present, there is some initial work on braiding of 2-d invariant tori in 4-d flows [50] which may lead to a forcing theory. There is a great deal now known about the peculiar constraints of embedding spheres and tori in symplectic manifolds, but as yet without much in the way of dynamical implications.

We now turn to a braid-theoretic forcing theory for certain types of PDEs, where the stationary equation allows us to import three-dimensional embedding constraints into an infinite-dimensional dynamical system.

## 2. Braids for parabolic dynamics

Our motivation for using braids to force dynamics comes from a very simple observation about parabolic partial differential equations.

**2.1. Motivation: parabolic PDEs.** Consider the scalar parabolic PDE

$$u_t = u_{xx} + f(x, u, u_x), \tag{1}$$

where $f$ satisfies one's favorite technical assumptions to guarantee no finite-time blowups of solutions. For simplicity, we assume periodic boundary conditions ($x \in [0, 1]/0 \sim 1$). We view Equation (1) as an evolution equation on the curve $u(\cdot, t)$. As $t$ increases, the graph of $u$ evolves in the $(x, u)$ plane. Thus, the PDE induces a flow on a certain infinite-dimensional space of curves. It is a result of Fiedler and Mallet-Paret [21] that a type of Poincaré–Bendixson Theorem holds for these types of equations: the only bounded invariant sets are stationary solutions, time-periodic solutions, and connecting orbits.

We augment the types of solutions under consideration as follows. First, we allow multiple graphs to evolve by the product flow. That is, if $u^1 = u^1(t)\colon [0,1] \to \mathbb{R}$ and $u^2 = u^2(t)\colon [0,1] \to \mathbb{R}$ are solutions to Equation (1), then we consider the union $\boldsymbol{u} = (u^1, u^2)$ as a solution to the product flow. These two strands evolve together, independently, as a pair of graphs on the $(x, u)$ plane. In general, we can consider an $n$-tuple $\boldsymbol{u} = (u^k)_1^n$ of *strands* which evolve under the dynamics.

Second, we allow for strands of multiple spatial period. That is, we allow for a collection $\boldsymbol{u} = (u^k)_1^n$ of strands of the form $u^k\colon [0,1] \to \mathbb{R}$ with the endpoints equivalent as sets: $\{u^k(0)\}_1^n = \{u_k(1)\}$. Even though the endpoints do not match strandwise, the union of the endpoints of the strands do match, and thus the entire collection evolves under the PDE so as to respect the spatial periodicity. One can think of such a collection of strands as a single-strand curve on the $n$-fold cover $[0, n]/0 \sim n$ of the spatial variable $x$.

It is a well-known fact (going back to Sturm, but revived and extended considerably by Matano [41], Brunovsky and Fiedler [10], Angenent [1], and others) that there is a *comparison principle* for Equation (1). Specifically, let $u^1(t)$ and $u^2(t)$ be solutions to Equation (1). Then the number of intersections of the graphs of $u^1(t)$ and $u^2(t)$ is a weak Lyapunov function for the dynamics: it is non-increasing in $t$. Furthermore, at those particular times $t$ for which the graphs of $u^1(t)$ and $u^2(t)$ are tangent, the number of intersections decreases strictly in $t$, even in the case where the tangencies are of arbitrarily high order [1]. These facts are all at heart an application of classical maximum principle arguments which have a topological interpretation: *parabolic dynamics separates tangencies monotonically.*

This monotonicity is easily seen. Assume that $u^1$ and $u^2$ are solutions to Equation (1) which have a simple tangency where $u^1(x,t) = u^2(x,t)$. Then the evolution of the difference between $u^1$ and $u^2$ is given by

$$\frac{\partial}{\partial t}\left(u^1(x,t) - u^2(x,t)\right) = \frac{\partial^2}{\partial x^2}\left(u^1(x,t) - u^2(x,t)\right). \tag{2}$$

Since the nonlinear terms cancel, the evolution is governed purely on the basis of the curvature of the graphs.

Using this comparison principle (also known as *lap number* or *zero crossing* techniques), numerous authors have analyzed the dynamics of Equation (1) in varying degrees of generality. We note in particular the paper of Fiedler and Mallet-Paret [21], in which the comparison principle is used to show that the dynamics of Equation (1) is often Morse–Smale, and also the paper of Fiedler and Rocha [22], in which the global attractor for the dynamics is roughly classified.

**2.2. Idea: dynamics on spaces of braids.** A typical collection of strands is illustrated in Figure 2 [left], in which one notices a resemblance to the planar projection of a braid. By lifting this collection of strands in the $(x, u)$ plane to the 1-jet extension of the strands in $(x, u, u_x)$ space, we obtain a *Legendrian braid* tangent to the contact structure $\{dy - z\,dx = 0\}$. Such a braid is *closed*, due to the periodicity of

the strands. Being Legendrian, the braid is *positive* – in the standard generators for the braid group, only positive powers of generators are permitted.

There is a globalization of the comparison principle using braids. For a motivating example, consider again a pair of evolving curves $u^1(t)$ and $u^2(t)$ in the $(x, u)$ plane. If we lift these curves to the three-dimensional $(x, u, u_x)$ space, we no longer have intersecting curves, unless $t$ is such that the planar graphs of $u^1$ and $u^2$ intersect tangentially. The graphs of $u^1$ and $u^2$ in the $(x, u, u_x)$ space are instead a closed braid on two strands. What was the intersection number of their projections is now the *linking number* of the pair of strands.

We see therefore that the comparison principle takes on a linking number interpretation (a fact utilized in a discrete setting by LeCalvez [38]). After lifting solutions $u^1$ and $u^2$ to the $(x, u, u_x)$ space, the comparison principle says that the linking number is a nonincreasing function of time which decreases strictly at those times at which the curves are tangent. This two-strand example is merely motivation for adopting a braid-theoretic perspective on multiple strands, as in Figure 2.

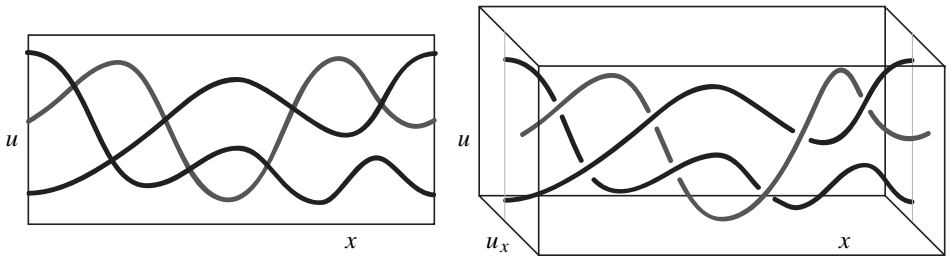

Figure 2. Curves in the $(x, u)$ plane lift to a braid in $(x, u, u_x)$.

The key observation is that the comparison principle passes from a local statement ("linking number decreases at a tangency") to a global statement ("algebraic length in the braid group decreases at a tangency"). A related globalization of the comparison principle for geodesic flows on Riemannian surfaces appears in the recent work of Angenent [2].

**2.3. Goal: forcing.** Our goal is to produce a forcing theory for the dynamics of Equation (1) and more general parabolic systems. For simplicity, we focus on forcing stationary solutions, though periodic and connecting orbits are likewise accessible. Say that one has found a *skeleton* of stationary strands $\{v^1, v^2, \ldots, v^m\}$ for a particular representative of Equation (1). How many and which types of other stationary curves are forced to be present? Since the skeleton of known fixed curves $\boldsymbol{v} = \{v^1\}_{i=1}^m$ lifts to a braid, the problem is naturally couched in braid-theoretic terms: given a braid $\boldsymbol{v}$ fixed by a particular uniform parabolic PDE, which other classes of braids $\boldsymbol{u}$ are forced to exist as stationary curves?

The spirit of our forcing theory is as follows:

1. Given a braid of stationary solutions $\boldsymbol{v}$, construct the configuration space of all $n$-strand braids $\boldsymbol{u}$ which have $\boldsymbol{v}$ as a sub-braid.

2. Use the braid-theoretic comparison principle to give a Morse-type decompose of this configuration space into dynamically isolated braid classes.

3. Define the *homotopy braid index* – a Conley index for relative braid classes which depends only on the topology of the braids, and not on the analytical details of the dynamics.

4. Prove Morse-type inequalities for forcing stationary and/or time-periodic solutions.

To execute this requires a significant generalization to spatially discretized systems, which in turn generalizes the results far beyond parabolic PDEs.

## 3. Spaces of braids for parabolic dynamics

**3.1. Braids, topological and discrete.** The motivation of §2.1 leads one to consider spaces of braids obtained from curves in the $(x, u)$ plane. Consider the space of all such $n$-strand braids $\boldsymbol{u}$ which are both closed and positive. For the sake of intuition, one should think of these topological braids as smooth braids lifted from the 1-jet extension of graphs in the plane. In reality, one completes this space to include non-smooth braids as well. These configuration spaces of braids are infinite dimensional. By projecting to finite dimensional approximations, we avoid a great deal of analytic and topological difficulties. We briefly outline the "finite dimensional" braid theory needed.

The class of *discretized braids* are best visualized as piecewise-linear braid diagrams, as in Figure 3 [left]. A discretized braid, $\boldsymbol{u}$, on $n$ strands of period $p$, is determined by *np anchor points*: $\boldsymbol{u} = \{u_i^\alpha\}_{i=0,\ldots,p}^{\alpha=1,\ldots,n}$. Superscripts $\alpha = 1, \ldots, n$ refer to strand numbers, and subscripts $i = 0, \ldots, p$ refer to spatial discretizations. One connects the anchor point $u_i^\alpha$ to $u_{i-1}^\alpha$ and $u_{i+1}^\alpha$ via straight lines. Since "height" is determined by slope, all crossings in the braid diagram are of the same sign (as in Figure 3 [left] but not in Figure 1 [left]). Since we employ periodic boundary conditions on the $x$ variable, all of the braids are closed: left and right hand endpoints of strands are abstractly identified and the endpoints are free to move. This necessitates a periodicity convention for the subscript. For a single-strand component $u^\alpha$, we have that $u_{i+p}^\alpha = u_i^\alpha$ for all $i$. For multi-strand components, one cycles between the strands according to the permutation of strands. Denote by $\mathcal{D}_p^n$ the space of all $n$-strand period $p$ discretized braids: $\mathcal{D}_p^n$ is homeomorphic to $\mathbb{R}^{np}$.

For topological braids, a *singular braid* is one for which one or more strands intersect. For braids which are lifts of graphs, the only possible intersection is that which occurs when two strands are tangent in the projection. For a discretized braid $\boldsymbol{u}$,

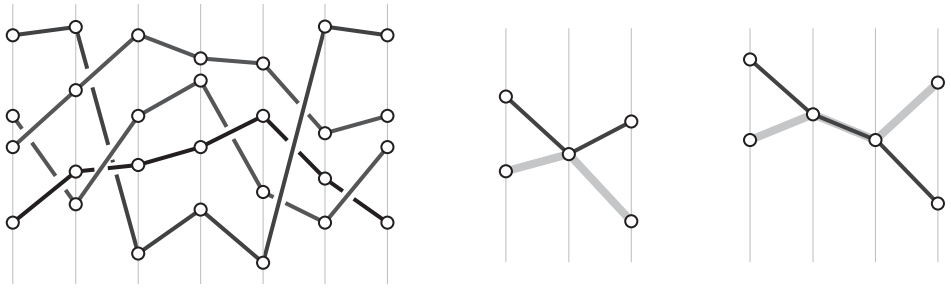

Figure 3. A discretized braid in $\mathcal{D}_6^4$ with three components (note: left and right hand sides are identified) [left]; Two types of singular discretized braids: a simple tangency, and a high-order contact [right].

the singular braids are defined to be those braids at which anchor points on two different strands coincide in a topologically non-transverse fashion with respect to immediate neighbors. Denote by $\Sigma$ the singular braids,

$$\Sigma = \{\boldsymbol{u} : u_i^\alpha = u_i^\beta \text{ for some } i \text{ and } \alpha \neq \beta, \text{ and } (u_{i-1}^\alpha - u_{i-1}^\beta)(u_{i+1}^\alpha - u_{i+1}^\beta) \geq 0\}. \tag{3}$$

The set $\Sigma$ is a discriminant that carves $\mathcal{D}_p^n$ into components: these are the *discretized braid classes*, denoted $[\boldsymbol{u}]$. Within $\Sigma$, there is a subspace of *collapsed* braids, $\Sigma^- \subset \Sigma$, consisting of those braids for which distinct components of the braid (or a single component with multiple period) collapse to yield a braid on fewer strands. More specifically,

$$\Sigma^- = \{\boldsymbol{u} \in \Sigma \, : \, u_i^\alpha = u_i^\beta \text{ for all } i \in \mathbb{Z} \text{ and some } \alpha \neq \beta\}, \tag{4}$$

under the convention of subscript periodicity mod $p$ as regulated by the braid.

**3.2. Parabolic dynamics on braids.** A parabolic PDE of the form in Equation (1) gives rise to a flow on the space of topological braids. There is likewise a broad class of flows on spaces of discretized braids which are best described as parabolic. These come from nearest-neighbor lattice dynamics.

Discretizing Equation (1) in the standard way would yield a family of nearest neighbor equations of the form $\frac{d}{dt}u_i = f_i(u_{i-1}, u_i, u_{i+1})$ in which uniform parabolicity would manifest itself in terms of the derivatives of $f_i$ with respect to the first and third variables. Instead of explicitly discretizing the PDE itself, we use the broadest possible category of nearest neighbor equations for which a comparison principle holds: these are related to the *monotone systems* of, e.g., [49], [34], [21] and others.

A *parabolic relation* of period $p$ is a sequence of maps $\mathcal{R} = \{\mathcal{R}_i : \mathbb{R}^3 \to \mathbb{R}\}$, such that $\partial_1 \mathcal{R}_i > 0$ and $\partial_3 \mathcal{R}_i \geq 0$ for every $i$. These include discretizations of uniform parabolic PDE's, as well as a variety of other discrete systems [40], [42], including

monotone twist maps [38]. The small amount of degeneracy permitted ($\partial_3 \mathcal{R}_i = 0$) does not prevent the manifestation of a comparison principle. Given a discretized braid $\boldsymbol{u} = \{u_i^\alpha\}$ and a parabolic relation $\mathcal{R}$, one evolves the braid according to the equation

$$\frac{d}{dt}(u_i^\alpha) = \mathcal{R}_i(u_{i-1}^\alpha, u_i^\alpha, u_{i+1}^\alpha). \tag{5}$$

Any parabolic relation $\mathcal{R}$ therefore induces a flow on $\mathcal{D}_p^n$. Fixed points of this flow correspond to stationary braids $\boldsymbol{u}$ satisfying $\mathcal{R}_i(u_i^\alpha) = 0$ for all $i$ and $\alpha$. It will be useful at certain points to work with parabolic relations which induce a gradient flow on $\mathcal{D}_p^n$. One calls $\mathcal{R}$ *exact* if there exist generating functions $S_i$ such that

$$\mathcal{R}_i(u_{i-1}, u_i, u_{i+1}) = \partial_2 S_{i-1}(u_{i-1}, u_i) + \partial_1 S_i(u_i, u_{i+1}), \tag{6}$$

for all $i$. In the exact case, the flow of Equation (5) is given by the gradient of $\sum_i S_i$.

All parabolic relations, exact or non-exact, possess a discrete braid-theoretic comparison principle.

**Lemma 4** (Comparison principle for braids [32]). *Let $\mathcal{R}$ be any parabolic relation and $\boldsymbol{u} \in \Sigma - \Sigma^-$ any non-collapsed singular braid. Then the flowline $\boldsymbol{u}(t)$ of $\mathcal{R}$ passing through $\boldsymbol{u} = \boldsymbol{u}(0)$ leaves a neighborhood of $\Sigma$ in forward and backward time so as to strictly decrease the algebraic length of $\boldsymbol{u}(t)$ in the braid group as $t$ increases through zero.*

Lemma 4 implies that the flow of parabolic dynamics is gradient-like on the (non-collapsed portions of) boundaries of braid classes. This suggests a Morse-theoretic approach. For example, if the flow points in to a given braid class everywhere along the boundary, then the braid class should serve as a 'sink' for the dynamics and thus be assigned a Morse index of zero. At least some invariant set would have to lie within this braid class, even if the dynamics is not gradient everywhere. For more complicated behaviors on the boundary of a braid class, Conley's version of Morse theory is the appropriate tool, with the notion of a Morse index generalizing to the Conley index, a homotopy class of spaces.

## 4. The homotopy braid index

One significant problem with this idea is the prevalence of collapsed braids, which are invariant under the flow and foil the straightforward application of Morse theory. Clearly, *any* braid class $[\boldsymbol{u}]$ borders the set of collapsed braids $\Sigma^-$ somewhere. One need simply collapse all the strands together as an extreme degeneracy.

**4.1. Relative braids.** We are therefore naturally confronted with the need for a forcing theory. Given that a particular parabolic relation possesses a stationary braid $\boldsymbol{v}$, does it force some other braid $\boldsymbol{u}$ to also be stationary with respect to the dynamics? This necessitates understanding how the strands of $\boldsymbol{u}$ braid relative to those of $\boldsymbol{v}$.

Given a discrete braid $\boldsymbol{v} \in \mathcal{D}_p^m$, consider the set of nonsingular braids

$$\left\{\boldsymbol{u} \in \mathcal{D}_p^n \ : \ \boldsymbol{u} \cup \boldsymbol{v} \in \mathcal{D}_p^{n+m} - \Sigma_p^{n+m}\right\},$$

the path components of which define the *relative braid classes* $[\boldsymbol{u} \text{ REL } \boldsymbol{v}]$. Not only are tangencies between strands of $\boldsymbol{u}$ illegal, so are tangencies with the strands of $\boldsymbol{v}$. In this setting, the braid $\boldsymbol{v}$ is called the *skeleton*. Elements within $[\boldsymbol{u} \text{ REL } \boldsymbol{v}]$ are equivalent as discrete braids fixing all strands of $\boldsymbol{v}$.

In this context, it is possible to define a Conley index for certain discrete relative braid classes. To do so, it must be shown that the braid classes $[\boldsymbol{u} \text{ REL } \boldsymbol{v}]$ are *isolated* in the sense that no flowlines within $[\boldsymbol{u} \text{ REL } \boldsymbol{v}]$ are tangent to the boundary of this set. It follows from Lemma 4 that $[\boldsymbol{u} \text{ REL } \boldsymbol{v}]$ is isolated for the flow of Equation (5) assuming that the braid class avoids the collapsed braids $\Sigma^-$. We therefore declare a braid class $[\boldsymbol{u} \text{ REL } \boldsymbol{v}]$ to be *proper* if no free strands of $\boldsymbol{u}$ can "collapse" onto $\boldsymbol{v}$ or onto each other: see Figure 4. Furthermore, to ensure compactness, it is convenient to assume that the braid class $[\boldsymbol{u} \text{ REL } \boldsymbol{v}]$ is *bounded* – free strands cannot wander off to $\pm\infty$.

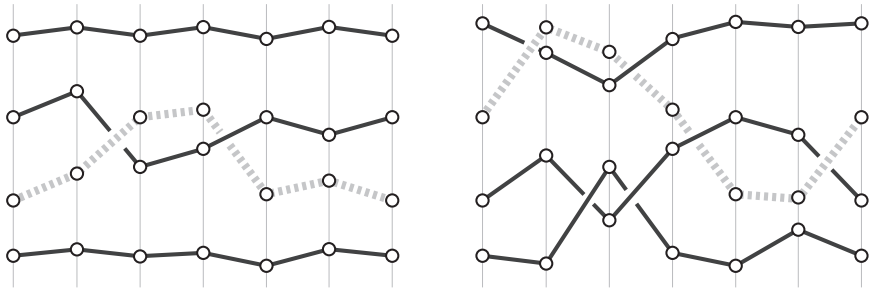

Figure 4. A bounded but improper braid class [left]. A proper, but unbounded braid class. Solid strands form the skeleton; dashed strands are free [right].

**4.2. The index: discrete version.** The *homotopy braid index* of a proper, bounded, discrete relative braid class $[\boldsymbol{u} \text{ REL } \boldsymbol{v}]$ is defined as follows. Choose any parabolic relation $\mathcal{R}$ which fixes $\boldsymbol{v}$ (such an $\mathcal{R}$ exists). Define $\mathcal{E}$ to be the *exit set*: those braids on the boundary of the braid class $[\boldsymbol{u} \text{ REL } \boldsymbol{v}]$ along which evolution under the flow of $\mathcal{R}$ exits the braid class. The homotopy braid index is defined to be the pointed homotopy class

$$h([\boldsymbol{u} \text{ REL } \boldsymbol{v}]) = \left(\overline{[\boldsymbol{u} \text{ REL } \boldsymbol{v}]}/\mathcal{E}, \{\mathcal{E}\}\right). \tag{7}$$

This is simply the Conley index of the closure of $[\boldsymbol{u} \text{ REL } \boldsymbol{v}]$ in $\mathcal{D}_p^n$ under the flow of $\mathcal{R}$. Lemma 4, combined with the basic stability properties of the Conley index yields the following:

**Lemma 5.** *The index $h([\boldsymbol{u} \text{ REL } \boldsymbol{v}])$ is well-defined and independent of the choice of $\mathcal{R}$ (so long as it is parabolic and fixes $\boldsymbol{v}$) as well as the choice of $\boldsymbol{v}$ within its braid class $[\boldsymbol{v}]$.*

Thanks to the comparison principle for braids, the computation of the index $h$ does not require a choice of $\mathcal{R}$. One can identify the exit set $\mathcal{E}$ purely on the basis of which singular braids will decrease algebraic length under parabolic evolution. This is the basis for an algorithm to compute the homological index $H_*(h[\boldsymbol{u} \text{ REL } \boldsymbol{v}])$ numerically [17].

**Example 6.** Consider the proper period-2 braid illustrated in Figure 5 [left]. There is exactly one free strand with two anchor points (via periodicity). The anchor point in the middle, $u_1$, is free to move vertically between the fixed points on the skeleton. At the endpoints, one has a singular braid in $\Sigma$ which is on the exit set. The end anchor point, $u_0$ ($= u_2$) can freely move vertically in between the two fixed points on the skeleton. The singular boundaries are not on the exit set since pushing $u_0$ across the skeleton increases the number of crossings.

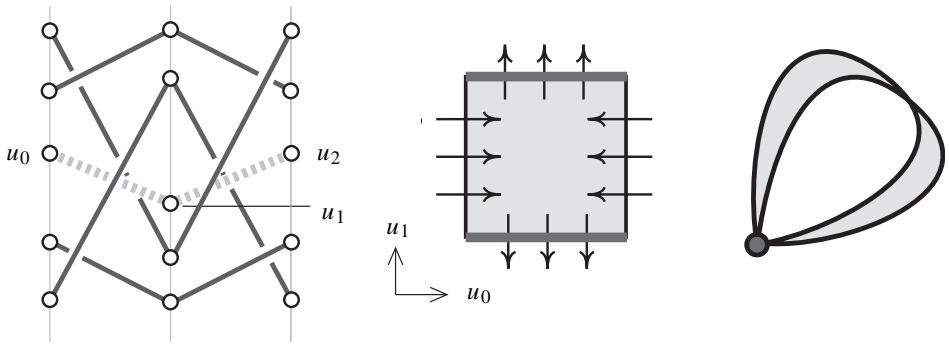

Figure 5. The braid of Example 6 [left] and the associated configuration space with parabolic flow [middle]. Collapsing out the exit set leads to a space [right] which has the homotopy type of a circle.

Since the points $u_0$ and $u_1$ can be moved independently, the braid class is the product of two intervals. The exit set consists of those points on the boundary for which $u_1$ is a boundary point. Thus, the homotopy braid index is $S^1$, as seen in Figure 5 [right].

**Example 7.** Consider the proper relative braid presented in Figure 6 [left]. Since there is one free strand of period three, the configuration space is determined by the vector of positions $(u_0, u_1, u_2)$ of the anchor points. This example differs greatly from the previous example. For instance, the point $u_0$ (as represented in the figure) may pass through the nearest strand of the skeleton above and below without changing the braid class. The points $u_1$ and $u_2$ may not pass through any strands of the skeleton

without changing the braid class unless $u_0$ has already passed through. In this case, either $u_1$ or $u_2$ (depending on whether the upper or lower strand is crossed) becomes free.

The skeleton induces a cubical partition of $\mathbb{R}^3$ by planes of singular braids. The relative braid class is the collection of cubes in $\mathbb{R}^3$ illustrated in Figure 6 [right]: it is homeomorphic to $D^2 \times S^1$. In this case, the exit set is the entire boundary and the quotient space is homotopic to the wedge-sum $S^2 \vee S^3$, the space defined by abstractly gluing a point of $S^2$ to a point of $S^3$.

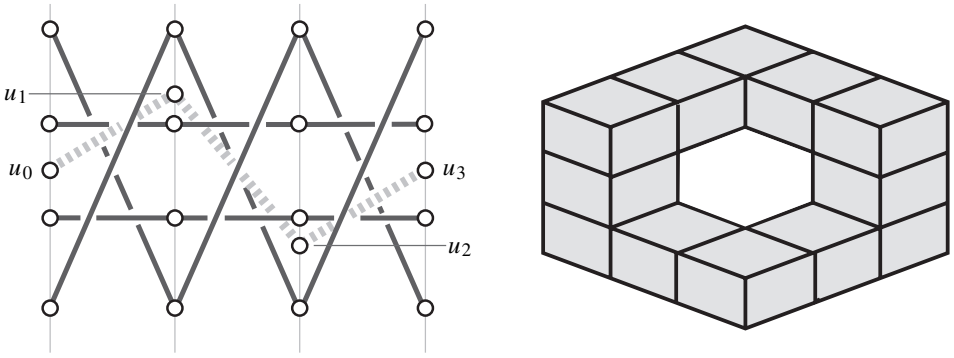

Figure 6. The braid of Example 7 and the associated relative braid class.

**Example 8.** The braid pair of Figure 7 [right] has index $h \simeq S^4 \vee S^5$ (as computed in [32, Lem. 50]); the pair on the left has trivial index, even though the linking numbers and periods of all strands are identical. This exemplifies the extra information carried by the braiding data.

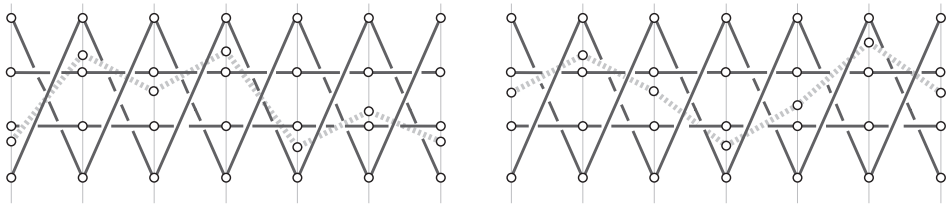

Figure 7. Discretized braid pairs with trivial [left] and nontrivial [right] homotopy index.

**4.3. The index: topological version.** As defined, the homotopy braid index $h$ is a function of discretized braid classes. For *topological* braids, one could hope that any discretization yields the same discrete index. It does, modulo two technicalities.

The first is simple. Given a topological relative braid pair $\boldsymbol{u}$ REL $\boldsymbol{v}$ and a discretization period $p$, consider the discrete braid pair whose anchor points are defined in the obvious way using $x_i = i/p$ as the spatial discretization points. Only for $p$ sufficiently large will this discrete braid pair be isotopic as a topological braid to the pair $\boldsymbol{u}$ REL $\boldsymbol{v}$. Thus, one must choose $p$ so that the correct braid class is obtained by discretization.

The second technicality is more subtle. Even if the discretized braid is topologically isotopic to the original, it is possible to "fracture" the homotopy type of the topological braid class via discretization. Consider the discrete braids of Figure 8: these braid pairs are equivalent as topological closed braids, but *not* as discrete closed braids. There is simply not enough freedom to maneuver.

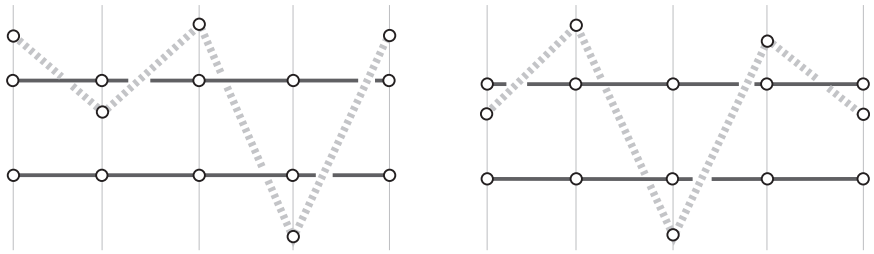

Figure 8. An example of two discretized braids which are of the same topological braid class but define disjoint discretized braid classes in $\mathcal{D}_4^1$ REL $\boldsymbol{v}$.

To overcome this difficulty, we define a modification of the homotopy braid index as follows. Given a fixed period $p$ and a discrete proper relative braid class $\beta = [\boldsymbol{u} \text{ REL } \boldsymbol{v}] \in \mathcal{D}_p^n$, let $\mathcal{S}(\beta)$ denote the set of all braid classes in $\mathcal{D}_p^n$ REL $\boldsymbol{v}$ which are isotopic as *topological* braids to a representative of $\beta$. Define the index $\boldsymbol{H}$ to be

$$\boldsymbol{H}(\beta) = \bigvee_{\beta_i \in \mathcal{S}(\beta)} h(\beta_i). \tag{8}$$

This is a wedge sum of the indices of all discrete period-$p$ representatives of the given topological braid class. The wedge sum is well-defined since each $h$ is a pointed homotopy class.

This index $\boldsymbol{H}$ is an invariant of topological braid classes. Consider the following *stabilization operator*, $\mathbb{E}\colon \mathcal{D}_p^n \to \mathcal{D}_{p+1}^n$, which appends a trivial period-1 braid to the end of a discrete braid:

$$(\mathbb{E}\boldsymbol{u})_i^\alpha = \begin{cases} u_i^\alpha, & i = 0, \ldots, p, \\ u_p^\alpha, & i = p+1. \end{cases} \tag{9}$$

The most important result about the index is the following invariance theorem:

**Theorem 9** (Stabilization [32]). *For $\boldsymbol{u}$ REL $\boldsymbol{v}$ any bounded proper discretized braid pair, the topological homotopy braid index is invariant under the extension operator:*

$$\boldsymbol{H}(\mathbb{E}\boldsymbol{u} \text{ REL } \mathbb{E}\boldsymbol{v}) = \boldsymbol{H}(\boldsymbol{u} \text{ REL } \boldsymbol{v}). \tag{10}$$

The proof of this theorem involves, surprisingly enough, a dynamical argument, utilizing a singular perturbation of a particular parabolic relation adapted to $\mathbb{E}$. This is a very convenient way to prove homotopy equivalence, given the robustness of the Conley index with respect to singular perturbations [15]. This theorem allows for a proof of topological invariance.

**Theorem 10** (Invariance [32]). *Given $\boldsymbol{u}$ REL $\boldsymbol{v} \in \mathcal{D}_p^n$ REL $\boldsymbol{v}$ and $\tilde{\boldsymbol{u}}$ REL $\tilde{\boldsymbol{v}} \in \mathcal{D}_{\tilde{p}}^n$ REL $\tilde{\boldsymbol{v}}$ which are topologically isotopic as bounded proper braid pairs, then*

$$\boldsymbol{H}(\boldsymbol{u} \text{ REL } \boldsymbol{v}) = \boldsymbol{H}(\tilde{\boldsymbol{u}} \text{ REL } \tilde{\boldsymbol{v}}). \tag{11}$$

The key ingredients in this proof are the Stabilization Theorem combined with a braid-theoretic argument that the moduli space of discretized braids converges to that of topological braids under sufficiently many applications of $\mathbb{E}$ – the length of the braid in the word metric suffices.

## 5. Forcing theorems: parabolic lattice dynamics

The dynamical consequences of the index are forcing results. A simple example: given any parabolic relation $\mathcal{R}$ which has as stationary solutions the skeleton of Figure 7 [right], then, since adding the dashed strand from that figure yields a nontrivial braid index, there must be some invariant set for $\mathcal{R}$ within this braid class. At this point, one uses Morse theory ideas: if $\mathcal{R}$ is exact, then there must be a stationary solution of the form of the grey strand. If the flow is not a gradient flow, then finer information can still detect stationary solutions.

More specifically, let $h$ be the homotopy braid index of a proper bounded discrete braid class $[\boldsymbol{u} \text{ REL } \boldsymbol{v}]$. Let $P_\tau(h)$ denote the *Poincaré polynomial* of the index – the polynomial in $\mathbb{Z}[\tau]$ whose coefficients are the Betti numbers of the homology of the index, $H_*(h;\mathbb{R})$. The following results are consequences of degenerate Morse theory (cf. [16]).

**Theorem 11** ([32]). *Given a parabolic relation $\mathcal{R}$ which fixes $\boldsymbol{v}$ and $h = h([\boldsymbol{u} \text{ REL } \boldsymbol{v}])$, the following hold:*

1. *The number of stationary braids in this braid class is bounded below by the Euler characteristic $\chi(h) = P_{-1}(h)$.*
2. *If $\mathcal{R}$ is exact, then the number of stationary braids in this braid class is bounded below by the number of nonzero monomials of $P_\tau(h)$.*

Stronger results are available if it is known that the parabolic relation is nondegenerate. By iterating the process of adding free strands and computing a nontrivial index, one can go quite far. The following forcing theorem (for exact $\mathcal{R}$) is very general, requiring only that the parabolic relation is exact (yielding a gradient flow) and *dissipative*, meaning that $\mathcal{R}_i \to -\infty$ as $|u_i| \to +\infty$.

**Theorem 12** ([32]). *Let $\mathcal{R}$ be a parabolic relation which is both exact and dissipative. If $\mathcal{R}$ fixes a discretized braid $\boldsymbol{v}$ which is not a trivial braid class, then there exist an infinite number of distinct braid classes which arise as stationary solutions of $\mathcal{R}$.*

This theorem is very much in the spirit of "period-three implies chaos." The dissipative boundary condition at infinity can be replaced with a coercive condition (infinity is attracting) or with mixtures thereof with only minor adjustments to the theorem statements [32].

## 6. Forcing theorems: second-order Lagrangians

This forcing theory gives an elegant approach to a class of fourth-order equations arising from a Lagrangian. Consider a *second order Lagrangian*, $L(u, u_x, u_{xx})$, such as is found in the Swift–Hohenberg equation:

$$L = \frac{1}{2}(u_{xx})^2 - (u_x)^2 + \frac{1-\alpha}{2}u^2 + \frac{u^4}{4}. \tag{12}$$

Assume the standard convexity assumption that $\partial^2_{u_{xx}} L \geq \delta > 0$. The Euler–Lagrange equations yield a fourth-order ODE. The objective is to find bounded functions $u : \mathbb{R} \to \mathbb{R}$ which are stationary for the action integral $J[u] = \int L(u, u_x, u_{xx})\, dx$. Due to the translation invariance $x \mapsto x + c$, the solutions of the Euler–Lagrange equation satisfy the energy constraint

$$\left(\frac{\partial L}{\partial u_x} - \frac{d}{dx}\frac{\partial L}{\partial u_{xx}}\right)u_x + \frac{\partial L}{\partial u_{xx}}u_{xx} - L(u, u_x, u_{xx}) = E = \text{ constant}, \tag{13}$$

where $E$ is the energy of a solution. To find bounded solutions for given values of $E$, we employ the variational principle $\delta_{u,T} \int_0^T (L(u, u_x, u_{xx}) + E)\, dx = 0$, which forces solutions to have energy $E$.

The Lagrangian problem can be reformulated as a two degree-of-freedom Hamiltonian system. In that context, bounded periodic solutions are closed characteristics of the corresponding energy manifold $M^3 \subset \mathbb{R}^4$. Unlike the case of first-order Lagrangian systems, the energy hypersurface is not of contact type in general [4], and is never compact. The recent stunning results in contact homology [18] are inapplicable.

**6.1. The twist condition.** The homotopy braid index provides a very effective means of forcing periodic orbits. By restricting to systems which satisfy a mild variational

hypothesis, one can employ a "broken geodesics" construction which yields a restricted form of parabolic relation.

Closed characteristics at a fixed energy level $E$ are concatenations of monotone laps between alternating minima and maxima $(u_i)_{i\in\mathbb{Z}}$, which form a periodic sequence with even period. The problem of finding closed characteristics can, in most cases, be formulated as a finite dimensional variational problem on the extrema $(u_i)$, as realized by Vandervorst, in his definition of the *twist condition*. The twist condition is a weaker version of the hypothesis that assumes that the monotone laps between extrema are unique and is valid for large classes of Lagrangians $L$, including Equation (12). The following result of [52] is the motivation and basis for the applications of the homotopy braid index to second-order Lagrangians.

**Lemma 13.** *Extremal points* $\{u_i\}$ *for bounded solutions of second order Lagrangian twist systems are solutions of an exact parabolic relation with the constraints that* (i) $(-1)^i u_i < (-1)^i u_{i+1}$*; and* (ii) *the relation blows up along any sequence satisfying* $u_i = u_{i+1}$.

**6.2. A general result.** It is necessary to retool the homotopy braid index to the setting of Lemma 13 and show that the index properties with respect to this restricted class of parabolic relations are invariant. Upon so doing, one extracts very general forcing theorems, a simple example of which is the following:

**Theorem 14** ([32]). *Let* $L(u, u_x, u_{xx})$ *be a Lagrangian which is dissipative* (*infinity is repelling*) *and twist. Then, at any regular energy level, the existence of a single periodic orbit which traces out a self-intersecting curve in the* $(u, u_x)$ *plane implies the existence of infinitely many other periodic orbits at this energy level.*

Additional results give lower bounds on the multiplicity of solutions in a given braid class based on the Poincaré polynomial and apply to singular energy levels, as well as to non-dissipative systems [32].

## 7. Forcing theorems: parabolic PDEs

The homotopy braid index, being inspired by parabolic PDEs, is efficacious in this context also, thanks to Theorem 10. By performing a spatial discretization of the dynamics of Equation (1), it is possible to reduce the dynamics of the PDE to those of a parabolic relation on a finite-dimensional space of discretized braids.

On account of the robustness of the homotopy index with respect to the dynamics, there is very little one needs to assume about the nonlinearity in Equation (1). The first, crucial, hypothesis is a growth condition on the $u_x$ term of $f$. For simplicity, let us call Equation (1) *subquadratic* if there exist constants $C > 0$ and $0 < \gamma < 2$, such that $|f(x, u, v)| \leq C(1 + |v|^\gamma)$, uniformly in both $x \in S^1$ and on compact intervals in $u$. This is necessary for regularity and control of derivatives of solution

curves, cf. [3]. This condition is sharp: one can find examples of $f$ with quadratic growth in $u_x$ for which solutions have singularities in $u_x$. Since our topological data are drawn from graphs of $u$, the bounds on $u$ imply bounds on $u_x$ and $u_{xx}$.

A second gradient hypothesis will sometimes be assumed. One says Equation (1) is *exact* if

$$u_{xx} + f(x, u, u_x) = a(x, u, u_x)\left[\frac{d}{dx}\partial_{u_x} L - \partial_u L\right], \tag{14}$$

for a strictly positive and bounded function $a = a(x, u, u_x)$ and some Lagrangian $L$ satisfying $a(x, u, u_x) \cdot \partial^2_{u_x} L(x, u, u_x) = 1$.

In this case, one has a gradient system whose stationary solutions are critical points of the action $\int L(x, u, u_x)\, dx$ over loops of integer period in $x$. This condition holds for a wide variety of systems. In general, systems with Neumann or Dirichlet boundary conditions admit a gradient-like structure which precludes the existence of nonstationary time-periodic solutions. It was shown by Zelenyak [55] that this gradient-like condition holds for many nonlinear boundary conditions which are a mixture of Dirichlet and Neumann.

**7.1. Stationary solutions.** Assume for the following theorems that $\{\boldsymbol{u} \text{ REL } \boldsymbol{v}\}$ is a topological braid class which is both bounded and proper. Assume further that $\boldsymbol{v}$ is stationary for Equation (1). We state our existence and multiplicity results in terms of the Poincaré polynomial $P_\tau(\boldsymbol{H})$ of the topological (as opposed to the discrete) braid index $\boldsymbol{H} = \boldsymbol{H}\{\boldsymbol{u} \text{ REL } \boldsymbol{v}\}$, computed via a discretization of the topological braid.

**Theorem 15** ([31]). *Let Equation* (1) *be subquadratic with* $\boldsymbol{v}$ *a stationary braid, and* $\boldsymbol{H} = \boldsymbol{H}(\{\boldsymbol{u} \text{ REL } \boldsymbol{v}\})$.

1. *There exists a stationary solution in this braid class if the Euler characteristic of the index,* $\chi(\boldsymbol{H}) = P_{-1}(\boldsymbol{H})$*, is nonvanishing.*

2. *If Equation* (1) *is furthermore exact, then there exists a stationary solution in this braid class if* $P_\tau(\boldsymbol{H}) \neq 0$.

Additional results are available concerning multiplicity of solutions, alternate boundary conditions, and non-uniformly parabolic equations: see [31]. A version of Theorem 12 on infinite numbers of braids being forced by a single nontrivial stationary braid persists in this context. The result is simplest to state if the PDE is *dissipative*; that is, $u\, f(x, u, 0) \to -\infty$ as $|u| \to +\infty$ uniformly in $x \in S^1$. This is a fairly benign restriction.

**Theorem 16** ([31]). *Let Equation* (1) *be subquadratic, exact, and dissipative. If* $\boldsymbol{v}$ *is a nontrivially braided stationary skeleton, then there are infinitely many braid classes represented as stationary solutions. Moreover, the number of single-free-strand braid classes is bounded from below by* $\lceil \iota/2 \rceil - 1$*, where* $\iota$ *is the maximal number of intersections between two strands of* $\boldsymbol{v}$.

**7.2. Examples.** The following family of spatially inhomogeneous Allen–Cahn equations was studied by Nakashima [45], [46]:

$$\varepsilon^2 u_t = \varepsilon^2 u_{xx} + g(x)u(1-u^2), \tag{15}$$

where $g\colon S^1 \to (0,1)$ is not a constant. This equation has stationary solutions $u = 0, \pm 1$ and is exact with Lagrangian

$$L = \frac{1}{2}\varepsilon^2 u_x^2 - \frac{1}{4}g(x)u^2(2-u^2).$$

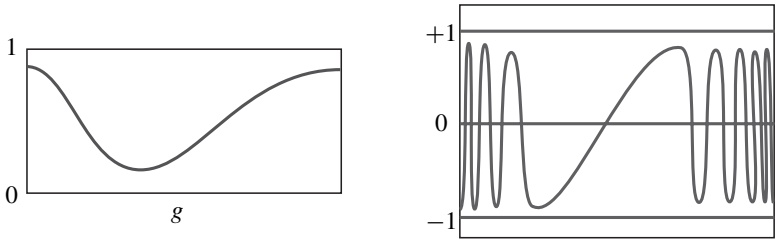

Figure 9. Given a function $g\colon S^1 \to (0,1)$ and $\varepsilon$ small, there exists a skeleton of stationary curves for Equation (15) which forms a nontrivial braid. This forces infinitely many other stationary braids.

According to [45], for any $N > 0$, there exists an $\varepsilon_N > 0$ so that for all $0 < \varepsilon < \varepsilon_N$, there exist at least two stationary solutions which intersect $u = 0$ exactly $N$ times. (The cited works impose Neumann boundary conditions: it is a simple generalization to periodic boundary conditions.) Via Theorem 16 we have that for any such $g$ and any small $\varepsilon$, this equation admits an infinite collection of stationary periodic curves; furthermore, there is a lower bound of $N$ on the number of 1-periodic solutions.

As a second explicit example, consider the equation

$$u_t = u_{xx} - \frac{5}{8}\sin 2x\, u_x + \frac{\cos x}{\cos x + \frac{3}{\sqrt{5}}}u(u^2-1), \tag{16}$$

with $x \in S^1 = \mathbb{R}/2\pi\mathbb{Z}$. This gives an exact system with Lagrangian

$$L = e^{-\frac{5}{16}\cos 2x}\left(\frac{1}{2}u_x^2 - \frac{\cos x}{\cos x + \frac{3}{\sqrt{5}}}\frac{(u^2-1)^2}{4}\right), \tag{17}$$

and weight $a(x,u,u_x) = e^{\frac{5}{16}\cos 2x}$ (cf. Equation (14)).

One checks easily that there are stationary solutions $\pm 1$ and $\pm\frac{1}{2}\big(\sqrt{5}\cos x + 1\big)$, as in Figure 10 [left]. These curves comprise a skeleton $\boldsymbol{v}$ which can be discretized to yield the skeleton of Example 6. This skeleton forces a stationary solution of the braid

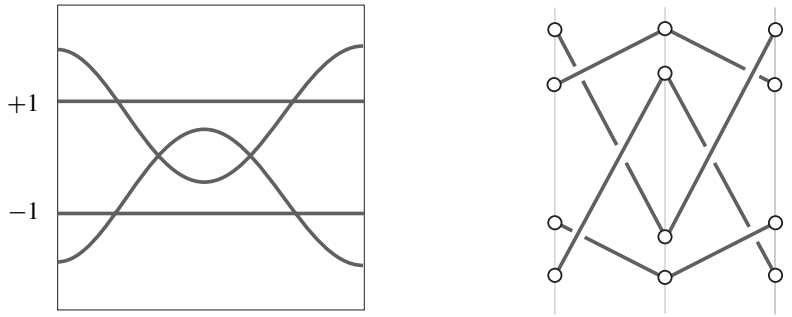

Figure 10. This collection of stationary solutions for Equation (16) [left] discretizes to the braid skeleton of Example 6.

class indicated in Figure 5 [left]: of course, this is detecting the obvious stationary solution $u = 0$. Note, however, that since $\boldsymbol{H} \simeq S^1$, this solution is unstable.

What is more interesting is the fact that one can take periodic extensions of the skeleton and add free strands in a manner which makes the relative braid spatially non-periodic. Let $\boldsymbol{v}^n$ be the $n$-fold periodic extension of $\boldsymbol{v}$ on $[0, n]/0 \sim n$ and consider a single free strand that weaves through $\boldsymbol{v}^n$ as in Figure 11. The homotopy index of such a braid is a sphere whose dimension is a function of the linking number of the free strand with the skeletal strands. The appropriate Morse inequalities imply that for each $n > 0$ there exist at least $3^n - 2$ distinct stationary solutions. This information can be used to prove that the time-$2\pi$ map of the stationary equation has positive entropy, see e.g. [47], [53].

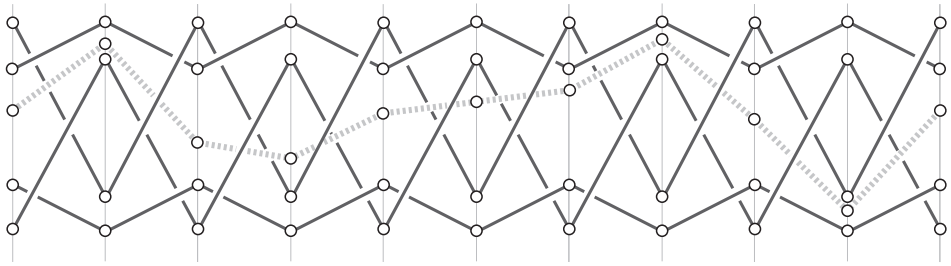

Figure 11. Taking a lift of the spatial domain allows one to weave free strands through the lifted skeleton. These project to multiply-periodic solutions downstairs. The braid pictured has index $\boldsymbol{H} \simeq S^2$.

**7.3. Time-periodic solutions.** A fundamental class of time-periodic solutions to Equation (1) are the so-called *rotating waves*. For an equation which is autonomous in $x$, one makes the rotating wave hypothesis that $u(t, x) = U(x - ct)$, where $c$ is

the unknown wave speed. Stationary solutions for the resulting equation on $U(\xi)$ yield rotating waves. In [3] it was proved that time-periodic solutions are necessarily rotating waves for an equation autonomous in $x$. However, in the non-autonomous case, the rotating wave assumption is highly restrictive.

The homotopy braid index presents a very general technique for finding time-periodic solutions without the rotating wave hypothesis.

**Theorem 17** ([31]). *Let* $\{\boldsymbol{u} \text{ REL } \boldsymbol{v}\}$ *be a bounded proper topological braid class with* $\boldsymbol{u}$ *a single-component braid,* $\boldsymbol{v}$ *an arbitrary stationary braid, and* $P_\tau(\boldsymbol{H}) \neq 0$. *If the braid class is not stationary for Equation* (1) *– the equation does not contain stationary braids in this braid class – then there exists a time-periodic solution in this braid class.*

It was shown in [3] that a singularly perturbed van der Pol equation,

$$u_t = \varepsilon u_{xx} + u(1 - \delta^2 u^2) + u_x u^2, \tag{18}$$

possesses an arbitrarily large number of rotating waves for $\varepsilon \ll 1$ sufficiently small and fixed $0 < \delta$. The homotopy braid index methods extend these results dramatically.

**Theorem 18** ([31]). *Consider the equation*

$$u_t = u_{xx} + ub(u) + u_x c(x, u, u_x), \tag{19}$$

*where c has sub-linear growth in* $u_x$ *at infinity. Moreover, b and c satisfy the following hypotheses:*

1. $b(0) > 0$, *and b has at least one positive and one negative root;*
2. $c(x, 0, 0) = 0$, *and* $c > 0$ *on* $\{uu_x \neq 0\}$.

*Then this equation possesses time-periodic solutions spanning an infinite collection of braid classes.*

All of the periodic solutions implied are dynamically unstable. In the most general case (those systems with $x$-dependence), the periodic solutions are not rigid rotating waves and thus would seem to be very difficult to detect.

## 8. What does this index mean?

The most important fact about the homotopy braid index $\boldsymbol{H}$ is that it is an invariant of topological braid pairs. Though it is not realistic to think that this is of interest in knot theory as a means of distinguishing braid pairs, the homotopy braid index nevertheless entwines both topological and dynamical content.

Thinking in terms of braid classes gives finer information than relying merely on intersection numbers. With the braid-theoretic approach, various analytic conditions

on a PDE or lattice system (dispersive, coercive, etc.) can be 'modeled' by an auxiliary braid when computing the index. Likewise, spatial boundary conditions (Neumann, Dirichlet, periodic, etc.) can be viewed as restrictions on braids (fixed, closed, etc.). Any such restrictions which yield topologically equivalent braids have the same dynamical implications with respect to forcing. One may replace complicated analytic constraints with braids.

The precise topological content to the homotopy braid index is not transparent. A few steps toward unmasking the meaning of the index are as follows.

**8.1. Duality.** One special feature of working with discretized braids in a fixed period is a natural duality made possible by the fact that the index pair used to compute the homotopy braid index can be chosen to be a manifold pair.

The *duality operator* on discretized braids of even period is the map $\mathbb{D}\colon \mathcal{D}^n_{2p} \to \mathcal{D}^n_{2p}$ given by

$$(\mathbb{D}\boldsymbol{u})^\alpha_i = (-1)^i u^\alpha_i. \tag{20}$$

Clearly $\mathbb{D}$ induces a map on relative braid diagrams by defining $\mathbb{D}(\boldsymbol{u} \text{ REL } \boldsymbol{v})$ to be $\mathbb{D}\boldsymbol{u} \text{ REL } \mathbb{D}\boldsymbol{v}$. The topological action of $\mathbb{D}$ is to insert a half-twist at each spatial segment of the braid. This has the effect of linking unlinked strands, and, since $\mathbb{D}$ is an involution, linked strands are unlinked by $\mathbb{D}$, as in Figure 12.

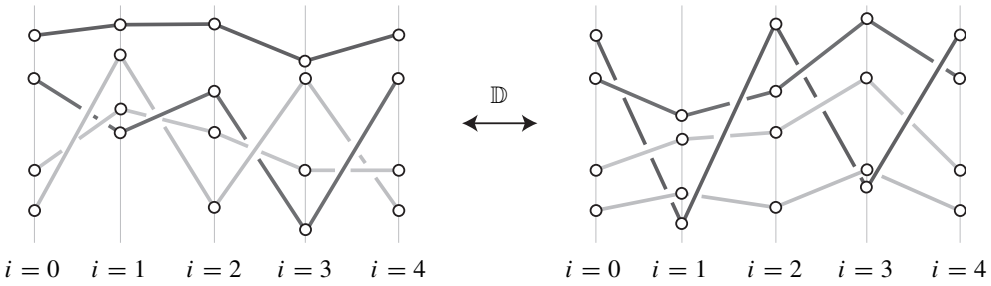

Figure 12. The topological action of $\mathbb{D}$.

For the two duality theorems to follow, we assume that all braids considered have even periods and that all of the braid classes and their duals are proper, so that the homotopy index is well-defined. In this case, the duality map $\mathbb{D}$ respects braid classes: if $[\boldsymbol{u}] = [\boldsymbol{u}']$ then $[\mathbb{D}(\boldsymbol{u})] = [\mathbb{D}(\boldsymbol{u}')]$. Bounded braid classes are taken to bounded braid classes by $\mathbb{D}$.

The effect of $\mathbb{D}$ on the index pair is to reverse the direction of the parabolic flow. This is the key to proving the following:

**Theorem 19** (Duality [32][1]). *For* $[\boldsymbol{u} \text{ REL } \boldsymbol{v}]$ *having period* $2p$ *and* $n$ *free strands,*

$$H_q(\boldsymbol{H}(\mathbb{D}(\boldsymbol{u} \text{ REL } \boldsymbol{v})); \mathbb{R}) \cong H_{2np-q}(\boldsymbol{H}(\boldsymbol{u} \text{ REL } \boldsymbol{v}); \mathbb{R}). \tag{21}$$

This duality operator is very useful in computing the homology of the braid index: see the computations in [32].

**8.2. Twists.** The duality operator yields a result on the behavior of the index under appending a full twist.

**Theorem 20** (Shift [32]). *Appending a full twist to a braid shifts the homology of the index up by dimension equal to twice the number of free strands.*

We include a sketch of the proof (a more careful version of which would deal with some boundedness issues). Assume that $[\boldsymbol{u} \text{ REL } \boldsymbol{v}]$ is a braid of period $2p$ with $n$ free strands. A period two full-twist braid can be realized as the dual of the trivial braid of period two. Thus, the effect of adding a full twist to a braid can be realized by the operator $\mathbb{DEED}$. By combining Theorems 9 and 19, we obtain:

$$\begin{aligned} H_q(\boldsymbol{H}(\mathbb{DEED}[\boldsymbol{u} \text{ REL } \boldsymbol{v}])) &\cong H_{2np+2n-q}(\boldsymbol{H}(\mathbb{DEE}[\boldsymbol{u} \text{ REL } \boldsymbol{v}])) \\ &\cong H_{2np+2n-q}(\boldsymbol{H}(\mathbb{D}[\boldsymbol{u} \text{ REL } \boldsymbol{v}])) \\ &\cong H_{q-2n}(\boldsymbol{H}([\boldsymbol{u} \text{ REL } \boldsymbol{v}])). \end{aligned} \tag{22}$$

A homotopy version of Equation (22) should be achievable by following a similar procedure as in the proof of Theorem 9. We suspect one obtains an iterated suspension of the homotopy index, as opposed to a shift in homology.

## 9. Toward arbitrary braids

Given the motivation from PDEs and the comparison principle, the types of braids considered in this paper are positive braids. One naturally wonders whether an extension to arbitrary braids – those with mixed crossing types – is possible. Unfortunately, passing to discretized braids is no longer simple, as anchor points alone cannot capture crossing information for arbitrary braids.

One way to define a formal index for general braid pairs is to use Garside's Theorem [6], slightly modified. Garside's Theorem states that any braid can be placed into a unique normal form of a positive braid times a (minimal) number of negative half-twists. Clearly, one can define a modified Garside normal form that gives a unique decomposition into a positive braid and a (minimal) number of negative full twists. By applying Theorem 20, one can define a homological braid index (with negative grading permitted) by shifting the braid index of the positive normal form down by

[1]The theorem in the reference has a slight error in the statement. There, it was implicitly assumed that the braid has one free strand. The present statement is correct for arbitrary numbers of strands.

the appropriate amount. A homotopy theoretic version could be defined in terms of spectra via suspensions. This, then, yields a formal index for arbitrary (proper) braid pairs.

The real question is what dynamical meaning this generalized index entails. The passage from positive braids to arbitrary braids is akin to the passage from a Lagrangian to a Hamiltonian settings, and such an extended index appears to be a relative Floer homology for (multiply) periodic solutions to time-periodic Hamiltonian systems.

# Newton interpolation polynomials, discretization method, and certain prevalent properties in dynamical systems

Anton Gorodetski, Brian Hunt*, and Vadim Kaloshin†

**Abstract.** We describe a general method of studying prevalent properties of diffeomorphisms of a compact manifold $M$, where by *prevalent* we mean true for Lebesgue almost every parameter $\varepsilon$ in a generic finite-parameter family $\{f_\varepsilon\}$ of diffeomorphisms on $M$.

Usually a dynamical property $\mathcal{P}$ can be formulated in terms of properties $\mathcal{P}_n$ of trajectories of finite length $n$. Let $\mathcal{P}$ be such a dynamical property that can be expressed in terms of only periodic trajectories. *The first idea* of the method is to *discretize* $M$ and split the set of all possible periodic trajectories of length $n$ for the entire family $\{f_\varepsilon\}$ into a *finite number* of approximating periodic pseudotrajectories. Then for each such pseudotrajectory, we estimate the measure of parameters for which it fails $\mathcal{P}_n$. This bounds the total parameter measure for which $\mathcal{P}_n$ fails by a finite sum over the periodic pseudotrajectories of length $n$. Application of Newton interpolation polynomials to estimate the measure of parameters that fail $\mathcal{P}_n$ for a given periodic pseudotrajectory of length $n$ is *the second idea*.

We outline application of these ideas to two quite different problems:

• Growth of number of periodic points for prevalent diffeomorphisms (Kaloshin–Hunt).

• Palis' conjecture on finititude of number of "localized" sinks for prevalent surface diffeomorphisms (Gorodetski–Kaloshin).

**Keywords.** Discretization method, Newton interpolation polynomials, prevalence, pseudotrajectory, growth of number of periodic points, Newhouse phenomenon.

## 1. Introduction

A classical problem in dynamics, geometry, and topology is the description of generic behavior. Given a set of objects what are the properties of a generic element of the set? This question applies to diffeomorphisms, Riemannian metrics, linear operators, and vector fields, just to give several examples. The traditional approach is based on the category theorem of Baire. A countable intersection of open, dense sets is called a *residual,* or *topologically generic*, set. The Baire category theorem says that topologically generic sets of a complete metric space (or, more generally, Baire space) are dense. The book of Oxtoby [O] provides a rich variety of topologically generic mathematical objects. However, in many different areas of mathematics examples

†Supported by an Alfred Sloan Research Fellowship, American Institute of Mathematics Fellowship, and NSF Grant No. DMS-0300229

Proceedings of the International Congress of Mathematicians, Madrid, Spain, 2006

of "wild behavior" of topologically generic objects have been detected (see [HSY], [Ka2], [OY], [Si] and references there). In this paper we are concerned with generic properties in dynamics, particularly those that are not generic topologically but are generic in a measure-theoretic sense.

In the 1960s two main theories in dynamical systems were developed, one of which was designed for conservative systems and called *KAM* for *Kolmogorov–Arnold–Moser* and the other was constructed for general dynamical systems (nonconservative, dissipative) and called *hyperbolic*.

Kolmogorov [Ko], in his plenary talk of ICM 1954, pointed out that a different notion of genericity may be appropriate: "In order to obtain negative results concerning insignificant or exceptional character of some phenomenon we shall apply the following, somewhat haphazard, technique: if in a class $K$ of functions $f(x)$ one can introduce a finite number of functionals

$$F_1(f),\ F_2(f), \ldots,\ F_r(f),$$

which in some sense can naturally be considered as taking "arbitrary" values in general

$$F_1(f) = C_1,\ F_2(f) = C_2, \ldots, F_r(f) = C_r$$

from some domain of the $r$-dimensional space of points $C = (C_1, \ldots, C_r)$, then any phenomenon that takes place only if $C$ belongs to a set of zero $r$-dimensional measure will be regarded exceptional and subject to "neglect"."

A somewhat similar way to define a measure-theoretic genericity, often called *prevalence*, is the following: *We call a property $\mathcal{P}$ prevalent if for a generic*[1] *finite-parameter family $\{f_\varepsilon\}_{\varepsilon\in B}$ for Lebesgue almost every parameter $\varepsilon$ the corresponding $f_\varepsilon$ satisfies $\mathcal{P}$. If complement of a property is prevalent such a property is called shy*. We shall discuss prevalence further in Section 9.

There are many examples when topological genericity and measure-theoretic genericity do not coincide. We just mention a few of them (see [HSY], [Ka2], [OY] for many more).

• *Diophantine numbers* form a set of full measure on the line $\mathbb{R}$, but are topologically negligible (that is the complement of the set is topologically generic).

• For a topologically generic, even open dense, set of circle maps preserving orientation there is a finite number of attracting and repelling periodic orbits. All other orbits accumulate to these orbits both forward or backward in time. However, as the famous example of Arnold, called *Arnold tongues*, shows in the family $f_{\alpha,\varepsilon}\colon \theta \mapsto \theta + \alpha + \varepsilon \sin\theta$ that the smaller $\varepsilon$ is, the smaller is the measure of $\alpha$ values such that $f_{\alpha,\varepsilon}$ has this property. Moreover, the main result of KAM theory says that for consevative systems close to integrable most, in a measure-theoretic sense, motions are *quasiperiodic*.

• In general dynamical systems a dream of the 1960s was to prove that a generic dynamical system is structurally stable. However, this dream evaporated by the end of

[1] We give a rigorous definition in Section 9.

that decade. One of the beautiful counterexamples is due to Newhouse [N1], [N2]. He shows that there is an open set in the space of diffemorphisms of a compact manifold such that a generic diffeomorphism in this open set has *infinitely many coexisting sinks* (attracting periodic orbits). Below we show in some weak sense this phenomenon is shy (see Section 7). This phenomenon is closely related to Palis' program [Pa] which is discussed next.

Let $\mathrm{Diff}^r(M)$ be the space of $C^r$ diffeomorphisms of a smooth compact manifold $M$ with the uniform $C^r$-topology, where $\dim M \geq 2$, and let $f \in \mathrm{Diff}^r(M)$. The main focus of the present paper is *the space of general* (*nonconservative*) *diffeomorphisms* $\mathrm{Diff}^r(M)$. The authors believe that the method presented here also applies to conservative systems.

While examples such as Newhouse's show that on open subsets of $\mathrm{Diff}^r(M)$, "wild" phenomena that are not structurally stable can be topologically generic, a measure-theoretic point of view may be more appropriate to describe the dynamical behavior that would typically be observed by a scientist. In the influential paper J. Palis [Pa] proposed a new global view of generic dynamics based on measure theory. He stated the following conjectures on finititude of attractors and their metric stability:

(I) *Denseness of finititude of attractors – there is* $C^r$ $(r \geq 1)$ *dense set* $D$ *of diffeomorphisms in* $\mathrm{Diff}^r(M)$ *such that each element of* $D$ *has finitely many attractors, the union of whose basins of attraction has full measure;*

(II) *Existence of physical* (*SRB*) *mesure – each attractor of an element of* $D$ *supports a physical measure that represents the limiting distribution for Lebesgue almost every initial condition in its basin;*

(III) *Metric stability of basins of attraction – for each element in* $D$ *and each of its attractors, for almost all small* $C^r$ *perturbations in generic* $k$*-parameter families of diffeomorphisms in* $\mathrm{Diff}^r(M)$, $k \in \mathbb{N}$, *there are finitely many attractors whose union of basins is nearly equal in the sense of Lebesgue measure to the basin of the initial attractor; such perturbed attractors support a physical measure.*

Such results have been established for certain examples of dynamical systems. Lyubich [Ly] for the quadratic family of 1-dimensional maps and Avila–Lyubich–de Melo [ALM] for a generic family of analytic unimodal 1-dimensional maps showed that for almost all parameters the attractors are either periodic sinks or carry an absolutely continuous invariant measure. For the 1-dimensional Schrödinger cocycles Avila–Krikorian [AK] showed that for all analytic or $C^\infty$ potentials and almost all rotation numbers the corresponding cocycle is either non-uniformly hyperbolic or reducible.

In this paper we discuss *two* important topologically negligible dynamical properties that are in fact prevalent. One property is (stretched) exponential growth of the number of periodic points and the other is finiteness of number of coexisting "localized" sinks for surface diffeomorphisms.

We hope that the method, outlined in this article, brings a better understanding of prevalent properties of $\mathrm{Diff}^r(M)$ in the direction of Palis' conjectures and other important dynamical properties.

## 2. Elementary events and a sample result

Here we expose ideas in a general setting. Consider a family of diffeomorphisms $\{f_\varepsilon\}_{\varepsilon\in B} \subset \mathrm{Diff}^r(M)$ of a compact manifold with a probability measure $\mu$ supported on the set of parameters $B$. To avoid distracting details we postpone specification of $\mu$ and $B$.

Let us fix a certain property $\mathcal{P}$ of periodic points of period $n$. In both cases that we will consider, $\mathcal{P}$ is some form of quantitative hyperbolicity. We split the problem into two parts.

• Estimate the measure of the set

$$\mu(B_n) \le \mu_n,\ B_n = \{\varepsilon \in B :\ f_\varepsilon \text{ has a periodic orbit that does not satisfy } \mathcal{P}\} \subset B.$$

• Derive some dynamically interesting properties from this estimate.

The second part essentially depends on the problem. As for the first part, application of the discretization method and Newton interpolation polynomials give a uniform approach to get a required estimate. First, we discuss the problem of growth of the number of periodic points (see Theorem 2.1 below).

For $\gamma > 0$ we say that $x = f^n(x)$ is $(n,\gamma)$-*hyperbolic* if all eigenvalues of the linearization $df^n(x)$ are at least $\gamma$-away from the unit circle[2]. For $\gamma > 0$ this is a weak analog of Kupka–Smale property. Fix some $c > 0$ and a decaying to zero sequence of positive numbers $c\Gamma = \{c\gamma_n\}_{n\in\mathbb{Z}_+}$.

We say that the map $f_\varepsilon$ satisfies *the inductive hypothesis of order n with constants* $c\Gamma$, denoted $f_\varepsilon \in IH(n, c\Gamma)$, if for all $k \le n$ all periodic orbits of period $k$ are $(k, c\gamma_k)$-hyperbolic. Consider a sequence of "bad" sets in the parameter space

$$B_n(c\Gamma) = \{\varepsilon \in B :\ f_\varepsilon \in IH(n-1, c\Gamma),\ \text{but } f_\varepsilon \notin IH(n, c\Gamma)\}. \tag{1}$$

In other words, $B_n(c\Gamma)$ is the set of "bad" parameter values $\varepsilon \in B$ for which all periodic points with period strictly less than $n$ are sufficiently hyperbolic, but there is a periodic point of period $n$ that is not $(n, c\gamma_n)$-hyperbolic.

Our goal is to find an upper bound

$$\mu\{B_n(c\Gamma)\} \le \mu_n(c\Gamma) \tag{2}$$

for the measure of the set of "bad" parameter values. Then the sum over $n$ of (2) gives an upper bound $\mu\big\{\bigcup_n B_n(c\Gamma)\big\} \le \sum_{n\ge1} \mu_n(c\Gamma)$ on the set of all parameters $\varepsilon$ for which $f_\varepsilon$ has a periodic point of some period $n$ that is not $(n, c\gamma_n)$-hyperbolic. If the sum converges and $\sum_{n\ge1} \mu_n(c\Gamma) = \mu(c) \to 0$ as $c \to 0$, then for $\mu$-almost every $\varepsilon$ there is $c > 0$ such that for every $n$ every periodic point of period $n$ is $(n, c\gamma_n)$-hyperbolic.

This statement (almost) implies that all periodic points of period $n$ are at least $\approx c\gamma_n$-apart and, therefore, the number of periodic points is bounded by $\approx (c\gamma_n)^{-\dim M}$

[2] In [KH1] we use a stronger property of hyperbolicity of periodic points (see Section 2 of that paper).

(see [KH1], Proposition 1.1.6). Thus, the key to prove a statement that a certain property is prevalent, i.e. holds for almost every parameter value, is *an estimate of the probability* (2) *of a "bad" event*. One could replace the property of hyperbolicity of periodic points by another property and still the key is to get an estimate of the probability to fail a certain dynamical property.

Our goal is to outline the proof of the following result:

**Theorem 2.1** ([KH1], [Ka3], [Ka4]). *For a prevalent set of diffeomorphisms* $f \in \mathrm{Diff}^r(M)$*, with* $1 < r < \infty$*, and for all* $\delta > 0$ *there exists* $C = C(\delta)$ *such that*

$$P_n(f) := \#\{\text{ isolated } x \in M : \ f^n(x) = x\} \le \exp(Cn^{1+\delta}).$$

Density of diffeomorphisms with this property is the classical result of Artin–Mazur [AM] (see also [Ka2] for a simple proof). In [Ka1], using [GST], it is shown that diffeomorphisms having an arbitrary ahead given growth along a subsequence are topologically generic.

In Section 7 we briefly describe application of the method of the paper to Newhouse phenomenon from [GK].

## 3. Strategy to estimate probability of a "bad" event: discretization method

The goal of this section is to outline how one can get estimate (2). Usually we do not know where is a "bad" trajectory, which fails $\mathcal{P}$, and what are the dynamics in its neighborhood. So our analysis will be *implicit*. More exactly, we shall consider all possible trajectories in the family $\{f_\varepsilon\}_{\varepsilon\in B}$ and the worst case scenario for each of them.

In order to fail the inductive hypothesis of order $n$ with constants $c\Gamma$, a diffeomorphism $f_\varepsilon$ should have a periodic, but not $(n, c\gamma_n)$-hyperbolic point $x = f_\varepsilon^n(x)$. There is a continuum of possible $n$-tuples $\{x_k\}_{0\le k\le n}$ such that for some $\varepsilon \in B$ we have $f(x_k) = x_{k+1 \pmod n}$ and $x_0$ is not $(n, c\gamma_n)$-hyperbolic. Instead of looking at the continuum of $n$-tuples, we discretize this space and consider only those $n$-tuples $\{x_k\}_{0\le k\le n}$ that lie on a particular grid, denoted $I_{\tilde\gamma_n}$, and replace trajectories by $\tilde\gamma_n$-pseudotrajectories. If we choose the grid spacing $\tilde\gamma_n$ small enough, then every (almost) periodic point of period $n$ that is not sufficiently hyperbolic will have a corresponding $\tilde\gamma_n$-pseudotrajectory of length-$n$ on the grid that also has small hyperbolicity. In this way we reduce the problem of bounding the measure of a set of "bad" parameters corresponding to a particular length-$n$ $\tilde\gamma_n$-pseudotrajectory on the chosen grid.

Thus, the basic requirement for the grid size $\tilde\gamma_n$ is that every real periodic trajectory $\{x_k = f_\varepsilon^k(x_0)\}_{0\le k\le n}$ of length $n$ can be approximated by a $\tilde\gamma_n$-pseudotrajectory $\{\tilde x_k\}_{0\le k\le n}$ so that if $x_0$ is periodic but not $(n, c\gamma_n)$-hyperbolic, then the $n$-tuple $\{\tilde x_k\}_{0\le k\le n}$ is not $(n, c\gamma_n/2)$-hyperbolic (see [KH1], sect. 3.2 and [GK], sect. 8 for various definitions).

We call an $n$-tuple $\{x_k\}_{k=0}^{n-1} \subset I_{\tilde\gamma_n}^n$ *a $\tilde\gamma_n$-pseudotrajectory associated to some $\varepsilon$ (or to the map $f_\varepsilon$)* if for each $k = 0, \dots, n-1$ we have $dist(f_\varepsilon(x_{k-1}),\ x_k) \le \tilde\gamma_n$ and we call it *a $\tilde\gamma_n$-pseudotrajectory associated to $B$ (or the family $\{f_\varepsilon\}_{\varepsilon\in B}$)* if it is associated to some $\varepsilon \in B$.

The naive idea of estimate (2) consists of two steps:
*Step* 1. Estimate the number of different $\tilde\gamma_n$-pseudotrajectories $\#_n(\tilde\gamma_n)$ associated to $B$;
*Step* 2. For an $n$-tuple $\{x_k\}_{0\le k\le n-1} \subset I_{\tilde\gamma_n}^n$ estimate the measure

$$\begin{aligned}&\mu\{\varepsilon \in B :\ \{x_k\}_{0\le k\le n-1} \text{ is a } \tilde\gamma_n\text{-pseudotrajectory associated to } \varepsilon\\ &\text{which is } \tilde\gamma_n\text{-periodic but not } (n, c\gamma_n/2)\text{-hyperbolic}\} \le \mu_n(c\gamma_n, \tilde\gamma_n).\end{aligned} \tag{3}$$

Then the product of two numbers $\#_n(\tilde\gamma_n)$ and $\mu_n(c\gamma_n, \tilde\gamma_n)$ that are obtained in Steps 1 and 2 gives the required estimate. In fact, this simpleminded scheme requires modifications discussed at the end of the next section (see (10–13)).

We start with the second step. For simplicity we shall discuss 1-dimensional maps (see [KH1], sect. 3). In [KH1], sect. 4.2 we discuss difficulties arising to extend this method to multidimensional maps. See also [GK], sect. 10 (resp. [Ka4], sect. 7–8), where 2-dimensional (resp. $N$-dimensional) case is considered. To treat the multidimensional case one use very similar ideas, however, technical difficulties arising due to multidimensionality are fairly involved. Now we show how to estimate probability (3) within a particular polynomial family and then show how to do Step 1 and incorporate the method into the global framework.

## 4. Newton interpolation polynomials and an estimate of probability of a $\tilde\gamma_n$-periodic but not $(n, c\gamma_n/2)$-hyperbolic $\tilde\gamma_n$-pseudotrajectory of length $n$

Let $M$ be an interval $[-1, 1]$ and $I_{\tilde\gamma_n} \subset [-1, 1]$ be a $\tilde\gamma_n$-grid. Fix an $n$-tuple of points $\{x_k\}_{k=0}^{n-1} \subset I_{\tilde\gamma_n}$. Consider the following $2n$-parameter family of maps:

$$f_u(x) = f(x) + \sum_{k=0}^{2n-1} u_k \prod_{j=0}^{k-1} (x - x_{j \pmod n}).$$

This family is nothing but the Newton interpolation polynomials associated to the $n$-tuple $\{x_k\}_{k=0}^{n-1}$. Denote $\phi_u(x) = \sum_{k=0}^{2n-1} u_k \prod_{j=0}^{k-1}(x - x_{j \pmod n})$. Notice that

$$\begin{aligned}\phi_u(x_0) &= u_0,\\ \phi_u(x_1) &= u_0 + u_1(x_1 - x_0),\\ \phi_u(x_2) &= u_0 + u_1(x_2 - x_0) + u_2(x_2 - x_0)(x_2 - x_1),\\ &\vdots\end{aligned}$$

$$
\begin{aligned}
&\vdots\\
\phi_u(x_{n-1}) &= u_0 + u_1(x_{n-1} - x_0) + \dots\\
&\quad + u_{n-1}(x_{n-1} - x_0)\dots(x_{n-1} - x_{n-2}),\\
\phi'_u(x_0) &= \frac{\partial}{\partial x}\Big(\sum_{k=0}^{2n-1} u_k \prod_{j=0}^{k}(x - x_{j(\mathrm{mod}\ n)})\Big)\Big|_{x=x_0},\\
&\vdots\\
\phi'_u(x_{n-1}) &= \frac{\partial}{\partial x}\Big(\sum_{k=0}^{2n-1} u_k \prod_{j=0}^{k}(x - x_{j(\mathrm{mod}\ n)})\Big)\Big|_{x=x_{n-1}}.
\end{aligned}
\tag{4}
$$

These formulas are very useful for dynamics. For a given map $f$ and an initial point $x_0$, the image $f_u(x_0) = f(x_0) + \phi_u(x_0)$ of $x_0$ depends only on $u_0$. Furthermore the image can be set to any desired point by choosing $u_0$ appropriately – we say then that it depends only and nontrivially on $u_0$. If $x_0$, $x_1$, and $u_0$ are fixed, the image $f_u(x_1)$ of $x_1$ depends only on $u_1$, and as long as $x_0 \neq x_1$ it depends nontrivially on $u_1$. More generally for $0 \leq k \leq n-1$, if distinct points $\{x_j\}_{j=0}^{k}$ and coefficients $\{u_j\}_{j=0}^{k-1}$ are fixed, then the image $f_u(x_k)$ of $x_k$ depends only and nontrivially on $u_k$.

Suppose now that an $n$-tuple of pairwise distinct points $\{x_j\}_{j=0}^{n-1}$ and Newton coefficients $\{u_j\}_{j=0}^{n-1}$ are fixed. Then derivative $f'_u(x_0)$ at $x_0$ depends only and nontrivially on $u_n$. Likewise for $0 \leq k \leq n-1$, if distinct points $\{x_j\}_{j=0}^{n-1}$ and Newton coefficients $\{u_j\}_{j=0}^{n+k-1}$ are fixed, then the derivative $f'_u(x_k)$ at $x_k$ depends only and nontrivially on $u_{n+k}$.

As Figure 1 illustrates, these considerations show that for any map $f$ and any desired trajectory of distinct points with any given derivatives along it, one can choose Newton coefficients $\{u_k\}_{k=0}^{2n-1}$ and explicitly construct a map $f_u = f + \phi_u$ with such a trajectory. While the parametrization depends on the $n$-tuple, the family is equivalent by a change of parameter coordinates (see Section 5) to the family $\{f_\varepsilon\}_\varepsilon$ of perturbations by degree $2n-1$ polynomials, given by (14).

Using these properties of Newton interpolation polynomials we can easily estimate probability (3). Let us split this compound dynamic event into simple ones and use the above properties:

$$
\begin{aligned}
&1. && |f_\varepsilon(x_0) - x_1| \leq \tilde{\gamma}_n;\\
&2. && |f_\varepsilon(x_1) - x_2| \leq \tilde{\gamma}_n;\\
&&& \vdots\\
&n. && |f_\varepsilon(x_{n-1}) - x_0| \leq \tilde{\gamma}_n;\\
&n+1. && \Big|\prod_{j=0}^{n-1} |f'_\varepsilon(x_j)| - 1\Big| \leq c\gamma_n/2.
\end{aligned}
\tag{5}
$$

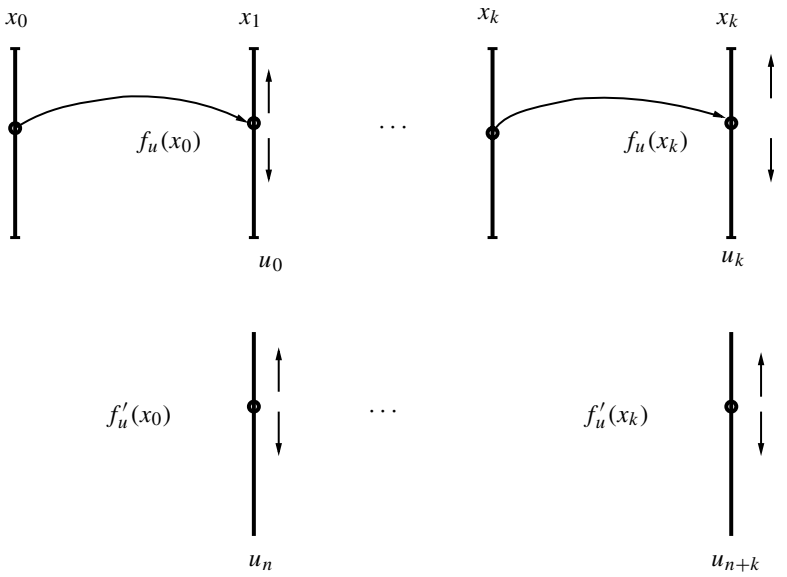

Figure 1. Newton coefficients and their action.

First, we find probabilities of these events with respect to $u$-parameters (see [KH1], sect. 3.3 for more details). It turns out that the map relating $\varepsilon$-parameters and $u$-parameters is one-to-one, linear, and volume-preserving (see Section 5).

Notice that in (4) and Figure 1, the image $f_u(x_0)$ of $x_0$ is independent of $u_k$ for all $k > 0$. Therefore, the position of $f_u(x_0)$ *depends only on* $u_0$. For the 1-dimensional Lebesgue measure of the $u_0$'s we have

$$\text{Leb}\,\{u_0 :\ |f_u(x_0) - x_1| = |f(x_0) + u_0 - x_1| \le \tilde{\gamma}_n\} \le 2\tilde{\gamma}_n.$$

Fix $u_0$. Similarly, the position of $f_u(x_1)$ *depends only on* $u_1$ (see (4) and Figure 1). Thus, we have

$$\text{Leb}\big\{u_1 :\ |f_u(x_1) - x_2| = |f(x_1) + u_0 + u_1(x_1 - x_0) - x_2| \le \tilde{\gamma}_n\} \le \frac{2\tilde{\gamma}_n}{|x_1 - x_0|}.$$

Inductively for $k = 2, \dots, n-1$, fix $u_0, \dots, u_{k-1}$. Then the position of $f_u(x_k)$ *depends only on* $u_k$. Moreover, for $k = 2, \dots, n-2$ we have

$$\begin{aligned}\text{Leb}\Big\{u_k :\ |f_u(x_k) - x_{k+1}| = \Big|f(x_k) + \sum_{m=0}^{k} u_m \prod_{j=0}^{m-1}(x_k - x_j) - x_0\Big| \le \tilde{\gamma}_n\Big\} \\ \le \frac{2\tilde{\gamma}_n}{\prod_{j=0}^{k-1}|x_k - x_j|},\end{aligned}$$

and for $k = n-1$ we have

$$\mathrm{Leb}\big\{u_{n-1} :\ |f_u(x_{n-1}) - x_0| \le \tilde{\gamma}_n\big\} \le \frac{2\tilde{\gamma}_n}{\prod_{j=0}^{n-2} |x_{n-1} - x_j|}. \tag{6}$$

In particular, the parameter $u_{n-1}$ *is responsible* for $(n, \gamma_n)$-periodicity of the $n$-tuple $\{x_k\}_{0\le k\le n}$. This formula estimates the *"measure of periodicity"*.

Choose $u_0, \dots, u_{n-1}$ so that the $n$-tuple $\{x_k\}_{k=0}^{n-1}$ is a $(n, \tilde{\gamma}_n)$-periodic $\tilde{\gamma}_n$-pseudo-trajectory. Notice that parameters $u_n, u_{n+1}, \dots, u_{2n-1}$ do not change the $\tilde{\gamma}_n$-pseudo-trajectory $\{x_k\}_{k=0}^{n-1}$. Fix now parameters $u_0, \dots, u_{2n-2}$ and vary only $u_{2n-1}$. Then for any $C^1$-smooth map $g\colon I \to I$, consider the 1-parameter family

$$g_{u_{2n-1}}(x) = g(x) + (x - x_{n-1}) \prod_{j=0}^{n-2} (x - x_j)^2.$$

Since the corresponding monomial $(x-x_{n-1}) \prod_{j=0}^{n-2}(x-x_j)^2$ has zeroes of the second order at all points $x_k$, except the last one $x_{n-1}$, we have

$$\prod_{j=0}^{n-1} (g_{u_{2n-1}})'(x_j) = \Big(g'(x_{n-1}) + u_{2n-1} \prod_{j=0}^{n-2} |x_{n-1} - x_j|^2\Big) \prod_{j=0}^{n-2} g'(x_j). \tag{7}$$

To get the final estimate, we use the fact that we are interested only in maps from the family $\{f_u\}_u$. Suppose $|f_u'(x_{n-1})|$ is uniformly bounded by some $M_1$. For condition $(n+1)$ of (5) to hold, $\big|\prod_{j=0}^{n-1} f_u'(x_j)\big|$ must lie in $[1 - c\gamma_n/2, 1 + c\gamma_n/2]$. If this occurs for any $u_{2n-1}$, then $\big|\prod_{j=0}^{n-2} f_u'(x_j)\big| \ge (1 - c\gamma_n/2)/M_1$ for all $u_{2n-1}$, because this product does not depend on $u_{2n-1}$. Using (7) and the fact that $1 - c\gamma_n/2 \ge 1/2$, we get

$$\mathrm{Leb}\left\{u_{2n-1} :\ \Big|\prod_{j=0}^{n-1} |f_u'(x_j)| - 1\Big| \le \frac{c\gamma_n}{2}\right\} \le M_1\, \frac{2c\gamma_n}{\prod_{j=0}^{n-2} |x_{n-1} - x_j|^2}. \tag{8}$$

This formula estimates the *"measure of hyperbolicity"*.

We can combine all these estimates and get

$$\begin{aligned} &\mathrm{Leb}^{n+1}\{(u_0, \dots, u_{n-1}, u_{2n-1}) : f_u \text{ satisfies conditions (5) and } \|f_u\|_{C^1} \le M_1\} \\ &\qquad \le \frac{2M_1 c\gamma_n}{\prod_{j=0}^{n-2} |x_{n-1} - x_j|^2} \prod_{m=1}^{n-1} \frac{2\tilde{\gamma}_n}{\prod_{j=0}^{m-1} |x_m - x_j|}. \end{aligned} \tag{9}$$

This completes Step 2, but leaves many open questions which we shall discuss while treating Step 1. The estimate of Step 1 then breaks down as follows:

$$\#_n(\tilde{\gamma}_n) \approx \boxed{\begin{array}{c}\#\text{ of initial}\\ \text{points in } I_{\tilde{\gamma}_n}\end{array}} \times \boxed{\begin{array}{c}\#\text{ of } \tilde{\gamma}_n\text{-pseudotrajectories}\\ \text{per initial point}\end{array}} \tag{10}$$

And up to an exponential function of $n$, the estimate of Step 2 breaks down like:

$$\mu_n(c\gamma_n, \tilde{\gamma}_n) \approx \frac{\boxed{\text{Measure of periodicity (6)}} \times \boxed{\text{Measure of hyperbolicity (8)}}}{\boxed{\#\text{ of } \tilde{\gamma}_n\text{-pseudotrajectories per initial point}}}$$

(Roughly speaking, the terms in the numerator represent respectively the measure of parameters for which a given initial point will be $(n, \tilde{\gamma}_n)$-periodic and the measure of parameters for which a given $n$-tuple is $(n, c\gamma_n)$-hyperbolic; they correspond to estimates (6) and (8) in the next section.) Thus after cancellation, the estimate of the measure of "bad" set $B_n(c\Gamma)$ associated to almost periodic, not sufficiently hyperbolic trajectories becomes:

$$\boxed{\text{Measure of bad parameters}} \leq \boxed{\#\text{ of initial points of } I_{\tilde{\gamma}_n}} \times \boxed{\text{Measure of periodicity (6)}} \times \boxed{\text{Measure of hyperbolicity (8)}} \quad (11)$$

*Consider only pseudotrajectories having* $\prod_{j=0}^{n-2} |x_{n-1} - x_j| \geq (c\gamma_n)^{1/4}$ *and suppose* $\tilde{\gamma}_n = M_1^{-n} c\gamma_n$. Then up to exponential function of $n$ the first term on the right hand side of (11) is of order $(c\gamma_n)^{-1}$. The second term has an upper bound of order $(c\gamma_n)^{3/4}$, and the third term is at most of order $(c\gamma_n)^{1/2}$, so that the product on the right-hand side of (11) is of order at most $(c\gamma_n)^{1/4}$ (up to an exponential function in $n$). If $c\gamma_n$ is exponentially small with a large exponent in $n$, then $\mu_n(c\gamma_n, \tilde{\gamma}_n)$ is at most exponentially small. This discussion motivates the following

**Definition 4.1.** A trajectory $x_0, \ldots, x_{n-1}$ of length $n$ of a diffeomorphism $f \in \mathrm{Diff}^r(B^N)$, where $x_k = f^k(x_0)$, is called $(n, \gamma)$-*simple* if

$$\prod_{k=0}^{n-2} |x_{n-1} - x_k| \geq \gamma^{1/4}.$$

A point $x_0$ is called $(n, \gamma)$-simple if its trajectory $\{x_k = f^k(x_0)\}_{k=0}^{n-1}$ of length $n$ is $(n, \gamma)$-simple. Otherwise a point (resp. a trajectory) is called non-$(n, \gamma)$-simple.

If a trajectory is simple, then perturbation of this trajectory by Newton interpolation polynomials is effective. The product of distances is a quantitative characteristic of recurrent properties of a trajectory. If it is small enough, then there are close returns of it to $x_0$ before time $n$.

Even though most of properties of periodic orbits do not depend on a starting point, it turns out that for the above product, even asymptotically, it *does* matter where to choose the starting point. A good example to look at is periodic trajectories in a neighborhood of a planar homoclinic tangency (see [KH1], sect. 2.4 for more). It motivates the following

**Definition 4.2.** A point $x$ is called *essentially* $(n, \gamma)$-simple if for some nonnegative $j < n$, the point $f^j(x)$ is $(n, \gamma)$-simple. Otherwise a point is called essentially non-$(n, \gamma)$-simple.

In (11) we consider only $(n, c\gamma_n)$-simple pseudotrajectories. To study nonsimple pseudotrajectories we look for their simple almost periodic parts. More exactly, *for each non-$(n, c\gamma_n)$-simple pseudotrajectory we find such a close return, say $x_k$, that $\{x_j\}_{j=0}^{n-1}$ is almost equal to $n/k$ copies of $\{x_j\}_{j=0}^{k-1}$ and $\{x_j\}_{j=0}^{k-1}$ is $(k, c\gamma_k)$-simple*. Due to closeness, sufficient hyperbolicity of $\{x_j\}_{j=0}^{k-1}$ implies sufficient hyperbolicity $\{x_j\}_{j=0}^{n-1}$. Then investigation of the measure of nonhyperbolicity of nonsimple pseudotrajectory reduces to the measure of nonhyperbolicity of its simple almost periodic parts. Thus to obtain $\mu_n(c\gamma_n, \tilde{\gamma}_n)$ from (3) we arrive at the following scheme:

| Measure of bad parameters associated to periodic nonhyperbolic orbits | = | | (12) |
|---|---|---|---|
| Measure of bad parameters associated to simple periodic nonhyperbolic orbits (I) | + | Measure of bad parameters associated to nonsimple periodic nonhyperbolic orbits (II) | |

| Measure of bad parameters associated to nonsimple periodic nonhyperbolic orbits | ≤ | | (13) |
|---|---|---|---|
| Partition of nonsimple periodic orbits into simple almost periodic parts (II.A) | & | Measure of bad parameters associated to short non-simple almost periodic nonhyperbolic orbits (II.B) | |

As a matter of fact (13) requires additional comments, since the left hand side is a number, while the right hand side is not. To estimate the number from the left hand side we do two step procedure described in the right hand side. First, we do a certain partition (II.A) and then estimate a different number (II.B), which turn out to be an upper bound for the left hand side.

This diagram summarizes the problems we face in the proof.

• Part (I): how to estimate the measure of parameter values (11) associated with simple periodic nonhyperbolic orbits;

• Part (II.A): how to partition a nonsimple periodic orbit into almost periodic parts so that hyperbolicity of an almost periodic part implies hyperbolicity of the whole orbit;

The part (II.B) (how to estimate the measure associated with (11) simple periodic nonhyperbolic shorter orbits) can be treated in the same way as part (I), even though the actual details are usually quite involved (see [KH1], sect. 3.5–3.6).

## 5. How to collect all simple (almost) periodic pseudotrajectories: the Distortion and Collection Lemmas

In this section for the model family we show how one can justify heuristic estimates (10 – 11). The model family is the family of perturbations of a $C^2$ map $f\colon I \to I$, $I = [-1, 1]$ such that $f(I)$ strictly belongs to $I$

$$f_\varepsilon(x) = f(x) + \sum_{k=0}^{2n-1} \varepsilon_k x^k, \quad \varepsilon = (\varepsilon_0, \dots, \varepsilon_{2n-1}). \tag{14}$$

This is a $2n$-parameter family. Assume that parameters belong to a brick, called *the brick of standard thickness* with width $\tau$ (see [KH1], sect. 3.1 in the 1-dimensional case, [KH1], sect. 4.3, [Ka4], sect. 8.3 in the $N$-dimensional case, [GK], sect. 2.3 and 11.2 for modified definitions in the 2-dimensional case applicable to the problem of finiteness of localized sinks)

$$HB^{\mathrm{st}}_{<2n}(\tau) = \left\{ \{\varepsilon_k\}_{k=0}^{2n-1} : \text{ for all } 0 \le k < 2n, \ |\varepsilon_k| < \frac{\tau}{k!} \right\}.$$

For small enough $\tau$ the map $f_\varepsilon\colon I \to I$ is well defined for all $\varepsilon \in HB^{\mathrm{st}}_{<2n}(\tau)$. Since we are interested in the measure 0 or 1 events, one could chop a brick of another shape into smaller bricks of standard thickness and use the same proof. Suppose $\sup_{\varepsilon \in HB^{\mathrm{st}}_{<2n}(\tau)} \|f_\varepsilon\|_{C^1} < M_1$ for some $M_1$.

Define the Lebesgue product probability measure, denoted by $\mu^{\mathrm{st}}_{<2n,\tau}$, on the Hilbert brick of parameters $HB^{\mathrm{st}}_{<2n}(\tau)$ by normalizing the 1-dimensional Lebesgue measure along each component to the 1-dimensional Lebesgue probability measure

$$\mu^{\mathrm{st}}_{m,\tau} = \left(\frac{m!}{2\tau}\right) \mathrm{Leb}_1, \quad \mu^{\mathrm{st}}_{<k,\tau} = \bigtimes_{m=0}^{k-1} \mu^{\mathrm{st}}_{m,\tau}.$$

By definition of $\mu^{\mathrm{st}}_{<2n,\tau}$ we have that $\varepsilon_0, \dots, \varepsilon_{2n-1}$ are independent uniformly distributed random variables.

How to get from this family to a "generic finite-parameter family" is a tedious two step procedure based on Fubini theorem. The first step, from finite-parameter polynomial families to families of analytic perturbations, is discussed in [KH1], sect. 2.3, see also [GK], sect. 3.2. The second step, from analytic perturbations to prevalent finite-parameter families, is discussed in [KH1] Appendix C.

Consider an ordered $n$-tuple of points $\boldsymbol{X}_n = \{x_k\}_{k=0}^{n-1} \in I^n$. One can define an linear map $\mathcal{L}^1_{\boldsymbol{X}_n}\colon \mathbb{R}^{2n}_\varepsilon \to \mathbb{R}^{2n}_u$ given implicitly by the following formulas

$$\sum_{k=0}^{2n-1} \varepsilon_k x^k = \sum_{k=0}^{2n-1} u_k \prod_{j=0}^{k-1} (x - x_{j\,(\mathrm{mod}\ n)}), \tag{15}$$

where $\mathcal{L}^1_{\boldsymbol{X}_n}(\varepsilon_0, \dots, \varepsilon_{2n-1}) = (u_0, \dots, u_{2n-1})$. In [KH1], sect. 2.2 we give an explicit definition of this map using so-called *divided differences*, and call it *Newton*

*map*. It provides relation between $\varepsilon$-coordinates and $u$-coordinates. It turns out that $\mathcal{L}^1_{\boldsymbol{X}_n}$ is *volume-preserving and* $\mu^{\mathrm{st}}_{<2n,\tau}$*-preserving* ([KH1] Lemma .2.2.2). *Therefore, estimate* (9) *in u-space and* $\varepsilon$*-space are the same*.

We now estimate the distortion of the Newton map $\mathcal{L}^1_{\boldsymbol{X}_n}$ as a map from the standard basis $\{\varepsilon_k\}_{k=0}^{2n-1}$ in the space of polynomials of degree $< 2n$ to the Newton basis $\{u_k\}_{k=0}^{2n-1}$. It helps to have in mind the following picture characterizing the distortion of the Newton map.

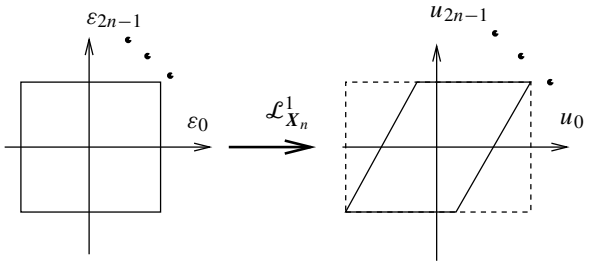

Figure 2. Distortion by the Newton map.

**The Distortion Lemma** ([KH1], sect 3.4). *Let* $\boldsymbol{X}_n = \{x_j\}_{j=0}^{n-1} \in I^n$ *be an ordered n-tuple of points in the interval* $I = [-1, 1]$ *and* $\mathcal{L}^1_{\boldsymbol{X}_n} : \mathbb{R}^{2n}_{\varepsilon} \to \mathbb{R}^{2n}_{u}$ *be the Newton map, defined implicitly by* (15). *Then the image of the brick of standard thickness* $HB^{\mathrm{st}}_{<2n}(\tau)$ *with width* $\tau > 0$ *is contained in the brick of standard thickness* $HB^{\mathrm{st}}_{<2n}(3\tau)$ *with width* $3\tau$:

$$\mathcal{L}^1_{\boldsymbol{X}_n}(HB^{\mathrm{st}}_{<2n}(\tau)) \subset HB^{\mathrm{st}}_{<2n}(3\tau) \subset \mathbb{R}^{2n}_{u}.$$

*In other words, independently of the choice of an n-tuple* $\{x_j\}_{j=0}^{n-1} \in I^n$ *for any* $0 \le m < 2n$, *the coefficient* $u_m$ *has at most the range of values* $|u_m| \le \frac{3\tau}{m!}$ *in the image* $\mathcal{L}^1_{\boldsymbol{X}_n}(HB^{\mathrm{st}}_{<2n}(\tau))$.

The proof is simple, provided the Newton map is explicitly defined (see [KH1], sect. 2.2).

In the $N$-dimensional case the statement of the necessary Distortion Lemma is somewhat involved. Even to define the $N$-dimesional Newton map one has to incorporate many multiindices (see [KH1], sect. 4.2–4.3, [Ka4], sect. 8.2–8.3) For the statement and the proof of a modified Distortion Lemma applicable to the problem of finiteness of localized sinks see [GK], sect. 11.4.

For a given $n$-tuple $\boldsymbol{X}_n = \{x_j\}_{j=0}^{n-1} \in I^n$, the parallelepiped

$$\mathcal{P}^{\mathrm{st}}_{<2n,\boldsymbol{X}_n}(\tau) := \mathcal{L}^1_{\boldsymbol{X}_n}(HB^{\mathrm{st}}_{<2n}(\tau)) \subset \mathbb{R}^{2n}_{u}$$

is the set of parameters $(u_0, \dots, u_{2n-1})$ that correspond to parameters $(\varepsilon_0, \dots, \varepsilon_{2n-1}) \in HB^{\mathrm{st}}_{<2n}(\tau)$. In other words, these are the Newton parameters *allowed by the family* (14) for the $n$-tuple $\boldsymbol{X}_n$. Since $\mathcal{L}^1_{\boldsymbol{X}_n}$ is volume-preserving it follows that $\mathcal{P}^{\mathrm{st}}_{<2n,\boldsymbol{X}_n}(\tau)$ has the same volume as $HB^{\mathrm{st}}_{<2n}(\tau)$, but the Distortion Lemma tells us in addition that the projection of $\mathcal{P}^{\mathrm{st}}_{<2n,\boldsymbol{X}_n}(\tau)$ onto any coordinate axis is at most a factor of 3 longer than the projection of $HB^{\mathrm{st}}_{<2n}(\tau)$.

Let $\boldsymbol{X}_m = \{x_j\}_{j=0}^{m-1}$ be the $m$-tuple of first $m$ points of the $n$-tuple $\boldsymbol{X}_n$. We now consider which Newton parameters are allowed by the family (14) when $\boldsymbol{X}_m$ is fixed but $x_m, \dots, x_{n-1}$ are arbitrary. Since we will only be using the definitions below for discretized $n$-tuples $\boldsymbol{X}_n \in I^n_{\tilde{\gamma}_n}$, we consider only the (finite number of) possibilities $x_m, \dots, x_{n-1} \subset I_{\tilde{\gamma}_n}$. Let

$$\pi^{u,\boldsymbol{X}_n}_{<2n,\le m} : \mathbb{R}^{2n}_u \to \mathbb{R}^m_u \quad \text{and} \quad \pi^{u,\boldsymbol{X}_n}_{<2n,m} : \mathbb{R}^{2n}_u \to \mathbb{R}_{u_m}$$

be the natural projections onto the space $\mathbb{R}^m_u$ of polynomials of degree $m$ and the space $\mathbb{R}_{u_m}$ of homogeneous polynomials of degree $m$ respectively. Denote the unions over all $x_m, \dots, x_{n-1} \in I_{\tilde{\gamma}_n}$ of the images of $\mathcal{P}^{\mathrm{st}}_{<2n,\boldsymbol{X}_n}(\tau)$ under the respective projections $\pi^{u,\boldsymbol{X}_n}_{<2n,\le m}$ and $\pi^{u,\boldsymbol{X}_n}_{<2n,m}$ by

$$\mathcal{P}^{\mathrm{st}}_{<2n,\le m,\boldsymbol{X}_m}(\tau) = \bigcup_{x_m,\dots,x_{n-1}\in I_{\tilde{\gamma}_n}} \pi^{u,\boldsymbol{X}_n}_{<2n,\le m}(\mathcal{P}^{\mathrm{st}}_{<2n,\boldsymbol{X}_n}(\tau)) \subset \mathbb{R}^m_u,$$
$$\mathcal{P}^{\mathrm{st}}_{<2n,m,\boldsymbol{X}_m}(\tau) = \bigcup_{x_m,\dots,x_{n-1}\in I_{\tilde{\gamma}_n}} \pi^{u,\boldsymbol{X}_n}_{<2n,m}(\mathcal{P}^{\mathrm{st}}_{<2n,\boldsymbol{X}_n}(\tau)) \subset \mathbb{R}_{u_m}.$$

For each $m < n$, the set $\mathcal{P}^{\mathrm{st}}_{<2n,\le m,\boldsymbol{X}_m}(\tau)$ is a polyhedron and $\mathcal{P}^{\mathrm{st}}_{<2n,m,\boldsymbol{X}_m}(\tau)$ is a segment of length at most $6\tau/m!$ by the Distortion Lemma. Both depend only on the $m$-tuple $\boldsymbol{X}_m$ and width $\tau$. The set $\mathcal{P}^{\mathrm{st}}_{<2n,\le m,\boldsymbol{X}_m}(\tau)$ consists of all Newton parameters $\{u_j\}_{j=0}^m \in \mathbb{R}^m_u$ that are allowed by the family (14) for the $m$-tuple $\boldsymbol{X}_m$.

For each $m < n$, we introduce the family of diffeomorphisms

$$f_{u(m),\boldsymbol{X}_m}(x) = f(x) + \sum_{s=0}^{m} u_s \prod_{j=0}^{s-1}(x - x_j), \tag{16}$$

where $u(m) = (u_0, \dots, u_m) \in \mathcal{P}^{\mathrm{st}}_{<2n,\le m,\boldsymbol{X}_m}(\tau)$. For each possible continuation $\boldsymbol{X}_n$ of $\boldsymbol{X}_m$, the family $f_{u(m),\boldsymbol{X}_m}$ includes the subfamily of $f_{u,\boldsymbol{X}_n}$ (with $u \in \mathcal{P}^{\mathrm{st}}_{<2n,\boldsymbol{X}_n}(\tau)$) corresponding to $u_{m+1} = u_{m+2} = \cdots = u_{2n-1} = 0$. However, the action of $f_{u,\boldsymbol{X}_n}$ on $x_0, \dots, x_m$ doesn't depend on $u_{m+1}, \dots, u_{2n-1}$, so for these points the family $f_{u(m),\boldsymbol{X}_m}$ is representative of the entire family $f_{u,\boldsymbol{X}_n}$. This motivates the definition

$$T^{1,\tilde{\gamma}_n}_{<2n,\le m,\tau}(f; x_0, \dots, x_{m-1}, x_m, x_{m+1})$$
$$= \big\{u(m) \in \mathcal{P}^{\mathrm{st}}_{<2n,\le m,\boldsymbol{X}_m}(\tau) \subset \mathbb{R}^m_u :$$
$$|f_{u(m),\boldsymbol{X}_m}(x_{j-1}) - x_j| \le \tilde{\gamma}_n \text{ for } j = 1, \dots, m+1\big\}.$$

The set $T^{1,\tilde{\gamma}_n}_{<2n,\le m,\tau}(f; x_0, \dots, x_{m-1}, x_m, x_{m+1})$ represents the set of Newton parameters $u(m) = \big(u_0, \dots, u_m\big)$ allowed by the family (14) for which $x_0, \dots, x_{m+1}$ is a $\tilde{\gamma}_n$-pseudotrajectory of $f_{u(m),\boldsymbol{X}_m}$ (and hence of $f_{u,\boldsymbol{X}_n}$ for all valid extensions $u$ and $\boldsymbol{X}_n$ of $u(m)$ and $\boldsymbol{X}_m$).

In the following lemma, we collect all possible $\tilde{\gamma}_n$-pseudotrajectories and estimates of "bad" measure corresponding to those $\tilde{\gamma}_n$-pseudotrajectories. The idea of the proof of this lemma is the following. Let $m$ be some number $0 \le m < n$. Suppose an $(m+1)$-tuple $x_0, \dots, x_m \subset I_{\tilde{\gamma}_n}$ is fixed and we are interested in the number of possible continuations $x_{m+1} \in I_{\tilde{\gamma}_n}$ so that $x_0, \dots, x_{m+1}$ is associated to the family (14). Consider the family (16), where $u_0, \dots, u_{m-1}$ are fixed. By Distortion Lemma we have $|u_m| \le \dfrac{3\tau}{m!}$. Rewrite this family, applied to $x_m$, as

$$f_{u(m),\boldsymbol{X}_m}(x_m) = f(x_m) + \sum_{s=0}^{m-1} u_s \prod_{j=0}^{s-1}(x_m - x_j) + u_m \prod_{j=0}^{m-1}(x_m - x_j).$$

Since all $u_k$'s except $u_m$ are fixed, the range of $x_{m+1}$ associated to the family (14) is bounded by $3\tau \prod_{j=0}^{m-1}(x_m - x_j)/m!$.

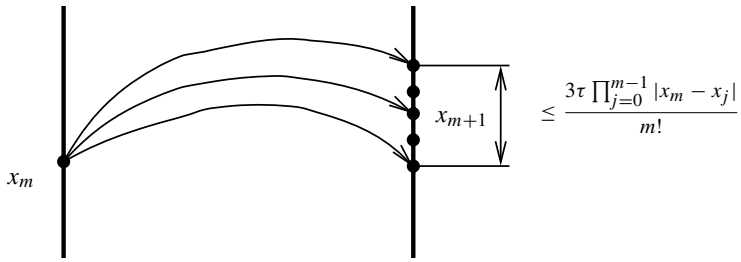

Figure 3. Collection of pseudotrajectories.

**The Collection Lemma.** *With the notations above, for all $x_0 \in I_{\tilde{\gamma}_n}$ the measure of the "bad" parameters satisfies*

$$\begin{aligned}&\mu^{\mathrm{st}}_{<2n,\tau}\big\{\varepsilon : \text{ there is a } \tilde{\gamma}_n\text{-periodic } \tilde{\gamma}_n\text{-pseudotrajectory from } I^n_{\tilde{\gamma}_n} \text{ starting at } x_0,\\ &\text{which is not } (n, M_1^{3n} c\gamma_n)\text{-hyperbolic}\big\} \le 6^{2n} M_1^{4n+1} \frac{(n-1)!}{\tau} \frac{(2n-1)!}{\tau} c^{1/4} \tilde{\gamma}_n \gamma_n^{1/4}.\end{aligned} \tag{17}$$

For the modified Collection Lemma for the $N$-dimensional case see [Ka4], sect. 9.3, and for the problem of finiteness of localized sinks in the 2-dimensional case see [GK], sect. 11.6, respectively.

**Corollary 5.1.** *With the notations above the measure of the "bad" parameters satisfies*

$$\begin{aligned}&\mu^{st}_{<2n,\tau}\big\{\varepsilon : \text{ there is a } \tilde{\gamma}_n\text{-periodic } \tilde{\gamma}_n\text{-pseudotrajectory from } I^n_{\tilde{\gamma}_n},\\ &\text{which is not } (n, M_1^{3n} c\gamma_n)\text{-hyperbolic}\big\} \le 2 \cdot 6^{2n} M_1^{4n+1} \frac{(n-1)!}{\tau} \frac{(2n-1)!}{\tau} c^{1/4} \gamma_n^{1/4}.\end{aligned}$$

Since there are $2/\tilde{\gamma}_n$-grid points of $I_{\tilde{\gamma}_n} \subset [-1, 1]$, this corollary follows directly from the Collection Lemma. Suppose that $\tilde{\gamma}_n$-discretization is fine enough to be able to approximate "real" trajectories by $\tilde{\gamma}_n$-pseudotrajectories well enough (see [KH1], Proposition 3.1.2, its proof, and (3.17) in the 1-dimensional case, [Ka4], sect. 9 in the $N$-dimensional case, and [GK], sect. 8 for the problem of finiteness of localized sinks). Then up to the error term $6^{2n} M_1^{4n+1}$ this proves (11).

*Proof of the Collection Lemma.* We prove by backward induction on $m$ that for $x_0, \dots, x_m \subset I_{\tilde{\gamma}_n}$,

$$\begin{aligned}
&\mu^{\mathrm{st}}_{<2n,\tau}\big\{\text{there is a } \tilde{\gamma}_n\text{-periodic } \tilde{\gamma}_n\text{-pseudotrajectory from } I^n_{\tilde{\gamma}_n} \text{ starting} \\
&\qquad\qquad \text{with } x_0, \dots, x_m \text{ which is not } (n, M_1^{3n} c\gamma_n)\text{-hyperbolic}\big\} \qquad (18)\\
&\le 6^{2n-m} M_1^{4n+1} \, \frac{(n-1)!}{\tau} \, \frac{(2n-1)!}{\tau} \, \mu^{\mathrm{st}}_{<m,\tau}\big\{T^{1,\tilde{\gamma}_n}_{<2n,\le m-1,\tau}(f; x_0, \dots, x_m)\big\} \, c^{1/4} \, \tilde{\gamma}_n \, \gamma_n^{1/4},
\end{aligned}$$

resulting when $m = 0$ in (17).

Consider the case $m = n - 1$. Fix an $(n, c\gamma_n/2)$-simple $n$-tuple $\boldsymbol{X}_n = \{x_j\}_{j=0}^{n-1} \in I^n_{\tilde{\gamma}_n}$. Using formulas (6) and (8), we get

$$\begin{aligned}
&\mu^{\mathrm{st}}_{n-1,\tau}\{u_{n-1} : \big|f_{u,\boldsymbol{X}_n}(x_{n-1}) - x_0\big| \le \tilde{\gamma}_n\} \\
&\qquad \le \frac{(n-1)!}{\tau} \frac{\tilde{\gamma}_n}{\prod_{m=0}^{n-2} |x_{n-1} - x_m|} \le \frac{2^{1/4}(n-1)!}{\tau} \, c^{-1/4} \, \tilde{\gamma}_n \, \gamma_n^{-1/4}
\end{aligned}$$

and

$$\begin{aligned}
&\mu^{\mathrm{st}}_{2n-1,\tau}\Big\{u_{2n-1} : \Big|\prod_{j=0}^{n-1} |(f_{u,\boldsymbol{X}_n})'(x_j)| - 1\Big| \le M_1^{3n} c\gamma_n\Big\} \\
&\qquad \le M_1 \frac{(2n-1)!}{\tau} \, \frac{4M_1^{3n} c\gamma_n}{\prod_{m=0}^{n-2} |x_{n-1} - x_m|^2} \le \frac{2^{5/2} M_1^{3n+1} (2n-1)!}{\tau} \, c^{1/2} \, \gamma_n^{1/2}.
\end{aligned}$$

The Fubini Theorem, preservation of generalized volume by the Newton map (see [KH1], Lemma 2.2.2), and the definition of the product measure $\mu^{\mathrm{st}}_{<2n,\tau}$ imply that

$$\begin{aligned}
&\mu^{\mathrm{st}}_{<2n,\tau}\big\{\text{there is a } \tilde{\gamma}_n\text{-periodic } \tilde{\gamma}_n\text{-pseudotrajectory from } I^n_{\tilde{\gamma}_n} \text{ starting} \\
&\qquad\qquad \text{with } x_0, \dots, x_{n-1} \text{ which is not } (n, M_1^{3n} c\gamma_n)\text{-hyperbolic}\big\} \\
&\le \mu^{\mathrm{st}}_{<n-1,\tau}\Big\{T^{1,\tilde{\gamma}_n}_{<2n,\le n-2,\tau}(f; x_0, \dots, x_{n-1})\Big\} \times \mu^{\mathrm{st}}_{n-1,\tau}\big\{u_{n-1} : \big|f_{u,\boldsymbol{X}_n}(x_{n-1}) - x_0\big| \le \tilde{\gamma}_n\big\} \\
&\qquad \times \prod_{s=n}^{2n-2} \mu^{\mathrm{st}}_{s,\tau}\{\mathcal{P}^{\mathrm{st}}_{<2n,s,\boldsymbol{X}_n}(\tau)\} \times \mu^{\mathrm{st}}_{2n-1,\tau}\Big\{u_{2n-1} : \Big|\prod_{j=0}^{n-1} |(f_{u,\boldsymbol{X}_n})'(x_j)| - 1\Big| \le M_1^{3n} c\gamma_n\Big\} \\
&\le 2^{11/4} 3^{n-1} M_1^{4n+1} \frac{(n-1)!}{\tau} \frac{(2n-1)!}{\tau} \, \mu^{\mathrm{st}}_{<n-1,\tau}\big\{T^{1,\tilde{\gamma}_n}_{<2n,\le n-2,\tau}(f; x_0, \dots, x_{n-1})\big\} \, c^{1/4} \, \tilde{\gamma}_n \, \gamma_n^{1/4}.
\end{aligned}$$

The last inequality follows from the Distortion Lemma, which says that for each $s = n, n+1, \dots, 2n-2$

$$\mu^{\mathrm{st}}_{s,\tau}\{\mathcal{P}^{\mathrm{st}}_{<2n,s,\boldsymbol{X}_n}(\tau)\} \le 3.$$

Since $2^{11/4}3^{n-1} < 6^{n+1}$, this yields the required estimate (18) for $m = n-1$.

Suppose now that (18) is true for $m+1$ and we want to prove it for $m$. Denote by $G^{1,\tilde\gamma_n}_{<2n,m,\tau}(f, u(m-1); x_0, \dots, x_m) \subset I_{\tilde\gamma_n}$ the set of points $x_{m+1}$ of the $\tilde\gamma_n$-grid $I_{\tilde\gamma_n}$ such that the $(m+2)$-tuple $x_0, \dots, x_{m+1}$ is a $\tilde\gamma_n$-pseudotrajectory associated to some extension $u(m) \in \mathcal{P}^{\mathrm{st}}_{<2n,\le m,\boldsymbol{X}_m}(\tau)$ of $u(m-1)$. In other words, $G^{1,\tilde\gamma_n}_{<2n,m,\tau}(f, u(m-1); x_0, \dots, x_m)$ is the set of all possible continuations of the $\tilde\gamma_n$-pseudotrajectory $x_0, \dots, x_m$ using all possible Newton parameters $u_m$ allowed by the family (14).

Now if $x_0, \dots, x_m$ is a $\tilde\gamma_n$-pseudotrajectory associated to $u(m) = (u_0, \dots, u_m)$, then at most one value of $x_{m+1} \in I_{\tilde\gamma_n}$ are within $\tilde\gamma_n$ of $f_{u(m),\boldsymbol{X}_m}(x_m)$. Thus for fixed $u(m-1) = (u_0, \dots, u_{m-1}) \in \mathcal{P}^{\mathrm{st}}_{<2n,\le m-1,\boldsymbol{X}_n}(\tau)$, each value of $u_m \in \mathcal{P}^{\mathrm{st}}_{<2n,m,\boldsymbol{X}_n}(\tau)$ corresponds to at most one point in $G^{1,\tilde\gamma_n}_{<2n,m,\tau}(f, u(m-1); x_0, \dots, x_m)$. It follows that

$$\sum_{x_{m+1}\in G^{1,\tilde\gamma_n}_{<2n,m,\tau}(f,u(m-1);x_0,\dots,x_m)} \mu^{\mathrm{st}}_{\le m,\tau}\big\{T^{1,\tilde\gamma_n}_{<2n,\le m,\tau}(f; x_0, \dots, x_{m+1})\big\}$$
$$\le 2\,\mu^{\mathrm{st}}_{m,\tau}\{\mathcal{P}^{\mathrm{st}}_{<2n,m,\boldsymbol{X}_n}(\tau)\}\,\mu^{\mathrm{st}}_{\le m-1,\tau}\big\{T^{1,\tilde\gamma_n}_{<2n,\le m-1,\tau}(f; x_0, \dots, x_m)\big\}.$$

The Distortion Lemma then implies that

$$\sum_{x_{m+1}\in G^{1,\tilde\gamma_n}_{<2n,m,\tau}(f,u(m-1);x_0,\dots,x_m)} \mu^{\mathrm{st}}_{\le m,\tau}\big\{T^{1,\tilde\gamma_n}_{<2n,\le m,\tau}(f; x_0, \dots, x_{m+1})\big\}$$
$$\le 6\,\mu^{\mathrm{st}}_{\le m-1,\tau}\big\{T^{1,\tilde\gamma_n}_{<2n,\le m-1,\tau}(f; x_0, \dots, x_m)\big\}.$$

Inductive application of this formula completes the proof of the Collection Lemma.□

This completes an outline of treatment of part (I) of (12) for the 1-dimensional case. To carry out part (I) of (12) in the $N$-dimensional case ($N > 1$) we use the same ideas, but have to overcome additional difficulties. We discuss them in details in [KH1], sect. 4.1 (detailed discussion of the 2-dimensional case can be found in [GK], sect. 10–11 and of the $N$-dimensional case in [Ka4], sect. 8–9) and just briefly mention them here.

• (*Nonuniqueness*) It turns out that there are many ways to write Newton interpolation polynomial in $N$ variables.

• (*Dynamically essential coordinates*) Among many $N$-dimensional Newton monomials we need to choose those effective for perturbation (see [KH1] (4.6–4.7), [GK], sect. 10.1, and [Ka4], sect. 8.2).

• (*The multidimensional Distortion Lemma*) The 1-dimensional Distortion Lemma leads to an exponential factor $6^{2n}$ coming from dimension of the space of polynomials of degree $< 2n$ in 1-variable. The space of polynomials of degree $< 2n$ in $N$-variables is $\sim (2n)^N$. This forces us to find a better multidimensional Distortion Lemma (see [KH1], sect. 4.3, [Ka4], sect. 8.3, and [GK], sect. 11.4).

To treat part (II.A) of (13) we need to analyze nonsimple (recurrent) periodic trajectories of period $n$ knowing that all periodic trajectories of period $< n$ are sufficiently hyperbolic (see (I) of (12)).

## 6. Partition of nonsimple periodic trajectories into simple almost periodic parts

Analysis of nonsimple periodic trajectories of multidimensional diffeomorphisms, performed in [KH1] and [Ka4], occupies sect. 2.4 and 3.5 in [KH1] and section 5 in [Ka4]. The goal for each nonsimple periodic trajectory $\{x_j = f^j(x_0)\}_{j=0}^{n-1}$ of period $n$ find a close return, say $x_k$, so that $\{x_j\}_{j=0}^{n-1}$ nearly repeats $\{x_j\}_{j=0}^{k-1}$ exactly $n/k$ times and $\{x_j\}_{j=0}^{k-1}$ is simple. This, in particular, means that hyperbolicity of $\{x_j\}_{j=0}^{k-1}$ and $\{x_j\}_{j=0}^{n-1}$ are closely related. Here we just summarize the strategy to obtain such a partition. This is exactly the step where *we cannot handle a sequence of* $\{c\gamma_n\}_{n\geq 1}$ *that decay slower than a stretched exponential* $\exp(-n^{1+\delta})$ $(\delta > 0)$. In other words, if $\gamma_n$ decays not too fast, say exponentially, we are unable to find a close return with the above properties (see [KH1], Appendix D for further discussion).

The following definitions are the key elements of the mechanism to find a close return. They quantitatively characterize close returns.

**Definition 6.1.** Let $g$ be a diffeomorphism and let $D$ be large and positive. A point $x_0$ (resp. a trajectory $x_0, \dots, x_{n-1} = g^{n-1}(x_0)$ of length $n$) has a *weak* $(D, n)$*-gap* at a point $x_k = g^k(x_0)$ if

$$|x_k - x_0| \leq D^{-n} \min_{0<j\leq k-1} |x_0 - x_j|.$$

and there is no $m < k$ such that $x_0$ has a weak $(D, n)$-gap at $x_m = g^m(x_0)$.

This definition characterizes a close return at $x_0$. For the proof we need a modification of this definition (see [KH1], Definition 3.5.3). See the Shift Theorem [KH1], sect. 3.5 and [Ka4], sect. 5 for all the details. Recall that $\{c\gamma_n\}_{n\geq 1}$ is the sequence tracking hyperbolicity of periodic trajectories of period $n$ introduced in the beginning of Section 2.

**Definition 6.2.** Let $g$ be a $C^2$-smooth diffeomorphism. Let also $c > 0$ and $k < n$ be positive integers. We say that a point $x_0$ has a $(k, n, c)$*-leading saddle* if $|x_0 - x_k| \leq n^{-1}(c\gamma_k)^2$. Also if $x_0$ is $(n, \tilde{\gamma}_n)$-periodic, we say that $x_0$ has no $(n, c)$-leading saddles if for all $k < n$ we have that $x_0$ has no $(k, n, c)$-leading saddles.

Now start with a diffeomophism $f$ satisfying the inductive hypothesis of order $n-1$ with constants $c\Gamma$, i.e. for any $k < n$ all periodic trajectories of period $k$ are $(k, c\gamma_k)$-hyperbolic. In particular, it means that all periodic trajectories of period $k < n$ are either sinks, or sources, or saddles.

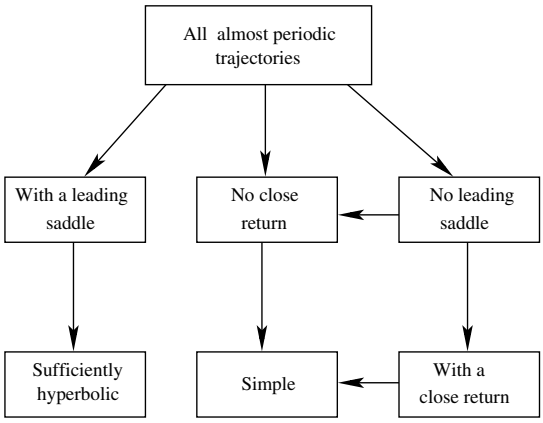

Figure 4. Various types of almost periodic periodic trajectories.

• The definition of a leading saddle is designed in such a way that if $x_0$ has a $(k, n, c)$-leading saddle, then there is a periodic point $x^* = f^k(x^*)$ close to $x_0$ (see [Ka4], Lemma 5.2.3). If $x_k, x_{2k}, \dots$ all stay close to $x^*$, then $x_0 = f^n(x_0)$ inherits hyperbolicity of $x^*$ (see [Ka4], Lemma 5.2.1).

• Suppose $x_0$ has a $(k, n, c)$-leading saddle, but for some $p < n/k$ the corresponding $x_{pk}$ leaves a small neighborhood of $x^*$. Then one can show that $x_{pk}$ has no $(n, c)$-leading saddles (see [Ka4], Lemma 5.2.4).

• Suppose $\tilde{x}_0 = x_{pk}$ has no $(n, c)$-leading saddles. It turns out that $\tilde{x}_0$ can have at most $\dim M$ weak $(D, n)$-gaps at some $\tilde{x}_{k_1}, \dots, \tilde{x}_{k_s}$, $s \le \dim M$. The reason is that each weak $(D, n)$-gap $\tilde{x}_{k_j}$ after the first one at $k_1$ implies that the linearization $df^{k_1}(\tilde{x}_0)$ has an almost eigenvalue that is a $k_j/k_1$-root of unity, and the same is true for $k_{s+1} = n$ (see [Ka4], Theorem 5.1.4).

• Suppose $\tilde{x}_0$ has no $(n, c)$-leading saddles and has $s < \dim M$ weak $(D, n)$-gaps. Then we can show that it is $(n, c\gamma_n)$-simple (see [Ka4], Theorem 5.3.1 and its extension necessary for the proof: Theorem 5.4.1).

This scheme is summarized in the diagram (see Figure 4).

## 7. Finititude of number of localized coexisting sinks

In this section we give a short exposition of a result from [GK] concerning the Newhouse phenomenon of infinitely many sinks. The primary goal of [GK] is to analyze

trajectories *localized in a neighborhood of a fixed HT*. A sink is the simplest attractor. We now introduce notions of an unfolding of a homoclinic tangency and localized trajectories of finite complexity associated to that homoclinic tangency.

Consider a 1-parameter family of perturbations $\{f_\varepsilon\}_{\varepsilon\in I}$, $I = [-\varepsilon_0, \varepsilon_0]$ of a 2-dimensional diffeomorphism $f = f_0 \in \mathrm{Diff}^r(M)$ with homoclinic tangency, where $\varepsilon_0$ is small (see Figure 5). Roughly speaking, $\varepsilon$ parameterizes oriented distance of the top tip of the unstable manifold to the stable manifold. Such a family is called an *unfolding of an HT*.

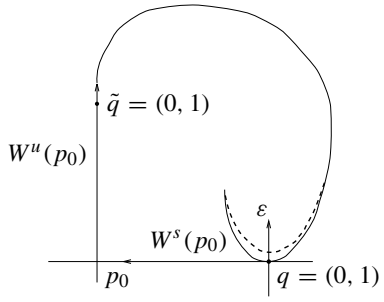

Figure 5. Homoclinic tangency.

Robinson [R], adapting Newhouse's ideas [N1], [N2], showed that for such an unfolding there is a sequence of open intervals converging to zero such that for a generic parameter from those intervals the corresponding diffeomorphism $f_\varepsilon$ has infinitely many coexisting sinks.

Assume that $f$ has a fixed saddle point $p_0 = f(p_0)$ and that the eigenvalues $\lambda$, $\mu$ of the linearization $Df(p_0)$, $0 < \lambda < 1 < \mu$, belong to the open dense set of pairs of eigenvalues for which Sternberg's linearization theorem holds. Then in a small neighborhood $\tilde{V}$ of $p_0$ there is a $C^r$ smooth normal coordinate system $(x, y) \in \tilde{V} \subset \mathbb{R}^2$ such that $f(x, y) = (\lambda x, \mu y)$. Suppose $q$ is the point of homoclinic tangency of $W^s(p_0)$ and $W^u(p_0)$ away from $\tilde{V}$, and let $\tilde{q} = f^{-1}(q)$ be its preimage.

Extend the coordinate neighborhood $\tilde{V}$ by iterating forward and backward until first it contains $\tilde{q}$ and $f(q)$, respectively. Decreasing $\tilde{V}$ if necessary we can assume that there are no overlaps. Denote such a neighborhood by $V$ and call it *a normal neighborhood*. By definition $V$ does not contain $q$ (see Figure 6). Consider a neighborhood $U$ (resp. $\tilde{U} \subset \hat{U}$) of $q$ (resp. $\tilde{q}$) such that $f(U) \cap U = \emptyset$ (resp. $f^{-1}(\hat{U}) \cap \hat{U} = \emptyset$), $f(\tilde{U}) \supset U$, and $f(\hat{U}) \cap V = \emptyset$. By rescaling coordinate axis one could set $q$ to have coordinates (1,0) and $\tilde{q}$ to have (0,1). Set $\mathcal{V} = V \cup U$. In what follows we *fix* a neighborhood $\mathcal{V}$ once and for all.

**Definition 7.1.** We call an invariant set of points $\mathcal{V}$-*localized* if it belongs to $\mathcal{V}$. In particular, any invariant set contained in

$$\Lambda_{\mathcal{V}} = \bigcap_{n\in\mathbb{Z}} f^n(\mathcal{V})$$

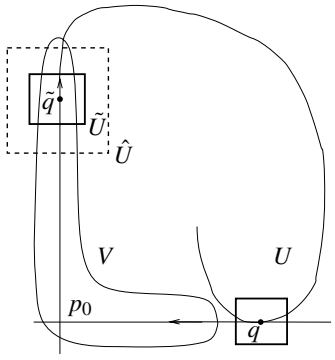

Figure 6. Localization for homoclinic tangency.

is $\mathcal{V}$-localized. A periodic point $f^n(p) = p$, $n \in \mathbb{N}$, is called $\mathcal{V}$-localized if it belongs to $\Lambda_{\mathcal{V}}$ and is called $(\mathcal{V}, s)$-localized if its trajectory $\mathfrak{P} = \{f^k(p)\}_{k=1}^n$ visits $U$ exactly $s$ times. Call $s = s(\mathfrak{P})$ the *cyclicity* of a $\mathcal{V}$-localized periodic orbit.

The zoo of $\mathcal{V}$-localized invariant sets is incredibly rich. Below we just mention the authors favorit animals: *Smale's horseshoe, infinitely many coexisting $\mathcal{V}$-localized sinks*[3], *strange attractor* (*Benedicks–Carleson* [BC], *Mora–Viana* [MV], *Young–Wang* [WY]), *arbitrarily degenerate periodic points of arbitrary high periods* (*Gonchenko–Shilnikov–Turaev* [GST1]), *uniformly and nonuniformly hyperbolic horseshoes as maximal invariant sets $\Lambda_{\mathcal{V}}$* (*Newhouse–Palis* [NP], *Palis–Takens* [PT], *Palis–Yoccoz* [PY1], [PY2], *Rios* [Ri]).

The main result of [GK] is the following

**Theorem 7.1.** *With the above notations, for a generic*[4] *1-parameter family $\{f_\varepsilon\}_{\varepsilon\in I}$ that unfolds an HT at $q$ there is a sequence of numbers $\{\boldsymbol{N}_s\}_{s\in\mathbb{N}}$ such that for almost every parameter $\varepsilon$ and any $D \in \mathbb{N}$ the corresponding $f_\varepsilon$ has only finitely many $\mathcal{V}$-localized sinks $\{\mathfrak{P}_j\}_{j\in J}$ whose cyclicity is bounded by $D$ or period exceeds $\boldsymbol{N}_{s_j}$, where $s_j = s(\mathfrak{P}_j) > D$ is cyclicity of a corresponding sink $\mathfrak{P}_j$. In other words, for almost every parameter $\varepsilon$ if there are infinitely many coexisting $\mathcal{V}$-localized sinks $\{\mathfrak{P}_j\}_{j\in J}$, then all but finitely many have cyclicity $s_j = s(\mathfrak{P}_j) > D$ and period $< \boldsymbol{N}_{s_j}$.*

**Remark 7.1.** For 1-loop periodic sinks a similar result is obtained by Tedeschini-Lalli–Yorke [LY]. Dynamical properties of periodic and homoclinic orbits of low cyclicity ($s = 1, 2, 3$) were studied in [GST1], [GStT]. In particular, Gonchenko–Shilnikov found the relation between existence of the infinite number of 2-loop sinks and numerical properties of the invariants of smooth conjugacy [GoS].

[3]Actually Newhouse [N2] (see also Palis–Takens [PT] for a simplified proof) proved that for a Baire generic set of diffeomorphisms in a Newhouse domain there are infinitely many coexisting sinks. However one can construct infinitely many of those as $\mathcal{V}$-localized.

[4]meaning of "generic" is in the sense of prevalence in the space of 1-parameter families see Section 9 for a definition.

**Remark 7.2.** We can choose $N_s = s^{5s^2}$.

Palis–Takens [PT] and Palis–Yoccoz [PY1], [PY2] investigated generic unfolding of an HT not only for saddle periodic points but also for horseshoes. They investigated parameters *outside* of Newhouse domains. We obtain less sharp properties of the dynamics, but we treat parameters *inside* Newhouse domains too.

## 8. Discussion of the proof of Theorem 7.1

To prove Theorem 7.1 we follow very similar strategy as to prove Theorem 2.1. First we introduce several notions:

**Trajectory type, hyperbolic and parabolic maps.** Any $(\mathcal{V}, s)$-localized periodic orbit, by definition, visits $U$ exactly $s$ times and spends $n_1, n_2, \dots, n_s$ consecutive iterates in $V$, $n = n_1+n_2+\ldots+n_s+s$. We call an ordered sequence $(n_1, \dots, n_s)$ *type* of a periodic orbit. For a given periodic orbit denote the points of intersection with $U$ by $\boldsymbol{p}_0,\ \boldsymbol{p}_1, \dots, \boldsymbol{p}_{s-1}$ and the corresponding points in $\tilde{U}$ by $\tilde{\boldsymbol{p}}_0 = f^{n_1}(\boldsymbol{p}_0),\ \tilde{\boldsymbol{p}}_1 = f^{n_2}(\boldsymbol{p}_1), \dots, \tilde{\boldsymbol{p}}_{s-1} = f^{n_s}(\boldsymbol{p}_{s-1})$.

Recall that $f$ is linear in $V \setminus \tilde{U}$ with eigenvalues $\lambda < 1 < \mu$, $f|_{V\setminus\tilde{U}}(x, y) = (\lambda x, \mu y)$. Call this linear map *hyperbolic*, denoted $L$, and $f|_{\tilde{U}}$ *parabolic*, denoted $\mathcal{P}$.

We replace hyperbolicity of periodic points from (1) by the *cone condition*.

**Cone condition.** To estimate the measure of parameters for which a periodic orbit of a given type is not a sink and even has exponentially large linearization, we introduce the following cone condition. Define at every point $p \in U$ a cone

$$K_A(p) = \{v = (v_x, v_y) \in T_p\mathcal{V} \simeq \mathbb{R}^2 :\ |v_y| \geq \mu^{-A}|v_x|\}.$$

To show that the periodic point $\boldsymbol{p}_0$ is hyperbolic it turns out that it suffices to find $0 < \alpha \ll 1$ independent of $n$ such that

$$Df_\varepsilon^n(K_{\alpha n}(\boldsymbol{p}_0)) \subset K_{\alpha n}(\boldsymbol{p}_0). \tag{19}$$

To verify this condition directly does not seem possible in general. Our plan is to verify that for most parameters this cone condition holds after each loop:

$$Df_\varepsilon^{n_i+1}(K_{\alpha n}(\boldsymbol{p}_i)) \ \subset\ K_{\alpha n}(\boldsymbol{p}_{i+1 \pmod s}) \quad \text{for each } i = 0, \dots, s-1. \tag{20}$$

This condition clearly implies (19), because the image of the first cone $K_{\alpha n}(\boldsymbol{p}_0)$ belongs to the second cone $K_{\alpha n}(\boldsymbol{p}_1)$. The image of the second one belongs to the third one and so on.

Fix $0 < \alpha \ll 1$. Notice that if all loops are *long*: $n_i > 3\alpha n$, then $L^{n_i}K_{\alpha n}(\boldsymbol{p}_i)$ is the cone of width angle $< 2\mu^{-\alpha n}$. Fix $1 \leq j \leq s$. To satisfy condition (20) for $j$

we need to avoid the intersection of the cone $Df_{\varepsilon,\tilde{\boldsymbol{p}}_j}(L^{n_j}K_{\alpha n}(\boldsymbol{p}_j))$ and a complement to $K_{\alpha n}(\tilde{\boldsymbol{p}}_{j+1})$ (see Figure 7 for $p = \boldsymbol{p}_{j+1}$). Assume that we can perturb $Df_{\varepsilon,\tilde{\boldsymbol{p}}_j}$ by composing with rotation and angle of rotation is a parameter. Then we need to avoid a phenomenon that has "probability" $\sim \mu^{-\alpha n}$. Taking the union over all types $\mathcal{N}_s$, $|\mathcal{N}_s| = n$ we get that probability to fail (20) for some $1 \le i \le s$ is $\sim n^s \mu^{-\alpha n}$. We avoid saying explicitly probability in what space, just assume that it is proportional to angle of rotation, and postpone the exact definition for further discussion.

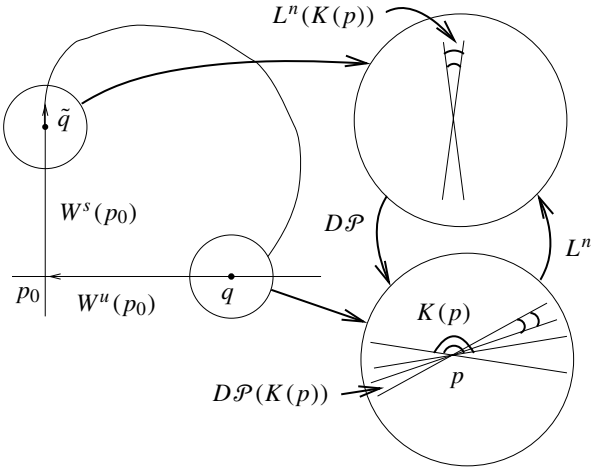

Figure 7. Evolution of cones.

However, it might happen that one of $n_i$'s is significantly smaller than $\alpha n$, e.g. $n_s \le \ln n$. In this case, the above argument fails. Indeed, let $n_s = [\ln n]$, $n \gg 1$. Consider the image of the cone $K_{\alpha n}(\boldsymbol{p}_{s-1})$ after the last loop $L^{n_s}K_{\alpha n}(\boldsymbol{p}_{s-1})$. It is the cone, whose width angle is of order 1. Taking into account possibility that $Df_{\varepsilon,\tilde{\boldsymbol{p}}_{s-1}}$ rotates a vertical vector by $\frac{\pi}{2}$ it is certainly not possible to fulfill (20) by a small perturbation. The natural idea is *to avoid looking at condition* (20) *after "short" loops*. This leads to combinatorial analysis of type $\mathcal{N}_s$ of trajectories.

**Combinatorial analysis of type $\mathcal{N}_s$ of $s$-loop trajectories.** Below we do not pay attention to dynamics of a trajectory of type $\mathcal{N}_s$ under consideration. We investigate only properties of the type $\mathcal{N}_s$ itself.

• *Short and long loops* ([GK], sect. 5.1). We shall divide an $s$-tuple $\mathcal{N}_s = (n_1, \dots, n_s)$ into two groups of *long* and *short* $n_i$'s, because they correspond to loops of a trajectory. After such a division long $n_i$'s should be *much longer* than short $n_i$'s. Denote by $t$ (resp. $s - t$) the number of long (resp. short) loops.

• *Generalized loops and essential returns* ([GK], sect. 5.2). Since we cannot fulfill (20) after short loops, we combine all loops into groups, called *generalized loops*. Each generalized loop starts with a long loop and is completed by all short loops

following afterwards. Therefore, the number of generalized loops equals the number of long loops. Then we *verify* (20) *not after each loop, but after each generalized loop*. Denote by $P_0, \dots, P_{t-1}, P_t = P_0 \subset U$ starting points of generalized loops, by $\tilde{P}_0, \dots, \tilde{P}_{t-1}, \tilde{P}_t = \tilde{P}_0$, prestarting points of generalized loops, i.e. $f(\tilde{P}_i) = P_{i+1}$, $i = 0, \dots, t-1$, and by $N_1, \dots, N_t$ their lengths respectively. Then we modify (20) to

$$Df^{N_{i+1}}(K_{\alpha n}(P_i)) \subset K_{\alpha n}(P_{i+1}) \quad \text{for each } i = 0, \dots, t-1. \tag{21}$$

Now the idea presented above has a chance to work. Indeed, let $n_j$ be a long loop and $n_{j+1}, \dots, n_{j+j'}$ be short ones from the corresponding generalized loop. Consider the image of the corresponding cone $K_{\alpha n}(P_j)$ after the generalized loop. Notice that after the long loop $n_j$ the cone $L^{n_j} K_{\alpha n}(P_j)$ is the cone of width angle $< 2\mu^{-\alpha n}$. Since long $n_j$ is so much longer than short loops $n_{j+1}, \dots, n_{j+j'}$ respectively the cone

$$\left(Df(\tilde{\boldsymbol{p}}_{j+j'}) \circ L^{n_{j+j'}} \circ \dots \circ Df(\tilde{\boldsymbol{p}}_{j+1}) \circ L^{n_{j+1}}\right) \circ \left(Df(\tilde{\boldsymbol{p}}_j) \circ L^{n_j} K_{\alpha n}(\boldsymbol{p}_j)\right)$$

has width angle $< 3\mu^{-\alpha n}$. To satisfy condition (20) for $j + j'$ we need to avoid an interval of rotations (i.e. of parameters) of length $< 5\mu^{-\alpha n}$. This phenomenon still has "probability" $\sim \mu^{-\alpha n}$.

After this combinatorial analysis we face the next difficulty. *We cannot perturb* $Df(\tilde{\boldsymbol{p}})$ *and* $Df(\tilde{\boldsymbol{p}}')$ *independently at nearby points* $\tilde{\boldsymbol{p}}$ *and* $\tilde{\boldsymbol{p}}'$.

**Dynamical analysis of trajectories.** Assume for a moment that we are interested in properties of *scattered* periodic orbits, that is, such orbits that $P_0, \dots, P_{t-1}$ in $U$ are pairwise well spaced. In particular, it is always the case for 1-loop orbits. In this case the difficulty of nearby points is removed. Using the discretization method and the cone condition (21) one can prove that for most parameters all but a finite number of the periodic orbits are hyperbolic saddles. Moreover, consider for $0 < \gamma' = \mu^{-\alpha' n} \ll \gamma'' = \mu^{-\alpha'' n}$ parameters for which a periodic not enough hyperbolic $\gamma''$-scattered $\gamma'$-pseudo-orbit of period $n$ exists. In fact, we can show that the measure of these parameters is small[5]. Now we are going to explain how this can be used to treat all periodic orbits, not necessarily scattered. Consider the 2-loop case for illustration. If starting points of loops $\boldsymbol{p}_0$ and $\boldsymbol{p}_1$ are far enough from each other, one can perturb differential of parabolic map at their preimages independently, and above arguments allow to estimate the measure of "bad" parameters. Otherwise a periodic orbit can be decomposed into a union of two 1-loop periodic pseudo-orbits, which have nearby endpoints in $U$. The cone condition (21) for each of these pseudo-orbits holds for most parameters, which implies (19).

Another illustration can be given by the case $t = 1$, i.e. we have one loop which is much longer than all the others. In this case the image of the cone $K_{\alpha n}(\boldsymbol{p}_0)$ after

[5]The discretization method in this case, compare to the one described in Sections 4–5, requires certain modifications (see [GK], sect. 9–11).

the application of differential of the map along the orbit has width angle $< 2\mu^{-\alpha n}$, as explained above. Point $\tilde{\boldsymbol{p}}_{s-1} = \tilde{P}_0 = f^{n-1}(\boldsymbol{p}_0) = f^{-1}(\boldsymbol{p}_0)$ can not be too close to points $\tilde{\boldsymbol{p}}_0, \tilde{\boldsymbol{p}}_1, \ldots, \tilde{\boldsymbol{p}}_{s-2}$. Indeed, the distance between $\boldsymbol{p}_i$ and $x$-axis is $(\boldsymbol{p}_i)_y \sim \mu^{-n_{i+1}}$. Since $n_1 \gg n_i$ we have $\mu^{-n_1} \ll \mu^{-n_i}$. Therefore the point $\boldsymbol{p}_0$ can not be too close to points $\boldsymbol{p}_1, \ldots, \boldsymbol{p}_{s-1}$, and we can perturb $\phi(\tilde{\boldsymbol{p}}_{s-1}) = \phi(f^{-1}(\boldsymbol{p}_0))$ independently of $\phi(\tilde{\boldsymbol{p}}_0), \ldots, \phi(\tilde{\boldsymbol{p}}_{s-2})$. This allows to estimate the measure of "bad" parameters.

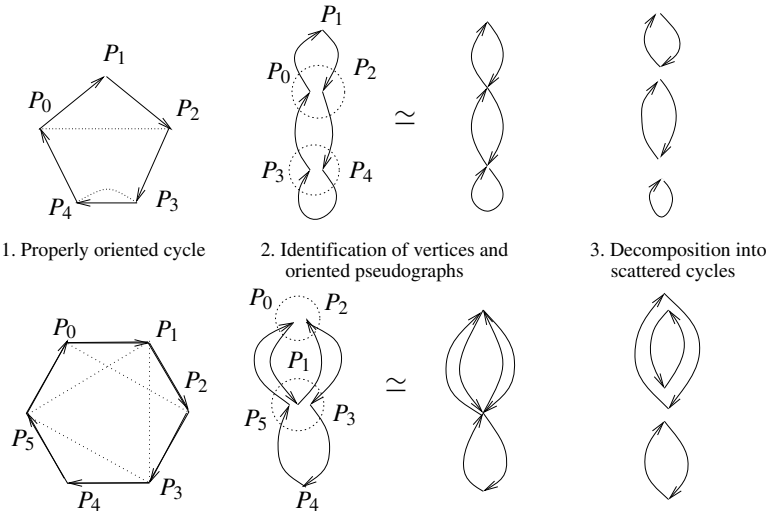

Figure 8. Graph surgery.

To consider the general case we represent a periodic orbit as an oriented cyclic graph. Starting points of generalized loops are vertices of this graph, and vertices corresponding to subsequent generalized loops are connected by an oriented edge (see Figure 8, picture 1). It turns out that for some $\gamma' \ll \gamma''$ for any pair of points $(P_i, P_j)$ either $\mathrm{dist}(P_i, P_j) > \gamma''$ or $\mathrm{dist}(P_i, P_j) < \gamma'$ (see [GK], sect. 7). Therefore every pair of vertices is either $\gamma'$-close or $\gamma''$-far apart (see Figure 8, picture 2). Now all the vertices can be divided into "clouds" or "clusters". Let us identify the vertices in the same cloud of nearby points, as shown on Figure 8, picture 2. The initial cycle is transformed now into oriented pseudograph (see [GK], Def. 20) with the same number of ingoing and outgoing edges at each vertex. Such a pseudograph can be decomposed into the union of oriented cycles (Figure 8, picture 3 and also see [GK], Lemma 7). Each of cycles from this decomposition represents a $\gamma''$-scattered $\gamma'$-pseudo-orbit. Application of the arguments above to these pseudo-orbits gives inclusion (21) for most values of parameters and implies the cone condition (19) for the initial periodic orbit.

## 9. Prevalence

Our definition of prevalence for a space $\mathrm{Diff}^r(M)$ of $C^r$ diffeomorphisms on a smooth manifold $M$ is based on the following definition from [HSY] for a complete metric linear space $V$.

**Definition 9.1** (Linear prevalence). A Borel set $S \subset V$ is called *shy* if there is a compactly supported Borel probability measure $\mu$ on $V$ such that $\mu(S - v) = 0$ for all $v \in V$. More generally, a subset of $V$ is called shy if it is contained in a shy Borel set. A subset of $V$ is called *prevalent* if its complement is shy.

(Shy sets were previously called "Haar null sets" by Christensen [Chr].) Some important properties of prevalence, proved in [HSY], are:

1. A prevalent set is dense.
2. A countable intersection of prevalent sets is prevalent.
3. A subset of $\mathbb{R}^m$ is prevalent if and only if its complement has Lebesgue measure zero.

Properties 2 and 3 above follow from the Fubini–Tonelli theorem, along with the Tychnoff theorem in the case of Property 2. Property 1 follows from the observation that a transverse measure $\mu$ can be localized in the following sense. By compactness of the support of $\mu$, there are arbitrarily small balls with positive measure. Every translation of $P$ must intersect these balls, or equivalently every translation of one of these balls must intersect $P$.

Along these lines, it is useful to think of a transverse measure for a prevalent set $P$ as a probability space of perturbations, such that at each point $v$ in the space $V$, choosing a random perturbation and adding it to $v$ yields a point in $P$ with probability one. Often the perturbations can be chosen from a finite dimensional space of parameters, using normalized Lebesgue measure on a bounded subset of parameter space. In this case, we say that $P$ is "finite-dimensionally prevalent".

In other cases, one needs an infinite number of parameters; for example, a property about periodic orbits might be finite-dimensionally prevalent for each fixed period, but higher periods require more parameters. One may be able to choose the parameters from a "Hilbert brick" $HB = J_1 \times J_2 \times \cdots$, where each $J_k$ is an interval of real numbers $\varepsilon_k$, the perturbation corresponding to $\varepsilon = (\varepsilon_1, \varepsilon_2, \ldots)$ is $\varepsilon_1 v_1 + \varepsilon_2 v_2 + \cdots$ for some vectors $v_1, v_2, \ldots \in V$, and the probability measure on $HB$ is the infinite product of normalized Lebesgue measure on each interval. We call this measure the uniform measure on $HB$. A property is then prevalent if for each $v \in V$, the property is true for $v + \varepsilon_1 v_1 + \varepsilon_2 v_2 + \cdots$ for almost every $\varepsilon$ with respect to the uniform measure on $HB$.

The notion of prevalence that we use in $\mathrm{Diff}^r(M)$ is based on this idea of choosing perturbations from a Hilbert brick. Though we cannot add perturbations in this non-linear space, by embedding $M$ in a Euclidean space $\mathbb{R}^N$, we can perturb elements of $\mathrm{Diff}^r(M)$ in a natural way by means of additive perturbations in the space $C^r(T, \mathbb{R}^N)$

of $C^r$ functions from $T$ to $\mathbb{R}^N$, where $T$ is a neighborhood of the embedded image of $M$ in $\mathbb{R}^N$. The details of this construction are given in Appendix C of [KH1]; here we provide a brief outline.

For $N$ sufficiently large, we can embed $M$ into $\mathbb{R}^N$ by the Whitney embedding theorem; choose an embedding and think of $M$ then as a subset of $\mathbb{R}^N$ (that is, identify it with its image). Choose a neighborhood $T$ of $M$ sufficiently small that the orthogonal projection $\pi : T \to M$ is well-defined. Extend each diffeomorphism $f \in \mathrm{Diff}^r(M)$ to a diffeomorphism $F$ on $T$, in such a way that $F$ is strongly contracting toward $M$. We then consider the family of perturbations

$$F_\varepsilon = F + \varepsilon_1 F_1 + \varepsilon_2 F_2 + \cdots .$$

for some functions $F_1, F_2, \ldots \in C^r(T, \mathbb{R}^N)$ and $\varepsilon$ in an appropriate Hilbert brick. For the results presented in this paper, $F_1, F_2, \ldots$ are a basis for the polynomials on $\mathbb{R}^N$, but in general they could be any functions that are chosen independently of $F$.

Next we associate to each $F_\varepsilon$ a diffeomorphism $f_\varepsilon \in \mathrm{Diff}^r(M)$. By Fenichel's theorem [Fen], for $\varepsilon$ sufficiently small, $F_\varepsilon$ has an invariant manifold $M_\varepsilon$ close to $M$, such that $\pi_\varepsilon = \pi|_{M_\varepsilon}$ is invertible. (To be precise, Fenichel's theorem is for flows, and we apply it by considering the suspension flow associated with $f$.) Furthermore, $F_\varepsilon$ is strongly contracting toward $M_\varepsilon$, so that all of its periodic orbits (indeed, all of its nonwandering points) are on $M_\varepsilon$. We then let $f_\varepsilon = \pi_\varepsilon \circ F_\varepsilon \circ \pi_\varepsilon^{-1}$. Because of this smooth conjugacy, we can prove many properties of $f_\varepsilon$ by proving them about $F_\varepsilon$.

Given this construction, we make the following definition.

**Definition 9.2** (Nonlinear prevalence). A subset $P \subset \mathrm{Diff}^r(M)$ is *prevalent* if for some functions $F_1, F_2, \ldots \in C^r(T, \mathbb{R}^N)$ and a sufficiently small Hilbert brick $HB$ such that the construction above works for every $\varepsilon \in HB$, we have that for each $f \in \mathrm{Diff}^r(M)$, the diffeomorphism $f_\varepsilon$ constructed above belongs to $P$ for almost every $\varepsilon$ with respect to the uniform measure on $HB$.

Of course, this definition depends on the choices made in our construction – the particular embedding of $M$ and the means of extending a diffeomorphism on $M$ to a neighborhood of its embedded image. We emphasize that the results in this paper and any results proved by a similar technique are independent of the details of the construction; the family of polynomial perturbations works regardless of the choices of embedding and extension. In this sense, we do not construct just a single family of perturbations for which our results are true with probability one, but rather an entire class of parametrized families that establish prevalence.

# From combinatorics to ergodic theory and back again

Bryna Kra*

**Abstract.** Multiple ergodic averages, such as the average of expressions like $f_1(T^n x)$ $f_2(T^{2n}x)\dots f_k(T^{kn}x)$, were first studied in the ergodic theoretic proof of Szemerédi's Theorem on arithmetic progressions. It turns out that all constraints on such averages (in a sense that we describe) have an algebraic character, arising from identities in nilpotent groups. We discuss these averages, several generalizations, and combinatorial implications of the results.

**Keywords.** Multiple ergodic theorem, multiple recurrence, arithmetic progressions, nilsystems.

## 1. Additive combinatorics and ergodic theory

A classic result of Ramsey Theory was proved by van der Waerden [53] in the 1920s, who showed that if the integers are partitioned into finitely many subsets, at least one of the subsets contains arbitrarily long arithmetic progressions. Erdős and Turán [12] conjectured that a weaker assumption suffices: if $A$ is a set of integers whose *upper density*

$$\bar{d}(A) = \limsup_{N\to\infty} \frac{1}{N}|A \cap [1, N]|$$

is positive, then $A$ contains arbitrarily long arithmetic progressions. Clearly the conjecture immediately implies van der Waerden's Theorem.

The first progress on the Erdős–Turán conjecture came in 1952, when Roth [45] used Fourier analysis to establish that a set of integers with positive upper density contains an arithmetic progression of length 3. Further progress was not until 1969, when Szemerédi [48] showed that the conjecture holds for progressions of length 4. Finally in 1975, Szemerédi [49] resolved the general case with an intricate combinatorial proof.

Soon thereafter, Furstenberg [18] used ergodic theory to give a new proof of Szemerédi's Theorem, and this proof marks the birth of the field of ergodic Ramsey Theory. Since then, ergodic theory has been used to prove new results in combinatorics, such as the multidimensional Szemerédi Theorem [22], the density Hales–Jewett Theorem [24], and the polynomial Szemerédi Theorem [4]; many of these results have yet to be obtained by other means. (Some of these results are explained

*The author was partially supported by NSF grant DMS-0244994.

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

in Section 4.) Furstenberg's pioneering work laid out the general strategy for these problems: translate the combinatorial statement into a problem on the intersection of sets in a measure preserving system and then study the average associated to this intersection. The convergence of these multiple ergodic averages is the main focus of this article. A key result is the convergence of the averages associated to Szemerédi's Theorem (see Section 2 for an explanation of the link):

**Theorem 1.1** (Host and Kra [36]). *Assume that* $(X, \mathcal{X}, \mu, T)$ *is a measure preserving system,*[1] $k \geq 1$ *is an integer, and* $f_1, f_2, \ldots, f_k \in L^\infty(\mu)$. *Then the limit*

$$\lim_{N\to\infty} \frac{1}{N} \sum_{n=0}^{N-1} f_1(T^n x) f_2(T^{2n} x) \ldots f_k(T^{kn} x) \tag{1}$$

*exists in* $L^2(\mu)$.

It turns out that a subsystem can be substituted for the original system without affecting the convergence or the value of the limit. Furthermore, this subsystem can be completely described algebraically, with a particular role played by nilpotent groups and their homogeneous spaces. We describe the structural analysis of measure preserving systems needed to prove this in Section 3.

This has led us to a greater understanding of other multiple ergodic averages, including averages with polynomial exponents, prime exponents, and certain averages of commuting transformations, and some of these results are discussed in Section 4. In turn, the multiple convergence theorems have lead to deeper connections with exciting developments in number theory and combinatorics, and we discuss some of these developments in Sections 4 and 5.

Although the connection between ergodic theory and additive combinatorics is well established, the depth of this connection is only now beginning to be understood. Szemerédi's original proof is combinatorial and Furstenberg's proof uses ergodic theory, yet the two proofs have many formal similarities. These features recur in more recent proofs of Szemerédi's Theorem, such as those of Gowers [26] and of Tao [50]. In the ergodic setup, with our work in [36] we have a complete understanding of the underlying structures in measure preserving systems that arise in the ergodic theoretic proof of Szemerédi's Theorem. To elucidate the true nature of the link with additive combinatorics, describing corresponding combinatorial constructions remains a deep open question.

[1] By an (*invertible*) *measure preserving* (*probability*) *system*, we mean a quadruple $(X, \mathcal{X}, \mu, T)$ where $X$ is a compact metrizable set, $\mathcal{X}$ denotes the Borel $\sigma$-algebra on $X$, $\mu$ is a probability measure on $(X, \mathcal{X})$, and $T\colon X \to X$ is an invertible measurable map with $\mu(A) = \mu(T^{-1}A)$ for all $A \in \mathcal{X}$. Even when not explicitly stated, the measure is assumed to be a probability measure and the transformation is assumed to be invertible.

## 2. Multiple ergodic averages

**2.1. Multiple recurrence.** We start with the connection between regularity properties of subsets of integers and recurrence in measure preserving systems:

**Correspondence Principle** (Furstenberg [18], [20]). *Let $E$ be a set of integers with positive upper density. There exist a measure preserving system $(X, \mathcal{X}, \mu, T)$ and a subset $A \subseteq \mathcal{X}$ such that $\mu(A) = \bar{d}(E)$ and*

$$\bar{d}((E+n_1) \cap (E+n_2) \cap \cdots \cap (E+n_k)) \geq \mu(T^{-n_1}A \cap T^{-n_2}A \cap \cdots \cap T^{-n_k}A)$$

*for any integer $k \geq 1$ and integers $n_1, n_2, \ldots, n_k \geq 0$.*

Furstenberg then deduced Szemerédi's Theorem by showing that any system $(X, \mathcal{X}, \mu, T)$ is *multiply recurrent*, meaning that for all $A \in \mathcal{X}$ with positive measure, there exists $n \in \mathbb{N}$ such that

$$\mu(A \cap T^n A \cap T^{2n} A \cap \cdots \cap T^{kn} A) > 0. \tag{2}$$

To produce such $n \in \mathbb{N}$ using ergodic theoretic methods, it is natural to average the expression in (2) over $n$. If one can show that the limit inferior of this average is positive, the existence of some $n \in \mathbb{N}$ satisfying (2) follows immediately. Thus combined with the Correspondence Principle, Szemerédi's Theorem follows from:

**Multiple Recurrence Theorem** (Furstenberg [18]). *Assume that $(X, \mathcal{X}, \mu, T)$ is a measure preserving system, $A \in \mathcal{X}$ has positive measure, and $k \geq 1$ is an integer. Then*

$$\liminf_{N\to\infty} \frac{1}{N} \sum_{n=0}^{N-1} \mu(A \cap T^n A \cap T^{2n} A \cap \cdots \cap T^{kn} A) > 0. \tag{3}$$

Poincaré Recurrence is implied by the case $k = 1$: for any set $A \in \mathcal{X}$ with positive measure, there exist infinitely many $n \in \mathbb{N}$ such that $\mu(A \cap T^n A) > 0$. Although it is easy to prove Poincaré Recurrence directly, we can also view it as a corollary of the von Neumann Ergodic Theorem, which implies that for a set $A \in \mathcal{X}$ with positive measure, the limit

$$\lim_{N\to\infty} \frac{1}{N} \sum_{n=0}^{N-1} \mu(A \cap T^n A)$$

exists and is positive. For higher order multiple recurrence ($k \geq 2$), this method of studying the corresponding multiple ergodic average is the only known method for producing $n$ such that (2) holds.

**2.2. Multiple ergodic averages.** A natural question arises: is the "lim inf" in (3) actually a limit? More generally, if $(X, \mathcal{X}, \mu, T)$ is a measure preserving system,

$k \geq 1$ is an integer, and $f_1, f_2, \ldots, f_k \in L^\infty(\mu)$, do the multiple ergodic averages

$$\frac{1}{N}\sum_{n=0}^{N-1} f_1(T^n x) f_2(T^{2n}x)\ldots f_k(T^{kn}x) \tag{4}$$

converge as $N$ tends to infinity, and in what sense do they converge? Taking each $f_i$ to be the indicator function $\mathbf{1}_A$ of a set $A$, multiplying by $\mathbf{1}_A$ and integrating with respect to $\mu$, we obtain the average in (3). For $k = 1$, the existence of this limit in $L^2(\mu)$ is the von Neumann Ergodic Theorem.

A measure preserving transformation $T\colon X \to X$ induces an operator $U_T$, on functions in $L^2(\mu)$ defined by $U_T f(x) = f(Tx)$. In a standard abuse of notation, we denote the operator $U_T$ by $T$ and write $Tf(x) = f(Tx)$. In general we assume that the measure preserving system $(X, \mathcal{X}, \mu, T)$ is *ergodic*, meaning that the only sets $A \in \mathcal{X}$ satisfying $T^{-1}A \subseteq A$ have either full or zero measure. Since a general system can be decomposed into its ergodic components, for most of the theorems we consider it suffices to assume that the system is ergodic.

When the system is ergodic, for $k = 1$ the limit of (4) in $L^2(\mu)$ is the integral $\int_X f_1\, d\mu$ and in particular is constant. However, without some assumption on the system, for $k \geq 2$, the limit in (4) need not be constant. For example, if $X$ is the circle $\mathbb{T} = \mathbb{R}/\mathbb{Z}$, $T\colon \mathbb{T} \to \mathbb{T}$ is the rotation $Tx = x + \alpha \mod 1$ for some $\alpha \in \mathbb{T}$, $f_1(x) = \exp(4\pi i x)$ and $f_2(x) = \exp(-2\pi i x)$, then $f_1(T^n x) f_2(T^{2n}x) = f_2^{-1}(x)$ for all $n \in \mathbb{N}$. In particular, the double average

$$\frac{1}{N}\sum_{n=0}^{N-1} f_1(T^n x) f_2(T^{2n}x)$$

converges to a nonconstant function. (More generally, if $\alpha \notin \mathbb{Q}$ and $f_1, f_2 \in L^\infty(\mu)$, the double average converges to $\int f_1(x+t) f_2(x+2t)\, dt$, which in general is not constant.)

The limit behavior of the double average depends on rotational behavior in the system. To make this more precise, we introduce some terminology. A *factor* of a measure preserving system $(X, \mathcal{X}, \mu, T)$ can be defined in one of several equivalent ways: it is a $T$-invariant sub-$\sigma$-algebra $\mathcal{Y}$ of $\mathcal{X}$, it is a measure preserving system $(Y, \mathcal{Y}, \nu, S)$ and a measurable map $\pi\colon X \to Y$ such that $\mu \circ \pi^{-1} = \nu$ and $S \circ \pi(x) = \pi \circ T(x)$ for $\mu$-almost all $x \in X$, and it is a $T$-invariant subspace $\mathcal{F}$ of $L^\infty(\mu)$. The equivalence between the first two definitions follows by identifying $\pi^{-1}(\mathcal{Y})$ with a $T$-invariant sub-$\sigma$-algebra of $\mathcal{X}$ and noting that any $T$-invariant sub-$\sigma$-algebra of $\mathcal{X}$ arises in this way. Setting $\mathcal{F} = L^\infty(\mathcal{Y})$, we have that the first definition implies the third and taking $\mathcal{Y}$ to be the $\sigma$-algebra generated by $\mathcal{F}$-measurable sets, we have the converse. Depending on the context, we use any of these three characterizations interchangeably. In a slight abuse of notation, we use the same letter to denote the transformation in the whole space and in a factor.

If $(Y, \mathcal{Y}, \nu, T)$ is a factor of $(X, \mathcal{X}, \mu, T)$ and $f \in L^2(\mu)$, the *conditional expectation* $\mathbb{E}(f \mid \mathcal{Y})$ *of* $f$ *with respect to* $\mathcal{Y}$ is the orthogonal projection of $f$ onto $L^2(\nu)$.

Let $\mathbb{E}(f \mid Y)$ denote the function on $Y$ defined by $\mathbb{E}(f \mid Y) \circ \pi = \mathbb{E}(f \mid \mathcal{Y})$, where $\pi : X \to Y$ is the natural projection. This expectation is characterized by

$$\int_Y \mathbb{E}(f \mid Y)(y) g(y)\, d\nu(y) = \int_X f(x) g(\pi(x))\, d\mu(x)$$

for all $g \in L^\infty(\mu)$.

A measure preserving system $(X, \mathcal{X}, \mu, T)$ is said to be *weakly mixing* if the only measurable eigenfunctions of the operator on $L^2(\mu)$ induced by the transformation $T$ are constant. An alternate characterization of weakly mixing can be given in terms of a factor: the measure preserving system $(X, \mathcal{X}, \mu, T)$ is not weakly mixing if and only if it has a nontrivial factor which is a rotation on a compact abelian group. The maximal such (group rotation) factor is known as the *Kronecker factor*. A rotation on a circle is not weakly mixing.

Taking the rotational behavior into account, the double average $\frac{1}{N} \sum T^n f_1 \cdot T^{2n} f_2$ can be understood. The obvious phenomenon is that for $\mu$-almost every $x$, the triple $(x, T^n x, T^{2n} x)$ projects to an arithmetic progression in the Kronecker factor $\mathcal{Z}$. Furstenberg showed that this restriction is the only restriction, meaning that

$$\left\| \frac{1}{N} \sum_{n=0}^{N-1} T^n f_1 \cdot T^{2n} f_2 - \frac{1}{N} \sum_{n=0}^{N-1} T^n \mathbb{E}(f_1 \mid \mathcal{Z}) \cdot T^{2n} \mathbb{E}(f_2 \mid \mathcal{Z}) \right\|_{L^2(\mu)}$$

tends to 0 as $N \to \infty$. Thus to prove convergence of the double average, it suffices to replace each $f_i$, for $i = 1, 2$, by its conditional expectation $\mathbb{E}(f_i \mid \mathcal{Z})$ on the Kronecker factor. In particular, this means that one can assume that the system is an ergodic rotation on a compact abelian group. Then one can easily use Fourier analysis to show the existence of the limit. (The Kronecker factor is said to be *characteristic* for the double average. See Section 3.1 for the general definition.) The double average is the simplest example of a "nonconventional ergodic average," where even if the system is assumed to be ergodic, the limit need not be constant.

Furthermore, if the system is assumed to be weakly mixing, Furstenberg [18] showed the existence of the limit in (4) for all $k \geq 1$. Moreover, in this case the limit takes on a particularly simple form: the average converges in $L^2(\mu)$ to the product of the integrals $\int f_1\, d\mu \int f_2\, d\mu \ldots \int f_k\, d\mu$.

For a general system, the limiting behavior for $k \geq 3$ is more complicated and group rotations do not suffice for describing the long term behavior. For example, if $f(Tx) = \lambda f(x)$ for some $|\lambda| = 1$ and $F(Tx) = f(x)F(x)$, then

$$F(T^n x) = f(x) f(Tx) \ldots f(T^{n-1} x) F(x) = \lambda^{\frac{n(n-1)}{2}} (f(x))^n F(x).$$

Therefore

$$F(x)(F(T^n x))^{-3} (F(T^{2n} x))^3 (F(T^{3n} x))^{-1} = 1.$$

Projection to the Kronecker factor does not capture the behavior of generalized eigenfunctions, meaning that there is some relation among $x$, $T^n x$, $T^{2n} x$ and $T^{3n} x$ that does

not arise from the Kronecker factor. See Furstenberg [21] for a more intricate example, showing that even such generalized eigenfunctions do not suffice in determining the limiting behavior for $k = 3$.

Using a new structural analysis for ergodic systems, we describe the algebraic constraints on $n$-tuples $x, T^n x, T^{2n} x, \ldots, T^{(k-1)n} x$, and use this to obtain convergence of the averages in (4). Existence of the limit in $L^2(\mu)$ for $k = 1$ is the von Neumann Ergodic Theorem and existence for $k = 2$ was proven by Furstenberg [18]. Existence of the limit for $k = 3$ with the hypothesis of total ergodicity, meaning that $T$ and all its powers are ergodic, was proven by Conze and Lesigne ([9], [10], and [11]); this is the first place that a natural generalization (playing a major role for higher $k$) of the Kronecker factor, a 2-step nilsystem, appears as a factor. In the general case for $k = 3$, existence was shown by Furstenberg and Weiss [25] and by Host and Kra [33] (see also [34]). We proved existence of the limit (1) for all integers $k \geq 1$ in [36] and this is the statement of Theorem 1.1. More recently, Ziegler [57] has a different approach for showing the existence of the limit in the general case. The existence of the pointwise limit is a much more difficult problem and convergence is only known for $k = 2$, due to Bourgain [8].

The key role in the analysis used to prove the existence of the limit in (1) is played by nilpotent groups and their homogeneous spaces. We start with a brief overview of the ingredients in the proof of Theorem 1.1.

## 3. Structural analysis

**3.1. Characteristic factors.** A general strategy for showing the existence of an average, such as that of (1), is to find a factor such that the limiting behavior is unchanged when each function is replaced by its conditional expectation on this factor. More precisely, a factor $\mathcal{Y} \subseteq \mathcal{X}$ is a *characteristic factor* (or more succinctly, is *characteristic*) for the average

$$\frac{1}{N} \sum_{n=0}^{N-1} T^{a_1(n)} f_1 \cdot T^{a_2(n)} f_2 \ldots T^{a_k(n)} f_k$$

if the difference between this average and the same average with each function replaced by its conditional expectation on $\mathcal{Y}$

$$\frac{1}{N} \sum_{n=0}^{N-1} T^{a_1(n)} \mathbb{E}(f_1 \mid \mathcal{Y}) \cdot T^{a_2(n)} \mathbb{E}(f_2 \mid \mathcal{Y}) \ldots T^{a_k(n)} \mathbb{E}(f_k \mid \mathcal{Y})$$

converges to 0 in $L^2(\mu)$ as $N$ tends to infinity. For example, when $a_1(n) = n$ and $a_2(n) = 2n$, the Kronecker factor is characteristic for the double average. Although the term characteristic factor only appeared explicitly in the literature fairly recently [21], the method is implicit in Furstenberg's original proof [18] of Szemerédi's Theorem.

If one can find a characteristic factor for a given average, then it suffices to prove convergence when the characteristic factor is substituted for the original system. Proving convergence for the factor is then easier when the factor has a sufficiently explicit and "simple" description.

We follow this general strategy, but with a different point of view. Rather than manipulating a particular average that we want to understand, we start with an abstract construction of characteristic factors. The construction (following [36]) is based on an inductively defined sequence of measures and of seminorms,[2] which are then used to define the factors. We now outline this construction.

**3.2. Definition of measures and seminorms.** Fix an integer $k \geq 0$. We write a point $\omega \in \{0,1\}^k$ as $\omega = \omega_1\omega_2 \dots \omega_k$ with $\omega_i \in \{0,1\}$, omitting commas and parentheses, and let $|\omega| = \omega_1 + \omega_2 + \cdots + \omega_k$. Fixing an ergodic measure preserving system $(X, \mathcal{X}, \mu, T)$, let $X^{[k]} = X^{2^k}$ and let $T^{[k]}\colon X^{[k]} \to X^{[k]}$ be the map $T \times T \times \cdots \times T$, taken $2^k$ times. Elements of $X^{[k]}$ are written $\boldsymbol{x} = (x_\omega\colon \omega \in \{0,1\}^k)$. There is a natural identification of $X^{[k+1]}$ and $X^{[k]} \times X^{[k]}$, with a point $\boldsymbol{x} \in X^{[k+1]}$ being identified with $(\boldsymbol{x}', \boldsymbol{x}'') \in X^{[k]} \times X^{[k]}$, where $x'_\omega = x_{\omega 0}$ and $x''_\omega = x_{\omega 1}$ for each $\omega \in \{0,1\}^k$.

By induction, we define a probability measure $\mu^{[k]}$ on $X^{[k]}$, that is invariant under $T^{[k]}$. Set $\mu^{[0]} = \mu$. Assume that $\mu^{[k]}$ is defined for some $k \geq 0$. Let $\mathcal{I}^{[k]}$ denote the $\sigma$-algebra of $T^{[k]}$-invariant subsets of $X^{[k]}$.

Under the natural identification of $X^{[k+1]}$ with $X^{[k]} \times X^{[k]}$, define the measure preserving (probability) system $(X^{[k+1]}, \mu^{[k+1]}, T^{[k+1]})$ to be the *relatively independent joining* of $(X^{[k]}, \mu^{[k]}, T^{[k]})$ with itself over $\mathcal{I}^{[k]}$; this means that the measure $\mu^{[k+1]}$ satisfies for all bounded functions $F'$ and $F''$ on $X^{[k]}$,

$$\int_{X^{[k+1]}} F'(\boldsymbol{x}')F''(\boldsymbol{x}')\,d\mu^{[k+1]}(x) = \int_{X^{[k]}} \mathbb{E}(F' \mid \mathcal{I}^{[k]})\,\mathbb{E}(F'' \mid \mathcal{I}^{[k]})\,d\mu^{[k]}.$$

The measure $\mu^{[k+1]}$ is invariant under $T^{[k+1]}$ and the two natural projections on $X^{[k]}$ are each $\mu^{[k]}$. By induction, each of the $2^k$ natural projections of $\mu^{[k]}$ on $X$ is equal to $\mu$. Letting $C\colon \mathbb{C} \to \mathbb{C}$ denote the conjugacy map $z \mapsto \overline{z}$, we have that for a bounded function $f$ on $X$, the integral

$$\int_{X^{[k]}} \prod_{\omega \in \{0,1\}^j} C^{|\omega|} f(x_\omega)\,d\mu^{[k]}(\boldsymbol{x})$$

is real and nonnegative.

[2] Although the definition and context are on the surface quite different, these seminorms turn out to be a generalization of the norms introduced by Gowers [26] in his proof of Szemerédi's Theorem. To recover the Gowers norms, consider the space $\mathbb{Z}/N\mathbb{Z}$, the transformation $x \mapsto x + 1 \mod N$, and the uniform measure assigning each element of $\mathbb{Z}/N\mathbb{Z}$ weight $1/N$. The Gowers norms were later used by Green and Tao [28] in a spirit closer to ergodic theory and their use in our work [36]. See [32] and [39] for more on this connection.

Therefore, for a function $f \in L^\infty(\mu)$ we can define

$$|||f|||_k = \left( \int_{X^{[k]}} \prod_{\omega \in \{0,1\}^k} C^{|\omega|} f(x_\omega)\, d\mu^{[k]}(\boldsymbol{x}) \right)^{1/2^k}.$$

One can also view this definition as an average over the cube $\{0, 1\}^k$. A convergence theorem for general averages along cubes is also proved in [36], and the connection between averages along cubes and along arithmetic progressions is more fully explained in Host [32].

Using the Ergodic Theorem and the definition of the measures, we have that for any $f \in L^\infty(\mu)$,

$$|||f|||_{k+1} = \left( \lim_{N\to\infty} \frac{1}{N} \sum_{n=0}^{N-1} |||f \cdot \overline{T^n f}|||_k^{2^k} \right)^{1/2^{k+1}}. \tag{5}$$

To show that the map $f \mapsto |||f|||_k$ is a seminorm on $L^\infty(\mu)$, one derives a version of the Cauchy–Schwarz inequality and uses it to show subadditivity. Positivity immediately follows from Equation (5). (See [36] for details.)

We now return to the original averages along arithmetic progressions and show that the long term behavior of the average (1) is controlled by the seminorms we have constructed:

**Theorem 3.1** (Host and Kra [36]). *Assume that $(X, \mathcal{X}, \mu, T)$ is an ergodic measure preserving probability system. Let $k \geq 1$ be an integer and assume that $f_1, f_2, \ldots, f_k$ are functions on $X$ with $\|f_1\|_\infty, \|f_2\|_\infty, \ldots, \|f_k\|_\infty \leq 1$. Then*

$$\limsup_{N\to\infty} \left\| \frac{1}{N} \sum_{n=0}^{N-1} T^n f_1 \cdot T^{2n} f_2 \ldots T^{kn} f_k \right\|_{L^2(\mu)} \leq \min_{1\leq j\leq k} (j|||f_j|||_k).$$

The proof relies on a standard method for finding characteristic factors, which is an iterated use of a variation of the van der Corput Lemma on differences (see for example [40] or [1]):

**van der Corput Lemma.** *Assume that $\mathcal{H}$ is a Hilbert space with inner product $\langle\ ,\ \rangle$ and norm $\|\cdot\|$, and that $\xi_n$, $n \geq 0$, is a sequence in $\mathcal{H}$ with $\|\xi_n\| \leq 1$ for all $n$. Then*

$$\limsup_{N\to\infty} \left\| \frac{1}{N} \sum_{n=0}^{N-1} \xi_n \right\|^2 \leq \limsup_{H\to\infty} \frac{1}{H} \sum_{h=0}^{H-1} \limsup_{N\to\infty} \left| \frac{1}{N} \sum_{n=0}^{N-1} \langle \xi_{n+h}, \xi_n \rangle \right|.$$

In our context, we apply this to the Hilbert space $L^2(\mu)$ of unitary operators that is naturally associated with the system $(X, \mathcal{X}, \mu, T)$. The seminorms we construct reflect $k$ successive uses of the van der Corput Lemma, with the number of steps in the iteration increasing with the complexity of the averages. Theorem 3.1 follows using induction, the Cauchy–Schwarz Inequality, and the van der Corput Lemma.

**3.3. The factors.** We then show that for every integer $k \geq 1$, the seminorms define factors $Z_{k-1}$. One presentation of these factors is obtained by defining their orthogonal complements: for $k \geq 1$, it can be shown that there exists a $T$-invariant $\sigma$-algebra $\mathcal{Z}_{k-1}$ of $\mathcal{X}$ such that for $f \in L^\infty(\mu)$,

$$\|\!| f |\!\|_k = 0 \quad \text{if and only if} \quad \mathbb{E}(f \mid \mathcal{Z}_{k-1}) = 0.$$

Therefore a bounded function $f$ is measurable with respect to $\mathcal{Z}_{k-1}$ if and only if $\int f g \, d\mu = 0$ for all functions $g \in L^\infty(\mu)$ with $\|\!| g |\!\|_{k-1} = 0$.

Then $Z_{k-1}$ is defined to be the factor of $X$ associated to the sub-$\sigma$-algebra $\mathcal{Z}_{k-1}$. Thus defined, $Z_0$ is the trivial factor, $Z_1$ is the Kronecker factor and more generally, $Z_k$ is a compact abelian group extension of $Z_{k-1}$. Furthermore, the sequence of factors is increasing

$$Z_0 \leftarrow Z_1 \leftarrow Z_2 \leftarrow \cdots \leftarrow X$$

and if $T$ is weakly mixing, then $Z_k$ is the trivial factor for all $k$. In this terminology, Theorem 3.1 states that the factor $Z_k$ is characteristic for the average (1).

The bulk of the work, and also the most technical portion, is devoted to the description of these factors. The initial idea is natural: we associate to each of these factors the group of transformations which preserves the natural cubic structure that arises in the construction. This group is nilpotent. We then conclude that for a sufficiently large (for our purposes) class of systems, this group is a Lie group and acts transitively on the space. Therefore, the constructed system is a *translation on a nilmanifold*. More precisely, if $G$ is a $k$-step nilpotent Lie group and $\Gamma$ is a discrete cocompact subgroup, then the compact space $X = G/\Gamma$ is said to be a *$k$-step nilmanifold*. The group $G$ acts on $G/\Gamma$ by left translation and the translation by a fixed element $a \in G$ is given by $T_a(g\Gamma) = (ag)\Gamma$. There exists a unique probability measure $m_{G/\Gamma}$, the *Haar measure*, on $X$ that is invariant under the action of $G$ by left translations. Fixing an element $a \in G$, we call the system $G/\Gamma$ with its associated Borel $\sigma$-algebra, Haar measure $m_{G/\Gamma}$, and translation $T_a$ a *$k$-step nilsystem*. The system $(X, \mathcal{X}, \mu, T)$ is an *inverse limit of a sequence of factors* $(X_n, \mathcal{X}_n, \mu_n, T)$ if $\mathcal{X}_n$, $n \in \mathbb{N}$, is an increasing sequence of $T$-invariant $\sigma$-algebras such that $\bigvee_{n\in\mathbb{N}} \mathcal{X}_n = \mathcal{X}$ up to a set of measure 0. If in addition each factor $(X_n, \mathcal{X}_n, \mu_n, T)$ is isomorphic to a $k$-step nilsystem for $n \in \mathbb{N}$, the system $(X, \mathcal{X}, \mu, T)$ is an *inverse limit of $k$-step nilsystems*.

The structure theorem states:

**Theorem 3.2** (Host and Kra [36]). *There exists a characteristic factor for the averages in* (1) *which is isomorphic to an inverse limit of $k$-step nilsystems.*

An expository outline of the proof is also given in Host [32]. A posteriori, the role played by the nilpotent structure is not surprising: for a $k$-step nilsystem $(X, \mathcal{X}, \mu, T)$ and $x \in X$, the $(k+1)$st term $T^k x$ of an arithmetic progression is constrained by the first $k$ terms $x, Tx, T^2x, \ldots, T^{k-1}x$.

Convergence of the linear (meaning the exponents $n, 2n, \ldots, kn$ are linear) multiple ergodic average then follows easily from general properties of nilmanifolds proved by Lesigne [43] for connected groups and proved in the general case by Leibman [41].

## 4. Generalizations of multiple convergence

**4.1. Polynomial averages.** It is natural to ask what configurations, other than arithmetic progressions, must occur in sets of integers with positive upper density. Sárközy [46] and Furstenberg [19] independently showed that if a subset of integers $E$ has positive upper density and $p\colon \mathbb{Z} \to \mathbb{Z}$ is a polynomial with $p(0) = 0$, then there exist $x, y \in E$ and $n \in \mathbb{N}$ such that $x - y = p(n)$. Furstenberg's proof used ergodic theory. Once again, Furstenberg's proof used the correspondence principle and a recurrence result, this time along polynomial times. Bergelson and Leibman generalized the recurrence result for multiple polynomials:

**Theorem 4.1** (Bergelson and Leibman [4]). *Assume that $(X, \mathcal{X}, \mu, T)$ is an invertible measure preserving system, $A \in \mathcal{X}$ has positive measure, $k \geq 1$ is an integer, and $p_1, p_2, \ldots, p_k\colon \mathbb{Z} \to \mathbb{Z}$ are polynomials with $p_j(0) = 0$ for $j = 1, 2, \ldots, n$. Then*

$$\liminf_{N\to\infty} \frac{1}{N} \sum_{n=0}^{N-1} \mu(A \cap T^{-p_1(n)}A \cap T^{-p_2(n)}A \cap \cdots \cap T^{-p_k(n)}A) > 0.$$

The result in [4] is actually quite a bit stronger; they prove a multidimensional version of this statement (see Section 4.2), meaning that one replaces the $j$-th occurrence of $T$ by $T_j$, for $k$ commuting measure preserving transformations $T_1, T_2, \ldots, T_k$ of the measure space $(X, \mathcal{X}, \mu)$. A polynomial version of Szemerédi's Theorem follows immediately via Furstenberg's Correspondence Principle.

The polynomial recurrence theorem naturally leads to the corresponding convergence question for multiple polynomial averages:

**Theorem 4.2** (Host and Kra [37], Leibman [42]). *Assume that $(X, \mathcal{X}, \mu, T)$ is a measure preserving system, $k \geq 1$ is an integer, $p_1, p_2, \ldots, p_k\colon \mathbb{Z} \to \mathbb{Z}$ are polynomials, and $f_1, f_2, \ldots, f_k \in L^\infty(\mu)$. Then the limit*

$$\lim_{N\to\infty} \frac{1}{N} \sum_{n=0}^{N-1} T^{p_1(n)} f_1 \cdot T^{p_2(n)} f_2 \ldots T^{p_k(n)} f_k \tag{6}$$

*exists in $L^2(\mu)$.*

For a weakly mixing system, convergence of (6) was proved by Bergelson [1]. In an arbitrary measure preserving system, Furstenberg and Weiss [25] proved convergence for $k = 2$ with $p_1(n) = n$ and $p_2(n) = n^2$ and $p_1(n) = n^2$ and $p_2(n) = n^2 + n$. Weak convergence was proven in [37], as well as convergence in $L^2(\mu)$ in most cases. The remaining case, along with a generalization for multiparameter polynomials, was completed in [42].

As with the linear average corresponding to exponents $n, 2n, \ldots, kn$, the behavior of a general polynomial average is controlled by the seminorms $\|\!| \cdot |\!\|_k$. Using an inductive procedure like that of [1], the averages in (6) can be reduced to an average only

with linear exponents and we obtain a result for a polynomial average analogous to Theorem 3.1. Using the structure theorem (Theorem 3.2), we have that a characteristic factor for a polynomial average is once again an inverse limit of nilsystems.

The number of steps needed in the inductive procedure used to reduce the average (6) to linear terms depends on the choice of polynomials. As might be expected, more terms and higher degree increases the number of steps needed and so the complexity of the corresponding the nilsystem rises. However, it turns out that the linearly dependent family $\{n, 2n, \dots, kn\}$ is in some sense the most difficult. For a general polynomial family, the minimal characteristic factor $Z_k$ (meaning smallest $k$) is unknown. Yet for *rationally independent polynomials*, meaning polynomials $p_1, p_2, \dots, p_k \colon \mathbb{Z} \to \mathbb{Z}$ with $\{1, p_1, p_2, \dots, p_k\}$ linearly independent over $\mathbb{Q}$, the characteristic factor (and therefore the value of the limit) is particularly simple and is independent of the choice of polynomials. Answering a question of Bergelson posed in [2], we show:

**Theorem 4.3** (Frantzikinakis and Kra [14]). *Assume that $(X, \mathcal{X}, \mu, T)$ is a totally ergodic measure preserving system, $k \geq 1$ is an integer, $p_1, p_2, \dots, p_k \colon \mathbb{Z} \to \mathbb{Z}$ are rationally independent polynomials, and $f_1, f_2, \dots, f_k \in L^\infty(\mu)$. Then*

$$\frac{1}{N}\sum_{n=0}^{N-1} T^{p_1(n)} f_1 \cdot T^{p_2(n)} f_2 \dots T^{p_k(n)} f_k - \int f_1 \, d\mu \int f_2 \, d\mu \dots \int f_k \, d\mu$$

*converges to 0 in $L^2(\mu)$ as $N \to \infty$.*

Our proof uses the machinery of the Structure Theorem, but we ultimately show that the procyclic factor (an inverse limit of cyclic groups), which is contained in the Kronecker factor, is characteristic for this average. It would be interesting to prove the theorem directly, avoiding the use of nilsystems.

**4.2. Averages for commuting transformations.** Furstenberg and Katznelson generalized multiple recurrence for commuting transformations:

**Theorem 4.4** (Furstenberg and Katznelson [22]). *Assume that $(X, \mathcal{X}, \mu)$ is a probability space, $k \geq 1$ is an integer, $T_1, T_2, \dots, T_k \colon X \to X$ are commuting measure preserving transformations, and $A \in \mathcal{X}$ has positive measure. Then*

$$\liminf_{N\to\infty} \frac{1}{N}\sum_{n=0}^{N-1} \mu(A \cap T_1^{-n} A \cap T_2^{-n} A \cap \dots \cap T_k^{-n} A) > 0.$$

(Other generalizations, including combinations of the commuting and polynomial averages, are contained in [23] and [5].) Furstenberg's correspondence principle immediately implies a combinatorial version, the multidimensional version of Szemerédi's Theorem.

Once again, it is natural to ask about convergence of the corresponding commuting multiple ergodic average:

**Question 4.5.** If $k \geq 1$ is an integer, $T_1, T_2, \ldots, T_k \colon X \to X$ are commuting measure preserving transformations of a probability space $(X, \mathcal{X}, \mu)$, $p_1, p_2, \ldots, p_k \colon \mathbb{Z} \to \mathbb{Z}$ are polynomials, and $f_1, f_2, \ldots, f_k \in L^\infty(\mu)$, does

$$\lim_{N\to\infty} \frac{1}{N} \sum_{n=0}^{N-1} T_1^{p_1(n)} f_1 \cdot T_2^{p_2(n)} f_2 \ldots T_k^{p_k(n)} f_k$$

exist in $L^2(\mu)$?

For two transformations and exponents $p_1(n) = p_2(n) = n$, existence of the limit in $L^2(\mu)$ was shown by Conze and Lesigne [9]. For arbitrary $k \geq 1$, under the assumptions that $T_j$ is ergodic for $j = 1, 2, \ldots, k$ and that $T_i T_j^{-1}$ is ergodic for $i \neq j$, $i, j \in \{1, 2, \ldots, k\}$, existence of the limit with exponents $p_1(n) = p_2(n) = \cdots = p_k(n) = n$ in $L^2(\mu)$ is shown in [15]. However, the general case (even with all exponents equal to $n$) remains open and it is easy to construct systems such that the characteristic factors are not nilsystems.

**4.3. Sequences related to prime numbers.** Recently, a new chapter in ergodic Ramsey Theory was opened, with ergodic theoretic techniques adapted for use outside of the field. A particularly spectacular result in this direction is Green and Tao's proof [28] that the prime numbers contain arbitrarily long arithmetic progressions. The connections between the proof of Green and Tao and ergodic theory are further explained in the expository articles of Host [32], Kra [39], and Tao [51]. In turn, Green and Tao's results make it possible to study convergence for other multiple ergodic averages, leading us to a greater understanding of patterns in a set of integers with positive upper density. Green and Tao ([29], [30], [31]) proved a strong uniformity result on the prime numbers and using this result, we can show that the shifted primes have multiple recurrence properties. (See also the survey articles of Green [27] and of Tao [52].) Letting $\mathbb{P}$ denote the primes, we show:

**Theorem 4.6** (Frantzikinakis, Host, and Kra [13]). *Assume that $(X, \mathcal{X}, \mu, T)$ is a measure preserving system and $A \in \mathcal{X}$ has positive measure. Then there exists $n \in \mathbb{P} - 1$ such that*

$$\mu(A \cap T^{-n} A \cap T^{-2n} A) > 0.$$

The same statement holds with $\mathbb{P} - 1$ replaced by $\mathbb{P} + 1$. Thus the shifted primes $\mathbb{P} - 1$ and $\mathbb{P} + 1$ are sets of 2-recurrence. For single recurrence, this was proven by Sárközy [47] and reproved using ergodic methods by Wierdl [54]. (Bourgain [7] and Wierdl [55] also proved several stronger results on pointwise convergence along primes.) An immediate corollary of Theorem 4.6 is that a set of integers with positive upper density contains infinitely many arithmetic progressions of length 3 whose common difference is of the form $p - 1$ for some prime $p$ (and similarly of the form $p + 1$).

Roughly speaking, we prove this by comparing the associated double average along primes with the usual double average, and show that the difference converges to 0. This relies on the uniformity result on the prime numbers of Green and Tao. It turns out that the Kronecker factor is characteristic for the associated average. The added complication is that one must work with $\mathbb{Z}/N\mathbb{Z}$ as the underlying space instead of $\mathbb{Z}$.

Using the same methods, we also show the existence of the related double ergodic average:

**Theorem 4.7** (Frantzikinakis, Host, and Kra [13]). *Assume that $(X, \mathcal{X}, \mu, T)$ is a measure preserving system and $f_1, f_2 \in L^\infty(\mu)$. Then*

$$\lim_{N\to\infty} \frac{1}{|\mathbb{P} \cap [0, N)|} \sum_{n\in\mathbb{P}, n<N} T^n f_1 \cdot T^{2n} f_2$$

*exists in $L^2(\mu)$.*

The same reduction to a uniformity statement about the prime numbers, for both recurrence and convergence, works for multiple recurrence and convergence of all lengths. However, the needed uniformity result for prime numbers remains open for longer progressions.

## 5. Lower bounds for multiple ergodic averages

**5.1. Khintchine Recurrence.** As described in Section 2, the first step in Furstenberg's Multiple Recurrence Theorem (Poincaré Recurrence) is an immediate corollary of the von Neumann Ergodic Theorem. However, using the full description of the limit, and not only positivity of the limit inferior, one can make a finer statement about the frequency of recurrence. More precisely, a set $E \subseteq \mathbb{Z}$ is *syndetic*[3] if there exists $M \in \mathbb{N}$ such that every interval of length $M$ has nontrivial intersection with the set $E$. Khintchine generalized Poincaré Recurrence and showed:

**Theorem 5.1** (Khintchine [38]). *If $(X, \mathcal{X}, \mu, T)$ is a measure preserving system and $A \in \mathcal{X}$, then for all $\varepsilon > 0$, the set*

$$\{n \in \mathbb{Z} \colon \mu(A \cap T^n A) > \mu(A)^2 - \varepsilon\}$$

*is syndetic.*

As this result follows easily from the von Neumann Ergodic Theorem, one can ask for the analogous results corresponding to other multiple recurrence theorems: if $(X, \mathcal{X}, \mu, T)$ is a measure preserving system, $A \in \mathcal{X}$, $k \geq 1$ is an integer,

[3] A syndetic set is sometimes known in the literature as *relatively dense*. A syndetic set in $\mathbb{Z}$ is said to have *bounded gaps*.

$p_1, p_2, \dots, p_k \colon \mathbb{Z} \to \mathbb{Z}$ are polynomials with $p_j(0) = 0$ for $j = 1, 2, \dots, k$, and $\varepsilon > 0$, is the set

$$\{n \in \mathbb{Z} \colon \mu(A \cap T^{-p_1(n)} A \cap \cdots \cap T^{p_k(n)} A) > \mu(A)^{k+1} - \varepsilon\} \tag{7}$$

syndetic?

Surprisingly enough, the answer depends on the number $k$ of polynomials and on the linear dependencies among the polynomials. For rationally independent polynomials, using the fact that a characteristic factor takes on a simple form, we show that the measure of the intersection in (7) is as large as possible on a syndetic set:

**Theorem 5.2** (Frantzikinakis and Kra [16]). *Assume that $(X, \mathcal{X}, \mu, T)$ is an invertible measure preserving system, $A \in \mathcal{X}$, $k \geq 1$ is an integer, and $p_1, p_2, \dots, p_k \colon \mathbb{Z} \to \mathbb{Z}$ are rationally independent polynomials with $p_j(0) = 0$ for $j = 1, 2, \dots, k$. Then for all $\varepsilon > 0$, the set*

$$\{n \in \mathbb{Z} \colon \mu(A \cap T^{p_1(n)} A \cap T^{p_2(n)} A \cap \cdots \cap T^{p_k(n)} A) \geq \mu(A)^{k+1} - \varepsilon\}$$

*is syndetic.*

This sharply contrasts the behavior for a family of linearly dependent polynomials, such as the linear polynomials corresponding to Szemerédi's Theorem, where the behavior depends on the number of linear terms. This dependence is illustrated in the following two theorems:

**Theorem 5.3** (Bergelson, Host, and Kra [3]). *Assume that $(X, \mathcal{X}, \mu, T)$ is an ergodic measure preserving system, $A \in \mathcal{X}$, and $k \geq 1$ is an integer. Then for all $\varepsilon > 0$, the sets*

$$\{n \in \mathbb{Z} \colon \mu(A \cap T^n A \cap T^{2n} A) \geq \mu(A)^3 - \varepsilon\}$$

*and*

$$\{n \in \mathbb{Z} \colon \mu(A \cap T^n A \cap T^{2n} A \cap T^{3n} A) \geq \mu(A)^4 - \varepsilon\}$$

*are syndetic.*

While ergodicity is not needed in Khintchine's Theorem, it is a necessary hypothesis in Theorem 5.3. In [3], we construct a counterexample for the nonergodic case.

For arithmetic progressions of length $\geq 5$, the analogous result does not hold. Based on a result of Ruzsa contained in the Appendix of [3], we show

**Theorem 5.4** (Bergelson, Host, and Kra [3]). *There exists an ergodic system $(X, \mathcal{X}, \mu, T)$ such that for all integers $\ell \geq 1$ and all $\varepsilon > 0$, there exists a set $A = A(\ell, \varepsilon) \in \mathcal{X}$ with positive measure such that*

$$\mu(A \cap T^n A \cap T^{2n} A \cap T^{3n} A \cap T^{4n} A) \leq \varepsilon \mu(A)^\ell$$

*for every integer $n \neq 0$.*

The proofs of these theorems are based on a decomposition result for the *multicorrelation sequence*

$$\int f(x) f(T^n x) f(T^{2n} x) \dots f(T^{kn} x)\, d\mu(x), \tag{8}$$

where $(X, \mathcal{X}, \mu, T)$ is a measure preserving system, $f \in L^\infty(\mu)$, and $k, n \geq 1$ are integers. We decompose such a sequence into two pieces, one of which is small in terms of density and the second of which arises from a nilsystem. We need some terminology to describe this decomposition more precisely. A bounded sequence $\{a_n\}_{n\in\mathbb{Z}}$ *tends to zero in uniform density* if

$$\lim_{N\to\infty} \sup_{M\in\mathbb{Z}} \frac{1}{N} \sum_{n=M}^{M+N-1} |a_n| = 0.$$

If $k \geq 1$ is an integer, the sequence $\{x_n\}$ is said to be a *basic $k$-step nilsequence* if there exists some $k$-step nilmanifold $X = G/\Gamma$, a continuous real valued function $\phi$ on $X$, $a \in G$ and $e \in X$ such that $x_n = \phi(a^n \cdot e)$ for all $n \in \mathbb{N}$. A *$k$-step nilsequence* is a uniform limit of basic $k$-step nilsequences. The general decomposition result is:

**Theorem 5.5** (Bergelson, Host, and Kra [3]). *Assume that $(X, \mathcal{X}, \mu, T)$ is an ergodic measure preserving system, $k \geq 1$ is an integer, and $f \in L^\infty(\mu)$. The multicorrelation sequence* (8) *is the sum of a sequence tending to zero in uniform density and a $k$-step nilsequence.*

By subtracting a sequence of integers that tends to 0 in uniform density, the sequences in Theorem 5.3 have the same behavior as the associated nilsequences (of lengths 3 and 4), and the problem reduces to studying lower bounds for the associated nilsequences. The factors constructed in [36] are used to understand the structure of these nilsequences and a key ingredient comes from the explicit formula for the average (1) given in Ziegler [56] (an alternate proof is given in [3]).

In [16], we prove a similar multicorrelation result for independent polynomials. In this case, the nilsequence takes on a simple form, as it is induced by a unipotent affine transformation.

**5.2. Combinatorial Implications.** Via a small modification of Furstenberg's Correspondence Principle, each of these results translates to a combinatorial result. The *upper Banach density* $d^*(E)$ of a set $E \subseteq \mathbb{Z}$ is defined by

$$d^*(E) = \lim_{N\to+\infty} \sup_{M\in\mathbb{Z}} \frac{1}{N} |E \cap [M, M+N-1]|.$$

Let $\varepsilon > 0$, $E \subseteq \mathbb{Z}$ have positive upper Banach density, and consider the set

$$\big\{n \in \mathbb{Z}\colon d^*\big(E \cap (E + p_1(n)) \cap \dots \cap (E + p_k(n))\big) \geq d^*(E)^{k+1} - \varepsilon\big\}. \tag{9}$$

For $k = 2$ or $k = 3$ and $p_j(n) = jn$ for $j = 1, 2, 3$, this set is syndetic, while for $k \geq 4$ and $p_j(n) = jn$ for $j = 1, 2, \ldots, k$, there exists a set of integers $E$ with positive upper Banach density such that the set in (9) is empty. On the other hand, in [16] we show that for all integers $k \geq 1$, if $p_1, p_2, \ldots, p_k \colon \mathbb{Z} \to \mathbb{Z}$ are rationally independent polynomials with $p_i(0) = 0$ for $i = 1, 2, \ldots, k$, then the set in (9) is always syndetic.

**Question 5.6.** If $\varepsilon > 0$, $E \subseteq \mathbb{Z}$ has positive upper Banach density, for which polynomials $p_1, p_2, \ldots, p_k \colon \mathbb{Z} \to \mathbb{Z}$ with $p_i(0) = 0$ for $i = 1, 2, \ldots, k$, is the set

$$\left\{n \in \mathbb{Z} \colon d^*\big(E \cap (E + p_1(n)) \cap (E + p_2(n)) \cap \cdots \cap (E + p_k(n))\big) \geq d^*(E)^{k+1} - \varepsilon\right\}$$

syndetic?

For the polynomials of Theorems 5.2, 5.3, and 5.4 we know the answer and it is sometimes yes and sometimes no. It is reasonable to conjecture that the answer is yes for $k = 2$ and 3, as we know it holds for two extreme cases: 2 (or 3) rationally independent polynomials and 2 (or 3) linear polynomials. For higher $k$, it may be possible to lift the independence condition of Theorem 5.2 under certain circumstances. The natural approach to the problem is via the corresponding statement in ergodic theory. A first step in answering this question is finding a general formula for the multiple polynomial average (6), generalizing the formula for the linear average (1).

## 6. Future directions

**6.1. Convergence along other sequences.** General conditions on sequences of integers under which one can prove a multiple ergodic theorem are unknown:

**Question 6.1.** If $k \geq 1$ is an integer and $a_1(n), a_2(n), \ldots, a_k(n)$ are sequences of integers with $a_j(n) \to \infty$ as $n \to \infty$ for $j = 1, 2, \ldots, n$, when does

$$\lim_{N\to\infty} \frac{1}{N} \sum_{n=0}^{N-1} T^{a_1(n)} f_1 \cdot T^{a_2(n)} f_1 \ldots T^{a_k(n)} f_k$$

exist in $L^2(\mu)$ for all measure preserving systems $(X, \mathcal{X}, \mu, T)$ and $f_1, f_2, \ldots, f_k \in L^\infty(\mu)$?

For $k = 1$, convenient necessary and sufficient conditions are given by the spectral theorem. However for $k \geq 2$, there is no such characterization and the proofs of multiple convergence for all known sequences (including arithmetic progressions, polynomials, and the primes) rely in some manner on a use of the van der Corput Lemma. Finding alternate proofs not relying on the van der Corput Lemma is a first step in describing choices for the sequences $a_j(n)$; a full characterization would probably require some sort of higher order spectral theorem.

Another natural question is the convergence of random multiple ergodic averages. Let $(\Omega, \mathcal{B}, P)$ be a probability space and let $\{Y_n\}_{n\in\mathbb{N}}$ be a sequence of independent random variables taking on values 0 and 1. Given $\omega \in \Omega$, let $E = E(\omega) = \{n \in \mathbb{N}\colon Y_n(\omega) = 1\}$. Ordering $E$ by size, we have defined a *random sequence* $\{a(n) = a(n, \omega)\}$ of natural numbers.

**Question 6.2.** Assume that $k \geq 1$ is an integer and that $a(n)$ is a random sequence of natural numbers generated by a sequence of independent random variables on some probability space $(\Omega, \mathcal{B}, P)$. When does

$$\lim_{N\to\infty} \frac{1}{N} \sum_{n=0}^{N-1} T^{a(n)} f_1 \cdot T^{2a(n)} f_2 \dots T^{ka(n)} f_k$$

exist in $L^2(\mu)$ for all measure preserving systems $(X, \mathcal{X}, \mu, T)$ and $f_1, f_2, \dots, f_k \in L^\infty(\mu)$?

For $k = 1$, Bourgain [6] showed that for a random nonlacunary sequence, meaning a sequence where $P(X_n(\omega) = 1) = p_n$ satisfies $\lim_{n\to\infty} np_n = \infty$, which is also decreasing, one has convergence in $L^2(\mu)$. For $k \geq 1$, convergence for $k = 1$ is of course a necessary condition, but it is not know if this is sufficient.

**6.2. Connections with additive combinatorics.** Since Furstenberg's proof of Szemerédi's Theorem, there has been a long and fruitful interaction between additive combinatorics and ergodic theory, with results and techniques passing from one field to the other. A major challenge remains: understand the mathematics behind the deep analogies between the two fields. The nilsystems that arise in the structural analysis of measure preserving systems should have some sort of combinatorial analog:

**Question 6.3.** What is the combinatorial analog of the Structure Theorem (Theorem 3.2)?

The uniformity norms on $\mathbb{Z}/N\mathbb{Z}$ (used in Gowers's [26] proof of Szemerédi's Theorem and in Green and Tao's [28] proof that the primes contain arbitrarily long progressions) play a role similar to the role that the seminorms described in Section 3 play in proving convergence of the multiple ergodic average along arithmetic progressions in [36]. A partial answer to this question is given by Green and Tao in [29], in which they show that generalized quadratic functions control the third uniformity norm, analogous to the way that 2-step nilsystems control the third seminorm. These generalized quadratic functions are controlled by 2-step nilsequences, and this gives a partial understanding of the combinatorial objects. It should be interesting and useful to obtain a more complete understanding of the precise nature of the link between these generalized quadratic functions and 2-step nilsequences, with a description in the finite setting of $\mathbb{Z}/N\mathbb{Z}$ rather than in $\mathbb{Z}$. For longer progressions, even partial results are not known.

It is not clear if one can directly use ergodic theory to prove statements about the primes, as the primes have zero density and Furstenberg's Correspondence Principle only applies for sets of positive upper density. However, even without a version of the Correspondence Principle that applies to zero density subsets, ergodic theory and especially its techniques has and will be further used to understand the finer structure of the primes. In analogy with multiple ergodic averages along polynomial sequences (and the use of seminorms), one may hope to combine techniques of additive combinatorics and ergodic theory to show, for example, that for all integers $k > 1$, there exist infinitely many pairs $(p, n)$ of integers with $p, n \geq 1$ such that $p$, $p + n$, $p + n^2, \ldots, p + n^k$ consists only of prime numbers.

# From Brouwer theory to the study of homeomorphisms of surfaces

Patrice Le Calvez

**Abstract.** We will state an equivariant foliated version of the classical Brouwer Plane Translation Theorem and will explain how to apply this result to the study of homeomorphisms of surfaces. In particular we will explain why a diffeomorphism of a closed oriented surface of genus $\geq 1$ that is the time-one map of a time dependent Hamiltonian vector field has infinitely many periodic orbits. This gives a positive answer in the case of surfaces to a more general question stated by C. Conley. We will give a survey of some recent results on homeomorphisms and diffeomorphisms of surfaces and will explain the links with the improved version of Brouwer's theorem.

**Mathematics Subject Classification (2000).** Primary 37E30, 37E35, 37J10; Secondary 37E45.

**Keywords.** Brouwer homeomorphism, Hamiltonian homeomorphism, periodic point, foliation on a surface, rotation number.

## 1. Introduction

It is a natural problem to ask if a given dynamical statement about time independent vector fields may be extended to periodic time dependent vector fields. Recall that a complete periodic time dependent smooth vector field on a manifold $M$ defines a family $(F_t)_{t\in\mathbb{R}}$ of diffeomorphisms such that $F_0 = \mathrm{Id}_M$ and $F_{t+T} = F_t \circ F_T$, for every $t \in \mathbb{R}$, if $T$ is the period. To study this system, one usually studies the discrete dynamical system induced by $F = F_T$.

Let us begin with a very simple example. Suppose that $M$ is compact and write $\chi(M)$ for the Euler characteristic of $M$. If $F$ is a homeomorphism homotopic to the identity with a finite number of fixed points, one knows by the Lefschetz formula that

$$\sum_{F(z)=z} i(F, z) = \chi(M),$$

where $i(F, z)$ is the Lefschetz index. If $F$ is the time-one map of a flow induced by a vector field, the fixed points are necessarily the singularities of $\xi$, and the previous formula may be deduced from the Poincaré–Hopf formula

$$\sum_{\xi(z)=0} i(\xi, z) = \chi(M),$$

where $i(\xi, z)$ is the Poincaré index.

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

Let us now give a more interesting example. Consider a symplectic compact manifold $(M, \omega)$ and write $n_M$ (resp. $n'_M$) for the minimum number of critical points that any smooth function (resp. Morse function) defined on $M$ must have. If $F$ is the time-one map of a family $(F_t)_{t\in\mathbb{R}}$ defined by a 1-periodic time dependent Hamiltonian vector field, we say that a fixed point $z$ is *contractible* if the *trajectory* $\gamma_z\colon t \mapsto F_t(z)$, defined on $[0, 1]$, is a loop homotopic to a point. Arnold's conjecture [1] states that the number of contractible fixed points is minimized by $n_M$, and that it is minimized by $n'_M$ if every fixed point of $F$ is non-degenerate (such results are obviously true in the case where the vector field is time independent). Now the the minoration by the sum of the Betti numbers is known to be true in the non-degenerate case (Liu, Tian [49], Fukaya, Ono [31]). See [36] for a history of this problem whose first proven case ($M = \mathbb{T}^{2n} = \mathbb{R}^{2n}/\mathbb{Z}^{2n}$) was solved by Conley and Zehnder [15].

Conley conjectured that the number of contractible periodic points is infinite in the case of a torus $\mathbb{T}^{2n}$. The conjecture is true if $F$ is a diffeomorphism with no degenerate fixed points (Salamon–Zehnder [53]). We will explain in Section 5 why Conley's conjecture is true if $M = \mathbb{T}^2$ and, more generally, if $M$ is a closed surface of genus $\geq 1$. The key result is an equivariant foliated version of the Brouwer Plane Translation Theorem, which will be stated in Section 4. Roughly speaking, it asserts that if $(F_t)_{t\in[0,1]}$ is an isotopy from the identity to $F$ on a surface $M$ which has no contractible point, there exists a continuous dynamics on $M$ which is "transverse" to the dynamics of $F$ in the following sense: every orbit is "pushed on its left" by the isotopy. Such a result may be applied in the presence of contractible fixed points if one takes out some of them. Suppose that $F$ is the time-one map of a Hamiltonian flow on a symplectic surface $M$ associated to $H\colon M \to \mathbb{R}$, then an example of a transverse dynamics is the dynamics of the gradient flow of $H$ if we endow $M$ with a Riemannian structure. We will see that such a transverse gradient-like dynamics may be produced even in the time dependent case.

We will recall the classical Brouwer theory of homeomorphisms of the plane in Section 2 and then state equivariant versions in the case of the annulus in Section 3. We will mention some recent results on dynamics of diffeomorphisms and homeomorphisms of surfaces. In particular, in Section 6 we will recall some new results due to Polterovich and to Franks and Handel about group actions on the space of area preserving diffeomorphisms of surfaces.

## 2. Brouwer's theory of plane homeomorphisms

The following result is due to Brouwer and recent proofs are given in [12], [16] or [32].

**Theorem 2.1** ([10]). *Let $f$ be an orientation preserving homeomorphism of the euclidean plane $\mathbb{R}^2$. If $f$ has a periodic point $z$ of period $q \geq 2$, then there is a simple closed curve $\Gamma$, disjoint from the fixed point set* $\mathrm{Fix}(f)$*, such that $i(f, \Gamma) = 1$, where*

*the index* $i(f, \Gamma)$ *is the degree of the map*

$$s \mapsto \frac{f(\Gamma(s)) - \Gamma(s)}{\|f(\Gamma(s)) - \Gamma(s)\|},$$

*and* $s \mapsto \Gamma(s)$ *is a parametrization defined on the unit circle* $S^1$.

A homeomorphism $f$ of $\mathbb{R}^2$ is orientation preserving if and only if it is isotopic to the identity; in the case where $f$ is the time-one map of a flow $(f_t)_{t\in\mathbb{R}}$ whose orbits are tangent to a given continuous vector field $\xi$, the result is obvious. Indeed, if $z$ is a periodic point of $f$ of period $q \geq 2$, the orbit of $z$ (for the flow) is a simple closed curve $\Gamma$, invariant by $f$, which is the union of periodic points of period $q$. This clearly implies that $i(f, \Gamma) = 1$.

Theorem 2.1 asserts that any fixed point free and orientation preserving homeomorphism of $\mathbb{R}^2$ is periodic point free. In fact its dynamics has no recurrence at all. More precisely, suppose that $f$ is an orientation preserving homeomorphism of $\mathbb{R}^2$ and that $f$ has a *non-wandering* point $z$ which is not fixed (i.e. every neighborhood of $z$ meets one of its iterate). Let us see why the conclusion of Theorem 2.1 is still satisfied. Choose a *free* topological open disk $V$ containing $z$ (i.e. disjoint from its image by $f$) and write $q \geq 2$ for the smallest positive integer such that $f^q(V) \cap V \neq \emptyset$. One can compose $f$ with a homeomorphism $h$ supported on $V$ to get a map with a periodic point of period $q$, so that Theorem 2.1 can be applied to $f \circ h$. The map $h$ being supported on a free set, $f \circ h$ and $f$ have the same fixed points. Moreover, $h$ being isotopic to the identity among the homeomorphisms supported on $V$, one has $i(f \circ h, \Gamma) = i(f, \Gamma)$ for every simple closed curve $\Gamma \subset \mathbb{R}^2 \setminus \mathrm{Fix}(f)$. The foregoing argument may be generalized to get the useful Franks Lemma:

**Proposition 2.2** ([21]). *Let* $f$ *be an orientation preserving homeomorphism of* $\mathbb{R}^2$. *If there is a periodic sequence* $(V_i)_{i\in\mathbb{Z}/q\mathbb{Z}}$ *of pairwise disjoint free topological open disks, and a sequence* $(n_i)_{i\in\mathbb{Z}/q\mathbb{Z}}$ *of positive integers such that* $f^{n_i}(V_i) \cap V_{i+1} \neq \emptyset$, *then there is a simple closed curve* $\Gamma \subset \mathbb{R}^2 \setminus \mathrm{Fix}(f)$ *such that* $i(f, \Gamma) = 1$.

It has been known for a long time that Brouwer theory may be applied to the study of homeomorphisms of surfaces. Let us explain for example why every orientation and area preserving homeomorphism on the sphere $S^2$ has at least two fixed points. The map $f$ being orientation preserving has at least one fixed point $z_1$ by the Lefschetz formula. The fact that $f$ preserves the area implies that every point is non-wandering; applying Proposition 2.2 to the map restricted to the topological plane $S^2 \setminus \{z_1\}$, one gets a second fixed point $z_2 \neq z_1$. As noticed by Hamilton [34], then by Brown [11], there is another fixed point result which can be deduced from Proposition 2.2: the Cartwright–Littlewood Fixed Point Theorem [14]. This theorem asserts that any non-separating continuum $K \subset \mathbb{R}^2$ which is invariant by an orientation preserving homeomorphism $f$ of $\mathbb{R}^2$ contains a fixed point. Let us recall Brown's argument. If $K \cap \mathrm{Fix}(f) = \emptyset$, then $K$ is included in a connected component $W$ of $\mathbb{R}^2 \setminus \mathrm{Fix}(f)$. One can choose a lift $\tilde{f}$ of $f|_W$ to the universal covering space $\widetilde{W}$ (homeomorphic

to $\mathbb{R}^2$) which fixes a given connected component $\widetilde{K}$ of the preimage of $K$. The set $\widetilde{K}$ being compact, $\tilde{f}$ should contain a non-wandering point (in fact a recurrent point) while being fixed point free.

Let us state now a much more difficult fixed point theorem, due to Handel, which is very useful in the study of homeomorphisms of surfaces (see [24], [25], [50]):

**Theorem 2.3** ([35]). *Let $f$ be an orientation preserving homeomorphism of the closed unit disk $D$ and suppose that*

- *there are $n \geq 3$ points $z_i$, $1 \leq i \leq n$, in $\mathrm{Int}(D)$ such that $\lim_{k\to-\infty} f^k(z_i) = \alpha_i \in \partial D$ and $\lim_{k\to+\infty} f^k(z_i) = \omega_i \in \partial D$;*
- *the $2n$ points $\alpha_i$ and $\omega_i$ are distinct;*
- *there is an oriented convex compact polygon in $\mathrm{Int}(D)$ whose $i$-th side joins $\alpha_i$ to $\omega_i$.*

*Then $f$ has a fixed point in $\mathrm{Int}(D)$.*

Handel's Fixed Point Theorem is usually applied to a lift $f$ to the universal covering space $\mathrm{Int}(D)$ of a homeomorphism $F$ of a hyperbolic surface (such a lift can always be extended to the closed disk). The core of the proof of Handel is a generalization of the Nielsen–Thurston classification of homeomorphisms of a compact surface $M$ to the case where $M$ is the complement in $\mathbb{R}^2$ of finitely many infinite proper orbits. In fact, it is possible to directly prove Theorem 2.3 by showing the existence of a *periodic free disk chain* of $f|_{\mathrm{Int}(D)}$ (i.e. a family of disks satisfying the assumptions of Proposition 2.2) and thus of a simple closed curve $\Gamma$ of index 1 (see [44]).

We will go on by recalling Brouwer's Plane Translation Theorem. By Schoenflies' Theorem, any proper topological embedding of the real line $\{0\} \times \mathbb{R}$ may be extended to an orientation preserving homeomorphism $h$ of $\mathbb{R}^2$. The open sets $L(\Gamma) = h(]-\infty, 0[\times\mathbb{R})$ and $R(\Gamma) = h(]0, +\infty[\times\mathbb{R})$ are the two connected components of the complement of the *oriented line* $\Gamma = h(\{0\} \times \mathbb{R})$.

**Theorem 2.4** ([10]). *If $f$ is a fixed point free and orientation preserving homeomorphism of $\mathbb{R}^2$, then every point belongs to a Brouwer line, that means an oriented line $\Gamma$ such that $f(\Gamma) \subset L(\Gamma)$ and $f^{-1}(\Gamma) \subset R(\Gamma)$.*

Such a homeomorphism is usually called a *Brouwer homeomorphism*. Observe that $W = \bigcup_{k\in\mathbb{Z}} f^{k+1}(R(\Gamma)) \setminus f^k(R(\Gamma))$ is an invariant open subset homeomorphic to $\mathbb{R}^2$ and that $f|_W$ is conjugate to a non-trivial translation of $\mathbb{R}^2$. Theorem 2.4 asserts that $\mathbb{R}^2$ can be covered by such invariant subsets. The quotient space $\mathbb{R}^2/f$ of orbits of $f$ is a topological surface which is Hausdorff if and only if $f$ is conjugate to a translation. Brouwer homeomorphisms have been studied for a long time. Among the more recent results one may mention the construction of the *oscillating set* by Béguin and Le Roux [3] which is a new topological invariant of Brouwer homeomorphisms. One may also mention the study of *Reeb components* of Brouwer homeomorphisms by Le Roux [48]. Such objects, which generalize the classical Reeb components of

foliations may be defined (in a not easy way) in the framework of Brouwer homeomorphisms and results that are true for foliations may be extended to this discrete case. One may also recall the following results about the topology of the space of Brouwer homeomorphisms when equipped with the compact-open topology: it is arcwise connected and locally contractible [8], more precisely the set of non-trivial affine translations is a strong deformation retract [46].

In the case where $f = f_1$ is the time-one map of a flow $(f_t)_{t\in\mathbb{R}}$ whose orbits are tangent to a continuous vector field $\xi$, Theorem 2.4 is also obvious. Indeed one may find a complete $C^1$ vector field $\eta$ such that $\eta(z) \wedge \xi(z) > 0$ for every $z \in \mathbb{R}^2$ (where $\wedge$ is the usual exterior product on $\mathbb{R}^2$). Every orbit $\Gamma$ of $\eta$ is a line by the Poincaré–Bendixson Theorem; it is a Brouwer line because $\xi$ points on $\Gamma$ from the right to the left. Note that the plane is foliated and not only covered by Brouwer lines. The proof of the Brouwer Plane Translation Theorem is much harder. In all known proofs (see [10], [23], [32], [45]) a non-recurrence lemma, a variation of Proposition 2.2, is needed. We will conclude this section by explaining the ideas of the proofs given in [45] and in Sauzet's thesis [54] as it will be the starting point of the proofs of the foliated versions that we will explain later.

A *brick decomposition* of $\mathbb{R}^2$ is given by a one dimensional stratified set $\Sigma$ (the *skeleton* of the decomposition) with a zero dimensional submanifold $V$ such that any vertex $v \in V$ is locally the extremity of exactly three edges. A *brick* is the closure of a connected component of $\mathbb{R}^2 \setminus \Sigma$. If $f$ is a fixed point free and orientation preserving homeomorphism of $\mathbb{R}^2$, one can construct a *maximal free decomposition*: it is a brick decomposition with free bricks such that the union of two adjacent bricks is no more free. Moreover if $z \in \mathbb{R}^2$ is a given point, one may suppose that $z \in \Sigma$. Let us write $B$ for the set of bricks. A slightly stronger version of Proposition 2.2, due to Guillou and Le Roux [47] asserts that there is no closed chain of bricks of $B$. This implies that the relation

$$b\mathcal{R}b' \iff f(b) \cap b' \neq \emptyset$$

generates by transitivity an order $\leq$ on $B$. The decomposition being maximal, two adjacent bricks are comparable. In fact, it appears that for every brick $b$, the union of bricks $b' > b$ adjacent to $b$ is non-empty and connected, as is the union of adjacent bricks $b' < b$. This implies that $b_\geq = \bigcup_{b'\geq b} b'$ is a connected closed subset satisfying $f(b_\geq) \subset \mathrm{Int}(b_\geq)$. The fact that we are working with bricks implies that the frontier of $b_\geq$ is a one dimensional manifold; the inclusion $f(b_\geq) \subset \mathrm{Int}(b_\geq)$ implies that every component of this frontier is a Brouwer line. One may cover the skeleton by Brouwer lines because $\Sigma = \bigcup_{b\in B} \partial b_\geq$.

Free cellular decompositions appear already in [32] and are explicitely constructed in a paper of Flucher [20] about a topological version of Conley–Zehnder theorem for $\mathbb{T}^2$. The trick to consider bricks to simplify the proofs was suggested by Guillou. Brick decompositions have been studied in detail in Sauzet's thesis [54] and have been used in some articles ([4], [9], [47]). In [47], Le Roux gives a very precise description of the dynamics of a homeomorphism $F$ of a surface in the neighborhood

of an isolated fixed point such that $i(F, z) \neq 1$. In [9], Bonino states the following result about any orientation reversing homeomorphim $f$ of $\mathbb{R}^2$: if $f$ has no periodic point of period 2, it has no periodic point of period $\geq 2$ and the complement of the fixed point set may be covered by invariant open subsets, where $f$ is conjugate either to the map $(x, y) \mapsto (x + 1, -y)$ or to the map $(x, y) \mapsto \frac{1}{2}(x, -y)$.

## 3. Equivariant versions of Brouwer's theory

Let us recall the classical Poincaré–Birkhoff Theorem which is the starting point of Arnold's conjecture:

**Theorem 3.1** ([6]). *Let $F$ be an area preserving homeomorphism of the annulus $\mathbb{T}^1 \times [0, 1]$ isotopic to the identity and let $f$ be a given lift to the universal covering space $\mathbb{R} \times [0, 1]$. Denote by $p_1 \colon \mathbb{R} \times [0, 1] \to \mathbb{R}$ the first projection and suppose that $p_1(f(x, 0)) < x < p_1(f(x, 1))$ for every $x \in \mathbb{R}$. Then $f$ has at least two fixed points which project in different points of $\mathbb{T}^1 \times [0, 1]$.*

Soon after the original proof of Birkhoff, it was noticed (see Birkhoff [7], Kerékjártó [37]) that the existence of one fixed point could be deduced by replacing the area preserving assumption with the following *intersection property*: any essential (i.e. not null-homotopic) simple closed curve of $\mathbb{T}^1 \times [0, 1]$ meets its image by $F$. Kerékjártó obtained the result as a consequence of Brouwer's Plane Translation Theorem. Suppose that $F$ and a given lift $f$ satisfy the assumptions of Theorem 3.1 but the area condition, and that $f$ is fixed point free. Then one can extend nicely $f$ to the whole plane in such a way that a Brouwer line may be constructed on $\mathbb{R}\times]0, 1[$ that is a lift of a simple closed curve of $\mathbb{T}^1\times]0, 1[$ (see [32] for a modern explanation). More recently, Guillou [33] and Sauzet [54] gave a proof of the following "equivariant" version of the Brouwer Plane Translation Theorem:

**Theorem 3.2.** *Let $F$ be a homeomorphism of $\mathbb{T}^1 \times \mathbb{R}$ isotopic to the identity and let $f$ be a given lift to the universal covering space $\mathbb{R}^2$ that is fixed point free. Then*

- *either there is an essential simple closed curve $\Gamma$ of $\mathbb{T}^1 \times \mathbb{R}$ such that $F(\Gamma) \cap \Gamma = \emptyset$,*
- *or there is a topological line joining the two ends of $\mathbb{T}^1 \times \mathbb{R}$ that is lifted to $\mathbb{R}^2$ by Brouwer lines of $f$.*

Franks [21] gave a different method to deduce the Poincaré–Birkhoff Theorem from Brouwer theory by using Proposition 2.2. Suppose that the assumptions of Theorem 3.1 are satisfied and moreover that the number $m$ of fixed points of $F$ which are lifted to fixed points of $f$ is finite. Then one can construct a closed chain of free disks of $f|_{\mathbb{R}\times]0,1[}$, which implies that there is a simple closed curve $\Gamma \subset \mathbb{R}\times]0, 1[$ such that $i(f, \Gamma) = 1$. The Lefschetz–Nielsen formula implies that $m \geq 2$. This argument has been used by Franks to give many generalizations of the Poincaré–Birkhoff Theorem, including results on the torus [22]. We will state below such a

result which is implicitly contained in Franks' papers and which can also be deduced directly from Theorem 3.2 (see [5]).

Under the hypothesis of the Poincaré–Birkhoff Theorem, $F$ admits periodic points of arbitrarily large period. Indeed, if $\rho_-$ and $\rho_+$ are the Poincaré rotation numbers defined respectively on $\mathbb{T}^1 \times \{0\}$ and $\mathbb{T}^1 \times \{1\}$, one has $\rho_- < 0 < \rho_+$. For every rational number $p/q \in ]\rho_-, \rho_+[$ written in an irreducible way, one may apply again the Poincaré–Birkhoff Theorem to $F^q$ and its lift $T^{-p} \circ f^q$ (where $T(x, y) = (x+1, y)$). One gets a fixed point of $T^{-p} \circ f^q$ which projects onto a periodic point of $F$ of period $q$. Moreover, the theory of homeomorphisms of the circle gives us such a periodic point if one of the numbers $\rho_-$ or $\rho_+$ is equal to $p/q$. Let us give now a more general statement. Let us denote by $\mathbb{A}$ one of the annulus $\mathbb{T}^1 \times [0, 1]$ or $\mathbb{T}^1 \times ]0, 1[$ and by $\tilde{\mathbb{A}}$ its universal lift. Write $\pi : \tilde{\mathbb{A}} \to \mathbb{A}$ for the covering projection and $T : (x, y) \mapsto (x+1, y)$ for the fundamental covering automorphism. Consider a homeomorphism $F$ of $\mathbb{A}$ isotopic to the identity and a lift $f$ to $\tilde{\mathbb{A}}$. Suppose that $z \in \mathbb{A}$ is a positively recurrent point of $F$ and that $\tilde{z} \in \tilde{\mathbb{A}}$ is a preimage of $z$. For every sequence $(F^{q_k}(z))_{k\geq 0}$ that converges to $z$, there exists a sequence $(p_k)_{k\geq 0}$ in $\mathbb{Z}$ such that $(T^{-p_k} \circ f^{q_k}(\tilde{z}))_{k\geq 0}$ converges to $\tilde{z}$. The sequence $(p_k)_{k\geq 0}$ is uniquely defined up to a finite number of terms and does not depend on $\tilde{z}$. Let us say that $z$ has a *rotation number* $\rho$ if, for every sequence $(F^{q_k}(z))_{k\geq 0}$ that converges to $z$, the sequence $(p_k/q_k)_{k\geq 0}$ converges to $\rho$. Another choice of lift $f$ changes the rotation number by adding an integer.

**Proposition 3.3.** *Let $F$ be a homeomorphism of $\mathbb{A}$ isotopic to the identity and $f$ a given lift to $\tilde{\mathbb{A}}$. We suppose that*

- *there is a positively recurrent point $z_-$ of rotation number $\rho_-$;*
- *there is a positively recurrent point $z_+$ of rotation number $\rho_+ > \rho_-$;*
- *every essential simple closed curve in $\mathbb{A}$ meets its image by $F$.*

*Then for every rational number $p/q \in ]\rho_-, \rho_+[$ written in an irreducible way, there is a periodic point $z$ of period $q$ and rotation number $p/q$.*

In the case where $F$ is area preserving, the intersection property is satisfied and Proposition 3.3 may be applied. More can be said in that case ([5], [24], [39]). First, one can prove the existence of a periodic point of period $q$ and rotation number $p/q$ if there is a positively recurrent point of rotation number $p/q$. Moreover one can prove the existence of a non-trivial interval of rational rotation numbers if there is a positively recurrent point that has no rotation number. As a consequence, the unique case where such a homeomorphism has no periodic point is the case where there exists an irrational number $\rho$ such that every positively recurrent point (thus almost every point) has a rotation number equal to $\rho$. Such a map is usually called an irrational *pseudo-rotation*.

One may notice the following recent result on irrational pseudo-rotations, previously stated by Kwapisz [38] in the context of the torus, revisited by Béguin, Crovisier,

Le Roux, Patou [4] in the case of a closed annulus and extended by Béguin, Crovisier, Le Roux [5] in the case of an open annulus:

*For any convergent $p/q$ of $\rho$, there exists a simple arc $\gamma$ joining the two ends of the annulus such that the iterates of $\gamma$, $F(\gamma), \dots, F^q(\gamma)$ are pairwise disjoint and cyclically ordered as the iterates of a vertical under a rigid rotation of angle $\rho$.*

As a consequence ([4], [5]) one has the following:

*The rigid rotation of angle $\rho$ is in the closure of the conjugacy class of the pseudo-rotation.*

Note that one does not know if an irrational pseudo-rotation of rotation number $\rho$ is in the closure of the conjugacy class of a rigid rotation of angle $\rho$.

It has been known for a long time that the dynamics of an irrational pseudo-rotation may be strongly different from the dynamics of a rigid rotation. Anosov and Katok [2] gave an example of a smooth ($C^\infty$) irrational pseudo-rotation on the closed annulus which is weakly mixing (and therefore ergodic) relatively to the Lebesgue measure. Many other pathological examples may be constructed as explained by Fayad and Katok in [17]. All these examples are constructed as a limit of diffeomorphisms which are smoothly conjugate to rigid rotations of rational angle. The rotation number is always a Liouville number. In fact, Fayad and Saprykina [18] proved that every Liouville number is the rotation number of a weakly mixing smooth pseudo-rotation on $\mathbb{T}^1 \times [0, 1]$. Such examples do not exist for Diophantine numbers. Indeed, an unpublished result of Herman states that for a smooth diffeomorphism of $\mathbb{T}^1 \times [0, 1]$, the circle $\mathbb{T}^1 \times \{1\}$ is accumulated by a set of positive measure of invariant curves of $F$ if the rotation number induced on $\mathbb{T}^1 \times \{1\}$ is Diophantine. Let us conclude this section by recalling the following old conjecture of Birkhoff, still unsolved, stating that an irrational pseudo-rotation on the closed annulus which is real analytic must be conjugate to a rigid rotation.

## 4. Foliated versions of Brouwer's Plane Translation Theorem

As noticed at the end of Section 2, if $f$ is a Brouwer homeomorphism which is the time-one map of a flow whose orbits are tangent to a continuous vector field $\xi$, then $\mathbb{R}^2$ may be foliated and not only covered by Brouwer lines. Suppose now that $G$ is a discrete group of orientation preserving diffeomorphisms acting freely and properly on $\mathbb{R}^2$ and that $\xi$ is *$G$-invariant* (that means invariant by every element of $G$). By considering the surface $M/G$ one can construct a $G$-invariant $C^1$ vector field $\eta$ satisfying $\eta(z) \wedge \xi(z) > 0$. One deduces that there exists a $G$-invariant foliation by Brouwer lines of $f$. The following result states that this is a general fact:

**Theorem 4.1** ([40], [41]). *If $f$ is a Brouwer homeomorphism, there is an oriented topological foliation $\mathcal{F}$ of $\mathbb{R}^2$ whose leaves are Brouwer lines for $f$. Moreover, if $G$ is a discrete group of orientation preserving homeomorphisms acting freely and properly on $\mathbb{R}^2$ and if $f$ commutes with every $T \in G$, then $\mathcal{F}$ may be chosen $G$-invariant.*

Let us give the idea of the proof of the first statement. Consider the maximal free brick decomposition introduced in Section 2. Using Zorn's Lemma one can extend the order $\leq$ to get a weaker one $\leq'$ which is a total order. If $C = (C_{\leftarrow}, C_{\rightarrow})$ is a cut of $\leq'$ the sets $\bigcup_{b\in C_{\leftarrow}}$ and $\bigcup_{b\in C_{\rightarrow}}$ have the same frontier and the (oriented) frontier of $\bigcup_{b\in C_{\rightarrow}}$ is a union of Brouwer lines because $f\left(\bigcup_{b\in C_{\rightarrow}}\right) \subset \operatorname{Int}\left(\bigcup_{b\in C_{\rightarrow}}\right)$. The set $\mathcal{B}$ of such lines covers the skeleton and may be written $\mathcal{B} = \bigcup_{e\in E} \mathcal{B}_e$, where $E$ denotes the set of edges and $\mathcal{B}_e$ the set of lines $\Gamma \in \mathcal{B}$ containing $e$. One can define a partial order $\preceq$ on the set of oriented lines of $\mathbb{R}^2$: $\Gamma \preceq \Gamma'$ if $R(\Gamma) \subset R(\Gamma')$. The fact that $\leq'$ is a total order implies that two lines of $\mathcal{B}$ do not intersect transversally and consequently that $\preceq$ is a total order when restricted to each $\mathcal{B}_e$. The space $\mathcal{B}$, equipped with the topology generated by the $\mathcal{B}_e$, $e \in E$, is not necessarily Hausdorff but each set $\mathcal{B}_e$ is. In fact each $\mathcal{B}_e$ is compact and the restricted topology coincides with the order topology. As an ordered topological space, $\mathcal{B}$ looks like a *lamination* of $\mathbb{R}^2$, that means a closed subset of leaves of a foliation (in fact it will be isomorphic to a lamination of the foliation that we want to construct). There is a natural (but not unique) way to foliate each brick and then to extend $\mathcal{B}$ by constructing a family of Brouwer lines that cover the plane and that do not intersect transversely. By a desingularization process around each vertex of $\Sigma$, one can blow up our extended family to get a foliation by Brouwer lines.

The proof of the second statement is much harder. First one considers a free brick decomposition invariant by every $T \in G$ and maximal for these properties. It is not necessarily maximal among all the free bricks decomposition; however there is a natural $G$-invariant order $\leq$ on $B$ such that

$$f(b) \cap b' \neq \emptyset \Rightarrow b < b'.$$

Moreover, for every brick $b$, the union of bricks $b' > b$ adjacent to $b$ is non-empty and connected, as is the union of adjacent bricks $b' < b$. As previously one can cover $\Sigma$ by a $G$-invariant family of Brouwer lines. To get our $G$-invariant foliation, one needs to cover $\Sigma$ by a $G$-invariant family of Brouwer lines that do not intersect transversally. If $G$ is abelian (that means if $G = \mathbb{Z}$ or $G = \mathbb{Z}^2$) one knows, by a simple set theory argument, that there is a $G$-invariant total order $\leq'$ weaker than $\leq$: the previous proof is still valid. If $G$ is not abelian, the existence of such an order does not seem so clear. The construction of $\mathcal{B}$ uses more subtle arguments based on the topology of the surface $\mathbb{R}^2/G$.

If $\mathcal{F}$ is an oriented topological foliation of $\mathbb{R}^2$ whose leaves are Brouwer lines of $f$, it is easy to prove that for every point $z$ there is an arc $\gamma\colon [0, 1] \to \mathbb{R}^2$ joining $z$ to $f(z)$ that is *positively transverse* to $\mathcal{F}$. That means that $\gamma$ intersects transversely each leaf that it meets, and locally from the right to the left. One deduces immediately (by lifting the isotopy $(F_t)_{t\in[0,1]}$ to an isotopy $(f_t)_{t\in[0,1]}$ from the identity and applying Theorem 4.1 to $f = f_1$):

**Corollary 4.2.** *Let $(F_t)_{t\in[0,1]}$ be an isotopy from the identity to $F$ on an oriented surface $M$. Suppose that $F$ has no contractible fixed point. Then there exists a*

*topological foliation $\mathcal{F}$ on $M$ that is dynamically transverse to the isotopy: the trajectory $\gamma_z : t \mapsto F_t(z)$ of every point is homotopic, relatively to the extremities, to an arc that is positively transverse to $\mathcal{F}$.*

This result belongs to the category of statements that are obviously true when $F$ is the time-one map of a flow and that can be extended to the case where $F$ is the time-one map of an isotopy from the identity. Let us give now a result that does not. One could ask similarly if there exists a foliation by invariant lines for a Brouwer homeomorphism, as it is true in the case of the time-one map of a flow. The answer is no, there exist Brouwer homeomorphisms without any invariant line (Brown, Slaminka, Transue [13]). Observe that in the case of a flow the foliation by invariant lines was explicitely and uniquely defined. In contrast to this, there are many choices of foliations by Brouwer lines and none of them is canonical.

The only closed surface $M$ where Corollary 4.2 can be applied is the torus $M = \mathbb{T}^2$. Indeed, the Lefschetz–Nielsen formula implies the existence of a contractible fixed point for any homeomorphism isotopic to the identity on an oriented closed surface of genus $\neq 1$. In the case of a torus, a stronger hypothesis on the isotopy will imply additional properties of the foliation. Write $f$ for the natural lift of $F$ to $\mathbb{R}^2$ defined by the isotopy and recall the definition of the *rotation set* $R(f)$ whose origin goes back to Schwartzman [55]. The map $f - \mathrm{Id}_{\mathbb{R}^2}$ is invariant by the integer translations and lifts a continuous function $\psi : \mathbb{T}^2 \to \mathbb{R}^2$. For every Borel probability measure which is invariant by $F$, one may define the *rotation vector* $\rho(\mu) = \int_{\mathbb{T}^2} \psi \, d\mu \in \mathbb{R}^2 \approx H_1(\mathbb{T}^2, \mathbb{R})$ and the set $R(f)$ of rotation vectors of all invariant probability measures. The set $R(f)$ is a non-empty convex compact subset of $H_1(\mathbb{T}^2, \mathbb{R})$. If one supposes that $0 \notin R(f)$ (which of course implies that $f$ is fixed point free) one can find cohomology classes $\kappa \in H^1(\mathbb{T}^2, \mathbb{R})$ that are positive on $R(f)$. One has the following:

**Theorem 4.3** ([43]). *Let $F$ be a homeomorphism of $\mathbb{T}^2$ isotopic to the identity and let $f$ be a lift of $F$ to $\mathbb{R}^2$. Suppose that $\kappa \in H^1(\mathbb{T}^2, \mathbb{R})$ is positive on the rotation set $R(f)$. Then there is a non-vanishing smooth closed 1-form $\omega$ whose cohomology class is $\kappa$, and such that $H(f(z)) - H(z) > 0$ if $H$ is a primitive of the lifted form on $\mathbb{R}^2$.*

The level curves of $H$ define a foliation of $\mathbb{R}^2$ by Brouwer lines of $f$. It projects onto a foliation diffeomorphic to a linear one, the leaves are closed if $\kappa$ is a rational class, they are dense if not. One may ask if a similar statement occurs in higher dimension. Let $(F_t)_{t\in[0,1]}$ be an isotopy from the identity on a compact manifold $M$ and write $\gamma_z : t \to F_t(z)$ for the trajectory of any point $z$. Let $\mu$ be a Borel probability measure invariant by $F$. If $\omega$ is a smooth closed 1-form, the integral $\int_M \left( \int_{\gamma_z} \omega \right) d\mu(z)$ is well defined and vanishes when $\omega$ is exact. As it depends linearly on the cohomology class $[\omega]$ of $\omega$, one may find $\rho(\mu) \in H_1(M, \mathbb{R})$ such that

$$\int_M \left( \int_{\gamma_z} \omega \right) d\mu(z) = \langle [\omega], \rho(\mu) \rangle.$$

The rotation set of the isotopy is the set of rotation vectors $\rho(\mu)$ of invariant probability measures. Here again it is a non-empty convex compact subset of $H_1(M, \mathbb{R})$. Suppose now that $\kappa \in H^1(M, \mathbb{R})$ is positive on the rotation set of the isotopy:

*Does there exist a non-vanishing smooth* 1*-form* $\omega$ *such that* $[\omega] = \kappa$ *and* $\int_{\gamma_z} \omega > 0$ *for every* $z \in M$?

The answer is yes if $F$ is the time-one map of a flow $(F_t)_{t\in\mathbb{R}}$ induced by a smooth vector field $\xi$ (see Fried [30] or Schwartzman [55]). More precisely, $\omega$ may be chosen such that $\langle \omega(z), \xi(z)\rangle > 0$ for every $z \in M$. Fried's proof may be adapted in the discrete case to find a smooth closed 1-form $\omega$ such that $[\omega] = \kappa$ and $\int_{\gamma_z} \omega > 0$ for every $z \in M$. The problem is that $\omega$ can vanish. In the case of a time-one map of a flow, if the rotation set does not contain zero, $\kappa$ may be chosen in $H^1(M, \mathbb{Z})$ and $\omega$ will be written $\omega = dH$ where $H : M \to \mathbb{T}^1$ is a submersion. Consequently $M$ fibers over $\mathbb{T}^1$. Therefore one may naturally ask:

*Suppose that on a given compact manifold* $M$ *one may find an isotopy from the identity whose rotation set does not contain* 0*, does the manifold necessarily fiber over* $\mathbb{T}^1$?

Theorem 4.3 gives us an example where a dynamical assumption on an isotopy implies dynamical properties of some foliation dynamically transverse to the isotopy. In many situations such an assumption will imply dynamical properties of every foliation dynamically transverse. This is the fundamental fact that will permit us to apply Theorem 4.1 and its corollary to the study of homeomorphisms of surfaces. We will conclude this section by an example: a short proof of Proposition 3.3. We will give first two useful statements which illustrate how conservative assumptions satisfied by a homeomorphism can be transposed to dissipative properties of a dynamically transverse foliation. Suppose that $(F_t)_{t\in[0,1]}$ is an isotopy from the identity to $F$ without contractible fixed point on a surface $M$ and that $\mathcal{F}$ is a foliation dynamically transverse. This implies that for every point $z' \in M$ and for every $k \geq 1$ one may find an arc joining $z'$ to $F^k(z')$ that is positively transverse to $\mathcal{F}$. It is easy to prove that this arc may be perturbed into a loop positively transverse to $\mathcal{F}$ if the extremities $z'$ and $F^k(z')$ are sufficiently close to a previously given point $z$. Hence the following holds:

*For every non-wandering point* $z$*, there is a loop based on* $z$ *that is positively transverse to* $\mathcal{F}$.

Fix now a point $z$ and define the set $W$ of points $z' \in M$ which can be joined by an arc from $z$ that is positively transverse to $\mathcal{F}$. It may be noticed that $F(\overline{W}) \subset \mathrm{Int}(W)$. Hence the next assertion is true:

*If every point is non-wandering, then for every points* $z$ *and* $z'$*, there is an arc joining* $z$ *to* $z'$ *that is positively transverse to* $\mathcal{F}$.

Let us now prove Proposition 3.3. Suppose for example that $\rho_- < 0 < \rho_+$ and that $\mathbb{A}$ is open. We want to prove that the intersection property is not satisfied if $f$ has no fixed point. In this case we can construct an oriented foliation $\mathcal{F}$ on $\mathbb{A}$ which is lifted to $\tilde{\mathbb{A}}$ into a foliation by Brouwer lines of $f$. The points $z_-$and $z_+$ being recurrent, there are loops $\Gamma_-$ and $\Gamma_+$ based respectively on $z_-$ and $z_+$ that are

positively transverse to $\mathcal{F}$. Write $[\Gamma] \in H_1(\mathbb{A}, \mathbb{Z})$ for the homology class of any loop $\Gamma$ and consider the generator $[\Gamma_0]$ of the loop $\Gamma_0 : t \mapsto (t + \mathbb{Z}, 1/2)$ defined on $[0, 1]$. The fact that $\rho_- < 0$ implies that $\Gamma_-$ may be chosen such that $[\Gamma_-] = n_-[\Gamma_0]$ where $n_- < 0$. Similarly one may suppose that $[\Gamma_+] = n_+[\Gamma_0]$ where $n_+ > 0$. Using the fact that $\mathcal{F}$ is a non-singular foliation, it is straightforward to prove the following:

- the loops $\Gamma_-$ and $\Gamma_+$ are disjoint;
- there is a unique relatively compact annular component $U$ of $\mathbb{A} \setminus (\Gamma_- \cup \Gamma_+)$;
- the frontier of $U$ is the union of two simple essential loops positively transverse to $\mathcal{F}$;
- the leaves on $\partial U$ are all leaving $U$ or all entering in $U$.

The Poincaré–Bendixson Theorem implies the existence of a closed leaf inside $U$. This leaf does not meet its image by $F$ because it is lifted into a Brouwer line of $f$.

## 5. Hamiltonian homeomorphisms of surfaces

Let us say that a homeomorphism $F$ on an oriented closed surface, time-one map of an isotopy from the identity $(F_t)_{t\in[0,1]}$, is *Hamiltonian* if it preserves a probability measure $\mu$ whose support is $M$ and whose rotation vector is 0. The classical example is obtained when $M$ is endowed with a symplectic structure $\omega$ and when the isotopy is defined by a time dependent Hamiltonian vector field. The measure is nothing but the normalized measure induced by the volume form $\omega$. Let us give another example. Consider an irrational pseudo-rotation $F$ on $\mathbb{T}^1 \times ]0, 1[$ and extend $F$ to the end compactification of the annulus. One gets a Hamiltonian homeomorphism on the sphere that has no periodic points but the two fixed ends. As we will see in this section, extended irrational pseudo-rotations are the only examples, up to conjugacy, of Hamiltonian homeomorphisms having finitely many periodic points.

It was shown by Franks [25] that a Hamiltonian homeomorphism on $S^2$ which has at least three fixed points admits infinitely many periodic points. More recently Franks and Handel [26] proved that a non-trivial Hamiltonian diffeomorphism of a surface of positive genus admits periodic points of arbitrarily large periods (and that this is also the case on a sphere if $F$ has at least three fixed points). Their arguments are mainly of topological nature. The differentiability condition prevents the dynamics to be too wild in a neighborhood of a non-isolated fixed point. For each connected component $U$ of the complement of the fixed point set, they construct a normal form of the restriction map $F|_U$ in the sense of Thurston–Nielsen's theory of homeomorphisms of surfaces like it is usually done for a surface of finite type. There are three cases to look at and in each case periodic orbits may be found for different reasons, the case where there exists at least one pseudo-Anosov component, the case where there is a twist condition in a reducing annulus, the case where the map is

isotopic to the identity. The last case is the most difficult one and subtle geometric arguments that already appeared in [35] are needed.

We will state now a more general result, which gives a positive answer to Conley's conjecture in the case of surfaces:

**Theorem 5.1** ([41], [42]). *Suppose that $F$ is a Hamiltonian time-one map of an isotopy from the identity $(F_t)_{t\in[0,1]}$ on a compact oriented surface $M$ of genus $g \geq 1$.*

i) *If $F \neq \mathrm{Id}_M$, there are periodic points of arbitrarily large period.*

ii) *If the set of contractible fixed points is contained in a disk of $M$, there are contractible periodic points of arbitrarily large period.*

*Moreover we have a similar result in the case where $M$ is a sphere if we suppose that $F$ has at least three fixed points.*

Let us explain first what happens when $F$ is the time-one map of a time independent Hamiltonian flow associated to a function $H : M \to \mathbb{R}$ on a surface of genus $\geq 1$. Let us suppose that there are finitely many critical points of $H$ (there are at least three). The minimum of $H$ corresponds to a contractible fixed point $z_0$. This point is surrounded by invariant curves which are level curves of $H$. The map $F$ is conjugate to a rotation on each curve. Thus one gets a foliated open annulus with one end corresponding to $z_0$ and one "critical" end which does not correspond to a point (because $M$ is not a sphere) but to a degenerate curve containing a critical point of $H$. The rotation number of $F$ on each curve (which is a well defined real number) depends continuously of the curve, never vanishes and tends to zero when the curve tends to the critical level. This implies that the rotation numbers take their values onto a non-trivial interval. One concludes that there are contractible periodic points of arbitrarily large period.

In the case where $F$ is the time-one map of a time dependent Hamiltonian flow, Floer [19] and Sikorav [56] proved that $F$ has at least three contractible fixed points, giving a positive answer to Arnold's conjecture for surfaces. In symplectic geometry contractible fixed points of Hamiltonian isotopies are usually found by studying the dynamics of the gradient flow of a function $\mathcal{H}$ defined on an infinite dimensional space (space of loops) or on a high dimensional space (if one uses generating functions) whose critical points are in bijection with contractible fixed points. Franks [24] gave a purely topological proof of the existence of three contractible fixed points for a Hamiltonian diffeomorphism making use of Handel's Fixed Point Theorem, the proof of which was extended by Matsumoto [50] to the case of Hamiltonian homeomorphisms. The fundamental idea in the proof of Theorem 5.1 is to make a link between the symplectic and the topological methods by producing a "singular" dynamically transverse foliation and by proving that its dynamics is "gradient-like". This will permit us first to find again Matsumoto's result, then to produce a topological "twist property". Such a property is easy to prove if $F$ is a diffeomorphism with no degenerate fixed points. We will give here some ideas of the proof of assertion ii) of Theorem 5.1. We will begin by the simplest case where the set $\mathrm{Fix}(F)_{\mathrm{cont}}$ of contractible fixed point is finite.

*Case where $M = S^2$ and $\sharp\mathrm{Fix}(F)_{\mathrm{cont}} < +\infty$.* Here $\mathrm{Fix}(F)_{\mathrm{cont}}$ coincides with the set $\mathrm{Fix}(F)$ of fixed points. We suppose that $F$ preserves a probability measure $\mu$ with total support and that $3 \leq \sharp\mathrm{Fix}(F) < +\infty$. We want to prove that $F$ has periodic points of arbitrarily large period. Let us say that $Z \subset \mathrm{Fix}(F)$ is *unlinked* if $F$ is isotopic to the identity relatively to $Z$. This is always the case if $\sharp Z \leq 3$. As $\mathrm{Fix}(F)$ is supposed to be finite, one can find a *maximal* (for the inclusion) unlinked set $Z$ and one knows that $\sharp Z \geq 3$. Fix an isotopy $(F_t)_{t\in[0,1]}$ such that $F_t(z) = z$ for every $z \in Z$ and every $t \in [0, 1]$, and look at the restricted isotopy to $N = S^2 \setminus Z$. It is standard to prove that $(F_t|_N)_{t\in[0,1]}$ has no contractible point, by maximality of $Z$. By Corollary 4.2, one may construct a foliation $\mathcal{F}$ on $N$ which is dynamically transverse to the isotopy. As we suppose that $F$ preserves $\mu$ we know that every point is non-wandering, which implies that every point belongs to a loop that is positively transverse to $\mathcal{F}$. This clearly implies that $\mathcal{F}$ has no closed leaf and more generally has only wandering leaves. In fact the dynamics of $\mathcal{F}$ is easy to understand:

- *any leaf $\lambda$ joins a point $\alpha(\lambda) \in Z$ to a different point $\omega(\lambda) \in Z$;*
- *there is no sequence of leaves $(\lambda_i)_{i\in\mathbb{Z}/p\mathbb{Z}}$ such that $\omega(\lambda_i) = \alpha(\lambda_{i+1})$ for any $i \in \mathbb{Z}/p\mathbb{Z}$.*

Fix a leaf $\lambda$ and consider the annulus $A = S^2 \setminus (\alpha(\lambda) \cup \omega(\lambda))$. The isotopy $(F_t|_A)_{t\in[0,1]}$ may be lifted to the universal covering space $\tilde{A}$ of $A$ into an isotopy $(f_t)_{t\in[0,1]}$ from the identity. We will apply Proposition 3.3 by finding two positively recurrent points with different rotation numbers. The map $f = f_1$ clearly fixes every point of the preimage of $Z \setminus (\alpha(\lambda) \cup \omega(\lambda))$, which implies that the rotation vector of any point of $Z \setminus (\alpha(\lambda) \cup \omega(\lambda))$ is 0. The foliation $\mathcal{F}$ is lifted to a foliation on the preimage $\widetilde{N}$ of $N$ which is dynamically transverse to the isotopy $(f_t|_{\widetilde{N}})_{t\in[0,1]}$. Any lift of $\lambda$ is a Brouwer line of $f$ because $\lambda$ joins the two ends of the annulus. It is not difficult, using classical arguments of Ergodic Theory (and in particular the Birkhoff Ergodic Theorem), to prove that $F$ has positively recurrent points whose rotation number is $\neq 0$ (this is the case for almost every point that has a preimage between a given lift $\tilde{\lambda}$ and its image by $f$).

*Case where $g \geq 1$ and $\sharp\mathrm{Fix}(F)_{\mathrm{cont}} < +\infty$.* Here again suppose that the set $\mathrm{Fix}_{\mathrm{cont}}(F)$ of contractible fixed points is finite and say that $Z \subset \mathrm{Fix}_{\mathrm{cont}}(F)$ is unlinked if there is an isotopy $(F_t)_{t\in[0,1]}$ (homotopic to the one given by hypothesis) such that $F_t(z) = z$ for every $z \in Z$ and every $t \in [0, 1]$. Fix a maximal unlinked set $Z$. Again, there exists a foliation $\mathcal{F}$ on $N = M \setminus Z$ which is dynamically transverse to the isotopy $(F_t|_N)_{t\in[0,1]}$, and we would like to understand the dynamics of $\mathcal{F}$. As we suppose that $F$ preserves $\mu$ we already know that every point belongs to a loop positively transverse to $\mathcal{F}$. The fact that the rotation of $\mu$ is zero implies a stronger result:

*For every $\upsilon \in H_1(M, \mathbb{Z})$ and every $z \in M$ there is a loop $\Gamma \subset N$ positively transverse to $\mathcal{F}$ and based in $z$ such that $[\Gamma] = \upsilon$.*

One must prove that the set $C(z) \subset H_1(M, \mathbb{Z})$ of homology classes of loops in $N$ based in $z$ and positively transverse to $\mathcal{F}$, which is stable by addition, is the whole

group $H_1(M,\mathbb{Z})$. The nullity of the rotation vector of $\mu$ implies that every class $\kappa \in H^1(M,\mathbb{R})$ takes different signs on $C(z)$ and therefore that the convex hull in $H_1(M,\mathbb{R})$ of $C(z)$ contains a neighborhood of 0. It becomes easy to prove that $C(z)$ is a subgroup and therefore a lattice of $H_1(M,\mathbb{Z})$. If one now applies the transverse transitivity condition stated in the previous section to a natural finite covering of $M$, one obtains that $C(z) = H_1(M,\mathbb{Z})$.

It is easy to deduce that there is no closed leaf and more precisely that every leaf is wandering. In fact one can prove that the dynamics of $\mathcal{F}$ is gradient-like. Note first that any loop $\Gamma \subset N$ homologous to zero induces naturally by duality a function $\Lambda_\Gamma : M\setminus\Gamma \to \mathbb{Z}$ defined up to a constant, where $\Lambda_\Gamma(z') - \Lambda_\Gamma(z)$ denotes the algebraic intersection number $\Gamma \wedge \Gamma'$ between $\Gamma$ and any arc $\Gamma'$ joining $z$ to $z'$. Observe now that $\Lambda_\Gamma$ decreases along the oriented leaves if $\Gamma$ is positively transverse to $\mathcal{F}$. In other words, the sub-level surfaces of $\Lambda_\Gamma$ define a filtration of $\mathcal{F}$. The property stated above permits us to construct a loop $\Gamma$ homologous to zero and positively transverse to $\mathcal{F}$ which sufficiently "fills" the surface in the following sense:

- *every connected component $U$ of $M \setminus \Gamma$ is the interior of a closed disk of $M$ and contains at most one point of $Z$;*
- *if there exists a leaf of $\mathcal{F}$ which joins $z \in Z$ to $z' \in Z$, then $\Lambda_\Gamma(z') < \Lambda_\Gamma(z)$.*

Using the Poincaré–Bendixson Theorem, one may deduce first that every leaf meets $\Gamma$ and then that it joins a point $z \in Z$ to a point $z' \in Z$. In fact, the dynamics of $F$ is trivial inside a component $U$ with no singularity and well understood inside a component that contains a singularity. Such a singularity is necessarily a sink, a source or a generalized saddle point (with $p \geq 1$ attracting sectors alternating with $p \geq 1$ repelling sectors).

An easy consequence of the previous results is the fact that $\sharp Z \geq 3$. Existence of contractible periodic points of arbitrarily large period is much more difficult to get. One wants to generalize the case where $F$ is the time-one map of a Hamiltonian flow associated to a function $H : M \to \mathbb{R}$. If $M$ is equipped with a Riemannian metric, the foliation by orbits of the gradient flow of $H$ on the complement of the set $Z$ of critical points is dynamically transverse to the isotopy and the point $z_0$ where $H$ reaches its minimum is a sink of the foliation. In our more general situation, one will choose a sink of $\mathcal{F}$ and then will prove that there exists periodic points inside the basin of attraction $W$ (for the foliation). The set $W$ has no reason to be invariant by $F$. However the two following facts

- there exists at least one contractible fixed point in the frontier of $W$,
- there is a radial foliation on $W$ which is pushed along the isotopy,

give us a weak twist condition. Some plane topology arguments and the use of the discrete Conley index permit us to find periodic points inside $W$.

*Case where* $\sharp\mathrm{Fix}(F)_{\mathrm{cont}} = +\infty$. The case where the set of contractible fixed points is infinite is much harder to deal with because it does not seem so easy to find maximal

unlinked sets, which are necessary to construct a dynamically transverse foliation. Under the hypothesis ii) of Theorem 5.1, there is a unique component $N$ of $M \setminus \mathrm{Fix}_{\mathrm{cont}}(F)$ such that the inclusion $i\colon N \to M$ induces an isomorphism between the first groups of homology and this component is fixed. If there is a lift $f$ of $F|_N$ to the universal covering space of $N$ which commutes with every covering transformation, then by Corollary 4.2 a dynamically transverse foliation $\mathcal{F}$ may be constructed. Of course there is no decomposition of the dynamics of $\mathcal{F}$ in elementary pieces as in the finite case. However, the previous arguments may be generalized, even if they are not so easy to get. In the case where such a lift does not exist, we will get contractible periodic orbits of arbitrarily large periods for different reasons, that will be explained in the next section.

There are natural reasons to study carefully homeomorphisms of surfaces of infinite type. Consider a volume form on $S^2$ and write $\mathrm{Diff}^k_\omega(S^2)$ for the set of $C^k$ diffeomorphisms that preserve $\omega$. Consider $F \in \mathrm{Diff}^k_\omega(S^2)$ and fix a connected component $U$ of $S \setminus \overline{\mathrm{Per}(F)}$. There is an integer $q$ such that $F^q(U) = U$. By Theorem 2.1, one knows that there would be a fixed point of $F^q$ in $U$ if $U$ were a disk, which is not the case. By Franks result stated above [25] it cannot be a hyperbolic surface of finite type. Therefore it is an annulus (and in that case the restricted map is an irrational pseudo-rotation) or a surface of infinite type. One may ask the following:

*Can $U$ be a surface of infinite type or should it be necessarily an annulus?*

The interest in this question comes from the following: it is not difficult to prove that there is a residual set $\mathcal{G} \subset \mathrm{Diff}^k_\omega(S^2)$ (for the $C^k$-topology) such that for every $F \in \mathcal{G}$ there are no annulus among the connected components of $S^2 \setminus \overline{\mathrm{Per}(F)}$ (see [29]). A positive answer to the previous question would imply that the periodic orbits are generically dense. What is known is that the union of the stable manifolds of the hyperbolic periodic points is dense [29], a result extended by Xia [57] to any compact surface.

## 6. On the group of diffeomorphisms of surfaces

Consider a compact Riemannian manifold $M$. If $F$ is a $C^1$ diffeomorphism one can define its *growth sequence* $(\Gamma_n(F))_{n\geq 0}$ where

$$\Gamma_n(F) = \max\Big(\max_{z\in M} \|T_z F^n\|,\ \max_{z\in M} \|T_z F^{-n}\|\Big).$$

The growth sequence of a non-trivial diffeomorphism may be bounded. This is the case for a periodic map, a translation on a torus or a rigid rotation on $S^2$. Even when it is not bounded it may tend to $+\infty$ not very quickly (see Polterovitch, Sodin [52]). The situation is different in the case of area preserving diffeomorphisms of surfaces. More precisely:

**Theorem 6.1.** *If $F$ is a non-trivial Hamiltonian diffeomorphism of a closed oriented surface of genus $\geq 1$, there exists $C > 0$ such that $\Gamma_n(F) \geq Cn$ for every $n \geq 0$.*

Proved by Sikorav and Polterovitch in the special case of the torus, the result was generalized to other surfaces by Polterovich [51] applying a result of Schwarz related to Floer homology. Note that in the case of a surface of genus $\geq 2$, the result is still true for any area preserving diffeomorphism isotopic to the identity. Indeed, by the Lefschetz–Nielsen formula, such a map has at least one contractible fixed point. Therefore the diffeomorphism admits two probability measures with different rotation vectors if it is not Hamiltonian. It is not difficult to see that such a property implies that the conclusion of Theorem 6.1 is necessarily true.

Applications of the previous result to actions of higher rank lattices in simple Lie groups on compact manifolds were given in [51], yielding a positive answer, in the special case of surfaces, to a more general conjecture of Zimmer:

**Theorem 6.2.** *Fix a volume form $\omega$ on a closed oriented surface $M$ of genus $g \geq 2$. Then any morphism $\psi$ of $\mathrm{SL}(n, \mathbb{Z})$ in the group $\mathrm{Diff}^{\infty}_{\omega}(M)$ of diffeomorphisms which preserves $\omega$ has a finite image if $n \geq 3$.*

Franks and Handel in [27] gave an alternative proof which works in the $C^1$ case and includes the case $g \leq 1$. The smoothness of $F$ is used in a much weaker way, mainly to construct a Thurston–Nielsen normal form on the complement of the fixed point set. The two important properties satisfied by the group $\mathrm{SL}(n, \mathbb{Z})$, $n \geq 3$, and by any normal subgroup of finite order are the following (the first one is due to Margulis):

- it is almost simple (every normal subgroup is finite or has a finite index);
- it contains a subgroup isomorphic to the group of upper triangular integer valued matrices of order 3 with 1 on the diagonal (the integer Heisenberg group).

More precisely, using algebraic properties of the mapping class group, it is sufficient to study the case where $\psi$ takes its values in the subgroup $\mathrm{Diff}^{1}_{\omega,*}(M)$ of diffeomorphisms of $\mathrm{Diff}^{1}_{\omega}(M)$ which are isotopic to the identity. Using the second property, there exist three elements $F$, $G$, $H$ in $\mathrm{Im}(\psi)$ such that $[G, H] = F$, $[F, G] = [F, H] = \mathrm{Id}_M$ and such that $F$ is the image of an element of infinite order. To get the theorem it is sufficient to prove that $F = \mathrm{Id}_M$, because this would imply that $\mathrm{Ker}(\psi)$, being an infinite normal subgroup, has a finite index. Note that $F$ is Hamiltonian because it is a commutator and that $F^{n^2} = [G^n, H^n]$. The fact that $F = \mathrm{Id}_M$ will follow from the next result (and the fact that $F$ has periodic orbits if it is not trivial):

**Theorem 6.3** ([28]). *Suppose that $F$ is a diffeomorphism of a closed surface $M$ of genus $g$ which satisfies the following distorsion property: it belongs to a finitely generated subgroup of diffeomorphisms isotopic to the identity and there are two sequences $n_k$ and $p_k$ with $p_k = o(n_k)$ and $n_k \to +\infty$ such that $F^{n_k}$ can be written as the product of $p_k$ elements chosen in the (finite) set of generators. Then $F$ is isotopic to the identity relatively to the fixed point set and has no periodic points except the fixed points if $g \geq 2$, if $g = 1$ and $\mathrm{Fix}\, F \neq \emptyset$, or if $g = 0$ and $\sharp\, \mathrm{Fix}\, F \geq 3$.*

The proof uses the Thurston–Nielsen normal form on the complement of the fixed point set explained in Section 5. The distorsion property implies that $F$ is isotopic to the identity relatively to the fixed point set. Every iterate $F^k$ will also satisfy the distorsion property and should be isotopic to the identity relatively to its fixed point set. But this situation cannot occur in case $\mathrm{Fix}(F^k) \neq \mathrm{Fix}(F)$ if $g \geq 2$, if $g = 1$ and $\mathrm{Fix}\, F \neq \emptyset$, or if $g = 0$ and $\sharp\, \mathrm{Fix}\, F \geq 3$.

Let us conclude this article by explaining how to get another interpretation of Theorem 6.1 and Theorem 6.3 with the use of the foliated version of Brouwer's Plane Translation Theorem. We will look at the case of a surface of genus $g \geq 1$ by using the notion of *linking number*. The case of the sphere may be studied in a similar way by using an appropriate notion of linking number.

Suppose that $F$ is the time-one map of an isotopy from the identity $(F_t)_{t\in[0,1]}$ on a closed surface $M$ of genus $g \geq 1$ and lift the isotopy to an isotopy from the identity $(f_t)_{t\in[0,1]}$ on the universal covering space $\widetilde{M}$. One may identify the universal lift $\widetilde{M}$ of $M$ with the complex plane if $g = 1$ or with the Poincaré disk if $g \geq 2$. If $z$ and $z'$ are two fixed points of $f$, the degree of the map $\xi : S^1 \to S^1$ defined by

$$\xi(e^{2i\pi t}) = \frac{f_t(z) - f_t(z')}{|f_t(z) - f_t(z')|}$$

is called the linking number $I(z, z')$ of $z$ and $z'$. One course $I(z, z') = 0$ if $z'$ is the image of $z$ by a covering automorphism. There exits a "natural lift" of $f|_{\widetilde{M}\setminus\{z\}}$ to the universal covering space of the annulus $\widetilde{M} \setminus \{z\}$ which fixes the preimages of every image of $z$ by a covering automorphism of $\widetilde{M}$. The linking number $I(z, z')$ is nothing but the rotation number (up to the sign) of the fixed point $z'$ of $f|_{\widetilde{M}\setminus\{z\}}$ for this natural lift. Note that for every integer $n \geq 1$, the linking number of $z$ and $z'$ for $f^n$ is equal to $nI(z, z')$. In the case where $I(z, z') \neq 0$ it is not difficult to deduce that there exists $C > 0$ such that $\Gamma_n(F) \geq Cn$ for every $n \geq 0$ and also that $F$ does not satisfy the distorsion property in the group of diffeomorphisms isotopic to the identity. Observe that if $F$ preserves a probability measure with total support, then $f|_{\widetilde{M}\setminus\{z\}}$ satisfies the intersection property. Therefore, in this case, if $f$ has two fixed points $z$ and $z'$ such that $I(z, z') \neq 0$, it has periodic points with arbitrarily large period which project onto contractible periodic points of $F$. The next statement permits us to understand why, in the proof of Theorem 5.1, it is sufficient to study the case where the map $F_{|N}$ has a lift to the universal covering space that commutes with the covering transformations.

**Proposition 6.4** ([42]). *Let $(F_t)_{t\in[0,1]}$ be an isotopy from the identity to $F$ on a closed surface $M$ of genus $g \geq 1$ and $(f_t)_{t\in[0,1]}$ the lifted isotopy to the universal covering space $\widetilde{M}$ starting from the identity. Suppose that there is a connected component $N$ of $M \setminus \mathrm{Fix}_{\mathrm{cont}}(F)$ such that the inclusion $i : N \to M$ induces an isomorphism between the first groups of homology and that there is no lift of $F|_N$ to the universal covering space of $N$ that commutes with the covering automorphisms. Then there are two fixed points $z$ and $z'$ of $f = f_1$ such that $I(z, z') \neq 0$.*

Let us give the ideas of the proof. By an approximation argument it is sufficient to study the case where $\mathrm{Fix}_{\mathrm{cont}}(F)$ is finite. One considers a maximal unlinked set $Z \subset \mathrm{Fix}_{\mathrm{cont}}(F)$. By hypothesis one knows that $Z \neq \mathrm{Fix}_{\mathrm{cont}}(F)$. One may suppose that our isotopy $(F_t)_{t\in[0,1]}$ fixes every point of $Z$. We consider a foliation $\mathcal{F}$ on $N' = M \setminus Z$ dynamically transverse to $(F_t|_{N'})_{t\in[0,1]}$ and lift it to a foliation $\widetilde{\mathcal{F}}$ onto the preimage $\widetilde{N}'$ of $N'$ in $\widetilde{M}$. Fix a point $z' \in \mathrm{Fix}(f) \cap \widetilde{N}'$. There is a loop $\Gamma_0 \subset \widetilde{N}'$ based in $z'$ that is positively transverse to $\widetilde{\mathcal{F}}$ and homotopic in $\widetilde{N}'$ to the trajectory $\Gamma_1$ of $z'$. The dual function $\Lambda_{\Gamma_0} : \widetilde{M} \setminus \Gamma_0 \to \mathbb{Z}$ assigning to $z$ the index of $\Gamma_0$ relatively to $z$ is zero outside a compact set and takes finitely many values. One may suppose for example that the maximum $l^+$ of $\Lambda_{\Gamma_0}$ is different from zero. The loop $\Gamma_0$ being positively transverse to the foliation, it is easy to prove that every component of $\widetilde{M} \setminus \Gamma_0$ where $\Lambda_{\Gamma_0}$ takes the value $l^+$ is the interior of a closed disk whose boundary is a simple loop transverse to the foliation. Therefore, there exists a singularity $z$ inside this component. The loop $\Gamma_1$ being homotopic to $\Gamma_0$ in $\widetilde{N}$, the index of $\Gamma_1$ relatively to $z$ is equal to $l^+$. This number is nothing but the linking number $I(z, z')$.

The linking number $I(z, z')$ between a fixed point $z$ and a periodic point $z'$ of $f$ may be defined similarly. The previous proof may be adapted to get:

**Proposition 6.5** ([42]). *Let $(F_t)_{t\in[0,1]}$ be an isotopy from the identity to $F$ on a closed surface $M$ of genus $g \geq 1$ and $(f_t)_{t\in[0,1]}$ the lifted isotopy to the universal covering space $\widetilde{M}$ starting from the identity. For every periodic point $z'$ of $f = f_1$ that is not fixed, there is a fixed point $z$ of $f$ such that $I(z, z') \neq 0$.*

Let us explain how to deduce Theorem 6.1 from Proposition 6.5. Suppose that $F$ is a non-trivial Hamiltonian diffeomorphism of a closed surface $M$ of genus $g \geq 1$. One can choose a periodic point $z'$ of period $\geq 2$. If $z'$ is contractible, then one gets the conclusion of Theorem 6.1 by applying Proposition 6.5. If the rotation vector of $z'$ is non-zero, the conclusion follows easily. It will follow also in the missing case where $z'$ is not contractible but has a rotation vector equal to zero. This is possible only if $g \geq 2$. Identify $\widetilde{M}$ with the Poincaré disk. If $\tilde{z}'$ is a preimage of $z'$ in $\widetilde{M}$, it is not difficult to prove that there exits $C > 0$ such that for every $n \geq 0$ the hyperbolic distance between $z'$ and $f^n(z')$ is minimized by $Cn$, which implies the validity of the conclusion of Theorem 6.1.

The previous arguments imply that a diffeomorphism which satisfies the assumptions of Theorem 6.3 has no periodic points of period $\geq 2$ if $g \geq 2$ or if $g = 1$ and $F$ has a contractible fixed point, and that every fixed point is contractible. One may adapt the arguments of Proposition 6.4 to prove that for every connected component $U$ of $M \setminus \mathrm{Fix}_{\mathrm{cont}}(F)$, the map $F|_U$ has necessarily a lift to the universal covering space which commutes with the covering automorphisms.

The analogs of Theorem 6.2 and Theorem 6.3 for homeomorphisms are unknown. They should be deduced from the (positive) answer to the following open question:

*Suppose that $f$ is the lift to the universal covering space of a homeomorphism $F$ isotopic to the identity defined by an isotopy $(F_t)_{t\in[0,1]}$ and that $f$ has two fixed*

*point $z$ and $z'$ such that $I(z,z') \neq 0$. Does this imply that $F$ does not satisfy the distorsion property in the group of homeomorphisms isotopic to the identity*?

# All, most, some differentiable dynamical systems

Michael Shub*

**Abstract.** In the first part of this paper we study dynamical systems from the point of view of algebraic topology. What features of all dynamical systems are reflected by their actions on the homology of the phase space? In the second part we study recent progress on the conjecture that most partially hyperbolic dynamical systems which preserve a smooth invariant measure are ergodic, and we survey the known examples. Then we speculate on ways these results may be extended to the statistical study of more general dynamical systems. Finally, in the third part, we study two special classes of dynamical systems, the structurally stable and the affine. In the first case we study the relation of structural stability to entropy, and in the second we study stable ergodicity in the homogeneous space context.

**Mathematics Subject Classification (2000).** Primary 37; Secondary 37C, 37D.

**Keywords.** Dynamical system, entropy, Entropy Conjecture, partial hyperbolicity, accessibility, ergodicity, Lyapunov exponent, SRB measure, structural stability, affine diffeomorphism.

## 1. Introduction

We study discrete differentiable dynamical systems $f: M \to M$ on a smooth closed manifold of dimension $m$.[†] Thus, $f \in \mathrm{Diff}^r(M)$ or $\mathrm{End}^r(M)$, the $C^r$ diffeomorphisms or endomorphisms of $M$ respectively, where $1 \leq r \leq \infty$, and occasionally, $r = 0$.

What can be said about differentiable dynamical systems? The best things that can be said concern *all* systems. When we cannot make statements about all systems we may content ourselves with *most* systems. We expect that properties which hold for most systems hold for a specific system under consideration, but we cannot be sure until we have proven it.

Section 2 concerns properties which may hold for *all* dynamical systems, mainly properties from algebraic topology. Principal among these is the Entropy Conjecture which relates the topological entropy of a dynamical system to the induced map on the homology groups.

In Section 3 we turn from *all* to *most*. We investigate the time honored role of (a) *some* hyperbolicity, especially as it concerns (b) the stable and unstable manifolds

*The author would like to thank Charles Pugh for years of collaboration and also for help in preparing this article.

[†] "Closed" means that $M$ is compact and has empty boundary.

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

of points, (c) their intersections and (d) the equivalence relation these intersections define in the manifold. In the by now classical uniformly hyperbolic case, the equivalence classes form Smale's spectral decomposition and the behavioral properties entailed are structural stability, SRB measures, and ergodicity in the volume preserving Anosov case.

Uniformly hyperbolic systems are *some*, not *most* dynamical systems. So from the point of view of hoping to describe most dynamical systems we relax the structural properties to *some* hyperbolicity . Our goal is to understand how hypotheses about (a)–(d) affect ergodicity of volume preserving diffeomorphisms and whether these hypotheses hold for most partially hyperbolic volume preserving diffeomorphisms. Later we speculate on how they may affect the existence of SRB measures. Our theme is that a little hyperbolicity goes a long way toward ergodicity. Part of our problem is that the (un)stable manifolds, their intersections, and the equivalences they define are topological objects, while the desired results we wish to conclude are measure theoretic. Working in mixed categories raises rather severe technical difficulties, some of which have only recently been overcome.

We conjecture that most volume preserving partially hyperbolic dynamical systems (initially studied by Brin and Pesin) are ergodic, and we survey the rather substantial recent results in this direction, especially by Keith Burns and Amie Wilkinson, and Federico and Jana Rodriguez Hertz and Raul Ures. Here we first confront the role of the equivalence relation on $M$ induced by the strong stable and unstable manifolds and their intersections. This equivalence relation divides the manifold into *accessibility classes*. The main problem is to understand the relationship of the topologically defined accessibility classes of a partially hyperbolic dynamical system to the measure theoretically defined ergodic components via the Anosov–Hopf argument for ergodicity.

In Section 4.1 we study flows on homogeneous spaces and more generally affine diffeomorphisms. The ergodic theory of affine diffeomorphisms and flows on homogeneous spaces is extremely well developed. It relies to a large extent on the structure of Lie groups and representation theory. The ergodicity results in Section 3 apply outside of the homogeneous space context and per force use different techniques such as the accessibility relationship and *julienne quasi-conformality*. Juliennes are dynamically defined sets and quasi-conformality applies to the holonomy maps of the invariant stable and unstable manifolds. How good are these techniques when applied back in the homogeneous space context where a more elaborate set of tools is available for the study of ergodicity and stable ergodicity? While the proofs are very different there is a remarkable coincidence between those affine diffeomorphisms which are stably ergodic when considered with respect to affine perturbations and those which are stably ergodic with respect to all perturbations. Some rather interesting cases remain unresolved. The coincidence of results makes us feel that we have landed in the right place with our definitions of accessibility and makes the outstanding cases even more interesting.

In Section 4.2 we see how the results of Section 2 and 3 relate to one another. The SRB measures were initially proven to exist for uniformly hyperbolic dynamical systems. The Entropy Conjecture holds for these diffeomorphisms and we consider how sharp it is. How much complexity must a diffeomorphism have beyond that which is forced by the Entropy Inequality? Of particular interest are the Morse–Smale diffeomorphisms. The study of these diffeomorphisms has a deep connection to the theory of the structure of manifolds in high dimensions accomplished by Smale. Yet there are new invariants and obstructions.

The relations between dynamics and algebraic topology studied in Sections 2 and 4.2 *may* hold for all $r \geq 1$ but there are definite distinctions between the ergodic theory of $C^1$ and $C^2$ dynamical systems, so in Sections 3 and 4.1 we mostly assume that $r \geq 2$. Sections 2 and 4.2 and Sections 3 and 4.1 may be read independently of one another. But I think it would be a mistake to disassociate them. For one thing, the hyperbolic systems are partially hyperbolic. To understand the partially hyperbolic we must first understand the hyperbolic. For another, the variational principle ties measure theoretic entropy to topological entropy. (See for example Problem 3 of Section 2.) One of the main themes of this talk are the structures that link and the ties that bond the topological and measure theoretic in the presence of smoothness and some hyperbolicity. Moreover, what is true for *all* must be taken into consideration when studying *most*.

## 2. *All* differentiable dynamical systems

What dynamical properties hold for *all* dynamical systems $f$? The answer often depends on the degree of differentiability of $f$.

- Every continuous dynamical system supports an invariant probability measure.
- Every Lipschitz dynamical system has finite topological entropy, but non-Lipschitz systems can have infinite topological entropy.
- Every $C^\infty$ dynamical system satisfies the Entropy Inequality explained below, but this can fail for Lipschitz dynamical systems that are not continuously differentiable.

Let us recall the concept of entropy and the statement of the Entropy Conjecture. The topological entropy of $f$ measures the growth rate of its epsilon distinguishable orbits. It makes sense for any continuous endomorphism of a compact metric space, $f\colon X \to X$. Given $\epsilon > 0$ and $n \in \mathbb{N}$, let $N(f, n, \epsilon)$ be the maximum cardinality of a subset $A \subset X$ such that for each pair of distinct points $x, y \in A$ there is an iterate $f^j$ with $0 \leq j \leq k$ and

$$d(f^j(x),\, f^j(y)) > \epsilon.$$

Then, $h(f, \epsilon)$ is the exponential growth rate of $h(f, n, \epsilon)$ as $n \to \infty$, namely

$$h(f, \epsilon) = \limsup_{n\to\infty} \frac{1}{n} \ln h(f, n, \epsilon).$$

The supremum of $h(f, \epsilon)$ over all $\epsilon > 0$, or what is the same thing, its limit as $\epsilon \to 0$, is the topological entropy of $f$, $h(f)$. In [New1], Newhouse surveys how the concept of entropy fits into the $C^r$ category.

There is a corresponding growth rate in algebraic topology. The map $f\colon M \to M$ induces a homology homomorphism $f_*\colon H_*(M, \mathbb{R}) \to H_*(M, \mathbb{R})$. Under $f_*^n$, homology classes grow no more rapidly than $s^n$ where $s = s(f_*)$ is the spectral radius of $f_*$, i.e., the modulus of the largest eigenvalue of $f_{*i}\colon H_i(M, \mathbb{R}) \to H_i(M, \mathbb{R})$, $0 \le i \le m$.

**Entropy Conjecture** ([Sh2]). For all $C^r$ dynamical systems, $r \ge 1$, we have the *Entropy Inequality*

$$h(f) \ge \ln s(f_*).$$

Of course, the conjecture for $r = 1$ implies all the others, so this is the principal case. But if it fails for $r = 1$ and holds for larger $r$, this is also interesting. The Entropy Conjecture is true for $C^\infty$ dynamics, but remains unknown for $C^r$ dynamics, $1 \le r < \infty$. The positive result is due to Yomdin, [Yom], who compares the growth rate of the volumes of submanifolds of $M$ under iteration of $f$ to the entropy. See also [Gro2].

The Entropy Conjecture is in general false for Lipschitz endomorphisms already on the 2-sphere, and also for Lipschitz or piecewise linear homeomorphisms in dimension four or larger, [Pu]. For $C^1$ $f$, Misiurewicz and Przytycki [MiPr] prove that $h(f) \ge \ln(\text{degree}(f_{*m}))$. Some entropy lower bounds are known for continuous endomorphisms in terms of the growth rate of the induced map on the fundamental or first homology group, [Ma1], [Bo], [FaSh]. These imply entropy lower bounds for homeomorphisms of manifolds below dimension 4 by Poincaré duality. See [MaPr] for recent results.

Here are some more problems which are of a similar nature, relating algebraic topology to differentiable dynamics. We use the notation

$$\text{GR}(a_n) = \limsup_{n\to\infty} \frac{1}{n} \ln a_n$$

to denote the exponential growth rate of a sequence $(a_n)$ in $(0, \infty]$.

Let $V$ and $W$ be closed smooth submanifolds of complementary dimension in the closed manifold $M$, and let $f$ be a smooth endomorphism of $M$. Let $N_n$ denote the number of distinct points of intersection of $f^n(V)$ with $W$ and let $I_n$ denote the intersection of the homology classes $f_*^n[V]$ and $[W]$, where $[V]$ and $[W]$ are the homology classes in $M$ represented by $V$ and $W$.

**Problem 1.** Is $\text{GR}(N_n) \ge \text{GR}(I_n)$?

A special case of this problem concerns the Lefschetz formula. Let $N_n(f)$ be the number of geometrically distinct periodic points of $f$ of period $n$. Let $L(f^n) = \sum_{i=0}^m (-1)^i \,\text{trace}(f_{*i}\colon H_i(M) \to H_i(M))$.

**Problem 2.** Is $\mathrm{GR}(N_n(f)) \geq \mathrm{GR}(|L(f^n)|)$?

By the transversality theorem the inequalities in the last two problems hold $C^r$ generically. The question is: Do they always hold? It is known that if $f$ is $C^1$ and $L(f^n)$ is unbounded then so is $N_n(f)$ [ShSu1]. This fails for Lipschitz maps.

A first interesting case is a smooth degree two map, $f$, of the 2-sphere. Let $N_n$ be the number of distinct periodic points of $f$ of period $n$.

**Problem 3.** Is $\mathrm{GR}(N_n) \geq \ln 2$?

The results of [MiPr] concerning topological entropy and degree and of Katok [Ka] comparing $\mathrm{GR}(N_n)$ to topological entropy for diffeomorphisms in dimension 2 make a start on this problem.

All these examples fall into the following general framework. Let $F$ be a functor from the category of manifolds to another category. Since a dynamical system $f$ may be iterated so may $F(f)$. We ask to compare the asymptotic behavior of the iterates of $F(f)$ and $f$. Here, we considered the functors of algebraic topology. Later the structures we consider and questions we ask for most or some $f$ consider functors such as the tangent bundle, measures, the de Rham complex, etc.

## 3. *Most* differentiable dynamical systems

Since the range of dynamical behavior exhibited by all dynamical systems seems too large to admit a meaningful universal description applicable to all systems, many attempts have been made to describe features of *most* dynamical systems. SRB measures were introduced by Sinai, Ruelle and Bowen in the 1970s in the study of uniformly hyperbolic dynamical systems. The space integrals for continuous functions with respect to these measures predict the time averages of almost every Lebesgue point in the manifold. It is a fundamental result of Sinai, Ruelle and Bowen [Si], [Ru1], [BoRu] that a finite number of SRB measures exist for $C^2$ hyperbolic dynamics (technically Smale's Axiom A and no cycle systems.) Ruelle [Ru2] suggested that these measures apply much more generally. Much effort in dynamical systems in recent years has focused on Ruelle's suggestion. One widespread optimistic program dating from the late 1970s suggests that most systems have a finite (or perhaps countable) collection of ergodic SRB measures. For volume preserving diffeomorphisms of closed manifolds this program can not be correct because the KAM phenomenon insures the robust existence of positive measure sets of codimension one tori with quasi-periodic motions [ChSu], [Yoc], [Xi]. These tori have no non-zero Lyapunov exponents. So the existence of some non-zero exponents may be decisive for the program.

**3.1. Partially hyperbolic diffeomorphisms.** In contrast, we have suggested that a little hyperbolicity goes a long way towards ergodicity of volume preserving diffeomorphisms and hence (trivially) a unique SRB measure. Concretely our principal

results are limited to $C^2$ partially hyperbolic volume preserving diffeomorphisms. These systems are generalizations of Anosov (globally hyperbolic) dynamical systems. In the Anosov case volume preserving $C^2$ diffeomorphisms are proved to be ergodic [An], [AnSi], [Ho]. Brin and Pesin [BrPe] studied ergodicity of partially hyperbolic diffeomorphism with an *accessibility* property. The hypotheses of their ergodicity theorem were too limiting to be broadly applicable. In fact they probably almost never hold, [ShWi2], [HiPe]. In a series of papers [GrPuSh] , [Wi1], [PuSh3], [PuSh4], [PuSh5], [BuWi2], [BuWi3], [RHRHUr] these hypotheses have been replaced by ones quite generally applicable.

More precisely:

**Definition.** A diffeomorphism $f: M \to M$ is *partially hyperbolic* if there is a continuous $Tf$-invariant splitting $TM = E^{\mathrm{u}} \oplus E^{\mathrm{c}} \oplus E^{\mathrm{s}}$ such that $Tf$ is hyperbolic on $E^{\mathrm{u}} \oplus E^{\mathrm{s}}$ and the hyperbolicity dominates $Tf$ on $E^{\mathrm{c}}$ in the sense that for some $\tau$, $\lambda$ with $1 \leq \tau < \lambda$ and positive constants $c$, $C$ we have the following:

(a) For all $v \in E^{\mathrm{u}}$ and all $n \geq 0$, $c\lambda^n|v| \leq |Tf^n(v)|$.

(b) For all $v \in E^{\mathrm{s}}$ and all $n \geq 0$, $|Tf^n(v)| \leq C\lambda^{-n}|v|$.

(c) For all $v \in E^{\mathrm{c}}$ and all $n \geq 0$, $c\tau^{-n}|v| \leq |Tf^n(v)| \leq C\tau^n|v|$.

(d) The bundles $E^{\mathrm{u}}$, $E^{\mathrm{s}}$ are non-zero.

Condition (d) is present to avoid triviality. Without it, every diffeomorphism would be partially hyperbolic, for we could take $E^{\mathrm{c}}$ as $TM$. Sometimes, one only requires $E^{\mathrm{u}} \oplus E^{\mathrm{s}} \neq 0$, but for simplicity we use the stronger assumption (d) in this paper.

Partial hyperbolicity means that under $Tf^n$, vectors in $E^{\mathrm{c}}$ grow or shrink more gradually than do vectors in $E^{\mathrm{u}}$ and $E^{\mathrm{s}}$. The center vectors behave in a relatively neutral fashion. The definition can be recast in several different ways. For instance, expansion of $E^{\mathrm{u}}$ under positive iteration of $Tf$ can be replaced by contraction under negative iteration. Also, non-symmetric rates can be used for expansion and contraction. More significantly, one could permit pointwise domination instead of the absolute domination as above. See [Puj], [BoDíVi] for a discussion of dominated splitting. All of these refinements to the notion of partial hyperbolicity are exploited by Burns and Wilkinson in their result discussed below.

Given a smooth manifold $M$, fix a smooth volume $\mu$ on $M$. Then we say $f$ is volume preserving if it preserves this volume and we write the set of $\mu$ preserving $C^r$ diffeomorphisms of $M$ as $\mathrm{Diff}^r_\mu(M)$.

A diffeomorphism is *ergodic* if it preserves a measure and each measurable invariant set is a zero set or the complement of a zero set. No measurable invariant set has intermediate measure. Ergodicity is *stable* if it persists under perturbation of the dynamical system. Towards our theme that a little hyperbolicity goes a long way toward ergodicity and more optimistically toward the goal of finding SRB measures, we have our main conjecture.

**Main Conjecture.** Among the volume preserving $C^r$ partially hyperbolic dynamical systems for $r \geq 2$, the stably ergodic ones form an open and dense set.

An approach to the Main Conjecture via two additional conjectures consists in generalizing the Anosov–Hopf proof of the ergodicity of Anosov systems ($E^c = \{0\}$) by studying the accessibility relationship. The Anosov–Hopf argument proceeds as follows. If $x, y$ are forward asymptotic then the time average of continuous functions along the orbit of $x$ equals the time average along the orbit of $y$. Reversing time, the same is true for $f^{-1}$ and points $x, y$ which are asymptotic in negative time. Now the Birkhoff ergodic theorem says that positive time averages equal negative time averages almost everywhere. So we say $x \sim y$ if $x$ and $y$ are positive or negative asymptotic and extend $\sim$ to an equivalence relation on $M$. In principle by the Birkhoff theorem time averages should be constant on equivalence classes and we may prove ergodicity by proving that the equivalence classes are measure zero or one. There are severe technical difficulties to this program but it can be made to work in the Anosov and the partially hyperbolic cases with some extra hypotheses. We say $x, y \in M$ are *us-accessible* if there is a piecewise differentiable path joining $x$ to $y$ and tangent either to $E^u$ or $E^s$ at every point of differentiability. A diffeomophism is *e-*(*ssentially*) *accessible* (in the measure theoretic sense) if the only subsets of $M$ saturated with respect to us-accessibility have measure 0 or 1. A diffeomorphism is *us-accesssible* if $M$ itself is a us-accessibility class. us-accessibility obviously implies e-accessibility.[‡]

**Conjecture A.** Every $C^2$ volume preserving e-accessible partially hyperbolic diffeomorphism is ergodic.

**Conjecture B.** The partially hyperbolic diffeomorphisms with the us-accessibility property are open and dense in the $C^r$ partially hyperbolic diffeomorphisms for every $r \geq 1$, volume preserving or not.

Conjectures A and B obviously imply the main conjecture.

Conjecture A was proven with two technical hypotheses in [PuSh4], center bunching and dynamical coherence. Burns and Wilkinson [BuWi2], [BuWi3] have since removed the dynamical coherence hypothesis and improved the center bunching condition. The center bunching condition puts bounds on the ratios of the expansions and contractions in $E^u$ and $E^s$ as compared to $E^c$. If $Tf|_{E^c}$ is close to conformal the center bunching conditions are satisfied.[§]

[‡]Note that the us-accessibility classes are contained in the $\sim$ equivalence classes we defined above. They are much more amenable to use in proofs.

[§]Burns and Wilkinson's center bunching conditions suppose that there are continuous positive functions $\nu(p), \hat{\nu}(p), \gamma(p), \hat{\gamma}(p)$ such that for every $p \in M$:

1. $\nu(p), \hat{\nu}(p) < 1$ and $\nu(p) < \gamma(p) < \hat{\gamma}(p)^{-1} < \hat{\nu}(p)^{-1}$.
2. $\| T_p f(v) \| < \nu(p)$ for $v \in E^s(p)$,
   $\gamma(p) < \| T_p f(v) \| < \hat{\gamma}(p)^{-1}$ for $v \in E^c(p)$,
   $\| T_p f(v) \| > \hat{\nu}(p)^{-1}$ for $v \in E^u(p)$ .
3. $\nu(p) < \gamma(p)\hat{\gamma}(p)$ and $\hat{\nu}(p) < \gamma(p)\hat{\gamma}(p)$.

The second condition is the partial hyperbolicity and the third the center bunching.

We say that $f$ is BW partially hyperbolic and center bunched, if it satisfies the Burns–Wilkinson conditions.

**Theorem** (Burns–Wilkinson [BuWi3]). *Let $f$ be $C^2$, volume preserving, BW partially hyperbolic and center bunched and essentially accessible. Then $f$ is ergodic and in fact a K-automorphism.*

When the dimension of the center bundle $E^c$ is one the bunching conditions are automatically satisfied. So it follows as a simple corollary that:

**Corollary** (Burns–Wilkinson). *Conjecture A is true when dimension $E^c$ is one.*

Even more is true when the dimension of the center bundle $E^c$ is one, Federico and Jana Rodrigues Hertz, and Raul Ures prove the Main Conjecture.

**Theorem** ([RHRHUr]). *When the dimension of $E^c$ is one, Conjecture A, Conjecture B for volume preserving diffeomorphisms and hence the Main Conjecture all are true.*

Towards Conjecture B in general there is [DoWi] in the $C^1$ topology.

The major new elements in the proofs of the series of theorems on stable ergodicity of partially hyperbolic systems are dynamically defined sets called juliennes which can be used to estimate Lebesgue volumes either directly or by proving that they form a Lebesgue density basis and an analysis of the stable and unstable holonomy maps which are julienne quasi-conformal.

Partial hyperbolicty and center bunching are easily seen to be open conditions and us-accessibility is frequently easily proven to hold in an open neighborhood of a given example. Sometimes even e-accessibility is (not so easily) proved to hold in the neighborhood of a given example [RH]. The situation is good enough to be able to conclude stable ergodicity in the $C^2$ topology of quite a few examples. Here are several examples. See [BuPuShWi], [PuSh5] for more details and for more on the current state of affairs.

1. The product of a volume preserving Anosov diffeomorphism and any other volume preserving diffeomorphism can be arbitrarily $C^\infty$ closely approximated by a partially hyperbolic, us-accessible stably ergodic diffeomorphism [ShWi1], [BuPuShWi], as long as the hyperbolicity of the Anosov diffeomorphism is strong enough to produce a partially hyperbolic splitting of the tangent bundle. (Conjecturally an open and dense set of perturbations is ergodic.) *So the KAM phenomenon seems to be dominated by the hyperbolic phenomenon and ergodicity of weakly coupled systems of KAM and Anosov type should be expected to be ergodic.*

2. The time $t$ map of the geodesic flow of a manifold of negative curvature is stably ergodic.

3. Skew products which are compact group extensions over standard Anosov diffeomorphisms are generically us-accessible and $C^2$ stably ergodic, [Br1], [Br2], [BuWi1], [FiPa].

4. Ergodic toral automorphisms having a two dimensional invariant subspace with isometric derivative and some mild extra technical conditions are $C^r$ stably ergodic for a fairly large $r$ [RH].

5. Partially hyperbolic affine diffeomorphisms of finite volume compact homogeneous spaces of simple Lie groups are stably ergodic. We discuss these below.

Systems whose Lyapunov exponents are non-zero, called non-uniformly hyperbolic, were introduced by Pesin and play a large role in the ergodic theory of volume preserving diffeomorphisms and the study of SRB measures. Pesin's paper [Pe1] raises the question if in dimension bigger than two those diffeomorphisms without zero Lyapunov exponents are generic. We have mentioned above that KAM theory produces open sets of volume preserving diffeomorphisms with positive measure sets of invariant tori which have no hyperbolicity. So the answer to the question is "no". But it may be an either/or situation.

**Problem 4** ([ShWi2]). Is it true for generic $f \in \mathrm{Diff}^r_\mu(M)$ that for almost every ergodic component of $f$ either all the Lyapunov exponents of $f$ are 0 or none of the Lyapunov exponents of $f$ are 0 ($\mu$-a.e.)?

For some partially hyperbolic diffeomorphisms zero exponents were perturbed away in [ShWi2], which produces pathological center foliations. More of this is carried out in [HiPe] and for the $C^1$ topology in [BaBo]. So there is some evidence that the answer to the problem is "yes" at least for stably ergodic or partially hyperbolic diffeomorphisms. The problem is even interesting when restricted to ergodic diffeomorphisms so there is only one ergodic component. When $r = 1$, Mañé and Bochi prove for two dimensional manifolds that generically all the exponents are zero or the diffeomorphism is Anosov [Mañ1], [Boc].

**3.2. Possible Extensions.** How might the Anosov–Hopf argument be transported from the category of volume preserving diffeomorphisms to most of $\mathrm{Diff}^r(M)$? and especially to the existence of SRB measures? Here we enter a more speculative realm. First we recall the definition of SRB measures and some suggestions from [ShWi2].

Given $f \in \mathrm{Diff}^r(M)$ (not necessarily preserving $\mu$) a closed $f$ invariant set $A \subset M$ and an $f$ invariant ergodic measure $\nu$ on $A$, we define the *basin* of $A$ to be the set of points $x \in M$ such that $f^n(x) \to A$ and for every continuous function $\phi\colon M \to \mathbb{R}$

$$\lim_{n\to\infty} \frac{1}{n}(\phi(x) + \cdots + \phi(f^n(x))) \to \int_A \phi(x)\, d\nu.$$

$\nu$ is an *SRB measure* and $A$ an *SRB attractor* (or an *ergodic attractor*) if the $\mu$ measure of the basin of $A$ with respect to $\mu$ is positive.

It follows from the definition that a diffeomorphism has at most countably many SRB measures. We can more formally describe the Sinai, Ruelle and Bowen [Si],

[Ru1], [BoRu] result already referred to. If $f$ is a $C^2$ Axiom A no cycle diffeomorphism then $\mu$ almost every point in $M$ is in a basin of an SRB measure and there are only finitely many SRB measures. It is this result that one would like to extend into a (more) general context.

The next problem obviously presents itself from the presentation.

**Problem 5.** For $r \geq 2$ is it true for the generic $f$ in $\mathrm{Diff}^r(M)$ that the union of the basins of the SRB attractors of $f$ has full $\mu$ measure in $M$?

This natural question is on the minds of quite a few people. See for example [Ru1], [BuPuShWi], [Pa], [Vi1], [You1], [You2], [BoDíVi]. One way to approach the problem along the lines of the Anosov–Hopf argument and as in [Pe1], [PuSh1] might be via an analogue of the either/or question on Lyapunov exponents for volume preserving diffeomorphisms above . For $r \geq 2$ there is no known analogue without the volume preserving hypothesis of the robust positive measure set of invariant tori with zero Lyapunov exponents which occurs via KAM theory. See [Vi2], [BuPuShWi].

**Problem 6.** For $r \geq 2$ is it true for the generic $f$ in $\mathrm{Diff}^r(M)$ and any weak limit $\nu$ of the push forwards $\frac{1}{n}\sum_1^n f_*^j\mu$ that almost every ergodic component of $\nu$ has some exponents not equal to 0 ($\nu$-a.e.)? All exponents not equal to 0?

Partially hyperbolic systems are a natural domain to begin considering problems [5] and [6]. When the volume is not preserved and we distinguish future behavior from the past the accessibility equivalence relation has to be adapted. Even for partially hyperbolic $f$ it is not entirely clear how to do this. So suppose $f$ partially hyperbolic . Let $W^{\mathrm{uu}}(x)$ and $W^{\mathrm{ss}}(x)$ denote the strong unstable and stable manifolds which are known to exist tangent to the $E^{\mathrm{u}}$ and $E^{\mathrm{s}}$ foliations. For $x, y \in M$ define $x > y$ if $W^{\mathrm{uu}}(x) \cap W^{\mathrm{ss}}(y) \neq \emptyset$. Transitivize $>$ to a partial order on $M$ and declare $x \sim y$ if $x > y$ and $y > x$. The $\sim$ equivalence classes may play a role similar to us-accessibility classes.

**Problem 7.** For the generic partially hyperbolic $f$, do all $\sim$ equivalence classes which are minimal with respect to $>$ have SRB measures?

**3.3. A little hyperbolicity.** Now that we have given a lot of examples, we return to our theme that a little hyperbolicity goes a long way towards ergodicity. We ask how often can we prove that hyperbolicity does exist in the guise of some non-zero Lyapunov exponents. Some specific families of non-uniformly hyperbolic dynamical systems have been worked out which contain positive measure sets in the parameter space with SRB measures having non-zero Lyapunov exponents. Most prominent among these families are the quadratic and Henon families, see [Ja], [Ly], [Be], [BeCa], [You1], [You2], [Vi1]. The proofs are difficult. One would like to find a fairly general principle which guarantees that a family has a positive measure set of parameters which have an SRB measure with a positive Lyapunov exponent.

One attempt posits that rich enough families of dynamical systems should have members with positive Lyapunov exponents. Examples have been constructed with uncertain but evocative results. Let $M$ have a Riemannian metric and let $G$ be a group of isometries of $M$ which is transitive on the projectivized tangent bundle of $M$. Let $\mu$ be the Riemannian volume. Let $f_\epsilon$ be a family of $C^r$ dynamical systems defined on $M$ depending on $\epsilon$. For fixed $\epsilon$, consider the family $Gf_\epsilon = \{gf_\epsilon, g \in G\}$. Give $Gf_\epsilon$ the push forward of the Haar measure on $G$. If $f_\epsilon$ preserves $\mu$ let $H(\epsilon)$ be the average over $Gf_\epsilon$ of the entropy of $gf_\epsilon$ with respect to $\mu$. This is the case in example 3 below. If $f_\epsilon$ does not preserve $\mu$ but $gf_\epsilon$ has a unique SRB measure for each $g \in G$, let $H(\epsilon)$ be the average over $Gf_\epsilon$ of the entropy of $gf_\epsilon$ with respect to this SRB measure. This is the case in examples 1 and 2 below. We compare $H(\epsilon)$ to the random Lyapunov exponents with respect to random products of elements of $Gf_\epsilon$ which we shall call

$$R(\epsilon) = \int_{\mathbb{P}TM} \ln|Tf_\epsilon(v)|\, dv,$$

where $\mathbb{P}TM$ is the projectivized tangent bundle of $M$. It is usually easy to see that $R(\epsilon)$ is positive. When $H(\epsilon)$ is positive then there are obviously positive measure sets in the parameter space with positive Lyapunov exponents and positive entropy. Here are the results for a few families.

1. *Blaschke products* ([PujRoSh]). The family of dynamical systems does not depend on $\epsilon$; we take $f_\epsilon = B$ where

$$B(z) = \theta_0 \prod_{i=1}^{n} \frac{z - a_i}{1 - z\overline{a_i}},$$

$n \geq 2$, $a_i \in \mathbb{C}$, $|a_i| < 1$, $i = 1, \ldots, n$, and $\theta_0 \in \mathbb{C}$ with $|\theta_0| = 1$.

The group $G$ is the unit circle $\mathbb{T}$ in the complex plane, $\mathbb{C}$. Its elements are denoted by $\theta$. Now we take

$$\mathbb{T}B = \{\theta B\}_{\{\theta \in \mathbb{T}\}}.$$

Then

$$H(\epsilon) \geq R(\epsilon).$$

($H(\epsilon)$ is always positive.)

2. *Expanding maps of the circle* ([LlShSi]). Here the dynamical systems are $f_{k,\alpha,\epsilon} : \mathbb{S}^1 \to \mathbb{S}^1$ which when written mod 1 are of the form

$$f_{k,\alpha,\epsilon} : x \mapsto kx + \alpha + \epsilon \sin(2\pi x). \tag{3.1}$$

The group is $\mathbb{S}^1$, $\alpha$ ranges over $\mathbb{S}^1$ and $k \geq 2$. Then for small $\epsilon$ the average over $\alpha$ of the entropy $H(\epsilon)$ is smaller than $R(\epsilon)$, while the max over $\alpha$ of the entropies of $f_{k,\alpha,\epsilon}$ is larger than $R(\epsilon)$. In the case of the averages the difference is on the order of $\epsilon^{2k+2}$. $H(\epsilon)$ is again obviously positive.

3. *Twist maps of the sphere* ([LeShSiWi]). For $\epsilon > 0$, we define a one-parameter family of twist maps $f_\epsilon$ as follows. Express $\mathbb{S}^2$ as the sphere of radius $1/2$ centered at $(0, 0)$ in $\mathbb{R} \times \mathbb{C}$, so that the coordinates $(r, z) \in \mathbb{S}^2$ satisfy the equation
$$|r|^2 + |z|^2 = 1/4.$$
In these coordinates define a twist map $f_\epsilon : \mathbb{S}^2 \to \mathbb{S}^2$, for $\epsilon > 0$, by
$$f_\epsilon(r, z) = (r, \exp(2\pi i (r + 1/2)\epsilon)z).$$
The group is SO(3). So $\mathrm{SO}(3) f_\epsilon = \{g f_\epsilon, g \in \mathrm{SO}(3)\}$.
For small $\epsilon$, $H(\epsilon)$ seems experimentally to be positive and is provably less than $R(\epsilon)$. $R(\epsilon)$ tends to infinity with $\epsilon$ and experimentally $R(\epsilon)$ and $H(\epsilon)$ are asymptotic. If we add a small fixed amount of randomization $\delta$ to the each $g$ in $g f_\epsilon$ and average the Lyapunov exponents of this randomized family over $g \in \mathrm{SO}(3)$, we obtain $R_\delta(\epsilon)$ which is indeed asymptotic to $R(\epsilon)$ as $\epsilon \to \infty$.

4. *Linear maps* ([DeSh]). If, instead of dynamical systems, we consider a linear map $A \in \mathrm{GL}(n, \mathbb{C})$ and the family $\mathrm{SU}(n)A$, then the average of the logarithms of the $k$ biggest moduli of eigenvalues of $UA$ over $U \in \mathrm{SU}(n)$ is greater than or equal to the sum of the $k$ largest Lyapunov exponents of random products of matrices from $\mathrm{SU}(n)A$.

There may be a general principle operating here that we have not put our finger on yet.

## 4. *Some* differentiable dynamical systems

**4.1. Affine diffeomorphisms.** The ergodic theory of affine diffeomorphisms of homogeneous spaces has been much studied in its own right, see for example [St1], and contains some of the principal examples studied in smooth dynamics such as the geodesic and horocycle flows on surfaces of constant negative curvature and toral automorphisms. Here we study the question of ergodicity of affine diffeomorphisms in the context of partially hyperbolic dynamical systems with $C^r$ perturbations. Our methods of proof recover the stable ergodicity of affine diffeomorphisms when they are stably ergodic among affine perturbations and usually extend this stability to $C^r$ perturbations. On this last point there remain some open problems.

Suppose that $G$ is a connected Lie group, $A : G \to G$ is an automorphism, $B$ is a closed subgroup of $G$ with $A(B) = B$, $g \in G$ is given, and the *affine diffeomorphism*
$$f : G/B \to G/B$$
is defined as $f(xB) = gA(x)B$. It is covered by the diffeomorphism
$$\bar{f} = L_g \circ A : G \to G,$$

where $L_g : G \to G$ is left multiplication by $g$.

An affine diffeomorphism $\bar{f}$ induces an automorphism of the Lie algebra $\mathfrak{g} = T_eG$, $\mathfrak{a}(\bar{f}) = \mathrm{Ad}_g \circ T_eA$, where $\mathrm{Ad}_g$ is the adjoint action of $g$, and $\mathfrak{g}$ splits into generalized eigenspaces,

$$\mathfrak{g} = \mathfrak{g}^{\mathrm{u}} \oplus \mathfrak{g}^{\mathrm{c}} \oplus \mathfrak{g}^{\mathrm{s}},$$

such that the eigenvalues of $\mathfrak{a}(\bar{f})$ are respectively outside, on, or inside the unit circle. These eigenspaces and the direct sums $\mathfrak{g}^{\mathrm{cu}} = \mathfrak{g}^{\mathrm{u}} \oplus \mathfrak{g}^{\mathrm{c}}$, $\mathfrak{g}^{\mathrm{cs}} = \mathfrak{g}^{\mathrm{c}} \oplus \mathfrak{g}^{\mathrm{s}}$ are Lie subalgebras and hence tangent to connected subgroups $G^{\mathrm{u}}$, $G^{\mathrm{c}}$, $G^{\mathrm{s}}$, $G^{\mathrm{cu}}$, $G^{\mathrm{cs}}$.

**Proposition** ([PuShSt1]). *Let $f : G/B \to G/B$ be an affine diffeomorphism as above such that $G/B$ is compact and supports a smooth $G$-invariant volume. Let $G^*$ be any of the groups $G^{\mathrm{u}}$, $G^{\mathrm{c}}$, $G^{\mathrm{s}}$, $G^{\mathrm{cu}}$, $G^{\mathrm{cs}}$. Then the orbits of the left $G^*$-action on $G/B$ foliate $G/B$. Moreover, $f$ exponentially expands the $G^{\mathrm{u}}$-leaves, exponentially contracts the $G^{\mathrm{s}}$-leaves, and affects the $G^{\mathrm{c}}$-leaves subexponentially.*

Now we characterize partial hyperbolicity, bunching and accessibility in the context of affine diffeomorphisms. Let $\mathfrak{h}$ denote the smallest Lie subalgebra of $\mathfrak{g}$ containing $\mathfrak{g}^{\mathrm{u}} \cup \mathfrak{g}^{\mathrm{s}}$. It is not hard to see that $\mathfrak{h}$ is an ideal in $\mathfrak{g}$. We call it the *hyperbolic Lie subalgebra* of $\bar{f}$, and we denote by $H$ the connected subgroup of $G$ tangent to $\mathfrak{h}$, calling it the *hyperbolic subgroup* of $\bar{f}$. Finally, let $\mathfrak{b}$ denote the Lie algebra of $B$, $\mathfrak{b} \subset \mathfrak{g}$.

**Theorem** ([PuSh4]). *Let $f : G/B \to G/B$ be an affine diffeomorphism as above such that $G/B$ is compact and supports a smooth $G$-invariant volume. Then*

(a) *$f$ is partially hyperbolic if and only if the hyperbolic Lie subalgebra of $\bar{f}$ is not contained in the Lie algebra of $B$, $\mathfrak{h} \not\subset \mathfrak{b}$.*

(b) *If $f$ is partially hyperbolic then it is center bunched.*

(c) *$f$ has the us-accessibility property if and only if $\mathfrak{g} = \mathfrak{b} + \mathfrak{h}$.*

(d) *$f$ has the e-accessibility property if and only if $\overline{HB} = G$.*

When the stable and unstable foliations are smooth, as in the affine case, us-accessibility is stable. Thus we have:

**Theorem** ([PuSh4]). *Let $f : G/B \to G/B$ be an affine diffeomorphism as above such that $G/B$ is compact and supports a smooth $G$-invariant volume. Then $f$ is stably ergodic among $C^2$ volume preserving diffeomorphisms of $G/B$ if* (*merely*) *the hyperbolic Lie subalgebra $\mathfrak{h}$ is large enough that $\mathfrak{g} = \mathfrak{b} + \mathfrak{h}$.*

If $G$ is simple then any nontrivial $\mathfrak{h}$ is large enough since it is an ideal.

Suppose that $A \in \mathrm{SL}(n, \mathbb{R})$ has some eigenvalues that are not of modulus one, and suppose that $\Gamma$ is a uniform discrete $A$-invariant subgroup of $\mathrm{SL}(n, \mathbb{R})$. Set $M = \mathrm{SL}(n, \mathbb{R})/\Gamma$. Then left multiplication by $A$, $L_A : M \to M$, is stably ergodic in

$\mathrm{Diff}^2_\mu(M)$. The case where $n$ is large and all but two eigenvalues have modulus one is interesting, in that the dimension of $G^{\mathrm{u}}$ and $G^{\mathrm{s}}$ is $n-1$ while the dimension of $G^{\mathrm{c}}$ is $(n-1)^2$, so the dimension of $G^{\mathrm{c}}$ is much larger than that of $G^{\mathrm{u}}$ and $G^{\mathrm{s}}$.

At the other extreme are abelian groups. If $G = \mathbb{R}^n$ and $B = \mathbb{Z}^n$ then translations on the torus, $\mathbb{T}^n = \mathbb{R}^n/\mathbb{Z}^n$ are ergodic if the entries of the element defining the translation are rationally independent, but they are never stably ergodic. An automorphism $A$ of $\mathbb{T}^n$ is ergodic if and only if $A$ has no eigenvalues that are roots of unity. A little bit of algebra quickly shows that the hypothesis that $A$ has no eigenvalues which are roots of unity is equivalent to the hypothesis that $\overline{H\mathbb{Z}^n} = \mathbb{R}^n$ where $H$ is the hyperbolically generated subgroup of $\mathbb{R}^n$.

We have concentrated on the accessibility condition because accessibility is a topological property and as such it is not difficult to stipulate easily verifiable conditions which guarantee that it persists under small perturbations.

In a recent remarkable paper, Federico Rodriguez Hertz gives the first examples of a stably e-accessible diffeomorphisms that are not us-accessible, [RH]. They are ergodic, non-hyperbolic diffeomorphisms of tori. The first such occurs in dimension four.

Rodriguez Hertz sometimes uses a technical assumption on the automorphism $A$, which we will refer to as the *Rodriguez Hertz condition*, namely that the characteristic polynomial of $A$ is irreducible over the integers and it can not be written as a polynomial in $t^k$, $k \geq 2$.

**Theorem** ([RH]). *Let $A$ be an ergodic toral automorphism of $\mathbb{T}^n$.*

(a) *If $n \leq 5$ then $A$ is stably ergodic in* $\mathrm{Diff}^{22}_\mu(\mathbb{T}^n)$.

(b) *If $n \geq 6$, $E^{\mathrm{c}}$ is two-dimensional, and $A$ satisfies the Rodriguez Hertz condition then $A$ is stably ergodic in* $\mathrm{Diff}^5(\mathbb{T}^n)$.

The differentiability degrees 22 and 5 are not misprints.

Part of Rodriguez Hertz' proof involves an alternative. Either the perturbation is us-accessible or the stable and unstable manifold foliations are differentiably conjugate to the foliations of the linear example and hence the perturbation has the e-accessibility property.

**Problem 8.** Is every ergodic toral automorphism stably ergodic in the $C^r$ topology for some $r$?

The next result is an approximate solution of this problem.

**Theorem** ([ShWi1]). *Every ergodic toral automorphism of $\mathbb{T}^n$ that is an isometry on the center bundle $E^{\mathrm{c}}$ can be approximated arbitrarily well in* $\mathrm{Diff}^\infty_\mu(\mathbb{T}^n)$ *by a stably us-accessible, stably ergodic diffeomorphism.*

Further examples of partially hyperbolic stably ergodic diffeomorphisms are considered in [BuPuShWi]. These include skew products, frame flows, and Anosov-like diffeomorphisms.

The next theorem shows that the condition for stable ergodicity of affine diffeomorphisms among perturbations which are restricted to be left multiplication by group elements near the identity is the same as e-accessibility. Hence, the julienne proof of stable ergodicity applies to prove the stable ergodicity of these affine diffeomorphisms among affine perturbations as well. This phenomenon is discussed in [PuShSt2].

**Theorem** ([St2]). *Suppose that $f: G/B \to G/B$ is an affine diffeomorphism such that $M = G/B$ is compact and supports a smooth $G$-invariant volume. Then the following are equivalent.*

(a) *$f$ is stably ergodic under perturbation by left translations.*

(b) *$\overline{HB} = G$ where $H$ is the hyperbolically generated subgroup of $G$.*

**Corollary.** *Suppose that $f: G/B \to G/B$ is an affine diffeomorphism such that $M = G/B$ is compact and supports a smooth $G$-invariant volume. Assume that $G$ is simple. Then stable ergodicity of $f$ with respect to perturbation by left translations is equivalent to stable ergodicity among $C^2$ volume preserving perturbations.*

This corollary and the result of Rodriguez Hertz naturally lead to a generalization of Problem 10.

**Problem 9.** For an affine diffeomorphism $f$ of a compact, finite volume $G/B$, is stable ergodicity of $f$ with respect to perturbation by left translations equivalent to stable ergodicity among $C^2$ volume preserving perturbations?

We end our discussion of partially hyperbolic diffeomorphisms with a question from [BuPuShWi] of a very different nature. We have used both the strong unstable and strong stable foliations in our proof of ergodicity, but we do not know an example where this is strictly necessary.

**Problem 10.** For a partially hyperbolic $C^2$ ergodic diffeomorphism $f$ with the e-accessibility property, are the unstable and stable foliations already ergodic and uniquely ergodic?

Unique ergodicity of for horocycle flows was proved by Furstenberg [Fu]. Bowen and Marcus [BoMa] proved the unique ergodicity of the strong stable and unstable manifold foliations in the case where $f$ is the time-one map of a hyperbolic flow. Rodriguez Hertz' result adds more cases in which the invariant foliations are uniquely ergodic, namely those in which they are differentiably conjugate to the invariant foliations of a linear ergodic toral automorphism. Starkov [PuShSt2] proves that unique ergodicity of the strong stable or unstable foliations for all affine diffeomorphisms which are stably ergodic under perturbation by left translation.

In the topological category Bonatti, Díaz, and Ures [BoDíUr] prove the minimality of the stable and unstable foliations for an open and dense set of robustly transitive diffeomorphisms.

**4.2. Models.** Two dynamical systems $f\colon M \to M$ and $g\colon N \to N$ are topologically conjugate if there is a homeomorphism $h\colon M \to N$ such that $hf = gh$. The dynamical system $f$ is structurally stable if there is a $C^r$ neighborhood of $f$ such that every $g$ in $U$ is topologically conjugate to $f$.[¶] By the work of Smale, Palis [PaSm], Robbin [Ro] and Robinson [Rob], diffeomorphisms that satisfy Smale's Axiom A and the strong transversality condition are structurally stable. Mañé [Mañ2] in general and Liao [Li] also in dimension 2 prove that in the $C^1$ topology this condition is also necessary. The $C^2$ Axiom A strong transversality diffeomorphisms also have finitely many attractors which have SRB measures. These Axiom A strong transversality diffeomorphisms are extraordinarily appealing since they have all the properties we hope for. They are fairly well understood. Yet there remain interesting questions about them. Some of the issues are discussed in [Su]. I will denote the set of Axiom A strong transversality diffeomorphisms of $M$ by $\mathrm{AS}^r(M)$.[‖]

Since topological entropy is a topological conjugacy invariant and $C^\infty$ is dense in $C^r$ the Entropy Inequality holds for all $C^r$ structurally stable diffeomorphisms. How sharp is the Entropy Inequality as a lower bound for the entropy of dynamical systems in $\mathrm{AS}^r(M)$? Smale [Sm3] proved that every isotopy class of diffeomorphisms contains an element of $\mathrm{AS}^r(M)$. Since the fundamental group can contribute information about the entropy not readable in the homology groups, we restrict ourselves to simply connected manifolds.[**]

**Problem 11.** Let $M$ be simply connected. Let $I$ be an isotopy class of diffeomorphisms of $M$. Is there a sequence of diffeomorphisms, $f_n \in I \cap \mathrm{AS}^r(M)$ such that $h(f_n) \to \ln(s(f_*))$?

If the restriction that the diffeomorphism lie in $\mathrm{AS}^r(M)$ is removed then it is even unknown whether equality may be achieved in the Entropy Inequality within every isotopy class of diffeomorphisms. There are examples where equality may not be achieved with elements of $\mathrm{AS}^r(M)$. A diffeomorphism in $\mathrm{AS}^r(M)$ with zero entropy is necessarily Morse–Smale. As a result of [ShSu2], [FrSh] and [Le], it is known that there are isotopy classes of diffeomorphisms of simply connected manifolds for which $\ln(s(f_*)) = 0$, yet there is no Morse–Smale diffeomorphism in the class. Are there diffeomorphisms in $\mathrm{AS}^r(M)$ with arbitrarily small topological entropy in these classes? If not, what is a lower bound on the entropy?

Model elements of $\mathrm{AS}^r(M)$ are constructed in every isotopy class of diffeomorphisms in [ShSu2], [Fr2], [Mal1] from information on chain complexes for $M$ and chain complex endomorphisms induced by $f$. This work is closely related to Smale's work on the structure of manifolds. See also [Sh2], [Sh3] for more discussion of this point. There are further relations between stability and homology theory established

[¶] We restrict ourselves to dynamical systems in $\mathrm{Diff}^r(M)$ even though the same concepts apply in $\mathrm{End}^r(M)$ and to structural stability as opposed to Omega stability for the sake of simplicity of exposition.

[‖] AS is a fortuitous selection of letters since Anosov, Sinai, Smale, Axiom A and Strong all begin with A and S.

[**] See Maller [Mal1], [Mal2] for non-simply connected manifolds.

in [ShWil], [RuSu] where the entropy conjecture was first proven for $C^1$ diffeomorphisms satisfying Smale's axioms. This work is also related to our next problem.

To close our discussion of structurally stable diffeomorphisms, I recall one other outstanding problem.

**Problem 12.** Are all Anosov diffeomorphisms infra-nil?

Smale [Sm2], considered the nil-manifold setting for Anosov diffeomorphisms which was later extended by example [Sh1] to infra-nil manifolds where the corresponding examples of expanding maps were considered. All expanding maps are infra-nil by the results of [Sh1], [Fr1] and Gromov [Gro1] on groups of polynomial growth. For Anosov diffeomorphisms defined on a manifold $M$, it is known that if $M$ is an infra-nil manifold then the diffeomorphism is conjugate to an affine example, [Ma2]. It is not known if all manifolds $M$ supporting Anosov diffeomorphisms are infra-nil manifolds. If one of the bundles $E^{\mathrm{s}}$ or $E^{\mathrm{u}}$ is one dimensional then problem is answered in the affirmative by [New2]. Perhaps the best results go back to [Fr1].

Questions about the classification of manifolds admitting partially hyperbolic diffeomorphisms are raised in section 20 of [PuSh5].

We end the paper by mentioning a few surveys which go into greater depth on some of the issues we have considered, [Sm2], [Fr2], [Sh1], [Sh3], [BuPuShWi], [PuSh5], [Pe3], [BoDíVi].

# Geodesics on flat surfaces

Anton Zorich*

**Abstract.** Various problems of geometry, topology and dynamical systems on surfaces as well as some questions concerning one-dimensional dynamical systems lead to the study of closed surfaces endowed with a flat metric with several cone-type singularities. In an important particular case, when the flat metric has trivial holonomy, the corresponding flat surfaces are naturally organized into families which appear to be isomorphic to moduli spaces of holomorphic one-forms.

One can obtain much information about the geometry and dynamics of an individual flat surface by studying both its orbit under the Teichmüller geodesic flow and under the linear group action on the corresponding moduli space. We apply this general principle to the study of generic geodesics and to counting of closed geodesics on a flat surface.

**Mathematics Subject Classification (2000).** Primary 57M50, 32G15; Secondary 37D40, 37D50, 30F30.

**Keywords.** Flat surface, Teichmüller geodesic flow, moduli space, asymptotic cycle, Lyapunov exponent, interval exchange transformation, renormalization.

## Introduction: families of flat surfaces as moduli spaces of Abelian differentials

Consider a collection of vectors $\vec{v}_1, \dots, \vec{v}_n$ in $\mathbb{R}^2$ and construct from these vectors a broken line in a natural way: a $j$-th edge of the broken line is represented by the vector $\vec{v}_j$. Construct another broken line starting at the same point as the initial one by taking the same vectors in the order $\vec{v}_{\pi(1)}, \dots, \vec{v}_{\pi(n)}$, where $\pi$ is some permutation of $n$ elements. By construction the two broken lines share the same endpoints; suppose that they bound a polygon like in Figure 1. Identifying the pairs of sides corresponding to the same vectors $\vec{v}_j$, $j = 1, \dots, n$, by parallel translations we obtain a surface endowed with a flat metric. (This construction follows the one in [M1].) The flat metric is nonsingular outside of a finite number of cone-type singularities corresponding to the vertices of the polygon. By construction the flat metric has trivial holonomy: a parallel transport of a vector along a closed path does not change the direction (and length) of the vector. This implies, in particular, that all cone angles are integer multiples of $2\pi$.

The polygon in our construction depends continuously on the vectors $\vec{v}_j$. This means that the combinatorial geometry of the resulting flat surface (its genus $g$, the

*The author is grateful to the MPI (Bonn) and to IHES for hospitality during the preparation of this paper.

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

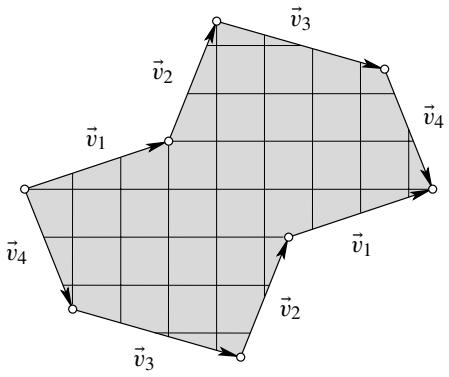

Figure 1. Identifying corresponding pairs of sides of this polygon by parallel translations we obtain a surface of genus two. It has single conical singularity with cone angle $6\pi$; the flat metric has trivial holonomy.

number $m$ and types of the resulting conical singularities) does not change under small deformations of the vectors $\vec{v}_j$. This allows to consider a flat surface as an element of a family of flat surfaces sharing common combinatorial geometry; here we do not distinguish isometric flat surfaces. As an example of such family one can consider a family of flat tori of area one, which can be identified with the space of lattices of area one:

$$\mathrm{SO}(2,\mathbb{R}) \backslash \mathrm{SL}(2,\mathbb{R}) / \mathrm{SL}(2,\mathbb{Z}) \quad = \quad \mathbb{H}^2 / \mathrm{SL}(2,\mathbb{Z})$$

The corresponding "modular surface" is not compact, see Figure 2. Flat tori representing points, which are close to the cusp, are almost degenerate: they have a very short closed geodesic. Similarly, families of flat surfaces of higher genera also form noncompact finite-dimensional orbifolds. The origin of their noncompactness is the same as for the tori: flat surfaces having short closed geodesics represent points which are close to the multidimensional "cusps".

We shall consider only those flat surfaces, which have trivial holonomy. Choosing a direction at some point of such flat surface we can transport it to any other point. It would be convenient to include the choice of direction in the definition of a flat structure. In particular, we want to distinguish the flat structure represented by the polygon in Figure 1 and the one represented by the same polygon rotated by some angle different from $2\pi$.

Consider the natural coordinate $z$ in the complex plane. In this coordinate the parallel translations which we use to identify the sides of the polygon in Figure 1 are represented as $z' = z + \mathrm{const}$. Since this correspondence is holomorphic, it means that our flat surface $S$ with punctured conical points inherits the complex structure. It is easy to check that the complex structure extends to the punctured points. Consider now a holomorphic 1-form $dz$ in the complex plane. When we pass to the surface $S$ the coordinate $z$ is not globally defined anymore. However, since the changes of

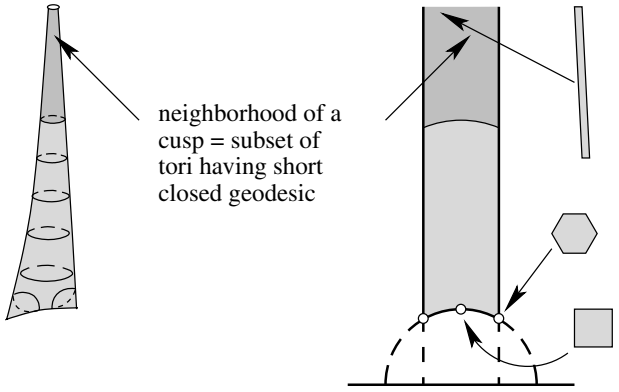

Figure 2. "Modular surface" $\mathbb{H}^2/\operatorname{SL}(2,\mathbb{Z})$ representing the space of flat tori is a noncompact orbifold of finite volume.

local coordinates are defined as $z' = z + \text{const}$, we see that $dz = dz'$. Thus, the holomorphic 1-form $dz$ on $\mathbb{C}$ defines a holomorphic 1-form $\omega$ on $S$ which in local coordinates has the form $\omega = dz$. It is easy to check that the form $\omega$ has zeroes exactly at those points of $S$ where the flat structure has conical singularities.

Reciprocally, one can show that a pair (Riemann surface, holomorphic 1-form) uniquely defines a flat structure of the type described above.

In an appropriate local coordinate $w$ a holomorphic 1-form can be represented in a neighborhood of zero as $w^d\,dw$, where $d$ is called the degree of zero. The form $\omega$ has a zero of degree $d$ at a conical point with cone angle $2\pi(d+1)$. The sum of degrees $d_1 + \cdots + d_m$ of zeroes of a holomorphic 1-form on a Riemann surface of genus $g$ equals $2g-2$. The moduli space $\mathcal{H}_g$ of pairs (complex structure, holomorphic 1-form) is a $\mathbb{C}^g$-vector bundle over the moduli space $\mathcal{M}_g$ of complex structures. The space $\mathcal{H}_g$ is naturally stratified by the strata $\mathcal{H}(d_1,\dots,d_m)$ enumerated by unordered partitions of the number $2g-2$ in a collection of positive integers $2g-2 = d_1+\cdots+d_m$. Any holomorphic 1-forms corresponding to a fixed stratum $\mathcal{H}(d_1,\dots,d_m)$ has exactly $m$ zeroes, and $d_1,\dots,d_m$ are the degrees of zeroes. Note, that an individual stratum $\mathcal{H}(d_1,\dots,d_m)$ in general does not form a fiber bundle over $\mathcal{M}_g$.

It is possible to show that if the permutation $\pi$ which was used to construct a polygon in Figure 1 satisfy some explicit conditions, vectors $\vec{v}_1,\dots,\vec{v}_n$ representing the sides of the polygon serve as coordinates in the corresponding family $\mathcal{H}(d_1,\dots,d_m)$. Consider vectors $\vec{v}_j$ as complex numbers. Let $\vec{v}_j$ join vertices $P_j$ and $P_{j+1}$ of the polygon. Denote by $\rho_j$ the resulting path on $S$ joining the points $P_j$, $P_{j+1} \in S$. Our interpretation of $\vec{v}_j$ as of a complex number implies that

$$\int_{\rho_j} \omega = \int_{P_j}^{P_{j+1}} dz = v_j \in \mathbb{C}.$$

The path $\rho_j$ represents a relative cycle: an element of the relative homology group

$H_1(S, \{P_1, \dots, P_m\}; \mathbb{Z})$ of the surface $S$ relative to the finite collection of conical points $\{P_1, \dots, P_m\}$. Relation above means that $\vec{v}_j$ represents a period of $\omega$: an integral of $\omega$ over the relative cycle $\rho_j$. In other words, a small domain in $H^1(S, \{P_1, \dots, P_m\}; \mathbb{C})$ containing $[\omega]$ can be considered as a local coordinate chart in our family $\mathcal{H}(d_1, \dots, d_m)$ of flat surfaces.

We summarize the correspondence between geometric language of flat surfaces and the complex-analytic language of holomorphic 1-forms on a Riemann surface in the dictionary below.

| Geometric language | Complex-analytic language |
|---|---|
| flat structure (including a choice of the vertical direction) | complex structure and a choice of a holomorphic 1-form $\omega$ |
| conical point with a cone angle $2\pi(d+1)$ | zero of degree $d$ of the holomorphic 1-form $\omega$ (in local coordinates $\omega = w^d\, dw$) |
| side $\vec{v}_j$ of a polygon | relative period $\int_{P_j}^{P_{j+1}} \omega = \int_{\vec{v}_j} \omega$ of the 1-form $\omega$ |
| family of flat surfaces sharing the same cone angles $2\pi(d_1+1), \dots, 2\pi(d_m+1)$ | stratum $\mathcal{H}(d_1, \dots, d_m)$ in the moduli space of Abelian differentials |
| coordinates in the family: vectors $\vec{v}_i$ defining the polygon | coordinates in $\mathcal{H}(d_1, \dots, d_m)$ : relative periods of $\omega$ in $H^1(S, \{P_1, \dots, P_m\}; \mathbb{C})$ |

Note that the vector space $H^1(S, \{P_1, \dots, P_m\}; \mathbb{C})$ contains a natural integer lattice $H^1(S, \{P_1, \dots, P_m\}; \mathbb{Z} \oplus \sqrt{-1}\,\mathbb{Z})$. Consider a linear volume element $d\nu$ in the vector space $H^1(S, \{P_1, \dots, P_m\}; \mathbb{C})$ normalized in such a way that the volume of the fundamental domain in the "cubic" lattice

$$H^1(S, \{P_1, \dots, P_m\}; \mathbb{Z} \oplus \sqrt{-1}\,\mathbb{Z}) \subset H^1(S, \{P_1, \dots, P_m\}; \mathbb{C})$$

equals one. Consider now the real hypersurface $\mathcal{H}_1(d_1, \dots, d_m) \subset \mathcal{H}(d_1, \dots, d_m)$ defined by the equation $area(S) = 1$. The volume element $d\nu$ can be naturally restricted to the hypersurface defining the volume element $d\nu_1$ on $\mathcal{H}_1(d_1, \dots, d_m)$.

**Theorem** (H. Masur; W. A. Veech). *The total volume* $\mathrm{Vol}(\mathcal{H}_1(d_1, \dots, d_m))$ *of every stratum is finite.*

The values of these volumes were computed by A. Eskin and A. Okounkov [EO].

Consider a flat surface $S$ and consider a polygonal pattern obtained by unwrapping $S$ along some geodesic cuts. For example, one can assume that our flat surface $S$ is glued from a polygon $\Pi \subset \mathbb{R}^2$ as on Figure 1. Consider a linear transformation $g \in \mathrm{GL}^+(2, \mathbb{R})$ of the plane $\mathbb{R}^2$. The sides of the new polygon $g\Pi$ are again arranged into pairs, where the sides in each pair are parallel and have equal length. Identifying the sides in each pair by a parallel translation we obtain a new flat surface $gS$ which, actually, does not depend on the way in which $S$ was unwrapped to a polygonal pattern $\Pi$. Thus, we get a continuous action of the group $\mathrm{GL}^+(2, \mathbb{R})$ on each stratum $\mathcal{H}(d_1, \dots, d_m)$.

Considering the subgroup $\mathrm{SL}(2, \mathbb{R})$ of area preserving linear transformations we get the action of $\mathrm{SL}(2, \mathbb{R})$ on the "unit hyperboloid" $\mathcal{H}_1(d_1, \dots, d_m)$. Considering the diagonal subgroup $\begin{pmatrix} e^t & 0 \\ 0 & e^{-t} \end{pmatrix} \subset \mathrm{SL}(2, \mathbb{R})$ we get a continuous action of this one-parameter subgroup on each stratum $\mathcal{H}(d_1, \dots, d_m)$. This action induces a natural flow on the stratum which is called the *Teichmüller geodesic flow*.

**Key Theorem** (H. Masur; W. A. Veech). *The actions of the groups* $\mathrm{SL}(2, \mathbb{R})$ *and* $\begin{pmatrix} e^t & 0 \\ 0 & e^{-t} \end{pmatrix}$ *preserve the measure* $d\nu_1$. *Both actions are ergodic with respect to this measure on each connected component of every stratum* $\mathcal{H}_1(d_1, \dots, d_m)$.

The following basic principle (which was first used in the pioneering works of H. Masur [M1] and of W. Veech [V1] to prove unique ergodicity of almost all interval exchange transformations) appeared to be surprisingly powerful in the study of flat surfaces. Suppose that we need some information about geometry or dynamics of an individual flat surface $S$. Consider the "point" $S$ in the corresponding family of flat surfaces $\mathcal{H}(d_1, \dots, d_m)$. Denote by $\mathcal{N}(S) = \overline{\mathrm{GL}^+(2, \mathbb{R})\, S} \subset \mathcal{H}(d_1, \dots, d_m)$ the closure of the $\mathrm{GL}^+(2, \mathbb{R})$-orbit of $S$ in $\mathcal{H}(d_1, \dots, d_m)$.

In numerous cases knowledge about the structure of $\mathcal{N}(S)$ gives a comprehensive information about geometry and dynamics of the initial flat surface $S$. Moreover, some delicate numerical characteristics of $S$ can be expressed as averages of simpler characteristics over $\mathcal{N}(S)$. We apply this general philosophy to the study of geodesics on flat surfaces.

Actually, there is a hope that this philosophy extends much further. A closure of an orbit of an abstract dynamical system might have extremely complicated structure. According to the optimistic hopes, the closure $\mathcal{N}(S)$ of a $\mathrm{GL}^+(2, \mathbb{R})$-orbit of any flat surface $S$ is a nice complex-analytic variety, and all such varieties might be classified. For genus two the latter statements were recently proved by C. McMullen (see [Mc1] and [Mc2]) and partly by K. Calta [Ca].

The following theorem supports the hope for some nice and simple description of orbit closures.

**Theorem** (M. Kontsevich). *Suppose that the closure in the stratum $\mathcal{H}(d_1, \dots, d_m)$ of a $\mathrm{GL}^+(2, \mathbb{R})$-orbit of some flat surface $S$ is a complex-analytic subvariety. Then in cohomological coordinates $H^1(S, \{P_1, \dots, P_m\}; \mathbb{C})$ this subvariety is represented by an affine subspace.*

## 1. Geodesics winding up flat surfaces

In this section we study geodesics on a flat surface $S$ going in generic directions. According to the theorem of S. Kerckhoff, H. Masur and J. Smillie [KeMS], for any flat surface $S$ the directional flow in almost any direction is uniquely ergodic. This implies, in particular, that for such directions the geodesics wind around $S$ in a relatively regular manner. Namely, it is possible to find a cycle $c \in H_1(S; \mathbb{R})$ such that a long piece of geodesic pretends to wind around $S$ repeatedly following this asymptotic cycle $c$. Rigorously it can be described as follows. Having a geodesic segment $X \subset S$ and some point $x \in X$ we emit from $x$ a geodesic transversal to $X$. From time to time the geodesic would intersect $X$. Denote the corresponding points as $x_1, x_2, \dots$. Closing up the corresponding pieces of the geodesic by joining the starting point $x_0$ and the point $x_j$ of $j$-th return to $X$ with a path going along $X$ we get a sequence of closed paths defining the cycles $c_1, c_2, \dots$. These cycles represent longer and longer pieces of the geodesic. When the direction of the geodesic is uniquely ergodic, the limit

$$\lim_{N\to\infty} \frac{1}{N}\, c_N = c$$

exists and the corresponding asymptotic cycle $c \in H_1(S; \mathbb{R})$ does not depend on the starting point $x_0 \in X$. Changing the transverse interval $X$ we get a collinear asymptotic cycle.

When $S$ is a flat torus glued from a unit square, the asymptotic cycle $c$ is a vector in $H_1(\mathbb{T}^2; \mathbb{R}) = \mathbb{R}^2$ and its slope is exactly the slope of our flat geodesic in standard coordinates. When $S$ is a surface of higher genus the asymptotic cycle belongs to a $2g$-dimensional space $H_1(S; \mathbb{R}) = \mathbb{R}^{2g}$. Let us study how the cycles $c_j$ deviate from the direction of the asymptotic cycle $c$. Choose a hyperplane $W$ in $H_1(S, \mathbb{R})$ orthogonal (transversal) to the asymptotic cycle $c$ and consider a parallel projection to this screen along $c$. Projections of the cycles $c_N$ would not be necessarily bounded: directions of the cycles $c_N$ tend to direction of the asymptotic cycle $c$ provided the norms of the projections grow sublinearly with respect to $N$.

Let us observe how the projections are distributed in the screen $W$. A heuristic answer is given by Figure 3.

We see that the distribution of projections of the cycles $c_N$ in the screen $W$ is anisotropic: the projections accumulate along some line. This means that in the original space $\mathbb{R}^{2g}$ the vectors $c_N$ deviate from the asymptotic direction $L_1$ spanned by $c$ not arbitrarily but along some two-dimensional subspace $L_2$ containing $L_1$, see

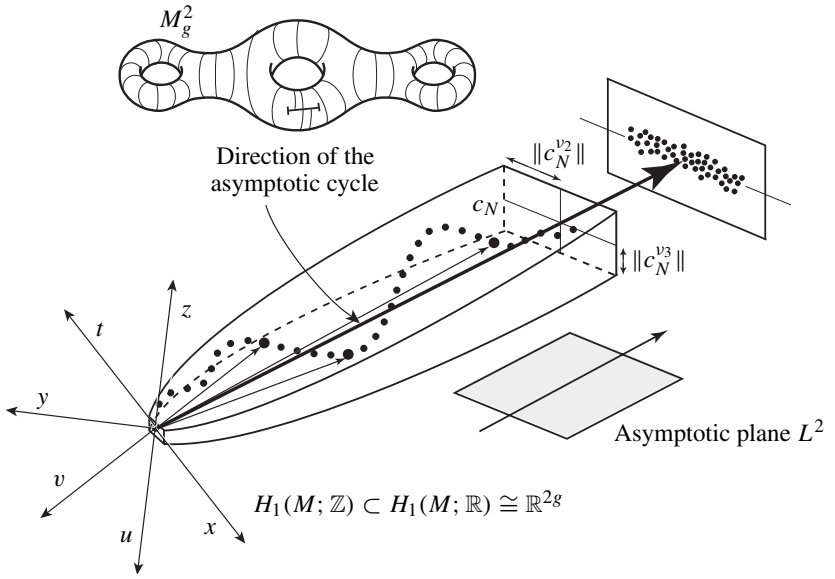

Figure 3. Deviation from the asymptotic direction exhibits anisotropic behavior: vectors deviate mainly along two-dimensional subspace, a bit more along three-dimensional subspace, etc. Their deviation from a Lagrangian $g$-dimensional subspace is already uniformly bounded.

Figure 3. Moreover, measuring the norms $\| \operatorname{proj}(c_N)\|$ of the projections we get

$$\limsup_{N\to\infty} \frac{\log \| \operatorname{proj}(c_N)\|}{\log N} = \nu_2 < 1.$$

Thus, the vector $c_N$ is located approximately in the two-dimensional plane $L_2$, and the distance from its endpoint to the line $L_1$ in $L_2$ is at most of the order $\|c_N\|^{\nu_2}$, see Figure 3.

Consider now a new screen $W_2 \perp L_2$ orthogonal to the plane $L_2$. Now the screen $W_2$ has codimension two in $H_1(S,\mathbb{R}) \simeq \mathbb{R}^{2g}$. Taking the projections of $c_N$ to $W_2$ along $L_2$ we eliminate the asymptotic directions $L_1$ and $L_2$ and we see how the vectors $c_N$ deviate from $L_2$. On the screen $W_2$ we observe the same picture as in Figure 3: the projections are again located along a one-dimensional subspace.

Coming back to the ambient space $H_1(S,\mathbb{R}) \simeq \mathbb{R}^{2g}$, this means that in the first term of approximation all vectors $c_N$ are aligned along the one-dimensional subspace $L_1$ spanned by the asymptotic cycle. In the second term of approximation, they can deviate from $L_1$, but the deviation occurs mostly in the two-dimensional subspace $L_2$, and has order $\|c_N\|^{\nu_2}$ where $\nu_2 < 1$. In the third term of approximation we see that the vectors $c_N$ may deviate from the plane $L_2$, but the deviation occurs mostly in a three-dimensional space $L_3$ and has order $\|c_N\|^{\nu_3}$ where $\nu_3 < \nu_2$.

Going on we get further terms of approximation. However, getting to a subspace $L_g$ which has half of the dimension of the ambient space we see that, in there

is no more deviation from $L_g$: the distance from any $c_N$ to $L_g$ is uniformly bounded. Note that the intersection form endows the space $H_1(S, \mathbb{R}) \simeq \mathbb{R}^{2g}$ with a natural symplectic structure. It can be checked that the resulting $g$-dimensional subspace $L_g$ is a Lagrangian subspace for this symplectic form.

A rigorous formulation of phenomena described heuristically in Figure 3 is given by the theorem below.

By convention we always consider a flat surface together with a choice of direction which is called the vertical direction, or, sometimes, "direction to the North". Using an appropriate homothethy we normalize the area of $S$ to one, so that $S \in \mathcal{H}_1(d_1, \dots, d_m)$.

We chose a point $x_0 \in S$ and a horizontal segment $X$ passing through $x_0$; by $|X|$ we denote the length of $X$. The interval $X$ is chosen in such way, that the interval exchange transformation induced by the vertical flow has the minimal possible number $n = 2g + m - 1$ of subintervals under exchange. (Actually, almost any other choice of $X$ would also work.) We consider a geodesic ray $\gamma$ emitted from $x_0$ in the vertical direction. (If $x_0$ is a saddle point, there are several outgoing vertical geodesic rays; choose any of them.) Each time when $\gamma$ intersects $X$ we join the point $x_N$ of intersection and the starting point $x_0$ along $X$ producing a closed path. We denote the homology class of the corresponding loop by $c_N$.

Let $\omega$ be the holomorphic 1-form representing $S$; let $g$ be genus of $S$. Choose some Euclidean metric in $H_1(S; \mathbb{R}) \simeq \mathbb{R}^{2g}$ which would allow to measure a distance from a vector to a subspace. Let by convention $\log(0) = -\infty$.

**Theorem 1.** *For almost any flat surface $S$ in any stratum $\mathcal{H}_1(d_1, \dots, d_m)$ there exists a flag of subspaces*

$$L_1 \subset L_2 \subset \cdots \subset L_g \subset H_1(S; \mathbb{R})$$

*in the first homology group of the surface with the following properties.*

*Choose any starting point $x_0 \in X$ in the horizontal segment $X$. Consider the corresponding sequence $c_1, c_2, \dots$ of cycles.*

*– The following limit exists:*

$$|X| \lim_{N\to\infty} \frac{1}{N} c_N = c,$$

*where the nonzero asymptotic cycle $c \in H_1(M_g^2; \mathbb{R})$ is Poincaré dual to the cohomology class of $\omega_0 = \mathrm{Re}[\omega]$, and the one-dimensional subspace $L_1 = \langle c \rangle_{\mathbb{R}}$ is spanned by $c$.*

*– For any $j = 1, \dots, g-1$ one has*

$$\limsup_{N\to\infty} \frac{\log \mathrm{dist}(c_N, L_j)}{\log N} = \nu_{j+1}$$

*and*

$$\mathrm{dist}(c_N, L_g) \leq \mathrm{const},$$

*where the constant depends only on S and on the choice of the Euclidean structure in the homology space.*

*The numbers* $2, 1 + \nu_2, \ldots, 1 + \nu_g$ *are the top g Lyapunov exponents of the Teichmüller geodesic flow on the corresponding connected component of the stratum* $\mathcal{H}(d_1, \ldots, d_m)$*; in particular, they do not depend on the individual generic flat surface S in the connected component.*

It should be stressed, that the theorem above was formulated in [Z3] as a conditional statement: under the conjecture that $\nu_g > 0$ there exist a Lagrangian subspace $L_g$ such that the cycles are in a bounded distance from $L_g$; under the further conjecture that all the exponents $\nu_j$, for $j = 2, \ldots, g$, are distinct, there is a complete Lagrangian flag (i.e. the dimensions of the subspaces $L_j$, where $j = 1, 2, \ldots, g$, rise each time by one). These two conjectures were later proved by G. Forni [Fo1] and by A. Avila and M. Viana [AvVi] correspondingly.

Currently there are no methods of calculation of individual Lyapunov exponents $\nu_j$ (though there is some experimental knowledge of their approximate values). Nevertheless, for any connected component of any stratum (and, more generally, for any $\mathrm{GL}^+(2;\mathbb{R})$-invariant suborbifold) it is possible to evaluate the *sum* of the Lyapunov exponents $\nu_1 + \cdots + \nu_g$, where $g$ is the genus. The formula for this sum was discovered by M. Kontsevich; morally, it is given in terms of characteristic numbers of some natural vector bundles over the strata $\mathcal{H}(d_1, \ldots, d_m)$, see [K]. Another interpretation of this formula was found by G. Forni [Fo1]; see also a very nice formalization of these results in the survey of R. Krikorian [Kr]. For some special $\mathrm{GL}^+(2;\mathbb{R})$-invariant suborbifolds the corresponding vector bundles might have equivariant subbundles, which provides additional information on corresponding subcollections of the Lyapunov exponents, or even gives their explicit values in some cases, like in the case of Teichmüller curves considered in the paper of I. Bouw and M. Möller [BMö].

Theorem 1 illustrates a phenomenon of *deviation spectrum*. It was proved by G. Forni in [Fo1] that ergodic sums of smooth functions on an interval along trajectories of interval exchange transformations, and ergodic integrals of smooth functions on flat surfaces along trajectories of directional flows have deviation spectrum analogous to the one described in Theorem 1. L. Flaminio and G. Forni showed that the same phenomenon can be observed for other parabolic dynamical systems, for example, for the horocycle flow on compact surfaces of constant negative curvature [FlFo].

**Idea of the proof: renormalization.** The reason why the deviation of the cycles $c_j$ from the asymptotic direction is governed by the Teichmüller geodesic flow is illustrated in Figure 4. In a sense, we follow the initial ideas of H. Masur [M1] and of W. Veech [V1].

Fix a horizontal segment $X$ and emit a vertical trajectory from some point $x$ in $X$. When the trajectory intersects $X$ for the first time join the corresponding point $T(x)$ to the original point $x$ along $X$ to obtain a closed loop. Here $T\colon X \to X$

denotes the first return map to the transversal $X$ induced by the vertical flow. Denote by $c(x)$ the corresponding cycle in $H_1(S;\mathbb{Z})$. Let the interval exchange transformation $T\colon X \to X$ decompose $X$ into $n$ subintervals $X_1 \sqcup \cdots \sqcup X_n$. It is easy to see that the "first return cycle" $c(x)$ is piecewise constant: we have $c(x) = c(x') =: c(X_j)$ whenever $x$ and $x'$ belong to the same subinterval $X_j$, see Figure 4. It is easy to see that

$$c_N(x) = c(x) + c(T(x)) + \cdots + c(T^{N-1}(x)).$$

The average of this sum with respect to the "time" $N$ tends to the asymptotic cycle $c$. We need to study the deviation of this sum from the value $N \cdot c$. To do this consider a shorter subinterval $X'$ as in Figure 4. Its length is chosen in such way, that the first return map of the vertical flow again induces an interval exchange transformation $T'\colon X' \to X'$ of $n$ subintervals. New first return cycles $c'(X'_k)$ to the interval $X'$ are expressed in terms of the initial first return cycles $c(X_j)$ by the linear relations below; the lengths $|X'_k|$ of subintervals of the new partition $X' = X'_1 \sqcup \cdots \sqcup X'_m$ are expressed in terms of the lengths $|X_j|$ of subintervals of the initial partition by dual linear relations:

$$c'(X'_k) = \sum_{j=1}^{n} A_{jk} \cdot c(X_j), \quad |X_j| = \sum_{k=1}^{n} A_{jk} \cdot |X'_k|,$$

where a nonnegative integer matrix $A_{jk}$ is completely determined by the initial interval exchange transformation $T\colon X \to X$ and by the choice of $X' \subset X$.

To construct the cycle $c_N$ representing a long piece of leaf of the vertical foliation we followed the trajectory $x, T(x), \ldots, T^{N-1}(x)$ of the initial interval exchange transformation $T\colon X \to X$ and computed the corresponding ergodic sum. Passing to a shorter horizontal interval $X' \subset X$ we can follow the trajectory $x, T'(x), \ldots, (T')^{N'-1}(x)$ of the new interval exchange transformation $T'\colon X' \to X'$ (provided $x \in X'$). Since the subinterval $X'$ is shorter than $X$ we cover the initial piece of trajectory of the vertical flow in a smaller number $N'$ of steps. In other words, passing from $T$ to $T'$ we accelerate the time: it is easy to see that the trajectory $x, T'(x), \ldots, (T')^{N'-1}(x)$ follows the trajectory $x, T(x), \ldots, T^{N-1}(x)$ but jumps over several iterations of $T$ at a time.

This approach would not be efficient if the new first return map $T'\colon X' \to X'$ would be more complicated than the initial one. But we know that passing from $T$ to $T'$ we stay within a family of interval exchange transformations of some fixed number $n$ of subintervals, and, moreover, that the new "first return cycles" $c'(X'_k)$ and the lengths $|X'_k|$ of the new subintervals are expressed in terms of the initial ones by means of the $n \times n$-matrix $A$, which depends only on the choice of $X' \subset X$ and which can be easily computed.

Our strategy can be now formulated as follows. One can define an explicit algorithm (generalizing Euclidean algorithm) which canonically associates to an interval exchange transformation $T\colon X \to X$ some specific subinterval $X' \subset X$ and, hence,

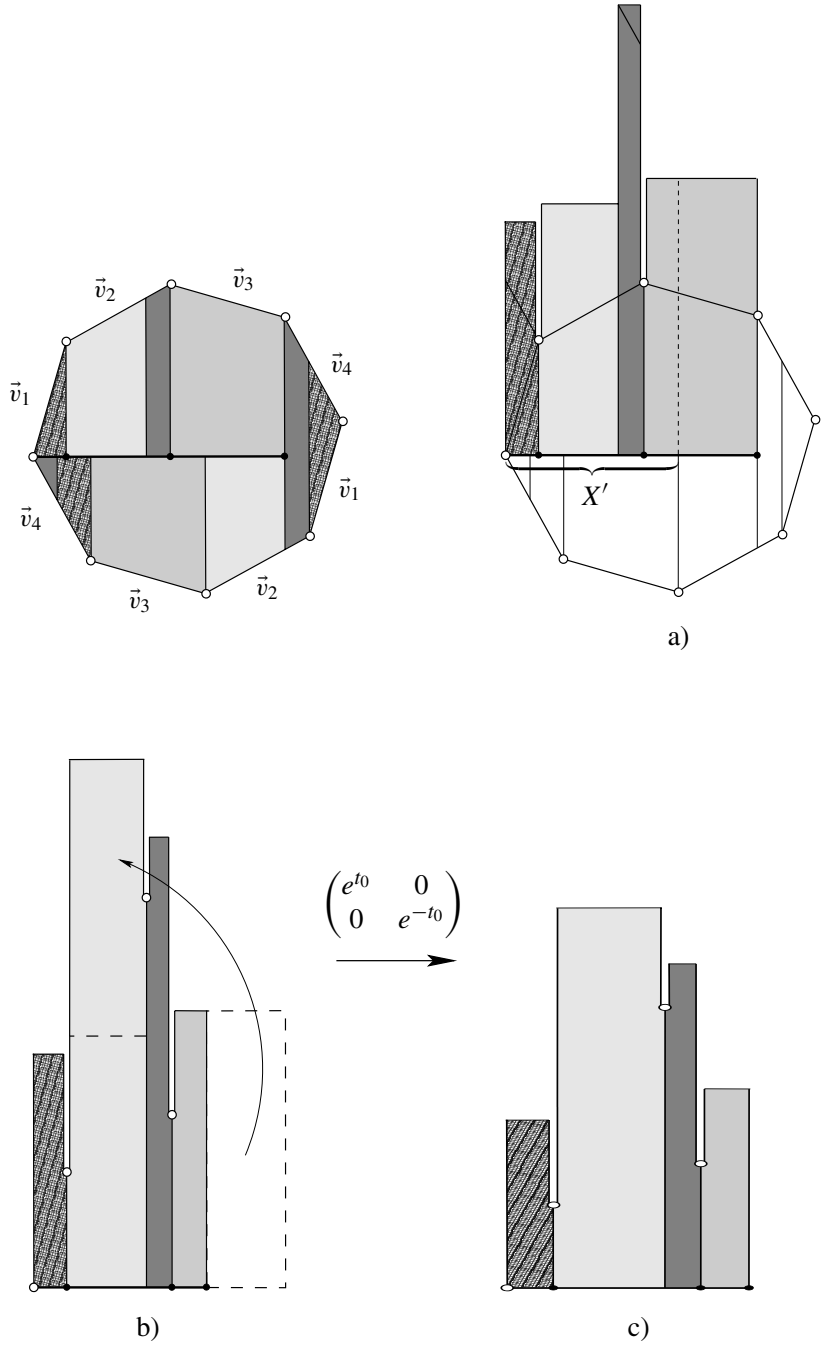

Figure 4. Idea of renormalization. a) Unwrap the flat surface into "zippered rectangles". b) Shorten the base of the corresponding zippered rectangles. c) Expand the resulting tall and narrow zippered rectangle horizontally and contract it vertically by same factor $e^{t_0}$.

a new interval exchange transformation $T'\colon X' \to X'$. Similarly to the Euclidean algorithm our algorithm is invariant under proportional rescaling of $X$ and $X'$, so, when we find it convenient, we can always rescale the length of the interval to one. This algorithm can be considered as a map $\mathcal{T}$ from the space of all interval exchange transformations of a given number $n$ of subintervals to itself. Applying recursively this algorithm we construct a sequence of subintervals $X = X^{(0)} \supset X^{(1)} \supset X^{(2)} \supset \cdots$ and a sequence of matrices $A = A(T^{(0)}), A(T^{(1)}), \ldots$ describing transitions form interval exchange transformation $T^{(r)}\colon X^{(r)} \to X^{(r)}$ to interval exchange transformation $T^{(r+1)}\colon X^{(r+1)} \to X^{(r+1)}$. Taking a product $A^{(s)} = A(T^{(0)}) \cdot A(T^{(1)}) \ldots A(T^{(s-1)})$ we can immediately express the "first return cycles" to a microscopic subinterval $X^{(s)}$ in terms of the initial "first return cycles" to $X$. Considering now the matrices $A$ as the values of a matrix-valued function on the space of interval exchange transformations, we realize that we study the products of matrices $A$ along the orbits $T^{(0)}, T^{(1)}, \ldots, T^{(s-1)}$ of the map on the space of interval exchange transformations. When the map is ergodic with respect to a finite measure, the properties of these products are described by the Oseledets theorem, and the cycles $c_N$ have a deviation spectrum governed by the Lyapunov exponents of the cocycle $A$ on the space of interval exchange transformations.

Note that the first return cycle to the subinterval $X^{(s)}$ (which is very short) represents the cycle $c_N$ corresponding to a very long trajectory $x, T(x), \ldots, T^{N-1}(x)$ of the initial interval exchange transformation. In other words, our renormalization procedure $\mathcal{T}$ plays a role of a time acceleration machine: morally, instead of getting the cycle $c_N$ by following a trajectory $x, T(x), \ldots, T^{N-1}(x)$ of the initial interval exchange transformation for the exponential time $N \sim \exp(\text{const} \cdot s)$ we obtain the cycle $c_N$ applying only $s$ steps of the renormalization map $\mathcal{T}$ on the space of interval exchange transformations.

It remains to establish the relation between the cocycle $A$ over the map $\mathcal{T}$ and the Teichmüller geodesic flow. Conceptually, this relation was elaborated in the original paper of W. Veech [V1].

First let us discuss how can one "almost canonically" (that is up to a finite ambiguity) choose a zippered rectangles representation of a flat surface. Note that Figure 4 suggests the way which allows to obtain infinitely many zippered rectangles representations of the same flat surface: we chop an appropriate rectangle on the right, put it atop the corresponding rectangle and then repeat the procedure recursively. This resembles the situation with a representation of a flat torus by a parallelogram: a point of the fundamental domain in Figure 2 provides a canonical representative though any point of the corresponding $\mathrm{SL}(2, \mathbb{Z})$-orbit represents the same flat torus. A "canonical" zippered rectangles decomposition of a flat surface also belongs to some fundamental domain. Following W. Veech one can define the fundamental domain in terms of some specific choice of a "canonical" horizontal interval $X$. Namely, let us position the left endpoint of $X$ at a conical singularity. Let us choose the length of $X$ in such way that the interval exchange transformation $T\colon X \to X$ induced by the first return of the vertical flow to $X$ has minimal possible number $n = 2g + m - 1$

of subintervals under exchange. Among all such horizontal segments $X$ choose the shortest one, which length is greater than or equal to one. This construction is applicable to almost all flat surfaces; the finite ambiguity corresponds to the finite freedom in the choice of the conical singularity and in the choice of the horizontal ray adjacent to it.

Since the interval $X$ defines a decomposition of (almost any) flat surface into "zippered rectangles" (see Figure 4) we can pass from the space of flat surfaces to the space of zippered rectangles (which can be considered as a finite ramified covering over the space of flat surfaces). Teichmüller geodesic flow lifts naturally to the space of zippered rectangles. It acts on zippered rectangles by expansion in horizontal direction and contraction in vertical direction; i.e. the zippered rectangles are modified by linear transformations $\begin{pmatrix} e^t & 0 \\ 0 & e^{-t} \end{pmatrix}$. However, as soon as the Teichmüller geodesic flow brings us out of the fundamental domain, we have to modify the zippered rectangles decomposition to the "canonical one" corresponding to the fundamental domain. (Compare to Figure 2 where the Teichmüller geodesic flow corresponds to the standard geodesic flow in the hyperbolic metric on the upper half-plane.) The corresponding modification of zippered rectangles (chop an appropriate rectangle on the right, put it atop the corresponding rectangle; repeat the procedure several times, if necessary) is illustrated in Figure 4.

Now everything is ready to establish the relation between the Teichmüller geodesic flow and the map $\mathcal{T}$ on the space of interval exchange transformations.

Consider some codimension one subspace $\Upsilon$ in the space of zippered rectangles transversal to the Teichmüller geodesic flow. Say, $\Upsilon$ might be defined by the requirement that the base $X$ of the zippered rectangles decomposition has length one, $|X| = 1$. This is the choice in the original paper of W. Veech [V1]; under this choice $\Upsilon$ represents part of the boundary of the fundamental domain in the space of zippered rectangles. Teichmüller geodesic flow defines the first return map $\mathcal{S}\colon \Upsilon \to \Upsilon$ to the section $\Upsilon$. The map $\mathcal{S}$ can be described as follows. Take a flat surface of unit area decomposed into zippered rectangles $Z$ with the base $X$ of length one. Apply expansion in horizontal direction and contraction in vertical direction. For some $t_0(Z)$ the deformed zippered rectangles can be rearranged as in Figure 4 to get back to the base of length one; the result is the image of the map $\mathcal{S}$. Actually, we can first apply the rearrangement as in Figure 4 to the initial zippered rectangles $Z$ and then apply the transformation $\begin{pmatrix} e^{t_0} & 0 \\ 0 & e^{-t_0} \end{pmatrix}$ – the two operations commute. This gives, in particular, an explicit formula for $t_0(Z)$. Namely let $|X_n|$ be the width of the rightmost rectangle and let $|X_k|$ be the width of the rectangle, which top horizontal side is glued to the rightmost position at the base $X$. (For the upper zippered rectangle decomposition in Figure 4 we have $n = 4$ and $k = 2$.) Then

$$t_0 = -\log\bigl(1 - \min(|X_n|, |X_k|)\bigr).$$

Recall that a decomposition of a flat surface into zippered rectangles naturally defines an interval exchange transformation – the first return map of the vertical flow

to the base $X$ of zippered rectangles. Hence, the map $\mathcal{S}$ of the subspace $\Upsilon$ of zippered rectangles defines an induced map on the space of interval exchange transformations. It remains to note that this induced map is exactly the map $\mathcal{T}$. In other words, the map $\mathcal{S}\colon \Upsilon \to \Upsilon$ induced by the first return of the Teichmüller geodesic flow to the subspace $\Upsilon$ of zippered rectangles is the suspension of the map $\mathcal{T}$ on the space of interval exchange transformations.

We complete with a remark concerning the choice of a section. The natural section $\Upsilon$ chosen in the original paper of W. Veech [V1] is in a sense too large: the corresponding invariant measure (induced from the measure on the space of flat surfaces) is infinite. Choosing an appropriate subset $\Upsilon' \subset \Upsilon$ one can get finite invariant measure. Moreover, the subset $\Upsilon'$ can be chosen in such way that the corresponding first return map $\mathcal{S}'\colon \Upsilon' \to \Upsilon'$ of the Teichmüller geodesic flow is a suspension of some natural map $\mathcal{G}$ on the space of interval exchange transformations, see [Z1]. According to the results of H. Masur [M1] and W. Veech [V1] the Teichmüller geodesic flow is ergodic which implies ergodicity of the maps $\mathcal{S}'$ and $\mathcal{G}$. To apply Oseledets theorem one should, actually, consider the induced cocycle $B$ over this new map $\mathcal{G}$ instead of the cocycle $A$ over the map $\mathcal{T}$ described above.

## 2. Closed geodesics on flat surfaces

Consider a flat surface $S$; we always assume that the flat metric on $S$ has trivial holonomy, and that the surface $S$ has finite number of cone-type singularities. By convention a flat surface is endowed with a choice of direction, refereed to as a "vertical direction", or as a "direction to the North". Since the flat metric has trivial holonomy, this direction can be transported in a unique way to any point of the surface.

A geodesic segment joining two conical singularities and having no conical points in its interior is called *saddle connection*. The case when boundaries of a saddle connection coincide is not excluded: a saddle connection might join a conical point to itself. In this section we study saddle connections and closed regular geodesics on a generic flat surface $S$ of genus $g \geq 2$. In particular, we count them and we explain the following curious phenomenon: saddle connections and closed regular geodesics often appear in pairs, triples, etc of parallel saddle connections (correspondingly closed regular geodesics) of the same direction and length. When all saddle connections (closed regular geodesics) in such configuration are short the corresponding flat surface is almost degenerate; it is located close to the boundary of the moduli space. A description of possible configurations of parallel saddle connections (closed geodesics) gives us a description of the multidimensional "cusps" of the strata.

The results of this section are based on the joint work with A. Eskin and H. Masur [EMZ] and on their work [MZ]. A series of beautiful results developing the counting problems considered here were recently obtained by Ya. Vorobets [Vo].

**Counting closed geodesics and saddle connections.** Closed geodesics on flat surfaces of higher genera have some similarities with ones on the torus. Suppose that we have a regular closed geodesic passing through a point $x_0 \in S$. Emitting a geodesic from a nearby point $x$ in the same direction we obtain a parallel closed geodesic of the same length as the initial one. Thus, closed geodesics appear in families of parallel closed geodesics. However, in the torus case every such family fills the entire torus while a family of parallel regular closed geodesics on a flat surfaces of higher genus fills only part of the surface. Namely, it fills a flat cylinder having a conical singularity on each of its boundaries. Typically, a maximal cylinder of closed regular geodesics is bounded by a pair of closed saddle connections. Reciprocally, any saddle connection joining a conical point $P$ to itself and coming back to $P$ at the angle $\pi$ bounds a cylinder filled with closed regular geodesics.

A geodesic representative of a homotopy class of a curve on a flat surface is realized in general by a broken line of geodesic segments with vertices at conical points. By convention we consider only closed *regular* geodesics (which by definition do not pass through conical points) or saddle connections (which by definition do not have conical points in its interior). Everywhere in this section we normalize the area of a flat surface to one.

Let $N_{\mathrm{sc}}(S, L)$ be the number of saddle connections of length at most $L$ on a flat surface $S$. Let $N_{\mathrm{cg}}(S, L)$ be the number of maximal cylinders filled with closed regular geodesics of length at most $L$ on $S$. It was proved by H. Masur that for any flat surface $S$ both counting functions $N(S, L)$ grow quadratically in $L$. Namely, there exist constants $0 < \mathrm{const}_1(S) < \mathrm{const}_2(S) < \infty$ such that

$$\mathrm{const}_1(S) \leq N(S, L)/L^2 \leq \mathrm{const}_2(S)$$

for $L$ sufficiently large. Recently Ya. Vorobets has obtained uniform estimates for the constants $\mathrm{const}_1(S)$ and $\mathrm{const}_2(S)$ which depend only on the genus of $S$, see [Vo]. Passing from *all* flat surfaces to *almost all* surfaces in a given connected component of a given stratum one gets a much more precise result, see [EM]:

**Theorem** (A. Eskin and H. Masur). *For almost all flat surfaces $S$ in any stratum $\mathcal{H}(d_1, \ldots, d_m)$ the counting functions $N_{\mathrm{sc}}(S, L)$ and $N_{\mathrm{cg}}(S, L)$ have exact quadratic asymptotics*

$$\lim_{L\to\infty} \frac{N_{\mathrm{sc}}(S, L)}{\pi L^2} = c_{\mathrm{sc}}(S), \quad \lim_{L\to\infty} \frac{N_{\mathrm{cg}}(S, L)}{\pi L^2} = c_{\mathrm{cg}}(S).$$

*Moreover, the Siegel–Veech constants $c_{\mathrm{sc}}(S)$ (correspondingly $c_{\mathrm{cg}}(S)$) coincide for almost all flat surfaces $S$ in each connected component $\mathcal{H}_1^{\mathrm{comp}}(d_1, \ldots, d_m)$ of the stratum.*

**Phenomenon of higher multiplicities.** Note that the direction to the North is well-defined even at a conical point of a flat surface, moreover, at a conical point $P_1$ with

a cone angle $2\pi k$ we have $k$ different directions to the North! Consider some saddle connection $\gamma_1 = [P_1 P_2]$ with an endpoint at $P_1$. Memorize its direction, say, let it be the North–West direction. Let us launch a geodesic from the same starting point $P_1$ in one of the remaining $k-1$ North–West directions. Let us study how big is the chance to hit $P_2$ ones again, and how big is the chance to hit it after passing the same distance as before. We do not exclude the case $P_1 = P_2$. Intuitively it is clear that the answer to the first question is: "the chances are low" and to the second one is "the chances are even lower". This makes the following theorem (see [EMZ]) somehow counterintuitive:

**Theorem 2** (A. Eskin, H. Masur, A. Zorich). *For almost any flat surface $S$ in any stratum and for any pair $P_1$, $P_2$ of conical singularities on $S$ the function $N_2(S, L)$ counting the number of pairs of parallel saddle connections of the same length joining $P_1$ to $P_2$ has exact quadratic asymptotics*

$$\lim_{L\to\infty} \frac{N_2(S, L)}{\pi L^2} = c_2 > 0,$$

*where the Siegel–Veech constant $c_2$ depends only on the connected component of the stratum and on the cone angles at $P_1$ and $P_2$.*

*For almost all flat surfaces $S$ in any stratum one cannot find neither a single pair of parallel saddle connections on $S$ of different length, nor a single pair of parallel saddle connections joining different pairs of singularities.*

Analogous statements (with some reservations for specific connected components of certain strata) can be formulated for arrangements of $3, 4, \dots$ parallel saddle connections. The situation with closed regular geodesics is similar: they might appear (also with some exceptions for specific connected components of certain strata) in families of $2, 3, \dots, g-1$ distinct maximal cylinders filled with parallel closed regular geodesics of equal length. A general formula for the Siegel–Veech constant in the corresponding quadratic asymptotics is presented at the end of this section, while here we want to discuss the numerical values of Siegel–Veech constants in a simple concrete example. We consider the principal strata $\mathcal{H}(1, \dots, 1)$ in small genera. Let $N_{k\_\mathrm{cyl}}(S, L)$ be the corresponding counting function, where $k$ is the number of distinct maximal cylinders filled with parallel closed regular geodesics of equal length bounded by $L$. Let

$$c_{k\_\mathrm{cyl}} = \lim_{L\to\infty} \frac{N_{k\_\mathrm{cyl}}(S, L)}{\pi L^2}.$$

The table below (extracted from [EMZ]) presents the values of $c_{k\_\mathrm{cyl}}$ for $g = 1, \dots, 4$. Note that for a generic flat surface $S$ of genus $g$ a configuration of $k \geq g$ cylinders is not realizable, so we do not fill the corresponding entry.

| $k$ | $g=1$ | $g=2$ | $g=3$ | $g=4$ |
|---|---|---|---|---|
| 1 | $\frac{1}{2}\cdot\frac{1}{\zeta(2)}\approx 0.304$ | $\frac{5}{2}\cdot\frac{1}{\zeta(2)}\approx 1.52$ | $\frac{36}{7}\cdot\frac{1}{\zeta(2)}\approx 3.13$ | $\frac{3150}{377}\cdot\frac{1}{\zeta(2)}\approx 5.08$ |
| 2 | – | – | $\frac{3}{14}\cdot\frac{1}{\zeta(2)}\approx 0.13$ | $\frac{90}{377}\cdot\frac{1}{\zeta(2)}\approx 0.145$ |
| 3 | – | – | – | $\frac{5}{754}\cdot\frac{1}{\zeta(2)}\approx 0.00403$ |

Comparing these values we see, that our intuition was not quite misleading. Morally, in genus $g = 4$ a closed regular geodesic belongs to a one-cylinder family with "probability" 97.1%, to a two-cylinder family with "probability" 2.8% and to a three-cylinder family with "probability" only 0.1% (where "probabilities" are calculated proportionally to the Siegel–Veech constants $5.08 : 0.145 : 0.00403$).

**Rigid configurations of saddle connections and "cusps" of the strata.** A saddle connection or a regular closed geodesic on a flat surface $S$ persists under small deformations of $S$ inside the corresponding stratum. It might happen that any deformation of a given flat surface which shortens some specific saddle connection necessarily shortens some other saddle connections. We say that a collection $\{\gamma_1, \dots, \gamma_n\}$ of saddle connections is *rigid* if any sufficiently small deformation of the flat surface inside the stratum preserves the proportions $|\gamma_1| : |\gamma_2| : \cdots : |\gamma_n|$ of the lengths of all saddle connections in the collection. It was shown in [EMZ] that all saddle connections in any rigid collection are *homologous*. Since their directions and lengths can be expressed in terms of integrals of the holomorphic 1-form $\omega$ along corresponding paths, this implies that homologous saddle connections $\gamma_1, \dots, \gamma_n$ are parallel and have equal length and either all of them join the same pair of distinct singular points, or all $\gamma_i$ are closed loops.

This implies that when saddle connections in a rigid collection are contracted by a continuous deformation, the limiting flat surface generically decomposes into several connected components represented by nondegenerate flat surfaces $S'_1, \dots, S'_k$, see Figure 5, where $k$ might vary from one to the genus of the initial surface. Let the initial surface $S$ belong to a stratum $\mathcal{H}(d_1, \dots, d_m)$. Denote the set with multiplicities $\{d_1, \dots, d_m\}$ by $\beta$. Let $\mathcal{H}(\beta'_j)$ be the stratum ambient for $S'_j$. The stratum $\mathcal{H}(\beta') = \mathcal{H}(\beta'_1) \sqcup \cdots \sqcup \mathcal{H}(\beta'_k)$ of disconnected flat surfaces $S'_1 \sqcup \cdots \sqcup S'_k$ is referred to as a *principal boundary* stratum of the stratum $\mathcal{H}(\beta)$. For any connected component of any stratum $\mathcal{H}(\beta)$ the paper [EMZ] describes all principal boundary strata; their

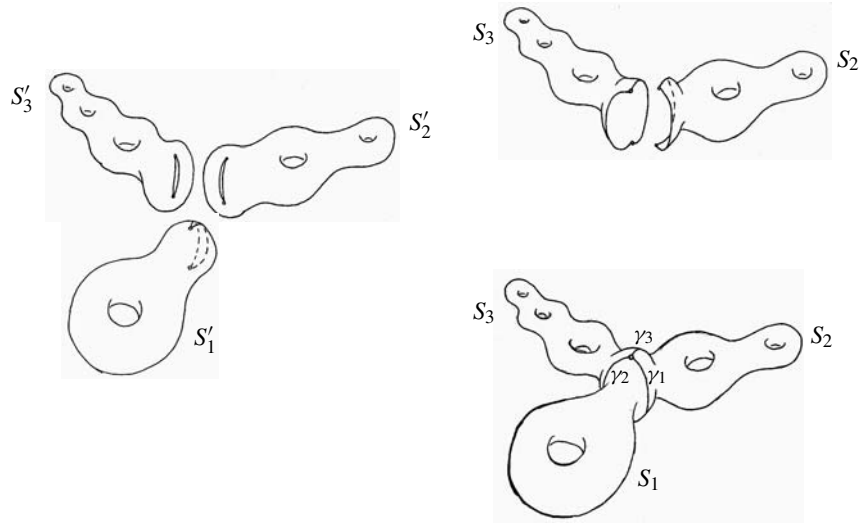

Figure 5. Multiple homologous saddle connections, topological picture (after [EMZ]).

union is called the principal boundary of the corresponding connected component of $\mathcal{H}(\beta)$.

The paper [EMZ] also presents the inverse construction. Consider any flat surface $S'_1 \sqcup \cdots \sqcup S'_k \in \mathcal{H}(\beta')$ in the principal boundary of $\mathcal{H}(\beta)$; consider a sufficiently small value of a complex parameter $\varepsilon \in \mathbb{C}$. One can reconstruct the flat surface $S \in \mathcal{H}(\beta)$ endowed with a collection of homologous saddle connections $\gamma_1, \ldots, \gamma_n$ such that $\int_{\gamma_i} \omega = \varepsilon$, and such that degeneration of $S$ contracting the saddle connections $\gamma_i$ in the collection gives the surface $S'_1 \sqcup \cdots \sqcup S'_k$. This inverse construction involves several surgeries of the flat structure. Having a disconnected flat surface $S'_1 \sqcup \cdots \sqcup S'_k$ one applies an appropriate surgery to each $S'_j$ producing a surface $S_j$ with boundary. The surgery depends on the parameter $\varepsilon$: the boundary of each $S_j$ is composed from two geodesic segments of lengths $|\varepsilon|$; moreover, the boundary components of $S_j$ and $S_{j+1}$ are compatible, which allows to glue the compound surface $S$ from the collection of surfaces with boundary, see Figure 5 as an example.

A collection $\gamma = \{\gamma_1, \ldots, \gamma_n\}$ of homologous saddle connections determines the following data on combinatorial geometry of the decomposition $S \setminus \gamma$: the number of components, their boundary structure, the singularity data for each component, the cyclic order in which the components are glued to each other. These data are referred to as a *configuration* of homologous saddle connections. A configuration $\mathcal{C}$ uniquely determines the corresponding boundary stratum $\mathcal{H}(\beta'_{\mathcal{C}})$; it does not depend on the collection $\gamma$ of homologous saddle connections representing the configuration $\mathcal{C}$.

The constructions above explain how configurations $\mathcal{C}$ of homologous saddle connections on flat surfaces $S \in \mathcal{H}(\beta)$ determine the "cusps" of the stratum $\mathcal{H}(\beta)$. Consider a subset $\mathcal{H}^{\varepsilon}_1(\beta) \subset \mathcal{H}(\beta)$ of surfaces of area one having a saddle connec-

tion shorter than $\varepsilon$. Up to a subset $\mathcal{H}_1^{\varepsilon,\text{thin}}(\beta)$ of negligibly small measure the set $\mathcal{H}_1^{\varepsilon,\text{thick}}(\beta) = \mathcal{H}_1^{\varepsilon}(\beta) \setminus \mathcal{H}_1^{\varepsilon,\text{thin}}(\beta)$ might be represented as a disjoint union

$$\mathcal{H}_1^{\varepsilon,\text{thick}}(\beta) \approx \bigsqcup_{\mathcal{C}} \mathcal{H}_1^{\varepsilon}(\mathcal{C})$$

of neighborhoods $\mathcal{H}_1^{\varepsilon}(\mathcal{C})$ of the corresponding "cusps" $\mathcal{C}$. Here $\mathcal{C}$ runs over a finite set of configurations admissible for the given stratum $\mathcal{H}_1(\beta)$; this set is explicitly described in [EMZ].

When a configuration $\mathcal{C}$ is composed from homologous saddle connections joining *distinct* zeroes, the neighborhood $\mathcal{H}_1^{\varepsilon}(\mathcal{C})$ of the cusp $\mathcal{C}$ has the structure of a fiber bundle over the corresponding boundary stratum $\mathcal{H}(\beta'_{\mathcal{C}})$ (up to a difference in a set of a negligibly small measure). A fiber of this bundle is represented by a finite cover over the Euclidean disc of radius $\varepsilon$ ramified at the center of the disc. Moreover, the canonical measure in $\mathcal{H}_1^{\varepsilon}(\mathcal{C})$ decomposes into a product measure of the canonical measure in the boundary stratum $\mathcal{H}(\beta'_{\mathcal{C}})$ and the Euclidean measure in the fiber (see [EMZ]), so

$$\text{Vol}\left(\mathcal{H}_1^{\varepsilon}(\mathcal{C})\right) = (\text{combinatorial factor}) \cdot \pi\varepsilon^2 \cdot \prod_{j=1}^{k} \text{Vol}\,\mathcal{H}_1(\beta'_j) \;+\; o(\varepsilon^2). \qquad (1)$$

**Remark.** We warn the reader that the correspondence between compactification of the moduli space of Abelian differentials and the Deligne–Mumford compactification of the underlying moduli space of curves is not straightforward. In particular, the desingularized stable curve corresponding to the limiting flat surface generically *is not* represented as a union of Riemann surfaces corresponding to $S'_1, \ldots, S'_k$ – the stable curve might contain more components.

**Evaluation of the Siegel–Veech constants.** Consider a flat surface $S$. To every closed regular geodesic $\gamma$ on $S$ we can associate a vector $\vec{v}(\gamma)$ in $\mathbb{R}^2$ having the length and the direction of $\gamma$. In other words, $\vec{v} = \int_\gamma \omega$, where we consider a complex number as a vector in $\mathbb{R}^2 \simeq \mathbb{C}$. Applying this construction to all closed regular geodesic on $S$ we construct a discrete set $V(S) \subset \mathbb{R}^2$. Consider the following operator $f \mapsto \hat{f}$ from functions with compact support on $\mathbb{R}^2$ to functions on a connected component $\mathcal{H}_1^{\text{comp}}(\beta)$ of the stratum $\mathcal{H}_1(\beta) = \mathcal{H}_1(d_1, \ldots, d_m)$:

$$\hat{f}(S) := \sum_{\vec{v} \in V(S)} f(\vec{v}).$$

Function $\hat{f}(S)$ generalizes the counting function $N_{\text{cg}}(S, L)$ introduced in the beginning of this section. Namely, when $f = \chi_L$ is the characteristic function $\chi_L$ of the disc of radius $L$ with the center at the origin of $\mathbb{R}^2$, the function $\hat{\chi}_L(S)$ counts the number of regular closed geodesics of length at most $L$ on a flat surface $S$.

**Theorem** (W. Veech). *For any function $f\colon \mathbb{R}^2 \to \mathbb{R}$ with compact support the following equality is valid:*

$$\frac{1}{\operatorname{Vol} \mathcal{H}_1^{\mathrm{comp}}(\beta)} \int_{\mathcal{H}_1^{\mathrm{comp}}(\beta)} \hat{f}(S)\, dv_1 = C \int_{\mathbb{R}^2} f(x, y)\, dx\, dy, \tag{2}$$

*where the constant $C$ does not depend on the function $f$.*

Note that this is an exact equality. In particular, choosing the characteristic function $\chi_L$ of a disc of radius $L$ as a function $f$ we see that for any positive $L$ the *average* number of closed regular geodesics not longer than $L$ on flat surfaces $S \in \mathcal{H}_1^{\mathrm{comp}}(\beta)$ is exactly $C \cdot \pi L^2$, where the Siegel–Veech constant $C$ does not depend on $L$, but only on the connected component $\mathcal{H}_1^{\mathrm{comp}}(\beta)$.

The theorem of Eskin and Masur cited above tells that for large values of $L$ one gets approximate equality $\hat{\chi}_L(S) \approx c_{\mathrm{cg}} \cdot \pi L^2$ "pointwisely" for almost all individual flat surfaces $S \in \mathcal{H}_1^{\mathrm{comp}}(d_1, \dots, d_m)$. It is proved in [EM] that the corresponding Siegel–Veech constant $c_{\mathrm{cg}}$ coincides with the constant $C$ in equation (2) above.

Actually, the same technique can be applied to count separately pairs, triples, or any other specific configurations $\mathcal{C}$ of homologous saddle connections. Every time when we find a collection of homologous saddle connections $\gamma_1, \dots, \gamma_n$ representing the chosen configuration $\mathcal{C}$ we construct a vector $\vec{v} = \int_{\gamma_i} \omega$. Since all $\gamma_1, \dots, \gamma_n$ are homologous, we can take any of them as $\gamma_i$. Taking all possible collections of homologous saddle connections on $S$ representing the fixed configuration $\mathcal{C}$ we construct new discrete set $V_{\mathcal{C}}(S) \subset \mathbb{R}^2$ and new functional $f \mapsto \hat{f}_{\mathcal{C}}$. Theorem of Eskin and Masur and theorem of Veech [V4] presented above are valid for $\hat{f}_{\mathcal{C}}$. The corresponding Siegel–Veech constant $c(\mathcal{C})$ responsible for the quadratic growth rate $N_{\mathcal{C}}(S, L) \sim c(\mathcal{C}) \cdot \pi L^2$ of the number of collections of homologous saddle connections of the type $\mathcal{C}$ on an individual generic flat surface $S$ coincides with the constant $C(\mathcal{C})$ in the expression analogous to (2).

Formula (2) can be applied to $\hat{\chi}_L$ for any value of $L$. In particular, instead of taking large $L$ we can choose a very small $L = \varepsilon \ll 1$. The corresponding function $\hat{\chi}_\varepsilon(S)$ counts how many collections of parallel $\varepsilon$-short saddle connections (closed geodesics) of the type $\mathcal{C}$ we can find on a flat surface $S \in \mathcal{H}_1^{\mathrm{comp}}(\beta)$. For the flat surfaces $S$ outside of the subset $\mathcal{H}_1^{\varepsilon}(\mathcal{C}) \subset \mathcal{H}_1^{\mathrm{comp}}(\beta)$ there are no such saddle connections (closed geodesics), so $\hat{\chi}_\varepsilon(S) = 0$. For surfaces $S$ from the subset $\mathcal{H}_1^{\varepsilon,\mathrm{thick}}(\mathcal{C})$ there is exactly one collection like this, $\hat{\chi}_\varepsilon(S) = 1$. Finally, for the surfaces from the remaining (very small) subset $\mathcal{H}_1^{\varepsilon,\mathrm{thin}}(\mathcal{C}) = \mathcal{H}_1^{\varepsilon}(\mathcal{C}) \setminus \mathcal{H}_1^{\varepsilon,\mathrm{thick}}(\mathcal{C})$ one has $\hat{\chi}_\varepsilon(S) \geq 1$. Eskin and Masur have proved in [EM] that though $\hat{\chi}_\varepsilon(S)$ might be large on $\mathcal{H}_1^{\varepsilon,\mathrm{thin}}$ the measure of this subset is so small (see [MS]) that

$$\int_{\mathcal{H}_1^{\varepsilon,\mathrm{thin}}(\mathcal{C})} \hat{\chi}_\varepsilon(S)\, dv_1 = o(\varepsilon^2)$$

and hence

$$\int_{\mathcal{H}_1^{\mathrm{comp}}(\beta)} \hat{\chi}_\varepsilon(S)\, d\nu_1 = \mathrm{Vol}\, \mathcal{H}_1^{\varepsilon,\mathrm{thick}}(\mathcal{C}) \;+\; o(\varepsilon^2).$$

This latter volume is almost the same as the volume $\mathrm{Vol}\, \mathcal{H}_1^{\varepsilon}(\mathcal{C})$ of the neighborhood of the cusp $\mathcal{C}$ evaluated in equation (1) above, namely, $\mathrm{Vol}\, \mathcal{H}_1^{\varepsilon,\mathrm{thick}}(\mathcal{C}) = \mathrm{Vol}\, \mathcal{H}_1^{\varepsilon}(\mathcal{C}) + o(\varepsilon^2)$ (see [MS]). Taking into consideration that

$$\int_{\mathbb{R}^2} \chi_\varepsilon(x, y)\, dx\, dy = \pi\varepsilon^2$$

and applying the Siegel–Veech formula (2) to $\chi_\varepsilon$ we finally get

$$\frac{\mathrm{Vol}\, \mathcal{H}_1^{\varepsilon}(\mathcal{C})}{\mathrm{Vol}\, \mathcal{H}_1^{\mathrm{comp}}(d_1, \ldots, d_m)} + o(\varepsilon^2) = c(\mathcal{C}) \cdot \pi\varepsilon^2$$

which implies the following formula for the Siegel–Veech constant $c(\mathcal{C})$:

$$\begin{aligned} c(\mathcal{C}) &= \lim_{\varepsilon\to 0} \frac{1}{\pi\varepsilon^2} \frac{\mathrm{Vol}(\text{“}\varepsilon\text{-neighborhood of the cusp } \mathcal{C}\text{ ”})}{\mathrm{Vol}\, \mathcal{H}_1^{\mathrm{comp}}(\beta)} \\ &= (\text{explicit combinatorial factor}) \cdot \frac{\prod_{j=1}^{k} \mathrm{Vol}\, \mathcal{H}_1(\beta_k')}{\mathrm{Vol}\, \mathcal{H}_1^{\mathrm{comp}}(\beta)}. \end{aligned}$$

Sums of the Lyapunov exponents $\nu_1 + \cdots + \nu_g$ discussed in Section 1 are closely related to the Siegel–Veech constants.

## 3. Ergodic components of the Teichmüller flow

According to the theorems of H. Masur [M1] and of W. Veech [V1] Teichmüller geodesic flow is ergodic on every connected component of every stratum of flat surfaces. Thus, the Lyapunov exponents $1 + \nu_j$ of the Teichmüller geodesic flow responsible for the deviation spectrum of generic geodesics on a flat surface (see Section 1), or Siegel–Veech constants responsible for counting of closed geodesics on a flat surface (see Section 2) are specific for each connected component of each stratum. The fact that the strata $\mathcal{H}_1(d_1, \ldots, d_m)$ are not necessarily connected was observed by W. Veech.

In order to formulate the classification theorem for connected components of the strata $\mathcal{H}(d_1, \ldots, d_m)$ we need to describe the classifying invariants. There are two of them: spin structure and hyperellipticity. Both notions are applicable only to part of the strata: flat surfaces from the strata $\mathcal{H}(2d_1, \ldots, 2d_m)$ have even or odd spin structure. The strata $\mathcal{H}(2g-2)$ and $\mathcal{H}(g-1, g-1)$ have a special hyperelliptic connected component.

The results of this section are based on the joint work with M. Kontsevich [KZ].

**Spin structure.** Consider a flat surface $S$ from a stratum $\mathcal{H}(2d_1, \dots, 2d_m)$. Let $\rho\colon S^1 \to S$ be a smooth closed path on $S$; here $S^1$ is a standard circle. Note that at any point of the surfaces $S$ we know where is the "direction to the North". Hence, at any point $\rho(t) = x \in S$ we can apply a compass and measure the direction of the tangent vector $\dot{x}$. Moving along our path $\rho(t)$ we make the tangent vector turn in the compass. Thus we get a map $G(\rho)\colon S^1 \to S^1$ from the parameter circle to the circumference of the compass. This map is called the *Gauss map*. We define the *index* $\operatorname{ind}(\rho)$ of the path $\rho$ as a degree of the corresponding Gauss map (or, in other words as the algebraic number of turns of the tangent vector around the compass) taken modulo 2.

$$\operatorname{ind}(\rho) = \deg G(\rho) \mod 2.$$

It is easy to see that $\operatorname{ind}(\rho)$ does not depend on parameterization. Moreover, it does not change under small deformations of the path. Deforming the path more drastically we may change its position with respect to conical singularities of the flat metric. Say, the initial path might go on the left of $P_k$ and its deformation might pass on the right of $P_k$. This deformation changes the $\deg G(\rho)$. However, if the cone angle at $P_k$ is of the type $2\pi(2d_k + 1)$, then $\deg G(\rho) \mod 2$ does not change! This observation explains why $\operatorname{ind}(\rho)$ is well-defined for a free homotopy class $[\rho]$ when $S \in \mathcal{H}(2d_1, \dots, 2d_m)$ (and hence, when all cone angles are odd multiples of $2\pi$).

Consider a collection of closed smooth paths $a_1, b_1, \dots, a_g, b_g$ representing a symplectic basis of homology $H_1(S, \mathbb{Z}/2\mathbb{Z})$. We define the *parity of the spin-structure* of a flat surface $S \in \mathcal{H}(2d_1, \dots, 2d_m)$ as

$$\phi(S) = \sum_{i=1}^{g} (\operatorname{ind}(a_i) + 1)\,(\operatorname{ind}(b_i) + 1) \mod 2.$$

**Lemma.** *The value $\phi(S)$ does not depend on symplectic basis of cycles $\{a_i, b_i\}$. It does not change under continuous deformations of $S$ in $\mathcal{H}(2d_1, \dots, 2d_m)$.*

The lemma above shows that the parity of the spin structure is an invariant of connected components of strata of those Abelian differentials (equivalently, flat surfaces) which have zeroes of even degrees (equivalently, conical points with cone angles which are odd multiples of $2\pi$).

**Hyperellipticity.** A flat surface $S$ may have a symmetry; one specific family of such flat surfaces, which are "more symmetric than others" is of a special interest for us. Recall that there is a one-to-one correspondence between flat surfaces and pairs (Riemann surface $M$ , holomorphic 1-form $\omega$). When the corresponding Riemann surface is hyperelliptic the hyperelliptic involution $\tau\colon M \to M$ acts on any holomorphic 1-form $\omega$ as $\tau^*\omega = -\omega$.

We say that a flat surface $S$ is a hyperelliptic flat surface if there is an isometry $\tau\colon S \to S$ such that $\tau$ is an involution, $\tau \circ \tau = \mathrm{id}$, and the quotient surface $S/\tau$

is a topological sphere. In flat coordinates differential of such involution obviously satisfies $D\tau = -\mathrm{Id}$.

In a general stratum $\mathcal{H}(d_1, \ldots, d_m)$ hyperelliptic flat surfaces form a small subspace of nontrivial codimension. However, there are two special strata, namely, $\mathcal{H}(2g-2)$ and $\mathcal{H}(g-1, g-1)$, for which hyperelliptic surfaces form entire hyperelliptic connected components $\mathcal{H}^{\mathrm{hyp}}(2g-2)$ and $\mathcal{H}^{\mathrm{hyp}}(g-1, g-1)$ correspondingly.

**Remark.** Note that in the stratum $\mathcal{H}(g-1, g-1)$ there are hyperelliptic flat surfaces of two different types. A hyperelliptic involution $\tau S \to S$ may fix the conical points or might interchange them. It is not difficult to show that for flat surfaces from the connected component $\mathcal{H}^{\mathrm{hyp}}(g-1, g-1)$ the hyperelliptic involution interchanges the conical singularities.

The remaining family of those hyperelliptic flat surfaces in $\mathcal{H}(g-1, g-1)$, for which the hyperelliptic involution keeps the saddle points fixed, forms a subspace of nontrivial codimension in the complement $\mathcal{H}(g-1, g-1) \setminus \mathcal{H}^{\mathrm{hyp}}(g-1, g-1)$. Thus, the hyperelliptic connected component $\mathcal{H}^{\mathrm{hyp}}(g-1, g-1)$ does not coincide with the space of all hyperelliptic flat surfaces.

**Classification theorem for Abelian differentials.** Now, having introduced the classifying invariants we can present the classification of connected components of strata of flat surfaces (equivalently, of strata of Abelian differentials).

**Theorem 3** (M. Kontsevich and A. Zorich). *All connected components of any stratum of flat surfaces of genus $g \geq 4$ are described by the following list:*

- *The stratum $\mathcal{H}(2g-2)$ has three connected components: the hyperelliptic one, $\mathcal{H}^{\mathrm{hyp}}(2g-2)$, and two nonhyperelliptic components: $\mathcal{H}^{\mathrm{even}}(2g-2)$ and $\mathcal{H}^{\mathrm{odd}}(2g-2)$ corresponding to even and odd spin structures.*

- *The stratum $\mathcal{H}(2d, 2d)$, $d \geq 2$ has three connected components: the hyperelliptic one, $\mathcal{H}^{\mathrm{hyp}}(2d, 2d)$, and two nonhyperelliptic components: $\mathcal{H}^{\mathrm{even}}(2d, 2d)$ and $\mathcal{H}^{\mathrm{odd}}(2d, 2d)$.*

- *All the other strata of the form $\mathcal{H}(2d_1, \ldots, 2d_m)$ have two connected components: $\mathcal{H}^{\mathrm{even}}(2d_1, \ldots, 2d_m)$ and $\mathcal{H}^{\mathrm{odd}}(2d_1, \ldots, 2d_n)$, corresponding to even and odd spin structures.*

- *The stratum $\mathcal{H}(2d-1, 2d-1)$, $d \geq 2$, has two connected components; one of them: $\mathcal{H}^{\mathrm{hyp}}(2d-1, 2d-1)$ is hyperelliptic; the other $\mathcal{H}^{\mathrm{nonhyp}}(2d-1, 2d-1)$ is not.*

*All the other strata of flat surfaces of genera $g \geq 4$ are nonempty and connected.*

In the case of small genera $1 \leq g \leq 3$ some components are missing in comparison with the general case.

**Theorem 3′.** *The moduli space of flat surfaces of genus $g = 2$ contains two strata: $\mathcal{H}(1,1)$ and $\mathcal{H}(2)$. Each of them is connected and coincides with its hyperelliptic component.*

*Each of the strata $\mathcal{H}(2,2)$, $\mathcal{H}(4)$ of the moduli space of flat surfaces of genus $g = 3$ has two connected components: the hyperelliptic one, and one having odd spin structure. The other strata are connected for genus $g = 3$.*

Since there is a one-to-one correspondence between connected components of the strata and extended Rauzy classes, the classification theorem above classifies also the extended Rauzy classes.

Connected components of the strata $\mathcal{Q}(d_1, \dots, d_m)$ of meromorphic quadratic differentials with at most simple poles are classified in the paper of E. Lanneau [L].

**Bibliographical notes.** As a much more serious accessible introduction to Teichmüller dynamics I can recommend a collection of surveys of A. Eskin [E], G. Forni [Fo2], P. Hubert and T. Schmidt [HSc] and H. Masur [M2], organized as a chapter of the Handbook of Dynamical Systems. I also recommend recent surveys of H. Masur and S. Tabachnikov [MT] and of J. Smillie [S] especially in the aspects related to billiards in polygons. The part concerning renormalization and interval exchange transformations is presented in the survey of J.-C. Yoccoz [Y]. The ideas presented in the current paper are illustrated in more detailed way in the survey [Z4].

**Acknowledgements.** A considerable part of the results presented in this survey is obtained in collaboration. I use this opportunity to thank A. Eskin, M. Kontsevich and H. Masur for the pleasure to work with them. I am grateful to M.-C. Vergne for her help with the preparation of the pictures.

# Asymptotic behavior of smooth solutions for partially dissipative hyperbolic systems and relaxation approximation

Stefano Bianchini

**Abstract.** We study two problems related to hyperbolic systems with a dissipative source.

In the first part, we consider the asymptotic time behavior of global smooth solutions to general entropy dissipative hyperbolic systems of balance law in $m$ space dimensions, under a coupling condition among hyperbolic and dissipative part known as the Shizuta–Kawashima condition. Under the assumption of small initial data, these solutions approach constant equilibrium state in the $L^p$-norm at a rate $O\big(t^{-\frac{m}{2}(1-\frac{1}{p})}\big)$, as $t \to \infty$, for $p \in [\min\{m, 2\}, \infty]$. The main tool is given by a detailed analysis of the Green function for the linearized problem. If the space dimension $m = 1$ or the system is rotational invariant, it is possible to give an explicit form to the main terms in the Green kernel.

In the second part, we consider the hyperbolic limit of special systems of balance laws: this means to study the limit of the solution to a system of balance laws under the rescaling $(t, x) \mapsto (t/\varepsilon, x/\varepsilon)$, as $\varepsilon \to 0$. For some special dissipative systems in one space dimension, it is possible to prove the existence of the limit and to identify it as a solution to a system of conservation laws.

**Keywords.** Dissipative hyperbolic systems, large time behavior, convex entropy functions, relaxation systems, Shizuta–Kawashima condition, BGK models.

## 1. Asymptotic behavior of smooth solutions to balance laws

We consider the Cauchy problem for a general hyperbolic symmetrizable $m$-dimensional system of balance laws

$$u_t + \sum_{\alpha=1}^{m} (f_\alpha(u))_{x_\alpha} = g(u), \tag{1.1}$$

with the initial conditions

$$u(x, 0) = u_0(x), \tag{1.2}$$

where $u = (u_1, u_2) \in \Omega \subseteq \mathbb{R}^{n_1} \times \mathbb{R}^{n_2}$ with $n_1 + n_2 = n$. We also assume that there are $n_1$ conservation laws in the system, namely that we can take

$$g(u) = \begin{pmatrix} 0 \\ q(u) \end{pmatrix} \quad \text{with } q(u) \in \mathbb{R}^{n_2}. \tag{1.3}$$

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

According to the general theory of hyperbolic systems of balance laws [11], if the flux functions $f_\alpha$ and the source term $g$ are smooth enough, it is well known that problem (1.1)–(1.2) has a unique local smooth solution, at least for some time interval $[0, T)$ with $T > 0$, if the initial data are also sufficiently smooth. In the general case, and even for very good initial data, smooth solutions may break down in finite time, due to the appearance of singularities, either discontinuities or blow-up in $L^\infty$.

The easiest example is Burgers equation with an initial data strictly decreasing in some interval. With more generality, if we have a system of balance laws, it may happen that the source terms have no influence on the mechanism generating a singularity, or it may also help the solution to blow up.

Despite these general considerations, sometimes dissipative mechanisms due to the source term can prevent the formation of singularities, at least for some restricted classes of initial data, as observed for many models which arise to describe physical phenomena. A typical and well-known example is given by the compressible Euler equations with damping, see [20], [14] for the 1-dimensional case and [23] for an interesting 3-dimensional extension.

Recently, in [13], it was proposed a quite general framework of sufficient conditions which guarantee the global existence in time of smooth solutions. Actually, for the systems which are endowed with a strictly convex entropy function $\mathcal{E} = \mathcal{E}(u)$, a first natural assumption is the *entropy dissipation condition*, see [10], [19], [21], [24], namely for every $u, \bar{u} \in \Omega$, with $g(\bar{u}) = 0$,

$$\big(\nabla \mathcal{E}(u) - \nabla \mathcal{E}(\bar{u})\big) \cdot g(u) \leq 0,$$

where $\mathcal{E}'(u)$ is considered as a vector in $\mathbb{R}^n$ and "$\cdot$" is the scalar product in the same space.

Roughly speaking, the above condition means that the source is dissipative in some integral norm, typically $L^2$. Thus one expects that blow up in $L^\infty$ could be prevented, or certainly it does not happen for space independent solutions.

Unfortunately, it is easy to see that this condition is too weak to prevent the formation of singularities: just consider the system

$$\begin{cases} u_t + uu_x = 0, \\ v_t = -v \end{cases} \tag{1.4}$$

with entropy $u^2 + v^2$. The key point in this system is that the dissipative source $(0, -v)$ is not acting on the first equation, so that it cannot prevent the shock formation.

A quite natural supplementary condition can be imposed to entropy dissipative systems, following the classical approach by Shizuta and Kawashima [16], [22], and in the following called condition (SK), which in the present case reads

$$\mathrm{Ker}(Dg(\bar{u})) \cap \Big\{\text{eigenspaces of } \textstyle\sum_{\alpha=1}^m Df_\alpha(\bar{u})\xi_\alpha\Big\} = \{0\}, \tag{1.5}$$

for every $\xi \in \mathbb{R}^m \setminus \{0\}$ and every $\bar{u} \in \Omega$, with $g(\bar{u}) = 0$. It is possible to prove that this condition, which is satisfied in many interesting examples, is also sufficient to

establish a general result of global existence for small perturbations of equilibrium constant states.

As an example, it is easy to see that (1.4) does not satisfy (SK) condition, while the system

$$\begin{cases} u_t + uu_x + v_x = 0, \\ v_t + u_x = -v \end{cases} \tag{1.6}$$

fulfills requirement (1.5).

We investigate the asymptotic behavior in time of the global solutions, always assuming the existence of a strictly convex entropy and the (SK) condition.

Our starting point is a careful and refined analysis of the behavior of the Green function for the linearized problem around an equilibrium state $\bar{u}$,

$$u_t + \sum_{\alpha=1}^{m} A_\alpha \partial_{x_\alpha} u = Bu, \quad A^\alpha = \nabla f^\alpha(u)|_{u=\bar{u}},\ B = \nabla g(u)|_{u=\bar{u}} \tag{1.7}$$

The conditions on the existence of a dissipative strictly convex entropy and (SK) condition (and also (1.3) implies that

1. the matrices $A_\alpha$ are symmetric and

$$B = \begin{bmatrix} 0 & 0 \\ 0 & D \end{bmatrix}, \quad D \in \mathbb{R}^{n_2 \times n_2}, \tag{1.8}$$

   with $D$ strictly negative definite;

2. no eigenvectors of $\sum_\alpha \xi_\alpha A_\alpha$ are in the null space of $B$ for all $\xi \in \mathbb{R}^m$.

It is possible to show that the Green kernel $\Gamma(t)$ can be written as the sum of the kernels

$$\Gamma(t) = K(t) + \mathcal{K}(t). \tag{1.9}$$

The first term corresponds to a uniformly parabolic (pseudo) differential operator, while the first satisfies a uniform exponential decay in $L^2$:

$$\|D^\beta \mathcal{K}(t) w^0\|_{L^2} \le Ce^{-ct} \|D^\beta w^0\|_{L^2}. \tag{1.10}$$

It can be also shown that $\Gamma(t)$ has bounded support, so that both $K(t)$, $\mathcal{K}(t)$ have bounded support.

For the term $K(t)$ it is possible to give a more precise description, by using the two projectors $Q_0$, $Q_- = I - Q_0$: $Q_0$ is the projector on the conservative part of (1.7), i.e.

$$Q_0 \begin{pmatrix} u_1 \\ u_2 \end{pmatrix} = \begin{pmatrix} u_1 \\ 0 \end{pmatrix}, \quad Q_- \begin{pmatrix} u_1 \\ u_2 \end{pmatrix} = \begin{pmatrix} 0 \\ u_2 \end{pmatrix}.$$

Writing then

$$K(t) = \begin{bmatrix} K_{11}(t) & K_{12}(t) \\ K_{21}(t) & K_{22}(t) \end{bmatrix}, \tag{1.11}$$

it is possible to prove that $K_{11}$ decays as a heat kernel, while the other three decays as a derivative of the heat kernel:

$$\begin{aligned}
\|D^\beta K_{11}(t)w\|_{L^p} &\le C(|\beta|)\min\left\{1, t^{-\frac{m}{2}(1-\frac{1}{p})-|\beta|/2}\right\}\|w\|_{L^1},\\
\|D^\beta K_{12}(t)w\|_{L^p},\, \|D^\beta K_{21}(t)w\|_{L^p} &\le C(|\beta|)\min\left\{1, t^{-\frac{m}{2}(1-\frac{1}{p})-1/2-|\beta|/2}\right\}\|w\|_{L^1},\\
\|D^\beta K_{22}(t)w\|_{L^p} &\le C(|\beta|)\min\left\{1, t^{-\frac{m}{2}(1-\frac{1}{p})-1-|\beta|/2}\right\}\|w\|_{L^1}.
\end{aligned} \tag{1.12}$$

Using this Green kernel representation, one can show that solution to (1.1) satisfies the same decay estimates as $\Gamma(t)$. More precisely, one can prove that

$$\|u(t) - K(t)Q_0u(0)\|_{L^p} \le C\min\left\{1, t^{-\frac{m}{2}(1-\frac{1}{p})-1/2}\right\}\|u(0)\|_{L^1}.$$

Clearly to have more information on the asymptotic behavior of $u(t)$ one needs to know more information on $K(t)$. This can be done in two situations: if the space dimension is $m = 1$, or under the assumption of rotational invariance. In both cases the Fourier components of the differential operators can be inverted.

As an example, we can consider the linearized isentropic Euler equations with damping,

$$\begin{cases} \rho_t + \operatorname{div} v = 0, \\ v_t + \nabla\rho = -v. \end{cases} \tag{1.13}$$

One can check that the three conditions are satisfied. We can decompose the Green kernel $\Gamma$ in three parts

$$\Gamma(t,x) = K(t,x) + R(t,x) + \mathcal{K}(t,x), \tag{1.14}$$

where $K(t,x)$ can be computed to be

$$K(t,x) = \begin{bmatrix} G(t,x) & (\nabla G(t,x))^T \\ \nabla G(t,x) & \nabla^2 G(t,x) \end{bmatrix} + R_1(t,x), \tag{1.15}$$

where $G(t,x)$ is the heat kernel for $u_t = \Delta u$, and the rest term $R_1(t,x)$ satisfies the bound

$$R_1(t,x) = \frac{e^{-c|x|^2/t}}{(1+t)^2}\begin{bmatrix} \mathcal{O}(1) & \mathcal{O}(1)(1+t)^{-1/2} \\ \mathcal{O}(1)(1+t)^{-1/2} & \mathcal{O}(1)(1+t)^{-1} \end{bmatrix}. \tag{1.16}$$

In particular the principal part of $\Gamma(t)$ is given by the heat kernel $G(t,x)$.

The rest part $R_1$ is exponentially decreasing and smooth, while $\mathcal{K}(t,x)$ can be computed to be

$$\mathcal{K}(t,x) = \begin{bmatrix} 0 & 0 \\ 0 & e^{-t}\mathcal{P} \end{bmatrix} + e^{-t}\begin{bmatrix} W_{00}(t,x) & W_{01}(t,x) \\ W_{10}(t,x) & W_{11}(t,x) \end{bmatrix} + R_2(t,x). \tag{1.17}$$

Here $\mathcal{P}: (L^2(\mathbb{R}^3))^3 \mapsto (L^2(\mathbb{R}^3))^3$ is the orthogonal projection of $L^2$ vector fields on the subspace of divergence free vector fields. $\mathcal{P}v$ is characterized by

$$\mathcal{P}v \in (L^2(\mathbb{R}^3))^3, \quad \mathrm{div}\mathcal{P}v = 0, \quad \mathrm{curl}(v - \mathcal{P}v) = 0,$$

and so we have that

$$v - \mathcal{P}v = \nabla\psi \quad \text{with } \Delta\psi = \mathrm{div}v.$$

This yields

$$\mathcal{P}v = v - \nabla(\Delta^{-1}\mathrm{div}v). \tag{1.18}$$

In fact, in Fourier coordinates, we have

$$\widehat{\mathcal{P}v}(\xi) = \hat{v}(\xi) - |\xi|^{-2}(\xi \cdot \hat{v}(\xi))\xi = \hat{v}(\xi) - |\xi|^{-2}\xi\xi^T \cdot \hat{v}(\xi). \tag{1.19}$$

The matrix valued function

$$W(t,x) = W_1(t,x) + W_2(t,x) = \begin{bmatrix} W_{00}(t,x) & W_{01}(t,x) \\ W_{10}(t,x) & W_{11}(t,x) \end{bmatrix} + \begin{bmatrix} 0 & 0 \\ 0 & \delta(x)\mathcal{P} \end{bmatrix} \tag{1.20}$$

is the matrix valued Green function of the system

$$\begin{cases} \rho_t + \mathrm{div}v = 0, \\ v_t + \nabla\rho = 0, \end{cases}$$

and it can be written by means of the fundamental solution to the wave equation $u_{tt} = \Delta u$. In fact, $W_{00}$ is the solution of $u_{tt} = \Delta u$ with initial data $u = \delta(x)$, $u_t = 0$, and

$$W_1 = \begin{bmatrix} W_{00} & \nabla^T\partial_t(-\Delta)^{-1}W_{00} \\ \nabla\partial_t(-\Delta)^{-1}W_{00} & -\nabla^2(-\Delta)^{-1}W_{00} \end{bmatrix}. \tag{1.21}$$

In particular one can check that $W_2$ corresponds to incompressible vector fields, while $W_1$ corresponds to curl free vector fields.

An interesting open question is whether the (SK) can be relaxed by considering it acting only on a subset of the eigenspaces of $\sum Df_\alpha\xi_\alpha$. As a trivial example, if $f^\alpha$ are linear functions, then no dissipativity condition is needed. In [27] it is possible to find a non trivial example of a system which does not satisfy (SK) condition but still the smooth solution exists for all $t \geq 0$.

## 2. Relaxation limit of balance laws

After having proved existence for small data of the system

$$u_t + \sum_{\alpha=1}^{m} (f_\alpha(u))_{x_\alpha} = \frac{g(u)}{\varepsilon}, \tag{2.1}$$

under the dissipativity and (SK) condition, one can ask the question of describing the hyperbolic limit as $\varepsilon \to 0$. At a formal level, by writing

$$g(u) = g(u_1, u_2) = 0 \quad \Longrightarrow \quad u_1 = q(u_2) \tag{2.2}$$

for the equilibrium manifold, at a formal level we obtain the symmetrizable hyperbolic system

$$u_{1,t} + \sum_{\alpha=1}^{m} \left(f_\alpha(u_1, q(u_1))\right)_{x_\alpha} = 0. \tag{2.3}$$

As an example, if (2.1) is a kinetic scheme, then this limit corresponds to the hydrodynamic limit, i.e. to the rescaling $(t, x) \mapsto (t/\varepsilon, x/\varepsilon)$. The most outstanding problem in this direction is the hydrodynamic limit of Boltzmann equation, at least in one space dimension. In this direction the major result is the convergence under the assumption of piecewise smooth solution to the limiting Euler system with non interacting shocks [26]. We remark that hyperbolic limit must be based on the proof of local existence for data which do not satisfy any integral estimates.

We want to underline the difference among the known results and the theory of hyperbolic system. The assumption of non interacting shocks is equivalent to saying that we do not need to control the non linear interaction among waves, which is one of the key aspects of hyperbolic systems.

The main tool for proving existence and stability of solutions to hyperbolic systems is the local decomposition of the solution into waves and the description of their interaction. As an example, for BV solutions of an $n \times n$ system, the derivative of the solution is decomposed in $n$ scalar measures, each measure representing the waves of one of the characteristic families of $u$. The key point is that one can describe the evolution of these waves as they interact and find an interaction functional which bounds the total interaction.

We believe that this functional would be a key point in proving hyperbolic limit of balance laws. It is clear that understanding this functional implies the understanding of the wave structure of the solution.

In general it seems difficult to prove convergence of (2.1) as $\varepsilon \to 0$, under the assumptions considered in the previous part. We thus restrict to particular quasilinear systems of the form (BGK schemes with one moment) in one space dimension:

$$\partial_t F^\alpha + \alpha F^\alpha_x = \frac{1}{\varepsilon}\big(M^\alpha(u) - F^\alpha\big), \quad u = \sum_\alpha F^\alpha. \tag{2.4}$$

The functions $M^\alpha(u)$ are the Maxwellians. At a formal level, as $\varepsilon \to 0$ one obtains

$$F^\alpha = M^\alpha(u), \quad u_t + \mathcal{F}(u)_x = 0,$$

where the flux function $\mathcal{F}(u)$ is given by

$$\mathcal{F}(u) = \sum_\alpha \alpha M^\alpha(u).$$

The easiest example is the scheme introduced in [15],

$$\begin{cases} u_t + v_x = 0, \\ v_t + \Lambda^2 u_x = \dfrac{1}{\varepsilon}(\mathcal{F}(u) - v), \end{cases} \tag{2.5}$$

which can be put in the form (2.4) by diagonalizing the semilinear part.

By differentiating the second equation of (2.5) w.r.t. $x$ and using the first one obtains the nonlinear wave equation

$$u_t + A(u)u_x = \frac{1}{\varepsilon}(u_{xx} - u_{tt}), \tag{2.6}$$

with $A(u) = D\mathcal{F}(u)$. The above equation is meaningful also in the case $A(u)$ is not a Jacobian matrix, so that one cannot write a conservative form like (2.5). For this particular system it is now proved the existence and stability of solutions with initial data of small BV norm [3].

In this last part we describe the structure of the waves of (2.6). Writing the system in the form

$$\begin{cases} F^-_t - F^-_x = (M^-(u) - F^-)/\varepsilon, \\ F^*_t + F^*_x = (M^+(u) - F^+)/\varepsilon, \end{cases} \qquad u = F^- + F^+,\ M^{\pm}(u) = \frac{u \pm \mathcal{F}(u)}{2} \tag{2.7}$$

with $F^-$, $F^+ \in \mathbb{R}^n$, and assuming the stability condition $|D\mathcal{F}(u)| < 1$, at a formal level one expects that as $\varepsilon \to 0$, the function $u$ converges to a solution to

$$u_t + \mathcal{F}(u)_x = 0, \quad u \in \mathbb{R}^n. \tag{2.8}$$

Concerning the solution of (2.8), we know that its structure can be described as the nonlinear sum of $n$ shock waves, corresponding to the characteristic speed of $D\mathcal{F}$,

$$u_x(t,x) = \sum_{i=1}^{n} v_i(t,x)\tilde{r}_i(t,x), \quad v_i \in \mathbb{R},\ \tilde{r}_i \in \mathbb{R}^n. \tag{2.9}$$

The vectors $\tilde{r}_i$ are in general not the eigenvectors of $D\mathcal{F}$, but are close to them for small data. Also the propagation speeds of the scalar $v_i$ is close to the $i$-th eigenvalue. Their interaction is described by a Glimm type functional [4]. Thus, a possible way of thinking of the waves in (2.7) is to imagine that the solution $(F^-, F^+)$ is the sum of $n$ waves (the wave decomposition of $u$) and some remaining term $v$ which is dissipating entropy.

It turns out that a more natural description is that the solution to (2.7) can be decomposed into $2n$ waves, $n$ for each component $F^-$, $F^+$,

$$F^-_x(t,x) = \sum_{i=1}^{n} f_i^-(t,x)\tilde{r}_i^-(t,x), \quad F^+_x(t,x) = \sum_{i=1}^{n} f_i^+(t,x)\tilde{r}_i^+(t,x). \tag{2.10}$$

This in some sense is a different philosophy, because we are not describing the solution as the approximate solution to the limiting hyperbolic system plus a term which is dissipating: we give a full nonlinear structure to the solution to the kinetic scheme.

We remark that with more generality, the BGK system (2.4) is decomposed as the sum of $n$ waves for each component $F^\alpha$. It is an open question which is the right decomposition in non linear waves for the more complicated discrete models, for example the well-known Broadwell model in one space dimension.

# Nonlinear Schrödinger equations in inhomogeneous media: wellposedness and illposedness of the Cauchy problem

Patrick Gérard

**Abstract.** We survey recent wellposedness and illposedness results for the Cauchy problem for nonlinear Schrödinger equations in inhomogeneous media such as Riemannian manifolds or domains of the Euclidean space, trying to emphasize the influence of the geometry. The main tools are multilinear Strichartz estimates for the Schrödinger group.

**Mathematics Subject Classification (2000).** Primary 35Q55; Secondary 35B30.

**Keywords.** Nonlinear Schrödinger equations, Strichartz inequalities, multilinear estimates, eigenfunction estimates.

## 1. Introduction

The nonlinear Schrödinger equation arises in several areas of Physics (see the book [55] for an introduction), such as Optics or Quantum Mechanics, where it is related to Bose–Einstein condensation or Superfluidity. From the mathematical point of view, this equation has been studied on the Euclidean space since the seventies. However, it is quite relevant, in the above applications, to consider this equation on inhomogeneous media. In Optics, for instance, this naturally corresponds to a variable optical index; more specifically, spatial inhomogeneity has been recently used in the modelization of broad-area semiconductor lasers (see [38]). One of the main mathematical questions is then to evaluate the impact of the inhomogeneity on the dynamics of the equation, in particular regarding the wellposedness theory of the Cauchy problem. The goal of this paper is to survey recent mathematical contributions in this direction.

Let us precise what we mean by inhomogeneous medium in this context. Our physical space $M$ is either the space $\mathbb{R}^d$ or a compact manifold, endowed in both cases with a second order differential operator $P$, which is elliptic, positive and selfadjoint with respect to some Lebesgue density $\mu$ and satisfies $P(1) = 0$.[1]

In coordinates, this means that $P$ and $\mu$ are given by

$$Pu = -\frac{1}{\rho}\nabla.(A\nabla u), \quad d\mu = \rho(x)\,dx, \tag{1.1}$$

[1] Notice that this latter condition prevents potential terms in $P$. We impose this condition here for the sake of concision, though potential terms may of course be quite relevant too.

Proceedings of the International Congress of Mathematicians, Madrid, Spain, 2006

where $\rho$ is a smooth positive function, and where $A$ is a smooth function valued in positive definite matrices. If $M = \mathbb{R}^d$, we shall impose the following additional conditions

$$0 < c \leq \rho(x), \quad cI \leq A(x), \quad |\partial^\alpha \rho(x)| + |\partial^\alpha A(x)| \leq C_\alpha, \quad \alpha \in \mathbb{N}^d, \tag{1.2}$$

in order to avoid degeneracy at infinity. An example of such an operator is of course minus the Laplace operator associated to a Riemannian metric $g$ on $M$ which, in the case $M = \mathbb{R}^d$, satisfies moreover

$$cI \leq g(x), \quad |\partial^\alpha g(x)| \leq C_\alpha, \quad \alpha \in \mathbb{N}^d.$$

In this setting, the nonlinear Schrödinger equation (NLS) reads

$$i\frac{\partial u}{\partial t} - Pu = F(u), \tag{1.3}$$

where the unknown complex function $u$ depends on $t \in \mathbb{R}$ and on $x \in M$, and the Cauchy problem consists in imposing the initial value of $u$ at $t = 0$. Here the nonlinearity $F$ is a smooth function on $\mathbb{C}$, which we assume to satisfy the following normalization and growth conditions:

$$F(0) = 0, \quad |D^k F(z)| \leq C_k(1 + |z|)^{1+\alpha-k}, \quad k = 0, 1, 2, \ldots. \tag{1.4}$$

In many situations, we require additional conditions on the structure of $F$. The most common one imposes that $F$ derives from a potential function

$$F(z) = \frac{\partial V}{\partial \bar{z}}, \quad V : \mathbb{C} \to \mathbb{R}. \tag{1.5}$$

In this case (1.3) is a Hamiltonian system with the following Hamiltonian functional:

$$H(u) = \int_M (Pu\,\bar{u} + V(u))\,d\mu, \tag{1.6}$$

and consequently it formally enjoys the conservation law

$$H(u(t)) = H(u(0)). \tag{1.7}$$

Furthermore, if we assume the following gauge-invariance condition

$$V(\mathrm{e}^{i\theta} z) = V(z), \quad \theta \in \mathbb{R}, \tag{1.8}$$

i.e. $V(z) = G(|z|^2)$, $F(z) = G'(|z|^2)z$, we also have the $L^2$ conservation law

$$\|u(t)\|_{L^2(M,\mu)} = \|u(0)\|_{L^2(M,\mu)}. \tag{1.9}$$

A typical example of nonlinearity $F$ satisfying (1.4), (1.5) and (1.8) is

$$F_{\alpha,\pm}(z) = \pm(1 + |z|^2)^{\alpha/2} z. \tag{1.10}$$

Finally, let us indicate that we shall sometimes discuss another kind of inhomogeneous NLS, namely when $-P$ is the Laplace operator with Dirichlet or Neumann boundary condition on a smooth domain of the Euclidean space. However, the theory is much less complete in this context.

This paper is organized as follows. After defining three different notions of well-posedness for the Cauchy problem for (1.3) on the scale of Sobolev spaces in Section 2, we make some general observations based on scaling considerations in Section 3. We begin Section 4 by recalling the role of Strichartz estimates in the analysis of (1.3) on the Euclidean space. We insist that this part is by no means an exhaustive review of the NLS theory on the Euclidean space. In particular, we did not discuss the recent contributions on scattering theory and on blow up. Then we really start the study of the influence of the geometry by observing that losses of derivatives may appear in Strichartz inequalities in the case of inhomogeneous media. In Section 5, we revisit the wellposedness problems by introducing multilinear Strichartz estimates, which originate in the works of Bourgain for Schrödinger and of Klainerman–Machedon for the wave equations. Finally, Section 6 is devoted to discussing in details the case of simple Riemannian compact manifolds, such as tori and spheres.

## 2. Some notions of wellposedness

We start with defining precisely the notions of wellposedness we are going to use throughout this paper. Indeed, since our evolution problem is nonlinear, several notions are available. We shall define these notions for the nonlinear Schrödinger equation (1.3) but it is clear that these notions are quite general and can be applied to other evolution equations.

**Definition 2.1.** We shall say that the Cauchy problem for equation (1.3) is (locally) *well-posed* on $H^s(M)$ if, for every bounded subset $B$ of $H^s(M)$, there exists $T > 0$ and a Banach space $X_T$ continuously contained in $C([-T, T], H^s(M))$ such that:

i) For every Cauchy data $u_0 \in B$, (1.3) has a unique solution $u \in X_T$ such that $u(0) = u_0$.

ii) If $u_0 \in H^\sigma(M)$ for $\sigma > s$, then $u \in C([-T, T], H^\sigma(M))$.

iii) The map
$$u_0 \in B \mapsto u \in X_T$$
is continuous.

Moreover, we shall say that the Cauchy problem for equation (1.3) is *globally well-posed* on $H^s(M)$ if properties i), ii), iii) above hold for every time $T > 0$.

Notice that in some cases local wellposedness can be combined with the conservation laws (1.9) and (1.7) to provide global wellposedness. Specifically, assume for instance that (1.3) is well-posed on $L^2(M) = H^0(M)$ and that $F$ is gauge-invariant.

Since the $L^2$ conservation law holds for every solution in $C([-T, T], H^s(M))$ with $s$ large enough, it results from requirements ii) and iii) that this conservation law holds on $[-T, T]$ as soon as $u_0 \in L^2$. Combining this observation with requirement i), we conclude that (local) wellposedness on $L^2$ implies global wellposedness on $L^2$. Similarly, one can show that local wellposedness on $H^1$ implies global wellposedness on $H^1$, under the assumption that a bound on $\|f\|_{L^2}$ and on $H(f)$ is equivalent to a bound on $\|f\|_{H^1}$, as it is the case, for instance, if $F$ is gauge invariant and derives from a nonnegative potential with $(d-2)\alpha \leq 4$.

**Definition 2.2.** We shall say that the Cauchy problem for equation (1.3) is (locally) *uniformly well-posed* on $H^s(M)$ if it is well-posed on $H^s(M)$ and if, with the notation of Definition 2.1 the map $u_0 \in B \mapsto u \in X_T$ is *uniformly* continuous.

One defines similarly *global uniform wellposedness*. Compared to Definition 2.1, uniform wellposedness can be understood as an additional requirement of high frequency stability for small uniform time. Let us mention that, in all the positive results of this paper, uniform continuity will come from Lipschitz continuity. As we shall see in the next sections, uniform wellposedness is rather natural for *semilinear* equations such as (1.3), but it may be violated for other natural evolution equations. For instance, it can be shown (see e.g. [59]) that the Burgers equation

$$\frac{\partial u}{\partial t} + u\frac{\partial u}{\partial x} = 0$$

is well-posed on $H^s(\mathbb{R}, \mathbb{R})$ for $s > 3/2$, but is not uniformly well-posed. This is related to the *quasilinear* hyperbolic feature of Burgers' equation. A more subtle example is the modified Korteweg–de Vries equation on the one-dimensional torus,

$$\frac{\partial u}{\partial t} + \frac{\partial^3 u}{\partial x^3} + \left(u^2 - \int_{\mathbb{T}} u^2\, dx\right)\frac{\partial u}{\partial x} = 0,$$

which is uniformly well-posed on $H^s(\mathbb{T}, \mathbb{R})$ for $s > 1/2$ (see [10]), but is not for $s \in ]3/8, 1/2[$, though it is well-posed for $s$ in this interval. (see [56] and [40]).

**Definition 2.3.** We shall say that the Cauchy problem for equation (1.3) is (locally) *regularly well-posed* on $H^s(M)$ if it is well-posed on $H^s(M)$ and if, with the notation of Definition 2.1, the map $u_0 \in \mathring{B} \mapsto u \in X_T$ is *smooth*.

One defines similarly *global regular wellposedness*. As we shall see in the next section, regular wellposedness is quite a stringent notion if $F$ is not a polynomial. On the other hand, for polynomial gauge-invariant nonlinearities, it will lead us to multilinear Strichartz estimates (see Section 5 below), which turn out to be the key estimates in this theory.

## 3. General observations

Since the free group $e^{-itP}$ acts on $H^s(M)$, the following result is an elementary consequence of the classical nonlinear estimates in Sobolev spaces $H^s$ for $s > d/2$, combined with the Duhamel formulation of the Cauchy problem for (1.3),

$$u(t) = e^{-itP}u_0 - i\int_0^t e^{-i(t-t')P}(F(u(t')))\,dt'. \tag{3.1}$$

**Proposition 3.1.** *If $s > d/2$, the Cauchy problem for* (1.3) *is regularly well-posed on $H^s(M)$.*

The above proposition has the following partial converse.

**Proposition 3.2.** *Assume $F(0) = 0$ and $D^kF(0) \neq 0$ for some $k \geq 2$ and that the Cauchy problem for* (1.3) *is regularly well-posed on $H^s(M)$. Then $s \geq \frac{d}{2} - \frac{2}{k-1}$.*

**Corollary.** *If $F(0) = 0$ and $F$ is real analytic and is not polynomial, then the Cauchy problem for* (1.3) *is not regularly well-posed on $H^s(M)$ for $s < \frac{d}{2}$.*

Proposition 3.2 relies on a very simple idea: if we solve (1.3) with the following bounded data in $H^s$,

$$u(0, x) = f_N(x) = N^{d/2-s}\varphi(Nx),$$

where $\varphi$ is a suitable cutoff function – so that the above expression makes sense on a manifold, choosing local coordinates –, and $N$ is a large parameter, then, because $P$ is a differential operator of order 2, on times $t$ such $|t| \ll N^{-2}$, the term $Pu$ can be neglected at the first order. For instance, for such times,

$$e^{-itP}f_N - f_N \to 0$$

in $H^s$ as $N$ tends to infinity. Then one uses this remark to compute successively

$$v_j(t) = \frac{d^j}{d\delta^j}(u^\delta(t))_{|\delta=0}, \quad j \geq 1,\ |t| \ll N^{-2},$$

where $u^\delta$ denotes the solution to (1.3) such that $u^\delta(0) = \delta f_N$. The continuity of the differential of order $k$ of the map $u_0 \in H^s \mapsto u(t) \in H^s$ implies

$$\|v_k(t)\|_{H^s} \leq C\|f_N\|_{H^s}^k$$

which, for $t = N^{-2-\varepsilon}$, yields the claimed condition on $s$.

Combined with more delicate estimates, this idea can also be used to disprove other kinds of wellposedness, as in the following adaptation to inhomogeneous media of a recent result by Christ, Colliander and Tao.

**Theorem 3.3** (Christ–Colliander–Tao [27], Burq–Gérard–Tzvetkov [17]). *If $\alpha > 0$, the Cauchy problem for* (1.3) *with $F = F_{\alpha,\pm}$ given by* (1.10) *is not uniformly well-posed on $H^s(M)$ if $s < 0$, and not well-posed on $H^s(M)$ if $0 < s < \frac{d}{2} - \frac{2}{\alpha}$.*

The main point of the proof is to establish that, for sufficiently small times – but not too small – , the solution of the above equation with data $\kappa_N f_N$, where $\kappa_N$ is a small coefficient to be adjusted, is approximated by the solution $v_N$ of the ordinary differential equation

$$i\partial_t v_N = \pm(1 + |v_N|^2)^{\alpha/2} v_N$$

with the same Cauchy data. Of course $v_N$ can be computed explicitly,

$$v_N(t, x) = \mathrm{e}^{\mp it(1+\kappa_N^2 |f_N(x)|^2)^{\alpha/2}} \kappa_N f_N(x),$$

and one checks that the above oscillating term induces instability in the first case, while in second case it produces norm inflation, namely the $H^s$ norm of the solution can become unbounded for a sequence of times tending to 0, though the Cauchy data tend to 0 in $H^s$.

## 4. The role of Strichartz inequalities

In this section we first recall the basic role played by Strichartz inequalities in the analysis of equation (1.3) on Euclidean spaces, quoting some important results in this context, without pretending to be exhaustive. Then we discuss extensions of these inequalities to different geometries.

**4.1. The Euclidean case.** In this subsection we assume that $M = \mathbb{R}^d$ and that $-P$ is the Laplace operator. In this case, the solution of the linear Schrödinger equation is explicit,

$$\mathrm{e}^{it\Delta} u_0(x) = \frac{1}{(4i\pi t)^{d/2}} \int_{\mathbb{R}^d} \mathrm{e}^{i|x-y|^2/4t} u_0(y)\, dy, \tag{4.1}$$

and this implies the following dispersion estimate:

$$\|\mathrm{e}^{it\Delta} u_0\|_{L^\infty(\mathbb{R}^d)} \leq \frac{1}{(4\pi|t|)^{d/2}} \|u_0\|_{L^1(\mathbb{R}^d)}. \tag{4.2}$$

By a classical functional-analytic tool (known as the $TT^*$ trick), this estimate implies important inequalities for the solution of the linear Schrödinger equation with $L^2$ data. In order to state these inequalities we shall say that a pair $(p, q) \in [1, \infty] \times [1, \infty]$ is $d$-admissible if

$$\frac{2}{p} + \frac{d}{q} = \frac{d}{2}, \quad p \geq 2, \ (p, q) \neq (2, \infty). \tag{4.3}$$

Moreover, if $r \in [1, \infty]$, we denote by $\bar{r}$ the conjugate exponent of $r$, characterized by

$$\frac{1}{\bar{r}} + \frac{1}{r} = 1.$$

**Proposition 4.1** (Strichartz [54], Ginibre–Velo [34], Yajima [61], Keel–Tao [42]). *Let $(p_1, q_1)$, $(p_2, q_2)$ be $d$-admissible pairs. There exists $C > 0$ such that, for every $u_0 \in L^2(\mathbb{R}^d)$, for every $T > 0$ and $f \in L^{\bar{p}_1}([0, T], L^{\bar{q}_1}(\mathbb{R}^d))$, the solution $u$ of*

$$i\partial_t u + \Delta u = f, \quad u(0) = u_0,$$

*satisfies $u \in L^{p_2}([0, T], L^{q_2}(\mathbb{R}^d))$ with the inequality*

$$\|u\|_{L^{p_2}([0,T],L^{q_2}(\mathbb{R}^d))} \leq C\,(\|u_0\|_{L^2(\mathbb{R}^d)} + \|f\|_{L^{\bar{p}_1}([0,T],L^{\bar{q}_1}(\mathbb{R}^d))}). \tag{4.4}$$

These inequalities were first proved in [54] in the particular cases $p_1 = q_1$ and $p_2 = q_2$, then in [34] in the cases $p_1 = p_2 > 2$, then in [61] for $p_1$, $p_2 > 2$ arbitrary, and finally, for the endpoint case $p = 2$, in [42], where an abstract presentation of the $TT^*$ trick is also available. Notice that these estimates are optimal: indeed, the first condition in (4.3) is related to the scale invariance of the Schrödinger equation, the second condition comes from general properties of translation invariant operators on $L^p$ (see *e.g.* Theorem 1.1 of Hörmander [39]), while the special forbidden case $p = 2, q = \infty$, which only arises for $d = 2$, has been checked by Montgomery-Smith [46]. A variant of the proof of the necessity of the scaling condition consists in testing the above estimates for $f = 0$ and

$$u_0(x) = \varphi(Nx),$$

where $\varphi \in C_0^\infty(\mathbb{R}^d)$ and $N$ is a large parameter. As we already observed in the previous section, for $t \ll N^{-2}$ the solution $u(t, x)$ stays essentially constant. This is made more precise by the ansatz

$$u(t, x) \sim \psi(N^2 t, Nx)$$

where $\psi(s, .)$ belongs to the Schwartz class, uniformly as $s$ stays bounded, and $\psi(0, x) = \varphi(x)$. Consequently, if $(p, q)$ is an admissible pair, then the $L_t^p(L_x^q)$ norm of $u$ on the thin slab $[0, N^{-2}] \times \mathbb{R}^d$ is equivalent to $N^{-2/p-d/q} = N^{-d/2}$, which is the magnitude of the $L^2$ norm of $u_0$. In other words, the main contribution in the $L_t^p(L_x^q)$ norm of $u$ already lies in the thin slab $[0, N^{-2}] \times \mathbb{R}^d$: this is a striking illustration of the dispersive character of the Schrödinger equation. Moreover, this remark can be carried out to inhomogeneous media, showing that *the above Strichartz inequalities cannot be improved in any inhomogeneous media.* On the other hand, as we shall see in the sequel, they may be dramatically altered.

We close this subsection by pointing that Strichartz inequalities on the Euclidean space essentially provide reverse statements of the necessary conditions to wellposedness of Proposition 3.2 and Theorem 3.3.

**Theorem 4.2** (Ginibre–Velo [33], [34], Kato [41], Cazenave–Weissler [24], Tsutsumi [58], Yajima [61]). *Let $F$ satisfy conditions* (1.4) *and let $s \geq 0$ satisfy*

$$s > \frac{d}{2} - \frac{2}{\alpha}.$$

*Then equation* (1.3) *is uniformly well-posed on $H^s(\mathbb{R}^d)$ if $d \leq 6$. Moreover, if $F$ is a polynomial of degree $1+\alpha$, then* (1.3) *is regularly well-posed on $H^s(\mathbb{R}^d)$ for every $d$.*

The unexpected condition $d \leq 6$ relies on lack of good estimates for large derivatives of $F(u)$ if $F$ is non-polynomial. This limitation may not be optimal, but so far it cannot be dropped, for instance for the proof of propagation of high regularity.

In the polynomial case, such a condition is not necessary, and we observe that, under the additional conditions (1.5) and (1.8), thresholds of the three wellposedness properties coincide, for every $d$, with $\max(0, d/2 - 2/\alpha)$. Furthermore, let us mention that some regular wellposedness results were proved on $H^s$ for $s < 0$, in the one-dimensional case, for quadratic nonlinearities which do not satisfy the gauge invariance condition (see Kenig–Ponce–Vega [43]).

The critical cases $s_c = d/2 - 2/\alpha \geq 0$ are not covered by the above theorem. Using the same Strichartz inequalities, it is possible to extend the wellposedness results of this theorem on a global time interval *for data which lie in a small neighborhood of* 0 *in $H^s$* (see [24]). For large data however, this question is still the object of intensive work, particularly for Hamiltonian gauge-invariant nonlinearities and $s_c = 0$ or 1. For instance, if $d = 2$ and $F(u) = -|u|^2 u$, $s_c = 0$ and the existence of blow up solutions (see Zakharov [62]) together with a scaling argument yields a family of solutions with bounded data in $L^2(\mathbb{R}^2)$ and which blow up at arbitrarily small times. On the other hand, if $F(u) = |u|^2 u$, the question of global existence of a solution with $L^2$ solution and the related question of (regular) wellposedness are widely open problems. Another important example of such critical problems is $d = 3$, $F(u) = |u|^4 u$, for which $s_c = 1$. In this case, Colliander–Keel–Staffilani–Takaoka–Tao [29] have recently proved global (regular) wellposedness.

**4.2. Operators on the real line.** The first kind of nonhomogeneous medium to which it is natural to generalize the above Strichartz inequalities – and hence the nonlinear results of Theorem 4.2 – is of course the real line, with an operator $P$ satisfying the assumptions (1.1), (1.2) of the introduction. In this case, the extension is rather straightforward for *local in time* Strichartz estimates. Indeed, if

$$P = -\frac{1}{\rho}\frac{d}{dx} a \frac{d}{dx},$$

the global change of variable $dy = (\rho(x)/a(x))^{1/2}\,dx$ and the conjugation $\lambda^{-1} P \lambda$ with the function $\lambda(y) = (a(x)\rho(x))^{-1/4}$ lead to the operator

$$\tilde{P} = -\frac{d^2}{dy^2} + V(y), \quad V = -\frac{\lambda''}{\lambda} + 2\left(\frac{\lambda'}{\lambda}\right)^2.$$

Since $V$ is a bounded function, the Strichartz inequalities for $\tilde{P}$ on a *finite time* interval $[0, T]$ with $C = C(T)$ are a straightforward consequence of the Euclidean ones, considering the term $Vu$ as a source term in the right hand side. We refer to [49] for a slightly different proof.

Though we shall not pursue in this direction, let us indicate that the question of singular coefficients $\rho, a$ has been addressed quite recently. In [2], Banica observed that, if $\rho = 1$ and $a$ is a piecewise constant function with a finite number of discontinuities, the dispersion estimate – and hence Strichartz inequalities – is valid, while it fails for an infinite number of discontinuities. Burq and Planchon [21] generalized this observation by proving that *global* Strichartz estimates hold as soon as $a$ has bounded variation. Notice that the BV regularity seems to be a relevant threshold, since, for every $s < 1$, $W^{s,1}$ functions $a$ are constructed in the appendix of [21] such that every kind of Strichartz inequality fails (see also an earlier result by Castro and Zuazua [22], which shows the same phenomenon for Hölder continuous functions $a$ of any exponent $\alpha < 1$).

**4.3. Strichartz inequalities with loss of derivative.** At this stage a natural question is of course to extend Strichartz inequalities (4.4) to variable coefficients in several space dimensions, as we did on the line. The following example shows that the situation is much more complicated. Our starting point is the following identity for the ground state of the harmonic oscillator,

$$(-h^2\partial_s^2 + s^2 - h)\big(\mathrm{e}^{-s^2/2h}\big) = 0.$$

Setting $s = r - 1$ and, for every positive integer $n$,

$$\psi_n(r, \theta) = \mathrm{e}^{-(r-1)^2/2h_n + in\theta}$$

where $h_n > 0$ is such that $h_n^{-2} = h_n^{-1} + n^2$, we infer

$$(-\partial_r^2 - \partial_\theta^2 - h_n^{-2}(1 - (r-1)^2))\psi_n = 0. \tag{4.5}$$

Notice that $\psi_n$ is the expression in polar coordinates of a smooth function on the complement of the origin in the plane, and that the operator

$$P_0 = -\frac{1}{1 - (r-1)^2}(\partial_r^2 + \partial_\theta^2)$$

is a positive elliptic operator of order 2 with smooth real coefficients, on the complement $\Omega$ of the origin in the disc of radius 2 endowed with the density $d\mu = (1 - (r-1)^2)\, dr\, d\theta = (2 - |x|)dx$. Since $P_0(1) = 0$, it follows that $P_0$ can be written $P_0 = -\frac{1}{\rho_0}\nabla.(A_0\nabla)$, where $\rho_0, A_0$ are smooth functions on $\Omega$ valued in positive numbers and definite positive matrices respectively. Notice that (4.5) reads $P_0\psi_n = h_n^{-2}\psi_n$, and that, as $n$ tends to $\infty$, $\psi_n$ is exponentially concentrating on the circle of radius 1. By cutting off $\psi_n$ near this circle, we obtain a sequence of

functions $\tilde{\psi}_n$ and a differential operator $P$ on $\mathbb{R}^2$ satisfying the assumptions of the introduction, such that

$$P\tilde{\psi}_n = h_n^{-2}\tilde{\psi}_n + r_n \tag{4.6}$$

where, for every $q \geq 1$ and for every $s \geq 0$,

$$\|\tilde{\psi}_n\|_{L^q} \sim n^{-1/2q}, \quad \|\tilde{\psi}_n\|_{H^s} \sim n^{s-1/4}, \quad \|r_n\|_{H^s} \leq C_s \mathrm{e}^{-\delta n}$$

for some $\delta > 0$. This sequence of functions is called a quasimode for the operator $P$. The geometric interpretation is that the circle of radius 1 is a (sufficiently stable) geodesic curve for the Riemannian metric defined by the principal symbol of $P$ (see e.g. Ralston [47]). By adding a suitable remainder term $w_n(t)$, we can write

$$u_n(t) := \mathrm{e}^{-itP}\tilde{\psi}_n = \mathrm{e}^{-ith_n^{-2}}\tilde{\psi}_n + w_n(t)$$

with $\|u_n\|_{L^p([0,T],L^q(\mathbb{R}^2))} \sim T^{1/p}\, n^{-1/2q}$ for every $p, q \geq 1$ and every $T > 0$. By using $u_n$ as a test function we conclude that, for every $q > 2$, for every $p \geq 1$, the estimate

$$\|u\|_{L^p([0,T],L^q)} \leq C\|u(0)\|_{L^2}$$

fails. More precisely, in view of the behavior of $u_n$ it is even impossible to replace the $L^2$ norm in the right hand side by the $H^s$ norm if

$$s < \frac{1}{4} - \frac{1}{2q}. \tag{4.7}$$

In other words, *in multidimensional heterogeneous media, losses of derivatives in Strichartz inequalities cannot be avoided.* The next question is of course to estimate precisely this loss of derivatives in terms of $p, q$ and the geometry of the medium. There is no need to say that this is a very difficult open problem. However, it is possible to give a general upper bound, which is valid for every geometry and already gives interesting applications to nonlinear problems.

**Theorem 4.3** (Staffilani–Tataru [53], Burq–Gérard–Tzvetkov [12]). *If $(p, q)$ is a d-admissible pair, the solution u of the equation*

$$i\partial_t u - Pu = f, \quad u(0) = u_0, \tag{4.8}$$

*satisfies the inequality*

$$\|u\|_{L^p([0,T],L^q(M))} \leq C_T \left(\|u_0\|_{H^{1/p}(M)} + \|f\|_{L^1([0,T],H^{1/p}(M))}\right). \tag{4.9}$$

*Proof* (*sketch*). Firstly, by Duhamel's formula and Minkowski's inequality, (4.9) is reduced to the case $f = 0$. Then, by Littlewood–Paley's analysis, we can assume that $u_0$ is spectrally supported in a dyadic interval, namely $\varphi(N^{-2}P)u_0 = u_0$ for some $\varphi \in C_0^\infty(\mathbb{R})$, where $N$ is a large dyadic integer. The advantage of this spectral

localization is that we can describe rather explicitly, by a standard semiclassical WKB analysis, the solution

$$u(t) = \mathrm{e}^{-itP}u_0$$

on a time interval of order $N^{-1} = h$. By a stationary phase argument, this implies the following dispersion estimate:

$$\|u(t)\|_{L^\infty(M)} \leq \frac{C}{|t|^{d/2}}\,\|u_0\|_{L^1(M)}, \quad |t| \lesssim \frac{1}{N}. \tag{4.10}$$

From this dispersion estimate, the $TT^*$ trick leads to the following semi-classical Strichartz inequalities

$$\|u\|_{L^p([0,N^{-1}],L^q(M))} \leq C\|u_0\|_{L^2(M)}, \quad u_0 = \varphi(N^{-2}P)u_0, \tag{4.11}$$

where $(p, q)$ stands for any $d$-admissible pair. The last step of the proof consists in iterating the estimates (4.11) on $N$ intervals of length $N^{-1}$ covering the interval $[0, 1]$. This yields a factor $N^{1/p}$ in the right hand side, and this completes he proof since

$$N^{1/p}\|u_0\|_{L^2(M)} \simeq \|u_0\|_{H^{1/p}(M)}. \qquad \square$$

**Remark 4.4.** Notice that when $d = 2$, the loss $\frac{1}{p} = \frac{1}{2} - \frac{1}{q}$ is twice as big as the threshold (4.7) derived from our counterexample in the beginning of this subsection. Indeed, the last step of the above proof may seem quite rough, since the decomposition of $[0, 1]$ into $N$ intervals of length $N^{-1}$ does not take into account the geometric features of $M$ and $P$. However, it is interesting to notice that there are geometries where some inequalities (4.9) are optimal. Indeed, if $M$ is compact and $d \geq 3$, inequality (4.9) with $p = 2$ applied to $f = 0$ and to the special Cauchy data $u_0 = \psi_\lambda$, where $\psi_\lambda$ is an eigenfunction of $P$ associated to a large eigenvalue $\lambda^2$, provides the estimate

$$\|\psi_\lambda\|_{L^q(M)} \leq C\,\lambda^{1/2}\|\psi_\lambda\|_{L^2(M)}, \quad q = \frac{2d}{d-2}. \tag{4.12}$$

Estimate (4.12) is one of the estimates obtained by Sogge [51] for the $L^r$ norms of the eigenfunctions of elliptic operators on compact manifolds, and it is known that this estimate is optimal if $M$ is the sphere $\mathbb{S}^d$ and $P$ is the standard Laplace operator, for spherical harmonics $\psi_\lambda$ which are functions of the distance to a fixed point (see [50]). A similar phenomenon occurs for $d = 2$ with $q = \infty$, except that our inequalities need an extra $\varepsilon$-derivative, due to the forbidden case $p = 2$, $q = \infty$.

Using inequalities (4.9), we obtain wellposedness results for nonlinear Schrödinger equations (1.3). For simplicity, we only state the case of polynomial nonlinearities.

**Corollary 4.5** (Burq–Gérard–Tzvetkov[12]). *Assume $d \geq 2$ and suppose that $F$ is a polynomial in $u$, $\bar{u}$ of degree $1 + \alpha \geq 2$. Then the Cauchy problem for* (1.3) *is regularly well-posed on $H^s(M)$ for*

$$s > \frac{d}{2} - \frac{1}{\max(\alpha, 2)}.$$

*Moreover, if $d = 3$ and $F(u) = |u|^2 u$, then the Cauchy problem for* (1.3) *is globally well-posed on $H^1(M)$, and it is globally regularly well-posed on $H^s(M)$ if $s > 1$.*

If $F$ is both gauge invariant and Hamiltonian with a nonnegative potential $V$, we can combine Corollary 4.5 with the conservation laws (1.9) and (1.7) to deduce global regular wellposedness on $H^1(M)$ if $d = 2$. In the special case of a cubic NLS in three space dimensions, observe that regular wellposedness is only known for $s > 1$; the uniform or regular wellposedness is still open in general on the energy space $H^1(M)$. This is in strong contrast with the case of the Euclidean case, where the critical nonlinearity is quintic. However, in Section 6 we shall improve Corollary 4.5 for several specific three-dimensional geometries.

We conclude this subsection by quoting a recent result concerning boundary value problems. In this case the WKB analysis is much more problematic, due to glancing rays. However it is possible to reduce the analysis, by a reflection argument, to the case of a boundaryless manifold endowed with a Lipschitz continuous Riemannian metric. Combining the method of proof of Theorem 4.3 with earlier smoothing ideas due to Bahouri and Chemin [3] (see also Tataru [57]) in the context of nonlinear wave equations, it is possible to obtain the following result, which, in the particular case of a plane domain, provides the first global wellposedness result for super-cubic nonlinearities (for the cubic case, earlier wellposedness results were due to Brezis–Gallouet [11] and Vladimirov [60], by different arguments).

**Theorem 4.6** (Anton [1]). *Assume that $M$ is a compact manifold and that $P$ is given by* (1.1) *where $\rho$ and $A$ are Lipschitz continuous. Then, for every $d$-admissible pair $(p, q)$, the solution of* (4.8) *satisfies*

$$\|u\|_{L^p([0,T],L^q(M))} \leq C_{s,T}\,(\|u_0\|_{H^s(M)} + \|f\|_{L^1([0,T],H^s(M))}), \quad s > \frac{3}{2p}. \tag{4.13}$$

*In particular, the estimate* (4.13) *still holds if $M$ is replaced by a smooth bounded open set in $\mathbb{R}^d$ if $-P$ is the Laplace operator $\Delta_D$ (resp. $\Delta_N$) with Dirichlet (resp. Neumann) boundary conditions and if the space $H^s(M)$ is replaced by the domain of the power $s/2$ of $P$. Consequently, if $d = 2$ and $F$ satisfies* (1.4)*, is gauge invariant and Hamiltonian with a nonnegative potential $V$, the equation* (1.3) *with Dirichlet (resp. Neumann) boundary condition has a unique global solution $u \in C(\mathbb{R}, H^1_0(\Omega))$ (resp. $u \in C(\mathbb{R}, H^1(\Omega))$) if $u_0 \in H^1_0(\Omega)$ (resp. $u_0 \in H^1(\Omega)$), and the map $u_0 \mapsto u$ is Lipschitz continuous.*

**4.4. Non-trapping metrics.** Though we are rather interested in new phenomena induced by the heterogeneity of the medium, we cannot conclude this section devoted to Strichartz inequalities without quoting a series of results giving sufficient conditions on the geometry of the operator $P$ on $M = \mathbb{R}^d$ in order that Euclidean inequalities (4.4) hold. All these conditions concern the Laplace operator with a non-trapping metric, namely a Riemannian metric on $\mathbb{R}^d$ such that no geodesic curve stays in a compact set during an arbitrarily long time: notice that this prevents counterexamples like

the one in the previous subsection. First of all, Staffilani–Tataru [53] proved (4.4) on finite time intervals if the non-trapping metric is the perturbation of the Euclidean metric by a $C^2$ compactly supported function. Then Robbiano–Zuily [48] generalized this result to short range perturbations of the Euclidean metric by a very precise parametrix construction. Similar results were obtained by Hassell–Tao–Wunsch on asymptotically conic manifolds, using different methods. Finally, Bouclet–Tzvetkov [5] recently tackled the case of long range perturbations of the Euclidean metric. Notice that the proofs in [53] and [5] rely on the local smoothing effect for non-trapping metrics (see Doi [30]) which appears to be the complementary property of estimates (4.9) to obtain Strichartz inequalitites (4.4) without loss on finite time intervals. Finally, we refer to [15] for applications of this smoothing effect for non-trapping exterior domains to boundary problems for nonlinear Schrödinger equations.

## 5. Multilinear Strichartz estimates

In Subsection 4.3, we observed that, in several space dimensions, the geometry of the medium may induce losses of derivatives in Strichartz inequalities, and that some of these losses are optimal in specific geometries such as the sphere. The wellposedness results deduced from these Strichartz inequalities with loss are altered with respect to the Euclidean case – compare Theorem 4.2 and Corollary 4.5. However, so far we did not give evidence of this alteration. Indeed, as we shall see in the sequel, the whole range of Strichartz inequalities is not necessary to give optimal wellposedness results for NLSs. In order to understand this, we begin with revisiting the question of regular wellposedness for the cubic NLS.

**5.1. A criterion for regular wellposedness of the cubic NLS.** Given a dyadic integer $N$, let us say that a function $u$ on $M$ is *spectrally localized at frequency $N$* if

$$\mathbf{1}_{[N,2N]}(\sqrt{1+P})(u) = u. \tag{5.1}$$

We start with the important notion of bilinear Strichartz estimate, which originates in the works of Bourgain [6] and of Klainerman–Machedon [45] in the context of null forms for the wave equation.

**Definition 5.1.** Let $s \geq 0$. We shall say that *the Schrödinger group for $P$ satisfies a bilinear Strichartz estimate of order $s$ on $M$* if there exists a constant $C$ such that, for all dyadic integers $N$, $L$, for all functions $u_0$, $v_0$ on $M$ spectrally localized at frequencies $N$, $L$ respectively, the functions

$$u(t) = \mathrm{e}^{-itP}(u_0), \quad v(t) = \mathrm{e}^{-itP}(v_0)$$

satisfy the inequality

$$\|uv\|_{L^2([0,1]\times M)} \leq C \min(N, L)^s \|u_0\|_{L^2(M)} \|v_0\|_{L^2(M)}. \tag{5.2}$$

Notice that by setting $v_0 = u_0$, $L = N$ and by using the Littlewood–Paley inequality, one easily shows that a bilinear Strichartz estimate of order $s$ implies a Strichartz-type estimate of the space-time $L^4$ norm of a solution to the linear Schrödinger equation in terms of the $H^{s/2}$ norm of the Cauchy data. However, if $s > 0$, a bilinear Strichartz estimate says more, since the price to pay for estimating the $L^2$ norm of a product of such solutions only involves the lowest frequency of these solutions. The importance of bilinear Strichartz estimates in the wellposedness theory for NLSs clearly appears in the following theorem, which is a slight reformulation of some results from [16].

**Theorem 5.2** (Burq–Gérard–Tzvetkov [16]). *Assume $F(u) = \pm|u|^2u$ and $s \geq 0$.*

i) *If the Cauchy problem for* (1.3) *is regularly well-posed on $H^s(M)$, then the Schrödinger group for $P$ satisfies a bilinear Strichartz estimate of order $s$ on $M$.*

ii) *If the Schrödinger group for $P$ satisfies a bilinear Strichartz estimate of order $s$ on $M$, then, for every $\sigma > s$, the Cauchy problem for* (1.3) *is regularly well-posed on $H^\sigma(M)$.*

In other words, the existence of a bilinear Strichartz estimate of order $s$ is *almost* a criterion for regular wellposedness for cubic NLSs on $H^s(M)$. Notice that the strict inequality $\sigma > s$ in ii) cannot be extended to an equality in general. Indeed, for the Euclidean Laplace operator on $\mathbb{R}^2$, the Strichartz inequality (4.4) for the admissible pair (4, 4) combined with the Hölder inequality implies a bilinear estimate of order 0; however, we already observed at the end of Subsection 4.1 that the focusing cubic equation with $F(u) = -|u|^2u$ is not well-posed on $L^2(\mathbb{R}^2)$.

Another comment on the above statement is that it provides counterexamples to regular wellposedness. Indeed, in the beginning of Subsection 4.3 we constructed an example of an operator $P$ on $\mathbb{R}^2$ such that the estimate

$$\|u\|_{L^4([0,1]\times\mathbb{R}^2)} \leq C\|u_0\|_{H^s(\mathbb{R}^2)}$$

fails if $s < 1/8$. Consequently, the Schrödinger group for this operator does not enjoy bilinear Strichartz estimates of order $s < 1/4$, and thus *the cubic NLS for this operator is not regularly well-posed on $H^s(\mathbb{R}^2)$ for $s < 1/4$*. This is in strong contrast with the Euclidean case, where we know that regular wellposedness holds for every $s > 0$ (see Theorem 4.2).

*Proof* (*sketch*). The proofs of parts i) and ii) of Theorem 5.2 are of unequal length and difficulty. As a matter of fact, using regular wellposedness of (1.3) for smooth data stated in Proposition 3.1 and the propagation of regularity contained in the definition of regular wellposedness, it is easy to check that the third differential at 0 of the map $\Phi_1 : u_0 \mapsto u(1)$ is given by the following polarized form of the first iteration of the Duhamel equation (3.1):

$$D^3\Phi_1(0)(u_0, u_0, v_0) = -2i \int_0^1 \mathrm{e}^{-i(1-t)P}(2|u(t)|^2v(t) + u(t)^2\overline{v(t)})\,dt.$$

Here we assumed $N \leq L$ without loss of generality. We now compute the scalar product of both members of the above identity with $\mathrm{e}^{-iP}v_0$, and we use the assumed continuity of the trilinear map $D^3\Phi_1(0)$ from $(H^s)^3$ to $H^s$. This yields

$$\|uv\|^2_{L^2([0,1]\times M)} \leq C\|u_0\|^2_{H^s}\,\|v_0\|_{H^s}\,\|v_0\|_{H^{-s}}.$$

Using that

$$\|f\|_{H^{\pm s}} \simeq N^{\pm s}\|f\|_{L^2}$$

if $f$ is spectrally supported at frequency $N$, we infer the bilinear Strichartz estimate (5.2), and hence part i) is proved.

Let us come to part ii). The main idea, which in this context is due to Bourgain [6], is to introduce the scale of Hilbert spaces

$$X^{s,b}(P, \mathbb{R}\times M) = \{v \in \mathcal{S}'(\mathbb{R}\times M) : (1+|i\partial_t - P|^2)^{b/2}\,(1+P)^{s/2}v \in L^2(\mathbb{R}\times M)\}$$

for $s, b \in \mathbb{R}$. We refer to [35] for a pedagogical introduction to this strategy. Denoting by $X^{s,b}_T(P)$ the space of restrictions of elements of $X^{s,b}(P, \mathbb{R}\times M)$ to $]-T, T[\times M$, it is easy to observe that

$$X^{s,b}_T(P) \subset C([-T, T], H^s(M)) \quad \text{for all } b > \tfrac{1}{2},$$

and that the solution of the linear Schrödinger equation with datum in $H^s$ lies in $X^{s,b}_T(P)$ for every $b$. Moreover, the Duhamel term in the integral equation (3.1) can be handled by means of these spaces as

$$\left\| \int_0^t \mathrm{e}^{-i(t-t')P} f(t')\,dt' \right\|_{X^{s,b}_T(P)} \leq C\,T^{1-b-b'}\|f\|_{X^{s,-b'}_T(P)}$$

if $0 < T \leq 1$, $0 < b' < \frac{1}{2} < b$, $b + b' < 1$. The crux of the proof is then to observe that a bilinear Strichartz estimate of order $s$ implies the following estimates, for $\sigma' \geq \sigma > s$ and suitable $b, b'$ as above,

$$\|v_1\bar{v}_2v_3\|_{X^{\sigma,-b'}(P)} \leq C\,\|v_1\|_{X^{\sigma,b}(P)}\,\|v_2\|_{X^{\sigma,b}(P)}\|v_3\|_{X^{\sigma,b}(P)},$$
$$\||v|^2v\|_{X^{\sigma',-b'}(P)} \leq C\,\|v\|^2_{X^{\sigma,b}(P)}\,\|v\|_{X^{\sigma',b}(P)},$$

which allow the use a fixed point argument in $X^{\sigma,b}_T(P)$ in the resolution of the integral equation (3.1). □

**Remark 5.3.** Combining the Strichartz inequalities of Theorem 4.3 with the Sobolev inequalities, one easily shows that, if $d \geq 2$ and if $u_0$ spectrally localized at frequency $N$, the solution of the linear Schrödinger equation satisfies

$$\|u\|_{L^2([0,1],L^\infty(M))} \leq C_s N^s \|u_0\|_{L^2(M)} \quad \text{for all } s > \tfrac{d-1}{2}.$$

Using Hölder's inequality and the conservation of the $L^2$ norm by the Schrödinger group, we infer, in the context of Definition 5.1,

$$\begin{aligned}\|uv\|_{L^2([0,1]\times M)} &\leq \|u\|_{L^2([0,1],L^\infty(M))}\,\|v\|_{L^\infty([0,1],L^2(M))}\\ &\leq C_s N^s\,\|u_0\|_{L^2(M)}\|v_0\|_{L^2(M)},\end{aligned}$$

namely a bilinear Strichartz estimate of order $s > (d-1)/2$. Applying Theorem 5.2, we conclude that a cubic NLS is regularly well-posed on $H^s(M)$ for every $s > (d-1)/2$ if $d \geq 2$, which is consistent with Corollary 4.5. However, we shall see in the next section that this bilinear Strichartz estimate is far from optimal in several specific cases, therefore the threshold of regular wellposedness will be improved through Theorem 5.2.

**5.2. Generalization to subcubic nonlinearities.** Bilinear Strichartz estimates can also be used to prove uniform wellposedness for (1.3) when $F$ is not polynomial. In particular, combining the method of proof of part ii) in Theorem 5.2 with paradifferential expansions, it is possible to prove the following result.

**Theorem 5.4.** *Assume that the Schrödinger group for $P$ satisfies a bilinear Strichartz estimate of order $s$ on $M$ and that $F$ satisfies* (1.4) *with $\alpha \leq 2$. Then the Cauchy problem for* (1.3) *is uniformly well-posed on $H^\sigma(M)$ for every $\sigma > s$.*

Compared to Theorem 4.2 it may seem surprising that the regularity threshold of uniform wellposedness for (1.3) does not depend on $\alpha$. However we shall see such an example in Section 6, in the case of the two-dimensional sphere.

**5.3. Higher order nonlinearities.** By mimicking Definition 5.1 it is easy to define the notion of $k$-linear estimate for $k \geq 3$.

**Definition 5.5.** Let $k$ be an integer $\geq 3$ and $s_1, \ldots, s_{k-1} \geq 0$ . We shall say that *the Schrödinger group for $P$ satisfies a $k$-linear Strichartz estimate of order* $(s_1, \ldots, s_{k-1})$ *on $M$* if there exists a constant $C$ such that, for all dyadic integers $N_1 \leq \cdots \leq N_k$, for all functions $u_{1,0}, \ldots, u_{k,0}$ on $M$ spectrally localized at frequencies $N_1, \ldots, N_k$ respectively, the functions

$$u_j(t) = \mathrm{e}^{-itP}(u_{j,0}), \quad j = 1, \ldots, k,$$

satisfy the inequality

$$\|u_1 \ldots u_k\|_{L^2([0,1]\times M)} \leq C\, N_1^{s_1} \ldots N_{k-1}^{s_{k-1}} \|u_{1,0}\|_{L^2(M)} \ldots |u_{k,0}\|_{L^2(M)}. \tag{5.3}$$

**Remark 5.6.** By an iterated use of Hölder's inequality, we can always assume $s_1 \geq \cdots \geq s_{k-1}$.

Next we have the equivalent of Theorem 5.2.

**Theorem 5.7.** *Let $s \geq 0$, $m$ be an integer $\geq 2$ and $F(u) = \pm|u|^{2m}u$. Then*

i) *If* (1.3) *is regularly well-posed on $H^s(M)$, the Schrödinger group for $P$ satisfies an $(m+1)$-linear Strichartz estimate of order $(s, \dots, s)$.*

ii) *If the Schrödinger group for $P$ satisfies an $(m+1)$-linear Strichartz estimate of order $(s, \dots, s)$, then* (1.3) *is regularly well-posed on $H^\sigma(M)$ for every $\sigma > s$.*

Moreover, the use of different exponents in the list $s_1, \dots, s_k$ can help to tackle non-polynomial nonlinearities. Let us give an example for nonlinearities which are intermediate between cubic and quintic, which is essentially borrowed from [17].

**Theorem 5.8.** *Assume the Schrödinger group for $P$ satisfies a trilinear Strichartz estimate of order $(s_1, s_2)$ with $s_1 > s_2 \geq 0$ and $M$ is compact. Let $F$ satisfy* (1.4) *with $2 < \alpha < 4$. Then* (1.3) *is uniformly well-posed on $H^s(M)$ for every*

$$s > \left(1 - \frac{2}{\alpha}\right) s_1 + \frac{2}{\alpha} s_2.$$

**5.4. Multilinear estimates for spectral projectors.** If $M$ is compact, a $k$-linear Strichartz estimate for the Schrödinger implies a $k$-linear estimate for eigenfunctions of $P$ of the following kind:

$$\|\varphi_1 \dots \varphi_k\|_{L^2(M)} \leq C\, \lambda_1^{s_1} \dots \lambda_{k-1}^{s_{k-1}} \|\varphi_1\|_{L^2(M)} \dots \|\varphi_k\|_{L^2(M)},$$

$\varphi_j$ an eigenfunction of $P$ associated to the eigenvalue $\lambda_j^2$ and $1 \leq \lambda_1 \leq \dots \leq \lambda_k$. These estimates can be seen as $k$-linear versions of Sogge's estimates [51], [52]. A first step is therefore to decide for which orders such $k$-linear estimates hold. The following result gives a fairly general answer to this question. For the sake of generality, we deal, as in [51], [52], with spectral projectors $\Pi_\lambda = \mathbf{1}_{\lambda \leq \sqrt{P} \leq \lambda+1}$ on clusters of bounded length for the square root of $P$. Notice that this is a much more stringent spectral localization than the dyadic one which we introduced in the beginning of this section. Under this form our result makes sense in the case $M = \mathbb{R}^d$ too.

**Theorem 5.9** (Burq–Gérard–Tzvetkov [17]). *We have the bilinear estimates*

$$\|\Pi_{\lambda_1} f_1\, \Pi_{\lambda_2} f_2\|_{L^2(M)} \leq C\, \|f_1\|_{L^2(M)} \|f_2\|_{L^2(M)} \begin{cases} \lambda_1^{1/4} & \text{if } d = 2, \\ (\lambda_1\, \log(\lambda_1))^{1/2} & \text{if } d = 3, \\ \lambda_1^{(d-2)/2} & \text{if } d \geq 4 \end{cases}$$

*if $2 \leq \lambda_1 \leq \lambda_2$. In the special case $d = 2$, we have the trilinear estimate*

$$\|\Pi_{\lambda_1} f_1\, \Pi_{\lambda_2} f_2\, \Pi_{\lambda_3} f_3\|_{L^2(M)} \leq C(\lambda_1\lambda_2)^{1/4} \|f_1\|_{L^2(M)}\, \|f_2\|_{L^2(M)}\, \|f_3\|_{L^2(M)}$$

*if $1 \leq \lambda_1 \leq \lambda_2 \leq \lambda_3$.*

**Remark 5.10.** The logarithmic factor in the right hand side of the bilinear estimate in three space dimensions may be just technical. Apart from this, the linear estimates deduced from the above bilinear and trilinear estimates by making all the frequencies $\lambda_j$ equal and all the functions $f_j$ equal, are exactly the $L^4$ and $L^6$ estimates among the $L^p$ estimates proved by Sogge in [51], which are known to be optimal. Moreover, all the exponents in the multilinear estimates of Theorem 5.9 are optimal in the particular case of the sphere.

Finally, we did not state the other multilinear estimates for those spectral projectors, since they are essentially straightforward consequences of the above ones and of the $L^\infty$ estimate due to Sogge,

$$\|\Pi_\lambda f\|_{L^\infty(M)} \leq C\lambda^{\frac{d-1}{2}}\|f\|_{L^2(M)}, \quad \lambda \geq 1. \tag{5.4}$$

*Proof* (*sketch*). There are several proofs of this result (see [16] for the bilinear estimate in the two-dimensional case, and [17] or [18] for the general case). Here we follow [18]. We set $u = \Pi_\lambda f$, $h = \lambda^{-1}$, and we observe that the spectral localization given by $\Pi_\lambda$ can be formulated as a semiclassical PDE:

$$h^2 Pu - u = h\, r, \quad \|r\|_{L^2(M)} \leq C\|u\|_{L^2(M)}. \tag{5.5}$$

The main observation is then that this equation can be seen microlocally as an evolution equation with respect to one of the spatial coordinates, say $x_1$. For this equation it is possible to perform exactly the same analysis as we did in the proof of Theorem 4.3. This yields semiclassical versions of Strichartz inequalities (4.9) for $(d-1)$-admissible pairs, and the result follows by using Hölder's inequality as in Remark 5.3. □

## 6. The case of some simple compact manifolds

In this section we investigate the Cauchy problem for (1.3) on tori, spheres and balls, where $-P$ is the standard Laplace operator, trying to improve the results of Section 4. The basic tools for positive results of wellposedness are borrowed from Section 5. Several illposedness results are also obtained by explicit constructions. Moreover, we point some open problems in this context.

**6.1. Tori.** The first compact manifolds on which the global Cauchy problem for (1.3) has been studied are the tori

$$\mathbb{T}^d = \mathbb{R}^d/(2\pi\mathbb{Z})^d.$$

The main reference is the fundamental work of Bourgain [6], [7] (see also [8] and Ginibre [35]). We start with the one-dimensional case.

**Theorem 6.1** (Bourgain [6]). *If* $F(u) = \pm|u|^2u$, *then* (1.3) *is globally regularly well-posed on* $L^2(\mathbb{T})$.

*If $F(u) = \pm|u|^4 u$, then* (1.3) *is locally regularly well-posed on $H^\varepsilon(\mathbb{T})$, but not on $L^2(\mathbb{T})$.*

If we compare with Theorem 4.2, we see that the quintic nonlinearity is critical for $L^2$ wellposedness on the line. However, on the line a quintic NLS is regularly well-posed on small neighborhoods of 0 in $L^2(\mathbb{R})$, while it is not the case on the circle.

The proof of Theorem 6.1 essentially combines Theorem 5.7 with the explicit spectral representation for the solution of the linear Schrödinger equation,

$$u(t,x) = \mathrm{e}^{it\partial_x^2} u_0\,(x) = \sum_{n\in\mathbb{Z}} \mathrm{e}^{-itn^2} \mathrm{e}^{inx} \hat{u}_0(n),$$

which yields the needed bilinear and trilinear estimates by a direct calculation based on the Parseval formula in both time and space variables, following an old idea due to Zygmund [63]. The lack of regular wellposedness of a quintic NLS on $L^2$ results from the first part of Theorem 5.7 and an explicit example of a sequence of data $u_0$ such that $\|u\|_{L^6(\mathbb{T}^2)}\,\|u_0\|^{-1}_{L^2(\mathbb{T})}$ is not bounded.

Let us say a word about data in $H^s(\mathbb{T})$ for $s < 0$. In this case, there are several results of illposedness for (1.3). The most elementary one (see [13]) is the lack of uniform wellposedness which can be deduced from the explicit solutions

$$u(t,x) = \kappa n^{|s|} \mathrm{e}^{-it(n^2 + G'(\kappa^2 n^{2|s|}))} \mathrm{e}^{inx}$$

if $F(z) = G'(|z|^2)z$. Notice that, if $G'$ behaves like a power at infinity, a small variation of $\kappa$ around 1 induces a large variation of the phase shift of $u(t,x)$ for $t > 0$ and $n$ large, whence some lack of stability. Notice that a similar argument had been used earlier by Birnir–Kenig–Ponce–Svanstedt–Vega [4] and by Kenig–Ponce–Vega [44] on the line. Furthermore, by a careful study of the interaction between high and low frequencies, Christ, Colliander and Tao prove in [28] that, for the cubic case, the flow map fails to be continuous from any ball of $H^s$ to the space of distributions. As for the quintic equation, the flow map fails to be uniformly continuous from any ball of $H^s$ endowed with the topology of $C^\infty$, to the space of distributions. More recently, Christ [25] constructed non trivial weak solutions in $C_t(H^s)$ of a modified version of a cubic NLS, with zero Cauchy datum.

Let us come to the multidimensional case. Using the same method as for Theorem 6.1, it is possible to prove multilinear Strichartz estimates on $\mathbb{T}^d$ for $d \geq 2$. The interesting point is that these estimates are the same as on $\mathbb{R}^d$, except the fact that they are local in time, and that a loss $\varepsilon$ may alter the orders. For instance, the Schrödinger group on $\mathbb{T}^d$ enjoys a bilinear Strichartz estimate of order $(d-2)/2 + \varepsilon$ for every $\varepsilon > 0$. In view of Theorems 5.2, 5.7 and 5.8, this implies in particular the following results.

**Theorem 6.2** (Bourgain [6]). *If $F(u) = \pm|u|^2 u$, then* (1.3) *is regularly well-posed on $H^\varepsilon(\mathbb{T}^2)$ for every $\varepsilon > 0$.*

*If $F$ satisfies* (1.4) *for some $\alpha \in [2,4]$, then* (1.3) *is uniformly wellposed on $H^s(\mathbb{T}^3)$ for every $s > 3/2 - 2/\alpha$. In particular, if moreover $\alpha < 4$, $F$ is gauge invariant and Hamiltonian with a nonnegative potential,* (1.3) *is globally uniformly well-posed on $H^1(\mathbb{T}^3)$.*

In the case $d = 4$, the regularity $s = 1$ is critical for the cubic NLS. However, by means of logarithmic estimates based on a careful study of exponential sums, global wellposedness in $H^s(\mathbb{T}^4)$, $s > 1$, can be obtained for (1.3) with nonlinearities with quadratic growth such as $F = F_{1,+}$ (see Bourgain [7]).

Let us conclude this subsection by quoting two open problems. The first one concerns the quintic defocusing problem, namely $F(u) = |u|^4 u$, on $\mathbb{T}^3$. According to Theorem 6.2, it is regularly wellposed on $H^s(\mathbb{T}^3)$ for every $s > 1$, but nothing is known about $s = 1$, even for small data. This would yield global regular wellposedness in view of conservation laws.

The second open problem is the generalization of the above results to tori of the type

$$\mathbb{T}^d(\theta_1, \dots, \theta_d) = \mathbb{R}/\theta_1\mathbb{Z} \times \cdots \times \mathbb{R}/\theta_d\mathbb{Z},$$

where the $\theta_j$'s are positive numbers, possibly irrationally independent. The possibly chaotic behavior of the spectrum

$$\lambda = \omega_1^2 n_1^2 + \cdots + \omega_d^2 n_d^2, \quad \omega_j = \frac{2\pi}{\theta_j},\ n_j \in \mathbb{Z},$$

makes the multilinear Strichartz estimates particularly delicate to obtain. For instance, if $d = 2$, the optimal order of the bilinear Strichartz estimate – and thus the threshold of regularity wellposedness of cubic NLSs – is not known. However, if $d = 3$, it is possible to prove that the local $L_t^p(L_x^4)$ norm of the solution of the linear Schrödinger equation scales as on the Euclidean space, for any $p > 16/3$ (see Bourgain [9]). This implies a trilinear estimate of order $\left(\frac{5}{4} - \varepsilon, \frac{3}{4} + \varepsilon\right)$ for every $\varepsilon > 0$, and, by Theorem 5.8, global uniform wellposedness of the defocusing subquintic NLS on $H^1(\mathbb{T}^3)$. Moreover, by more refined counting arguments, it is possible to reduce the order of the bilinear Strichartz estimate from $\frac{3}{4} + \varepsilon$ to $\frac{2}{3} + \varepsilon$ ([9]).

**6.2. Spheres.** The case of multidimensional spheres is of course very natural, since we observed in Subsection 4.3 that the loss in endpoint Strichartz inequalities is optimal on them. Therefore we could expect that the wellposedness results for (1.3) are the worst ones on spheres. The two-dimensional case is particularly interesting in this respect. The following theorem is a slight generalization of results in [13] and [16].

**Theorem 6.3** (Burq–Gérard–Tzvetkov [13], [16]). *The Cauchy problem for the cubic NLS, i.e.* (1.3) *with $F(u) = \pm|u|^2 u$, is regularly well-posed on $H^s(\mathbb{S}^2)$ for every $s > 1/4$ and* not *uniformly well-posed on $H^s(\mathbb{S}^2)$ for every $s < 1/4$.*

*If $F = F_{\alpha,\pm}$ (see* (1.10)*) with $\alpha \in ]0, 2]$, it is uniformly well-posed on $H^s(\mathbb{S}^2)$ for every $s > 1/4$, and* not *uniformly well-posed for $s < 1/4$.*

*The Cauchy problem for the quintic NLS, i.e.* (1.3) *with $F(u) = \pm|u|^4u$ is uniformly well-posed on $H^s(\mathbb{S}^2)$ for every $s > 1/2$.*

**Remark 6.4.** The first striking fact contained in the above result is that, unlike cubic NLSs on the Euclidean plane or on the (square) torus, a cubic NLS on the sphere has a threshold of regular (or uniform) wellposedness which is $1/4$ and not 0. Notice that we already met this exponent $1/4$ in Subsection 5.1, in connection with the counterexample of Subsection 4.3. In fact, the geometric phenomenon is the same here, namely concentration on a closed geodesic, but specific information about the sphere allow to get optimal results. A very natural open problem is of course to decide whether the *wellposedness* threshold is also $1/4$, or if it is smaller (for instance 0), as we quoted in Section 2 about the modified KdV equation.

Another important open question is raised by the comparison of the above result with Corollary 4.5, which, for a cubic NLS on general surfaces, needs $s > 1/2$ for regular wellposedness. In fact, we ignore if there is a compact surface where a cubic NLS is not regularly well-posed on $H^s$ for some $s \in ]1/4, 1/2]$.

A third observation is that, unlike positive thresholds on the Euclidean space, the one on the sphere is not always changing with the parameter $\alpha$. Indeed, for $0 < \alpha < 2$, it is frozen at $1/4$.

Finally, for the quintic NLS, the last statement of Theorem 6.3, combined with Theorem 3.3 shows that the three wellposedness thresholds coincide with $1/2$, which is the Euclidean one. This suggests a general mechanism which we already met in the context of tori, namely that *the $L^p_t(L^q_x)$ estimates of the solutions of the linear Schrödinger equation seem to become as good as the Euclidean ones if $p, q$ are large enough, so that, for $\alpha$ large enough, the wellposedness thresholds become identical to the Euclidean ones.* We shall check this phenomenon for higher dimensional spheres as well. However, we do not have any argument for proving it on a general compact manifold.

*Proof* (*sketch*). The positive results on uniform and regular wellposedness are consequences of Theorems 5.2, 5.4 and 5.7 and of multilinear Strichartz estimates for the Schrödinger group on $\mathbb{S}^2$. As in the previous subsection, we use the exact spectral representation of solutions to the linear Schrödinger equation,

$$u(t, x) = \sum_{n\sim N} \mathrm{e}^{-itn(n+1)} H_n(x),$$

where $H_n$ are spherical harmonics of degree $n$, and the condition $n \sim N$ corresponds to the spectral localization at frequency $N$. Using Parseval formula in the time variable and multilinear spectral estimates given by Theorem 5.9, we obtain a bilinear Strichartz estimate of order $1/4+\varepsilon$ and a trilinear estimate of order $(3/4+\varepsilon, 1/4+\varepsilon)$ for every $\varepsilon > 0$. The latter is even better than what we need. In particular, using Theorem 5.8, we infer that (1.3), with $F = F_{\alpha,\pm}$ (see (1.10)) and $\alpha \in ]2, 4[$, is uniformly

well-posed on $H^s(\mathbb{S}^2)$ for every $s > 3/4 - 1/\alpha$. However we do not know if this threshold is optimal.

Here an important role is played by the localization of the spectrum around squares of the integers, so that this proof can only be generalized to Zoll manifolds (see [12] and [16] for details).

We come now to the illposedness result. We observe that, as in the counterexample given in Subsection 4.3, the following sequence of spherical harmonics

$$\psi_n(x) = (x_1 + ix_2)^n, \quad x_1^2 + x_2^2 + x_3^2 = 1$$

is concentrating exponentially on the closed geodesic $x_1^2 + x_2^2 = 1$ and satisfies

$$\|\psi_n\|_{L^q} \simeq n^{\frac{1}{4} - \frac{1}{2q}} \|\psi_n\|_{L^2}, \quad q \geq 2.$$

Moreover, $\psi_n$ has the remarkable property that it is the ground state of the Laplace operator on the space $V_n$ of functions $f$ satisfying the symmetry property

$$f(R_\theta(x)) = \mathrm{e}^{in\theta} f(x),$$

where $R_\theta$ is the rotation of angle $\theta$ around the $x_3$ axis. The idea is to construct stationary solutions to (1.3) by minimizing the energy $H(f)$ on the $L^2$ sphere of $V_n$ for small radii $\delta_n = \kappa_n n^{-s}$, for different values of the parameter $\kappa_n \sim 1$. It turns out that the minimizers $f_n$ are very close to the line directed by $\psi_n$, and that the nonlinear eigenvalue $\omega_n$ can be precisely estimated as $n$ goes to $\infty$, creating for the solution

$$u_n(t, x) = \mathrm{e}^{-it\omega_n} f_n(x)$$

the same kind of instability that we already observed in the case of the one-dimensional torus. We refer to [31] for details, or to [13] for a slightly different approach. □

Finally, we observe that the above methods can be applied to higher-dimensional spheres. We gather the most striking facts in the following theorem.

**Theorem 6.5** (Burq–Gérard–Tzvetkov). *The Cauchy problem for a cubic NLS is regularly well-posed on $H^s(\mathbb{S}^3)$ for $s > 1/2$, and not uniformly well-posed for $s < 1/2$* ([17], [13]).

*If $F = F_{\alpha,\pm}$ (see (1.10)), it is uniformly well-posed on $H^s(\mathbb{S}^3)$ if $s > s(\alpha)$, and not uniformly well-posed for $s < s(\alpha)$, with $s(\alpha) = 1/2$ if $\alpha \leq 2$, and $s(\alpha) = 3/2 - 2\alpha$ if $\alpha \in [2, 4]$. In particularly it is globally uniformly well-posed on $H^1(\mathbb{S}^3)$ if $\alpha < 4$* ([17], [13]).

*The Cauchy problem for a cubic NLS is regularly well-posed on $H^s(\mathbb{S}^4)$ if $s > 1$, but not for $s = 1$* ([16], [12]).

*The Cauchy problem for* (1.3) *with $F = F_{\alpha,\pm}$ is not uniformly well-posed on $H^1(\mathbb{S}^6)$ for every $\alpha \in ]0, 1]$* ([13]).

In the case $d = 3$, as in the torus case, the question of (regular) wellposedness of the quintic NLS on small data in $H^1$ remains open. See however some partial results in this direction in [19]. As for global wellposedness of the subquintic case, it is also known on $\mathbb{S}^2 \times \mathbb{T}$, but is completely open for an arbitrary three–manifold.

In the case $d = 4$, global wellposedness for some smoothed variants of the cubic NLS can be found in [32].

Finally, let us emphasize that the illposedness result on $\mathbb{S}^6$ is in strong contrast with the case $d = 6$ in Theorem 4.2.

**6.3. Balls.** If $-P$ is the Laplace operator on the ball $\mathbb{B}^d$ of the $d$-dimensional Euclidean space with Dirichlet or Neumann boundary conditions, it is possible to take advantage of stronger concentration phenomena of the eigenfunctions at the boundary to produce illposedness for higher regularity.

**Theorem 6.6** (Burq–Gérard–Tzvetkov [14], [20]). *Let $-P$ be the Laplace operator on $\mathbb{B}^d$ with Dirichlet (resp. Neumann) boundary conditions.*

*If $d = 2$, the Cauchy problem for the cubic NLS is not uniformly well-posed on the domain of $P^{s/2}$ for $s \in [0, 1/3[$.*

*The Cauchy problem for* (1.3) *with $F = F_{\alpha,\pm}$ (see* (1.10)) *is not uniformly well-posed on $H^1_0(\mathbb{B}^5)$ (resp. $H^1(\mathbb{B}^5)$) for every $\alpha \in ]0, 1]$.*

Finally, let us mention that, contrarily to the case of spheres, global wellposedness for subquintic (1.3) with boundary conditions on $\mathbb{B}^3$ remains an open problem.

# The periodic Lorentz gas in the Boltzmann-Grad limit

François Golse*

**Abstract.** Consider the motion of a single point particle bouncing in a fixed system of spherical obstacles. It is assumed that collisions are perfectly elastic, and that the particle is subject to no external force between collisions, so that the particle moves at constant speed. This type of dynamical system belongs to the class of dispersing billiards, and is referred to as a "Lorentz gas". A Lorentz gas is called periodic when the obstacle centers form a lattice. Assuming that the initial position and direction of the particle are distributed under some smooth density with respect to the uniform measure, one seeks the evolution of that density under the dynamics defined by the particle motion in some large scale limit for which the number of collisions per unit of time is of the order of unity. This scaling limit is known as "the Boltzmann-Grad limit", and is the regime of validity for the Boltzmann equation in the kinetic theory of gases. Whether this evolution is governed in such a limit by a PDE analogous to the Boltzmann equation is a natural question, and the topic of this paper.

**Keywords.** Lorentz gas, dispersing billiards, Boltzmann-Grad limit, kinetic models, mean free path.

## 1. Introduction

In 1905, H. Lorentz proposed the following linear kinetic equation to describe the motion of electrons in a metal [23]:

$$\partial_t f + v \cdot \nabla_x f + \tfrac{1}{m} F(t,x) \cdot \nabla_v f(t,x,v) = N_{\mathrm{at}} r_{\mathrm{at}}^2 |v| \mathcal{C}(f(t,x,\cdot))(v), \qquad (1)$$

where the unknown $f(t,x,v)$ is the density of electrons which, at time $t$, are located at $x$ and have velocity $v$. In (1), $F$ is the electric force field, $m$ the mass of the electron, while $N_{\mathrm{at}}$ and $r_{\mathrm{at}}$ designate respectively the number of metallic atoms per unit volume and the radius of each such atom. Finally $\mathcal{C}(f)$ is the collision integral: it acts on the velocity variable only, and is given, for each continuous $\phi \equiv \phi(v)$ by the formula

$$\mathcal{C}(\phi)(v) = \int_{|\omega|=1, v\cdot\omega>0} \big(\phi(v - 2(v\cdot\omega)\omega) - \phi(v)\big) \cos(v,\omega)\, d\omega. \qquad (2)$$

*The author is grateful to Profs. E. Caglioti, H. S. Dumas and F. Murat for helpful comments during the writing of this paper.

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

Although a microscopic model, this equation is only a statistical description of electron motion and by no means a first principle of electrodynamics. For instance, (1) only holds for probability densities $f$, and does not have distributional solutions of the form

$$f \equiv \delta_{(x(t),v(t))},$$

as one would expect in any situation where there is only one electron and its trajectory in phase space $(x(t), v(t))$ is known exactly (i.e. with probability 1). Obviously, this inconsistency comes from the Lorentz collision integral $\mathcal{C}$, and not from the electric force. Hence we shall assume throughout this lecture that the electric force

$$F \equiv 0$$

and restrict our attention to the collision integral.

Since the Lorentz equation is not itself a first principle of physics, it is natural to understand whether it can be derived from one such first principle. This question belongs to the class of problems known as "hydrodynamic limits" – although in the present case, the term "mesoscopic limit" would be more appropriate.

The interest of mathematicians in this type of question originates in Hilbert's attempts to justify rigorously the equations of fluid mechanics on the basis of the kinetic theory of gases, which he cited as an example in his 6th problem on the axiomatization of physics [19]. In [23], Lorentz himself established his model by analogy with the Boltzmann equation for a gas of hard spheres, and did not seek any rigorous derivation for it – avoiding in particular the rather subtle arguments proposed by L. Boltzmann as a justification for the equation bearing his name.

In this paper, we shall discuss whether the Lorentz equation (1) can be rigorously derived in some asymptotic limit from a very simple mechanistic model for electron motion known as the "Lorentz gas". Although not entirely satisfactory in the context of electrodynamics, this model is to the kinetic theory of electrons what molecular gas dynamics is to the kinetic theory of gases.

## 2. The Lorentz gas

Let[1] $\vec{C} \subset \mathbb{R}^{\mathrm{D}}$ (the dimensions of interest being $\mathrm{D} = 2$ or $\mathrm{D} = 3$) satisfy the condition

$$d(\vec{C}) := \inf_{c,c' \in \vec{C}} |c - c'| > 0. \tag{3}$$

Pick $r \in \left(0, \frac{1}{2} d(\vec{C})\right)$, and consider the motion of a point particle moving at a constant velocity in the domain outside the union of fixed balls of radius $r$ centered at the elements of $\vec{C}$, henceforth denoted

$$Z_r[\vec{C}] := \{x \in \mathbb{R}^{\mathrm{D}} \mid \mathrm{dist}(x, \vec{C}) > r\}. \tag{4}$$

[1] We designate by $\vec{C}$ the set of obstacle centers, to avoid confusion with several constants denoted by $C$ in the sequel.

It is assumed that each collision between the particle and any of the balls is perfectly elastic. Put in other words, denoting by $z$ the collision point and by $n_z$ the inward unit normal to $\partial Z_r[\vec{C}]$ at the point $z$, the pre- and postcollisional velocities $v_-$ and $v_+$ of the particle are related by the Descartes law of specular reflection

$$v_+ = v_- - 2(v_- \cdot n_z)n_z.$$

Obviously, the speed of the particle (i.e. the Euclidian norm of its velocity vector) is invariant under this law of reflection, so that we can assume without loss of generality that this speed is $|v| = 1$.

Assuming that the position and the velocity of the particle are respectively $x$ and $v$ at time $t = 0$, we denote by $X_r(t, x, v; \vec{C})$ and $V_r(t, x, v; \vec{C})$ respectively the position and the velocity of the particle at time $t$. They satisfy the differential equations

$$\begin{aligned} \dot{X}_r &= V_r \quad \text{if } \operatorname{dist}(X(t), \vec{C}) > r, \\ \dot{V}_r &= 0 \quad \text{if } \operatorname{dist}(X(t), \vec{C}) > r, \end{aligned} \tag{5}$$

while

$$\begin{aligned} X_r(t+0) &= X_r(t-0) && \text{if } \operatorname{dist}(X_r(t-0), \vec{C}) = r, \\ V_r(t+0) &= \mathcal{R}[n_{X_r(t-0)}]V_r(t-0) && \text{if } \operatorname{dist}(X_r(t-0), \vec{C}) = r, \end{aligned} \tag{6}$$

where $\mathcal{R}[n]$ designates the specular reflection

$$\mathcal{R}[n]v = v - 2(v \cdot n)n.$$

The dynamical system $(X_r, V_r)$ is referred to as *the Lorentz gas* in the configuration of spherical obstacles of radius $r$ centered at the points of $\vec{C}$.

Let $f^{\text{in}} \equiv f^{\text{in}}(x, v)$ be a probability density on the single-particle phase-space, i.e. a nonnegative measurable function defined a.e. on $Z_r[\vec{C}] \times \mathbb{S}^{D-1}$ such that

$$\iint_{Z_r[\vec{C}]\times\mathbb{S}^{D-1}} f^{\text{in}}(x, v)\, dxdv = 1.$$

Define $f_r \equiv f_r(t, x, v; \vec{C})$ to be the density with respect to $dxdv$ of the image measure of $f^{\text{in}}(x, v)dxdv$ under the flow $(X_r, V_r)$, i.e.

$$f_r(t, x, v; \vec{C}) = f^{\text{in}}(X_r(-t, x, v; \vec{C}), V_r(-t, x, v; \vec{C})). \tag{7}$$

A natural question is whether $f_r(t, x, v; \vec{C})$ converges to a solution of the kinetic equation (1) with $F \equiv 0$ in the vanishing $r$ limit, and under some appropriate scaling assumption on the obstacle configuration $\vec{C}$.

Observe that (5) is the system of ordinary differential equations defining the characteristics of the free transport equation in $Z_r[\vec{C}] \times \mathbb{S}^{D-1}$; therefore the density $f_r$ is the solution of

$$\begin{aligned} \partial_t f_r + v \cdot \nabla_x f_r &= 0, && x \in Z_r[\vec{C}],\ |v| = 1,\ t > 0, \\ f_r(t, x, \mathcal{R}[n_x]v) &= f_r(t, x, v), && x \in \partial Z_r[\vec{C}],\ |v| = 1,\ t > 0, \\ f_r(0, x, v) &= f^{\text{in}}(x, v), && x \in Z_r[\vec{C}],\ |v| = 1. \end{aligned} \tag{8}$$

Hence the question above can be viewed as a some kind of homogenization problem for the transport equation. Analogous homogenization problems for the diffusion (Laplace) equation have been thoroughly studied – the work of Hruslov [20] is one of the first references on this topic; see also the lucid presentation of this class of problems in [10].

G. Gallavotti considered in [14] the case of random configurations $\vec{C}$ of obstacles; specifically, the points in $\vec{C}$ are independent and identically distributed, under Poisson's law with density $N_{\mathrm{at}}$. The radius of the obstacles is $r > 0$; it is assumed that $N_{\mathrm{at}} \to +\infty$ while $r \to 0$ so that $N_{\mathrm{at}} r^2 \to \sigma$. He proved that, in this limit, the expectation of $f_r(t, x, v; \vec{C})$ converges to the solution of (1) with initial data $f^{\mathrm{in}}$ and with $F \equiv 0$. His analysis is written in detail on pp. 48–55 in [15]. Later on, his result was strengthened in [29] by H. Spohn, who considered slightly more general distributions of obstacles. The a.s. convergence of $f_r(t, x, v; \vec{C})$ in $\vec{C}$ was proved by C. Boldrighini, L. A. Bunimovich and Ya. G. Sinai [5].

Obviously, the case of a Poisson distribution of obstacles is very natural in the context of the kinetic theory of (neutral) gases. For instance, one could think of a mixture of two hard sphere gases, one with light molecules, the other one with heavy molecules in equilibrium. If the concentration of the light gas is small, collisions between light molecules can be neglected; only binary collisions involving one molecule of each type are considered. This is essentially[2] the microscopic model studied in [14], [15]. For other applications (such as the motion of electrons in a metal) it may be useful to know what happens for other distributions of obstacles. In this paper, we shall discuss the case of a periodic distribution of obstacles.

## 3. The distribution of free path lengths

From now on, we shall restrict our attention to the case of a periodic Lorentz gas with spherical obstacles of radius $r \in \left(0, \frac{1}{2}\right)$ centered at the integer points, i.e. $\vec{C} = \mathbb{Z}^{\mathrm{D}}$. Since the configuration of obstacle centers is thus fixed, we shall henceforth abbreviate the notation introduced above by setting $X_r(t, x, v) := X_r(t, x, v; \mathbb{Z}^{\mathrm{D}})$, $V_r(t, x, v) := V_r(t, x, v; \mathbb{Z}^{\mathrm{D}})$, while $Z_r := Z_r[\mathbb{Z}^{\mathrm{D}}]$ and $f_r(t, x, v) := f_r(t, x, v, \mathbb{Z}^{\mathrm{D}})$.

In view of the probabilistic interpretation of the kinetic equation (1) and of the definition of the Boltzmann-Grad scaling, one expects that the free path lengths should play an important role in studying the periodic Lorentz gas above in that limit.

**Definition 3.1.** For $x \in Z_r$ and $v \in \mathbb{S}^{\mathrm{D}-1}$, the free path length (or forward exit time) for a particle starting at the position $x$ in the direction $v$ is

$$\tau_r(x, v) = \inf\{t > 0 \mid x + tv \in \partial Z_r\}.$$

[2] Except for the fact that heavy molecules may overlap in Gallavotti's model, while this cannot occur for real hard spheres: see condition (3).

For each $v \in \mathbb{S}^{D-1}$, the function $x \mapsto \tau_r(x, v)$ has a unique continuous extension to $Z_r \cup \{x \in \partial Z_r \mid v \cdot n_x \neq 0\}$ for which we shall abuse the notation $\tau_r(x, v)$.

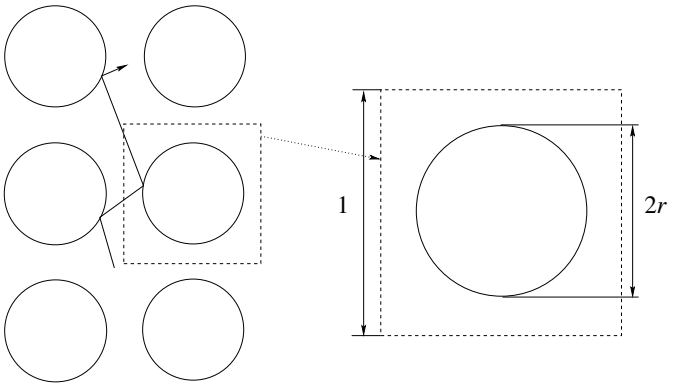

Figure 1. The periodic Lorentz gas.

Notice that $\tau_r(x + k, v) = \tau_r(x, v)$ for each $(x, v) \in Z_r \times \mathbb{S}^{D-1}$ and $k \in \mathbb{Z}^D$: hence $\tau_r$ can be seen as a $[0, +\infty]$-valued function defined on $Y_r \times \mathbb{S}^{D-1}$ and a.e. on $\bar{Y}_r \times \mathbb{S}^{D-1}$, with $Y_r = Z_r/\mathbb{Z}^D$.

If the components of $v \in \mathbb{S}^{D-1}$ are rationally independent – i.e. if $k \cdot v \neq 0$ for each $k \in \mathbb{Z}^D \setminus \{0\}$ – each orbit of the linear flow $x \mapsto x + tv$ is dense on $\mathbb{T}^D = \mathbb{R}^D/\mathbb{Z}^D$, so that $\tau_r(x, v)$ is finite for each $x \in Z_r$.

There are two different, natural phase spaces on which to study the free path length $\tau_r$.

The first one is $\Gamma_r^+ = \{(x, v) \in \partial Z_r \times \mathbb{S}^{D-1} \mid v \cdot n_x > 0\}$ – or its quotient under the action of $\mathbb{Z}^D$-translations on space variables $\tilde{\Gamma}_r^+ = \Gamma_r/\mathbb{Z}^D$ – equipped with its Borel $\sigma$-algebra and the probability measure $\nu_r$ proportional to $\gamma_r$, where

$$d\gamma_r(x, v) = (v \cdot n_x) ds(x) dv,$$

$ds$ being the surface element on $\partial Z_r$.

The second one is $Y_r \times \mathbb{S}^{D-1}$, equipped with its Borel $\sigma$-algebra and the probability measure $\mu_r$ proportional to the uniform measure on $Y_r \times \mathbb{S}^{D-1}$. The measure $\mu_r$ is obviously invariant under the flow ($X$ mod. $\mathbb{Z}^D$, $V$) of the Lorentz gas.

Hence, there are two natural notions of a mean free path for the Lorentz gas:

$$\int_{\tilde{\Gamma}_r^+} \tau_r(x, v)\, d\nu_r(x, v) \quad \text{and} \quad \int_{Y_r \times \mathbb{S}^{D-1}} \tau_r(x, v)\, d\mu_r(x, v). \tag{9}$$

**3.1. Santalò's formula for the mean free path.** In [26], L. Santalò proposed the following simple and elegant explicit expression[3] for the first notion of mean free path.

$$\int_{\tilde{\Gamma}_r^+} \tau_r(x,v)\, d\nu_r(x,v) = \frac{|Y_r||\mathbb{S}^{D-1}|}{\gamma_r(\tilde{\Gamma}_r^+)} = \frac{1-|\mathbb{B}^D|r^D}{|\mathbb{B}^{D-1}|r^{D-1}} \qquad (\textit{Santalò's formula})$$

where $\mathbb{B}^d$ is the d-dimensional unit ball (for the Euclidian norm).

For $D = 3$, one finds

$$\int_{\tilde{\Gamma}_r^+} \tau_r(x,v)\, d\nu_r(x,v) = \frac{1-\frac{4}{3}\pi r^3}{\pi r^2}.$$

With $N_{\mathrm{at}} = 1$ and $|v| = 1$, this is indeed equivalent in the vanishing $r$ limit to the reciprocal of the factor

$$N_{\mathrm{at}} r^2 |v| \int_{|\omega|=1,\, v\cdot\omega>0} \cos(v,\omega)\, d\omega = \pi r^2$$

that appears in (1). However encouraging, this by itself is not enough to justify the relevance of (1) in the description of the Boltzmann-Grad limit of the periodic Lorentz gas (see the discussion in Section 4 below).

Here is a quick proof of Santalò's formula.

**Lemma 3.2** (Dumas–Dumas–Golse [13]). *Let $f \in C^1(\mathbb{R}_+)$ be such that $f(0) = 0$. Then one has*

$$\gamma_r(\tilde{\Gamma}_r^+) \int_{\Gamma_r^+} f(\tau_r(x,v))\, d\nu_r(x,v) = |Y_r||\mathbb{S}^{D-1}| \int_{Y_r\times\mathbb{S}^{D-1}} f'(\tau_r(x,v))\, d\mu_r(x,v)$$

This lemma entails Santalò's formula by letting $f(z) = z$, since the integral on the right-hand side of the identity above is equal to 1.

*Proof.* For each $x \in Z_r$, one has $\tau_r(x+tv,v) = \tau_r(x,v) + t$ for all $t$ near 0. Differentiating in $t$ shows that

$$\begin{aligned} v\cdot\nabla_x\tau_r &= 1, \quad x \in Y_r,\ |v| = 1,\\ \tau_r|_{\tilde{\Gamma}_r^+} &= 0. \end{aligned}$$

Multiplying each side of the first equality by $f'(\tau_r(x,v))$ and integrating for the uniform measure gives

$$\int_{Y_r\times\mathbb{S}^{D-1}} \mathrm{div}_x(vf(\tau_r(x,v)))\, dxdv = |Y_r||\mathbb{S}^{D-1}| \int_{Y_r\times\mathbb{S}^{D-1}} f'(\tau_r(x,v))\, d\mu_r(x,v).$$

We conclude by applying Green's formula to the integral on the left-hand side. □

[3] If $A$ is a d-dimensional measurable subset of $\mathbb{R}^D$ (with $d \le D$), the notation $|A|$ denotes its d-dimensional volume.

**3.2. Bounds on the distribution of free path lengths.** For each point of the form $x = \frac{1}{2}(1, \dots, 1) \in Z_r$, the free path length $\tau_r(x, v)$ is infinite for some $v \in \mathbb{Q}^{\mathrm{D}}$, while it is finite whenever the components of $v$ are not rationally dependent. This suggests the presence of tremendous oscillations in the graph of the function $\tau_r$.

Therefore, it becomes interesting to study the distribution of values of $\tau_r(x, v)$. We shall do so in the phase space $Y_r \times \mathbb{S}^{\mathrm{D}-1}$ equipped with the probability measure $\mu_r$. On the other hand, Santalò's formula suggests that the appropriate scale to measure the free path length is the reciprocal of $r^{\mathrm{D}-1}$. Hence we consider

$$\Phi_r(t) = \mu_r\Big(\Big\{(x, v) \in Y_r \times \mathbb{S}^{\mathrm{D}-1} \;\Big|\; \tau_r(x, v) > \frac{t}{r^{\mathrm{D}-1}}\Big)\Big\}.$$

One could also choose to consider instead

$$\Psi_r(t) = \nu_r\Big(\Big\{(x, v) \in \tilde{\Gamma}_r^+ \;\Big|\; \tau_r(x, v) > \frac{t}{r^{\mathrm{D}-1}}\Big)\Big\}.$$

However, the formula in Lemma 3.2 can be recast in the form

$$\int_0^\infty f(t)\Psi_r(r^{\mathrm{D}-1}t)\,dt = \frac{1 - |\mathbb{B}^{\mathrm{D}}|r^{\mathrm{D}}}{|\mathbb{B}^{\mathrm{D}-1}|r^{\mathrm{D}-1}} \int_0^\infty f'(t)\Phi_r(r^{\mathrm{D}-1}t)\,dt$$

for each $f \in C^1(\mathbb{R}_+)$ such that $f(0) = 0$, which means that

$$\Psi_r = -\tfrac{1-|\mathbb{B}^{\mathrm{D}}|r^{\mathrm{D}}}{|\mathbb{B}^{\mathrm{D}-1}|}\Phi_r' \quad \text{on } \mathbb{R}_+^*. \tag{10}$$

Hence it suffices to study $\Phi_r$.

We begin with the following uniform bounds on $\Phi_r$.

**Theorem 3.3** (Bourgain–Golse–Wennberg [6], [18]). *For any space dimension* D *such that* $\mathrm{D} > 1$*, there exists two positive constants* $C'_{\mathrm{D}} > C_{\mathrm{D}}$ *such that*

$$\frac{C_{\mathrm{D}}}{t} \le \Phi_r(t) \le \frac{C'_{\mathrm{D}}}{t} \quad \textit{for each } t > 1 \textit{ and } r \in \big(0, \tfrac{1}{2}\big).$$

The proof of the upper estimate uses Fourier series in a way that is somewhat reminiscent of Siegel's proof [27] of Minkowski's convex body theorem – see also Theorem 9 in chapter 5 of [24].

The proof of the lower bound is very different in spirit: it is based on a precise counting of infinite open strips included in the billiard table $Z_r$, very similar to Bleher's analysis for the diffusion limit of the periodic Lorentz gas in [2]. Indeed, the free path length $\tau_r(x, v)$ for $x$ in any such strip is bounded from below by the time $\tilde{\tau}_r(x, v)$ at which the trajectory $\{x + tv \mid t > 0\}$ exits the strip. Since $\tilde{\tau}_r(x, v)$ is explicitly known, its distribution is also explicit, and this provides the lower bound for $\Phi_r$.

Since the function $t \mapsto 1/t$ does not belong to $L^1([1, +\infty))$, the lower estimate in Theorem 3.3 implies that the second notion of mean free path in (9) is

$$\int_{Y_r \times \mathbb{S}^{\mathrm{D}-1}} \tau_r(x, v)\,d\mu_r(x, v) = \int_0^\infty \Phi_r(r^{\mathrm{D}-1}t)\,dt = +\infty \quad \text{for each } r \in \big(0, \tfrac{1}{2}\big).$$

**3.3. The distribution of free path lengths for $\mathrm{D} = 2$ as $r \to 0$.** Numerical simulations in [18] suggest that the double inequality in Theorem 3.3 could be strengthened into some asymptotic equivalence as $r \to 0$. However, given the very different nature of the proofs for the upper and the lower bounds in Theorem 3.3, one cannot expect this asymptotic equivalence to be established by the same techniques as in [6].

The proof of Theorem 3.3 suggests that rational approximation plays an important role in the slow decay of the distribution of free path lengths. It is well-known that continued fractions provide a fast algorithm for finding the best rational approximants of any irrational number. For that reason, the Lorentz gas in the case $\mathrm{D} = 2$ can be analyzed in a quite detailed manner with continued fractions, as we shall see below. The same analysis in the case of dimension $\mathrm{D} > 2$ would require using simultaneous rational approximation, a much more difficult problem for which no satisfying analogue of the continued fraction algorithm seems to be available at the time of this writing.

For each $v \in \mathbb{S}^1$, define

$$\phi_r(t, v) = \frac{1}{|Y_r|} \left| \left\{ x \in Y_r \;\middle|\; \tau_r(x, v) > \frac{t}{r^{\mathrm{D}-1}} \right\} \right|.$$

**Theorem 3.4** (Caglioti–Golse [7], [8]). *In the case of space dimension* $\mathrm{D} = 2$*,*

- *for each* $t > 0$ *and a.e.* $v \in \mathbb{S}^1$*,* $\phi_r(t, v)$ *converges in the sense of Cesàro as* $r \to 0$*: there exists* $\phi(t) \in \mathbb{R}_+$ *such that*

$$\lim_{\varepsilon \to 0} \frac{1}{\ln \frac{1}{\varepsilon}} \int_\varepsilon^{r^*} \phi_r(t, v) \, \frac{dr}{r} = \phi(t);$$

- *one has*

$$\phi(t) = \frac{1}{\pi^2 t} + O\Big(\frac{1}{t^2}\Big) \quad \text{as } t \to +\infty.$$

Obviously

$$\Phi_r(t) = \frac{1}{2\pi} \int_{\mathbb{S}^1} \phi_r(t, v) dv, \qquad \text{so that} \qquad \lim_{\varepsilon \to 0} \frac{1}{\ln \frac{1}{\varepsilon}} \int_\varepsilon^{r^*} \Phi_r(t) \, \frac{dr}{r} = \phi(t). \tag{11}$$

The asymptotic expansion $\frac{1}{\pi^2 t} + O\big(\frac{1}{t^2}\big)$ has been identified for the first time in [7]. In fact, the result in [7] stated that both the lim sup and the lim inf of the Cesàro mean of $\Phi_r$ for the scaling invariant measure $\frac{dr}{r}$ as in (11) have that same asymptotic expansion. The a.e. pointwise (in $v$) convergence is new – see [8].

**3.3.1. Method of proof.** Before sketching the proof of the result above, let us recall some background on continued fractions.

The Gauss map is defined as

$$T : (0, 1) \setminus \mathbb{Q} \ni x \mapsto \frac{1}{x} - \left[ \frac{1}{x} \right] \in (0, 1) \setminus \mathbb{Q};$$

it is an ergodic automorphism of $(0,1)\setminus\mathbb{Q}$ with respect to the Gauss measure $dg(x) = \frac{1}{\ln 2}\frac{dx}{1+x}$ that is invariant under $T$.

Let $x \in (0,1)\setminus\mathbb{Q}$; define the sequence of positive integers

$$a_k = \left[\frac{1}{T^{k-1}x}\right], \quad k \geq 1.$$

Then $x$ is represented by the continued fraction

$$x = \cfrac{1}{a_1 + \cfrac{1}{a_2 + \cfrac{1}{a_3 + \cdots}}} =: [0; a_1, a_2, a_3, \dots].$$

Define by induction the sequences of integers $p_n$ and $q_n$ by

$$\begin{aligned} p_{n+1} &= a_n p_n + p_{n-1}, \quad \text{for each } n \geq 1, \quad p_0 = 1,\ p_1 = 0, \\ q_{n+1} &= a_n q_n + q_{n-1}, \quad \text{for each } n \geq 1, \quad q_0 = 0,\ q_1 = 1, \end{aligned} \tag{12}$$

For each $n \geq 2$, the integers $p_n$ and $q_n$ are coprime, and the rational number $\frac{p_n}{q_n}$ is called the $n$-th convergent of $x$. The distance from $x$ to its $n$-th convergent is measured by

$$d_n = (-1)^{n-1}(q_n x - p_n) > 0; \tag{13}$$

for each $n \geq 0$, one has

$$d_n = \prod_{k=0}^{n-1} T^k x. \tag{14}$$

(see for instance the third formula on p. 89 of [28]).

*Step* 1. *A three-term partition of* $\mathbb{T}^2$. A key idea in the proof of Theorem 3.4 is provided by the answer found by S. Blank and N. Krikorian [1] to the following question raised by R. Thom: *"What is the longest orbit of a linear flow with irrational slope on a flat torus with a disk removed?"*

Without loss of generality, assume that the linear flow is $x \mapsto x + tv$ with $v = (\cos\theta, \sin\theta)$ and $\theta \in (0, \frac{\pi}{4})$. The removed disk of radius $r$ is then replaced with the vertical slit $S_r(v)$ of length $2r/\cos\theta$ as shown in Figure 2 (left). Blank and Krikorian found that the set of lengths of all orbits of the linear flow above on $\mathbb{T}^2 \setminus S_r(v)$ consists of exactly three positive values, $l_A(r,v) < l_B(r,v)$ and $l_C(r,v) = l_A(r,v) + l_B(r,v)$.

This suggests considering the three-term partition of $\mathbb{T}^2 \setminus S_r(v)$

$$\{Y_A(r,v), Y_B(r,v), Y_C(r,v)\}$$

defined as follows: $Y_A(r,v)$ (resp. $Y_B(r,v)$, $Y_C(r,v)$) is the union of all orbits of length $l_A(r,v)$ (resp. $l_B(r,v)$, $l_C(r,v)$). Set

$$S_A(r,v) = \{y \in S_r(v) \mid \text{ the orbit starting from } y \text{ is of type } A\}$$

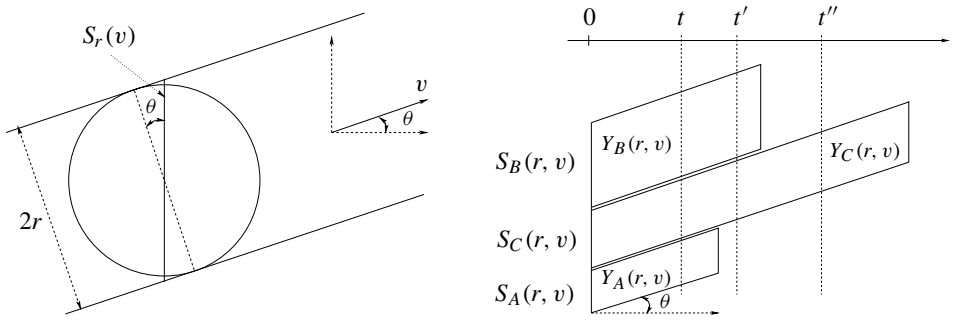

Figure 2. Left: The obstacle and the slit. Right: The 3-strip partition of the 2-torus. This figure gives a simple geometric interpretation of $\psi_r(rs, v)$ for $rs\cos\theta = t$, $rs\cos\theta = t'$ or $rs\cos\theta = t''$.

with analogous definitions for $S_B(r,v)$ and $S_C(r,v)$. Then $S_A(r,v)$, $S_B(r,v)$ and $S_C(r,v)$ are segments while $Y_A(r,v)$, $Y_B(r,v)$ and $Y_C(r,v)$ are (mod 1) parallelograms with one side being $S_A(r,v)$, $S_B(r,v)$ or $S_C(r,v)$ while the adjacent sides are of lengths $l_A(r,v)$, $l_B(r,v)$, or $l_C(r,v)$: see Figure 2 (right).

The orbit lengths $l_A(r,v)$, $l_B(r,v)$ and $l_C(r,v)$, and the lengths of the three segments $S_A(r,v)$, $S_B(r,v)$ and $S_C(r,v)$ are computed in terms of $r$ and the continued fraction expansion of $\tan\theta$ as follows.

Set $\alpha = \tan\theta$, and denote by $\alpha = [0; a_1(\theta), a_2(\theta), a_3(\theta), \dots]$ the continued fraction expansion of $\alpha = \tan\theta$, also let $p_n(\alpha)/q_n(\alpha)$ be the $n$-th convergent of $\alpha$ as in (12). Finally, let $d_n(\alpha)$ be the sequence of errors as defined in (13).

Define

$$N(\alpha, r) = \min\left\{n \in \mathbb{N} \mid d_n(\alpha) \le 2r\sqrt{1+\alpha^2}\right\}; \tag{15}$$

and

$$k(\alpha, r) = -\left[\frac{2r\sqrt{1+\alpha^2} - d_{N(\alpha,r)-1}}{d_{N(\alpha,r)}}\right] \tag{16}$$

Then, the three-strip partition above is characterized by the formulas below:

$$\begin{aligned} l_A(r,v) &= q_{N(\alpha,r)}(\alpha)\sqrt{1+\alpha^2}, \\ l_B(r,v) &= \left(q_{N(\alpha,r)-1}(\alpha) + k(\alpha,r)q_{N(\alpha,r)}(\alpha)\right)\sqrt{1+\alpha^2}, \\ l_C(r,v) &= \left(q_{N(\alpha,r)-1}(\alpha) + (k(\alpha,r)+1)q_{N(\alpha,r)}(\alpha)\right)\sqrt{1+\alpha^2}, \end{aligned} \tag{17}$$

while

$$\begin{aligned} |S_A(\alpha,r)| &= 2r\sqrt{1+\alpha^2} - d_{N(\alpha,r)}(\alpha), \\ |S_B(\alpha,r)| &= 2r\sqrt{1+\alpha^2} - \left(d_{N(\alpha,r)-1}(\alpha) - k(\alpha,r)d_{N(\alpha,r)}(\alpha)\right), \\ |S_C(\alpha,r)| &= d_{N(\alpha,r)-1}(\alpha) - (k(\alpha,r)-1)d_{N(\alpha,r)}(\alpha) - 2r\sqrt{1+\alpha^2}. \end{aligned} \tag{18}$$

*Step* 2. *Computing* $\phi_r$. Let $\lambda_r(x, v) = \inf\{t > 0 \mid x + tv \in S_r(v)\}$ for each $x \in \mathbb{T}^2 \setminus S_r(v)$; clearly

$$|\tau_r(x, v) - \lambda_r(x, v)| \leq r \quad \text{for each } x \in Y_r \setminus S_r(v). \tag{19}$$

Define

$$\psi_r(t, v) := \text{Prob}\{x \in \mathbb{T}^2 \setminus S_r(v) \mid \lambda_r(x, v) \geq t/r\},$$

where the probability is computed with respect to the uniform measure on $Y_r$. Because of (19), one has

$$\psi_r(t - r^2, v) - \pi r^2 \leq (1 - \pi r^2)\phi_r(t, v) \leq \psi_r(t + r^2, v) \quad \text{for each } t \geq r^2. \tag{20}$$

On the other hand, $\psi_r$ can be computed explicitly with the help of the three-term partition above. It is found that

$$\begin{aligned}\psi_r(t, v) = \max\big(1 - 2t,\, 1 - \tfrac{1-\delta_N}{\delta_{N-1}}\mu_N - 2t\delta_N,\, 1 - \tfrac{(k-1)\delta_N+1}{\delta_{N-1}}\mu_N - \tfrac{\delta_N}{\delta_{N-2}}\mu_{N-1} \\ - (\delta_{N-1} - (k-1)\delta_N - 1)\big(2t - \tfrac{\mu_{N-1}}{\delta_{N-2}} - k\tfrac{\mu_N}{\delta_{N-1}}\big),\, 0\big).\end{aligned} \tag{21}$$

In the formula above, $N = N(\alpha, r)$ and $\delta_n = \frac{d_n(\alpha)}{2r\sqrt{1+\alpha^2}}$ while $\mu_n = d_{n-1}(\alpha)q_n(\alpha)$; also $k = k(\alpha, r) = -\big[-\big(\frac{\delta_{N-1}}{\delta_N} - \frac{1}{\delta_N}\big)\big]$. The direction is $v = \big(\frac{1}{\sqrt{1+\alpha^2}}, \frac{\alpha}{\sqrt{1+\alpha^2}}\big)$.

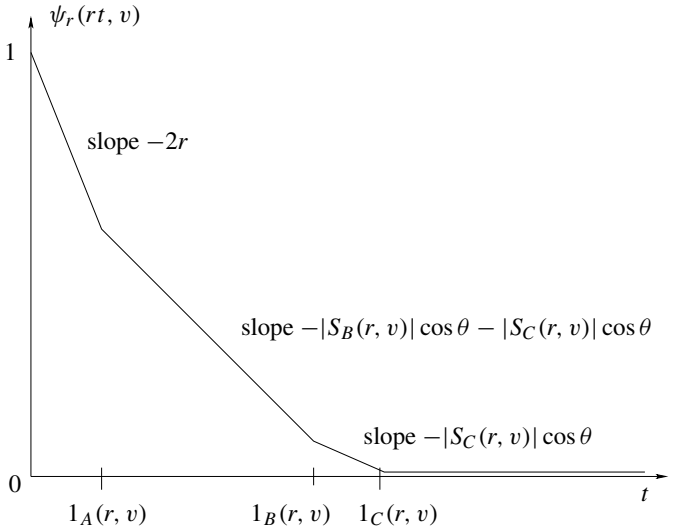

Figure 3. Graph of $\psi_r(rt, v)$.

*Step* 3. *Using the ergodicity of the Gauss map.* Birkhoff's ergodic theorem says that, for each $h \in L^1\big((0,1), \frac{dx}{1+x}\big)$, one has

$$\frac{1}{N}\sum_{j=0}^{N-1} h(T^m\alpha) \to \frac{1}{\ln 2}\int_0^1 \frac{h(z)dz}{1+z} \quad \text{a.e. in } \alpha \in (0,1) \text{ as } N \to +\infty. \tag{22}$$

Together with formula (14) and the definition of $N(\alpha, r)$, the convergence in (22) for $h = \ln$ implies that

$$N(\alpha, r) \sim \tfrac{12\ln 2}{\pi^2}|\ln r| \quad \text{as } r \to 0, \text{ for a.e. } \alpha \in (0,1). \tag{23}$$

Define

$$\Delta_j(\alpha, x) := -\ln \delta_{N(\alpha,e^{-x})-j}(\alpha) = -\ln d_{N(\alpha,e^{-x})-j}(\alpha) - x + \ln(2\sqrt{1+\alpha^2}) \tag{24}$$

for each $j \geq 0$, $\alpha \in (0,1) \setminus \mathbb{Q}$ and $x > \ln 2$. A further application of Birkhoff's theorem (22) leads to

**Lemma 3.5.** *Let $f$ be a bounded continuous function on $\mathbb{R}^{m+1}$. Then, for each $x_* \geq \ln 2$, one has*

$$\frac{1}{\ln(1/r)}\int_{x^*}^{\ln(1/r)} f(\Delta_0(\alpha,x), \dots, \Delta_m(\alpha,x))dx \to \int_0^1 \frac{F(\theta)d\theta}{1+\theta} \quad \textit{a.e. in } \alpha \in (0,1)$$

*as $r \to 0$, where*

$$F(\theta) = \int_0^{|\ln(T^m\theta)|} f(Y_m(y,\theta))\, dy.$$

*In the formula above, $Y_m(y,\theta)$ denotes*

$$Y_m(y,\theta) = (y,\, y + \ln T^m\theta,\, y + \ln T^m\theta + \ln T^{m-1}\theta,\, \dots,\, y + \ln T^m\theta + \cdots + \ln T\theta).$$

*Step* 4. *The small scatterer limit for the Cesàro mean of $\Phi_r$.* We seek to apply the lemma above to compute

$$\frac{1}{\ln(1/\varepsilon)}\int_\varepsilon^{1/2} \psi_r(t,v)\,\frac{dr}{r} \quad \text{in the limit as } \varepsilon \to 0.$$

Unfortunately, $\psi_r$ given by (21) is not a function of any fixed, finite number of ratios of the form $\frac{\delta_n}{\delta_{n-1}}$, but also involves a few $\mu_n$s – in the original variables, $\psi_r$ explicitly depends on the $q_n(\alpha)$s which involve the complete string of all the $T^j\alpha$s for $j = 0, 1, \dots, n-1$, not only the last one.

Next observe that $\frac{\mu_N}{\delta_{N-1}} \leq 1$, and hence $t \geq 1$ implies that

$$\begin{aligned}\psi_r(t,v) &= \max\big(1 - \tfrac{1-\delta_N}{\delta_{N-1}}\mu_N - 2t\delta_N,\, 1 - \tfrac{(k-1)\delta_N+1}{\delta_{N-1}}\mu_N - \tfrac{\delta_N}{\delta_{N-2}}\mu_{N-1} \\ &\qquad - (\delta_{N-1} - (k-1)\delta_N - 1)\big(2t - \tfrac{\mu_{N-1}}{\delta_{N-2}} - k\tfrac{\mu_N}{\delta_{N-1}}\big),\, 0\big) \\ &= \max\big(1 - \tfrac{1-\delta_N}{\delta_{N-1}}\mu_N - 2t\delta_N, \\ &\qquad (\delta_{N-1} - (k-1)\delta_N - 1)\big(\tfrac{\mu_{N-1}}{\delta_{N-2}} + (k+1)\tfrac{\mu_N}{\delta_{N-1}} - 2t\big),\, 0\big).\end{aligned} \tag{25}$$

In this last equality we have used formula (8) in chapter 1 of [21].

On the other hand, $\delta_{N-1} - (k-1)\delta_N - 1 \leq \delta_N$ so that

$$\begin{aligned} 0 \leq \psi_r(t,v) - (1 - \tfrac{1-\delta_N}{\delta_{N-1}}\mu_N - 2t\delta_N)_+ \\ \leq \tfrac{\delta_N}{\delta_{N-1}}\mu_N \mathbf{1}_{2t \leq \frac{\mu_{N-1}}{\delta_{N-2}} + (k+1)\frac{\mu_N}{\delta_{N-1}}} \leq \tfrac{\delta_N}{\delta_{N-1}}\mu_N \mathbf{1}_{2t \leq (k+2)\frac{\mu_N}{\delta_{N-1}}} \leq \tfrac{1}{k}\mathbf{1}_{k+2 \geq t}. \end{aligned}$$

Finally $\frac{\delta_N}{\delta_{N-1}}\mu_N \leq \frac{1}{k}$ and $1 - \mu_N \leq \frac{2}{k}$ (see Lemma 4.1 in [7]) so that

$$\begin{aligned} \left|\left(1 - \tfrac{1-\delta_N}{\delta_{N-1}}\mu_N - 2t\delta_N\right)_+ - \left(1 - \tfrac{1}{\delta_{N-1}} - 2t\delta_N\right)_+\right| &\leq \left(\tfrac{\delta_N}{\delta_{N-1}}\mu_N + \tfrac{1-\mu_N}{\delta_{N-1}}\right)\mathbf{1}_{k+2 \geq t} \\ &\leq \tfrac{3}{k}\mathbf{1}_{k+2 \geq t} \end{aligned}$$

and $\psi_r(t,v)$ can be replaced with $(1 - \frac{1}{\delta_{N-1}} - 2t\delta_N)_+$ modulo an error term controlled by $\frac{3}{k}\mathbf{1}_{k+2 \geq t}$. Applying Lemma 3.5 to $f(\Delta_0, \Delta_1) = (1 - e^{\Delta_1} - 2te^{-\Delta_0})_+$ leads to the asymptotic behavior in the second part of Theorem 3.4.

The proof of the a.e. in $v$ convergence uses Steps 1–3 above, in a way that is somehow more involved: see [8] for more details.

**3.3.2. Later improvements.** Theorem 3.4 was later strengthened by F. Boca and A. Zaharescu [4], in two different ways. First, they were able to remove the need for Cesàro averaging in the convergence statement of (11). Also, they obtained a (semi-)explicit formula for $\phi$. Here is their result:

**Theorem 3.6** (Boca–Zaharescu [4]). *In the case of space dimension* $\mathrm{D} = 2$*, one has*

$$\Phi_r(t) \to \phi(t) \quad \text{as } r \to 0 \text{ for each } t > 0$$

*where*

$$\begin{aligned} \phi(t) &= 1 - 2t + \tfrac{12}{\pi^2}t^2, && t \in \left(0, \tfrac{1}{2}\right], \\ \phi(t) &= \tfrac{6}{\pi^2}\int_0^{2t-1} a(x,t)\,dx + \tfrac{6}{\pi^2}\int_{2t-1}^1 b(x,t)\,dx, && t \in \left(\tfrac{1}{2}, 1\right], \\ \phi(t) &= \tfrac{6}{\pi^2}\int_0^1 a(x,t)\,dx, && t \in (1, +\infty), \end{aligned}$$

*with the functions a and b given by*

$$\begin{aligned} a(x,t) &= \tfrac{(1-x)^2}{x}\left(2\ln\tfrac{2t-x}{2(t-x)} - \tfrac{2t}{x}\ln\tfrac{(2t-x)^2}{4t(t-x)}\right), \\ b(x,t) &= \tfrac{1-2t}{x}\ln\tfrac{1}{2t-x} + \tfrac{(2t-x)(x+1-2t)}{x} + \tfrac{(1-x)^2}{x}\left(2\ln\tfrac{2t-x}{1-x} - \tfrac{2t}{x}\ln\tfrac{(2t-x)}{2t(1-x)}\right). \end{aligned}$$

The formulas above for $\Phi$ were first conjectured by P. Dahlqvist in [11], by an argument involving Farey fractions, which however remained incomplete since it ultimately relied on the equidistribution of a certain geometrical quantity, which remained to be proved.

The proof by Boca and Zaharescu is essentially based on two ideas: a) using the same 3-strip partition as in [7], in the language of Farey instead of continuous fractions, and b) computing certain sums indexed by lattice points with coprime coordinates by replacing them with integrals while controlling the resulting error terms.

However, being based on averaging in $x$ and $v$, their proof fails to provide a.e. pointwise convergence in $v$, unlike the proof of Theorem 3.4, based on Birkhoff's ergodic theorem for the Gauss map, which requires instead averaging in $r$, thereby proving only convergence in Cesàro's sense.

**3.4. The entropy of the billiard map as $r \to 0$.** The semi-explicit formula for $\Phi$ in Theorem 3.6 has at least one important application besides the problem of justifying the Lorentz equation (1). Define the *billiard map* in the case of the Lorentz gas to be

$$\mathcal{B}_r : \tilde{\Gamma}_r^+ \to \tilde{\Gamma}_r^+, \quad (x, v) \mapsto \mathcal{B}_r(x, v) = (x + \tau_r(x, v)v, \mathcal{R}[n_{x+\tau_r(x,v)v}]v); \quad (26)$$

one easily checks that the measure $\nu_r$ is invariant under the map $\mathcal{B}_r$. Denote by $h(\mathcal{B}_r)$ the Kolmogorov–Sinai entropy of the billiard map $\mathcal{B}_r$ with respect to the measure $\nu_r$. A consequence of Theorem 3.6 and of formula (10)[4] is the following asymptotic formula for the entropy of the billiard map in dimension $\mathrm{D} = 2$ and in the small obstacle limit:

$$h(\mathcal{B}_r) = 2 \ln \frac{1}{r} + 2 + C + o(1) \quad \text{as } r \to 0.$$

Here the constant $C$ is defined as

$$C = \lim_{r \to 0} \left( \int_{\tilde{\Gamma}_r^+} \ln \tau_r(x, v)\, d\nu_r(x, v) - \ln \int_{\tilde{\Gamma}_r^+} \tau_r(x, v)\, d\nu_r(x, v) \right) = \frac{9\zeta(3)}{4\zeta(2)} - 3 \ln 2$$

while $\zeta$ is Riemann's zeta function.

In 1991, N. Chernov had proved that, in dimension D, the entropy of the billiard map satisfies

$$h(\mathcal{B}_r) = \mathrm{D}(\mathrm{D} - 1) \ln \frac{1}{r} + O(1) \quad \text{as } r \to 0;$$

see [9] and the references therein. That the $O(1)$ error term should actually converge as $r \to 0$ had been conjectured earlier by B. Friedman, Y. Oono and I. Kubo on the basis of numerical simulations; the correct value of the limit was then proposed by Dahlqvist in [11] before Boca–Zaharescu's proof in [4].

## 4. The Boltzmann-Grad limit: a negative result

In this section, we return to the formulation of the Boltzmann-Grad limit for the periodic Lorentz gas in terms of a homogenization problem for the transport equation, as in Section 2.

[4] In [4], Boca and Zaharescu do not use formula (10); instead they derive the formula for the distribution $\Psi_r$ by using again the 3-term partition and the approximation of sums over coprime lattice points as in the proof of Theorem 3.6.

Going back to the free transport equation (8), we set

$$\vec{C} := \varepsilon\mathbb{Z}^{\mathrm{D}}, \quad r_\varepsilon = \varepsilon^{\frac{\mathrm{D}}{\mathrm{D}-1}}, \quad \Omega_\varepsilon := Z_{r_\varepsilon}[\varepsilon\mathbb{Z}^{\mathrm{D}}] \quad \text{and} \quad f_\varepsilon(t,x,v) := f_{r_\varepsilon}(t,x,v;\varepsilon\mathbb{Z}^{\mathrm{D}}),$$

where $\varepsilon \in (0, 2^{-\mathrm{D}})$. Hence $f_\varepsilon$ satisfies

$$\begin{aligned} &\partial_t f_\varepsilon + v\cdot\nabla_x f_\varepsilon = 0, && x\in\Omega_\varepsilon,\ v\in\mathbb{S}^{\mathrm{D}-1},\\ &f_\varepsilon(t,x,v) = f_\varepsilon(t,x,\mathcal{R}[n_x]v), && x\in\partial\Omega_\varepsilon,\ v\in\mathbb{S}^{\mathrm{D}-1}. \end{aligned} \tag{27}$$

For simplicity, we shall assume that $\varepsilon$ is of the form $\varepsilon = \frac{1}{n}$ for $n > 2^{\mathrm{D}}$, and that the initial data $f^{\mathrm{in}} \equiv f^{\mathrm{in}}(x,v)$ is continuous and periodic in $x$ with period 1 in each coordinate direction. In other words, $f^{\mathrm{in}} \in C(\mathbb{T}^{\mathrm{D}}\times\mathbb{S}^{\mathrm{D}-1})$.

With the choice of $\varepsilon = \frac{1}{n}$, the solution $f_\varepsilon$ of (27) with initial data

$$f_\varepsilon(0,x,v) = f^{\mathrm{in}}(x,v), \quad x\in\Omega_\varepsilon,\ v\in\mathbb{S}^{\mathrm{D}-1}, \tag{28}$$

is also periodic in the variable $x$ with period 1 in each coordinate direction; if one extends $f_\varepsilon$ by 0 inside the obstacles and abuse the notation $f_\varepsilon$ to designate this extension, one sees that

$$f_\varepsilon \in L^\infty(\mathbb{R}_+\times\mathbb{T}^{\mathrm{D}}\times\mathbb{S}^{\mathrm{D}-1}) \quad \text{with } \|f_\varepsilon\|_{L^\infty} = \|f^{\mathrm{in}}\|_{L^\infty}.$$

By the Banach–Alaoglu theorem, the sequence $f_\varepsilon$ (for $\varepsilon = \frac{1}{n}$ with $n > 2^{\mathrm{D}}$) is relatively compact in $L^\infty(\mathbb{R}_+\times\mathbb{T}^{\mathrm{D}}\times\mathbb{S}^{\mathrm{D}-1})$ for the weak-* topology. It is therefore natural to investigate the limit points of $f_\varepsilon$ as $\varepsilon\to 0$ – this being exactly the Boltzmann-Grad limit of the periodic Lorentz gas viewed as a homogenization problem for the transport equation.

We begin with the following negative result:

**Theorem 4.1** (Golse [17]). *There exists initial data $f^{\mathrm{in}} \in L^\infty(\mathbb{T}^{\mathrm{D}}\times\mathbb{S}^{\mathrm{D}-1})$ such that no subsequence of $f_\varepsilon$ converges in $L^\infty(\mathbb{R}_+\times\mathbb{T}^{\mathrm{D}}\times\mathbb{S}^{\mathrm{D}-1})$ weak-* to the solution of the Lorentz kinetic equation* (1).

In fact, the result in [17] is stronger: it excludes the possibility that any subsequence of $f_\varepsilon$ converges in $L^\infty(\mathbb{R}_+\times\mathbb{T}^{\mathrm{D}}\times\mathbb{S}^{\mathrm{D}-1})$ weak-* to the solution of any linear Boltzmann equation of the form

$$(\partial_t + v\cdot\nabla_x) f(t,x,v) = \sigma\int_{\mathbb{S}^{\mathrm{D}-1}} k(v,v')(f(t,x,v') - f(t,x,v))\,dv' \tag{29}$$

with $\sigma > 0$ and $k \in C(\mathbb{S}^{\mathrm{D}-1}\times\mathbb{S}^{\mathrm{D}-1})$ such that

$$k(v,w) = k(w,v) > 0, \quad \int_{\mathbb{S}^{\mathrm{D}-1}} k(v,w)\,dv = 1.$$

The proof is based on the fact that the operator

$$f \mapsto v\cdot\nabla_x f + \sigma\int_{\mathbb{S}^{\mathrm{D}-1}} k(v,v')(f(t,x,v) - f(t,x,v'))\,dv'$$

with domain

$$\{f \equiv f(x,v) \in L^2(\mathbb{T}^D \times \mathbb{S}^{D-1}) \mid v \cdot \nabla_x f \in L^2(\mathbb{T}^D \times \mathbb{S}^{D-1})\}$$

is Fredholm with nullspace the set of constant functions. Hence there exists $c > 0$ such that

$$\begin{aligned} &\left\| f(t,\cdot,\cdot) - \tfrac{1}{|\mathbb{S}^{D-1}|} \iint_{\mathbb{T}^D \times \mathbb{S}^{D-1}} f(t,y,w)\, dy dw \right\|_{L^2(\mathbb{T}^D \times \mathbb{S}^{D-1})} \\ &\qquad \le C \| f|_{t=0} \|_{L^2(\mathbb{T}^D \times \mathbb{S}^{D-1})} e^{-ct} \end{aligned} \tag{30}$$

for each solution of (29). On the other hand, if $f^{\mathrm{in}} \ge 0$ a.e., the solution $f_\varepsilon$ of (27) satisfies

$$f_\varepsilon(t,x,v) \ge f^{\mathrm{in}}(x - tv, v) \mathbf{1}_{t \le \varepsilon \tau_\varepsilon^{1/(D-1)}(x,v)}$$

– the right-hand side being the solution of the same transport equation as in (27) but with absorbing boundary condition

$$f_\varepsilon(t,x,v) = 0 \quad \text{for } x \in \partial\Omega_\varepsilon \text{ and } v \cdot n_x > 0.$$

Hence, if $f$ is any weak-* limit point of $f_\varepsilon$ in $L^\infty(\mathbb{R}_+ \times \mathbb{T}^D \times \mathbb{S}^{D-1})$ as $\varepsilon \to 0$, it must satisfy

$$f(t,x,v) \ge \frac{C_D}{t} f^{\mathrm{in}}(x - tv, v)$$

by Theorem 3.3. This is incompatible with (30) as can be seen by taking $f^{\mathrm{in}}(x,v) \equiv \rho(x)$ with $\|\rho\|_{L^2(\mathbb{T}^D)} = 1$ while $\|\rho\|_{L^1(\mathbb{T}^D)} = o(1)$.

The case of a Lorentz gas with purely absorbing obstacles is much simpler and yet not without interest. Let $g_\varepsilon \equiv g_\varepsilon(t,x,v)$ be the solution of

$$\begin{aligned} \partial_t g_\varepsilon + v \cdot \nabla_x g_\varepsilon &= 0, && x \in \Omega_\varepsilon,\ v \in \mathbb{S}^{D-1},\ t > 0, \\ g_\varepsilon(t,x,v) &= 0, && x \in \partial\Omega_\varepsilon,\ v \cdot n_x > 0, \\ g_\varepsilon(0,x,v) &= f^{\mathrm{in}}(x,v), && x \in \Omega_\varepsilon,\ v \in \mathbb{S}^{D-1}. \end{aligned} \tag{31}$$

In the 2-dimensional case, Theorem 3.4 provides a complete description of the limit:

**Theorem 4.2** (Caglioti–Golse [7], [8]). *For each $f^{\mathrm{in}} \in L^\infty(\mathbb{T}^2 \times \mathbb{S}^1)$,*

$$\frac{1}{\ln \frac{1}{\eta}} \int_\eta^{1/2} g_\varepsilon \frac{d\varepsilon}{\varepsilon} \to g$$

*weakly-* in $L^\infty(\mathbb{T}^2 \times \mathbb{S}^1)$ and pointwise in $t \ge 0$ as $\varepsilon \to 0$, with $g$ given by*

$$g(t,x,v) = f^{\mathrm{in}}(x - tv, v)\phi(t),$$

*where $\phi$ is the small scatterer limit of the distribution of free path lengths, whose explicit expression is provided by Theorem* 3.6.

In other words, $g$ is the solution of

$$\begin{aligned} \partial_t g + v \cdot \nabla_x g &= \tfrac{\phi'(t)}{\phi(t)} g, \quad x \in \mathbb{R}^2,\ v \in \mathbb{S}^1,\ t > 0, \\ g_\varepsilon|_{t=0} &= f^{\mathrm{in}}. \end{aligned} \tag{32}$$

Notice that $\frac{\phi'(t)}{\phi(t)} < 0$, so that the term on the right-hand side of (32) indeed models the loss of particles impinging on the obstacles.

This result can be viewed as a homogenization problem for the free transport equation in a domain with holes. The analogous problem for the diffusion (Laplace) equation has been analyzed in detail: see for instance [20], [10]. It describes the steady, D-dimensional motion of particles on Brownian trajectories in a periodic array of circular holes with radius $\varepsilon^{\frac{\mathrm{D}}{\mathrm{D}-2}}$ centered at the points of the cubic lattice $\varepsilon\mathbb{Z}^{\mathrm{D}}$, each particle falling into a hole being permanently removed. Notice the different critical size of the obstacles – $\varepsilon^{\frac{\mathrm{D}}{\mathrm{D}-2}}$ in the diffusion case, instead of $\varepsilon^{\frac{\mathrm{D}}{\mathrm{D}-1}}$ in the transport case – which comes from the fact that the diffusion and free transport operators are of order 2 and 1 respectively, thereby leading to different scalings. More importantly, in the case of the diffusion problem, the loss of particles falling into the holes is described in this limit with a constant absorption coefficient. Indeed, successive increments in Brownian trajectories are independent random variables, so that the periodic structure of the array of holes is somehow ignored by the particles. On the contrary, in the case of the free transport problem (31), the trajectories are straight lines, which introduces correlations between the obstacles. Intuitively, particles which have not encountered any obstacle over some interval of time $[0, T]$ move in a direction that is well approximated by a rational direction – with increasing quality of approximation as $T$ increases. Such particles are therefore much less likely to encounter obstacles after time $T$, and this agrees with the fact that the absorption rate $\frac{\phi'(t)}{\phi(t)}$ vanishes as $t \to +\infty$.

## 5. Conclusion

The methods presented above explain why the Lorentz kinetic equation (1) fails to describe the Lorentz gas in the Boltzmann-Grad limit, when the obstacles are centered at the vertices of the cubic lattice $\mathbb{Z}^{\mathrm{D}}$. The ergodic theory of continued fractions provides additional insight on this example of periodic Lorentz gas in the case $\mathrm{D} = 2$, especially on the asymptotic distribution of free path lengths in the small obstacle limit.

Obviously, it would be desirable to obtain as much information in higher dimensions, particularly for the physically relevant case $\mathrm{D} = 3$. This could be difficult, as it might require accurate estimates on simultaneous rational approximation.

Otherwise, it would be useful to have analogues of the results above for 2-dimensional lattices other than $\mathbb{Z}^2$. Specifically, one would like to know whether

Theorems 3.3, 3.4 and 3.6 can be extended or adapted to the case of arbitrary 2-dimensional lattices. If so, it would be particularly interesting to find the intrinsic meaning of the constants $\frac{1}{\pi^2}$ and $\frac{9\zeta(3)}{4\zeta(2)} - 3\ln 2$ that appear in Theorem 3.4 and in Section 3.4.

Finally, the problem of finding an equation describing the Boltzmann-Grad limit of the periodic Lorentz gas – even in the simplest 2-dimensional case and for the cubic lattice $\mathbb{Z}^2$ – remains open. So far, we have no clue as to the structure of such an equation, should it exist: we only know that it cannot be a linear Boltzmann equation of the type (29).

# Conformal invariants and nonlinear elliptic equations

Matthew J. Gursky

**Abstract.** We describe several "uniformizing" problems in conformal geometry, all of which can be formulated as problems of existence for solutions of certain elliptic partial differential equations. For the sake of exposition we divide the discussion according to the type of PDE, beginning with semilinear equations related to the scalar curvature, then higher order equations arising from the $Q$-curvature, and finally fully nonlinear equations.

**Mathematics Subject Classification (2000).** Primary 58J05; Secondary 53A30.

**Keywords.** Conformal geometry, Yamabe equation, Paneitz operator, $\sigma_k$-curvature.

## 1. Introduction

In this article we outline several problems related to finding a canonical representative of a conformal equivalence class of Riemannian metrics. The earliest and best known result of this kind is the Uniformization Theorem for surfaces. Although originally conceived as a problem in complex function theory, in view of the modern development of the theory of Riemann surfaces it can be stated in purely geometric terms: Given a compact surface $(M^2, g)$, there is a conformal metric $\tilde{g} = e^{2w}g$ with constant curvature.

In higher dimensions the Uniformization Theorem is no longer true, even locally. For example, in dimensions $n \geq 4$ the Weyl tensor $W(g)$ provides an obstruction to a metric being locally conformal to a flat metric. Despite this fact – or perhaps because of it – there are numerous ways to define what constitutes a canonical metric. In this article we will outline several "uniformizing" problems, each involving the study of a PDE of a different type: second order semilinear (in the case of the scalar curvature), higher order semilinear (for the $Q$-curvature), and fully nonlinear (when considering the $\sigma_k$-curvature). An underlying theme will be the connection between conformal invariants associated to the problem, spectral properties of the relevant differential operator, and the interplay of both with the topology of the manifold.

## 2. Semilinear examples

**2.1. The modified scalar curvature.** Let $(M^n, g)$ be a closed Riemannian manifold of dimension $n \geq 3$, and let $R(g)$ denote its scalar curvature. If $\tilde{g} = u^{4/(n-2)}g$ is a

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

conformal metric, then the scalar curvature $R(\tilde{g})$ of $\tilde{g}$ is given by

$$L_g u + R(\tilde{g}) u^{\frac{n+2}{n-2}} = 0, \tag{2.1}$$

where $L_g = \frac{4(n-1)}{(n-2)}\Delta_g - R(g)$ is the *conformal laplacian*. The *Yamabe problem* is to establish the existence of a conformal metric with constant scalar curvature (see [32]). Since the scalar curvature of a surface is twice the Gauss curvature, the Yamabe problem can be viewed as one possible generalization of the Uniformization Theorem.

An important property of the operator $L_g$ is its *conformal covariance*: If $\tilde{g} = u^{4/(n-2)} g$, then

$$L_{\tilde{g}} v = u^{-\frac{n+2}{n-2}} L_g(uv). \tag{2.2}$$

Consequently, the sign of the principle eigenvalue $\lambda_1(-L_g)$ is a conformal invariant ([30]).

A generalization of the Yamabe problem was introduced by the author, for the purposes of studying a rigidity question for Einstein metrics [22]. Subsequently it has been used to estimate the Yamabe invariant of certain four-manifolds [23], the principal eigenvalue of the Dirac operator [28], and in the context of Seiberg–Witten theory [31].

Given a Riemannian manifold $(M^n, g)$, let $\mathcal{G} \subset S^2T^*M^n$ denote the ray bundle consisting of metrics in the conformal class of $g$. Let $\delta_s : \mathcal{G} \to \mathcal{G}$ denote the dilations $\delta_s(g) = s^2 g$, with $s > 0$. Functions on $\mathcal{G}$ which are homogeneous of degree $\beta$ with respect to $\delta_s$ are known as *conformal densities of weight* $\beta$.

**Definition 2.1.** Given a density $\phi$ of weight $-2$, we define the *modified scalar curvature* associated to $\phi$ by

$$\hat{R}(g) = R(g) - \phi. \tag{2.3}$$

For example, in some applications $(M^4, g)$ is an oriented four-dimensional manifold and $\phi = 2\sqrt{6}|W^{\pm}(g)|$, the (anti-) self-dual part of the Weyl curvature tensor. For Kähler manifolds of positive scalar curvature the corresponding modified scalar curvature $\hat{R}(g) = R(g) - 2\sqrt{6}|W^+|^2 \equiv 0$. As this example illustrates, in general we do not assume the density is smooth, but at least Lipschitz continuous.

Since $\phi$ is a conformal density of weight $-2$ the operator $\hat{L}_g = \frac{4(n-1)}{(n-2)}\Delta_g - \hat{R}(g)$ enjoys the same invariance as the conformal laplacian given in (2.2). In particular, the sign of $\lambda_1(-\hat{L}_g)$ is a conformal invariant.

In analogy with the Yamabe problem, we can ask whether there exists a conformal metric whose modified scalar curvature is constant. Due to the conformal covariance of $\hat{L}$, the sign of this constant will agree with the sign of $\lambda_1(-\hat{L}_g)$. Since the choice of density obviously plays an important role in the question of existence, a completely general theory would seem unlikely. For particular cases, though, some existence results have been appeared (see [29]).

In fact, for many applications the relevant question is the *sign* of the modified scalar curvature, or equivalently, the sign of $\lambda_1(-\hat{L}_g)$. Typically, the density $\phi$ is chosen by examining the curvature term in the Weitzenböck formula for a harmonic section of some vector bundle; then the sign of $\lambda_1(-\hat{L}_g)$ can be thought of as an obstruction to the existence of non-trivial harmonic sections. Of course, Lichnerowicz used precisely this kind of argument with the Dirac operator on a spin manifold to prove obstructions to the existence of metrics with positive scalar curvature [33].

To illustrate this technique with one important example, consider a self-dual harmonic two-form $\omega \in H^2_+(M^4, \mathbb{R})$. In this case the Weitzenböck formula is given by

$$\frac{1}{2}\Delta_g|\omega|^2 = |\nabla\omega|^2 - 2W^+(\omega,\omega) + \frac{1}{3}R(g)|\omega|^2. \tag{2.4}$$

Another intriguing element in the study of the modified scalar curvature is the important role played by *refined Kato inequalities* (see [24]). In the case of self-dual harmonic two-forms this takes the form

$$|\nabla\omega|^2 \geq \frac{3}{2}|\nabla|\omega||^2 \tag{2.5}$$

([37]). Substituting into (2.4), and using the fact that $W^+\colon \Lambda^2_+ \to \Lambda^2_+$ is a trace-free endomorphism, we eventually arrive at

$$\Delta_g|\omega|^{2/3} \geq \frac{1}{6}\big[-2\sqrt{6}|W^+(g)| + R(g)\big]|\omega|^{2/3}. \tag{2.6}$$

Taking $\phi = 2\sqrt{6}|W^+|$, we conclude

$$\hat{L}_g|\omega|^{2/3} \geq 0 \tag{2.7}$$

which implies $\lambda_1(-\hat{L}_g) \leq 0$. Thus, there are cohomological obstructions to the existence of metrics with positive first eigenvalue.

On the other hand, when $\lambda_1(-\hat{L}_g) \leq 0$ one obtains $L^p$-estimates for the scalar curvature. For example, in four dimensions

$$\int R(g)^2\, dv(g) \leq \int \phi^2\, dv(g). \tag{2.8}$$

Since $\phi$ is a density of weight $-2$, the integral on the right-hand side of (2.8) is a conformal invariant. Thus, we have a connection between the spectral properties of the conformally covariant operator $\hat{L}_g$, and $L^2$-conformal invariants. We will encounter a similar phenomenon when considering higher order elliptic equations.

**2.2. Higher order equations and the $Q$-curvature.** In an unpublished preprint [35], the late Stephen Paneitz constructed a fourth order conformally covariant operator defined on a (pseudo)-Riemannian manifold $(M^4, g)$ of dimension $n \geq 3$. In

four dimensions, his operator is given by

$$P_g = (-\Delta_g)^2 - \delta_g\left\{\left[\frac{2}{3}R(g)g - 2\,\mathrm{Ric}(g)\right]\circ\nabla\right\}, \tag{2.9}$$

where $\delta_g\colon \Lambda^1(M^4) \to C^\infty(M^4)$ is the divergence. If $\tilde{g} = e^{2w}g$ is a conformal metric, then

$$P_{\tilde{g}} = e^{-4w}P_g. \tag{2.10}$$

In particular, the sign of $\lambda_1(P_g)$ and the kernel of $P_g$ are both conformally invariant. Since $P_g(1) = 0$, we always have $\lambda_1(P_g) \leq 0$.

Branson [4] subsequently observed the connection between Paneitz's operator and what Branson called the *Q-curvature*, defined by

$$Q(g) = \frac{1}{12}\big(-\Delta_g R(g) + R(g)^2 - 3|\,\mathrm{Ric}(g)|^2\big). \tag{2.11}$$

In fact, if $\tilde{g} = e^{2w}g$, then the $Q$-curvature of $\tilde{g}$ is given by

$$P_g w + 2Q(g) = 2Q(\tilde{g})e^{4w}. \tag{2.12}$$

It follows that the integral of the $Q$-curvature is another conformal invariant:

$$\int Q(\tilde{g})\,dv(\tilde{g}) = \int Q(g)\,dv(g). \tag{2.13}$$

The $Q$-curvature and Paneitz operator have become important objects of study in the geometry of four-manifolds, and play a role in the such diverse topics as the Moser–Trudinger inequalities ([3], [5]), twistor theory ([14]), gauge choices for Maxwell's equations ([13]), and conformally compact AHE manifolds ([15], [16]). In addition, they naturally suggest another "uniformizing" problem, that of finding a conformal metric with constant $Q$-curvature.

Chang and Yang ([9]) studied this problem using the direct variational method, by attempting to prove the existence of minimizers of the non-convex functional

$$\begin{aligned} F[w] = &\int w P_g w\,dv(g) + 4\int wQ(g)\,dv(g) \\ &- \left(\int Q(g)\,dv(g)\right)\log\int e^{4w}\,dv(g). \end{aligned} \tag{2.14}$$

However, if the Paneitz operator has a negative eigenvalue and the conformal invariant (2.13) is positive, then Chang and Yang showed that $\inf F = -\infty$. Even when $F$ is bounded below the compactness of a minimizing sequence is a delicate matter. Using a sharp form of Adam's inequality ([1]) Chang and Yang [9] were able to prove the existence of minimizer assuming the invariant (2.13) is less than its value on the standard sphere:

**Theorem 2.2.** *Let* $(M^4, g)$ *be a closed four-manifold, and assume* (i) $P_g \geq 0$ *with* $\operatorname{Ker} P_g = \{\text{const.}\}$, *and* (ii) $\int Q(g)dv(g) < 8\pi^2$. *Then there exists a minimizer* $w \in C^\infty$ *of* $F$, *which satisfies* (2.12) *with* $Q(\tilde{g}) = \text{const.}$

Thus, the question of existence is reduced to studying the spectrum of the Paneitz operator and the conformal invariant (2.13). As we shall see, there is a connection between these problems.

First, it is not difficult to see that when $g$ has positive scalar curvature, the invariant (2.13) is *always* dominated by its value on the sphere. (Somewhat surprisingly, equality can be characterized without resorting to the Positive Mass Theorem; see [21]). Thus, when $(M^4, g)$ has positive scalar curvature the assumption $(ii)$ in the Theorem of Chang-Yang is superfluous, except in the case of the sphere.

Turning to the first assumption of Theorem 2.2, we begin by noting the Dirichlet form associated to the Paneitz operator is given by

$$\int \psi P_g \psi \, dv(g) = \int \left[ (\Delta_g \psi)^2 + \frac{2}{3} R(g) |\nabla \psi|^2 - 2 \operatorname{Ric}(g)(\nabla \psi, \nabla \psi) \right] dv(g). \tag{2.15}$$

Using the Bochner formula we can rewrite this as

$$\begin{aligned} \int \psi P_g \psi \, dv(g) &= \int \left[ \frac{4}{3} |\mathring{\nabla}^2 \psi|^2 \, dv(g) + \frac{2}{3} \big( R(g) g - \operatorname{Ric}(g) \big)(\nabla \psi, \nabla \psi) \right] dv(g) \\ &\geq \int \frac{4}{3} |\mathring{\nabla}^2 \psi|^2 \, dv(g) + \int \frac{2}{3} T(\nabla \psi, \nabla \psi) \, dv(g), \end{aligned} \tag{2.16}$$

where $\mathring{\nabla}^2 \psi = \nabla^2 \psi - \frac{1}{4}(\Delta_g \psi) g$ is the trace-free Hessian and $T = R(g)g - \operatorname{Ric}(g)$. Consequently, if the right-hand side of (2.16) is positive for all $\psi \in C^\infty$, then $\lambda_1(P_g) = 0$ and $\operatorname{Ker} P_g = \{\text{const.}\}$. By conformal invariance it is enough to show that this property holds for some metric in the conformal class of $g$.

By using a kind of "regularized" version of the functional $F$ (which was also studied by Chang and Yang), the author was able to construct a metric $\tilde{g} \in [g]$ for which the right-hand side of (2.16) is positive for all $\psi \in C^\infty$, provided the scalar curvature of $g$ is positive (see [21]):

**Theorem 2.3.** *If* $(M^4, g)$ *has positive scalar curvature and* $\int Q(g) \, dv(g) \geq 0$, *then* $P_g \geq 0$ *and* $\operatorname{Ker} P_g = \{\text{const.}\}$. *In particular, there is a conformal metric* $\tilde{g}$ *with* $Q(\tilde{g}) = \text{const.}$

The assumptions of Theorem 2.3 imply the first Betti number of $M^4$ vanishes; see [20]. On the other hand, in [14] Eastwood–Singer constructed metrics on $k(S^3 \times S^1)$ for all $k > 0$ with $P_g \geq 0$ and $\operatorname{Ker} P_g = \{\text{const.}\}$. For this reason, it would be desirable to relax the assumption on the integral of $Q(g)$. A result of this kind appears in [25], which relied on solving a fully nonlinear equation of the type described in the next section to prove the positivity of the tensor field $T = R(g)g - \operatorname{Ric}(g)$ appearing in (2.16):

**Theorem 2.4.** *If $(M^4, g)$ has positive Yamabe invariant $Y(g)$ and the $Q$-curvature satisfies $\int Q(g)\, dv(g) + \frac{1}{6}Y(g)^2 \geq 0$, then $P_g \geq 0$ and $\operatorname{Ker} P_g = \{\text{const.}\}$. In particular, there is a conformal metric $\tilde{g}$ with $Q(\tilde{g}) = \text{const.}$*

Since Theorem 2.4 allows the integral of $Q$ to be negative, we are able to construct many new examples of conformal manifolds which admit a metric with constant $Q$-curvature (see Section 7 of [25].

There have been other approaches to the problem of finding metrics with constant $Q$-curvature. Malchiodi [34], Malchiodi–Djadli [11], and Druet–Robert [12] have studied existence and compactness of the solution space by a delicate blow-up analysis. In particular, the positivity of the total $Q$-curvature is not required. However, their work indicates that the assumption $\operatorname{Ker} P_g = \{\text{const.}\}$ is unlikely to be merely technical. Brendle [7] and Baird–Fardoun–Regbauoi [2] have used parabolic methods; they also assume $P_g \geq 0$ with trivial kernel.

The problem of finding metrics with constant $Q$-curvature originally appeared in the more general context of studying variational properties of the regularized determinant (see [9]). In contrast to the study of the $Q$-curvature, the existence theory has not developed very much beyond the results in [9] and [21]. The associated Euler–Lagrange equation includes terms which are nonlinear in the second derivatives of the solution, providing an important link to the material in the next section.

## 3. Fully nonlinear equations

Finally, we give a brief synopsis of a very active area which can be viewed as a fully nonlinear version of the Yamabe problem. For Riemannian manifolds of dimension $n \geq 3$ we define the *Weyl–Schouten* tensor by

$$A(g) = \frac{1}{(n-2)}\left(\operatorname{Ric}(g) - \frac{1}{2(n-1)}R(g)g\right). \tag{3.1}$$

In [39], J. Viaclovsky initiated the study of the fully nonlinear equations arising from the transformation of $A$ under conformal deformations. More precisely, let $g_u = e^{-2u}g$ denote a conformal metric, and consider the equation

$$\sigma_k^{1/k}(g_u^{-1} \circ A_u) = f(x), \tag{3.2}$$

where $\sigma_k(\cdot)$ denotes the $k$-th elementary symmetric polynomial, applied to the eigenvalues of $g_u^{-1} \circ A_u$. Since $A_u$ is related to $A$ by the formula

$$A(g_u) = A(g) + \nabla^2 u + du \otimes du - \frac{1}{2}|\nabla u|^2 g, \tag{3.3}$$

equation (3.2) is equivalent to

$$\sigma_k^{1/k}(A(g) + \nabla^2 u + du \otimes du - \frac{1}{2}|\nabla u|^2 g) = f(x)e^{-2u}. \tag{3.4}$$

Note that when $k = 1$, $\sigma_1(g^{-1}A(g)) = \text{trace}(A) = \frac{1}{2(n-1)}R(g)$; therefore, (3.4) is equivalent to equation (2.1). When $k > 1$ the equation is fully nonlinear, but not necessarily elliptic. A sufficient condition for a solution $u \in C^2(M^n)$ to be elliptic is that the eigenvalues of $A = A(g)$ are in $\Gamma_k^+ = \{\lambda = (\lambda_1, \ldots, \lambda_n) \in \mathbb{R}^n \mid \sigma_1(\lambda) > 0, \sigma_2(\lambda) > 0, \ldots, \sigma_k(\lambda) > 0\}$ at each point of $M^n$. In this case we say that $g$ is *admissible* (or $k$-admissible); likewise, if $-A(g) \in \Gamma_k^+$ then we say $g$ is *negative admissible*.

The most straightforward question one can pose about equation (3.4) is existence: given an admissible metric $g \in \Gamma_k^+(M^n)$ and a positive function $f \in C^\infty(M^n)$, does there always exist a solution $u \in C^\infty(M^n)$ to (3.4)? When $f(x) = \text{const.} > 0$ this is referred to as the *$\sigma_k$-Yamabe problem*. An important distinction between the $\sigma_k$-Yamabe problem and the classical Yamabe problem is that the former is not in general variational.

The study of equation (3.4) in general and the $\sigma_k$-Yamabe problem in particular has seen an explosion of activity in recent years. We will highlight some results for the case $k > n/2$ as the theory is more developed; admissibility has a more geometric interpretation; and in contrast to the case $k \leq n/2$, solutions of (3.4) have a variational characterization.

First, Guan–Viaclovsky–Wang [19] showed that when $g$ is $k$-admissible the Ricci curvature satisfies the sharp inequality

$$\text{Ric}(g) \geq \frac{(2k-n)}{2n(k-1)}R(g)g. \tag{3.5}$$

In particular, if $k > n/2$, the Ricci curvature is positive. Using the Newton–Maclaurin inequality and Bishop's volume comparison, one can quantify this in the following way: If $g_u = e^{-2u}g$ is an admissible solution of (3.4) with $f(x) \geq c_0 > 0$, then

$$\text{Vol}(g_u) = \int e^{-nu}\, dv(g) \leq C(k, n, c_0). \tag{3.6}$$

We define the *$k^{\text{th}}$-maximal volume* of the admissible metric $g$ by

$$\Lambda_k(M^n, [g]) = \sup\{\text{Vol}(g_u) \mid A(g_u) \in \Gamma_k^+, \sigma_k(g_u^{-1}A(g_u)) \geq \sigma_k(S^n)\}, \tag{3.7}$$

where $\sigma_k(S^n)$ is the value attained by the round sphere. This definition suggests the following variational problem: given a $k$-admissible metric $g$, is there is conformal metric which attains the $k^{\text{th}}$-maximal volume? It is easy to see that any metric which does will satisfy (3.4) with $f(x) \equiv \sigma_k^{1/k}(S^n)$. A similar variational problem was formulated by Guan and Spruck in studying the curvature of hypersurfaces in Euclidean space [17].

In joint work with J. Viaclovsky we used this variational scheme to study the $\sigma_k$-Yamabe problem in three- and four-dimensions [26]. The dimension restriction is a result of the difficulty of proving sharp estimates for the maximal volume in high dimensions. In three dimensions we could prove such estimates thanks to Bray's

Football Theorem [6], and in four dimensions by using the Chern–Gauss–Bonnet formula. An approach somewhat similar in spirit was implicit in earlier work of Chang–Gursky–Yang [8] and Viaclovsky [40].

Another consequence of the volume bound (3.6) is the finiteness of the blow-up set for a sequence of solutions to (3.4). This follows from the $\varepsilon$-regularity result of Guan and Wang [18], which in turn is based on their local $C^1$- and $C^2$-estimates for solutions. In fact, using the estimates of Guan-Wang, it is possible to show that a divergent sequence $\{u_i\}$ of solutions to (3.4) will blow up at finitely many points, and converge uniformly to $-\infty$ off the singular set. By rescaling this sequence, one obtains a limiting viscosity solution $w \in C^{1,1}_{\text{loc}}$ with $f(x) \geq 0$.

In recent work with Viaclovsky [27], we carried out a careful analysis of the tangent cone at infinity of the $C^{1,1}$-metric $g_\infty = e^{2w}g$. In particular, we showed the volume growth at infinity is Euclidean. Since the Ricci curvature is non-negative, this implies the metric is flat, and $(M^n, g)$ is conformally the sphere.

**Theorem 3.1.** *Let $(M^n, g)$ be closed $n$-dimensional Riemannian manifold, and assume*

(i) *$g$ is $k$-admissible with $k > n/2$, and*

(ii) *$(M^n, g)$ is not conformally equivalent to the round $n$-dimensional sphere.*

*Then given any smooth positive function $f \in C^\infty(M^n)$ there exists a solution $u \in C^\infty(M^n)$ of* (3.4)*, and the set of all such solutions is compact in the $C^m$-topology for any $m \geq 0$.*

In fact, our proof gives the existence of solutions to

$$F(A_u) = f(x)e^{-2u},$$

where $F\colon \Gamma \to \mathbb{R}$ is a symmetric function of the eigenvalues of $A_u$ defined on a cone $\Gamma \subset \mathbb{R}^n$ which satisfies some explicit structural conditions. For more general equations we need to use the $C^2$-estimates developed by S. Chen [10]. Trudinger and Wang [38] have proved a similar existence result, along with a remarkable Harnack inequality for admissible metrics.

# Asymptotic solutions for large time of Hamilton–Jacobi equations

Hitoshi Ishii*

**Abstract.** In this article we discuss some recent results on the large-time behavior of solutions of Hamilton–Jacobi equations as well as some ideas and observations behind them and historical remarks concerning them.

**Mathematics Subject Classification (2000).** Primary 35B40; Secondary 35F25, 37J99, 49L25.

**Keywords.** Large-time behavior, asymptotic solutions, Hamilton–Jacobi equations, Aubry sets, weak KAM theory, viscosity solutions.

## 1. Introduction

Hamilton–Jacobi equations play important roles in classical mechanics, geometric optics, optimal control, differential games, etc. We are here interested in global solutions of Hamilton–Jacobi equations. A well-known classical method of finding solutions of Hamilton–Jacobi equations is that of characteristics and its applications have serious difficulties in practice because of developments of shocks in solutions. At the beginning of 1980s M. G. Crandall and P.-L. Lions [10], [11] introduced the notion of viscosity solution in the study of Hamilton–Jacobi equations. It is a notion of generalized solutions for partial differential equations and it is based on the maximum principle while, in this regard, distributions theory is based on integration by parts. This notion has been successfully employed to study fully nonlinear partial differential equations (PDE for short), especially Hamilton–Jacobi equations and fully nonlinear elliptic or parabolic PDE. Important basic features of viscosity solutions are: they enjoy nice properties such as (1) stability under uniform convergence or under the processes of pointwise supremum or infimum, and (2) existence and uniqueness of solutions, under mild assumptions, of boundary value problems or the Cauchy problem for fully nonlinear PDE. See [2], [3], [24], [9] for general overviews and developments of the theory of viscosity solutions.

We recall the definition of viscosity solutions of $F(x, u(x), Du(x)) = 0$ in $\Omega$. Let $u \in C(\Omega, \mathbb{R})$. It is called a viscosity subsolution (resp., supersolution) of $F[u] = 0$ in $\Omega$ if whenever $\varphi \in C^1(\Omega)$ and $u - \varphi$ attains a maximum (resp., minimum) at $y \in \Omega$, then $F(y, u(y), D\varphi(y)) \leq 0$ (resp., $F(y, u(y), D\varphi(y)) \geq 0$). Then, $u \in C(\Omega)$

*The author was supported in part by Grant-in-Aids for Scientific Research, No. 15340051, JSPS.

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

is called a viscosity solution of $F[u] = 0$ in $\Omega$ if it is both a viscosity sub- and supersolution of $F[u] = 0$ in $\Omega$. We will be here focused on viscosity solutions, subsolutions, or supersolutions and will suppress the term "viscosity" in what follows as far as there is no danger of confusion.

In this article we consider the stationary Hamilton–Jacobi equation

$$H(x, Du) = 0 \quad \text{in } \Omega, \tag{1}$$

where $\Omega$ is an open subset of $\mathbb{R}^n$, and the Cauchy problem

$$u_t + H(x, Du) = 0 \quad \text{in } \Omega \times (0, \infty), \tag{2}$$

$$u(\cdot, 0) = u_0 \quad \text{in } \Omega. \tag{3}$$

Here $H$ is a continuous function on $\overline{\Omega} \times \mathbb{R}^n$ and $u$ represents the real-valued unknown function on $\Omega$ in the case of (1) or on $\overline{\Omega} \times [0, \infty)$ in the case of (2) and (3), respectively. We write frequently $H[u]$ for $H(x, Du(x))$ for notational simplicity. We will be concerned also with the additive eigenvalue problem

$$H[v] = c \quad \text{in } \Omega. \tag{4}$$

Here the unknown is a pair $(c, v)$ of a constant $c \in \mathbb{R}$ and a function $v$ on $\Omega$ for which $v$ satisfies (4).

The purpose of this article is to review some of recent results concerning the large-time behavior of solutions of (2). An interesting feature of the investigations towards such results is the interaction with the developments of weak KAM theory, and this review will touch upon weak KAM theory. For overviews and developments of weak KAM theory, we refer to [17], [14].

In Section 2 we discuss projected Aubry sets and representation formulas for solutions of (1). In Section 3 the main result concerning the large-time behavior of solutions of (2) are explained. In Section 4 we outline the proof of the main result.

## 2. Projected Aubry sets and representation of solutions

Weak KAM theory introduced by A. Fathi in [15], [17] has changed the viewpoint of uniqueness questions regarding (1).

To begin with, we recall that classical uniqueness or comparison results in viscosity solutions theory applied to the following simple PDE

$$\lambda u + H(x, Du) = 0 \quad \text{in } \Omega, \tag{5}$$

where $\lambda$ is a positive constant, states:

**Theorem 2.1.** *Let $u,\ v \in C(\overline{\Omega})$ be a subsolution and a supersolution of* (5)*, respectively. Assume that $\Omega$ is bounded, that either $u$ or $v$ is locally Lipschitz in $\Omega$, and that $u \le v$ on $\partial\Omega$. Then $u \le v$ in $\Omega$.*

See [2], [3], [8] for general comparison results for Hamilton–Jacobi equations. The above theorem guarantees uniqueness of locally Lipschitz continuous solutions of the Dirichlet problem for (5). We will be concerned mostly with viscosity sub-, super-, or solutions of (1) which are locally Lipschitz continuous, and thus the assumption concerning local Lipschitz continuity of solutions in the above theorem is not any real restriction.

Another way of stating the above theorem is as follows.

**Theorem 2.2.** *Let $u,\ v \in C(\overline{\Omega})$ be solutions, respectively, of $H[u] \leq -\varepsilon$ in $\Omega$ and of $H[v] \geq 0$ in $\Omega$, where $\varepsilon$ is a positive constant. Assume that $\Omega$ is bounded, that either $u$ or $v$ is locally Lipschitz in $\Omega$, and that $u \leq v$ on $\partial\Omega$. Then $u \leq v$ in $\Omega$.*

Let $\Omega = \operatorname{int} B(0, r)$, where $B(0, r)$ denotes the closed ball of radius $r > 0$ with center at the origin and $\operatorname{int} A$ denotes the interior of $A \subset \mathbb{R}^n$. The eikonal equation $|Du| = |x|$ in $\Omega$ has two solutions $u_\pm(x) := \pm(1-|x|^2)/2$, which in addition satisfies the boundary condition, $u(x) = 0$ on $\partial\Omega$. Indeed, the solutions of the Dirichlet problem, $|Du| = |x|$ in $\Omega$ and $u = 0$ on $\partial\Omega$, are given by the family of functions $u_a(x) := \min\{u_+(x), a + u_-(x)\}$ parametrized by $a \in [0,\ 1]$. This example tells us that the Dirichlet problem, $|Du| = |x|$ in $\Omega$ and $u = 0$ on $\partial\Omega$, has many solutions and that the condition, $\lambda > 0$, in Theorem 2.1 is sharp. Thus uniqueness of solution of the Dirichlet problem does not hold in general for (1).

We *assume* henceforth the following two assumptions, the convexity and coercivity of the Hamiltonian $H$:

$$\text{for each } x \in \Omega \text{ the function } p \mapsto H(x, p) \text{ is convex in } \mathbb{R}^n, \tag{6}$$

$$\lim_{r\to\infty} \inf\{H(x, p) \mid x \in \Omega,\ p \in \mathbb{R}^n \setminus B(0, r)\} = \infty. \tag{7}$$

We set $L(x, \xi) = \sup_{p\in\mathbb{R}^n}(\xi\cdot p - H(x, p))$ for $(x, \xi) \in \Omega\times\mathbb{R}^n$, where $\xi\cdot p$ denotes the Euclidean inner product of $\xi,\ p \in \mathbb{R}^n$. We call the function $L\colon \Omega \times \mathbb{R}^n \to (-\infty, \infty]$ the *Lagrangian*.

We define the function $d_H$ on $\Omega \times \Omega$ by

$$d_H(x, y) = \sup\{v(x) \mid H[v] \leq 0,\ v(y) = 0\}.$$

Classical results in viscosity solutions theory assure that the function $d_H$ has the properties:

$$H[d(\,\cdot\,, y)] \leq 0 \quad \text{in } \Omega, \tag{8}$$

$$H[d(\,\cdot\,, y)] \geq 0 \quad \text{in } \Omega \setminus \{y\}. \tag{9}$$

Following [18], we define the (projected) *Aubry set* $\mathcal{A}$ for the Lagrangian $L$ (or for the Hamiltonian $H$) as the subset of $\Omega$ given by

$$\mathcal{A} = \{y \in \Omega \mid H[d(\,\cdot\,, y)] \geq 0 \text{ in } \Omega\}. \tag{10}$$

In view of (8), (9), and (10), it is easily seen that $y \in \Omega \setminus \mathcal{A}$ if and only if $H(y, p) < 0$ for some $p \in D_1^- d_H(y, y)$, where $D_1^- d_H(x, y)$ denotes the subdifferential of $d_H(\cdot, y)$ at $x$. Similarly, we may state that $y \in \Omega \setminus \mathcal{A}$ if and only if there are functions $\sigma \in C(\Omega)$ and $\psi \in C^{0+1}(\Omega)$ such that $\sigma \geq 0$ in $\Omega$, $\sigma(y) > 0$, and $H[\psi] \leq -\sigma$ in $\Omega$.

We now assume for simplicity of presentation that $\Omega$ is an $n$-dimensional torus $\mathbb{T}^n$. The following theorem is an improved version of classical results such as Theorems 2.1 or 2.2

**Theorem 2.3.** *Let $u, v \in C(\Omega)$ be a subsolution and a supersolution of $H = 0$ in $\Omega$, respectively. Assume that $u \leq v$ on $\mathcal{A}$. Then $u \leq v$ in $\Omega$.*

This theorem can be found in [17, Chap. 8]. A key observation for the proof of the above theorem is that for each compact $K \subset \Omega \setminus \mathcal{A}$ there exist a function $\psi_K \in C^{0+1}(\Omega)$ and a constant $\varepsilon_K > 0$ such that $H[\psi_K] \leq -\varepsilon_K$ in a neighborhood $V_K$ of $K$.

Indeed, with such $K$, $\psi_K$, $\varepsilon_K$, and $V_K$, we see that for any $\lambda \in (0, 1)$, the function $u_\lambda := (1 - \lambda)u + \lambda\psi_K$ is a subsolution of $H[u_\lambda] \leq -\lambda\varepsilon_K$ in $V_K$, and hence from Theorem 2.2 that for all $x \in V_K$,

$$(1 - \lambda)u(x) + \lambda\psi_K(x) \leq v(x) + \sup_{\Omega \setminus K}[(1 - \lambda)u + \lambda\psi_K - v],$$

which implies that for all $x \in \Omega \setminus \mathcal{A}$,

$$u(x) \leq v(x) + \sup_{\mathcal{A}}(u - v).$$

In their study of semicontinuous viscosity solutions, E. N. Barron and R. Jensen [4], [5] have observed that under the convexity assumption (6), a function $u \in C(\Omega)$ is a viscosity subsolution of (1) if and only if $H(x, p) \leq 0$ for all $p \in D^- u(x)$ and $x \in \Omega$, where $D^- u(x)$ denotes the subdifferential of $u$ at $x$. A consequence of this observation is that the pointwise infimum of a uniformly bounded family of solutions of (1) yields a solution of (1).

**Theorem 2.4.** *If $u \in C(\Omega)$ is a viscosity solution of $H[u] = 0$ in $\Omega$, then*

$$u(x) = \inf\{d_H(x, y) + u(y) \mid y \in \mathcal{A}\} \quad \textit{for all } x \in \Omega.$$

We remark that if $\mathcal{A} = \emptyset$, then there exists no solution $u$ of $H[u] = 0$ in $\Omega$. The above theorem is a weaker version of [19, Theorem 10.4] which is formulated with the Mather set in place of the Aubry set $\mathcal{A}$ and with quasi-convex Hamiltonian $H$. In the case where $\mathcal{A}$ is a finite set, a corresponding result for the Dirichlet problem for bounded domains has already been obtained in [24].

Another remark here is on the representation of $d_H$ as the value function of an optimal control problem associated with the Hamiltonian $H$. Let $I \subset \mathbb{R}$ be an interval and $\gamma : I \to \Omega$. We say that $\gamma$ is a *curve* if it is absolutely continuous on any compact subinterval of $I$. For $(x, t) \in \Omega \times (0, \infty)$, let $\mathcal{C}(x, t)$ denote the space of curves $\gamma$ on $[0, t]$ such that $\gamma(t) = x$.

**Theorem 2.5.** *Let $x, y \in \Omega$. Then*

$$d_H(x, y) = \inf\left\{ \int_0^t L(\gamma(s), \dot\gamma(s))\mathrm{d}s \;\Big|\; t > 0,\ \gamma \in \mathcal{C}(x, t),\ \gamma(0) = y \right\}, \quad (11)$$

*where $\dot\gamma$ denotes the derivative of $\gamma$.*

Now we turn to the case when $\Omega$ is an open bounded subset of $\mathbb{R}^n$ with regular boundary. We consider the Dirichlet problem

$$H[u] = 0 \quad \text{in } \Omega, \quad (12)$$

$$u|_{\partial\Omega} = g, \quad (13)$$

where $g$ is a given continuous function on $\partial\Omega$. For the Dirichlet problem, we have to modify the definition of the Aubry set and for this we set $\mathcal{A}_D = \mathcal{A} \cup \partial\Omega$, where $\mathcal{A}$ is defined as before. Let $g \in C(\mathcal{A}_D)$ and assume that the following compatibility condition, for the solvability of the Dirichlet problem (12) and (13), holds:

$$g(x) - g(y) \le d_H(x, y) \quad \text{for all } x, y \in \mathcal{A}_D. \quad (14)$$

**Theorem 2.6.** *Under assumption* (14)*, the function $u \in C(\overline{\Omega})$, defined by*

$$u(x) = \inf\{d_H(x, y) + g(y) \mid y \in \mathcal{A}_D\} \quad \textit{for all } x \in \overline{\Omega},$$

*is a solution of* (12) *and* (13)*. Moreover it is a unique solution of* (12) *satisfying $u|_{\mathcal{A}_D} = g$.*

## 3. Asymptotic solutions

The following result is concerned with the unbounded domain $\Omega = \mathbb{R}^n$ and we need a further restriction on $H$. Indeed, we assume that there exist functions $\phi_i$ and $\sigma_i$, with $i = 0, 1$, such that

$$H[\phi_i] \le -\sigma_i \quad \text{in } \mathbb{R}^n,$$

$$\lim_{|x|\to\infty} \sigma_i(x) = \infty,$$

$$\lim_{|x|\to\infty} (\phi_0 - \phi_1)(x) = \infty.$$

Also, we need the following hypothesis:

$$\text{for each } x \in \Omega, \text{ the function } H(x, \cdot) \text{ is strictly convex in } \mathbb{R}^n. \quad (15)$$

We introduce the spaces $\Phi_0$ and $\Psi_0$ of functions on $\mathbb{R}^n$ and on $\mathbb{R}^n \times [0, \infty)$, respectively, as

$$\Phi_0 = \{f \in C(\mathbb{R}^n, \mathbb{R}) \mid \inf_{\mathbb{R}^n}(f - \phi_0) > -\infty\},$$

$$\Psi_0 = \{g \in C(\mathbb{R}^n \times [0, \infty), \mathbb{R}) \mid \inf_{\mathbb{R}^n \times [0,T]}(g - \phi_0) > -\infty, \ \text{ for all } T > 0\}.$$

**Theorem 3.1.** (a) *The additive eigenvalue problem* (4) *has a solution* $(c, v) \in \mathbb{R} \times \Phi_0$*, and moreover the additive eigenvalue* $c$ *is uniquely determined. That is, if* $(d, w) \in \mathbb{R} \times \Phi_0$ *is another solution of* (4)*, then* $d = c$.

(b) *Let* $u_0 \in \Phi_0$. *Then there exists a unique solution* $u \in \Psi_0$ *of the Cauchy problem* (2) *and* (3).

(c) *Let* $\mathcal{A}_c$ *be the Aubry set for the Hamiltonian* $H - c$ *and* $d_{H,c} := d_{H-c}$. *Let* $u \in \Psi_0$ *be the solution of* (2) *and* (3). *Assume that* (15) *holds. Then there exists a solution* $v_0 \in \Phi_0$ *of* (4) *with* $c$ *being the additive eigenvalue for* $H$ *such that*

$$\lim_{t\to\infty} \sup_{x\in B(0,R)} |u(x,t) + ct - v_0(x)| = 0 \quad \textit{for any } R > 0.$$

*Moreover,*

$$v_0(x) = \inf\{d_{H,c}(x, y) + d_{H,c}(y, z) + u_0(z) \mid z \in \mathbb{R}^n,\ y \in \mathcal{A}_c\} \quad \textit{for all } x \in \mathbb{R}^n.$$

The above result is contained in [23]. This result is a variant of those obtained by Fathi, Namah, Roquejoffre, Barles, Souganidis, Davini, Siconolfi, and others for compact manifolds $\Omega$. We refer to [16], [26], [28], [6], [12] for previous results and developments. See also [21] for results in $\mathbb{R}^n$ and [7], [20] for similar results for viscous Hamilton–Jacobi equations. In [21], Hamilton–Jacobi equations of the form $u_t + \alpha x \cdot Du + H_0(Du) = f(x)$ are treated, where $\alpha$ is a positive constant and $H_0, f \in C(\mathbb{R}^n)$. It is assumed that $H_0$ is convex and coercive and that there is a convex function $l \in C(\mathbb{R}^n)$ such that

$$\lim_{|x|\to\infty} (l(-\alpha x) + f(x)) = \infty \quad \text{and} \quad \lim_{|\xi|\to\infty} (L_0 - l)(\xi) = \infty,$$

where $L_0$ is the convex conjugate of $H_0$. If we assume that $H_0$ is strictly convex, then the hypotheses of Theorem 3.1 are satisfied with the choice of $\phi_0(x) := -(1/\sigma)l(-\alpha x)$, $\phi_1(x) := -(1/\alpha)L(-\alpha x)$, $\sigma_0(x) := l(-\alpha x) + f(x) - C$, and $\sigma_1(x) := L(-\alpha x) + f(x)$, where $C$ is a sufficiently large constant.

Another example of $H$ which satisfies the hypotheses of Theorem 3.1 is given by $H(x, p) = H_0(x, p) - f(x)$, where $H_0 \in C(\mathbb{R}^n \times \mathbb{R}^n)$ satisfies (15), (7), and

$$\sup_{\mathbb{R}^n\times B(0,\delta)} |H_0| < \infty \quad \text{for some } \delta > 0,$$

and $f \in C(\mathbb{R}^n)$ satisfies $\lim_{|x|\to\infty} f(x) = \infty$. A possible choice of $\phi_i$, $i = 0, 1$, is as follows: $\phi_0(x) := -(\delta/2)|x|$ and $\phi_1(x) = -\delta|x|$.

## 4. Outline of proof of Theorem 3.1

**4.1. Additive eigenvalue problem.** Additive eigenvalue problem (4) appears in ergodic optimal control or the homogenization of Hamilton–Jacobi equations. In ergodic optimal control the additive eigenvalue $c$ corresponds to averaged long-run optimal costs while $c$ determines the effective Hamiltonian in the homogenization of

Hamilton–Jacobi equations. See [25], [13] for periodic homogenization of Hamilton–Jacobi equations.

To avoid technicalities, we assume in this subsection that $\phi_0 = 0$. One method of solving problem (4) is to approximate it by a regular problem

$$\lambda v_\lambda + H(x, Dv_\lambda) = 0 \quad \text{in } \mathbb{R}^n, \tag{16}$$

where $\lambda$ is a positive constant, and then send $\lambda \to 0$ along an appropriate sequence $\lambda_j \to 0$, to obtain a solution $(c, v) \in \mathbb{R} \times \Phi_0$ of (4) as the limits

$$c := \lim_{j\to\infty} (-\lambda_j v_{\lambda_j}(0)) \quad \text{and} \quad v(x) := \lim_{j\to\infty} (v_{\lambda_j}(x) - v_{\lambda_j}(0)). \tag{17}$$

Indeed, thanks to the coercivity of $H$, we may build a solution $\psi_0 \in C^{0+1}(\mathbb{R}^n)$ of $H[\psi_0] \geq -C_0$ in $\mathbb{R}^n$ for some constant $C_0 > 0$ which satisfies $\phi_0 \leq \psi_0$ in $\mathbb{R}^n$. If $C > 0$ is large enough, then the functions

$$f_\lambda(x) := \phi_0(x) - \lambda^{-1}C \quad \text{and} \quad g_\lambda(x) := \psi_0(x) + \lambda^{-1}C$$

are a subsolution and a supersolution of (16), respectively. The Perron method now yields a solution $v_\lambda \in C^{0+1}(\mathbb{R}^n)$ of (16) which satisfies $f_\lambda \leq v_\lambda \leq g_\lambda$ in $\mathbb{R}^n$. Again the coercivity of $H$ guarantees that the family $\{v_\lambda\}_{\lambda\in(0,1)}$ is locally equi-Lipschitz in $\mathbb{R}^n$, while the inequality $f_\lambda \leq v_\lambda \leq g_\lambda$ in $\mathbb{R}^n$ assures that $\{\lambda v_\lambda(0)\}_{\lambda\in(0,1)}$ is bounded. These observations allow us to pass to the limit in (17).

Another approach to solving (4) is to define the additive eigenvalue $c \in \mathbb{R}$ by

$$c = \inf\{a \in \mathbb{R} \mid \text{there exists a solution } \phi \in C(\mathbb{R}^n) \text{ of } H[\phi] \leq a\}$$

and then to prove that $\mathcal{A}_c \neq \emptyset$. Any pair of $c$ and $v := d_{H,c}(\,\cdot\,, y)$, with $y \in \mathcal{A}_c$, is a solution of (4).

In what follows we *assume* by replacing $H$ by $H - c$, where $c$ is the additive eigenvalue for $H$, that $c = 0$.

**4.2. Critical curves.** An important tool in the weak KAM approach is the collection of critical curves for the Lagrangian $L$. It allows us to analyze the asymptotic behavior for large time of solutions of (2) in the viewpoint of the Lagrangian dynamical system behind (2), which may not be well-defined under our regularity assumptions on $H$.

According to [12], a curve $\gamma : \mathbb{R} \to \mathbb{R}^n$ is said to be *critical* for the Lagrangian $L$ if for any $a, b \in \mathbb{R}$, with $a < b$, and any subsolution $\phi \in C(\mathbb{R}^n)$ of $H[\phi] = 0$ in $\mathbb{R}^n$,

$$\phi(\gamma(b)) - \phi(\gamma(a)) = \int_a^b L(\gamma(s), \dot\gamma(s))\mathrm{d}s.$$

We denote by $\Gamma$ the set of all critical curves $\gamma$. Note that, in general, if $\gamma$ is a curve on $[a, b]$ and $\phi \in C(\mathbb{R}^n)$ is a subsolution of $H[\phi] = 0$ in $\mathbb{R}^n$, then

$$\phi(\gamma(b)) - \phi(\gamma(a)) \leq \int_a^b L(\gamma(s), \dot\gamma(s))\mathrm{d}s. \tag{18}$$

Indeed, we compute by assuming $\phi \in C^1(\mathbb{R}^n)$ that for any curve $\gamma$ on $[a, b]$,

$$\begin{aligned}\phi(\gamma(b)) - \phi(\gamma(a)) &= \int_a^b D\phi(\gamma(s)) \cdot \dot\gamma(s)\mathrm{d}s \\ &\le \int_a^b [L(\gamma, \dot\gamma) + H(\gamma, D\phi(\gamma(s))]\mathrm{d}s \le \int_a^b L(\gamma, \dot\gamma)\mathrm{d}s.\end{aligned}$$

Here we have used the Fenchel inequality: $p \cdot \xi \le H(x, p) + L(x, \xi)$ for all $x$, $p, \xi$ in $\mathbb{R}^n$. The above computation can be justified by the standard mollification technique for general $\phi$ which is locally Lipschitz because of the coercivity of $H$.

**Theorem 4.1.** *For any $y \in \mathcal{A}$ there exists a critical curve $\gamma$ such that $\gamma(0) = y$.*

Existence of critical curves is one of crucial observations in weak KAM theory. See [15], [17], [18], [12] for results on the existence of critical curves.

A main point in the proof of the above theorem is the following general observation concerning the Aubry set, which gives another definition of the Aubry set in terms of the Lagrangian $L$. We remark that this latter definition of the Aubry set has been employed in [15], [18], [19].

**Theorem 4.2.** *Let $y \in \mathbb{R}^n$. Then $y \in \mathcal{A}$ if and only if for any $\varepsilon > 0$,*

$$\inf\left\{ \int_0^t L(\gamma(s), \dot\gamma(s))\mathrm{d}s \;\middle|\; t \ge \varepsilon,\ \gamma \in \mathcal{C}(y, t),\ \gamma(0) = y \right\} = 0.$$

Once we have the above theorem in hand, the proof of Theorem 4.1 goes like this. For any $y \in \mathcal{A}$ and $k \in \mathbb{N}$ we may choose a curve $\gamma_k$ on $[0, T_k]$, where $T_k \ge k$ such that $\gamma_k(0) = \gamma_k(T_k) = y$ and

$$\int_0^{T_k} L(\gamma_k(s), \dot\gamma_k(s))\mathrm{d}s < \frac{1}{k}.$$

We define the curve $\eta_k$ on $[-T_k,\ T_k]$ by setting

$$\eta_k(s) = \begin{cases} \gamma_k(s + T_k) & \text{for } s \in [-T_k, 0], \\ \gamma_k(s) & \text{for } s \in [0, T_k]. \end{cases}$$

Using the observations that

$$\lim_{r\to\infty} \inf\left\{ \frac{L(x, \xi)}{|\xi|} \;\middle|\; x \in B(0, R),\ \xi \in \mathbb{R}^n \setminus B(0, r) \right\} = \infty \quad \text{for any } R > 0, \tag{19}$$

since $H \in C(\mathbb{R}^n \times \mathbb{R}^n)$ and that $\mathcal{A}$ is compact, we may send $k \to \infty$ along a subsequence so that $\eta_k$ has a limit $\gamma$ in $C(\mathbb{R}, \mathbb{R}^n)$, which is a critical curve.

For any $\gamma \in \Gamma$ we have

$$\gamma(t) \in \mathcal{A} \quad \text{for all } t \in \mathbb{R}. \tag{20}$$

This can be seen easily by recalling that for any $y \in \mathbb{R}^n \setminus \mathcal{A}$ there are functions $\phi \in C(\mathbb{R}^n)$ and $\sigma \in C(\mathbb{R}^n)$ such that $\sigma \ge 0$ in $\mathbb{R}^n$, $\sigma(y) > 0$, and $H[\phi] \le -\sigma$ in $\mathbb{R}^n$ and using (18), with $H(x, p)$ replaced by $H(x, p) + \sigma(x)$.

**4.3. Cauchy problem.** To prove existence of a solution of (2) and (3), we may use the well-known formula

$$u(x,t) = \inf\left\{ \int_0^t L(\gamma(s), \dot\gamma(s))\mathrm{d}s + u_0(\gamma(0)) \mid \gamma \in \mathcal{C}(x,t)\right\} \quad \text{for } (x,t) \in \mathbb{R}^n \times (0,\infty). \tag{21}$$

We have to check if this formula really gives a solution of (2) and (3). For this the first thing to do is to check that the function $u$ defined by (21) is a locally bounded function in $\mathbb{R}^n \times (0,\infty)$. Fix a subsolution $\phi \in C(\mathbb{R}^n)$ of $H[\phi] = 0$ in $\mathbb{R}^n$ and set $\phi_2(x) = \min\{\phi(x) - A, \phi_1(x)\}$, where $A > 0$ is a constant. If $A$ is large enough, then $\phi_2$ has the following properties: (a) $H[\phi_2] \le 0$ in $\mathbb{R}^n$ and (b) $\phi_2 \le u_0$ in $\mathbb{R}^n$. Then, for any $(x,t) \in \mathbb{R}^n \times (0,\infty)$ and $\gamma \in \mathcal{C}(x,t)$, we have

$$\phi_2(\gamma(t)) \le u_0(\gamma(0)) + \int_0^t L(\gamma, \dot\gamma)\mathrm{d}s,$$

from which we get $\phi_2(x) \le u(x,t)$.

In order to get a local upper bound of the function $u$ defined by (21), we fix any $(x,t) \in \mathcal{A} \times (0,\infty)$ and choose a curve $\gamma \in \Gamma$ so that $\gamma(t) = x$. Existence of such a critical curve is guaranteed by Theorem 4.1. As before let $\phi \in C(\mathbb{R}^n)$ be a solution of $H[\phi] \le 0$ in $\mathbb{R}^n$. We have

$$\begin{aligned} u(x,t) &\le u_0(\gamma(0)) + \int_0^t L(\gamma, \dot\gamma)\mathrm{d}s \le u_0(\gamma(0)) + \phi(\gamma(t)) - \phi(\gamma(0)) \\ &\le \max_{\mathcal{A}} u_0 + 2\max_{\mathcal{A}} |\phi|. \end{aligned}$$

Since $H \in C(\mathbb{R}^n \times \mathbb{R}^n)$, for each $R > 0$ there are constants $\delta_R > 0$ and $C_R > 0$ such that $L(x,\xi) \le C_R$ for all $(x,\xi) \in B(0,R) \times B(0,\delta_R)$. Fix any $R > 0$ such that $\mathcal{A} \subset B(0,R)$ and any $x \in B(0,R)$. There is a $T_R > 0$, independent of $x$, and a curve (e.g., the line segment connecting a point in $\mathcal{A}$ and $x$) $\gamma_x \in C^1([0,T_R], \mathbb{R}^n)$ such that $\gamma_x(0) \in \mathcal{A}$, $\gamma_x(T_R) = x$, and $|\gamma_x(s)| \le R$, $|\dot\gamma_x(s)| \le \delta_R$ for all $s \in [0,T_R]$. Using the dynamic programming principle which states that for any $x \in \mathbb{R}^n$ and $t, s \in (0,\infty)$,

$$u(x,t+s) = \inf\left\{ \int_0^s L(\gamma(\tau), \dot\gamma(\tau))\mathrm{d}\tau + u(\gamma(0),t) \;\Big|\; \gamma \in \mathcal{C}(x,s)\right\}, \tag{22}$$

we find that

$$\begin{aligned} u(x,t+T_R) &\le \int_0^{T_R} L(\gamma_x(s), \dot\gamma_x(s))\mathrm{d}s + u(\gamma_x(0),t) \\ &\le C_R T_R + \max_{\mathcal{A}} u_0 + 2\max_{\mathcal{A}} |\phi| \quad \text{for all } t \ge 0. \end{aligned}$$

Noting that $u(x,t) \le u_0(x) + tL(x,0)$, we obtain for all $t > 0$,

$$u(x,t) \le \max\{\max_{B(0,R)} (|u_0| + T_R|L(\,\cdot\,,0)|), C_R T_R + \max_{\mathcal{A}} u_0 + 2\max_{\mathcal{A}} |\phi|\}.$$

Setting $u(x, 0) = u_0(x)$ for $x \in \mathbb{R}^n$ and making further standard estimates on $u$, we conclude the following theorem.

**Theorem 4.3.** *The function $u$ belongs to $\Psi_0$ and moreover $u$ is bounded and uniformly continuous on $B(0, R) \times [0, \infty)$ for any $R > 0$.*

Furthermore, using the dynamic programming principle (22), we have:

**Theorem 4.4.** *The function $u$ is a solution of* (2) *and* (3).

Uniqueness of solutions of (2) and (3) follows from the following comparison theorem.

**Theorem 4.5.** *Let $u \in C(\mathbb{R}^n \times [0, \infty))$ and $v \in \Psi_0$ be a subsolution and a supersolution of* (2). *Assume that $u(\cdot, 0) \le v(\cdot, 0)$ in $\mathbb{R}^n$. Then $u \le v$ in $\mathbb{R}^n \times [0, \infty)$.*

An outline of the proof of this theorem goes like this. Let $A$ and $B$ be large positive constants. We set $\psi(x, t) = \phi_1(x) - At$ for $(x, t) \in \mathbb{R}^n \times [0, \infty)$. We may fix $A$ so that $\psi$ is a subsolution of (2). We set $u_B(x, t) = \min\{u(x, t), \psi(x, t) + B\}$ for $(x, t) \in \mathbb{R}^n \times (0, \infty)$ and observe that $u_B$ is a subsolution of (2), that $u_B(\cdot, 0) \le v(\cdot, 0)$ in $\mathbb{R}^n$, and that for each $T > 0$,

$$\lim_{|x| \to \infty} \sup\{(u_B - v)(x, t) \mid t \in [0, T]\} = -\infty. \tag{23}$$

Applying the standard comparison result to $u_B$ and $v$ on the set $B(0, R) \times [0, R)$, with $R > 0$ sufficiently large, we find that $u_B \le v$ in $\mathbb{R}^n \times [0, R)$. Because of the arbitrariness of $R$, $B$, we conclude that $u \le v$ in $\mathbb{R}^n \times [0, \infty)$.

### 4.4. Asymptotic analysis.

**4.4.1. Equilibrium points.** A point $y$ in the Aubry set $\mathcal{A}$ is called an *equilibrium point* if $\min_{p \in \mathbb{R}^n} H(y, p) = 0$ or equivalently $L(y, 0) = 0$. Under the assumption that $\mathcal{A}$ consists only of equilibrium points, the convergence assertion of Theorem 3.1 can be proved in an easy way compared to the general case. To see this, let $u \in \Psi_0$ be the solution of (2) and (3), and set $v_0(x) = \liminf_{t \to \infty} u(x, t)$ for $x \in \mathbb{R}^n$. We then observe in view of the convexity of $H(x, p)$ in $p$ that $v_0$ is a solution of $H[v_0] = 0$ in $\mathbb{R}^n$. Also, we observe at least formally that $u_t \le 0$ in $\mathcal{A} \times (0, \infty)$, which can be stated correctly that the function $t \mapsto u(x, t)$ is nonincreasing in $(0, \infty)$ for any $x \in \mathcal{A}$. Now, by Theorem 4.3 and Dini's lemma, we see that the functions $u(\cdot, t)$ converge to $v_0$ uniformly on $\mathcal{A}$ as $t \to \infty$.

We take a small digression here and state a comparison theorem for (1) with $\Omega = \mathbb{R}^n$, a version of Theorem 2.3 for $\Omega = \mathbb{R}^n$.

**Theorem 4.6.** *Let $u, v \in C(\mathbb{R}^n)$ be a subsolution and a supersolution of $H = 0$ in $\mathbb{R}^n$, respectively. Assume that $u \le v$ on $\mathcal{A}$ and that $v \in \Phi_0$. Then $u \le v$ in $\mathbb{R}^n$.*

For the proof of this theorem, we may assume by a simple modification of $\phi_1$ that $\phi_1$ is a solution of $H[\phi_1] \le 0$ in $\mathbb{R}^n$. We then replace $u$ by $\varepsilon\phi_1 + (1-\varepsilon)u$, with a small $\varepsilon \in (0,1)$, so that we are in the situation that $\lim_{|x|\to\infty}(u-v)(x) = -\infty$, which allows us to work on a ball $B(0,R)$, with sufficiently large $R > 0$. Now, as in the proof of Theorem 2.3, we get $u \le v$ in $\mathbb{R}^n$. This is an outline of the proof of Theorem 4.6.

Back to the main theme, we use the same argument as the proof of Theorem 4.6 just outlined, to control the functions $u(\cdot, t)$ through their restrictions on $\mathcal{A}$ and to conclude the desired convergence of $u(\cdot, t)$ to $v_0$ in $\mathbb{R}^n$ as $t \to \infty$.

We remark that if $\mathcal{A}$ is a finite set, then all the points of $\mathcal{A}$ are equilibrium points. Also, if there is a function $f \in C(\mathbb{R}^n)$ such that $H(x, Df) \le \min_{p\in\mathbb{R}^n} H(x,p)$ for $x \in \mathbb{R}^n$ in the viscosity sense, then all the points of $\mathcal{A}$ are equilibrium points.

**4.4.2. General case.** We turn to the general case. Let $u \in C(\mathbb{R}^n \times [0,\infty))$ be a solution of (2). A formal calculation reveals that for any $\gamma \in \Gamma$, any $t, T \in [0,\infty)$ satisfying $t < T$, and any solution of $\phi \in C(\mathbb{R}^n)$ of $H[\phi] \le 0$ in $\mathbb{R}^n$,

$$\begin{aligned} u(\gamma(T),T) - u(\gamma(t),t) &= \int_t^T \big[Du(\gamma(s),s)\cdot\dot\gamma(s) + u_t(\gamma(s),s)\big]\,\mathrm{d}s \\ &= \int_t^T \big[Du(\gamma(s),s)\cdot\dot\gamma(s) - H(\gamma(s), Du(\gamma(s),s))\big]\,\mathrm{d}s \\ &\le \int_t^T L(\gamma(s),\dot\gamma(s))\mathrm{d}s = \phi(\gamma(T)) - \phi(\gamma(t)). \end{aligned}$$

Indeed, we have

**Lemma 4.7.** *Under the above assumptions, the function $t \mapsto u(\gamma(t),t) - \phi(\gamma(t))$ is nonincreasing on $[0,\infty)$.*

In what follows we denote by $S_t$, with $t \ge 0$, the semigroup generated by (2), i.e., the map $S_t : \Phi_0 \to \Phi_0$ defined by $S_t u_0 = u(\cdot, t)$, where $u$ is the solution in $\Psi_0$ of (2) and (3).

The continuous dependence of the solution of (2) and (3) on the initial data can be stated as follows.

**Theorem 4.8.** *Let $f, g \in \Phi_0$ be a subsolution and a supersolution of $H = 0$ in $\mathbb{R}^n$, respectively. Assume that $f \le g$ in $\mathbb{R}^n$. Then for each $\varepsilon > 0$ there exists $\delta > 0$ such that for any $u_0,\ v_0 \in [f,\ g] \cap C(\mathbb{R}^n)$, if*

$$\max_{B(0,\delta^{-1})} (u_0 - v_0) \le \delta,$$

*then*

$$\sup_{(x,t)\in B(0,\varepsilon^{-1})\times[0,\infty)} (S_t u_0(x) - S_t v_0(x)) \le \varepsilon.$$

*Here* $[f, g]$ *denotes the space of those functions* $w : \mathbb{R}^n \to \mathbb{R}$ *which satisfy* $f \le w \le g$ *in* $\mathbb{R}^n$.

This theorem can be proved by an argument similar to the proof of Theorem 4.5, and we omit presenting it here.

For any $u_0 \in \Phi_0$, the *ω-limit set* $\omega(u_0)$ for the initial point $u_0$ is defined as the set consisting of those $w \in \Phi_0$ for which there exists a sequence $\{t_j\} \subset (0, \infty)$ diverging to infinity such that $S_{t_j} u_0 \to w$ in $C(\mathbb{R}^n)$ as $j \to \infty$. It is obvious from Theorem 4.3 that $\omega(u_0) \neq \emptyset$ for all $u_0 \in \Phi_0$. Another basic property of $\omega$-limit sets, which follows from Theorems 4.8 and 4.3, is the following.

**Lemma 4.9.** *Let* $u_0 \in \Phi_0$ *and let* $\{t_j\}, \{r_j\} \subset (0, \infty)$ *be sequences diverging to infinity such that* $S_{t_j} u_0 \to v$ *and* $S_{t_j + r_j} u_0 \to w$ *in* $C(\mathbb{R}^n)$ *as* $j \to \infty$ *for some* $v, w \in \omega(u_0)$. *Then* $S_{r_j} v \to w$ *in* $C(\mathbb{R}^n)$ *as* $j \to \infty$.

So far, we have needed only the convexity of the Hamiltonian $H(x, p)$ in $p$, but not its strict convexity (15) although this point may not be clear because of the rough presentation. In the next lemma we need the strict convexity assumption (15), which guarantees that $L(x, \xi)$ and $D_\xi L(x, \xi)$ are continuous on the set $\{(x, \xi) \in \mathbb{R}^{2n} \mid L(x, \xi) < \infty\}$. The following lemma is an equivalent of [12, Lemma 5.2] and a key observation for the convergence proof.

**Lemma 4.10.** *Assume that* (15) *holds. Then there exist a* $\delta > 0$ *and a function* $\rho \in C([0, \infty))$, *with* $\rho(0) = 0$, *such that for any* $u_0 \in \Phi_0$, $\gamma \in \Gamma$, $\varepsilon \in (-\delta, \delta)$, *and* $t > 0$,

$$S_t u_0(\gamma(t)) \le u_0(\gamma(\varepsilon t)) + \int_{\varepsilon t}^{t} L(\gamma(s), \dot\gamma(s)) \mathrm{d}s + |\varepsilon t|\, \rho(|\varepsilon|).$$

*Proof of Theorem* 3.1 (c). We denote by $\omega(\Gamma)$ the set of all those curves $\gamma$ to which there correspond a curve $\eta \in \Gamma$ and a sequence $\{t_j\}$ diverging to infinity such that $\eta(\cdot + t_j) \to \gamma$ in $C(\mathbb{R})$ as $j \to \infty$. We set $\mathcal{M} = \{\gamma(0) \mid \gamma \in \omega(\Gamma)\}$. We remark that any $\gamma \in \omega(\Gamma)$ is a critical curve for $L$. Consequently, we have $\mathcal{M} \subset \mathcal{A}$. Moreover, it is easily seen that for any two solutions $\phi, \psi \in C(\mathbb{R}^n)$ of $H = 0$ in $\mathbb{R}^n$, if $\phi \le \psi$ on $\mathcal{M}$, then $\phi \le \psi$ on $\mathcal{A}$.

As before we define the function $v_0 \in \Phi_0$ by

$$v_0(x) = \liminf_{t \to \infty} S_t u_0(x),$$

which is a solution of $H[v_0] = 0$ in $\mathbb{R}^n$.

We prove that $u(\cdot, t) \to v_0$ in $C(\mathbb{R}^n)$ as $t \to \infty$. To this end, it is enough to show that $w = v_0$ for all $w \in \omega(u_0)$. By the definition of $v_0$, we have $v_0 \le w$ in $\mathbb{R}^n$ for all $w \in \omega(u_0)$. Hence, recalling the proof in the case when $\mathcal{A}$ consists only of equilibrium points and using the remark made above, we find that it is enough to show that $w \le v_0$ in $\mathcal{M}$ for all $w \in \omega(u_0)$. (We omit here proving the formula for $v_0$ in the theorem.)

Fix any $w \in \omega(u_0)$ and $y \in \mathcal{M}$. Choose a curve $\gamma \in \Gamma$ and sequences $\{a_j\},\ \{b_j\} \subset (0, \infty)$ diverging to infinity so that, as $j \to \infty$, $\gamma(a_j) \to y$ and $S_{b_j} w \to w$ in $C(\mathbb{R}^n)$. Existence of such a sequence $\{b_j\}$ is assured by Lemma 4.9. We may assume that $c_j := a_j - b_j \to \infty$ as $j \to \infty$. We fix any $s \geq 0$ and apply Lemma 4.10, with $w$ and $\gamma(\cdot + c_j)$ in place of $u_0$ and $\gamma$, respectively, and with $t = b_j$ and $\varepsilon = s/b_j$, to obtain for sufficiently large $j$,

$$S_{b_j} w(\gamma(b_j + c_j)) - w(\gamma(s + c_j)) \leq v_0(\gamma(b_j + c_j)) - v_0(\gamma(s + c_j)) + s\rho(s/b_j),$$

where $\rho \in C([0, \infty))$ is the function from Lemma 4.10. Sending $j \to \infty$ yields

$$w(y) - v_0(y) \leq w(\eta(s)) - v_0(\eta(s)) \quad \text{for all } s \geq 0 \tag{24}$$

and for some $\eta \in \omega(\Gamma)$.

The final step is to show that

$$\liminf_{t \to \infty} [w(\eta(t)) - v_0(\eta(t))] \leq 0, \tag{25}$$

which yields, together with (24), $w(y) \leq v_0(y)$. To do this, we choose sequences $\{t_j\},\ \{\tau_j\} \subset (0, \infty)$ diverging to infinity so that, as $j \to \infty$, $S_{t_j} u_0(\eta(0)) \to v_0(\eta(0))$ and $S_{t_j + \tau_j} u_0 \to w$ in $C(\mathbb{R}^n)$. We calculate by using Lemma 4.7 that

$$\begin{aligned} w(\eta(\tau_j)) - v_0(\eta(\tau_j)) &\leq |w(\eta(\tau_j)) - S_{t_j+\tau_j} u_0(\eta(\tau_j))| + S_{t_j+\tau_j} u_0(\eta(\tau_j)) - v_0(\eta(\tau_j)) \\ &\leq \max_{\mathcal{A}} |w - S_{t_j+\tau_j} u_0| + S_{t_j} u_0(\eta(0)) - v_0(\eta(0)). \end{aligned}$$

Sending $j \to \infty$, we get

$$\limsup_{j \to \infty} \left[ w(\eta(\tau_j)) - v_0(\eta(\tau_j)) \right] \leq 0,$$

which shows that (25) is valid. □

# The weak-coupling limit of large classical and quantum systems

Mario Pulvirenti*

**Abstract.** In this contribution we illustrate the delicate transition from the microscopic description of a particle system, given in terms of fundamental equations as the Newton or the Schrödinger equation, to the reduced kinetic picture, given in terms of the Boltzmann and Landau equations which are obtained under suitable scaling limits. Special emphasis is given to the so called weak-coupling limit.

The content of the lecture is mostly devoted to the very many open problems, rather than to the few known results.

**Mathematics Subject Classification (2000).** Primary 35Q99; Secondary 82C40.

**Keywords.** Boltzmann equation, Landau equation, weak-coupling limit.

## 1. The Boltzmann and Landau equations

The present section is largely discursive: its scope is the heuristic introduction of the Boltzmann and Landau equations on the basis of physical arguments.

In 1872 Ludwig Boltzmann, starting from the mathematical model of elastic balls and using mechanical and statistical considerations, established an evolution equation to describe the behavior of a rarefied gas. The starting point of the Boltzmann analysis is to renounce to study the behavior of a gas in terms of the detailed motion of the molecules which constitute it because of their huge number. It is rather better to investigate a function $f(x, v)$ which is the probability density of a given particle, where $x$ and $v$ denote position and velocity of such a particle. Actually $f(x, v)dxdv$ is often confused with the fraction of molecules falling in the cell of the pase space of size $dx\,dv$ around $x$, $v$. The two concept are not exactly the same but they are asymptotically equivalent (when the number of particles is diverging) if a law of large numbers holds.

The Boltzmann equation is the following:

$$(\partial_t + v \cdot \nabla_x) f = Q(f, f) \tag{1.1}$$

*Most of the considerations developed here are due to a systematic collaboration of the author with D. Benedetto, F. Castella and R. Esposito.

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

where $Q$, the collision operator, is defined for $\lambda > 0$ by

$$Q(f, f) = \lambda^{-1} \int dv_1 \int_{S_+} dn\, (v - v_1) \cdot n\, [f(x, v') f(x, v_1') - f(x, v) f(x, v_1)] \tag{1.2}$$

and

$$v' = v - n[n \cdot (v - v_1)], \quad v_1' = v_1 + n[n \cdot (v - v_1)]. \tag{1.3}$$

Also $n$ (the impact parameter) is a unitary vector and $S_+ = \{n \mid n \cdot (v - v_1) \geq 0\}$. Note that $v'$, $v_1'$ are the outgoing velocities after a collision of two elastic balls with incoming velocities $v$ and $v_1$ and centers $x$ and $x + dn$, being $d$ the diameter of the spheres. Obviously the collision takes place if $n \cdot (v - v_1) \geq 0$. Equations (1.3) are consequence of the energy, momentum and angular momentum conservation. Note also that $d$ does not enter in equation (1.1) as a parameter.

As fundamental features of equation (1.1) we have the conservation in time of the following five quantities

$$\iint dx dv f(x, v; t) v^\alpha \tag{1.4}$$

with $\alpha = 0, 1, 2$ expressing conservation of the probability, momentum and energy.

Moreover Boltzmann introduced the (kinetic) entropy defined by

$$H(f) = \int dx \int dv f \log f(x, v) \tag{1.5}$$

and proved the famous H-theorem asserting the decreasing of $H(f(t))$ along the solutions to equation (1.1).

Finally, in case of bounded domains, the distribution defined for $\beta > 0$:

$$M(v) = \text{const}\, e^{-\beta v^2},$$

called Maxwellian distribution, is stationary for the evolution given by equation (1.1). In addition $M$ minimizes $H$ among all distributions with zero mean velocity, and given energy.

In conclusion Boltzmann was able to introduce an evolutionary equation with the remarkable properties of expressing mass, momentum, energy conservations, but also the trend to the thermal equilibrium. In other words he tried to conciliate the Newton laws with the second principle of Thermodynamics.

Boltzmann's heuristic argument in deriving equation (1.1) is, roughly speaking, the following. The molecular system we are considering consists of $N$ identical particles of diameter $d$ in the whole space $\mathbb{R}^3$ and we denote by $x_1, v_1, \ldots, x_N, v_N$ a state of the system, where $x_i$ and $v_i$ indicate the position and the velocity of the particle $i$. The particles cannot overlap, that is the centers of two particles cannot be at distance smaller than the diameter $d$.

The particles are moving freely up to the first contact instant, that is the first time in which two particles arrive at distance $d$. Then the pair interacts performing

an elastic collision. This means that they change instantaneously their velocities, according to the conservation of the energy, linear and angular momentum. After the first collision the system goes on by iterating the procedure. Here we neglect triple collisions because unlikely. The evolution equation for a tagged particle is of the form

$$(\partial_t + v \cdot \nabla_x) f = \text{Coll} \tag{1.6}$$

where Coll denotes the variation of $f$ due to the collisions. We have

$$\text{Coll} = G - L \tag{1.7}$$

where $L$ and $G$ (loss and gain term respectively) are the negative and positive contribution to the variation of $f$ due to the collisions. More precisely $Ldxdvdt$ is the probability of our test particle to disappear from the cell $dxdv$ of the phase space because of a collision in the time interval $(t, t + dt)$ and $Gdxdvdt$ is the probability to appear in the same time interval for the same reason. Let us now consider the sphere of center $x$ with radius $d$ and a point $x + dn$ over the surface, where $n$ denotes the generic unit vector. Consider also the cylinder with base area $dS = d^2 dn$ and height $|V|dt$ along the direction of $V = v_2 - v$.

Then a given particle (say particle 2) with velocity $v_2$, can contribute to $L$ because it can collide with our test particle in the time $dt$, provided it is localized in the cylinder and if $V \cdot n \leq 0$. Therefore the contribution to $L$ due to the particle 2 is the probability of finding such a particle in the cylinder (conditioned to the presence of the first particle in $x$). This quantity is $f_2(x, v, x + nd, v_2)|(v_2 - v) \cdot n|d^2 dn dv_2 dt$, where $f_2$ is the joint distribution of two particles. Integrating in $dn$ and $dv_2$ we obtain that the total contribution to $L$ due to any predetermined particle is:

$$d^2 \int dv_2 \int_{S_-} dn f_2(x, v, x + nd, v_2)|(v_2 - v) \cdot n| \tag{1.8}$$

where $S_-$ is the unit hemisphere $(v_2 - v) \cdot n < 0$. Finally we obtain the total contribution multiplying by the total number of particles:

$$L = (N - 1)d^2 \int dv_2 \int_{S_-} dn f_2(x, v, x + nd, v_2)|(v_2 - v) \cdot n|. \tag{1.9}$$

The gain term can be derived analogously by considering that we are looking at particles which have velocities $v$ and $v_2$ after the collisions so that we have to integrate over the hemisphere $S_+ = (v_2 - v) \cdot n > 0$:

$$G = (N - 1)d^2 \int dv_2 \int_{S_+} dn f_2(x, v, x + nd, v_2)|(v_2 - v) \cdot n|. \tag{1.10}$$

Summing $G$ and $-L$ we get

$$\text{Coll} = (N - 1)d^2 \int dv_2 \int dn f_2(x, v, x + nd, v_2)(v_2 - v) \cdot n. \tag{1.11}$$

which, however, is not a very useful expression because the time derivative of $f$ is expressed in term of another object namely $f_2$. An evolution equation for $f_2$ will imply $f_3$, the joint distribution of three particles and so on up to arrive to the total particle number $N$. Here the basic Boltzmann's main assumption enters, namely that two given particles are uncorrelated if the gas is rarefied, namely:

$$f(x, v, x_2, v_2) = f(x, v) f(x_2, v_2). \tag{1.12}$$

Condition (1.12), called *propagation of chaos*, seems contradictory at a first sight: if two particles collide, correlations are created. Even though we could assume equation (1.12) at some time, if the test particle collides with the particle 2, such an equation cannot be satisfied anymore after the collision.

Before discussing the propagation of chaos hypothesis, we first analyze the size of the collision operator. We remark that, in practical situations for a rarefied gas, the combination $Nd^3 \approx 10^{-4}\text{cm}^3$ (that is the volume occupied by the particles) is very small, while $Nd^2 = O(1)$. This implies that $G = O(1)$. Therefore, since we are dealing with a very large number of particles we are tempted to perform the limit $N \to \infty$ and $d \to 0$ in such a way that $d^2 = O(N^{-1})$. As a consequence the probability that two tagged particles collide (which is of the order of the surface of a ball, that is $O(d^2)$), is negligible. However the probability that a given particle performs a collision with any one of the remaining $N-1$ particles (which is $O(Nd^2) = O(1)$) is not negligible. Condition (1.12) is referring to two preselected particles (say particle 1 and particle 2) so that it is not unreasonable to conceive that it holds in the limiting situation in which we are working.

However we cannot insert (1.12) in (1.11) because this latter equation refer both to instants before and after the collision and, if we know that a collision took place, we certainly cannot invoke (1.12). Hence we assume (1.12) in the loss term and work over the gain term to keep advantage of the factorization property which will be assumed *only* before the collision.

Coming back to equation (1.10) for the outgoing pair velocities $v, v_2$ (satisfying the condition $(v_2 - v) \cdot n > 0$) we make use of the continuity property

$$f_2(x, v, x + nd, v_2) = f_2(x, v', x + nd, v_2') \tag{1.13}$$

where the pair $v', v_2'$ is pre-collisional. On $f_2$ expressed before the collision we can reasonably apply condition (1.12) obtaining:

$$\begin{aligned} G - L = (N-1)r^2 \int dv_2 \int_{S_-} dn (v - v_2) \cdot n \\ \cdot [f(x, v') f(x - nd, v_2') - f(x, v) f(x + nd, v_2)] \end{aligned} \tag{1.14}$$

after a change $n \to -n$ in the Gain term. This transforms the pair $v', v_2'$ from a pre-collisional to a post-collisional pair.

Finally, in the limit $N \to \infty$, $r \to 0$, $Nd^2 = \lambda^{-1}$ we find equation (1.1) where $Q$, the collision operator, has the form (1.2). The parameter $\lambda$, called *mean*

*free path*, represents, roughly speaking, the typical length a particle can cover without undergoing any collision.

Equation (1.1) is has a statistical nature and it is not equivalent to the Hamiltonian dynamics from which it has been derived. In particular, due to the H-Theorem, it is not time reversal.

The heuristic arguments we have developed so far can be extended to different potentials than that of the hard-sphere systems. If the particles interact via a two-body interaction $\phi = \phi(x)$ the resulting Boltzmann equation is equation (1.1) with

$$Q(f, f) = \int dv_1 \int_{S_+} dn B(v - v_1; n) [f' f_1' - f f_1], \tag{1.15}$$

where we are using the usual short hand notation:

$$f' = f(x, v'), \quad f_1' = f(x, v_1'), \quad f = f(x, v), \quad f_1 = f(x, v_1) \tag{1.16}$$

and $B = B(v - v_1; n)$ is a suitable function of the relative velocity and the impact parameter, proportional to the cross-section relative to the potential $\phi$. Another equivalent, some times convenient way to express $Q$ is

$$Q(f, f) = \int dv_1 \int dv' \int dv_1' W(v, v_1 | v', v_1') [f' f_1' - f f_1] \tag{1.17}$$

with

$$W(v, v_1 | v', v_1') = w(v, v_1 | v', v_1') \cdot \delta(v + v_1 - v' + v_1') \delta\left(\frac{1}{2}(v^2 + v_1^2 - (v')^2 + (v_1')^2)\right). \tag{1.18}$$

and $w$ a suitable kernel. All the qualitative properties as the conservation laws and the H-theorem are obviously still valid.

The arguments we have used in deriving the Boltzmann equation are delicate and require a more rigorous and deeper analysis. If we want that the Boltzmann equation is not a phenomenological model, derived by assumptions *ad hoc* and justified by its practical relevance, but rather a consequence of a mechanical model, we must derive it rigorously from a logical and mathematical viewpoint. In particular the propagation of chaos should be not an hypothesis but the statement of a theorem.

Many scientists, among them Loschmidt, Zermelo and Poincaré, outlined inconsistencies between the irreversibility of the equation and the reversible character of the Hamiltonian dynamics. Boltzmann argued the statistical nature of his equation and his answer to the irreversibility paradox was that *most* of the configurations behave as expected by the thermodynamical laws. However he did not have the probabilistic tools for formulating in a precise way the statements of which he had a precise intuition. In 1949 H. Grad [25] stated clearly the limit $N \to \infty$, $d \to 0$, $Nd^2 \to$ const, where $N$ is the number of particles and $d$ is the diameter of the molecules, in which the Boltzmann equation is expected to hold. This limit is usually called the Boltzmann-Grad (or low-density limit).

The problem of a rigorous derivation of the Boltzmann equation was an open and challenging problem for a long time. O. E. Lanford [31] showed that, although for a very short time, the Boltzmann equation can be derived starting from the mechanical model of the hard-sphere system. The proof has a deep content but is relatively simple from a technical view point. Later on [28] it has been proved that this technique can be adapted to prove a result holding globally in time, but for the special situation of a rare claud of gas expanding in the vacuum.

We address the reader to references [31], [14] and [19] for a deeper discussion on the validation problem of the Boltzmann equation. We also warmly suggest the monograph [13] for a critical and historical discussion on the Boltzmann equation and the scientist who conceived it.

A preliminary problem to the validation of the Boltzmann equation for an arbitrary time interval, still open in general, is the construction of a global solution, hopefully unique. See [14] and [42] for the state of art of existence problems at present times. We just mention that the most general result we have up to now is due to Di Perna and Lions [16] who showed the existence of suitable weak solutions to equation (1.1). However we still do not know whether such solutions, which preserve mass, momentum and satisfy the H-theorem, are unique and preserve also the energy.

The Boltzmann equation works for rarefied gas, however one can ask whether a useful kinetic picture can be invoked for dense gas. Here we want to describe a situation in which the gas particles are weakly interacting, but $N = O(r^{-3})$ being $r \ll 1$ the interaction length of the particles. To express the weakness of the interaction, we assume that the two-particle potential is $O(\sqrt{r})$. In this case we want to compute the total momentum variation for a unit time. Note that the force is $O\left(\frac{1}{\sqrt{r}}\right)$ but acts on the time interval $O(r)$. The momentum variation due to the single scattering is therefore $O(\sqrt{r})$. The number of particles met by a test particles is $O\left(\frac{1}{r}\right)$. Hence the total momentum variation for unit time is $O\left(\frac{1}{\sqrt{r}}\right)$. However this variation, in case of homogeneous gas and symmetric force, should be zero in the average. If we compute the variance, it should be $\frac{1}{r}O(\sqrt{r})^2 = O(1)$. As a consequence of this central limit type of argument we expect that the kinetic equation which holds in the limit (if any), should be a diffusion equation in velocity variable.

A more convincing argument will be presented in the next section. For the moment let us now argue at level of kinetic equation. Consider the collision operator in the form (1.17). Suppose that $\varepsilon > 0$ is a small parameter. To express the fact that the transferred momentum is small, we rescale $w$ as $\frac{1}{\varepsilon^3} w\left(\frac{p}{\varepsilon}\right)$. In addition we also rescale the mean-free path inverse by a factor $\frac{1}{\varepsilon}$ to take into account the high density situation. The collision operator becomes:

$$Q_\varepsilon(f, f) = \frac{1}{\varepsilon^4} \int dv_1 \int dp w\left(\frac{p}{\varepsilon}\right) \delta(p^2 + (v - v_1) \cdot p)[f' f_1' - f f_1] \qquad (1.19)$$

$$
\begin{aligned}
&= \frac{1}{2\pi\varepsilon^2}\int dv_1 \int dp\ w(p) \int_{-\infty}^{+\infty} ds e^{is(p^2\varepsilon+(v-v_1)\cdot p)} \\
&\quad \cdot [f(v+\varepsilon p) f(v_1-\varepsilon p) - f(v) f(v_1)] \\
&= \frac{1}{2\pi\varepsilon}\int dv_1 \int dp\ w(p) \int_0^1 d\lambda \int_{-\infty}^{+\infty} ds e^{is(p^2\varepsilon+(v-v_1)\cdot p)} \\
&\quad \cdot p(\nabla_v - \nabla_{v_1}) f(v+\varepsilon\lambda p) f(v_1-\varepsilon\lambda p).
\end{aligned}
$$

Here the smooth function $w$, which modulates the collision, is assumed depending only on $p$ trough its modulus. The $\delta$ appearing in equation (1.19) expresses the energy conservation.

To outline the behavior of $Q_\varepsilon(f, f)$ in the limit $\varepsilon \to 0$, we introduce a test function $\varphi$ for which, after a change of variables ( here $(\cdot,\cdot)$ denotes the scalar product in $L_2(v)$):

$$
\begin{aligned}
(\varphi, Q_\varepsilon(f,f)) &= \frac{1}{2\pi\varepsilon}\int dv \int dv_1 \int dp\ w(p) \int_0^1 d\lambda \int_{-\infty}^{+\infty} ds e^{is(p^2(\varepsilon-2\varepsilon\lambda)+(v-v_1)\cdot p)} \\
&\quad \cdot \varphi(v-\varepsilon\lambda p)\ p\cdot(\nabla_v - \nabla_{v_1}) f f_1 \\
&= \frac{1}{2\pi\varepsilon}\int dv \int dv_1 \int dp w(p) \int_0^1 d\lambda \int_{-\infty}^{+\infty} ds e^{is(v-v_1)\cdot p} \\
&\quad \cdot [\varphi(v) + \varepsilon p\cdot\nabla_v\varphi(v)] p\cdot(\nabla_v - \nabla_{v_1}) f f_1 \\
&\quad + \frac{1}{2\pi}\int dv \int dv_1 \int dp\ w(p) \int_{-\infty}^{+\infty} ds e^{is(v-v_1)\cdot p)}\varphi(v) \\
&\quad \cdot isp^2 \int_0^1 d\lambda(1-2\lambda)\ p\cdot(\nabla_v - \nabla_{v_1}) f f_1 + O(\varepsilon).
\end{aligned}
\tag{1.20}
$$

Note now that the term $O(\varepsilon^{-1})$ vanishes because of the symmetry $p \to -p$ ($w$ is even). Also the imaginary part of the $O(1)$ term is vanishing, being null the integral in $d\lambda$. As a result:

$$
\begin{aligned}
(\varphi, Q_\varepsilon(f,f)) = \frac{1}{2\pi}\int dv \int dv_1 \int dp\ w(p) \int_{-\infty}^{+\infty} ds\ e^{is(v-v_1)\cdot p)} \\
\cdot p\cdot\nabla_v\varphi\ p\cdot(\nabla_v - \nabla_{v_1}) f f_1 + O(\varepsilon).
\end{aligned}
\tag{1.21}
$$

Therefore we have recovered the kinetic equation (1.1) with a new collision operator

$$
Q_L(f,f) = \int dv_1 \nabla_v\, a(\nabla_v - \nabla_{v_1}) f f_1, \tag{1.22}
$$

where $a = a(v - v_1)$ denotes the matrix

$$
a_{i,j}(V) = \int dp\ w(p)\ \delta(V\cdot p)\ p_i p_j. \tag{1.23}
$$

This matrix can be handled in a better way by introducing polar coordinates:

$$a_{i,j}(V) = \frac{1}{|V|}\int dp\ |p|w(p)\ \delta(\hat{V}\cdot\hat{p})\ \hat{p}_i\hat{p}_j \cdot \frac{B}{|V|}\int d\hat{p}\ \delta(\hat{V}\cdot\hat{p})\ \hat{p}_i\hat{p}_j, \tag{1.24}$$

where $\hat{V}$ and $\hat{P}$ are the versor of $V$ and $p$ respectively and

$$B = \int_0^{+\infty} drr^3 w(r). \tag{1.25}$$

Note that $B$ is the only parameter describing the interaction appearing in the equation. Finally a straightforward computation yields:

$$a_{i,j}(V) = \frac{B}{|V|}(\delta_{i,j} - \hat{V}_i\hat{V}_j). \tag{1.26}$$

The collision operator $Q_L$ has been introduced by Landau ([32]) for the study of a weakly interacting dense plasma. Note that the qualitative properties of the solutions to the Landau equation are the same as for the Boltzmann equation as regards the basic conservation laws and the H-theorem.

A rigorous derivation of the Landau equation starting from the Boltzmann equation in the grazing collision limit (that is what we presented here at a formal level), has been obtained in [1], [24] and [43] for spatially homogeneous solutions. The (diverging) asymptotics for the Coulomb forces is discussed in [15] and in [43]. However, in the present lecture, we are interested in deriving the Landau equation in terms of particle systems. In the next section we present a formal derivation outlining the difficulties in trying a rigorous proof.

## 2. Weak-coupling limit for classical systems

We consider a classical system of $N$ identical particles of unitary mass. Positions and velocities are denoted by $q_1, \ldots, q_N$ and $v_1, \ldots, v_N$. The Newton equations reads as:

$$\frac{d}{d\tau}q_i = v_i, \quad \frac{d}{d\tau}v_i = \sum_{\substack{j=1,\ldots,N:\\ j\neq i}} F(q_i - q_j). \tag{2.1}$$

Here $F = -\nabla\phi$ denotes the interparticle (conservative) force, $\phi$ the two-body interaction potential and $\tau$ the time.

We are interested in a situation where the number of particles $N$ is very large and the interaction quite moderate. In addition we look for a reduced or macroscopic description of the system. Namely if $q$ and $\tau$ refer to the system seen in a microscopic

scale, we introduce $\varepsilon > 0$ a small parameter expressing the ratio between the macro and microscales. Indeed it is often convenient to rescale equation (2.1) in terms of the macroscopic variables

$$x = \varepsilon q, \quad t = \varepsilon \tau$$

whenever the physical variables of interest are varying on such scales and are almost constant on the microscopic scales. Therefore, rescaling the potential according to

$$\phi \to \sqrt{\varepsilon}\phi, \tag{2.2}$$

system (2.1), in terms of the $(x, t)$ variables, becomes

$$\frac{d}{dt}q_i = v_i, \quad \frac{d}{dt}v_i = -\frac{1}{\sqrt{\varepsilon}} \sum_{\substack{j=1,\dots,N: \\ j\neq i}} \nabla\phi\Big(\frac{x_i - x_j}{\varepsilon}\Big). \tag{2.3}$$

Note that the velocities are automatically unscaled. Moreover we also assume that $N = O(\varepsilon^{-3})$, namely the density is $O(1)$.

Let $W^N = W^N(X_N, V_N)$ be a probability distribution on the phase space of the system. Here $(X_N, V_N)$ denote the set of positions and velocities:

$$X_N = x_1, \dots, x_N, \quad V_N = v_1, \dots, v_N.$$

Then from equations (2.3) we obtain the following Liouville equation:

$$(\partial_t + V_N \cdot \nabla_N) W^N(X_N, V_N) = \frac{1}{\sqrt{\varepsilon}} \big(T_N^\varepsilon W^N\big)(X_N, V_N), \tag{2.4}$$

where $V_N \cdot \nabla_N = \sum_{i=1}^N v_i \cdot \nabla_{x_i}$ and $(\partial_t + V_N \cdot \nabla_N)$ is the usual free stream operator. Also, we have introduced the operator

$$(T_N^\varepsilon W^N)(X_N, V_N) = \sum_{0<k<\ell\leq N} (T_{k,\ell}^\varepsilon W^N)(X_N, V_N), \tag{2.5}$$

with

$$T_{k,\ell}^\varepsilon W^N = \nabla\phi\Big(\frac{x_k - x_\ell}{\varepsilon}\Big) \cdot (\nabla_{v_k} - \nabla_{v_\ell}) W^N. \tag{2.6}$$

To investigate the limit $\varepsilon \to 0$ it is convenient to introduce the BBKGY hierarchy for the $j$- particle distributions defined as

$$\begin{aligned} f_j^N(X_j, V_j) = \int dx_{j+1} \dots \int dx_N \int dv_{j+1} \dots \int dv_N \\ \cdot W^N(X_j, x_{j+1}, \dots, x_N; V_j, v_{j+1}, \dots, v_N) \end{aligned} \tag{2.7}$$

for $j = 1, \dots, N-1$. Obviously, we set $f_N^N = W^N$. Note that BBKGY stands for Bogoliubov, Born, Green, Kirkwood and Yvon, the names of physicists who introduced independently this system of equations (see e.g. [2] and [19]).

From now on we shall suppose that, due to the fact that the particles are identical, the objects which we have introduced ($W^N$, $f_j^N$) are all symmetric in the exchange of particles.

A partial integration of the Liouville equation (2.4) and standard manipulations give us the following hierarchy of equations (for $1 \le j \le N$):

$$\Big(\partial_t + \sum_{k=1}^{j} v_k \cdot \nabla_k\Big) f_j^N = \frac{1}{\sqrt{\varepsilon}} T_j^\varepsilon f_j^N + \frac{N-j}{\sqrt{\varepsilon}} C_{j+1}^\varepsilon f_{j+1}^N. \tag{2.8}$$

The operator $C_{j+1}^\varepsilon$ is defined as

$$C_{j+1}^\varepsilon = \sum_{k=1}^{j} C_{k,j+1}^\varepsilon, \tag{2.9}$$

and

$$\begin{aligned} &C_{k,j+1}^\varepsilon f_{j+1}(x_1, \dots, x_j; v_1, \dots, v_j) \\ &\quad = -\int dx_{j+1} \int dv_{j+1} F\Big(\frac{x_k - x_\ell}{\varepsilon}\Big) \nabla_{v_k} f_{j+1}(x_1, x_2, \dots, x_{j+1}; v_1, \dots, v_{j+1}). \end{aligned} \tag{2.10}$$

$C_{k,j+1}^\varepsilon$ describes the "collision" of particle $k$, belonging to the $j$-particle subsystem, with a particle outside the subsystem, conventionally denoted by the number $j+1$ (this numbering uses the fact that all particles are identical). The total operator $C_{j+1}^\varepsilon$ takes into account all such collisions. The dynamics of the $j$-particle subsystem is governed by three effects: the free-stream operator, the collisions "inside" the subsystem (the $T$ term), and the collisions with particles "outside" the subsystem (the $C$ term).

We finally fix the initial value $\{f_j^0\}_{j=1}^N$ of the solution $\{f_j^N(t)\}_{j=1}^N$ assuming that $\{f_j^0\}_{j=1}^N$ is factorized, that is, for all $j = 1, \dots, N$

$$f_j^0 = f_0^{\otimes j}, \tag{2.11}$$

where $f_0$ is a given one-particle distribution function. This means that the states of any pair of particles are statistically uncorrelated at time zero. Of course such a statistical independence is destroyed at time $t > 0$. Dynamics creates correlations and equation (2.8) shows that the time evolution of $f_1^N$ is determined by the knowledge of $f_2^N$ which turns out to be dependent on $f_3^N$ and so on. However, since the interaction between two given particle is going to vanish in the limit $\varepsilon \to 0$, we can hope that such statistical independence is recovered in the same limit. Note that the physical meaning of the propagation of chaos here is quite different from that arising in the contest of the Boltzmann equation. Here two particles can interact but the effect of the collision is small, while in a low-density regime the effect of a collision between two given particles is large but quite unlikely.

Therefore we expect that in the limit $\varepsilon \to 0$ the one-particle distribution function $f_1^N$ converges to the solution of a suitable nonlinear kinetic equation $f$ which we are going to investigate.

If we expand $f_j^N(t)$ as a perturbation of the free flow $S(t)$ defined as

$$(S(t)f_j)(X_j, V_j) = f_j(X_j - V_j t, V_j), \tag{2.12}$$

we find

$$\begin{aligned} f_j^N(t) = S(t)f_j^0 + \frac{N-j}{\sqrt{\varepsilon}} \int_0^t S(t-t_1) C_{j+1}^{\varepsilon} f_{j+1}^N(t_1) dt_1 \\ + \frac{1}{\sqrt{\varepsilon}} \int_0^t S(t-t_1) T_j^{\varepsilon} f_j^N(t_1) dt_1. \end{aligned} \tag{2.13}$$

We now try to keep information on the limit behavior of $f_j^N(t)$. Assuming for the moment that the time evolved $j$-particle distributions $f_j^N(t)$ are smooth (in the sense that the derivatives are uniformly bounded in $\varepsilon$), then

$$\begin{aligned} &C_{j+1}^{\varepsilon} f_{j+1}^N(X_j; V_j; t_1) \\ &\quad = -\varepsilon^3 \sum_{k=1}^{j} \int dr \int dv_{j+1} F(r) \cdot \nabla_{v_k} f_{j+1}(X_j, x_k - \varepsilon r; V_j, v_{j+1}, t_1). \end{aligned} \tag{2.14}$$

Assuming now, quite reasonably, that

$$\int dr F(r) = 0, \tag{2.15}$$

we find that

$$C_{j+1}^{\varepsilon} f_{j+1}^N(X_j; V_j; t_1) = O(\varepsilon^4)$$

provided that $D_v^2 f_{j+1}^N$ is uniformly bounded. Since

$$\frac{N-j}{\sqrt{\varepsilon}} = O\big(\varepsilon^{7/2}\big)$$

we see that the second term in the right-hand side of (2.13) does not give any contribution in the limit.

Moreover

$$\begin{aligned} &\int_0^t S(t-t_1) T_j^{\varepsilon} f_j^N(t_1) dt_1 \\ &\quad = \sum_{i \neq k} \int_0^t dt_1 F\Big( \frac{(x_i - x_k) - (v_i - v_k)(t-t_1)}{\varepsilon} \Big) g(X_j, V_j; t_1) \end{aligned} \tag{2.16}$$

where $g$ is a smooth function.

Obviously the above time integral is $O(\varepsilon)$ so that also the last term in the right-hand side of (2.13) does not give any contribution in the limit. Then we are facing the alternative: either the limit is trivial or the time evolved distributions are not smooth. This is indeed a bed new because, if we believe that the limit is not trivial (actually we expect to get the Landau equation, according to the previous discussion) a rigorous proof of this fact seems problematic.

The difficulty in obtaining a-priori estimates induce us to exploit the full series expansion of the solution, namely

$$f_1^N(t) = \sum_{n\geq 0}\sum_{G_n} K(G_n)\int_0^t dt_1 \int_0^{t_1} dt_2 \ldots \int_0^{t_{n-1}} dt_n \cdot \left[S(t-t_1)O_1 S(t_1-t_2)\ldots O_n S(t_n)\right] f_m^0. \tag{2.17}$$

Here $O_j$ is either an operator $C$ or $T$ expressing a creation of a new particle or a recollision between two particles respectively. $G_n$ is a graph namely a sequence of indices

$$(r_1, l_1),\ (r_2, l_2), \ldots, (r_n, l_n)$$

where $(r_j, l_j)$, $r_j < l_j$ is the pair of indices of the particles involved in the interaction at time $t_j$. $m-1$ is the number of particles created in the process. It is convenient to represent the generic graph in the following way.

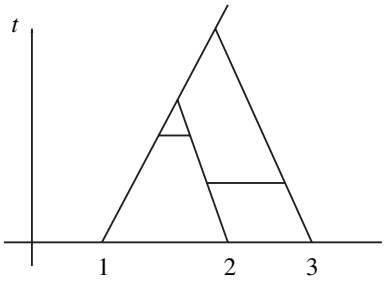

Figure 1

Here the legs of the graph denotes the particles and the nodes the creation of new particles (operators $C$). Recollisions (operators $T$) are represented by horizontal links. For instance the graph in the figure is

$$(1,2),\quad (1,3),\quad (1,3),\quad (2,3)$$

($m=3$), and the integrand in equation (2.17) in this case is

$$\left[S(t-t_1)C_{1,2}S(t_1-t_2)C_{1,3}S(t_2-t_3)T_{1,3}S(t_3-t_4)T_{2,3}S(t_4)\right] f_3^0. \tag{2.18}$$

Note that the knowledge of the graph determines completely the sequence of operators in the right-hand side of (2.17). Finally the factor $K(G_n)$ takes into account

the divergences:

$$K(G_n) = O\left(\left(\frac{1}{\sqrt{\varepsilon}}\right)^n \varepsilon^{-3(m-1)}\right). \tag{2.19}$$

We are not able to analyze the asymptotic behaviour of each term of the expansion (2.17) however we can compute the limit for $\varepsilon \to 0$ of the few terms up to the second order (in time). We have:

$$\begin{aligned} &g^N(x_1, v_1; t) \\ &\quad = f^0(x_1 - v_1 t, v_1) + \frac{N-1}{\sqrt{\varepsilon}} \int_0^t S(t-t_1) C^{\varepsilon}_{1,2} S(t_1) f_2^0 dt_1 \\ &\qquad + \frac{(N-1)}{\varepsilon} \frac{(N-2)}{\varepsilon} \sum_{j=1,2} \int_0^t \int_0^{t_1} dt_2 S(t-t_1) C^{\varepsilon}_{1,2} S(t_1 - t_2) C^{\varepsilon}_{j,3} S(t_2) f_3^0 \\ &\qquad + \frac{N-1}{\varepsilon} \int_0^t dt_1 \int_0^{t_1} dt_2 S(t-t_1) C^{\varepsilon}_{1,2} S(t_1 - t_2) T^{\varepsilon}_{1,2} S(t_2) f_2^0. \end{aligned} \tag{2.20}$$

Here the right-hand side of (2.20) defines $g^N$.

The second and third term in (2.20) corresponding to the graphs in Figure 2 are indeed vanishing as follows by the use of the previous arguments. The most interesting term is the last one (collision–recollision) in Figure 3.

Figure 2

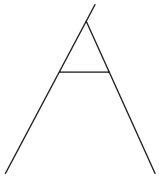

Figure 3

To handle this term we denote by $w = v_1 - v_2$ the relative velocity and note that, for

a given function $u$,

$$\begin{aligned} &S(t_1-t_2)T^{\varepsilon}_{1,2}u(x_1,x_2;v_1,v_2)\\ &\quad=-F\Big(\frac{(x_1-x_2)-w(t_1-t_2)}{\varepsilon}\Big)\\ &\qquad\cdot[(\nabla_{v_1}-\nabla_{v_2})u](x_1-v_1(t_1-t_2),x_2-v_2(t_1-t_2);v_1,v_2) \qquad (2.21)\\ &\quad=-F\Big(\frac{(x_1-x_2)-w(t-t_1)}{\varepsilon}\Big)\\ &\qquad\cdot(\nabla_{v_1}-\nabla_{v_2}+(t_1-t_2)(\nabla_{x_1}-\nabla_{x_2}))S(t_1-t_2)u(x_1,x_2;v_1,v_2) \end{aligned}$$

Therefore the last term in the right-hand side of (2.21) is

$$\begin{aligned} &\frac{N-1}{\varepsilon}\int_0^t dt_1 S(t-t_1)\int_0^{t_1}dt_2\int dx_2\int dv_2\\ &\quad\cdot F\Big(\frac{x_1-x_2}{\varepsilon}\Big)\cdot\nabla_{v_1}F\Big(\frac{(x_1-x_2)-w(t_1-t_2)}{\varepsilon}\Big) \qquad (2.22)\\ &\qquad\cdot(\nabla_{v_1}-\nabla_{v_2}+(t_1-t_2)(\nabla_{x_1}-\nabla_{x_2}))S(t_1)f_2^0(x_1,x_2;v_1,v_2). \end{aligned}$$

Setting now $r=\frac{x_1-x_2}{\varepsilon}$ and $s=\frac{t_1-t_2}{\varepsilon}$ then

$$\begin{aligned} &g^N(x_1,v_1)\\ &\quad=(N-1)\varepsilon^3\int_0^t dt_1\int_0^{\frac{t_1}{\varepsilon}}ds\int dr\int dv_2\ F(r)\cdot\nabla_{v_1}\cdot F(r-ws) \qquad (2.23)\\ &\qquad\cdot(\nabla_{v_1}-\nabla_{v_2}+\varepsilon s(\nabla_{x_1}-\nabla_{x_2}))S(t_1-\varepsilon s)f_2^0(x_1,x_2;v_1,v_2)+O(\sqrt{\varepsilon}). \end{aligned}$$

The formal limit is of (2.20) is

$$g(t)=S(t)f_0+\int_0^t dt_1 S(t-t_1)\nabla_{v_1}a(v_1-v_2)\ (\nabla_{v_1}-\nabla_{v_2})\ S(t_1)f_2^0, \qquad (2.24)$$

where (using $F(r)=-F(-r)$) the matrix $a$ is given by

$$\begin{aligned} a(w)&=\int dr\int_0^{+\infty}ds\ F(r)\otimes F(r-ws)\\ &=\frac{1}{2}\int dr\int_{-\infty}^{+\infty}ds\ F(r)\otimes F(r-ws)\\ &=\frac{1}{2}\left(\frac{1}{2\pi}\right)^3\int_{-\infty}^{+\infty}ds\int dk k\otimes k\ \hat{\phi}(k)^2e^{i(w\cdot k)s}\\ &=\left(\frac{1}{8\pi}\right)^2\int dk k\otimes k\ \hat{\phi}(k)^2\delta(w\cdot k). \end{aligned} \qquad (2.25)$$

Here the interaction potential $\phi$ has been assumed spherically symmetric. Therefore the matrix $a$ has the same form (1.26) with $B$ given by

$$B=\left(\frac{1}{8\pi}\right)^2\int_0^{+\infty}drr^3\hat{\phi}(r)^2. \qquad (2.26)$$

Consider now the Landau equation

$$(\partial_t + v \cdot \nabla_x) f = Q_L(f, f) \tag{2.27}$$

with the collision operator $Q_L$ given by (1.22) and the matrix $a$ given by

$$a_{i,j}(V) = \frac{B}{|V|}(\delta_{i,j} - \hat{V}_i \hat{V}_j), \tag{2.28}$$

$B$ being defined by (2.26). We obtain the following (infinite) hierarchy of equations

$$(\partial_t + V_j \cdot \nabla_{X_j}) f_j = C_{j+1} f_{j+1} \tag{2.29}$$

for the quantities

$$f_j(t) = f(t)^{\otimes j}, \tag{2.30}$$

where $f(t)$ solves equation (2.27). Accordingly $C_{j+1} = \sum_k C_{k,j+1}$, where

$$C_{k,j+1} f_{j+1}(x_1, \ldots, x_j; v_1, \ldots, v_j) = \prod_{r \neq k} f(x_r.v_r) Q_L(f, f)(x_k, v_k). \tag{2.31}$$

Therefore $f$ has the following series expansion representation

$$\begin{aligned} f(t) = \sum_{n \geq 0} \int_0^t dt_1 \int_0^{t_1} dt_2 \ldots \int_0^{t_{n-1}} dt_n \\ \cdot \left[ S(t - t_1) C_2 S(t_1 - t_2) C_3 \ldots C_n S(t_n) \right] f_{n+1}^0. \end{aligned} \tag{2.32}$$

As matter of fact we showed the formal convergence of $g^N$ to the first two terms of the expansion (2.32), namely we have an agreement between the particle system (2.17) and the solution to the Landau equation (2.32) at least up to the first order in time (or second order in the potential). Although the above arguments can be made rigorous under suitable assumption on the initial condition $f_0$ and the potential $\phi$, it seems difficult to show the convergence of the whole series. On the other hand it is clear that the graphs which should contribute in the limit are those formed by a collision–recollision sequence like:

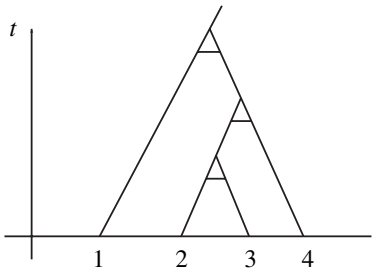

Figure 4

For those terms it is probably possible to show the convergence. For instance the case in the figure has the asymptotics

$$\int_0^t dt_1 \int_0^{t_1} dt_2 \int_0^{t_2} dt_3 \big[S(t-t_1)C_{1,2}S(t_1-t_2)C_{2,3}S(t_2-t_3)C_{3,4}S(t_3)\big] f_4^0. \quad (2.33)$$

However the proof that all other graphs are vanishing in the limit is not easy. Even more difficult is a uniform control of the series expansion (2.17), even for short times. As we shall see in the next section, something more can be obtained for quantum systems under the same scaling limit. Note finally that the diffusion coefficient found here given by equation (2.26), is different from that obtained in the grazing collision limit (see (1.25)). Indeed the transition kernel $w$ appearing in equation (1.18) is in general different from $\hat{\phi}^2$. Actually to recover the Landau equation by a low-density limit (to get the Boltzmann equation) and then selecting the grazing collision part, is not equivalent to the direct, and more physical, weak-coupling limit.

## 3. Weak-coupling limit for quantum systems

We consider now the quantum analog of the system considered in Section 2, namely $N$ identical quantum particles with unitary mass in $\mathbb{R}^3$.

The interaction between particles is still a two-body potential $\phi$ so that the total potential energy is taken as

$$U(x_1, \dots, x_N) = \sum_{i<j} \phi(x_i - x_j). \quad (3.1)$$

The associated Schrödinger equation reads

$$i\partial_t \Psi(X_N, t) = -\frac{1}{2}\Delta_N \Psi(X_N, t) + U(X_N)\Psi(X_N, t), \quad (3.2)$$

where $\Delta_N = \sum_{i=1}^N \Delta_i$, $\Delta_i$ is the Laplacian with respect to the $x_i$ variables, $X_N = x_1, \dots, x_N$ and $\hbar$ is normalized to unity.

As for the classical system considered in Section 2 we rescale the equation and the potential by

$$x \to \varepsilon x, \quad t \to \varepsilon t, \quad \phi \to \sqrt{\varepsilon}\phi. \quad (3.3)$$

The resulting equation is,

$$i\varepsilon\partial_t \Psi^\varepsilon(X_N, t) = -\frac{\varepsilon^2}{2}\Delta_N \Psi^\varepsilon(X_N, t) + U_\varepsilon(X_N)\, \Psi^\varepsilon(X_N, t), \quad (3.4)$$

where

$$U_\varepsilon(x_1, \dots, x_N) = \sqrt{\varepsilon} \sum_{i<j} \phi\Big(\frac{x_i - x_j}{\varepsilon}\Big). \quad (3.5)$$

We want to analyze the limit $\varepsilon \to 0$ in the above equations, when $N = \varepsilon^{-3}$.

Note that this limit looks, at a first sight, similar to a semiclassical (or high frequence) limit. It is not so: indeed the potential varies on the same scale of the typical oscillations of the wave functions so that the scattering process is a genuine quantum process. Obviously, due to the oscillations, we do not expect that the wave function does converge to something in the limit. The right quantity to look at was introduced by Wigner in 1922 [44] to deal with kinetic problems. It is called the Wigner transform (of $\Psi^\varepsilon$) and is defined as

$$W^N(X_N, V_N) = \left(\frac{1}{2\pi}\right)^{3N} \int dY_N \; e^{iY_N \cdot V_N} \overline{\Psi}^\varepsilon \left(X_N + \frac{\varepsilon}{2} Y_N\right) \Psi^\varepsilon \left(X_N - \frac{\varepsilon}{2} Y_N\right). \quad (3.6)$$

As it is standard, $W^N$ satisfies a transport-like equation, completely equivalent to the Schrödinger equation:

$$(\partial_t + V_N \cdot \nabla_N) W^N(X_N, V_N) = \frac{1}{\sqrt{\varepsilon}} \big(T_N^\varepsilon W^N\big)(X_N, V_N). \quad (3.7)$$

The operator $T_N^\varepsilon$ on the right-hand-side of (3.7) plays the same role of the classical operator denoted with the same symbol in Section 2. It is

$$(T_N^\varepsilon W^N)(X_N, V_N) = \sum_{0<k<\ell\leq N} (T_{k,\ell}^\varepsilon W^N)(X_N, V_N), \quad (3.8)$$

where each $T_{k,\ell}^\varepsilon$ describes the interaction of particle $k$ with particle $\ell$:

$$\begin{aligned}(T_{k,\ell}^\varepsilon W^N)&(X_N, V_N) \\ &= \frac{1}{i} \left(\frac{1}{2\pi}\right)^{3N} \int dY_N \, dV'_N \; \mathrm{e}^{iY_N \cdot (V_N - V'_N)} \\ &\quad \cdot \left[\phi\left(\frac{x_k - x_\ell}{\varepsilon} - \frac{y_k - y_\ell}{2})\right) - \phi\left(\frac{x_k - x_\ell}{\varepsilon} + \frac{y_k - y_\ell}{2}\right)\right] W^N(X_N, V'_N).\end{aligned} \quad (3.9)$$

Equivalently, we may write

$$\begin{aligned}(T_{k,\ell}^\varepsilon W^N)&(X_N, V_N) \\ &= -i \sum_{\sigma=\pm 1} \sigma \int \frac{dh}{(2\pi)^3} \; \hat{\phi}(h) \; \mathrm{e}^{i\frac{h}{\varepsilon}(x_k - x_\ell)} \\ &\quad \cdot W^N\big(x_1, \ldots, x_N; v_1, \ldots, v_k - \sigma\tfrac{h}{2}, \ldots, v_\ell + \sigma\tfrac{h}{2}, \ldots, v_N\big).\end{aligned} \quad (3.10)$$

Note that $T_{k,\ell}^\varepsilon$ is a pseudodifferential operator which formally converge, at fixed $\varepsilon$, for $\hbar \to 0$ (here $\hbar = 1$) to its classical analog. Note also that in (3.10), "collisions" may take place between *distant* particles ($x_k \neq x_\ell$). However, such distant collisions are penalized by the highly oscillatory factor $\exp(ih(x_k - x_\ell)/\varepsilon)$. These oscillations

turn out to play a crucial role throughout the analysis, and they explain why collisions tend to happen when $x_k = x_\ell$ in the limit $\varepsilon \to 0$.

The formalism we have introduced is similar to the one of the classical case so that we proceed as before by transforming equation (3.7) into a hierarchy of equations. We introduce the partial traces of the Wigner transform $W^N$, denoted by $f_j^N$. They are defined through the following formula, valid for $j = 1, \dots, N-1$:

$$f_j^N(X_j, V_j) = \int dx_{j+1} \dots \int dx_N \int dv_{j+1} \dots \int dv_N \cdot W^N(X_j, x_{j+1}, \dots, x_N; V_j, v_{j+1}, \dots, v_N). \tag{3.11}$$

Obviously, we set $f_N^N = W^N$. The function $f_j^N$ is the kinetic object that describes the state of the $j$ particles subsystem at time $t$.

Due to the fact that the particles are identical, the wave function $\Psi$, as well as $W^N$ and $f_j^N$, are assumed to be symmetric in the exchange of particle, a property that is preserved in time.

Proceeding then as in the derivation of the BBKGY hierarchy for classical systems, we readily transform equation (3.7) into the following hierarchy:

$$\Big(\partial_t + \sum_{k=1}^{j} v_k \cdot \nabla_k\Big) f_j^N(X_j, V_j) = \frac{1}{\sqrt{\varepsilon}} T_j^\varepsilon f_j^N + \frac{N-j}{\sqrt{\varepsilon}} C_{j+1}^\varepsilon f_{j+1}^N, \tag{3.12}$$

where

$$C_{j+1}^\varepsilon = \sum_{k=1}^{j} C_{k,j+1}^\varepsilon, \tag{3.13}$$

and $C_{k,j+1}^\varepsilon$ is defined by

$$\begin{aligned} &C_{k,j+1}^\varepsilon f_{j+1}^N(X_j; V_j) \\ &\quad = -i \sum_{\sigma=\pm 1} \sigma \int \frac{dh}{(2\pi)^3} \int dx_{j+1} \int dv_{j+1}\, \hat{\phi}(h)\, e^{i\frac{h}{\varepsilon}(x_k - x_{j+1})} \\ &\qquad \cdot f_{j+1}^N\big(x_1, x_2, \dots, x_{j+1}; v_1, \dots, v_k - \sigma\tfrac{h}{2}, \dots, v_{j+1} + \sigma\tfrac{h}{2}\big). \end{aligned} \tag{3.14}$$

As before the initial value $\{f_j^0\}_{j=1}^N$ is assumed completely factorized: for all $j = 1, \dots, N$, we suppose

$$f_j^0 = f_0^{\otimes j}, \tag{3.15}$$

where $f_0$ is a one-particle Wigner function, and $f^0$ is assumed to be a probability distribution.

In the limit $\varepsilon \to 0$, we expect that the $j$-particle distribution function $f_j^N(t)$, that solves the hierarchy (3.12) with initial data (3.15), tends to be factorized for all times: $f_j^N(t) \sim f(t)^{\otimes j}$ (propagation of chaos).

As for the classical case, if $f_{j+1}$ is smooth, then

$$\begin{aligned} &C^{\varepsilon}_{k,j+1} f^N_{j+1}(X_j; V_j) \\ &\quad = -i\varepsilon^3 \sum_{\sigma=\pm 1} \sigma \int \frac{dh}{(2\pi)^3} \hat{\phi}(h) \int dr \int dv_{j+1}\, e^{ih\cdot r} \\ &\qquad \cdot f^N_{j+1}\big(X_j, x_k - \varepsilon r;\ v_1, \dots, v_k - \sigma\tfrac{h}{2}, \dots, v_{j+1} + \sigma\tfrac{h}{2}\big) = O(\varepsilon^4). \end{aligned} \tag{3.16}$$

Indeed, setting $\varepsilon = 0$ in the integrand, the integration over $r$ produces $\delta(h)$. As a consequence the integrand is independent of $\sigma$ and the sum vanishes. Therefore the integral is $O(\varepsilon)$. Also

$$\begin{aligned} &\frac{1}{\sqrt{\varepsilon}} \int_0^t dt_1 S(t-t_1) T_{r.k} f^N_j(t_1) \\ &\quad = -i \sum_{\sigma=\pm 1} \sigma \int_0^t dt_1 \frac{dh}{(2\pi)^3} \hat{\phi}(h) \\ &\qquad \cdot e^{i\frac{h}{\varepsilon}\cdot(x_r - x_k) - (v_r - v_k)(t-t_1)} f^N_j(X_j - V_j(t-t_1); V_j; t_1) \end{aligned} \tag{3.17}$$

is weakly vanishing, by a stationary phase argument (see [4]). Therefore we are in the same situation as for the classical case for which we are led to analyze the asymptotics of $g^N$ (see (2.20)) which means to study the limit of the collision–recollision term:

$$\frac{N-1}{\varepsilon} \int_0^t dt_1 \int_0^{t_1} d\tau_1\ S(t-t_1) C_{1,2} S(t_1 - \tau_1) T_{1.2} S(\tau_1) f^0_2. \tag{3.18}$$

Explicitly it looks as follows:

$$\begin{aligned} &-\frac{N-1}{\varepsilon} \sum_{\sigma,\sigma'=\pm 1} \sigma\sigma' \int_0^t dt_1 \int_0^{t_1} d\tau_1 \int dx_2 \int dv_2 \int \frac{dh}{(2\pi)^3} \int \frac{dk}{(2\pi)^3} \\ &\quad \cdot \hat{\phi}(h)\ \hat{\phi}(k)\ \mathrm{e}^{i\frac{h}{\varepsilon}\cdot(x_1 - x_2 - v_1(t-t_1))} \mathrm{e}^{i\frac{k}{\varepsilon}\cdot(x_1 - x_2 - v_1(t-t_1) - (v_1 - v_2 - \sigma h)(t_1 - \tau_1))} \\ &\qquad \cdot f^0_2\left(x_1 - v_1 t + \sigma\tfrac{h}{2} t_1 + \sigma'\tfrac{k}{2}\tau_1, x_2 - v_2 t_1 - \sigma\tfrac{h}{2} t_1 - \sigma'\tfrac{k}{2}\tau_1;\right. \\ &\qquad\quad \left. \cdot\ v_1 - \sigma\tfrac{h}{2} - \sigma'\tfrac{k}{2}, v_2 + \sigma\tfrac{h}{2} + \sigma'\tfrac{k}{2}\right). \end{aligned} \tag{3.19}$$

By the change of variables

$$t_1 - \tau_1 = \varepsilon s_1 \ (\text{i.e. } \tau_1 = t_1 - \varepsilon s_1), \quad \xi = (h+k)/\varepsilon, \tag{3.20}$$

we have

$$\begin{aligned} (3.19) = -(N-1)\,\varepsilon^3 &\sum_{\sigma,\sigma'=\pm 1} \sigma\sigma' \int_0^t dt_1 \int_0^{t_1/\varepsilon} ds_1 \int dx_2 \int dv_2 \int \frac{d\xi}{(2\pi)^3} \int \frac{dk}{(2\pi)^3} \\ &\cdot \hat{\phi}(-k + \varepsilon\xi_1)\ \hat{\phi}(k)\ \mathrm{e}^{i\xi\cdot\left(x_1 - x_2 - v_1(t-t_1)\right)} \mathrm{e}^{-is_1 k\cdot(v_1 - v_2 - \sigma(-k+\varepsilon\xi))} f^0_2(\dots), \end{aligned}$$

In the limit $\varepsilon \to 0$, the above formula gives the asymptotics

$$(3.19)\quad \underset{\varepsilon\to 0}{\sim} -\sum_{\sigma,\sigma'=\pm 1} \sigma\sigma' \int_0^t dt_1 \int dv_2 \int \frac{dk}{(2\pi)^3} \tag{3.21}$$
$$|\hat{\phi}(k)|^2 \left(\int_0^{+\infty} e^{-is_1 k\cdot(v_1-v_2+\sigma k)}\, ds_1\right) f_2^0\left(x_1 - v_1 t - (\sigma-\sigma')\tfrac{k}{2}t_1,\right.$$
$$\left. x_1 - v_1(t-t_1) - v_2 t_1 + (\sigma-\sigma')\tfrac{k}{2}t_1;\, v_1 + (\sigma-\sigma')\tfrac{k}{2},\, v_2 - (\sigma-\sigma')\tfrac{k}{2}\right).$$

In [4], we completely justify formula (3.21) and its forthcoming consequences.

Now, we turn to identifying the limiting value obtained in (3.21). To do so, we observe that symmetry arguments allow us to replace the integral in $s$ by its real part:

$$\mathrm{Re}\int_0^{\infty} e^{-is_1 k\cdot(v_1-v_2+\sigma k)}\, ds_1 = \pi\delta(k\cdot(v_1-v_2+\sigma k)). \tag{3.22}$$

Using formula (3.22) we realize that the contribution $\sigma = -\sigma'$ in (3.21) gives rise to the gain term:

$$\int_0^t dt_1 \int dv_2 \int d\omega\, B(\omega, v_1-v_2) \cdot f_2^0(x_1 - v_1(t-t_1) - v_1' t_1, x_2 - v_2(t-t_1) - v_2' t_1;\, v_1', v_2'), \tag{3.23}$$

where

$$B(\omega, v) = \frac{1}{8\pi^2}|\omega\cdot v|\,|\hat{\phi}(\omega\,(\omega\cdot v))|^2. \tag{3.24}$$

Similarly, the term $\sigma = \sigma'$ in (2.2) yields the loss term:

$$\int_0^t dt_1 \int dv_2 \int d\omega\, B(\omega, v_1-v_2) f_2^0(x_1 - v_1 t, x_2 - v_2(t-t);\, v_1, v_2). \tag{3.25}$$

By the same arguments used in the previous section we can conclude that the full series expansion (2.17) (of course for the present quantum case) agrees, up to the second order in the potential, with

$$S(t)f_0 + \int_0^t dt_1 S(t-t_1) Q(S(t_1)f_0, S(t_1)f_0) \tag{3.26}$$

where

$$Q(f,f) = \int dv_1 \int d\omega\, B(\omega, v-v_1)[f'f_1' - ff_1] \tag{3.27}$$
$$= \int dv_1 \int dh |\hat{\phi}(h)|^2 \delta((h\cdot(v-v_1+h))[f(v+h)f(v_1-h) - f(v)f(v_1)].$$

In other words the kinetic equation which comes out is the Boltzmann equation with cross-section $B$.

We note once more that the $\delta$ function in equation (3.27) expresses the energy conservation, while the momentum conservation is automatically satisfied.

Note that the cross-section $B$ is the only quantum factor in the purely classical expression (3.27). It retains the quantum features of the elementary "collisions".

An important comment is in order. Why is the kinetic equation for quantum systems of Boltzmann type in contrast with the classical case where we got a diffusion? The answer is related to the asymptotics of a single scattering (see [35], [36] and [8]). For quantum systems the probability of a zero angle scattering is finite (that is a sort of tunnel effect), while for a classical particle we have surely a small deviation from the free motion. Therefore a quantum particle, in this asymptotic regime, is going to perform a jump process (in velocity) rather than a diffusion.

From a mathematical view point we observe that [4] proves more than agreement up to second order. We indeed consider the subseries (of the full series expansion expressing $f_j^N(t)$) formed by *all* the collision–recollision terms. In other words, we consider the subseries of $f_j^N(t)$ given by

$$\sum_{n\geq 1} \sum_{\alpha_1,\ldots,\alpha_n,\beta_1,\ldots,\beta_n} \varepsilon^{-4n} \int_0^t dt_1 \int_0^{t_1} d\tau_1 \; S(t-t_1) C^{\varepsilon}_{\alpha_1,\beta_1} S(t_1-\tau_1) T^{\varepsilon}_{\alpha_1,\beta_1} \cdots \int_0^{\tau_{n-1}} dt_n \int_0^{t_n} d\tau_n \; S(\tau_{n-1}-t_n) C^{\varepsilon}_{\alpha_n,\beta_n} S(t_n-\tau_n) T^{\varepsilon}_{\alpha_n,\beta_n} S(\tau_n) f^0_{j+n+1}. \tag{3.28}$$

Here the sum runs over all possible choices of the particles number $\alpha$'s and $\beta$'s, namely we sum over the subset of graphs of the form in Figure 4. We establish in [4] that the subseries (3.28) is indeed absolutely convergent, for short times, uniformly in $\varepsilon$. Moreover, we prove that it approaches the corresponding complete series expansion obtained by solving iteratively the Boltzmann equation with collision operator given by equation (3.27) extending and making rigorous the above argument.

However, this does not completely finishes the proof yet: the true series expansion of $f_j^N(t)$ contains many more terms than those we consider in (3.28) and we are not able to show uniform bound on the full series. Thus a mathematical justification of the quantum Boltzmann equation is a still an open and difficult problem. More recently we proved in [7], although under severe assumptions on the potential, that all other terms than those considered in the subseries (3.28) are vanishing in the limit, but this is, unfortunately, not yet conclusive.

## 4. The weak coupling limit in the Bose–Einstein or the Fermi–Dirac statistics

From a physical viewpoint it is certainly more realistic to consider particles obeying the Fermi–Dirac or Bose–Einstein statistics, than considering the Maxwell–Boltzmann situation. In this case, the starting point still is the rescaled Schrödinger equation (3.4),

or the equivalent hierarchy (3.12). The only new point is that we cannot take a totally uncorrelated initial datum as in (3.15). Indeed, the Fermi–Dirac or Bose–Einstein statistics yield correlations even at time zero. In this perspective, the most uncorrelated states one can introduce, and that do not violate the Fermi–Dirac or Bose–Einstein statistics, are the so-called quasi-free states. They have, in terms of the Wigner formalism, the following form:

$$f_j(x_1, v_1, \dots, x_j, v_j) = \sum_{\pi \in \mathcal{P}_j} \theta^{s(\pi)} \, f_j^{\pi}(x_1, v_1, \dots, x_j, v_j), \tag{4.1}$$

where each $f_j^{\pi}$ has the value

$$f_j^{\pi}(x_1, v_1, \dots, x_j, v_j) = \int dy_1 \dots dy_j \int dw_1 \dots dw_j \; e^{i(y_1 \cdot v_1 + \dots + y_j \cdot v_j)} \tag{4.2}$$

$$\prod_{k=1}^{j} e^{-\frac{i}{\varepsilon} w_k \cdot (x_k - x_{\pi(k)})} \; e^{-\frac{i}{2} w_k \cdot (y_k + y_{\pi(k)})} \; f\Big( \frac{x_k + x_{\pi(k)}}{2} + \varepsilon \frac{y_k - y_{\pi(k)}}{4}, w_k \Big)$$

and $f$ is a given one-particle Wigner function. Here $\mathcal{P}_j$ denotes the group of all the permutations of $j$ objects and $\pi$ its generic element.

Note that the Maxwell–Boltzmann case treated so far is recovered by the contribution due the permutation $\pi =$ identity.

Note also that quasi-free states converge weakly to the completely factorized states as $\varepsilon \to 0$, that is a physically obvious fact because the quantum statistics become irrelevant in the semiclassical limit. However the dynamics take place on the scale $\varepsilon$ so that the effects of the statistics are present in the limit. Indeed it is expected that the one-particle distribution function $f_1^N(t)$ converges to the solution of the following cubic Boltzmann equation:

$$(\partial_t + v \cdot \nabla_x) \, f(t, x, v) = Q_{\mathrm{w},\theta}(f, f, f)(t, x, v), \tag{4.3}$$

$$\begin{aligned} Q_\theta(f, f, f)(t, x, v) = \int dv_1 \, d\omega \; B_\theta(\omega, v - v_1) \\ \cdot \big[ f(x, v') f(x, v_1')(1 + 8\pi^3 \theta f(x, v) \, f(x, v_1)) \\ - f(x, v) f(x, v_1)(1 + 8\pi^3 \theta f(x, v') f(x, v_1')) \big]. \end{aligned} \tag{4.4}$$

Here $\theta = +1$ or $\theta = -1$, for the Bose–Einstein or the Fermi–Dirac statistics respectively. Finally, $B_\theta$ is the symmetrized or antisymmetrized cross-section derived from $B$ (see (3.24)) in a natural way.

As we see, the modification of the statistics transforms the quadratic Boltzmann equation of the Maxwell–Boltzmann case, into a cubic one (fourth order terms cancel). Also, the statistics affects the form of the cross-section and $B$ has to be (anti)symmetrized into $B_\theta$. The collision operator (4.4) has been introduced by Uehling and Uhlembeck in 1933 on the basis of purely phenomenological considerations [41].

Plugging in the hierarchy (3.12) an initial datum satisfying (4.1), we can follow the same procedure as for the Maxwell–Boltzmann statistics: we write the full perturbative series expansion expressing $f_j^N(t)$ in terms of the initial datum and try to analyse its asymptotic behaviour.

As we did before, we first restrict our attention to those terms of degree less than two in the potential.

The analysis up to second order is performed in [5]. We actually recover here equation (4.3), (4.4) with the suitable $B_\theta$. Now the number of terms to control is much larger due to the sum over all permutations that enters the definition (4.1) of the initial state. Also, the asymptotics is much more delicate. In particular, we stress the fact that the initial datum brings its own highly oscillatory factors in the process, contrary to the Maxwell–Boltzmann case where the initial datum is uniformly smooth, and where the oscillatory factors simply come from the collision operators $T$ and $C$. In [5] we consider the second order graphs

Figure 5

which, because of the permutation of initial state, yields various terms: two of them are bilinear in the initial condition $f_0$, and twelve are trilinear in $f_0$. Some of these terms vanish in the limit due to a non-stationary phase argument. Others give rise to truly diverging contributions (negative powers of $\varepsilon$). However, when grouping the terms in the appropriate way, those terms are seen to cancel each other. Last, some terms give the collision operator (4.4). The computation is heavy and hence we address the reader to [5] for the details.

This ends up the analysis of terms up to second order in the potential.

Obviously, as for the Maxwell–Boltzmann case, we could try to re-sum the dominant terms. This would lead to analyzing a true subseries of the complete series expansion expressing $f_j^N(t)$. We do not see any conceptual difficulty, however, this resummation procedure has not been explicitly done in [5].

We mention that a similar analysis, using commutator expansions in the framework of the second quantization formalism, has been performed in [27] (following [26]) in the case of the van Hove limit for lattice systems (that is the same as the weak-coupling limit, yet without rescaling the distances). For more recent formal results in this direction, but in the context of the weak-coupling limit, we also quote [22].

We finally observe that the initial value problem for equation (4.3) is somehow

trivial for Fermions. Indeed we have the a-priori bounds $f \leq \frac{1}{(8\pi)^3}$ making everything easy. For Bosons the situation is much more involved even for the spatially homogeneous case. The statistics favours large values of $f$ and it is not clear whether the equation can explain dynamical condensation. See, for the mathematical side, references [33], [34].

Summarizing, the main scope of this lecture is to show why in the weak-coupling limit, the one-particle distribution function is expected to converge to a solution of Landau equation or Boltzmann equation, for classical and quantum system respectively. From a rigorous view point very little is known.

## 5. Concluding remarks

Other scaling limits yielding different kinetic equations are of course possible. We address the reader to the excellent reference [38] where the various scales and the corresponding kinetic equations are discussed. Here we analyzed in some detail the weak-coupling, however, as mentioned in Section 1, the low-density limit (or the Boltzmann-Grad limit) yields the usual Boltzmann equation for classical systems and this result has been proved for short times. It is natural to investigate what happens, in the same scaling limit, to a quantum system. Here the scaling is

$$t \to \varepsilon t, \quad x \to \varepsilon x, \quad \phi \to \phi, \quad N = \varepsilon^{-2}. \tag{5.1}$$

In other words, the density of obstacles is $\varepsilon$, which is a rarefaction regime, but the potential is unscaled and keeps an $O(1)$ amplitude. Now due to the fact that the density is vanishing, the particles are too rare to make the statistical correlations effective. As a consequence, we expect that the Maxwell–Boltzmann, Bose–Einstein, and Fermi–Dirac situations, all give rise to the same Boltzmann equation along the low-density limit.

As a matter of fact, the expected Boltzmann equation still is a quadratic Boltzmann equation in that case, namely

$$(\partial_t + v \cdot \nabla_x) f(t, x, v) = Q_\ell(f, f)(t, x, v), \tag{5.2}$$

$$Q_\ell(f, f)(t, x, v) \tag{5.3}$$
$$= \int dv_1 \, d\omega \, B_\ell(\omega, v - v_1) \left[ f(t, x, v') f(t, x, v_1') - f(t, x, v) f(t, x, v_1) \right].$$

Here, the index "$\ell$" refers to "low-density".

The factor $B_\ell(\omega, v - v_1)$ is the cross-section. In the low-density limit, collisions take place at a large energy (contrary to the weak-coupling situation), and at a distance of order $\varepsilon$. For this reason, the cross section $B_\ell$ is computed at large energy, and via the quantum rules. In other words, it agrees with the *full* Born series expansion of

quantum scattering, namely

$$B_\ell(\omega, v) = \frac{1}{8\pi^2}|\omega \cdot v|\,|\hat{\phi}(\omega\,(\omega \cdot v))|^2 + \sum_{n\geq 3} B_\ell^{(n)}(\omega, v), \tag{5.4}$$

where each $B_\ell^{(n)}(\omega, v)$ is an explicitly known function, which is $n$-linear in $\phi$ (see [37]). Note that the convergence of the Born series expansion (4.8) is well-known for potentials satisfying a smallness assumption. As it is seen on these formulae, the only difference between the low-density and the weak-coupling regimes (at least for Maxwell–Boltzmann particles) lies in the form of the cross-section. Note also that

$$B_\ell(\omega, v) = B(\omega, v) + O([\phi]^3), \tag{5.5}$$

which reflects the fact that the weak-coupling regime involves only low-energy phenomena.

The analysis of the partial series of the dominant terms (uniform bounds and convergence as for the weak-coupling limit) has been performed in [6] (on the basis of [11] and [12]).

Related problem connected with the ones discussed here are the homogeneization of the distribution function of a single particle in a random distribution of obstacles $\boldsymbol{c} = \{c_1, \ldots, c_N\}$. The basic equations are

$$\dot{x}(t) = v(t), \quad \dot{v}(t) = -\sum_j \nabla\phi(x(t) - c_j) \tag{5.6}$$

for a classical particle and, for a quantum particle

$$i\,\partial_t\psi = -\frac{1}{2}\Delta\psi + \sum_j \phi(x - c_j)\psi. \tag{5.7}$$

We are interested in the behavior of

$$f_\varepsilon(x, v; t) = \mathbb{E}[f_{\boldsymbol{c}}(x, v; t)] \tag{5.8}$$

where $f_{\boldsymbol{c}}(t)$ is the time evolved classical distribution function or the Wigner transform of $\psi$ according to equations (5.6) or (5.7) respectively, under the action of the obstalcle configuration $\boldsymbol{c}$. Finally $\mathbb{E}$ denotes the expectation with respect to the obstacle distribution. For the low-density scaling under a Poisson distribution of obstacles (this is the so called Lorentz model) we obtain, for classical systems, a linear Boltzmann equation (see [23], [39], [3], [17], [10]). It is also known that the system does not homogenize to a jump process given by a linear Boltzmann equation in case of a periodic distribution of obstacles [9]. For the weak-coupling limit we obtain, by a central-limit type of argument, a linear Landau equation as it is shown in [29] and [18].

As regards the corresponding weak-coupling quantum problem, the easiest case is when $\phi$ is a Gaussian process. The kinetic equation is still a linear Boltzmann

equation. The first result, holding for short times, has been obtained in [39] (see also [30]). More recently this result has been extended to arbitrary times [21]. The technique of [21] can been applied to deal with a Poisson distribution of obstacles. Obviously the cross section appearing in the Boltzmann equation is that computed in the Born approximation. Finally in [20] the low-density case has been successfully approached. The result is a linear Boltzmann equation with the full cross-section.

# Symmetry of entire solutions for a class of semilinear elliptic equations

Ovidiu Savin

**Abstract.** We discuss a conjecture of De Giorgi concerning the one dimensional symmetry of bounded, monotone in one direction, solutions of semilinear elliptic equations of the form $\Delta u = W'(u)$ in all $\mathbb{R}^n$.

**Mathematics Subject Classification (2000).** 35J70, 35B65.

**Keywords.** Phase transitions models, sliding method, minimal surfaces.

## 1. Introduction

In 1978 De Giorgi [13] made the following conjecture about bounded solutions of a certain semilinear equation:

**Conjecture** (De Giorgi). Let $u \in C^2(\mathbb{R}^n)$ be a solution of

$$\Delta u = u^3 - u, \tag{1}$$

such that

$$|u| \leq 1, \quad u_{x_n} > 0$$

in the whole $\mathbb{R}^n$. Is it true that all the level sets of $u$ are hyperplanes, at least if $n \leq 8$?

The problem originates in the theory of phase transitions and it is closely related to the theory of minimal surfaces. As we explain later, the conjecture is sometimes referred to as "the $\varepsilon$ version of the Bernstein problem for minimal graphs". This relation with the Bernstein problem is the reason why $n \leq 8$ appears in the conjecture.

De Giorgi's conjecture is often considered with the additional natural hypothesis

$$\lim_{x_n \to \pm\infty} u(x', x_n) = \pm 1. \tag{2}$$

Under the much stronger assumption that the limits in (2) are uniform in $x'$, the conjecture is known as the "Gibbons conjecture". This conjecture was first proved for $n \leq 3$ by Ghoussoub and Gui in [18] and then for all dimensions $n$ independently by Barlow, Bass and Gui [4], Berestycki, Hamel and Monneau [6] and Farina [16].

The first positive partial result on the De Giorgi conjecture was established in 1980 by Modica and Mortola [30]. They proved the conjecture in dimension $n = 2$

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

under the additional hypothesis that the level sets $\{u = s\}$ are equi-Lipschitz in the $x_2$ direction. Their proof used a Liouville-type theorem for elliptic equations in divergence form, due to Serrin, for the bounded ratio

$$\sigma := \frac{u_{x_1}}{u_{x_2}}.$$

In 1997 Ghoussoub and Gui [18] proved De Giorgi's conjecture for $n = 2$. They used a different Liouville-type theorem for $\sigma$ developed by Berestycki, Caffarelli and Nirenberg in [5] for the study of symmetry properties of positive solutions of semilinear elliptic equations in half spaces. This theorem does not require for $\sigma$ to be bounded, but rather a compatibility condition between the growth of $\sigma$ and the degeneracy of the coefficients of the equation.

Using similar techniques, Ambrosio and Cabre [2] extended these results up to dimension $n = 3$. Also, Ghoussoub and Gui showed in [19] that the conjecture is true for $n = 4$ or $n = 5$ for a special class of solutions that satisfy an anti-symmetry condition.

In 2003 I proved in [33] that the conjecture is true in dimension $n \leq 8$ under the additional hypothesis (2). The proof is nonvariational and uses the sliding method for a special family of radially symmetric functions.

If the level sets of $u$ are assumed to be Lipschitz in the $x_n$ direction, then it was shown by Barlow, Bass and Gui [4] and later in [33] that the solutions are planar in all dimensions.

It is not known whether or not the conjecture is true for all dimensions. Jerison and Monneau [22] showed that the existence of a symmetric minimizer for the energy associated with (1) in $\mathbb{R}^{n-1}$ implies the existence of a counter-example to the conjecture of the De Giorgi in $\mathbb{R}^n$. However, existence of such global minimizer has not been proved.

## 2. Phase transitions

Equations of type (1) arise in variational problems associated with the energy

$$J(u, \Omega) = \int_\Omega \frac{1}{2}|\nabla u|^2 + W(u)\, dx, \quad |u| \leq 1, \tag{3}$$

where $W \in C^2$ is a double well potential with minima at $\pm 1$,

$$W(\pm 1) = W'(\pm 1) = 0, \quad W > 0 \quad \text{on } (-1, 1),$$

$$W''(-1) > 0, \quad W''(1) > 0.$$

We say that $u$ is a local minimizer for $J$ in $\Omega$ if

$$J(u, \Omega) \leq J(u + \varphi, \Omega)$$

for any $\varphi \in C_0^\infty(\Omega)$. Local minimizers of (3) satisfy the Euler–Lagrange equation

$$\Delta u = W'(u). \tag{4}$$

Equation (1) is obtained for the particular choice of the potential

$$W(t) = \frac{1}{4}(1 - t^2)^2.$$

The behavior of minimizers at $\infty$ is given by the properties of blow down solutions

$$u_\varepsilon(x) = u\left(\frac{x}{\varepsilon}\right).$$

These rescalings are local minimizers for the $\varepsilon$ energy functional

$$J_\varepsilon(u_\varepsilon) = \int \frac{\varepsilon}{2}|\nabla u_\varepsilon|^2 + \frac{W(u_\varepsilon)}{\varepsilon}dx.$$

This is a typical energy modeling the phase separation phenomena within the van der Walls–Cahn–Hilliard theory [8]. In this context, $u_\varepsilon$ represents the density of a multi-phase fluid, where the zero points of $W$ correspond to stable fluid phases and the free energy $J_\varepsilon$ depends both on the density potential and the density gradient.

One expects that $u_\varepsilon$ has a transition region of $\mathcal{O}(\varepsilon)$ thickness which approaches a minimal surface as $\varepsilon \to 0$. The intuition behind this comes from the following calculation. By the coarea formula

$$J_\varepsilon(u_\varepsilon, \Omega) \geq \int_\Omega |\nabla u_\varepsilon|\sqrt{2W(u_\varepsilon)}dx = \int_{-1}^{1} \sqrt{2W(s)}\mathcal{H}^{n-1}(\{u_\varepsilon = s\} \cap \Omega)ds.$$

Heuristically, $J_\varepsilon(u_\varepsilon, \Omega)$ is minimized if, in the interior of $\Omega$, the level sets $\{u_\varepsilon = s\}$ are (almost) minimal and

$$|\nabla u_\varepsilon| = \frac{1}{\varepsilon}\sqrt{2W(u_\varepsilon)}. \tag{5}$$

This equation suggests that "the profile" of $u_\varepsilon$ behaves like

$$u_\varepsilon(x) \simeq g\left(\frac{d_{\{u=0\}}(x)}{\varepsilon}\right)$$

where $g$ is the solution of the ordinary differential equation

$$g' = \sqrt{2W(g)}, \quad g(0) = 0,$$

and $d_{\{u=0\}}$ represents the signed distance to the 0 level surface of $u$.

The asymptotic behavior of $u_\varepsilon$ was first studied by Modica and Mortola in [31] and Modica in [25] within the framework of $\Gamma$-convergence. Later, Modica [27], Sternberg [36] and many authors [3], [17], [24], [29], [32], [37] generalized these results for minimizers with volume constraint.

Modica proved in [25] that as $\varepsilon \to 0$, $u_\varepsilon$ has a subsequence

$$u_{\varepsilon_k} \to \chi_E - \chi_{E^c} \quad \text{in } L^1_{\text{loc}} \tag{6}$$

where $E$ is a set with minimal perimeter. Actually, the convergence in (6) is better, as it was shown by Caffarelli and Cordoba in [10]. They proved a uniform density estimate for the level sets of local minimizers $u_\varepsilon$ of $J_\varepsilon$ i.e, if $u_\varepsilon(0) = 0$, then

$$\frac{|\{u_\varepsilon > 0\} \cap B_\delta|}{|B_\delta|} \geq C \tag{7}$$

for $\varepsilon \leq \delta$, $C > 0$ universal. In particular, this implies that in (6) the level sets $\{u_{\varepsilon_k} = \lambda\}$ converge uniformly on compact sets to $\partial E$.

Next we recall some known facts about sets with minimal perimeter.

## 3. Minimal surfaces

The Plateau problem consist in finding a surface of least area (the minimal surface) among those bounded by a given curve. De Giorgi studied this problem by looking at hypersurfaces in $\mathbb{R}^n$ as boundaries of sets. Thus, for a measurable set $E$, he defined the perimeter of $E$ in a domain $\Omega \subset \mathbb{R}^n$ (or the area of $\partial E$ in $\Omega$) as the total variation of $\nabla \chi_E$ in $\Omega$, i.e.

$$P_\Omega(E) = \int_\Omega |\nabla \chi_E| := \sup \left| \int_E \operatorname{div} g \, dx \right|,$$

where the supremum is taken over all vector fields $g \in C_0^1(\Omega)$ with $\|g\|_{L^\infty} \leq 1$.

It is not difficult to show existence to the Plateau problem in this context of minimal boundaries. It is much more difficult to prove that the sets so obtained are actually regular except possibly for a closed singular set.

The main idea to prove "almost everywhere" regularity uses an improvement of flatness theorem due to De Giorgi [14], [21]. Caffarelli and Cordoba gave a different proof in [11] using nonvariational techniques.

**Theorem 3.1** (De Giorgi). *Suppose that $E$ is a set having minimal perimeter in $\{|x'| < 1,\ |x_n| < 1\}$, $0 \in \partial E$ and assume that $\partial E$ is "flat", i.e.*

$$\partial E \subset \{|x_n| < \varepsilon\},$$

*$\varepsilon \leq \varepsilon_0$, $\varepsilon_0$ small universal.*

*Then, possibly in a different system of coordinates, $\partial E$ can be trapped in a flatter cylinder*

$$\{|y'| \leq \eta_2\} \cap \partial E \subset \{|y_n| \leq \varepsilon \eta_1\},$$

*with $0 < \eta_1 < \eta_2$ universal constants.*

This theorem implies that flat minimal surfaces are $C^{1,\alpha}$, and therefore analytic by elliptic regularity theory.

The question of whether or not all points of a minimal surface are regular is closely related to the Bernstein problem. Singular points can exist if and only if there exist nonplanar entire minimal surfaces (or minimal cones). Simons [35] proved that in dimension $n \leq 7$ entire minimal surfaces are planar. Bombieri, De Giorgi and Giusti showed in [7] that the Simons cone

$$\{x \in \mathbb{R}^8 : \ x_1^2 + x_2^2 + x_3^2 + x_4^2 < x_5^2 + x_6^2 + x_7^2 + x_8^2\}$$

is minimal in $\mathbb{R}^8$. Moreover, if the minimal surface is assumed to be a "graph" in some direction, then there are nonplanar minimal graphs only in dimension $n \geq 9$.

Finally we mention that an entire minimal surface that is a "graph" and has at most linear growth at $\infty$ is planar.

## 4. Symmetry of minimizers

It is natural to ask if some properties of minimal surfaces hold also for local minimizers of (3) or solutions of (4). Actually, the conjecture of De Giorgi corresponds to such a question. Results in this direction were obtained by several authors.

Caffarelli and Cordoba proved the uniform density estimate (7) for the level sets of local minimizers $u_\varepsilon$ of $J_\varepsilon$. Modica proved in [28] that solutions of (4) satisfy a monotonicity formula for the energy functional,

$$\frac{J(u, B_R)}{R^{n-1}} \quad \text{increases with } R.$$

I proved in [33] an improvement of flatness theorem for local minimizers of (3) which corresponds to the flatness theorem of De Giorgi for minimal surfaces. It asserts that, if a level set is trapped in a flat cylinder whose height is greater than some given $\theta_0$, then it is trapped in a flatter cylinder in the interior (the flatness depends on $\theta_0$).

**Theorem 4.1** (Savin [33]). *Suppose that $u$ is a local minimizer of* (3) *in the cylinder $\{|x'| < l, \ |x_n| < l\}$, and assume that the* 0 *level set is "flat",*

$$\{u = 0\} \subset \{|x'| < l, \ |x_n| < \theta\},$$

*and contains the point* 0. *Then there exist small constants $0 < \eta_1 < \eta_2 < 1$ depending only on $n$ such that:*

*Given $\theta_0 > 0$ there exists $\varepsilon_1(\theta_0) > 0$ depending on $n$, $W$ and $\theta_0$ such that if*

$$\frac{\theta}{l} \leq \varepsilon_1(\theta_0), \quad \theta_0 \leq \theta$$

*then*

$$\{u = 0\} \cap \{|\pi_\xi x| < \eta_2 l,\ |x \cdot \xi| < \eta_2 l\}$$

*is included in a flatter cylinder*

$$\{|\pi_\xi x| < \eta_2 l,\ |x \cdot \xi| < \eta_1 \theta\}$$

*for some unit vector* $\xi$ ($\pi_\xi$ *denotes the projection along* $\xi$).

The proof uses the fact that at large scales the level sets behave like minimal surfaces and at small scales the equation behaves like Laplace's equation. The ideas are based on a viscosity solution proof of the flatness theorem of De Giorgi (see [34]). As a corollary of the above theorem we obtain that, if the level sets are asymptotically flat at $\infty$ then they are, in fact, hyperplanes.

**Corollary.** *Let* $u$ *be a local minimizer of* $J$ *in* $\mathbb{R}^n$ *with* $u(0) = 0$. *Suppose that there exist sequences of positive numbers* $\theta_k$, $l_k$ *and unit vectors* $\xi_k$ *with*

$$\frac{\theta_k}{l_k} \to 0, \quad l_k \to \infty$$

*such that*

$$\{u = 0\} \cap \{|\pi_{\xi_k} x| < l_k,\ |x \cdot \xi_k| < l_k\} \subset \{|x \cdot \xi_k| < \theta_k\}.$$

*Then the* 0 *level set is a hyperplane.*

*Proof.* Fix $\theta_0 > 0$, and choose $k$ large such that

$$\frac{\theta_k}{l_k} \le \varepsilon \le \varepsilon_1(\theta_0).$$

If $\theta_k \ge \theta_0$ then, by the theorem above, $\{u = 0\}$ is trapped in a flatter cylinder. We apply the theorem repeatedly till the height of the cylinder becomes less than $\theta_0$.

In some system of coordinates we obtain

$$\{u = 0\} \cap \{|y'| < l_k',\ |y_n| < l_k'\} \subset \{|y_n| \le \theta_k'\}$$

with

$$\theta_0 \ge \theta_k' \ge \eta_1 \theta_0, \quad \frac{\theta_k'}{l_k'} \le \frac{\theta_k}{l_k} \le \varepsilon,$$

hence

$$l_k' \ge \frac{\eta_1 \theta_0}{\varepsilon}.$$

We let $\varepsilon \to 0$ and obtain $\{u = 0\}$ is included in an infinite strip of width $\theta_0$. The corollary is proved since $\theta_0$ is arbitrary. □

As a consequence we have the following theorem.

**Theorem 4.2.** *Suppose that $u$ is a local minimizer of $J$ in $\mathbb{R}^n$ and $n \leq 7$. Then the level sets of $u$ are hyperplanes.*

Alberti, Ambrosio and Cabre showed in [1] that monotone solutions of (4) satisfying (2) are in fact local minimizers for the energy (3) (see also the paper of Jerison and Monneau [22]), hence we obtain:

**Theorem 4.3.** *Let $u \in C^2(\mathbb{R}^n)$ be a solution of*

$$\Delta u = W'(u) \tag{8}$$

*such that*

$$|u| \leq 1, \quad \partial_{x_n} u > 0, \quad \lim_{x_n \to \pm\infty} u(x', x_n) = \pm 1. \tag{9}$$

a) *If $n \leq 8$ then the level sets of $u$ are hyperplanes.*

b) *If the 0 level set has at most linear growth at $\infty$ then the level sets of $u$ are hyperplanes.*

The methods developed in [33] are quite general and can be applied for other types of nonlinear, possibly degenerate elliptic equations. Recently Valdinoci, Sciunzi and Savin [40] proved the theorems above for the energy

$$J_p(u, \Omega) := \int_\Omega \frac{1}{p} |\nabla u|^p + W(u) dx,$$

and the corresponding $p$-Laplace equation

$$\Delta_p u = W'(u), \quad \Delta_p u := \operatorname{div}(|\nabla u|^{p-2} \nabla u).$$

Similar results can be obtained for solutions of nonlinear reaction–diffusion equations of the type

$$F(D^2 u) = f(u), \quad u \in C^2(\mathbb{R}^n), \; u_{x_n} > 0, \; \lim_{x_n \to \pm\infty} u(x', x_n) = \pm 1, \tag{10}$$

where $F$ is uniformly elliptic, and $F$, $f$ are such that there exists a one dimensional solution $g$ which solves the equation in all directions, i.e.,

$$F(D^2 g(x \cdot \nu) = f(g(x \cdot \nu)), \quad \text{for all } \nu \in \mathbb{R}^n, |\nu| = 1.$$

If the rescaled level sets $\varepsilon_k \{u = 0\}$ converge uniformly on compact sets as $\varepsilon_k \to 0$, then the limiting surface satisfies a uniformly elliptic equation (depending on $F$, $f$) for its second fundamental form (instead of the minimal surface equation). Following ideas from [33] one can prove a Liouville property for level sets of solutions of (10). More precisely, if $\{u = 0\}$ stays above a hyperplane $x \cdot \nu = \text{const.}$, then $u$ depends only on one variable i.e,

$$u(x) = g(x \cdot \nu).$$

Moreover, if $F$ is smooth, then the level sets satisfy an improvement of the flatness theorem. This implies that if the 0 level set is asymptotically flat at $\infty$, then $u$ depends only on one variable. In particular, if the 0 level set is a Lipschitz graph in the $x_n$ direction, then the same conclusion holds.

# Vortices in the Ginzburg–Landau model of superconductivity

Sylvia Serfaty

**Abstract.** We review some mathematical results on the Ginzburg–Landau model with and without magnetic field. The Ginzburg–Landau energy is the standard model for superconductivity, able to predict the existence of vortices (which are quantized, topological defects) in certain regimes of the applied magnetic field. We focus particularly on deriving limiting (or reduced) energies for the Ginzburg–Landau energy functional, depending on the various parameter regimes, in the spirit of $\Gamma$-convergence. These passages to the limit allow to perform a sort of dimension-reduction and to deduce a rather complete characterization of the behavior of vortices for energy-minimizers, in agreement with the physics results. We also describe the behavior of energy critical points, the stability of the solutions, the motion of vortices for solutions of the gradient-flow of the Ginzburg–Landau energy, and show how they are also governed by those of the limiting energies.

**Mathematics Subject Classification (2000).** Primary 00A05; Secondary 00B10.

**Keywords.** Ginzburg–Landau equations, variational methods, $\Gamma$-convergence, superconductivity, vortices.

## 1. Introduction

**1.1. Presentation of the Ginzburg–Landau model.** We are interested in describing mathematical results on the two-dimensional Ginzburg–Landau model. This is a model of great importance and recognition in physics (with several Nobel prizes awarded for it: Landau, Ginzburg, Abrikosov). It was introduced by Ginzburg and Landau (see [15]) in the 1950s as a phenomenological model to describe superconductivity. Superconductivity was itself discovered in 1911 by Kammerling Ohnes. It consists in the complete loss of resistivity of certain metals and alloys at very low temperatures. The two most striking consequences of it are the possibility of permanent *superconducting currents* and the particular behavior that, when the material is submitted to an external magnetic field, that field gets expelled from it. Aside from explaining these phenomena, and through the very influential work of Abrikosov [1], the Ginzburg–Landau model allowed to predict the possibility of a *mixed state* in type-II superconductors where triangular vortex lattices appear. These vortices – a vortex can be described in a few words as a quantized amount of vorticity of the superconducting current localized near a point – have since been the objects of many observations and experiments.

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

The Ginzburg–Landau theory has also been justified as a limit of the Bardeen–Cooper–Schrieffer (BCS) quantum theory, which explains superconductivity by the existence of "Cooper pairs" of superconducting electrons.

In addition to its importance in the modelling of superconductivity, the Ginzburg–Landau model turns out to be the simplest case of a gauge theory, and vortices to be the simplest case of topological solitons (for these aspects see [34], [21] and the references therein); moreover, it is mathematically extremely close to the Gross–Pitaevskii model for superfluidity and models for rotating Bose–Einstein condensates in which quantized vortices are also essential objects, to which the Ginzburg–Landau techniques have been successfully exported.

The 2D Ginzburg–Landau model leads (after various suitable rescalings) to describing the state of the superconducting sample submitted to the external field $h_{\text{ex}}$, below the critical temperature, through the energy functional

$$G_\varepsilon(u, A) = \frac{1}{2}\int_\Omega |\nabla_A u|^2 + |\text{curl } A - h_{ex}|^2 + \frac{1}{2\varepsilon^2}\left(1 - |u|^2\right)^2. \qquad (1)$$

In this expression, $\Omega$ is a two-dimensional open subset of $\mathbb{R}^2$, which in our study is always assumed for simplicity to be smooth, bounded and simply connected. One can imagine it represents the section of an infinitely long cylinder, or a thin film.

The first unknown $u$ is a *complex*-valued function, called "order parameter" in physics, where it is generally denoted $\psi$. It is a condensed wave function, indicating the local state of the material or the phase in the Landau theory approach of phase transitions: $|u|^2$ is the density of "Cooper pairs" of superconducting electrons (responsible for superconductivity in the BCS approach). With our normalization $|u| \leq 1$ and where $|u| \simeq 1$ the material is in the superconducting phase, while where $|u| = 0$, it is in the normal phase (i.e. behaves like a normal conductor), the two phases being able to coexist in the sample.

The second unknown is $A$, the electromagnetic vector-potential of the magnetic field, a function from $\Omega$ to $\mathbb{R}^2$. The magnetic field in the sample is deduced by $h = \text{curl } A = \partial_1 A_2 - \partial_2 A_1$, it is thus a real-valued function in $\Omega$. The notation $\nabla_A$ denotes the covariant gradient $\nabla - iA$; $\nabla_A u$ is thus a vector with complex components.

The *superconducting current* is a real vector given by $\langle iu, \nabla_A u\rangle$ where $\langle .\,, .\rangle$ denotes the scalar-product in $\mathbb{C}$ identified with $\mathbb{R}^2$, it may also be written as $\frac{i}{2}\left(u\overline{\nabla_A u} - \bar{u}\nabla_A u\right)$, where the bar denotes complex conjugation.

The parameter $h_{\text{ex}} > 0$ represents the intensity of the applied field (assumed to be perpendicular to the plane of $\Omega$). Finally, the parameter $\varepsilon$ is the inverse of the "Ginzburg–Landau parameter" usually denoted $\kappa$, a non-dimensional parameter depending on the material only. We will be interested in the regime of small $\varepsilon$ or $\kappa \to +\infty$, corresponding to high-$\kappa$ superconductors (also called the London limit). In this limit, the characteristic size of the vortices, which is $\varepsilon$, tends to 0 and vortices become point-like.

The stationary states of the system are the critical points of $G_\varepsilon$, or the solutions of the Ginzburg–Landau equations (Euler–Lagrange equations associated to $G_\varepsilon$):

$$\text{(GL)}\quad \begin{cases} -(\nabla_A)^2 u = \dfrac{1}{\varepsilon^2} u(1-|u|^2) & \text{in } \Omega \\ -\nabla^\perp h = \langle iu, \nabla_A u\rangle & \text{in } \Omega \\ h = h_{\text{ex}} & \text{on } \partial\Omega \\ \nu \cdot \nabla_A u = 0 & \text{on } \partial\Omega, \end{cases}$$

where $\nabla^\perp$ denotes the operator $(-\partial_2, \partial_1)$, and $\nu$ the outer unit normal to $\partial\Omega$.

The Ginzburg–Landau equations and functional are invariant under $\mathbb{U}(1)$-gauge transformations (it is an Abelian gauge-theory):

$$\begin{cases} u \mapsto u e^{i\Phi}, \\ A \mapsto A + \nabla\Phi. \end{cases} \tag{2}$$

The physically relevant quantities are those that are gauge-invariant, such as the energy $G_\varepsilon$, $|u|$, $h$, etc.

For more on the model and on the physics, we refer to the physics literature, in particular [53], [13]. For more reference on the results we present here, we refer to our monograph with E. Sandier [47].

We will also mention results on the simplified Ginzburg–Landau model, without magnetic field. It consists in taking $A = 0$ and $h_{\text{ex}} = 0$, then the energy reduces to

$$E_\varepsilon(u) = \frac{1}{2}\int_\Omega |\nabla u|^2 + \frac{(1-|u|^2)^2}{2\varepsilon^2} \tag{3}$$

with still $u\colon \Omega \to \mathbb{C}$. Critical points of this energy are solutions of

$$-\Delta u = \frac{u}{\varepsilon^2}(1-|u|^2). \tag{4}$$

It is a complex-valued version of the Allen–Cahn model for phase-transitions. The first main study of this functional was done by Bethuel–Brezis–Hélein in the book [6], where they replace the effect of the applied field $h_{\text{ex}}$ by a fixed Dirichlet boundary condition. Since then, this model has been extensively studied.

**1.2. Vortices.** A vortex is an object centered at an isolated zero of $u$, around which the phase of $u$ has a nonzero winding number, called the *degree of the vortex*. When $\varepsilon$ is small, it is clear from (1) that $|u|$ prefers to be close to 1, and a scaling argument hints that $|u|$ is different from 1 in regions of characteristic size $\varepsilon$. A typical vortex centered at a point $x_0$ "looks like" $u = \rho e^{i\varphi}$ with $\rho(x_0) = 0$ and $\rho = f(\frac{|x-x_0|}{\varepsilon})$ where $f(0) = 0$ and $f$ tends to 1 as $r \to +\infty$, i.e. its characteristic core size is $\varepsilon$, and

$$\frac{1}{2\pi}\int_{\partial B(x_0, R\varepsilon)} \frac{\partial\varphi}{\partial\tau} = d \in \mathbb{Z}$$

is an integer, called the *degree of the vortex*. For example $\varphi = d\theta$ where $\theta$ is the polar angle centered at $x_0$ yields a vortex of degree $d$. We have the important relation

$$\operatorname{curl} \nabla\varphi = 2\pi \sum_i d_i \delta_{a_i} \tag{5}$$

where the $a_i$'s are the centers of the vortices, the $d_i$'s their degrees, and $\delta$ the Dirac mass.

In the limit $\varepsilon \to 0$ vortices become *point-like* or more generally, in any dimension, *codimension* 2 singularities (see [30], [7]) – to be compared with the case of real-valued phase-transition models (Allen–Cahn), where the order parameter $u$ is real-valued, leading to codimension 1 singular sets in the limit.

**1.3. Critical fields.** When an external magnetic field is applied to a superconductor, several responses can be observed depending on the intensity of the field $h_{\text{ex}}$.

There are three main critical values of $h_{\text{ex}}$ or *critical fields* $H_{c_1}$, $H_{c_2}$, and $H_{c_3}$, for which phase-transitions occur. Below the first critical field, which is of order $O(|\log \varepsilon|)$ (as first established by Abrikosov), the superconductor is everywhere in its superconducting phase $|u| \sim 1$ and the magnetic field does not penetrate (this is called the Meissner effect or Meissner state). At $H_{c_1}$, the first vortice(s) appear. Between $H_{c_1}$ and $H_{c_2}$, the superconducting and normal phases (in the form of vortices) coexist in the sample, and the magnetic field penetrates through the vortices. This is called the *mixed state*. The higher $h_{\text{ex}} > H_{c_1}$, the more vortices there are. Since they repel each other, they tend to arrange in these triangular Abrikosov lattices in order to minimize their repulsion. Reaching $H_{c_2} \sim \frac{1}{\varepsilon^2}$, the vortices are so densely packed that they overlap each other, and at $H_{c_2}$ a second phase transition occurs, after which $|u| \sim 0$ inside the sample, i.e. all superconductivity in the bulk of the sample is lost.

In the interval $[H_{c_2}, H_{c_3}]$ however, superconductivity persists near the boundary, this is called *surface superconductivity*. Above $H_{c_3} = O\left(\frac{1}{\varepsilon^2}\right)$ (defined in decreasing fields), the sample is completely in the normal phase $u \equiv 0$, the magnetic field completely penetrates, and decreasing the field below $H_{c_3}$, surface superconductivity is observed.

**1.4. Questions, results and methods.** The main question is to understand mathematically the behavior above, and in particular:

– To understand the vortices and their repartition, interaction.

– To understand the influence of the boundary conditions and/or of the applied field.

– To find the asymptotic values of the critical fields (as $\varepsilon \to 0$).

– To prove compactness results and derive *limiting energies/reduced problems*, thus following the strategy of $\Gamma$-convergence. This enables to understand the behavior of global minimizers (or energy minimizers) and their vortices. In order to achieve

this, one needs to find *lower bounds* for the energy, together with matching upper bounds.

– To understand and find local minimizers. This is done through a special "local minimization in energy sectors" method.

– To understand the behavior of critical points of the energy (i.e. solutions which are not necessarily stable), that is to pass to the limit $\varepsilon \to 0$ in the Ginzburg–Landau equations (GL). The method used here is to pass to the limit in the "stress-energy tensor".

– To derive the limiting motion law of vortices, and to understand its link with the reduced energies mentioned above.

## 2. Mathematical tools

Various methods were introduced to describe vortices, since [6]. A crucial difference between the analysis for (1) and the one for (3) is that for the case with magnetic field (1) we really need to be able to handle numbers of vortices which are *unbounded* as $\varepsilon \to 0$. We designed tools able to capture vortices for arbitrary maps $u$ (not necessarily solutions), and to treat possibly unbounded numbers.

Let us describe the two main technical tools which we use throughout: the *"vortex ball construction"*, yielding the lower bounds on the energy, and the *vorticity measures*, which serve to describe vortex-densities instead of individual vortices.

**2.1. The vortex-ball construction.** This serves to obtain lower bounds for bounded or unbounded numbers of vortices. The idea is that, whatever the map $u$, for topological reasons, a vortex of degree $d$ confined in a ball of radius $r$ should cost at least an energy $\pi d^2 \log \frac{r}{\varepsilon}$. Then, since there may be a large number of these vortices, one must find a way to add up those estimates. It is done following the ball-growth method of Sandier [38] and Jerrard [22] (which consists in growing annuli of same conformal type and merging them appropriately). The best result to date is the following:

**Theorem 2.1** (see [47]). *Let $(u, A)$ be a configuration such that $E_\varepsilon(|u|) \leq C\varepsilon^{\alpha-1}$ with $\alpha > 0$, then for any $r \in (\varepsilon^{\frac{\alpha}{2}}, 1)$, and $\varepsilon$ small enough, there exists a finite collection of disjoint closed balls $\{B_i\}_i$ of centers $a_i$, of sum of the radii $r$, covering $\{|u| \leq 1 - \varepsilon^{\frac{\alpha}{4}}\} \cap \{x \in \Omega, \operatorname{dist}(x, \partial\Omega) \geq \varepsilon\}$, and such that*

$$\frac{1}{2}\int_{\bigcup_i B_i} |\nabla_A u|^2 + |\operatorname{curl} A|^2 + \frac{(1-|u|^2)^2}{2\varepsilon^2} \geq \pi D\left(\log\frac{r}{D\varepsilon} - C\right) \tag{6}$$

*where $D = \sum_i |d_i|$ and $d_i = \deg(u, \partial B_i)$.*

This lower bound is very general, it does not require any hypothesis on $(u, A)$ other than a reasonable (but quite large) upper bound on its energy, and it is in fact sharp (examples where it is can be constructed).

**2.2. The vorticity measures.** Recall that a complex-valued map $u$ can be written in polar coordinates $u = \rho e^{i\varphi}$ with a phase $\varphi$ which can be multi-valued. Given a configuration $(u, A)$, we define its *vorticity* by

$$\mu(u, A) = \operatorname{curl} \langle iu, \nabla_A u \rangle + \operatorname{curl} A. \tag{7}$$

Formally

$$\langle iu, \nabla u \rangle = \rho^2 \nabla \varphi \simeq \nabla \varphi,$$

considering that $\rho = |u| \simeq 1$. Taking the curl of this expression and using (5), one would get the approximate (formal) relation

$$\mu(u, A) \simeq 2\pi \sum_i d_i \delta_{a_i} \tag{8}$$

where $a_i$'s are the vortices of $u$ and $d_i$'s their degrees. Thus we see why the quantity $\mu$ corresponds to a vorticity-measure of the map $u$ (just like the vorticity for fluids). The following theorem gives a rigorous content to (8).

**Theorem 2.2** (see [24] and [47]). *The $(a_i, d_i)'$s being given by the previous theorem, we have*

$$\left\| \mu(u, A) - 2\pi \sum_i d_i \delta_{a_i} \right\|_{(C_0^{0,\gamma}(\Omega))^*} \leq C r^\gamma G_\varepsilon^0(u, A) \quad \textit{for all } 0 < \gamma < 1,$$

*where $G_\varepsilon^0$ is the energy when $h_{\text{ex}} = 0$.*

The previous theorem allowed to give a control on the mass of $2\pi \sum_i d_i \delta_{a_i}$ as measures. This one ensures that if $r$ is taken small enough, $\mu(u, A)$ and $2\pi \sum_i d_i \delta_{a_i}$ are close in a weak norm. Combining the two yields a compactness result on the vorticity $\mu(u, A)$, if rescaled by dividing by the number of vortices. It also ensures the limiting vorticity is a bounded Radon measure. This is the limiting "vortex-density" we are looking to characterize in various situations.

**Remark 2.3.** When the Ginzburg–Landau equations (GL) are satisfied, taking the curl of the second relation, we find that the vorticity and the induced field are linked by the relation

$$\begin{cases} -\Delta h + h = \mu(u, A) & \text{in } \Omega, \\ h = h_{\text{ex}} & \text{on } \partial\Omega. \end{cases} \tag{9}$$

Thus the knowledge of the vorticity is equivalent to that of the induced field $h$.

## 3. Global minimization ($\Gamma$-convergence type) results

### 3.1. Results for $E_\varepsilon$

**3.1.1. In two dimensions.** For the two-dimensional simplified model (3), the main result of [6] can be written in the following form.

**Theorem 3.1** (Bethuel–Brezis–Hélein [6]). *Let $\Omega$ be a strictly starshaped simply connected domain of $\mathbb{R}^2$ and $g\colon \partial\Omega \to \mathbb{S}^1$ a smooth map of degree $d > 0$. If $u_\varepsilon$ minimizes $E_\varepsilon$ among maps with values $g$ on $\partial\Omega$, then, as $\varepsilon \to 0$, up to extraction of a subsequence, there exist $d$ distinct points $a_1, \dots, a_d \in \Omega$ such that $u_\varepsilon \to u_*$ in $C^k_{\mathrm{loc}}\big(\Omega \setminus \bigcup_i \{a_i\}\big)$ where*

1. *$u_*$ is a harmonic map from $\Omega\setminus\{a_1, \dots, a_d\}$ to $\mathbb{S}^1$ with $u_* = g$ on $\partial\Omega$ and with degree $d_i = 1$ around each $a_i$,*
2. *$(a_1, \dots, a_d)$ is a minimizer of the renormalized energy $W$ with $d_i = 1$,*
3. *$E_\varepsilon(u_\varepsilon) \geq \pi d|\log\varepsilon| + W(a_1, \dots, a_d) + o(1)$.*

Here $W$ denotes a function of the points $a_i \in \Omega$ (depending also on the degrees), called *"renormalized energy"* and which has a form

$$W(x_1, \dots, x_n) = -\pi \sum_{i\neq j} d_i d_j \log|x_i - x_j| + \text{terms of interaction with the boundary.}$$

$W$ corresponds to the finite part of the energy left when subtracting the "infinite" self-interaction cost of the vortices $\pi d|\log\varepsilon|$, i.e. to the interaction between the vortices (vortices of same sign repel, of opposite sign attract).

This result can be phrased as a $\Gamma$-convergence result (in the sense of DeGiorgi):

**Proposition 3.2** ($\Gamma$-convergence of $E_\varepsilon$).

1. *For any family $\{u_\varepsilon\}_\varepsilon$ such that $E_\varepsilon(u_\varepsilon) \leq C|\log\varepsilon|$ and $u_\varepsilon = g$ on $\partial\Omega$; up to extraction, there exists a finite family $(a_i, d_i)$ of $n$ points + degrees such that $\sum_{i=1}^n d_i = d$ and*

$$\operatorname{curl}\langle i u_\varepsilon, \nabla u_\varepsilon\rangle \rightharpoonup 2\pi \sum_{i=1}^n d_i \delta_{a_i},$$

$$E_\varepsilon(u_\varepsilon) \geq \pi \sum_{i=1}^n |d_i||\log\varepsilon| + W(a_1, \dots, a_n) + o(1) \quad \text{as } \varepsilon \to 0.$$

2. *For all distinct $a_i$'s and $d_i = \pm 1$, there exists $u_\varepsilon$ such that*

$$E_\varepsilon(u_\varepsilon) \leq \pi n|\log\varepsilon| + W(a_1, \dots, a_n) + o(1).$$

Fixing the degrees $d_i = \pm 1$ and the number of vortices $n$, this result states exactly that $E_\varepsilon - \pi n |\log \varepsilon|$ $\Gamma$-converges to $W$. This reduces the dimension of the problem, by reducing the minimization of $E_\varepsilon$ to the simple one of the limiting energy $W$, which is a function on a finite dimensional set.

**3.1.2. In higher dimensions.** Three-dimensional as well as higher-dimensional versions of Theorem 3.1 have been given, in particular by Lin–Rivière [30], Sandier [39], Bethuel–Brezis–Orlandi [7]. Jerrard and Soner gave a $\Gamma$-convergence formulation (i.e. analogous to Proposition 3.2), later improved by Alberti–Baldo–Orlandi [2]. Here $E_\varepsilon$ refers to the $n$-dimensional version of the energy (3). When $n = 3$ the vortex-set (or zero-set of $u$) is a set of lines, in higher dimensions it is a set of codimension 2, and the vorticity is best described in the language of currents.

**Theorem 3.3** (Jerrard–Soner [24]). *Let $\{u_\varepsilon\}_\varepsilon$ be a family such that $E_\varepsilon(u_\varepsilon) \leq C|\log \varepsilon|$; up to extraction, there exists an integer-multiplicity rectifiable $(n-2)$-dimensional current $J$ such that*

$$\mu_\varepsilon(u_\varepsilon) := *d\langle i u_\varepsilon, d u_\varepsilon\rangle \rightharpoonup 2\pi J \quad \text{in } (C_0^{0,\gamma}(\Omega))^*$$

*for all $\gamma < 1$ (in the language of differential forms) and*

$$\varliminf_{\varepsilon\to 0} \frac{E_\varepsilon(u_\varepsilon)}{|\log\varepsilon|} \geq \pi \|J\|(\Omega),$$

*where $\|J\|(\Omega)$ is the total mass of the current.*

The total mass of the current corresponds in dimension 3 to the total length of the vortex-lines. The result of [30], [39] essentially states that minimizers of $E_\varepsilon$ have a vorticity $\mu_\varepsilon$ which converges to minimizers of the length $\|J\|(\Omega)$, thus have vortices which converge to straight lines or minimal connections (or codimension 2 minimal currents in higher dimension). The result of [7] generalizes it to critical points and proves that critical points of $E_\varepsilon$ have vortices which converges to stationary varifolds.

Observe that the situation is quite different from the dimension 2, because the main order $|\log\varepsilon|$ of the energy already gives a nontrivial limiting problem: the mass of the limiting object $J$; in contrast with the 2D problem which only leads to minimizing the number of points (one needs to go to the next order in the energy to get an interesting problem: the minimization of $W$).

### 3.2. Global minimization results for $G_\varepsilon$

**3.2.1. Close to $H_{c_1}$.** Let us introduce $h_0$ the solution of

$$\begin{cases} -\Delta h_0 + h_0 = 0 & \text{in } \Omega, \\ h_0 = 1 & \text{on } \partial\Omega, \end{cases} \tag{10}$$

and

$$C(\Omega) = (2 \max |h_0 - 1|)^{-1}. \tag{11}$$

We also introduce the set $\Lambda = \{x \in \Omega / h_0(x) = \min h_0\}$ and we will assume here for simplicity that it is reduced to only one point called $p$, and denote $Q(x) = \langle D^2 h_0(p)x, x\rangle$, assumed to be definite positive. With these notations, a first essential result is the asymptotic formula for $H_{c_1}$ (confirming physical predictions that $H_{c_1} = O(|\log \varepsilon|)$):

$$H_{c_1} = C(\Omega)|\log \varepsilon| + O(1). \tag{12}$$

**Theorem 3.4** ([48], [47]). *Assume* $h_{\text{ex}} \leq H_{c_1} + O(\log\ |\log \varepsilon|)$, *then for* $h_{\text{ex}} \in (H_n, H_{n+1})$ *where* $H_n$ *has the expansion*

$$H_n = C(\Omega)\left(|\log \varepsilon| + (n-1)\log \frac{|\log \varepsilon|}{n}\right) + \textit{lower order terms,}$$

*global minimizers of* $G_\varepsilon$ *have exactly n vortices of degree* 1, $a_i^\varepsilon \to p$ *as* $\varepsilon \to 0$ *and the* $\tilde{a_i^\varepsilon} = \sqrt{\frac{h_{\text{ex}}}{n}}(a_i^\varepsilon - p)$ *converge as* $\varepsilon \to 0$ *to a minimizer of*

$$w_n(x_1, \ldots, x_n) = -\pi \sum_{i \neq j} \log |x_i - x_j| + \pi n \sum_{i=1}^{n} Q(x_i). \tag{13}$$

Through this theorem we see that the behavior is as expected: below $H_{c_1} = H_1$ there are no vortices in energy minimizers (in addition it was proved in [49] that the minimizer is unique), then at $H_{c_1}$ the first vortex becomes favorable, close to the point $p$. Then, there is a sequence of additional critical fields $H_2, H_3, \ldots$ separated by increments of $\log\ |\log \varepsilon|$, for which a second, third, etc, vortex becomes favorable. Each time the optimal vortices are located close to $p$ as $\varepsilon \to 0$, and after blowing-up at the scale $\sqrt{\frac{h_{\text{ex}}}{n}}$ around $p$, they converge to configurations which minimize $w_n$ in $\mathbb{R}^2$. Now, $w_n$, which appears as a limiting energy (after that rescaling) contains a repulsion term like $W$, and a confinement term due to the applied field. It is a standard two-dimensional interaction, however rigorous results on its minimization are hard to obtain as soon as $n \geq 3$. When $Q$ has rotational symmetry, numerical minimization (see Gueron–Shafrir [17]) yields very regular shapes (regular polygons for $n \leq 6$, regular stars) which look very much like the birth of a triangular lattice as $n$ becomes large. All these results are in very good agreement with experimental observations.

**3.2.2. Global minimizers in the intermediate regime.** In the next higher regime of applied field, the result is the following:

**Theorem 3.5** ([47]). *Assume* $h_{\text{ex}}$ *satisfies, as* $\varepsilon \to 0$,

$$\log\ |\log \varepsilon| \ll h_{\text{ex}} - H_{c_1} \ll |\log \varepsilon|.$$

*Then there exists* $1 \ll n_\varepsilon \ll h_{\text{ex}}$ *such that*

$$h_{\text{ex}} \sim C(\Omega)\left(|\log\varepsilon| + n_\varepsilon \log\frac{|\log\varepsilon|}{n_\varepsilon}\right)$$

*and if* $(u_\varepsilon, A_\varepsilon)$ *minimizes* $G_\varepsilon$*, then*

$$\frac{\tilde{\mu}(u_\varepsilon, A_\varepsilon)}{2\pi n_\varepsilon} \rightharpoonup \mu_0$$

*where* $\tilde{\mu}(u_\varepsilon, A_\varepsilon)$ *is the push-forward of the measure* $\mu(u_\varepsilon, A_\varepsilon)$ *under the blow-up* $x \mapsto \sqrt{\frac{h_{\text{ex}}}{n_\varepsilon}}(x - p)$*, and* $\mu_0$ *is the unique minimizer over probability measures of*

$$I(\mu) = -\pi \int_{\mathbb{R}^2\times\mathbb{R}^2} \log|x-y|\, d\mu(x)\, d\mu(y) + \pi \int_{\mathbb{R}^2} Q(x)\, d\mu(x). \tag{14}$$

Here, $n_\varepsilon$ corresponds to the expected optimal number of vortices. In [47] our result is really phrased as a $\Gamma$-convergence of $G_\varepsilon$ in the regime $1 \ll n \ll h_{\text{ex}}$, reducing the minimization of $G_\varepsilon$ to that of the limiting energy $I$. The problem of minimizing $I$ is a classical one in potential theory. Its minimizer $\mu_0$ is a probability measure of constant density over a subdomain of $\mathbb{R}^2$ (typically a disc or an ellipse). This result is in continuous connection with Theorem 3.4, except $n_\varepsilon \gg 1$. Again, vortices in the minimizers converge to $p$ as $\varepsilon \to 0$, and when one blows up at the right scale $\sqrt{\frac{h_{\text{ex}}}{n_\varepsilon}}$ around $p$, one obtains a uniform density of vortices $\mu_0$ in a subdomain of $\mathbb{R}^2$.

**3.2.3. Global minimizers in the regime $n_\varepsilon$ proportional to $h_{\text{ex}}$.** This happens in the next regime: $h_{\text{ex}} \sim \lambda|\log\varepsilon|$ with $\lambda > C(\Omega)$.

**Theorem 3.6** ([42], [47]). *Assume* $h_{\text{ex}} = \lambda|\log\varepsilon|$ *where* $\lambda > 0$ *is a constant independent of* $\varepsilon$*. As* $\varepsilon \to 0$*,* $\frac{G_\varepsilon}{h_{\text{ex}}^2}$ $\Gamma$*-converges to*

$$E_\lambda(\mu) = \frac{\|\mu\|}{2\lambda} + \frac{1}{2}\int_\Omega |\nabla h_\mu|^2 + |h_\mu - 1|^2,$$

*defined over bounded Radon measures which are in* $H^{-1}(\Omega)$*, where* $\|\mu\|$ *is the total mass of* $\mu$ *and* $h_\mu$ *is the solution to*

$$\begin{cases} -\Delta h_\mu + h_\mu = \mu & \text{in } \Omega, \\ h_\mu = 1 & \text{on } \partial\Omega. \end{cases} \tag{15}$$

*Consequently, if* $(u_\varepsilon, A_\varepsilon)$ *minimizes* $G_\varepsilon$*, then*

$$\frac{\mu(u_\varepsilon, A_\varepsilon)}{h_{\text{ex}}} \rightharpoonup \mu_*,$$

$\mu_*$ *being the unique minimizer over* $H^{-1}(\Omega) \cap (C_0^0(\Omega))^*$ *of* $E_\lambda$*.*

Observe also that

$$E_\lambda(\mu) = \frac{1}{2\lambda}\int_\Omega |\mu| + \frac{1}{2}\int_{\Omega\times\Omega} G(x,y)\, d(\mu-1)(x)\, d(\mu-1)(y) \qquad (16)$$

where $G$ is the solution to $-\Delta G + G = \delta_y$ with $G = 0$ on $\partial\Omega$. That way, the similarity with $I$ is more apparent.

Again, by $\Gamma$-convergence, we reduce to minimizing the limiting energy $E_\lambda$ on the space of bounded Radon measures on $\Omega$. It turns out that this problem is dual, in the sense of convex duality, to an obstacle problem:

**Proposition 3.7.** *$\mu$ minimizes $E_\lambda$ if and only if $h_\mu$ is the minimizer for*

$$\min_{\substack{h\geq 1-\frac{1}{2\lambda}\\ h=1 \text{ on } \partial\Omega}} \int_\Omega |\nabla h|^2 + h^2. \qquad (17)$$

The solution of the obstacle problem (17) is well-known, and given by a variational inequality (see [28]). Obstacle problems are a particular type of *free-boundary problems*, the free-boundary here being the boundary of the coincidence set

$$\omega_\lambda = \left\{ x\in\Omega / h(x) = 1 - \frac{1}{2\lambda} \right\}.$$

Then $h$ verifies $-\Delta h + h = 0$ outside of $\omega_\lambda$, so $\omega_\lambda$ is really the support of $\mu_*$, on which $\mu_*$ is equal to the constant density $\left(1-\frac{1}{2\lambda}\right)dx$. An easy analysis of this obstacle problem yields the following:

1. $\omega_\lambda = \varnothing$ (hence $\mu_* = 0$) if and only if $\lambda < C(\Omega)$, where $C(\Omega)$ was given by (11). (This corresponds to the case $h_{\text{ex}} < H_{c_1}$.)

2. For $\lambda = C(\Omega)$, $\omega_\lambda = \{p\}$. This is the case when $h_{\text{ex}} \sim H_{c_1}$ at leading order. In the scaling chosen here $\mu_* = 0$ but the true behavior of the vorticity is ambiguous unless going to the next order term as done in Theorems 3.4 and 3.5.

3. For $\lambda > C(\Omega)$, the measure of $\omega_\lambda$ is nonzero, so the limiting vortex density $\mu_* \neq 0$. Moreover, as $\lambda$ increases (i.e. as $h_{\text{ex}}$ does), $\omega_\lambda$ increases. When $\lambda = +\infty$, $\omega_\lambda$ becomes $\Omega$ and $\mu_* = 1$, this corresponds to the case $h_{\text{ex}} \gg |\log\varepsilon|$ of the next subsection.

**3.2.4. Global minimizers in the regime $|\log\varepsilon| \ll h_{\text{ex}} \ll \varepsilon^{-2}$.** For applied fields much larger than $|\log\varepsilon|$ but below $H_{c_2}$, even though the number of vortices becomes very large, the minimization problem becomes local and can be solved by blowing-up and using Theorem 3.6. The energy-density and the vortex repartition are thus found to be uniform, as seen in:

**Theorem 3.8** ([41], [47]). *Assume, as $\varepsilon \to 0$, that $|\log \varepsilon| \ll h_{\text{ex}} \ll 1/\varepsilon^2$. Then, if $(u_\varepsilon, A_\varepsilon)$ minimizes $G_\varepsilon$, and letting $g_\varepsilon(u, A)$ denote the energy-density $\frac{1}{2}\big(|\nabla_A u|^2 + |h - h_{\text{ex}}|^2 + \frac{1}{2\varepsilon^2}(1 - |u|^2)^2\big)$, we have*

$$\frac{2g_\varepsilon(u_\varepsilon, A_\varepsilon)}{h_{\text{ex}} \log \frac{1}{\varepsilon\sqrt{h_{\text{ex}}}}} \rightharpoonup dx \quad \text{as } \varepsilon \to 0$$

*in the weak sense of measures, where $dx$ denotes the two-dimensional Lebesgue measure; and thus*

$$\min_{(u,A)\in H^1\times H^1} G_\varepsilon(u, A) \sim \frac{|\Omega|}{2} h_{\text{ex}} \log \frac{1}{\varepsilon\sqrt{h_{\text{ex}}}} \quad \text{as } \varepsilon \to 0,$$

*where $|\Omega|$ is the area of $\Omega$. Moreover*

$$\frac{h_\varepsilon}{h_{\text{ex}}} \to 1 \quad \text{in } H^1(\Omega)$$
$$\frac{\mu(u_\varepsilon, A_\varepsilon)}{h_{\text{ex}}} \to dx \quad \text{in } H^{-1}(\Omega).$$

In Theorems 3.5, 3.6 and 3.8 we find an optimal limiting density which is constant on its support ($\omega_\lambda$ or $\Omega$). This provides a first (but very incomplete) confirmation of the Abrikosov lattices of vortices observed and predicted in physics.

**3.2.5. Global minimizers in higher applied field.** Here, we will present the situation with decreasing applied field. For large enough applied field, the only solution is the (trivial) normal one $u \equiv 0$, $h \equiv h_{\text{ex}}$.

Giorgi and Phillips have proved in [16] that this is the case for $h_{\text{ex}} \geq C\varepsilon^{-2}$.

**Theorem 3.9** (Giorgi–Phillips [16]). *There exists a constant $C$ such that if $h_{\text{ex}} \geq C\varepsilon^{-2}$ and $\varepsilon$ is small enough, then the only solution to* (GL) *is the normal one $u \equiv 0$, $h \equiv h_{\text{ex}}$.*

This result implies the upper bound $H_{c_3} \leq C\varepsilon^{-2}$ for that constant $C$.

Decreasing the applied field to $H_{c_3}$, a bifurcation from the normal solution of a branch of solutions with surface superconductivity occurs. The linear analysis of this bifurcation was first performed in the half-plane by De Gennes [13], then by Bauman–Phillips–Tang [4] in the case of a disc; and for general domains, formally by Chapman [11], Bernoff–Sternberg [5], Lu and Pan [33], then rigorously by Del Pino–Felmer–Sternberg [14], Helffer–Morame [19], Helffer–Pan [18]. The nucleation of surface superconductivity takes place near the point of maximal curvature of the boundary, and the asymptotics for $H_{c_3}$ is given by the following result.

**Theorem 3.10.**

$$H_{c_3} \sim \frac{\varepsilon^{-2}}{\beta_0} + \frac{C_1}{\beta_0^{3/2}} \max(\text{curv}(\partial\Omega))\varepsilon^{-1},$$

*where $\beta_0$ is the smallest eigenvalue of a Schrödinger operator with magnetic field in the half-plane.*

The behavior of energy minimizers for $H_{c_2} \leq h_{\text{ex}} \leq H_{c_3}$ has been studied by Pan [37] (see also Almog), who showed that, as known by physicists, minimizers present surface superconductivity which spreads to the whole boundary, with exponential decay of $|u|$ from the boundary of the domain.

At $H_{c_2}$, one goes from surface superconductivity to bulk-superconductivity. It was established by Pan [37] that

$$H_{c_2} = \varepsilon^{-2}.$$

Qualitative results on bulk-superconductivity below $H_{c_2}$ were obtained in [44], where we established in particular how bulk-superconductivity increases (in average) as $h_{\text{ex}}$ is lowered immediately below $H_{c_2}$.

## 4. Local minimizers: branches of solutions

The techniques developed to describe energy-minimizers also allow to find branches of locally minimizing (hence stable, and physically observable) solutions, with prescribed numbers of vortices. This is a problem of inverse type: given critical points or minimizers of the limiting energy $w$, can we find critical points / local minimizers of $G_\varepsilon$ which converge to it? For answers on that question regarding $E_\varepsilon$, see the book of Pacard and Rivière [36].

**Theorem 4.1** ([49], [47]). *For $\varepsilon < \varepsilon_0$, and for any $n$ and $h_{\text{ex}}$ belonging to appropriate intervals, there exists a locally minimizing critical point $(u_\varepsilon, A_\varepsilon)$ of $G_\varepsilon$ such that $u_\varepsilon$ has exactly $n$ zeroes $a_1^\varepsilon, \ldots, a_n^\varepsilon$ and there exists $R > 0$ such that $|u_\varepsilon| \geq \frac{1}{2}$ in $\Omega \backslash \bigcup_i B(a_i^\varepsilon, R\varepsilon)$, with $\deg(u_\varepsilon, \partial B(a_i^\varepsilon, R)) = 1$. Moreover:*

1. *If $n$ and $h_{\text{ex}}$ are constant, independent of $\varepsilon$, up to extraction of a subsequence, the configuration $(a_1^\varepsilon, \ldots, a_n^\varepsilon)$ converges as $\varepsilon \to 0$ to a minimizer of the function*

$$R_{n,h_{\text{ex}}} = -\pi \sum_{i \neq j} \log |x_i - x_j| + \pi \sum_{i,j} S_\Omega(x_i, x_j) + 2\pi h_{\text{ex}} \sum_{i=1}^{n} (h_0 - 1)(x_i).$$

   *where $S_\Omega$ is the regular part of a Green function associated to $\Omega$.*

2. *If $n = O(1)$ and $h_{\text{ex}} \to \infty$, up to extraction of a subsequence, the configuration of the $\tilde{a}_i^\varepsilon = \sqrt{\frac{h_{\text{ex}}}{n}}(a_i^\varepsilon - p)$ converges as $\varepsilon \to 0$ to a minimizer of $w_n$.*

3. *If $n \to \infty$ and $h_{\text{ex}} \to \infty$, then denoting again $\tilde{a}_i^\varepsilon = \sqrt{\frac{h_{\text{ex}}}{n}}(a_i^\varepsilon - p)$,*

$$\frac{1}{n} \sum_{i=1}^{n} \delta_{\tilde{a}_i^\varepsilon} \rightharpoonup \mu_0$$

   *where $\mu_0$ is the unique minimizer of $I$ (defined in* (14)).

The method of the proof consists in finding these solutions as local minimizers by minimizing $G_\varepsilon$ over some open sets of the type $U_n = \{(u, A)/\pi(n-1)|\log\varepsilon| < G^0_\varepsilon(u, A) < \pi(n+1)|\log\varepsilon|\}$. Minimizing over $U_n$ consists, roughly speaking, in minimizing over configurations with $n$ vortices, the difficulty is in proving that the minimum over $U_n$ is achieved at an interior point (this comes from the quantization of the energetic cost of vortices), thus yielding a local energy minimizer.

We thus show the multiplicity of locally minimizing solutions, for a given $h_{\text{ex}}$, in a wide range (from $h_{\text{ex}} = O(1)$ to $h_{\text{ex}} \gg |\log\varepsilon|$): essentially, solutions with 0, 1, 2, 3, ... vortices coexist and are all stable, even if not energy-minimizing.

We also have derived multiple "renormalized energies" $R_{n,h_{\text{ex}}}$, $w_n$, $I(\mu)$ corresponding to the three regimes above. Observe that $w_n$ corresponds somewhat to the limit of $R_{n,h_{\text{ex}}}$ as $h_{\text{ex}} \to \infty$, while $I$ is a continuum limit as $n \to \infty$ (but still $n \ll h_{\text{ex}}$) of $w_n$. $E_\lambda$ can also be seen as the limit as both $n$ and $h_{\text{ex}}$ tend to $\infty$ but $n/h_{\text{ex}}$ not tending to 0. Thus these limiting or renormalized energies are not only valid for global minimization, but also for local minimization.

## 5. Critical points approach

The issue here is to derive conditions on limiting vortices or vortex-densities just assuming that we start from a family of solutions to (GL) or critical points of $G_\varepsilon$, not necessarily stable. This strategy was already implemented for the functional $E_\varepsilon$ in [6], leading to

**Theorem 5.1** (Bethuel–Brezis–Hélein [6]). *If $u_\varepsilon$ is a sequence of solutions of* (4) *in $\Omega$ with $u_\varepsilon = g$ on $\partial\Omega$, $\deg(g) = d > 0$, and $E_\varepsilon(u_\varepsilon) \le C|\log\varepsilon|$ then, as $\varepsilon \to 0$ and up to extraction of a subsequence, there exist distinct points $a_1, \dots, a_n \in \Omega$, and degrees $d_1, \dots, d_n$ with $\sum_{i=1}^n d_i = d$, such that $u_\varepsilon \to u_*$ in $C^k_{\text{loc}}\big(\Omega\backslash\bigcup_i\{a_i\}\big)$ where $u_*$ is a harmonic map from $\Omega\backslash\{a_1, \dots, a_n\}$ to $\mathbb{S}^1$ with $u_* = g$ on $\partial\Omega$ and with degree $d_i$ around each $a_i$. Moreover $(a_1, \dots, a_n)$ is a critical point of $W$ (the $d_i$'s being fixed).*

Thus, the vortices of critical points of $E_\varepsilon$ converge to critical points of the limiting energy $W$.

It is a corresponding result that we obtain for the vortex-densities for $G_\varepsilon$. The strategy consists similarly in passing to the limit $\varepsilon \to 0$, not in (GL), but in the stationarity relation

$$\frac{d}{dt}_{|t=0} G_\varepsilon(u \circ \chi_t, A \circ \chi_t) = 0$$

satisfied for the critical points (with $\chi_t$ a one-parameter family of diffeomorphisms such that $\chi_0 = Id$). That relation is equivalent by Noether's theorem to a relation of the form

$$\text{div } T_\varepsilon = 0$$

where $T_\varepsilon$ is called the "stress-energy" or "energy-momentum" tensor. For the present energy-functional

$$T_\varepsilon = \frac{1}{2}\begin{pmatrix} |\partial_1^A u|^2 - |\partial_2^A u|^2 & 2\langle \partial_1^A u, \partial_2^A u\rangle \\ 2\langle \partial_1^A u, \partial_2^A u\rangle & |\partial_2^A u|^2 - |\partial_1^A u|^2 \end{pmatrix} + \left(\frac{h^2}{2} - \frac{(1-|u|^2)^2}{2\varepsilon^2}\right)\begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix},$$

where $\partial_j^A = \partial_j - iA_j$.

In what follows we assume that $(u_\varepsilon, A_\varepsilon)$ are sequences of critical points of $G_\varepsilon$ such that $G_\varepsilon(u_\varepsilon, A_\varepsilon) \le C\varepsilon^{-\alpha}$, $\alpha < \frac{1}{3}$, and $n_\varepsilon$ is defined as $\sum_i |d_i|$ where the $d_i$'s are the degrees of the balls of total radius $r = \varepsilon^{2/3}$ given by Theorem 2.1.

**Theorem 5.2** ([43], [47]). *Let $(u_\varepsilon, A_\varepsilon)$ and $n_\varepsilon$ be as above. If $n_\varepsilon$ vanishes in a neighborhood of 0 then $\mu(u_\varepsilon, A_\varepsilon)$ tends to 0 in $W^{-1,p}(\Omega)$ for some $p \in (1,2)$. If not, then going to a subsequence*

$$\frac{\mu(u_\varepsilon, A_\varepsilon)}{n_\varepsilon} \to \mu \tag{18}$$

*in $W^{-1,p}(\Omega)$ for some $p \in (1,2)$ where $\mu$ is a measure. Moreover, one of the two following possibilities occur (after extraction of a subsequence if necessary).*

1. *If $n_\varepsilon = o(h_{\mathrm{ex}})$ then*
$$\mu \nabla h_0 = 0. \tag{19}$$
2. *If $h_{\mathrm{ex}}/n_\varepsilon \to \lambda \ge 0$, then, letting $h_\mu$ be the solution of (15), the symmetric 2-tensor $T_\mu$ with coefficients*
$$T_{ij} = \frac{1}{2}\begin{pmatrix} |\partial_1 h_\mu|^2 - |\partial_2 h_\mu|^2 & 2\partial_1 h_\mu \partial_2 h_\mu \\ 2\partial_1 h_\mu \partial_2 h_\mu & |\partial_2 h_\mu|^2 - |\partial_1 h_\mu|^2 \end{pmatrix} - \frac{h_\mu^2}{2}\begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}$$
*is divergence-free in finite part.*

*In the latter case, if $\mu$ is such that $h_\mu \in H^1(\Omega)$ then $T_\mu$ is in $L^1$ and divergence-free in the sense of distributions. Moreover $|\nabla h_\mu|^2$ is in $W^{1,q}_{\mathrm{loc}}(\Omega)$ for any $q \in [1, +\infty)$.*

*If we assume in addition that $\mu \in L^p(\Omega)$ for some $p > 1$, then*

$$\mu \nabla h_\mu = 0.$$

*Finally, if we assume $\nabla h_\mu \in C^0(\Omega) \cap W^{1,1}(\Omega)$ (this is the case if $\mu$ is in $L^p$, for some $p > 1$ for instance), then $h_\mu$ is in $C^{1,\alpha}(\Omega)$ for any $\alpha \in (0,1)$ and $0 \le h_\mu \le 1$. In this case*

$$\mu = h_\mu \mathbf{1}_{\{|\nabla h_\mu| = 0\}}, \tag{20}$$

*(where $\mathbf{1}$ stands for the characteristic function) and thus $\mu$ is a nonnegative $L^\infty$ function.*

To sum up, the limiting condition is $\mu\nabla h_0$ in the first case, it means that when there are too few of them, vortices all concentrate at the critical points of $h_0$ at the limit. In the second case, it is a weak form of the relation $\mu\nabla h_\mu = 0$ (which cannot be written as such when $h_\mu$ is not regular enough, counterexamples can be built).

We obtained an analogous result for critical points of $E_\varepsilon$ with possibly large numbers of vortices.

Also, once more, the result has a higher-dimensional version for the functional $E_\varepsilon$: as mentioned in Section 3.1.2, it was proved in [30], [7] that the vorticities for critical points of $E_\varepsilon$ converge to stationary varifolds, i.e. critical points for the length/area.

## 6. Study of the dynamics

The philosophy that has been successful in the minimization approach has been to extract limiting reduced energies (most often depending on some parameter regimes). These energies come up as $\Gamma$-limits, thus giving the behavior of energy-minimizers, but we have seen that they are not only relevant for energy-minimizers, but also for critical points ("critical points converge to critical points") and for local minimizers. It turns out that these limiting energies are also relevant for the study of dynamical problems, such as that of the heat-flow of (GL) and (4).

### 6.1. Energy-based method

**6.1.1. Abstract argument.** In [46], [50], we gave criteria to determine when a family of energies $F_\varepsilon$ converges to its $\Gamma$-limit $F$ in a sort of $C^1$ or $C^2$ sense which allows to pass to the limit in the associated gradient-flow (we called this "$\Gamma$-convergence of gradient flows"). The abstract situation is the following: assume that $F_\varepsilon$ $\Gamma$-converges to $F$ for the sense of convergence $S$ (the sense of convergence can be a weak convergence or a convergence of some nonlinear quantity), that means in particular

$$\underline{\lim}_{\varepsilon\to 0} F_\varepsilon(u_\varepsilon) \geq F(u) \quad \text{when } u_\varepsilon \overset{S}{\rightharpoonup} u, \tag{21}$$

and consider the gradient of $F_\varepsilon$ with respect to some Hilbert structure $X_\varepsilon$, denoted $\nabla_{X_\varepsilon} F_\varepsilon$. The question is to find conditions to get that solutions of the gradient flow $\partial_t u_\varepsilon = -\nabla_{X_\varepsilon} F_\varepsilon(u_\varepsilon)$ converge (in the sense $S$) to a solution of the gradient flow of $F$ with respect to some structure $Y$ to be determined. In the problem on Ginzburg–Landau vortices, $F_\varepsilon$ should be taken to be $E_\varepsilon - \pi n|\log\varepsilon|$ and $F = W$ (see Proposition 3.2), the sense of convergence to be considered is $u_\varepsilon \rightharpoonup^S u = (a_1, \ldots, a_n)$ if $\operatorname{curl}\langle iu_\varepsilon, \nabla u_\varepsilon\rangle \rightharpoonup 2\pi\sum_{i=1}^n d_i\delta_{a_i}$, where the $d_i = \pm 1$ and $n$ are fixed a priori. In that case the limiting flow is a finite dimensional one, so the proof of existence of its solution is easy.

The two sufficient abstract conditions are that there should exist another Hilbert structure $Y$ on the space where $F$ is defined, satisfying the following:

1) For a subsequence such that $u_\varepsilon(t) \overset{S}{\rightharpoonup} u(t)$ for every $t \in [0, T)$, we have for all $s \in [0, T)$,
$$\varliminf_{\varepsilon\to 0} \int_0^s \|\partial_t u_\varepsilon\|^2_{X_\varepsilon}(t)\,dt \geq \int_0^s \|\partial_t u\|^2_Y(t)\,dt. \tag{22}$$

2) For any $u_\varepsilon \overset{S}{\rightharpoonup} u$
$$\varliminf_{\varepsilon\to 0} \|\nabla_{X_\varepsilon} F_\varepsilon(u_\varepsilon\|^2_{X_\varepsilon} \geq \|\nabla_Y F(u)\|^2_Y. \tag{23}$$

These conditions suffice in the case where $F$ is defined on a finite-dimensional space, to derive that if $u_\varepsilon$ solves
$$\partial_t u_\varepsilon = -\nabla_{X_\varepsilon} F_\varepsilon(u_\varepsilon) \quad \text{on } [0, T) \tag{24}$$
with $u_\varepsilon(0) \overset{S}{\rightharpoonup} u_0$, and is well-prepared in the sense that $F_\varepsilon(u_\varepsilon(0)) = F(u_0) + o(1)$, then $u_\varepsilon(t) \overset{S}{\rightharpoonup} u(t)$, where $u$ is the solution to
$$\begin{cases} \partial_t u = -\nabla_Y F(u), \\ u(0) = u_0. \end{cases}$$

The proof of this abstract result is rather elementary: for all $t < T$ we may write
$$\begin{aligned} F_\varepsilon(u_\varepsilon(0)) - F_\varepsilon(u_\varepsilon(t)) &= -\int_0^t \langle \nabla_{X_\varepsilon} F_\varepsilon(u_\varepsilon(s)),\, \partial_t\, u_\varepsilon(s)\rangle_{X_\varepsilon}\, ds \\ &= \frac{1}{2}\int_0^t \|\nabla_{X_\varepsilon} F_\varepsilon(u_\varepsilon)\|^2_{X_\varepsilon} + \|\partial_t u_\varepsilon\|^2_{X_\varepsilon}\, ds \\ &\geq \frac{1}{2}\int_0^t \|\nabla_Y F(u)\|^2_Y + \|\partial_t u\|^2_Y\, ds - o(1) \\ &\geq \int_0^t -\langle \nabla_Y F(u(s)),\, \partial_t u(s)\rangle_Y\, ds - o(1) \qquad (25) \\ &= F(u(0)) - F(u(t)) - o(1), \end{aligned}$$

hence
$$F(u(0)) - F(u(t)) \leq F_\varepsilon(u_\varepsilon(0)) - F_\varepsilon(u_\varepsilon(t)) + o(1).$$
But by well-preparedness, $F_\varepsilon(u_\varepsilon(0)) = F(u(0)) + o(1)$, thus
$$F_\varepsilon(u_\varepsilon(t)) \leq F(u(t)) + o(1).$$
But $F_\varepsilon \xrightarrow{\Gamma} F$ implies $\varliminf_{\varepsilon\to 0} F_\varepsilon(u_\varepsilon(t)) \geq F(u(t))$. Therefore we must have equality everywhere and in particular equality in the Cauchy–Schwarz type relation (25), that is
$$\frac{1}{2}\int_0^t \|\nabla_Y F(u)\|^2_Y + \|\partial_t u\|^2_Y\, ds = \int_0^t -\langle \nabla_Y F(u(s)),\, \partial_t u(s)\rangle_Y$$

or

$$\int_0^t \|\nabla F(u) + \partial_t u\|_Y^2 \, ds = 0.$$

Hence, we conclude that $\partial_t u = -\nabla_Y F(u)$, for a.e. $t \in [0, T)$.

The method should and can be extended to infinite-dimensional limiting spaces and to the case where the Hilbert structures $X_\varepsilon$ and $Y$ (in particular $Y$) depend on the point, forming a sort of Hilbert manifold structure. In fact we can write down an analogous abstract result using the theory of "minimizing movements" of De Giorgi formalized by Ambrosio–Gigli–Savarè [3], a notion of gradient flows on structures which are not differentiable but simply metric structures.

**6.1.2. The result for Ginzburg–Landau without magnetic field.** Applying this abstract method to $F_\varepsilon = E_\varepsilon - \pi n |\log \varepsilon|$ and $F = W$ (with a prescribed number of vortices, and prescribed degrees), we retrieve the dynamical law of vortices which had been first established by Lin and Jerrard–Soner by PDE methods:

**Theorem 6.1** ([29], [25], [46]). *Let $u_\varepsilon$ be a family of solutions of*

$$\frac{\partial_t u}{|\log \varepsilon|} = \Delta u + \frac{u}{\varepsilon^2}(1 - |u|^2) \quad \text{in } \Omega$$

*with either*

$$u_\varepsilon = g \ \text{ on } \partial\Omega \quad \text{or} \quad \frac{\partial u_\varepsilon}{\partial n} = 0 \ \text{ on } \partial\Omega$$

*such that*

$$\operatorname{curl} \langle i u_\varepsilon, \nabla u_\varepsilon \rangle (0) \rightharpoonup 2\pi \sum_{i=1}^n d_i \delta_{a_i^0} \quad \text{as } \varepsilon \to 0$$

*with $a_i^0$ distinct points in $\Omega$, $d_i = \pm 1$, and*

$$E_\varepsilon(u_\varepsilon)(0) - \pi n |\log \varepsilon| \le W(a_i^0) + o(1). \tag{26}$$

*Then there exists $T^* > 0$ such that for all $t \in [0, T^*)$,*

$$\operatorname{curl} \langle i u, \nabla u \rangle (t) \rightharpoonup 2\pi \sum_{i=1}^n d_i \delta_{a_i(t)}$$

*as $\varepsilon \to 0$, with*

$$\begin{cases} \dfrac{da_i}{dt} = -\dfrac{1}{\pi} \nabla_i W(a_1(t), \dots, a_n(t)), \\ a_i(0) = a_i^0, \end{cases} \tag{27}$$

*where $T^*$ is the minimum of the collision time and exit time of the vortices under this law.*

Thus, as expected, vortices move along the gradient flow for their interaction $W$, and this reduces the PDE to a finite dimensional evolution (a system of ODE's).

The difficulty is in proving that the abstract conditions (22)–(23) hold in the Ginzburg–Landau setting. For example the first relation (22) relates the velocity of underlying vortices to $\partial_t u_\varepsilon$ and can be read

$$\varliminf_{\varepsilon\to 0} \frac{1}{|\log\varepsilon|} \int_{[0,t]\times\Omega} |\partial_t u_\varepsilon|^2 \, ds \geq \pi \sum_i \int_0^t |d_t\, a_i|^2 \, ds \tag{28}$$

assuming $\operatorname{curl}\langle iu, \nabla u_\varepsilon\rangle(t) \rightharpoonup 2\pi \sum_i d_i \delta_{a_i(t)}$, as $\varepsilon \to 0$, for all $t$ and $d_i = \pm 1$. This turns out to hold as a general relation (as proved in [45]), without requiring the configurations to solve any particular equation; it is related to the topological nature of the vortices.

**6.1.3. Dynamical law for Ginzburg–Landau with magnetic field.** By the same method, we obtained the dynamics of a bounded number of vortices for the full Ginzburg–Landau equations with magnetic field, i.e. the gradient-flow of (1), for large applied fields (the result for bounded applied fields had been obtained by Spirn [52]).

Assuming that $h_{\text{ex}} = \lambda|\log\varepsilon|$, $0 < \lambda < \infty$, we obtained in [46] that, for energetically well-prepared solutions $(u_\varepsilon, A_\varepsilon)$ of (GL), such that $\mu(u_\varepsilon, A_\varepsilon)(0) \rightharpoonup 2\pi \sum_{i=1}^n d_i \delta_{a_i^0}$, with $d_i = \pm 1$, we have for all $t \in [0, T^*)$,

$$\mu(u_\varepsilon, A_\varepsilon)(t) \rightharpoonup 2\pi \sum_{i=1}^n d_i \delta_{a_i(t)}$$

with the dynamical law

$$\frac{da_i}{dt} = -d_i \lambda \nabla h_0(a_i(t)), \quad a_i(0) = a_i^0$$

for all $i$, where $T^*$ is the minimum of the collision time and of the exit time from $\Omega$ for this law of motion.

**6.1.4. Stability of critical points.** In [50], we extended the "$\Gamma$-convergence of gradient flows" method above to the second order, i.e. we gave conditions on the second derivatives of the energies $F_\varepsilon$ $\Gamma$-converging to $F$ which ensure that critical points of $F_\varepsilon$ converge to critical points of $F$ (condition (23) above already ensures it) and that *moreover* stable critical points (in the sense of nonnegative Hessian) of $F_\varepsilon$ converge to stable critical points of $F$ (and more generally bounding from below the Morse index of the critical points of $F_\varepsilon$ by that of those of $F$). The abstract condition is roughly the following: for any family $u_\varepsilon$ of critical points of $F_\varepsilon$ such that $u_\varepsilon \overset{S}{\rightharpoonup} u$; for any $V$, we can find $v_\varepsilon(t)$ defined in a neighborhood of $t = 0$, such that $\partial_t v_\varepsilon(0)$

depends on $V$ in a linear and one-to-one manner, and

$$v_\varepsilon(0) = u_\varepsilon \tag{29}$$

$$\lim_{\varepsilon\to 0} \tfrac{d}{dt}_{|t=0} F_\varepsilon(v_\varepsilon(t)) = \tfrac{d}{dt}_{|t=0} F(u+tV) = dF(u).V \tag{30}$$

$$\lim_{\varepsilon\to 0} \tfrac{d^2}{dt^2}_{|t=0} F_\varepsilon(v_\varepsilon(t)) = \tfrac{d^2}{dt^2}_{|t=0} F(u+tV) = \langle D^2F(u)V, V\rangle. \tag{31}$$

We show that these conditions hold for (3) and deduce the result

**Theorem 6.2** ([50]). *Let $u_\varepsilon$ be a family of solutions of* (4) *such that $E_\varepsilon(u_\varepsilon) \le C|\log\varepsilon|$, with either Dirichlet or homogeneous Neumann boundary conditions. Then, there exists a family of points $a_1, \dots, a_n$ and nonzero integers $d_1, \dots, d_n$ such that, up to extraction of a subsequence,*

$$\operatorname{curl}(iu_\varepsilon, \nabla u_\varepsilon) \rightharpoonup 2\pi \sum_{i=1}^{n} d_i \delta_{a_i},$$

*where $(a_1, \dots, a_n)$ is a critical point of $W$. Moreover, if $u_\varepsilon$ is a stable solution of* (4) *then $(a_1, \dots, a_n)$ is a stable critical point of $W$; and more generally, denoting by $n_\varepsilon^+$ the dimension of the space spanned by eigenvectors of $D^2E_\varepsilon(u_\varepsilon)$ associated to positive eigenvalues and $n^+$ the dimension of the space spanned by eigenvectors of $D^2W(a_i)$ associated to positive eigenvalues* (*resp. $n_\varepsilon^-$ and $n^-$ for negative eigenvalues*)*, we have, for $\varepsilon$ small enough,*

$$n_\varepsilon^+ \ge n^+, \quad n_\varepsilon^- \ge n^-. \tag{32}$$

One of the interesting consequences of the theorem is the following, a consequence of the fact that the renormalized energy in Neumann boundary condition has no nontrivial stable critical point.

**Theorem 6.3.** *Let $u_\varepsilon$ be a family of nonconstant solutions of* (4) *with homogeneous Neumann boundary condition $\frac{\partial u}{\partial n} = 0$ on $\partial\Omega$, such that $E_\varepsilon(u_\varepsilon) \le C|\log\varepsilon|$, then for $\varepsilon$ small enough, $u_\varepsilon$ is unstable.*

This shows that the model without magnetic field (4) cannot stabilize vortices, contrarily to the one with nonzero applied magnetic field.

This extended a result of Jimbo–Morita [26] (see also Jimbo–Sternberg [27] with magnetic field) valid for any $\varepsilon$ but for convex domains.

**6.2. PDE-based results.** Most results on convergence of solutions of the Ginzburg–Landau flow to solutions of the flow for limiting energies were proved by PDE-based methods. We briefly review them.

**6.2.1. Heat flow in higher dimensions.** The convergence of the flow for $E_\varepsilon$ is also true in higher dimensions where the limiting energy-density is length/surface, it was established (see [8], [31]) that the limit of the parabolic evolution of $E_\varepsilon$ is a Brakke flow (a weak form of mean-curvature flow, which is the expected gradient flow of the limiting energy).

**6.2.2. Other flows.** The Schrödinger flow of (4), also called the Gross–Pitaevskii equation, is considered in superfluids, nonlinear optics and Bose–Einstein condensation. The limiting dynamical law of vortices is still the corresponding one (i.e. the Hamiltonian flow) for the limiting renormalized energy

$$\frac{da_i}{dt} = -\frac{1}{\pi}\nabla_i^{\perp} W(a_1, \ldots, a_n).$$

The convergence was proved, still with well-prepared assumptions, by Colliander–Jerrard [12] on a torus, and by Lin–Xin [32] in the whole plane. In the case of the wave flow, the analogous limiting dynamical law was established by Jerrard in [23].

**6.3. Collision issues.** The result of Theorem 6.1 is valid only up to collision time under the law (27), but collisions do happen if there are vortices of opposite degrees. The question of understanding the collisions and extending the motion law passed them is delicate. Bethuel–Orlandi–Smets [9], [10] treated this question, as well as other issues of non well-prepared data, vortex-splitting and phase-vortex interaction in infinite domains.

In [51], the collision problem was approached with the idea of basing the study on the energy, like for the "Γ-convergence of gradient flow". We proved that when several vortices become very close to each other (but not too close) a dynamical law after blow-up can be derived through the same method presented above. When vortices become too close to apply this, we focused on evaluating energy dissipation rates, through the study of the perturbed Ginzburg–Landau equation

$$\Delta u + \frac{1}{\varepsilon^2} u(1 - |u|^2) = f_\varepsilon \quad \text{in } \Omega, \tag{33}$$

with Dirichlet or Neumann boundary data, where $f_\varepsilon$ is given in $L^2(\Omega)$ (the instantaneous energy-dissipation rate in the dynamics is exactly $|\log\varepsilon| \|f_\varepsilon\|^2_{L^2(\Omega)}$). We prove that the "energy-excess" (meaning the difference between $E_\varepsilon - \pi n |\log\varepsilon|$ and the renormalized energy $W$ of the underlying vortices) is essentially controlled by $C\|f_\varepsilon\|^2_{L^2}$. We then show that when $u$ solves (33) and has vortices which become very close, forming what we call an "unbalanced cluster" in the sense that $\sum_i d_i^2 \neq \left(\sum_i d_i\right)^2$ in the cluster (see [51] for a precise definition), then a lower bound for $\|f_\varepsilon\|_{L^2}$ must hold:

**Theorem 6.4** ([51]). *Let $u_\varepsilon$ solve* (33) *with $E_\varepsilon(u_\varepsilon) \leq C|\log\varepsilon|$, $|\nabla u_\varepsilon| \leq \frac{M}{\varepsilon}$ and $|u_\varepsilon| \leq 1$. There exists $l_0 > 0$ such that, if $u_\varepsilon$ has an unbalanced cluster of vortices at the scale $l < l_0$ then*

$$\|f_\varepsilon\|^2_{L^2(\Omega)} \geq \min\left(\frac{C}{l^2|\log\varepsilon|}, \frac{C}{l^2\log^2 l}\right). \tag{34}$$

In particular, when vortices get close to each other, say two vortices of opposite degrees for example, then they form an unbalanced cluster of vortices at scale

$l =$ their distance, and the relation (34) gives a large energy-dissipation rate (scaling like $1/l^2$). This serves to show that such a situation cannot persist for a long time and we are able to prove that the vortices collide and disappear in time $Cl^2 + o(1)$, with all energy-excess dissipating in that time. Thus after this time $o(1)$, the configuration is again "well-prepared" and Theorem 6.1 can be applied again, yielding the dynamical law with the remaining vortices, until the next collision, etc.

# Recent developments in elliptic partial differential equations of Monge–Ampère type

Neil S. Trudinger*

**Abstract.** In conjunction with applications to optimal transportation and conformal geometry, there has been considerable research activity in recent years devoted to fully nonlinear, elliptic second order partial differential equations of a particular form, given by functions of the Hessian plus a lower order matrix function. Regularity is determined through the behaviour of this function with respect to the gradient variables. We present a selection of second derivative estimates and indicate briefly their application to optimal transportation and conformal deformation of Riemannian manifolds.

**Mathematics Subject Classification (2000).** Primary 35J60, 35J65; Secondary 53A30.

**Keywords.** Fully nonlinear elliptic partial differential equations, Monge–Ampère type, optimal transportation, conformal deformation.

## 1. Introduction

In conjunction with applications to optimal transportation and conformal geometry, there has been considerable research activity in recent years devoted to fully nonlinear, elliptic second order partial differential equations of the form,

$$\mathcal{F}[u] := F\{D^2u + A(\cdot, u, Du)\} = B(\cdot, u, Du), \tag{1.1}$$

in domains $\Omega$ in Euclidean $n$-space, $\mathbb{R}^n$, as well as their extensions to Riemannian manifolds. Here the functions $F\colon \mathbb{R}^n \times \mathbb{R}^n \to \mathbb{R}$, $A\colon \Omega \times \mathbb{R} \times \mathbb{R}^n \to \mathbb{R}^n \times \mathbb{R}^n$, $B\colon \Omega \times \mathbb{R} \times \mathbb{R}^n \to \mathbb{R}$ are given and the resultant operator $\mathcal{F}$ is well-defined classically for functions $u \in C^2(\Omega)$. As customary $Du$ and $D^2u$ denote respectively the gradient vector and Hessian matrix of second derivatives of $u$, while we also use $x$, $z$, $p$, $r$ to denote points in $\Omega$, $\mathbb{R}$, $\mathbb{R}^n$, $\mathbb{R}^n \times \mathbb{R}^n$ respectively with corresponding partial derivatives denoted, when there is no ambiguity, by subscripts. For example $F_r = \left[\frac{\partial F}{\partial r_{ij}}\right]$, $F_p = \left(\frac{\partial F}{\partial p_1}, \ldots, \frac{\partial F}{\partial p_n}\right)$ etc. The operator $\mathcal{F}$ is *elliptic* with respect to $u$ whenever the matrix

$$F_r\left\{D^2u + A(\cdot, u, Du)\right\} > 0. \tag{1.2}$$

Unless indicated otherwise we will assume the matrix $A$ is symmetric, but it is also important to address the possibility that it is not. When $A \equiv 0$, (1.1) reduces to the

*Research supported by the Australian Research Council.

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

well-studied Hessian equation,

$$\mathcal{F}[u] = F\left(D^2u\right) = B, \tag{1.3}$$

while for $F(r) = \det r$, we obtain a *Monge–Ampère equation* of the form

$$\mathcal{F}[u] = \det\left\{D^2u + A(\cdot, u, Du)\right\} = B(\cdot, u, Du), \tag{1.4}$$

which is preserved under coordinate changes, unlike the standard Monge–Ampère equation, when $A \equiv 0$. The operator $\mathcal{F}$ in (1.4) is elliptic with respect to $u$ whenever

$$D^2u + A(\cdot, u, Du) > 0, \tag{1.5}$$

which implies $B > 0$.

Monge–Ampère equations of the general form (1.4) arise in applications, notably in optimal transportation, through the prescription of the absolute value of the Jacobian determinant of a mapping $T = T_u : \Omega \to \mathbb{R}^n$ given by

$$T_u = Y(\cdot, u, Du), \tag{1.6}$$

where $Y : \Omega \times \mathbb{R} \times \mathbb{R}^n \to \mathbb{R}^n$ is a given vector field, that is

$$|\det DT_u| = \psi(\cdot, u, Du) \tag{1.7}$$

for a given nonnegative $\psi : \Omega \times \mathbb{R} \times \mathbb{R}^n \to \mathbb{R}$. To write (1.7) in the form (1.4) we assume that $Y$ is differentiable and

$$\det Y_p \neq 0, \tag{1.8}$$

whence by calculation, we obtain

$$\mathcal{F}[u] = \det\{D^2u + Y_p^{-1}(Y_x + Y_z \otimes Du)\} = \psi/|\det Y_p|, \tag{1.9}$$

assuming $\mathcal{F}$ elliptic with respect to $u$. When the vector field $Y$ is independent of $z$ and generated by a *cost function* $c : \mathbb{R}^n \times \mathbb{R}^n \to \mathbb{R}$, through the equations

$$c_x(\cdot, Y(\cdot, p)) = p \tag{1.10}$$

we obtain the *optimal transportation* equation,

$$\mathcal{F}[u] = \det\left\{D^2u - D_x^2c(\cdot, Y(\cdot, Du))\right\} = \psi/|\det Y_p|. \tag{1.11}$$

Note that by differentiation of (1.10) we have

$$\begin{aligned} c_{x,y}(\cdot, Y) &= Y_p^{-1}, \\ c_{xx}(\cdot, Y) &= -Y_p^{-1}Y_x. \end{aligned} \tag{1.12}$$

In conformal geometry, equations of the form (1.1) arise from the study of the Schouten tensor of a Riemannian manifold under conformal deformation of its metric.

When the functions $F$ are homogeneous we obtain, in the special case of Euclidean space $\mathbb{R}^n$, equations of the form (1.1), where the matrix $A$ is given by

$$A(p) = -\tfrac{1}{2}|p|^2 I + p \otimes p. \tag{1.13}$$

Here we observe that, as in equation (1.9), we may write

$$A(p) = Y_p^{-1} Y_x(\cdot, p), \tag{1.14}$$

where $Y$ is the vector field

$$Y(x, p) = x - p/|p|^2 \tag{1.15}$$

generated by the cost function

$$c(x, y) = \log|x - y|. \tag{1.16}$$

The regularity of solutions of equations of the form (1.1) depends on the behaviour of the matrix $A$ with respect to the $p$ variables. Letting $\mathcal{U} \subset \Omega \times \mathbb{R} \times \mathbb{R}^n$, we say that $A$ is *regular* in $\mathcal{U}$ if

$$D_{p_k p_\ell} A_{ij}\, \xi_i\, \xi_j\, \eta_k\, \eta_\ell \leq 0 \tag{1.17}$$

in $\mathcal{U}$, for all $\xi, \eta \in \mathbb{R}^n$ with $\xi \cdot \eta = 0$; and *strictly regular* in $\mathcal{U}$ if there exists a constant $a_0 > 0$ such that

$$D_{p_k p_\ell} A_{ij}\, \xi_i\, \xi_j\, \eta_k\, \eta_\ell \leq -a_0|\xi|^2|\eta|^2 \tag{1.18}$$

in $\mathcal{U}$, for all $\xi, \eta \in \mathbb{R}^n$ with $\xi \cdot \eta = 0$.

These conditions were introduced in [23], [31] and called there A3w, A3 respectively. As we will explain in this paper, they are the natural conditions for regularity. Note that the matrix $A$ in (1.13) trivially satisfies (1.18) in $\mathbb{R}^n$, with $a_0 = 1$.

## 2. Second derivative estimates

The key estimates for classical solutions of equations of the form (1.1) are bounds for second derivatives as higher order estimates and regularity follows from the fully nonlinear theory [10], [21]. Here we present a selection of estimates for regular and strictly regular matrix functions $A$. For all these estimates we will assume $A$ and $B$ are $C^2$ smooth.

**2.1. Interior estimates.** Under the hypothesis of strict regularity we get quite strong interior estimates for very general functions $F$. Indeed we may assume that $F$ is positive, increasing and concave on some convex open set $\Gamma \subset \mathbb{S}^n$, which is closed under addition of the positive cone. Here $\mathbb{S}^n$ denotes the subspace of $\mathbb{R}^n \times \mathbb{R}^n$ consisting of the symmetric matrices. Suppose also that

$$\text{trace } F_r \to \infty \quad \text{as } \lambda_{\max}(r) \to \infty \tag{2.1}$$

on subsets of $\Gamma$ where $F \geq \delta$ for any $\delta > 0$. The following estimate extends Theorem 4.1 and Remark 4.1 in [23].

**Theorem 2.1.** *Let $u \in C^4(\Omega)$, $D^2u + A \in \Gamma$, be a solution of* (1.1)*, with $A$ strictly regular on the set $\mathcal{U} = \{(x, z, p) \mid x \in \Omega, z = u(x), p = Du(x)\}$. Then for any $\Omega' \subset\subset \Omega$ we have*

$$\sup_{\Omega'} |D^2u| \leq C, \tag{2.2}$$

*where $C$ is a constant depending on $\Omega'$, $\Omega$, $A$, $B$ and $|u|_{1;\Omega}$.*

**2.2. Dirichlet problem.** We present a global second derivative estimate for solutions of the Dirichlet problem, or first boundary value problem, for the Monge–Ampère type equation (1.4). First we introduce a convexity condition for domains, which was fundamental in our applications to optimal transportation in [23], [31]. Namely if $\Omega$ is a connected domain in $\mathbb{R}^n$, with $\partial\Omega \in C^2$, and $A \in C^1(\Omega \times \mathbb{R} \times \mathbb{R}^n; \mathbb{S}^n)$ we say that $\Omega$ is *$A$-convex* (*uniformly $A$-convex*), with respect to $\mathcal{U} \subset \Omega \times \mathbb{R} \times \mathbb{R}^n$, if

$$\left[D_i\, \gamma_j(x) + A_{ij,p_k}(x, z, p)\, \gamma_k(x)\right] \tau_i\, \tau_j \geq 0, \quad (\delta_0), \tag{2.3}$$

for all $x \in \partial\Omega$, $x, z, p \in \overline{\mathcal{U}}$, unit outer normal $\gamma$ and unit tangent vector $\tau$ (for some $\delta_0 > 0$).

When $A \equiv 0$, $A$-convexity reduces to the usual convexity. We also say that a domain $\Omega$ is *$A$-bounded*, with respect to $\mathcal{U} \subset \Omega \times \mathbb{R} \times \mathbb{R}^n$, if there exists a function $\varphi \in C^2(\Omega)$ satisfying

$$D^2\varphi(x) + A_{p_k}(x, z, p)\, D_k\, \varphi \geq \delta_0\, I \tag{2.4}$$

for all $x \in \Omega$, $(x, z, p) \in \mathcal{U}$. Note that when $A \equiv 0$, any bounded domain is $A$-bounded. A domain $\Omega$ is then both uniformly $A$-convex and $A$-bounded if there exists a defining function $\varphi \in C^2(\overline{\Omega})$, satisfying $\varphi = 0$ on $\partial\Omega$, $D\varphi \neq 0$ on $\partial\Omega$, together with (2.4).

**Theorem 2.2.** *Let $u \in C^4(\overline{\Omega})$ be an elliptic solution of equation* (1.4) *in $\Omega$, satisfying $u = g$ on $\partial\Omega$, where $\partial\Omega \in C^4$, $g \in C^4(\overline{\Omega})$. Suppose that $A$ is regular on the set $\mathcal{U} = \{(x, z, p) \mid x \in \Omega, z = u(x), p = Du(x)\}$, with $\Omega$ uniformly $A$-convex and $A$-bounded with respect to $\mathcal{U}$. Then we have the estimate,*

$$\sup_{\Omega} |D^2u| \leq C, \tag{2.5}$$

*where $C$ is a constant depending on $A$, $B$, $\Omega$, $\varphi$ and $|u|_{1;\Omega}$.*

**2.3. Second boundary value problem.** Now we turn our attention to the prescribed Jacobian equation, in the form (1.9). The second boundary value problem, or natural boundary condition, involves the prescription of the image of the mapping $T_u$ in (1.6), that is

$$T(\Omega) = \Omega^* \tag{2.6}$$

for some given domain $\Omega^* \subset \mathbb{R}^n$. If the positive function $\psi$ is given by

$$\psi(x, z, p) = f(x)/g \circ Y(x, z, p) \tag{2.7}$$

for positive $f, g \in C^0(\Omega), C^0(\Omega^*)$ respectively, and $T$ is a diffeomorphism (for example when $\Omega$ is convex), we obtain the necessary condition for solvability,

$$\int_\Omega f = \int_{\Omega^*} g, \tag{2.8}$$

which is the *mass balance condition* in optimal transportation. Following our previous notions of domain convexity, we will say that $\Omega$ is *$Y$-convex* (*uniformly $Y$-convex*, *$Y$-bounded*) with respect to $\Omega^*$ if $\Omega$ is $A$-convex (uniformly $A$-convex, $A$-bounded) with respect to $\mathcal{U}_Y = \{(x, z, p) \mid x \in \Omega, Y(x, z, p) \in \Omega^*\}$, where the matrix function $A$ is given by

$$A = Y_p^{-1}(Y_x + Y_z \otimes p) \tag{2.9}$$

as in equation (1.9). The target domain $\Omega^*$ is *$Y^*$-convex*, with respect to $\Omega$, if for each $(x, z) \in \Omega \times \mathbb{R}$, the set

$$\mathcal{P}(x, z) = \{p \in \mathbb{R}^n \mid Y(x, z, p) \in \Omega^*\} \tag{2.10}$$

is *convex* in $\mathbb{R}^n$ and *uniformly $Y^*$-convex*, with respect to $\Omega$, if $\mathcal{P}(x, z)$ is uniformly convex, with respect to $(x, z) \in \Omega \times \mathbb{R}$. Note that for $\partial\Omega^* \in C^2$, these concepts may also be expressed in the form (2.3), and that when $Y$ is generated by a cost function, which happens when $Y_z \equiv 0$, by virtue of the assumed symmetry of $A$, they are dual to each other (see Section 3).

**Theorem 2.3.** *Let $u \in C^4(\overline{\Omega})$ be an elliptic solution of equation* (1.4) *in $\Omega$, satisfying* (2.6)*, where $\partial\Omega, \partial\Omega^* \in C^4$ and $\Omega, \Omega^*$ are uniformly $Y$-convex, $Y^*$-convex with respect to each other. Suppose also that $\Omega$ is $Y$-bounded and that $A$ is regular on $\mathcal{U}_Y$. Then we have the estimate*

$$\sup_\Omega |D^2 u| \leq C, \tag{2.11}$$

*where $C$ depends on $Y$, $\psi$, $\Omega$, $\Omega^*$ and $|u|_{1;\Omega}$.*

### 2.4. Remarks

**1.** Estimates in $C^3(\overline{\Omega})$ automatically follow from the assumed data regularity in Theorems 2.2 and 2.3, by virtue of the global $C^{2,\alpha}$ estimates [18] and [21]. Classical existence theorems then follow by the method of continuity under additional hypotheses to control the solutions and their gradients.

**2.** The boundary condition (2.6) is a nonlinear *oblique* boundary condition of the form

$$G(x, u, Du) := \varphi^* \circ Y(x, u, Du) = 0, \tag{2.12}$$

where $\varphi^*$ is a defining function for $\Omega^*$. If $|\nabla\varphi^*| = 1$ on $\partial\Omega^*$ we obtain, for $c^{i,j} = D_{p_i} Y^j$,

$$\chi := \gamma \, . G_p(x, u, Du) = c^{i,j} \, \gamma_i \, \gamma_j^* > 0, \tag{2.13}$$

by virtue of ellipticity, and the geometric conditions on $\Omega$ and $\Omega^*$ are used to estimate $\chi$ from below, [31].

**3.** The special cases $A \equiv 0$ of the standard Monge–Ampère equation in Theorems 2.2 and 2.3 are due to Ivochkina [17], Krylov [18], Caffarelli, Nirenberg and Spruck [5] (Theorem 2.2), and Caffarelli [2] and Urbas [32] (Theorem 2.3). Sharp versions for Hölder continuous inhomogeneous terms were proved by Trudinger and Wang [29] and Caffarelli [2].

**4.** Theorems 2.1, 2.2 and 2.3 extend to non-symmetric matrices $A$ in two dimensions.

**5.** The condition of uniform $A$-convexity in Theorem 2.2 may be replaced by the more general condition that there exists a strict sub-solution taking the same boundary conditions, as for the case $A \equiv 0$ in [12].

## 3. Optimal transportation

Let $\Omega$ and $\Omega^*$ be bounded domains in $\mathbb{R}^n$ and $f, g$ nonnegative functions in $L^1(\Omega)$, $L^1(\Omega^*)$ respectively satisfying the mass balance condition (2.8). Let $c \in C^0(\mathbb{R}^n \times \mathbb{R}^n)$ be a cost function. The corresponding Monge–Kantorovich problem of optimal transportation is to find a measure preserving mapping $T_0$ which maximizes (or minimizes) the cost functional,

$$\mathcal{C}(T) = \int_\Omega f(x) \, c(x, T(x)) \, dx, \tag{3.1}$$

over the set $\mathcal{T}$ of measure preserving mappings $T$ from $\Omega$ to $\Omega^*$. A mapping T is called measure preserving if it is Borel measurable and for any Borel set $E \subset \Omega^*$,

$$\int_{T^{-1}(E)} f = \int_E g. \tag{3.2}$$

For the basic theory the reader is referred to the accounts in works such as [9], [24], [33], [34]. To fit the exposition in our previous sections, we consider maximization problems rather than minimization, noting that it is trivial to pass between them replacing $c$ by $-c$.

**3.1. Kantorovich potentials.** The dual functional of Kantorovich is defined by

$$I(u, v) = \int_\Omega f(x) \, u(x) \, dx + \int_{\Omega^*} g(y) \, v(y) \, dy, \tag{3.3}$$

for $(u, v) \in K$ where

$$K = \{(u, v) \mid u \in C^0(\Omega), v \in C^0(\Omega^*), \\ u(x) + v(y) \geq c(x, y), \text{ for all } x \in \Omega, y \in \Omega^*\}. \tag{3.4}$$

It is readily shown that $\mathcal{C}(T) \leq I(u, v)$, for all $T \in \mathcal{T}$, $u, v \in K$. To solve the Monge–Kantorovich problem, we assume $c \in C^2(\mathbb{R}^n \times \mathbb{R}^n)$ and that for each $x \in \Omega$, $p \in \mathbb{R}^n$ there exists a unique $y = Y(x, p)$ satisfying (1.10), together with the corresponding condition for $x$ replaced by $y \in \Omega^*$ and

$$|\det c_{x,y}| \geq c_0 \tag{3.5}$$

on $\Omega \times \Omega^*$ for some constant $c_0 > 0$. Then there exist semi-convex functions $(u, v) \in K$ and a mapping $T = T_u$, given by

$$T_u = Y(\cdot, Du) \tag{3.6}$$

almost everywhere in $\Omega$, such that

$$\mathcal{C}(T) = I(u, v). \tag{3.7}$$

The functions $u, v$, which are uniquely determined up to additive constants, are called *potentials* and are related by

$$u(x) = \sup_{\Omega^*}\{c(x, \cdot) - v(\cdot)\}, \quad v(y) = \sup_{\Omega}\{c(\cdot, y) - u(\cdot)\}. \tag{3.8}$$

Furthermore, for positive densities $f$, $g$, the potential function $u$ will be an elliptic solution of equation (1.11) almost everywhere in $\Omega$ (at points where it is twice differentiable). If $u \in C^2(\overline{\Omega})$, then $u$ is a classical solution of the second boundary value problem (2.6).

**3.2. Interior regularity.** Consistent with our definitions in Section 2, $\Omega$ is $c$-convex with respect to $\Omega^*$ if $c_y(\cdot, y)(\Omega)$ is convex for all $y \in \Omega^*$ and $\Omega^*$ is $c^*$-convex if $c_x(x, \cdot)(\Omega^*)$ is convex for all $x \in \Omega$. As a consequence of Theorem 2.1, we have the main result in [23].

**Theorem 3.1.** *Let $\Omega, \Omega^*$ be bounded domains in $\mathbb{R}^n$, $f \in C^2(\Omega) \cap L^\infty(\Omega)$, $g \in C^2(\Omega^*) \cap L^\infty(\Omega^*)$, $\inf f, \inf g > 0$. Let $c \in C^4(\mathbb{R}^n \times \mathbb{R}^n)$ and $\Omega^*$ be $c^*$-convex with respect to $\Omega$. Suppose that $A$ is strictly regular on the set $\mathcal{U}_Y$, where $A(x, p) = -D_x^2 c(x, Y(x, p))$ and $Y$ is given by* (1.10)*. Then the potential $u \in C^3(\Omega)$.*

**3.3. Global regularity.** From the global second derivative estimate, Theorem 2.3, we obtain a global regularity result, corresponding to Theorem 3.1, which is proved in [31]. For its formulation we say that $\Omega$ ($\Omega^*$) is *uniformly c-convex* (*c*-convex*), with respect to $\Omega^*$, ($\Omega$), if the images $c_y(\cdot, y)(\Omega)$ ($c_x(x, \cdot)(\Omega^*)$) are uniformly convex with respect to $y \in \Omega^*$ ($x \in \Omega$). This agrees with our previous definitions in terms of the vector field $Y$ and matrix $A$ determined by $c$.

**Theorem 3.2.** *Let $\Omega$ and $\Omega^*$ be bounded $C^4$ domains in $\mathbb{R}^n$, $f \in C^2(\overline{\Omega})$, $g \in C^2(\overline{\Omega^*})$, $\inf f > 0$, $\inf g > 0$. Let $c \in C^4(\mathbb{R}^n \times \mathbb{R}^n)$ and let $\Omega$, $\Omega^*$ be uniformly c-convex, $c^*$-convex with respect to each other. Suppose also that $\Omega$ is $Y$-bounded and $A$ is regular on $\mathcal{U}_Y$. Then the potential function $u \in C^3(\overline{\Omega})$.*

### 3.4. Remarks

**1.** For the case of quadratic cost functions,

$$c(x, y) = x.y, \quad Y(x, p) = p, \quad A \equiv 0, \tag{3.9}$$

Theorem 3.1 is due to Caffarelli [1], Theorem 3.2 is due to Caffarelli [2] and Urbas [32]. Note that this case is excluded from Theorem 3.1 but embraced by Theorem 3.2. The interior estimate (2.2) is not valid when $A \equiv 0$.

**2.** By exploiting the geometric interpretation of strict regularity, Loeper [22] has shown that the potential $u \in C^{1,\alpha}(\Omega)$ for certain $\alpha > 0$, when the smoothness of the densities $f, g$ is dropped. Moreover he has shown that the regularity of $A$ is a necessary condition for $u \in C^1(\Omega)$ for arbitrary smooth positive densities.

**3.** As shown in [23], the $c^*$-convexity of $\Omega^*$ is also necessary for interior regularity for arbitrary smooth positive densities.

**4.** The condition of $Y$-boundedness may be dropped in Theorem 2.3 in the optimal transportation case [31].

**5.** Various examples of cost functions for which $A$ is regular or strictly regular are presented in [23] and [31].

## 4. Conformal geometry

In recent years the Yamabe problem for the $k$-curvature of the Schouten tensor, or simply the $k$-Yamabe problem, has been extensively studied. Let $(\mathcal{M}, g_0)$ be a smooth compact manifold of dimension $n > 2$ and denote by Ric and $R$ respectively the Ricci tensor and scalar curvature. The $k$-Yamabe problem is to prove the existence of a conformal metric $g = g_u = e^{-2u} g_0$ such that

$$\sigma_k(\lambda(S_g)) = 1 \quad \text{on } \mathcal{M}, \tag{4.1}$$

where $k = 1, \ldots, n$, $\lambda = (\lambda_1, \ldots, \lambda_n)$ denotes the eigenvalues of $S_g$ with respect to the metric $g$, $\sigma_k$ is the $k$th elementary symmetric function given by

$$\sigma_k(\lambda) = \sum_{i_1 < \cdots < i_k} \lambda_{i_1} \cdots \lambda_{i_k}, \tag{4.2}$$

and $S_g$ is the Schouten tensor of $(\mathcal{M}, g)$ given by

$$\begin{aligned} S_g &= \frac{1}{n-2}\Big(\operatorname{Ric} g - \frac{R_g}{2(n-1)}g\Big) \\ &= \nabla^2 u + \nabla u \otimes \nabla u - \tfrac{1}{2}|\nabla u|^2 g_0 + S_{g_0}. \end{aligned} \tag{4.3}$$

Accordingly we obtain the equation

$$\mathcal{F}_k[u] = F_k^{1/k}\big\{g_0^{-1}\left(\nabla^2 u + \nabla u \otimes \nabla u - \tfrac{1}{2}|\nabla u|^2 g_0 + S_{g_0}\right)\big\} = e^{-2u}, \tag{4.4}$$

where $F_k(r)$ denotes the sum of the $k \times k$ principal minors of the matrix $r \in \mathbb{S}^n$, which is elliptic for $\lambda(S_g) \in \Gamma_k$ where $\Gamma_k$ is the cone in $\mathbb{R}^n$ given by

$$\Gamma_k = \{\lambda \in \mathbb{R}^n \mid \sigma_j(\lambda) > 0,\ j = 1, \ldots, k\}, \tag{4.5}$$

(see for example [3], [28]). When $k = 1$, we arrive at the well-known Yamabe problem [27], that was completely resolved by Schoen in [25]. Note that for Euclidean space $\mathbb{R}^n$, we have

$$S_g = D^2 u + Du \otimes Du - \tfrac{1}{2}|Du|^2 I, \tag{4.6}$$

in agreement with (1.13).

The operators $\mathcal{F}_k$ are *strictly regular* in the sense of (1.18) so that interior estimates corresponding to Theorem 2.1 are readily proven, [35], [13], [7], [14]. However crucial ingredients in the solution of the $k$-Yamabe problem are estimates in terms of $\inf u$ only. These were obtained by Guan and Wang [14] and recently simplified by Chen [8], who derived the gradient estimates directly from the second derivative estimates using $\sigma_1(\lambda) \geq 0$. The following theorem, due to Sheng, Trudinger and Wang [26] ($k \leq n/2$), Gursky and Viaclovsky [16] ($k > n/2$) concerns the solvability of the higher order Yamabe problem, $k > 1$.

**Theorem 4.1.** *Let $(\mathcal{M}, g_0)$ be a smooth compact manifold of dimension $n > 2$ and suppose there exists some metric $g_1$ conformal to $g_0$ for which $\lambda(S_{g_1}) \in \Gamma_k$. Then there exists a conformal metric $g$ satisfying* (4.1) *if either $k > n/2$ or $k \leq n/2$ and* (4.1) *has variational structure, that is it is equivalent to an Euler equation of a functional.*

We remark that (4.1) is variational for $k = 1, 2$ and if $(\mathcal{M}, g_0)$ is locally conformally flat otherwise. The case of Theorem 4.1 when $k = 2$, $n = 4$ was proved in the pioneering work of Chang, Yang and Gursky [6], while the locally conformally flat case was proved by Guan and Wang [15] and Li and Li [19], [20]. The cases $k = 2$, $n > 8$ were obtained independently by Ge and Wang [11]. The reader is referred to the various papers cited above for further information. Also a more elaborate treatment of the case $k > n/2$ is presented in [30].

# The initial value problem for nonlinear Schrödinger equations

Luis Vega*

**Abstract.** I will review some recent work done in collaboration with C. E. Kenig, G. Ponce and C. Rolvung on a general method to solve locally in time the initial value problem for non-linear Schrödinger equations under some natural hypotheses of decay and regularity of the coefficients. Also some non-trapping conditions of the solutions of the hamiltonian flow associated to the initial data is needed. We will not assume ellipticity on the matrix of the leading order coefficients but just a non-degeneracy condition. The method is based on energy estimates which can be performed thanks to the construction of an integrating factor. This construction is of independent interest and relies on the analysis of some new pseudo-differential operators.

**Mathematics Subject Classification (2000).** Primary 35Q20; Secondary 35B45.

**Keywords.** Non-linear Schrödinger equations, ultrahyperbolic operators.

## 1. Introduction

In this lecture I shall describe some joint work with C. E. Kenig and G. Ponce on general non-linear Schrödinger equations built on spatial operators which are given by just non-degenerate quadratic forms. It has been and still is a great pleasure and a privilege to work with both of them.

This research was started some time ago in [14], and we could say it has come to a natural end with [16], [22] and [23], these two latter works written in collaboration with C. Rolvung. In the process we have used some fundamental work done by other authors, in particular those by Hayashi and Ozawa [10], Doi [6], [7], [8], and Craig, Kappeler and Strauss [4]. A look at the introduction of the papers [16], [22], and [23] is enough to realize that the precise results are rather technical and lengthy to write. Therefore, this lecture will be mainly expository, and I refer to the reader to the papers mentioned above and to the review given in [21] for the precise statement of the theorems.

We are interested in solving the initial value problem

$$\begin{cases} \partial_t u = i\tilde{\mathcal{L}}u + F(u, \nabla u, \bar{u}, \nabla \bar{u}), \\ u(x,0) = u_0(x), \end{cases} \tag{1}$$

*This work is partially supported by the grant MTM2004-03029.

Proceedings of the International Congress of Mathematicians, Madrid, Spain, 2006

where

- $u(x,t) \in \mathbb{C}$, $x = (x_1, x_2) \in \mathbb{R}^{n_1} \times R^{n_2} = \mathbb{R}^n$, $n = n_1 + n_2$, and $t \in [0, T]$;
- $\tilde{\mathcal{L}}u(x) = \partial_j(\tilde{a}_{jk}(x,t,u,\nabla u,\bar{u},\nabla\bar{u})\partial_k u)$, and $\tilde{A}(u) = (\tilde{a}_{jk})_{jk}$ is a real, symmetric, invertible matrix such that

$$\lim_{|x|\to\infty} \tilde{A} = \begin{pmatrix} \mathbb{I}_{n_1} & 0 \\ 0 & -\mathbb{I}_{n_2} \end{pmatrix}; \tag{2}$$

- $F$ is a regular non-linear function, as is a polynomial with no linear terms.

By solving this equation I mean to find a large enough space $X$ of initial data, and a unique solution $u$ for each $u_0 \in X$ up to a time $T = T(u_0)$ such that $u$ is unique in some space $Y$, and the map $u_0 \mapsto u$ from $X$ to $Y$ is continuous. Typically

$$X = X_{\alpha_0\beta_0} = \{u_0 \text{ such that } x^\alpha \partial^\beta u_0 \in L^2;\ |\alpha| \le \alpha_0,\ |\beta| \le \beta_0\},$$
$$Y = Y_{\alpha_1\beta_1} = \{\mathcal{C}([0,T] : X_{\alpha_1\beta_1})\}$$

for some finite $(\alpha_j, \beta_j)$, $j = 0, 1$, and with possibly $0 < \alpha_1 < \alpha_0$, $0 < \beta_1 < \beta_0$.

There are several reasons which motivate the study of such a general initial value problem. First of all, within this general model there are relevant equations which appear in the physics literature, as Davey–Stewartson and Zakharov–Schulman systems, Landau–Lipschitz equations, the Schrödinger map and others; see [32]. These physical models usually have a very rich algebraic structure which in many cases allows for some short cuts in their analysis; in particular regarding existence results. However, uniqueness generally involves considering the PDE solved by the difference of two solutions which need not have the same algebraic structure as the starting one, but that still is under the general setting given in (1). I will be more precise about this point in Section 3, where the particular case of the Schrödinger map is analyzed.

Another motivation is to get a better understanding of ultrahyperbolic operators including the constant coefficient case

$$\mathcal{L}_0 = \Delta_{x_1} - \Delta_{x_2}.$$

Notice that neither the heat nor the wave flow can be defined for $\mathcal{L}_0$, while the Schrödinger flow

$$e^{it\mathcal{L}_0} \tag{3}$$

makes perfect sense. Our knowledge about this operator is far behind the classical one $e^{it\Delta}$. In Section 9, I gather some information and open questions about linear and non-linear perturbations of the free propagator (3).

The rest of the paper is devoted to explain the assumptions needed to solve (1), and to exhibit the algebraic tools we use to construct the solution. The main result is given in Section 7, and some remarks about the elliptic setting can be found in Section 8.

## 2. Energy estimates

In order to solve equation (1) we use the so-called energy method. This is based on three steps. The first one is to add some artificial viscosity to the right-hand side of (1) depending on $\varepsilon > 0$, and to consider for some $T_\varepsilon > 0$ the equation

$$\begin{cases} \partial_t u_\varepsilon = -\varepsilon \Delta_x^2 + i\tilde{\mathcal{L}} u + F, & t \in [0, T_\varepsilon), \\ u_\varepsilon = u_0, & t = 0. \end{cases} \tag{4}$$

The existence of a solution $u_\varepsilon$ of (4) can be easily proved by Picard iteration, using the regularity properties of the free propagator $e^{-\varepsilon t \Delta^2}$.

The second step relies on proving energy estimates for $u_\varepsilon$ independent of $\varepsilon$. These estimates will give a universal time of existence valid for all $u_\varepsilon$, and also will allow us to pass to the limit in $\varepsilon$ to obtain a solution of (1).

The final step is to prove uniqueness by looking at the equation satisfied by the difference $u_{\varepsilon\varepsilon'} = u_\varepsilon - u_{\varepsilon'}$. It is at this point where to work in a general setting as (1) turns out to be fundamental because the equation for $u_{\varepsilon\varepsilon'}$ is again of the same type.

In the rest of the paper I will mainly focus on the question of the energy estimates, exhibiting the algebraic tools needed to obtain them.

Recall that we have already built the solution $u_\varepsilon$ of (4) with $\tilde{\mathcal{L}}$ as in (1). Hence we can now understand (4) as a linear equation

$$\begin{cases} \partial_t u = \mathcal{L}_\varepsilon u + i\big(\overrightarrow{b_1} \cdot \nabla u + \overrightarrow{b_2} \cdot \nabla \bar{u} + c_1 u + c_2 \bar{u}\big) + f, \\ u(x, 0) = u_0(x), \end{cases} \tag{5}$$

with

$$\mathcal{L}_\varepsilon u = \partial_t a_j(x,t)\partial_k u - \varepsilon \Delta^2 u; \;\; A = \big(a_{jk}(x,t)\big)_{jk} = \big(\tilde{a}_{jk}(x,t,u,\nabla u, \bar{u}, \nabla \bar{u})\partial_k u\big)_{jk}.$$

Therefore it seems appropriate to assume the following hypotheses regarding $A$ and the coefficients $\overrightarrow{b_1}$, $\overrightarrow{b_2}$ and $c_1, c_2$:

H1. $A$ is a regular real symmetric non-degenerate matrix, i.e. there exists $\gamma_0 \in (0, 1)$ such that

$$\gamma_0 |\xi| \leq |A\xi| \leq \gamma_0^{-1} |\xi|.$$

H2. The coefficients $\partial_x a_{jk}$, $\partial_{tx} a_{jk}$, $\partial_t a_{jk}$ have a pointwise decay for a sufficiently large $|x|$,

$$\sup_{|t| \leq T} |\partial_x^\alpha a_{jk}(x,t)| + |\partial_t \partial_x^{\alpha'} a_{jk}(x,t)| \leq \frac{C}{(1+|x|)^N},$$

with $N$, $|\alpha|$ and $|\alpha'|$ large enough, and so that

$$A - \begin{pmatrix} \mathbb{I}_{n_1} & 0 \\ 0 & -\mathbb{I}_{n_2} \end{pmatrix}$$

has a similar decay for a large $|x|$.

H3. $\overrightarrow{b_1}$ and $\overrightarrow{b_2}$ are smooth complex vector fields that decay pointwise together with their derivatives at infinity.

H4. $c_1$ and $c_2$ are smooth complex scalar fields bounded together with their derivatives at infinity.

Let us start assuming that in (5) the external forces $f$ and the potentials $\overrightarrow{b_1}$, $\overrightarrow{b_2}$ and $c_1$, $c_2$ are zero. Then because $A$ is real and symmetric we trivially have

$$\begin{aligned}\frac{d}{dt}\langle u, u\rangle &= \langle \mathcal{L}_\varepsilon u, u\rangle + \langle u, \mathcal{L}_\varepsilon u\rangle \\ &= -\langle iA\partial_x u, \partial_x u\rangle - \langle \partial_x u, iA\partial_x u\rangle - 2\varepsilon\langle \Delta u, \Delta u\rangle \\ &= -2\varepsilon\langle \Delta u, \Delta u\rangle \le 0.\end{aligned} \tag{6}$$

Therefore

$$\sup_{0\le t\le T}\langle u, u\rangle + 2\varepsilon\int_0^T \langle \Delta u, \Delta u\rangle dt \le \langle u(0), u(0)\rangle. \tag{7}$$

If in the above calculation we add zero order terms $c_1$ and $c_2$ we will obtain after integration in time

$$\langle u, u\rangle(t) \le e^{Mt}\langle u, u\rangle(0), \tag{8}$$

with $M = \sup(|c_1| + |c_2|)$. As a conclusion from the point of view of energy estimates zero order terms are harmless.

Let us know consider that first order terms are not trivial. It is straightforward that if $\operatorname{Re}\overrightarrow{b_1}$ is zero and $\overrightarrow{b_2}$ just bounded, an integration by parts as the one given in (6) leads to the same estimate. However, the situation is completely different if $\operatorname{Re}\overrightarrow{b_1} \neq 0$. This can be easily seen even in one dimension.

Consider the model problem

$$\partial_t u = i(\partial_x^2 u + b_1\partial_x u) - \varepsilon\partial_x^4 u, \quad x \in \mathbb{R}. \tag{9}$$

Take for simplicity $b_1 = 1$. Using $\hat{u}$ the Fourier transform of $u$ and Parseval's identity the calculation given in (6) becomes

$$\begin{aligned}\frac{d}{dt}\langle u, u\rangle &= \langle (i\partial_x^2 - \varepsilon\partial_4^x + i\partial_x)u, u\rangle + \langle u, i\partial_x^2 - \varepsilon\partial_x^4 + i\partial_x\rangle \\ &= -\varepsilon\langle \xi^4\hat{u}, \hat{u}\rangle - \langle \xi\hat{u}, \hat{u}\rangle.\end{aligned} \tag{10}$$

Therefore if $\operatorname{supp}\hat{u} \subset (-\infty, 0)$ we can not obtain a uniform bound in $\varepsilon$ for $\langle u, u\rangle$. This is usually called the loss of derivatives obstruction, because regardless of $\varepsilon$ there is in (10) one derivative more on the right-hand side than on the left-hand side. The final conclusion is that we should get rid, if possible, of $\operatorname{Re} b_1$.

Nevertheless there is a simple way of removing the first order term in (9) creating other ones of order zero, which is to use the integrating factor $\exp\left(\frac{1}{2}\int_x^\infty b_1\right)$. For this purpose define

$$v(x, t) = \mathcal{K}u = e^{1/2\int_x^\infty b_1(y,t)dy}u(x, t). \tag{11}$$

The equation for $v$ becomes

$$\partial_t v = i\partial_x^2 v - \varepsilon \mathcal{K} \partial_x^4 u + c(x,t)v, \tag{12}$$

with

$$c(x,t) = \frac{i}{2}\partial_x b_1 + i\frac{b_1^2}{4} + \frac{i}{2}\int_x^\infty \partial_t b_1(y,t)dy. \tag{13}$$

Notice that $\mathcal{K}$ given in (11) is invertible so that

$$\varepsilon \mathcal{K}\partial_x^4 u = \mathcal{K}\partial_x^4 \mathcal{K}^{-1} v = \varepsilon \partial_x^4 v + \varepsilon \text{ (lower order)}.$$

This lower order terms are harmless because they are of order $\varepsilon$ and can be easily absorbed using (7) and taking $T$ small enough. Looking carefully at the calculation above we see that the only assumption we need on $b_1$ is that

$$\sup_{x,\, 0\le t\le T} \left|\operatorname{Re}\int_x^\infty b_1(y,t)\right| + \left|\operatorname{Re}\int_x^\infty \partial_t b_1(y,t)dt\right| \le M. \tag{14}$$

Notice also that because the operator $\mathcal{K}$ is given by multiplication by the integrating factor we have

$$\mathcal{K}\bar{u} = \overline{\mathcal{K}u}. \tag{15}$$

Therefore the symmetry of the good terms $\operatorname{Im} b_1$ and $b_2$ is not destroyed and can be added to (9) so that the computation given above works the same without any extra difficulty.

Finally let us recall that the condition given in (14) is very reminiscent of the one obtained by Mizohata in [27] (see also [11]), and suggests that H3 and H4 are natural assumptions.

## 3. The Schrödinger map

The above analysis rises the natural question of whether or not the integrating factor can be constructed also in higher dimensions. It is at this stage where considering a specific equation and not the general case given in (1) can make a big difference. An illustrative example is the so-called Schrödinger map given by

$$\begin{cases} \overrightarrow{u_t} = \overrightarrow{u} \wedge \Delta \overrightarrow{u}, \quad \overrightarrow{u} = \overrightarrow{u}(x,t), \quad x \in \mathbb{R}^d,\ t \in \mathbb{R},\ d = 1,2, \\ |\overrightarrow{u}|^2 = 1. \end{cases} \tag{16}$$

This equation written in coordinates (for example using the stereographic projection) involves non-linearities in the first order terms. Let us try to understand first the

one dimensional case $d = 1$. Then $\overrightarrow{u}$ is nothing but the tangent vector to a three dimensional curve $\overrightarrow{\gamma}(x,t)$ (i.e. $\overrightarrow{u} = \overrightarrow{\gamma}_x$) which satisfies

$$\begin{cases} \overrightarrow{\gamma}_t = \overrightarrow{\gamma}_x \wedge \overrightarrow{\gamma}_{xx}, \quad x \in \mathbb{R},\ t \in \mathbb{R}, \\ |\overrightarrow{\gamma}_x|^2 = 1. \end{cases} \tag{17}$$

This equation, which is sometimes called the Localized Induction Approximation, was obtained for the first time by Da Rios in 1906, see [5], as a crude approximation of the evolution of a vortex filament within Euler equations. From a geometrical point of view is better to call it the binormal flow because using Frenet equations (17) can be written as

$$\overrightarrow{\gamma}_t = c\,\overrightarrow{b},$$

where $c$ denotes the curvature and $\overrightarrow{b}$ the binormal vector.

In 1972 Hasimoto [9] proposed the transformation

$$\psi(x,t) = c(x,t)e^{i\int_0^x \tau(y,t)\,dy}, \tag{18}$$

with $\tau$ denoting the torsion, to simplify (17) and therefore (16). After some computations he proves that if $\overrightarrow{\gamma}$ satisfies (17) then $\psi$ solves

$$\psi_t = i\psi_{xx} + \frac{i}{2}(|\psi|^2\psi + a(t)), \tag{19}$$

for some real function $a(t)$. Therefore we could understand Hasimoto's transformation (18) as some kind of integrating factor which removes the non-linear first order terms appearing when (16) is written in local coordinates, to the expense of cubic zero order terms which are much easier to handle.

The situation for the Schrödinger map in dimension 2 is much more delicate. Hasimoto's transformation can still be used but it is not possible to remove completely the first order terms; see [1]. The equation obtained after the transformation has a good symmetry from the point of view of energy estimates which allows to prove existence even for $H^1$-solutions. However, much of this symmetry is lost when considering difference of solutions.

Therefore, we are back to the question we started this section with. In the one dimensional case it is possible to construct the integrating factor which greatly simplifies the equations, but a similar transformation even in the two dimensional case is far from clear.

## 4. The integrating factor

Let us go back to our linear equation (5) and to simplify assume in this section that $\varepsilon = 0$. Accordingly we shall write $\mathcal{L}_\varepsilon = \mathcal{L}$. We are looking for an operator $\mathcal{K}$ such that

$$(\mathcal{L}\mathcal{K} - \mathcal{K}\mathcal{L}) = \mathcal{K}\overrightarrow{b_1}\cdot\nabla + \text{ zero order}. \tag{20}$$

It turns out that this equation, except in very simple cases, does not have a solution when just the algebra of classical differential operators is considered, as it happens in the one dimensional case, where $\mathcal{K}$ was constructed using the elemental operations of multiplication and integration. Therefore we need to consider $\mathcal{K}$ to be a pseudo-differential operator $\mathcal{K} = \mathcal{K}(x, t, D)$ given by:

$$\mathcal{K}u = \frac{1}{(2\pi)^n} \int_y \int_\xi k(x, t, \xi) e^{i(x-y)\xi} u d\xi \, dy. \tag{21}$$

If in the expression above we take

$$k(x, t, \xi) = a_\alpha(x, t)(i\xi)^\alpha, \tag{22}$$

then $\mathcal{K} = a_\alpha(x, t)\partial_x^\alpha$. Notice that in this case if $a_\alpha$ is regular and bounded together with its derivatives we get

$$|\partial_x^{\beta_1} \partial_\xi^{\beta_2} k(x, t, \xi)| \leq C_{\beta_1\beta_2}(1 + |\xi|)^{|\alpha|-|\beta_2|}. \tag{23}$$

Assume for a moment that $\mathcal{L}$ is the constant coefficient operator $\mathcal{L}_0$. That is to say

$$A = \begin{pmatrix} \mathbb{I}_{n_1} & 0 \\ 0 & -\mathbb{I}_{n_2} \end{pmatrix}.$$

Solving formally in (20) we get that $k$ should be given by

$$k(x, t, \xi) = \exp\left(\frac{1}{2} \int_0^\infty \overrightarrow{b_1}(x + s\tilde{\xi}, t)\right) \cdot \xi ds, \tag{24}$$

with $\tilde{\xi} = A\xi = (\xi_1, -\xi_2)$.

Notice that in (24) $s \mapsto x + s\tilde{\xi}$ is a geodesic associated to the pseudo-metric (or metric if $A = \mathbb{I}_n$) given by $A$. In the variable coefficient case $A = (a_{jk})_{jk}$ we have to define

$$k(x, t, \xi) = \exp\left(\frac{1}{2} \int_0^\infty \overrightarrow{b_1}\,(X(s; x, \xi)) \cdot \Xi(s; x, \xi) ds\right) \tag{25}$$

with $(X(s; x, \xi), \Xi(s; x, \xi))$ solutions of the hamiltonian flow $H_A$ given by

$$\begin{cases} \dfrac{d}{ds} X_j(s; x_0, \xi_0) = -2 \displaystyle\sum_{k=1}^n a_{jk}\,(X(s; x_0, \xi_0) \Xi_k(s; x_0, \xi_0)) \\ \dfrac{d}{ds} \Xi_j\,(s; x_0, \xi_0) = \displaystyle\sum_{k,l=1}^n \partial_j a_{kl}\,(X(s; x_0, \xi_0))\; \Xi_k(s; x_0, \xi_0) \Xi_l(s; x_0, \xi_0) \\ (X(0; x_0, \xi_0), \Xi(0, x_0, \xi_0)) = (x_0, \xi_0). \end{cases} \tag{26}$$

Notice that above we have dropped the dependence on time to simplify the exposition. In fact, in our main result which is given in Section 7, we will impose some hypothesis on $H_A$ where $A$ is determined just by the initial condition $u_0$.

It follows from (26) that

$$\frac{d}{ds}\langle A\Xi(s;x,\xi),\,\Xi\rangle = 0,$$

and therefore in the elliptic case (i.e. $\langle A\xi,\xi\rangle > C|\xi|^2$ with $C>0$) we get that there is a constant $\gamma_0 > 0$ such that

$$\gamma_0|\xi_0|^2 \le |\Xi|^2 \le \gamma_0^{-1}|\xi_0|^2,$$

and $(X(s;x,\xi),\,\Xi(s;x,\xi))$ are globally defined. However, the situation in the non-elliptic case is different and the following properties have to be proved, see [22]:

a) global existence;

b) continuous dependence w.r.t. $(x_0,\xi_0)$ with just a polynomial growth on $|x_0|$;

c) the trajectories are asymptotically free.

In order to obtain these three conditions we will need $A(x,t)$ to verify the hypotheses H1, H2, H3 and H4 given in Section 2 together with the following non-trapping condition.

H5. The solutions $(X,\,\Xi)$ of the hamiltonian flow $H_A$ associated to $A$ verifies that given $M$ and $(x,\xi)\in\mathbb{R}^n\times(\mathbb{R}^n-\{0\})$ there is $s_0$ such that

$$|X(s;x,\zeta)| > M \quad \text{for all } s > s_0.$$

It is easy to justify that H5 is necessary because otherwise the integral given in (24) will not convergence even for compactly supported $\overrightarrow{b_1}$.

This non-trapping condition is not easy to verify, although it is obviously true in the constant coefficient case. Nevertheless it is a stable condition. In [22] the following lemma is proved.

**Lemma 4.1.** *Consider $A(x,t)=A(x)$ such that the hypotheses* H1, H2 *and* H5 *hold. Let $B(x)$ be an $n\times n$ real matrix with entries in the Schwartz class $\mathcal{S}(\mathbb{R}^n)$, and define $A_\delta(x)=A(x)+\delta B(x)$ with $\delta$ so small that there is a constant $\gamma_0>0$ such that for all $\xi\in\mathbb{R}^n$*

$$\frac{\gamma_0}{2}|\xi| \le |A_\delta\xi| \le 2\gamma_0^{-1}|\xi|.$$

*Then there is $\delta_0>0$ such that $A_\delta$ is non-trapping for all $0<\delta<\delta_0$.*

**Remark.** In the statement of the lemma above it is sufficient to assume that the entries of $B$ have a finite number of derivatives with a finite power like decay.

So in the particular case of IVP (1) it will be sufficient to impose the non-trapping condition H5 to

$$A_{u_0}(x) = A(x,0,u_0,\bar{u}_0,\nabla u_0,\nabla\bar{u}_0). \tag{27}$$

## 5. The symbols

Once the hamiltonian flow is built we can construct the "integrating factor" given by the symbol (25). Nevertheless a new problem appears. This symbol is not in any known class of pseudo differential operators even if $A = \mathbb{I}_n$ and $X(x,\xi) = x + s\xi$, $\Xi = \xi$. A model example of a symbol which behaves as the one in (24) and it is easier to handle is, in dimension two,

$$k(x,\xi) = \psi(x \cdot (A\omega)^{\perp})\chi(|\xi|), \quad \omega = \frac{\xi}{|\xi|}, \quad \xi = (\xi_1,\xi_2), \quad \xi^{\perp} = (-\xi_2,\xi_1) \tag{28}$$

with $\psi \in \mathcal{S}(\mathbb{R})$ and $\chi$ regular, $\chi(0) = 0$ and $\chi(t) = 1$ if $t > 1$. We observe that

$$|\partial_\xi^\alpha k| \le \left(\frac{1+|x|}{1+|\xi|}\right)^{|\alpha|}, \tag{29}$$

being the growth in $|x|$ a problem to handle $k(x,\xi)$ (compare this situation with the one exhibited in (23)). In [22] we prove the following result.

**Proposition 5.1.** *Take $\overrightarrow{b_1}$ in the vector valued Schwartz class $\overrightarrow{\mathcal{S}} \in (\mathbb{R}^n)$ and*

$$\begin{aligned} k(x,\xi) &= \exp\left(\frac{1}{2}\int_0^\infty \overrightarrow{b_1}(x + s\tilde{\xi}) \cdot \xi \, ds\right)\chi(|\xi|), \\ \tilde{\xi} &= A\xi, \quad A = \begin{pmatrix} \mathbb{I}_{n_1} & 0 \\ 0 & -\mathbb{I}_{n_2} \end{pmatrix}, \end{aligned} \tag{30}$$

*with $\chi(|\xi|)$ as in* (28)*. Then $\mathcal{K}(x,D)$ given in* (21) *is bounded from $L^2$ into $L^2$.*

This proposition and a more general result was proved if $A = \mathbb{I}_n$ (i.e. $n_2 = 0$) by Craig, Kappeler and Strauss [4]. A key part of their argument is the good behaviour of the radial derivatives of the symbol $k$ given in (30). It is easy to check that

$$\left|\left(\frac{\xi}{|\xi|} \cdot \nabla_\xi\right)^\alpha k(x,\xi)\right| \le \frac{C_\alpha}{(1+|\xi|)^\alpha}. \tag{31}$$

This property is still true for general non-degenerate matrices $A$ but it is not sufficient to prove Proposition 5.1. In fact in [4] another geometric assumption on the "essential" support of the symbol $k$ is needed besides (31). This property does not hold when $A$ is not the identity matrix, see [19] for a detailed discussion of this issue.

The $L^2$ estimate given above is not enough. Other results regarding the composition and the computation of the adjoints of these operators have to be proved in order to do the algebraic manipulations we exhibited in the one dimensional case. The results can be seen in [22].

Now it is time to recall that to simplify the exposition we assumed that $\varepsilon = 0$. To avoid this restriction some other properties about the symbols introduced in the above proposition are needed. These were proved in [23]. However the results in [22]

and [23], although sufficient for our purposes, are quite restrictive and the algebraic manipulations we can do with these operators are very rigid.

There is also another important constraint, which is that we are able to handle just symbols as (24) but not the general cases given in (25). The reader could then ask how we overcome this difficulty. The answer is in our previous work done on the I.V.P. (1) in [14] and [15]. That paper deals with non-linearities which are small perturbations of the constant coefficient case. Smallness allows hiding the first order terms thanks to some smoothing properties of the solutions of the corresponding free propagator. These properties are the subject of the next section.

## 6. The local smoothing

In [14] and [15] we proved that if the first order terms in (1) are small they can be handled by the so called local smoothing property of the free operators $e^{it(\Delta_{x_1}-\Delta_{x_2})}$. Notice that this family of operators is reversible in time and leave invariant the Hilbert space $L^2$. Moreover they commute with differentiation, and therefore the classical $L^2$-Sobolev spaces $H^s$ of distributions with $s$ derivatives in $L^2$ also remain invariant under the flow. For this reason there can not be any gain of global derivatives in $L^2$, because otherwise making the flow go backwards we would get a contradiction. It was proved by Kato in [12] and independently by Kruzhkov and Faminskii in [24] that the solutions of the Korteweg–de Vries (KdV) equation

$$\begin{cases} u_t + u_{xxx} + uu_x = 0, \quad u = u(x,t), \quad x \in \mathbb{R},\ t \in \mathbb{R}, \\ u(x,0) = 0 \end{cases}$$

gain for almost every time and locally in space one derivative in $x$ with respect to the initial condition $u_0$. This "local smoothing" is a consequence of the dispersive character of the linear part of the KdV equation, and still holds if the non-linear term $uu_x$ is removed.

It is well known that the free Schrödinger equation is also dispersive, and therefore it should have an analogous smoothing property. In that case the solution gains $1/2$-derivative locally in $x$ and again for a.e. time with respect to the initial data. This property was established independently in [3], [31], and [35], [36], (see also [37]), in the elliptic setting, and in [13] for the general case.

However, this 1/2 gain is not sufficient to deal with first order terms which involve a full derivative. In [14] and [15] it is proved that the solution of

$$\begin{cases} i\partial_t u + \Delta_{x_1} u - \Delta_{x_2} u = F \\ u(x,0) = 0 \end{cases}$$

gains one full derivative with respect to the right-hand side $F$. The proof in [14] strongly uses the Fourier transform and is not adapted to the variable coefficient

situation necessary to treat (1). This was proved later on by S. Doi in [6], [7] and [8]. The results by Doi are remarkably robust, and for example, although he proves it for the elliptic case and for scalar equations, it can be extended without any difficulty to the non-elliptic setting and for systems; see [17], [22] and [23]. The idea is to construct a classical pseudo-differential operator $b(x, D)$ such that the commutator with the general $\mathcal{L} = \partial_j(a_{jk}\partial_k)$ satisfies

$$\begin{aligned}\int_0^T \langle i\,[b(x,D)\mathcal{L} - \mathcal{L}\,b(x,D)]\,u, u\rangle\,dt \\ \geq \frac{c_0}{2}\int_0^T \left\langle \frac{(1-\Delta)^{1/2}u}{1+|x|^2}, u\right\rangle dt - \frac{2}{c_0}T\sup_{0<t<T}\langle u,u\rangle,\end{aligned} \tag{32}$$

for some universal constant $c_0 > 0$. Here I am purposely using "universal" without giving a precise definition. The full argument given in [23] depends on this constant in a crucial way, and I refer to the reader to the introduction of that paper for a more precise statement. It is also important to notice that the above inequality is useful as long as there is a control on the $L^2$ norm given by the term $\langle u, u\rangle$.

## 7. The main result

Our main result in [23] is the following.

**Theorem 7.1.** *Under the hypotheses* H1–H4 *there exists* $N = N(n) \in \mathbb{Z}^+$ *such that given any*

$$u_0 \in H^s(\mathbb{R}^n) \quad \text{with } \langle x\rangle^N \partial_x^\alpha u_0 \in L^2(\mathbb{R}^n),\ |\alpha| \leq s_1, \tag{33}$$

$s, s_1 \in \mathbb{Z}^+$ *sufficiently large, and* $s > s_1 + 4$, *for which the hamiltonian flow* $H_A$ *given in* (26) *associated to the quadratic form*

$$A = A_{u_0}(x,\xi) = \sum_{j.k=1}^n a_{jk}(x, 0, u_0, \bar{u}_0, \nabla u_0, \nabla\bar{u}_0)\xi_j\xi_k \tag{34}$$

*is non-trapping, there exist* $T_0 > 0$, *depending on*

$$\lambda = \|u_0\|_{s,2} + \sum_{|\alpha_1|\leq s_1} \left\|\langle x\rangle^N \partial_x^\alpha u_0\right\|_2$$

*the constants in* H1–H4 *and on the non-trapping condition* H5, *and a unique solution* $u = u(x,t)$ *of the equation* (1) *with initial data* $u(x,0) = u_0(x)$ *on the time interval* $[0, T_0]$ *satisfying*

$$\begin{aligned}&u \in C\big([0,T_0]\,:\,H^{s-1}\big) \cap L^\infty\big([0,T_0]\,:\,H^s\big) \cap C^1\big((0,T_0)\,:\,H^{s-3}\big),\\ &\langle x\rangle^N \partial_x^\alpha u \in C\left([0,T_0]\,:\,L^2\right), \quad |\alpha| \leq s_1.\end{aligned} \tag{35}$$

*Moreover, if* $u_0 \in H^{s'}(\mathbb{R}^n)$ *with* $s' > s$ *then* (35) *holds with* $s'$ *instead of* $s$ *in the same interval* $[0, T_0]$.

We have seen in Section 2 that we can obtain energy estimates as (7) if we are able to get rid of the first order terms, and that we can achieve that using an integrating factor. But also we pointed out at the end of Section 5 that the integrating factor we were able to construct was just for a hamiltonian flow which is free outside of a ball. However as we see in the statement of Theorem 7.1, this is not the case when $H_A$ is given as in (35). The way to bypass this obstruction is to write

$$A = A_R + \left( \begin{pmatrix} \mathbb{I}_{n_1} & 0 \\ 0 & -\mathbb{I}_{n_2} \end{pmatrix} - A_R \right)$$

with

$$A_R = \begin{pmatrix} \mathbb{I}_{n_1} & 0 \\ 0 & -\mathbb{I}_{n_2} \end{pmatrix}$$

if $|x| \geq R$ and $R > 0$ is a large parameter to be fixed. The error terms created by this decomposition are of first order and can be done small by taking a large enough $R$. Then the local smoothing inequality (32) can be used as in [14] to control them. This creates the problem of how to handle

$$\sup_{0<t<T} \langle u, u \rangle.$$

But this quantity is precisely the one we started with when doing the energy estimate (7). Notice that in (32) appears multiplied by the factor $T$, and therefore it can be absorbed by the left-hand side of (7) by taking a small enough $T$, which closes the argument.

## 8. The elliptic case

In this section we give some comments that illustrate the substantial differences that appear when in (1) $A$ is the identity matrix. To start with the main result in this case is far more general, and I refer to the reader to the work [17] for a precise statement; see also [29], [28], and [26].

The key difference is the existence of a fundamental argument due to Chihara, see [2], which goes as follows. He first writes (1) as a system in $(u, \bar{u})$. The problem of doing this is that Doi's trick, explained in Section 6, can not be carried out because the pseudo-differential operator $b(x, D)$ needed to prove the estimate (32) does not have the algebraic property (15). Therefore the good structure that the terms

$$\overrightarrow{b_2} \cdot \nabla \bar{u}$$

have for the integration by parts we exhibited in Section 2 is lost after applying the operator $b(x, D)$. Notice these bad terms are off the diagonal. The observation of Chihara is that the corresponding matrix can be easily diagonalized to the expense of zero order terms that as usual are harmless.

In order to explain how this diagonalization is done let us consider the model problem

$$\begin{cases} \partial_t u = i\Delta u + \overrightarrow{b_2}\cdot\nabla\bar{u}. \\ u(x,0) = u_0(x), \end{cases} \tag{36}$$

with $\overrightarrow{b_2} \in \mathbb{C}^n$ a constant vector.

As a system this equation is written as

$$\begin{pmatrix} u \\ \bar{u} \end{pmatrix}_t = \begin{pmatrix} i\Delta & \overrightarrow{b_2}\cdot\nabla \\ \overrightarrow{\bar{b}_2}\cdot\nabla & -i\Delta \end{pmatrix}\begin{pmatrix} u \\ \bar{u} \end{pmatrix}.$$

The eigenvalues of the above matrix are

$$\pm i\big(\Delta^2 - (\overrightarrow{b_2}\cdot\nabla)\big(\overrightarrow{\bar{b}_2}\cdot\nabla\big)\big)^{1/2}.$$

Therefore we are lead to consider the system

$$\begin{pmatrix} v \\ \bar{v} \end{pmatrix}_t = i\begin{pmatrix} \big(\Delta^2 - (\overrightarrow{b_2}\cdot\nabla)\big(\overrightarrow{\bar{b}_2}\cdot\nabla\big)\big)^{1/2} & 0 \\ 0 & -\big(\Delta^2 - (\overrightarrow{b_2}\cdot\nabla)\big(\overrightarrow{\bar{b}_2}\cdot\nabla\big)\big)^{1/2} \end{pmatrix}\begin{pmatrix} v \\ \bar{v} \end{pmatrix}.$$

Notice that

$$\big(\Delta^2 - (\overrightarrow{b_2}\cdot\nabla)\big(\overrightarrow{\bar{b}_2}\cdot\nabla\big)\big)^{1/2} = \Delta\big(1 - \Delta^{-2}(\overrightarrow{b_2}\cdot\nabla)\big(\overrightarrow{\bar{b}_2}\cdot\nabla\big)\big)^{1/2}.$$

The argument ends observing that

$$\Delta\big(1 - \Delta^{-2}(\overrightarrow{b_2}\cdot\nabla)\big(\overrightarrow{\bar{b}_2}\cdot\nabla\big)\big)^{1/2} = \Delta + \text{zero order}. \tag{37}$$

However, the identity (37) is false if the laplacian is changed by an operator of the type $\Delta_{x_1} - \Delta_{x_2}$ and therefore this trick does not work in that situation. Although we have oversimplified the problem considering $\overrightarrow{b_2} \in \mathbb{C}^n$ as a constant vector, the above computations can also be carried out without major difficulty for $\overrightarrow{b_2}(x)$ regular and bounded to the expense of creating zero order terms which as usual are harmless; see [20].

Another important difference of the elliptic setting is that perturbations of the type $\Delta\bar{u}$ are also allowed. The way of seeing this is by a diagonalization argument similar to the one we have just done. Consider $a > 0$ and $b \in \mathbb{C}$ and the equation

$$u_t = ia\Delta u + ib\Delta\bar{u}.$$

Then differentiating with respect to $t$ on both sides we get

$$u_{tt} = (-a^2 + |b|^2)\Delta^2 u$$

which is well posed as long as

$$a^2 > |b|^2.$$

This elemental algebra is much more rigid in the non-elliptic setting and works only for some trivial cases; see [23].

## 9. Remarks on ultrahyperbolic operators

In this final section we gather some information and open questions about linear and non-linear perturbations of the free propagator

$$e^{it\mathcal{L}_0} \quad \text{with } \mathcal{L}_0 = \Delta_{x_1} - \Delta_{x_2}. \tag{38}$$

As we saw in Section 6 one of the fundamental properties of this flow is the local smoothing effect. In fact (32) was a key ingredient to overcome the loss of derivatives obstruction which was explained in Section 2. In order to use (32) one is lead to study the following maximal function

$$\sup_t |e^{it\mathcal{L}_0} u_0|^2, \tag{39}$$

which is defined for all $x \in \mathbb{R}^n$.

In our study of (1) we did not look at the question of which is the minimal regularity to be assumed on the initial condition so that the equation is solvable. This is something which strongly depends on the specific equation one is looking at. Therefore, and for our purposes, the necessary bounds for (39) are rather simple to obtain and there is no difference between the elliptic and the non-elliptic situation at that level. The situation is completely different when looking at a specific model as for example the Schrödinger map I mentioned in Section 3. In that case having sharp bounds for the maximal function can be very useful.

It has been recently proved in [30] that the maximal function given in (39) has a different behaviour for $\mathcal{L}_0$ than for the laplacian, being worse in the former case. Also and with respect to the local smoothing it is known that $\mathcal{L}_0$ is much more sensitive to first order perturbations than the laplacian. In [20] it is proved that the $\frac{1}{2}$ derivative gain of classical Schrödinger flows I mentioned in Section 6 can be reduced to just $\frac{1}{4}$ for $\mathcal{L}_0$.

Regarding non-linear perturbations very little is known about ill-posedness results. In fact and to the best of my knowledge the only one obtained in that direction is about the semilinear equation

$$\begin{cases} \frac{1}{i}\partial_t u = \Delta_{x_1} u - \Delta_{x_2} u \pm |u|^p u \\ u(x,0) = u_0, \end{cases} \tag{40}$$

and is given in [18] with $u_0 = c\delta$. There it is proved that (40) is ill-posed if $p \geq \frac{2}{n}$ (the proof is done for $\Delta$ but it works the same for $\mathcal{L}_0$).

The question of well-posedness of (40) is related to the existence of Strichartz estimates for the free propagator $e^{it\mathcal{L}_0}u_0$ with $u_0 \in L^2$. In that case it is well known that there is no difference between a general $\mathcal{L}_0$ and the laplacian. This type of estimates are very relevant in Harmonic Analysis in order to understand the restriction properties of the Fourier transform to curved surfaces. From that point of view it is

very natural to assume initial conditions $u_0$ such that its Fourier transform $\hat{u}_0$ is in $L^p$. A lot of progress has been done when $\mathcal{L}_0 = \Delta$ but as far as I know there are no results for general $\mathcal{L}_0$ for $p > 2$; see [33], [34], and [25].

Finally let us recall the pseudo-differential operators mentioned in Section 5. As I already said the calculus we develop in [22] and [23] is quite rudimentary, and I think there are many interesting properties to be understood. For example, we do not know if the inequality proved in Proposition 5.1 can be extended to $L^p$ for $p \neq 2$. Another limitation of our approach is that we can construct the integrating factor only for hamiltonians which are free outside of a compact set. It should be enough to assume only that the hamiltonian satisfies hypothesis H2.

# Singular solutions of partial differential equations modelling chemotactic aggregation

Juan J. L. Velázquez

**Abstract.** This paper reviews several mathematical results for partial differential equations modelling chemotaxis. In particular, questions like singularity formation for the Keller–Segel model and continuation of the solutions beyond the blow-up time will be discussed. Some of the open problems that remain for the Keller–Segel model as well as some new mathematical problems arising in the study of chemotaxis problems will be discussed.

**Mathematics Subject Classification (2000).** 35K55, 35B40, 92B05.

**Keywords.** Keller–Segel model, singularity formation, chemotaxis, continuation beyond the blow-up.

## 1. Introduction

There are several relevant biological phenomena that involve the type of cell interaction that is known as chemotaxis. This word denotes the capability of many cells to react to chemical stimuli and move towards an increasing or decreasing chemical gradient. Chemotaxis plays a relevant role in biological processes like embryogenesis, angiogenesis or others.

A particular biological process that has deserved considerable attention by biologists, mathematicians and physicists is the phenomenon of chemotactic aggregation. Several unicellular organisms, like Dictyostelium discoideum and Myxococcus xanthus under conditions of environmental stress begin a complex cascade of chemical processes having as a major consequence the release away from the cell of a chemical substance that has chemoattractant properties in the cells themselves. As a consequence, cells begin to approach to each other. This yields to the formation of dense cellular aggregates where the cells usually begin a differentiation process and as a final result the formation of a fruiting body containing cell sporae that remain in such dormant state until they find suitable environmental conditions where they can proliferate again. From the biological point of view an appealing feature of these social organisms is that they expend part of their life cycle as unicellular organisms and the other part as multicellular organisms.

The details of the phenomenon of chemotactic aggregation change very much from organism to organism. On the other hand, even during the simplest stages of the

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

process it is possible to observe many interesting patterns like spiral waves, cell stream formation and others. Nevertheless, in spite of the complexity of this biological process, some of the main features of the problem are simple enough to motivate several mathematicians to derive models that could amount at least for some of the most important features of the phenomenon.

## 2. The Keller–Segel model

The earliest attempt to describe chemotactic aggregation using a system of partial differential equations was the Keller–Segel model that was introduced in [33]. The authors of this model introduced a continuum description of the aggregation process for Dictyostelium discoideum (from now on Dd) containing some of the biological knowledge that had been gained from the experiments made in previous decades. The book [7] contains a great part of the information available on this biological problem at the time of the formulation of the Keller–Segel model.

In a typical aggregation experiments made with Dd many individual amoebae are distributed in the basement of a Petri dish and covered by a liquid layer. Under suitable conditions the cells begin emitting chemical pulses that trigger the aggregation process.

The Keller–Segel model describes this process assuming that there are only two relevant variables in the problem, namely the cell concentration $n$ and the chemical concentration of the substance that propagates the signals between the cells that will be denoted as $c$. Both concentrations are understood to be measured for unit of surface in the basis of the Petri dish. The chemical substance propagating the chemical signals in the case of Dd was identified in the late 60s and it turns out to be the chemical known as cAMP. The functions are assumed to be during the aggregation process functions of the position in the Petri dish $x$ as well as the time $t$, i.e.,

$$n = n(x, t),$$
$$c = c(x, t).$$

The validity of this description requires to measure the functions $n$ and $c$ in a length scale larger than the typical distance between cells that is of the order of some hundreds of microns. Under this assumption it is natural to write the following continuity equations for the densities $n$ and $c$:

$$\frac{\partial n}{\partial t} + \nabla \cdot (j_n) = 0, \tag{1}$$
$$\frac{\partial c}{\partial t} + \nabla \cdot (j_c) = f(n, c), \tag{2}$$

where $j_n$, $j_c$ are the cell fluxes and chemical fluxes respectively. The function $f(n, c)$ describes the production of chemical by the cells as well as the decay of the concentration of $c$ due to its interaction with the substances placed in the extracellular matrix.

It is implicitly assumed in (1) that processes like mitosis or cell death do not play any relevant role. This assumption is reasonable because such processes take place in a time scale much longer than the one related to chemotactic aggregation.

In order to complete model it remains to prescribe the functions $j_n$, $j_c$, $f(n, c)$. Concerning the chemical fluxes the most natural assumption is to assume that the chemical diffuses according to the classical Fick's law:

$$j_c = -D_c \nabla c \tag{3}$$

where $D_c$ is the diffusion coefficient for the chemical.

On the other hand, the Keller–Segel model assumes that the cell motions are the superposition of two effects, namely a random motility and a drift towards the regions having a larger concentration of chemical due to the effect of the chemotaxis. In the case of amoeba-like cells like Dd it is experimentally observed that the cells, that move by means of the expansion and retraction of pseudopods, have some kind of random component in their motion resembling, in a suitable length scale the motion of a brownian particle. On the other hand, it is experimentally observed that the drifting motion of the cells is, on average, proportional to the gradient of chemical concentration. These features make reasonable to assume that the random motility follows the standard Fick's law for diffusive processes and that the drifting motion yields an additional cell flux proportional to $n\nabla c$. The closure relation for the cell flux then becomes

$$j_n = -D_n \nabla n + \chi n \nabla c, \tag{4}$$

where $D_n$ is the diffusion coefficient for the cells and $\chi$ will be termed as chemotactic sensitivity.

Finally, in order to determine the function $f(n, c)$ there are two features that it is important to take into account. The molecules of cAMP degrade with a characteristic life-time, due to their interaction with the molecules of the extracellular membrane. On the other hand, the production of chemical for unit of area is proportional to the cell concentration $n$ if the chemical production of each cell it is assumed to be approximately independent from the others. Under these assumptions the formula for $f(n, c)$ would be

$$f(n, c) = \alpha n - \beta c \tag{5}$$

with $\alpha > 0$, $\beta > 0$.

Combining the equations (1)–(5) the following system of equations follows:

$$\frac{\partial n}{\partial t} = D_n \Delta n - \chi \nabla \cdot (n \nabla c), \tag{6}$$

$$\frac{\partial c}{\partial t} = D_c \Delta c + \alpha n - \beta c. \tag{7}$$

The system (6), (7) is a particular case of classical Keller–Segel model that was introduced in [33]. Using a suitable set of dimensionless variables, it is possible to

reduce (6), (7) to the analysis of the particular case:

$$\frac{\partial n}{\partial t} = \Delta n - \chi \nabla \cdot (n \nabla c), \tag{8}$$

$$\frac{\partial c}{\partial t} = L \Delta c + n - \beta c. \tag{9}$$

This system is usually solved in a domain $\Omega \subset I\!R^2$ for positive times $t > 0$ with suitable initial data $n(x, 0) = n_0(x) \geq 0, c(x, 0) = c_0(x) \geq 0$ and zero flux boundary conditions:

$$\frac{\partial n}{\partial \nu} - \chi n \frac{\partial c}{\partial \nu} = 0, \quad \frac{\partial c}{\partial \nu} = 0, \quad x \in \partial\Omega, \quad t > 0 \tag{10}$$

where $\nu$ is the outer normal at the boundary $\partial\Omega$. Notice that, under these boundary conditions, the total number of cells $\int_\Omega n_0(x)\, dx \equiv N_0$ is conserved during the evolution of the system. In several of the discussions below it will be assumed that $N_0$ is a real number of order one, something that at a first glance might look strange for a number that denotes the rather large number of cells contained in $\Omega$. However, this is due only to the fact that in the formulation (8), (9) dimensionless variables have been used. A number $N_0$ of order one for the solutions of the system (8), (9) is in reality a huge number of cells if the dimensional form of the equations (6), (7) is used.

The problem (8), (9) turned out to be a source of interesting mathematical problems. From the mathematical point of view the most interesting feature of the system (8), (9) is the nonlinear term $\chi \nabla \cdot (n \nabla c)$. If the chemotactic interaction between cells is chemoattractive, i.e. if $\chi > 0$, this term yields singularity formation in finite time. The peculiar form of this nonlinear term is a rather common feature of the chemotaxis models. The study of the consequences of this term in the dynamics of the solutions of (8), (9) has led to the development of several mathematical tools by different authors.

## 3. Singularity formation in chemotaxis models

Childress suggested that the solutions of (6), (7) could generate singularities and that the process of chemotactic aggregation could be thought as the formation of a singularity (cf. [13]). The first rigorous proof of blow-up in a chemotaxis model was obtained by Jäger and Luckhaus in [31]. These authors took advantage of the fact that the diffusion coefficient for the chemical $D_c$ is much larger than the diffusion coefficient $D_n$ for the cells. In that particular limit the system of equations (8), (9) with nonzero flux boundary conditions can be reduced to the simpler problem

$$\frac{\partial n}{\partial t} = \Delta n - \chi \nabla \cdot (n \nabla c), \tag{11}$$

$$0 = L \Delta c + n - \bar{n}, \tag{12}$$

where $\bar{n} = \frac{1}{|\Omega|} \int_\Omega n\, dx$. Notice that in order to solve (11), (12) only the initial data $n(x, 0) = n_0(x)$ must be prescribed.

Jäger and Luckhaus obtained two basic results for the solutions of (11), (12) that established the basic framework for many of the subsequent researches in this type of problems. They proved that the solutions of (11), (12) with $N_0$ small are globally bounded. On the other hand, [31] contains also a large class of radial initial data $n_0(x)$ for which the corresponding solution of (11), (12) becomes unbounded in finite time, or using the standard terminology used by the partial differential community, the solutions of (11), (12) blow up in finite time for suitable initial data.

Notice that the global existence result in [31] implies that there exists a threshold for the number of cells $N_0$, below which the solutions of (11), (12) do not exhibit singularities in finite time. There have been several researches trying to compute the value of such threshold number. In the case of radial solutions, it was proved by Nagai (cf. [37]) that the smallest number of cells needed to have blow up in finite time is $8\pi/\chi$. In nonradial cases the threshold for the mass is $4\pi/\chi$ (cf. [6], [16]).

## 4. Chemotactic aggregation

The blow up results mentioned in the previous section do not imply that the solutions of the system (11), (12) develop a Dirac mass in a finite time. The onset of such Dirac mass at the time of formation of the singularity $t = T$ seems the most natural outcome, as the previous discussion concerning the existence of a threshold for the number of cells needed to create a singularity suggests. However, the derivation of such conclusion is not so obvious. Indeed, a possibility that cannot be excluded in principle is the formation of a singularity where the number of cells contained in a small ball near the point where the singularity appears would oscillate infinitely often without converging to any number. Another possibility that is not easy to rule out in nonradial cases is the existence of a family of balls containing a large fraction of the total number of cells whose diameter decreases to zero as $t \to T^-$ and whose centers move erratically by the domain $\Omega$.

We will denote as chemotactic aggregation the formation of a Dirac mass at a finite time $t = T < \infty$. In [17] was obtained a class of solutions yielding chemotactic aggregation. Moreover, for such a solutions there was a detailed description of the asymptotic behaviour of the solutions near the singularity. These solutions satisfy

$$n(\cdot, t) \rightharpoonup \frac{8\pi}{\chi}\delta(\cdot) + f(\cdot) \quad \text{as } t \to T^-, \tag{13}$$

where

$$f(x) \sim \frac{8e^{-(\gamma+2)}}{|x|^2} e^{-2\sqrt{|\log(|x|)|}}(1 + o(1)) \quad \text{as } |x| \to 0, \tag{14}$$

$\gamma$ being the classical Euler constant. Moreover:

$$n(x,t) \sim \frac{8}{(T-t)(\varepsilon(|\log(T-t)|))^2} \frac{1}{\left(1 + \frac{|x|^2}{(T-t)(\varepsilon(|\log(T-t)|))^2}\right)^2} \quad \text{as } t \to T^- \tag{15}$$

for $|x| \leq C\sqrt{T-t}\varepsilon(|\log(T-t)|)$, where

$$\varepsilon(\tau) \sim 2e^{-\frac{2+\gamma}{2}} e^{-\sqrt{\frac{\tau}{2}}} \left(1 + O\left(\frac{\log(\tau)}{\sqrt{\tau}}\right)\right) \quad \text{as } \tau \to \infty. \tag{16}$$

It is interesting to point out that these solutions are not self-similar solutions in the sense that such term is usually understood. The most common meaning that it is given to the term self-similar solutions is the one of solutions that are invariant by a group of symmetries, and most often by a group of rescalings. If the term $\overline{n}$ that gives a low order contribution is ignored in the equations (11), (12) the resulting equations are invariant under the rescaling group:

$$x \to \lambda x, \quad t \to \lambda^2 t, \quad n \to \frac{1}{\lambda^2} n, \quad c \to c, \tag{17}$$

where $\lambda$ is an arbitrary positive number. It can be shown that at least in the radial two dimensional case there are not self-similar solutions of (11), (12), even if the term $\overline{n}$ is neglected (cf. [20]). On the other hand, it is not hard to see that solutions with the asymptotics (15) are not invariant under the rescaling group (17) due to the presence of the terms $e^{-\sqrt{\frac{|\log(T-t)|}{2}}}$ in (16) that are not power laws. More precisely

$$(T-t)^a \ll e^{-\sqrt{\frac{|\log(T-t)|}{2}}} \ll 1 \quad \text{as } t \to T^-$$

for any $a > 0$. In the terminology of applied mathematicians such terms are often called "logarithmic corrections", even if they are not strictly logarithmic functions.

The computation of this logarithmic corrective term is the main technical difficulty solved in [17]. The key idea used in that paper was to derive first an approximation of the solution near the blow-up time using the so-called "matched asymptotic expansions". Such expansions are a heuristic, non fully mathematically rigorous procedure of deriving approximated formulae for the solutions different types of equations that contain large or small parameters. These methods are widely used in many fields applied mathematics, often combined with numerical simulations that provide an independent test of their validity. The basic idea of this method consists in to compute perturbative series for the solutions of the equations under consideration by simpler equations, something that is possible due to the presence of large or small parameters in the problem. However, such approximations of the solutions often lose their validity in some regions of the space because the form of the obtained solutions determines that some of the terms that had been previously ignored become important in some particular areas of the space of parameters. The solutions are then analysed in these specific regions introducing suitable rescalings and changes of variables that are often suggested by the form of the approximate solutions previously computed. The resulting equations can then be also analysed in a perturbative manner and in this way the form of the solutions in such new variables can be obtained too. In order to assert the validity of the obtained formula it remains to check that both obtained approximated

solutions agree in a region of common validity. This agreement is usually termed as "matching".

In the study of (11), (12) the small parameter is the distance between the time variable and the blow-up time, i.e. $(T-t)$. The analysis of the solutions was made decomposing the space of independent variables $(x,t)$ in three different regions, namely:

$$\begin{aligned} &\text{(A)} \quad |x| \ll \sqrt{T-t}, \\ &\text{(B)} \quad |x| \approx \sqrt{T-t}, \\ &\text{(C)} \quad |x| \gg \sqrt{T-t}. \end{aligned}$$

The onset of the parabolic rescaling $\sqrt{T-t}$ it is very natural due to the parabolic character of the system (11), (12). In each of these regions these equations can be approximated to the leading order by a different type of equation whose solution can be obtained in an explicit manner. More precisely, the derived solutions solve a nonlinear ordinary differential equation in the region (A), a linear parabolic equation that reduces to the heat equation in the region (B), and a quasilinear hyperbolic equation in the region (C). The corrective term $e^{-\sqrt{\frac{|\log(T-t)|}{2}}}$ was obtained setting that the width of the region where the aggregating mass is concentrated is an unknown function $\varepsilon(t)$ whose precise form is computed matching the solutions obtained in the regions (A) and (B). Such matching condition provides an integro-differential equation for $\varepsilon(t)$ that allows to compute the "logarithmic correction" $e^{-\sqrt{\frac{|\log(T-t)|}{2}}}$. The details of this formal computation can be found in [18] and also in [45], [46].

The rigorous construction of the solutions whose formal description is given above was made reducing the problem to the one of finding the zeroes of a finite dimensional problem. This was achieved choosing an initial class of initial data depending on a finite number of parameters and showing that the choice of such parameters that solves a suitable equation provide some initial data whose corresponding solution blows up at the time $t = T$ with the asymptotic behaviour computed in an heuristic manner before. The details of the argument can be found in [17]. A crucial point in the argument is to use the formal asymptotics of the solutions as a guide to derive suitable "a priori" estimates for the solutions of (11), (12). This argument have been used in the construction of solutions with a prescribed blow-up behaviour in many other problems (cf. for instance [3], [10]).

All the previous analysis was made for the simplified version of the Keller–Segel model introduced by Jäger and Luckhaus. Nevertheless, the same results can be obtained for the whole Keller–Segel system (8), (9) (cf. [22]). Some technical difficulties arise due to the fact that for radial solutions it is possible to reduce (11), (12) to the study of a scalar equation. Such reduction is not possible in the case of the whole system (8), (9).

It is worth mentioning that this study provides a simple formula, originally derived in [13], relating the different parameters from the Keller–Segel model and the number

of aggregating cells. Indeed, rewriting (13) with the original dimensional variables it follows that the number of cells aggregating for the solutions of (8), (9) is

$$N_{\text{aggr.cells}} = \frac{8\pi D_c D_n}{\alpha \chi}.$$

## 5. Some analogies between chemotactic aggregation and the melting of ice balls

It is interesting to remark that the same type of "logarithmic correction" that has been described above (cf. (15)) appears in other problem that at a first glance looks rather different from the problem of chemotactic aggregation. Suppose that one tries to describe the size of a melting ice cylinder immersed in a big reservoir of water. One usual way of describing such process is by means of the so-called Stefan problem. In the resulting model it is assumed that the heat transfer in both the ice and the water follows the classical Fourier's law. Therefore, in both phases the temperature satisfies a heat equation. On the other hand, in the interface separating both phases the temperature takes a constant value that is the melting temperature of the water at the value of the pressure that the experiment is made. This assumption is not completely true if surface tension effects are taken into account, but these effects are relevant only for very small radii of the cylinder and therefore they can be ignored during most of the process. Moreover, we will assume also that the heat conductivity of the ice is much higher than the one of the ice, since this makes the problem easier to analyse and it does not change the final conclusions. A final feature that must be incorporated in the model is the fact that the melting of a given volume of ice requires to provide to it the amount of energy known as latent heat. The mathematical formulation of this condition provides an equation for the motion of the interface separating the ice and the liquid water. The resulting model, in dimensionless units and in the radial case is the following:

$$\frac{\partial \theta}{\partial t} = \Delta \theta \quad x \in I R^2, \quad |x| > R(t), \quad t > 0, \tag{18}$$

$$\theta = \theta_m, \quad |x| = R(t), \quad t > 0, \tag{19}$$

$$\dot{R}(t) = -\frac{\partial \theta}{\partial r}(R(t), t), \tag{20}$$

where $\theta(x, t)$ is the temperature of the liquid water. In absence of undercooled water we must assume that $\theta(x, 0) = \theta_0(x) \geq 0$.

This problem has classical solutions for a large class of initial data $\theta_0(x)$. Let us suppose also that $\theta_0(x) \to \theta_\infty > 0$ as $|x| \to \infty$. It might be seen that for such data the radius of the ice ball $R(t)$ decreases and eventually disappears in finite time. At such time a singularity arises for this free boundary problem.

As in the case of the Keller–Segel model there are not self-similar solutions describing this singularity. A description of this singularity using formal asymptotic

expansions was obtained in [39]. It turns out that the radius of such balls near the time $t = T$ for the vanishing of the spheres is given by:

$$R(t) \sim C\sqrt{T-t}e^{-\frac{\sqrt{2}}{2}|\log(T-t)|^{\frac{1}{2}}} \quad \text{as } t \to T$$

Asymptotic expansions for the solutions of the same problem in the non radial case were obtained in [19]. For these solutions the interface behaves asymptotically as an ellipsoidal cylinder near the time of the vanishing of the ice.

## 6. Some results for the Jäger–Luckhaus model in three dimensions

There are biological situations where it makes sense to analyse the three dimensional version of the Keller–Segel. A relevant example is the study of the aggregates of the bacteria E.coli.

From the mathematical point of view the type of singularities arising for the Keller–Segel model are very different in the three dimensional case and in the two dimensional case. It is possible to construct singular solutions blowing up in a line, just adding an additional dimension to the solution behaving as in (13)–(15). On the other hand, in three dimensions there exist radial self-similar solutions that yield singularities in a finite time without mass aggregation. On the other hand in three dimensions there exist a mechanism of chemotactic aggregation that is rather different from the one previously described for the two dimensional case. Such aggregation mechanism is driven by the first order terms in (11), except for a small boundary layer where the diffusive term $\Delta c$ becomes essential. For these solutions the mass is concentrated as $t \to T^-$ in a layer placed at a distance of order $(T-t)^{1/3}$. The detailed description of such solutions can be found in [9], [20], [21].

## 7. On the continuation of the solutions beyond the blow-up Time

In the last decade several models have been suggested in order to describe the effects that could stop the aggregation process in different organisms. Several biochemical processes that could stop the aggregation of E. coli if the cell density reach high values were described in [8]. Another partial differential equations that stop cell aggregation were considered in [25], [46], [47]). It was assumed in [25] that the cell velocity vanishes for high cell concentrations. In [46] was assumed also that the cell velocity decreases also with the velocity for high values of the concentration. More precisely, the model studied in [46], [47] was the following:

$$\frac{\partial n}{\partial t} = \Delta n - \nabla \cdot (g_\varepsilon(n)\nabla c), \tag{21}$$

$$0 = \Delta c + n, \tag{22}$$

where

$$g_\varepsilon(n) = \frac{1}{\varepsilon} Q(\varepsilon n), \quad \varepsilon > 0, \tag{23}$$

and $Q$ is an increasing function satisfying

$$Q(s) \sim s - \alpha s^2 \quad \text{as } s \to 0,$$
$$Q(s) \sim L > 0 \quad \text{as } s \to \infty.$$

The solutions of (23) are globally bounded for each $\varepsilon > 0$. On the other hand, the model (21)–(23) converges formally as $\varepsilon \to 0$ to the model

$$\frac{\partial n}{\partial t} = \Delta n - \nabla \cdot (n \nabla c), \tag{24}$$
$$0 = \Delta c + n, \tag{25}$$

that in two dimensions might yield chemotactic aggregation in finite time. It would be then natural try to understand the asymptotics of the solutions of (21)–(23) for arbitrary times as $\varepsilon \to 0$. Notice that the number of cells $\int_\Omega n\, dx$ remains constant for the solutions of (21)–(23). Therefore, even if the solutions of (21)–(23) become unbounded, the solutions of these equations should not become unbounded everywhere. The study of the dynamics of the solutions of (21)–(23) as $\varepsilon \to 0$ was made in [46], [47] using formal matched asymptotic expansions. The conclusion of such analysis was that it is possible to obtain asymptotic expansions valid in all the regions of the space for some solutions of (21)–(23) that behave asymptotically as $\varepsilon \to 0$ as

$$n(x,t) = \sum_{i=1}^{N} M_i(t) \delta(x - x_i(t)) + n_{\text{reg}}(x,t),$$

where $n_{\text{reg}}(x,t)$ is a bounded function. Moreover, the functions $M_i(t), x_i(t), n_{\text{reg}}(x,t)$ satisfy the following problem:

$$\frac{\partial n_{\text{reg}}}{\partial t} = \Delta n_{\text{reg}} + \sum_{j=1}^{N} \frac{M_j(t)}{2\pi} \frac{(x - x_j(t))}{|x - x_j(t)|^2} \cdot \nabla n_{\text{reg}} - \nabla (n_{\text{reg}} \nabla c_{\text{reg}}), \tag{26}$$

$$c_{\text{reg}} = -\frac{1}{2\pi} \int_{I R^2} \log(|x - y|) n_{\text{reg}}(y,t)\, dy, \tag{27}$$

$$\dot{x}_i(t) = \Gamma(M_i(t)) A_i(t), \quad i = 1, \ldots, N, \tag{28}$$

$$A_i(t) = -\sum_{j=1}^{N} \frac{M_j(t)}{2\pi} \frac{(x - x_j(t))}{|x - x_j(t)|^2} + \nabla c_{\text{reg}}(x_i(t), t), \tag{29}$$

$$\frac{dM_i(t)}{dt} = c_{\text{reg}}(x_i(t), t) M_i(t), \quad i = 1, \ldots, N, \tag{30}$$

where $\Gamma(\cdot)$ is a positive function defined for values of its argument larger than $8\pi$.

The problem (26)–(30) can be considered as a moving boundary problem. These equations indicate that there exist solutions of (21)–(23) having some concentration regions where the cells accumulate and that interact between themselves and with the cells away from the aggregates.

The solvability of the problem (26)–(30) is not entirely obvious due to the motion of the points $x_i(t)$ as well as the presence of the terms $\frac{M_j(t)}{2\pi}\frac{(x-x_j(t))}{|x-x_j(t)|^2}\cdot\nabla n_{\text{reg}}$ in (26). The local well-posedness of (26)–(30) in Hölder spaces has been proved in [48].

In [47] has been obtained using matched asymptotic expansions a description of the way in which the saturation of the chemotactic attraction for high values of the concentration stops the aggregation process and yields the formation of a concentration region for the density.

## 8. Some open questions for the Keller–Segel model

In the last two decades there have been several relevant advances in the understanding of the Keller–Segel model. There are, however, still many unsolved questions that could pose challenging analysis problems. I will describe shortly some of the ones that in my opinion are more relevant.

Probably, the most important problem that remains in order to understand completely the blow-up for the Keller–Segel model is to show that for arbitrary two dimensional domains $\Omega$ and arbitrary initial data, all the blowing up solutions of (8), (9), (or the simplified version (11), (12)) converge locally near the blow-up to a Dirac mass.

A more ambitious version of this problem would be to show that all the solutions that blow up in finite time behave near the singularity as indicated in (13)–(15). Experts in blow-up would immediately argue here that, since the solutions with large amount of cells blow up and the solutions with a small number of cells do not blow-up, there exists a transition regime between the one associated to global existence and the one associated to blow-up in finite time. I think that the most spread opinion among the mathematicians working in the Keller–Segel model about this point is that the transition regime corresponds precisely to the solutions having a total number of cells of $8\pi/\chi$, and that this critical amount of cells should lead to the type of behaviour that it is usually known as "blow-up in infinity time" (cf. for instance [29]). This would mean that the solutions would be globally defined but the solutions of (8), (9), (or (11), (12)) should eventually approach to a Dirac mass as $t \to \infty$. The blow-up mechanism (13)–(15) might be obtained with any number of cells strictly greater $8\pi/\chi$ cells. For the critical number of cells, the description of the long time asymptotics as $t \to \infty$ has not been obtained even at the formal level.

A problem that could shed some light in the question of finding a complete classification of the singular behaviours for the Keller–Segel model is the study of the stability of the solutions of (11), (12) with the behaviour (13)–(15). In principle this

problem looks more amenable to analysis because it reduces to the study of a local problem. This stability study for these particular solutions has been made in [45] using formal computations linearizing formally around the solution obtained in [17]. This kind of linearization is customarily made by applied mathematicians working in problems that involve blow-up phenomena. Nevertheless, the study of such stability is more involved that in many of the blow-up problems so far considered due to the involved structure of boundary layers that is needed to describe the solution behaving as in (13)–(15). To prove in a fully rigorous manner that the solutions of (11), (12) with the behaviour (13)–(15) would require, most likely, to make fully rigorous the arguments in [45], something that would require to study in detail several parabolic problems described in [45]. A similar analysis challenge is the one posed by the proof in a fully rigorous manner of the results concerning "continuation beyond blow-up" mentioned in Section 7.

There is a huge wealth of problems associated to the study of the singularities for the Keller–Segel or the Jäger–Luckhaus problems in three spatial dimensions. As indicated in Section 6 in this case there are many more singular behaviours, whence a complete classification of blowing up solutions seems much harder. It is interesting to point out that the solutions of the Jäger–Luckhaus model blowing up in a line that are obtained adding an additional dimension to the solutions blowing up as in (13)–(15) seem to be unstable under nonconstant perturbations along that line, as the formal computations in [5] suggest.

Let us finally remark that there seem to be several analogies between the Keller–Segel model (or the Jäger–Luckhaus approximation) and the classical Stefan problem. This is particularly clear in the results mentioned in Section 5, but there are other points in the mathematical analysis of both problems where these analogies can be seen. It is not unlikely that the Stefan problem could be derived, at least formally, as a suitable asymptotic limit of the Keller–Segel model, in the same form as the Stefan problem and many other related free boundary problems can be derived from the so-called phase field limits. If the connection between these problems is found, it would be perhaps possible to explain the analogies found in Section 5. It would probably be possible also to use the large amount of information available for the Stefan problem in order to describe the behaviour of some class of initial data for the Keller–Segel model.

In this paper the description and stability of the steady states solutions of the Keller–Segel model has not been considered. There are several results concerning the structure of the steady states of this problem (cf. [40]). A detailed review of the different mathematical results available in the literature for the stationary and the evolutionary Keller–Segel model can be found in [27], [28].

## 9. Beyond the Keller–Segel model

All the previous discussion has focused exclusively in the study of the Keller–Segel model. As it was explained in Section 2 the Keller–Segel model is a continuous approximation of a rather complicated aggregation process. In recent decades the study of the process of chemotactic aggregation has developed in many more directions than in the study of this specific model. In this section, I will describe briefly some of this researches to illustrate the type of mathematical problems that have arisen in the study of this biological process.

One of the research directions that has deserved great attention and that was originated by the papers [1], [15], [38] is the study of kinetic or stochastic models describing the cell dynamics.

The idea underlying the stochastic models is to describe the dynamics of each individual cell using a stochastic differential equation. The information contained in the differential equation is that cells move in a rectilinear manner at constant speed during some time intervals. At the end of such intervals the direction of the velocity changes in a random manner. In order to obtain a chemotactic dynamics the models introduce some bias towards the regions having greater chemical concentration, something that can be made in several different ways. One possibility is to assume that the rate of change in the direction of motion is a function on the change of concentration of chemical. Another different possibility is to assume that the new direction of motion is biased towards the direction of largest chemical concentration. The first possibility is motivated by the well studied motion mechanism of E. coli that takes place by means of different types of discrete jumps in the space known as "runs" and "tumbles" (cf. the description in [4]). The second one can be thought as a reasonable approximation to the dynamics of amoebae-like cells like Dd. In order to avoid introducing in this model direct cell-cell interactions it must be assumed that the mean free path between jumps is much smaller than the cell distance. If it is assumed, in addition, that the characteristic distance for the chemical variation are much larger than the cell distance it might be seen that the particle distributions have small correlations and therefore they might be approximated as the product of one-particle distributions in the space of velocities and positions having the form $f(x, v, t)$. In all the mentioned asymptotic limits it is possible to approximate the evolution equation for the one-particle distribution function by means of the kinetic equation

$$f_t + v\nabla_x f = \int [T(x, v, w) f(x, w, t) - T(x, w, v) f(x, v, t)]\, dw. \tag{31}$$

The transition kernel $T(x, w, v)$ contains the bias towards higher concentrations, and therefore it depends in general in quantities like the chemical concentration, of its time or space derivatives.

In recent years there have been obtained several results proving that in some suitable asymptotic limits the solutions of (31) converge to the solutions of the Keller–Segel system (cf. [12], [23], [24], [30]). Readers familiar with gas-dynamics would

realize that the main assumption in these studies is that the mean free path between jumps is much smaller than the characteristic length associated to the chemical concentration. In all these studies the cell concentration is given by $n(x,t) = \int f(x,v,t)\,dv$. A more direct study of a system of stochastic differential equations that are coupled only through the concentration of the chemical was made in [42]. Nevertheless in this paper was also assumed that the distance between particles is small compared with the characteristic length associated to the chemical, and therefore the correlations between particle distributions are also small.

These results point out to some of the new possible directions for the development of the kinetic (or stochastic) theory of cell motion. Given the huge number of different situations that can arise in the study of cell interactions in biological situations it would be relevant to study the dynamics of stochastic equations in limits where the particle correlations could play a relevant role. The study of such problems, at least in biological problems is largely open.

On the other hand, all the studies of cell dynamics using stochastic or kinetic models described above assume that the cells are separated enough from each other to make cell-cell interaction effects negligible. However in many phenomena of chemotactic aggregation this hypothesis fails at least during some part of the process. For instance, in the case of Dd the cells become at some point a dense aggregate package. Even before reaching that state the cells distribute in some cell streams that cannot be described using a simple model as Keller–Segel, but that had been explained to be due to the instabilities of planar fronts for some more complicated reaction-diffusion systems (cf. [26]). Concerning the aggregate state there have been several attempts to model such cellular state by means of different approaches. I will not try to describe in detail all the results that have been obtained in this extensive research area, but I will mention a few results that could describe some of the main ideas that are been used to study this problem.

An approach that is rather popular in the field of mathematical biology is the use of cellular automata models, often in lattices, having a dynamic that mimics the laws of cell motion. Using this approach it is possible to obtain numerical simulations that very often resemble very much the patterns observed in biological systems. In the specific case of Dd the most remarkable results in this direction are those of [35]. These numerical simulations were able to reproduce the whole life cycle of Dd, including the aggregation, the formation of cell mounds, and the development of the fruiting body. The main difficulty with this approach is that the relation between the parameters in the cellular automata and the biochemical parameters is not an obvious one. On the other hand, the evolution rules that are used in the model are not true mechanical or chemical equations. In any case this approach is providing some insight in several biological problems about the type of interactions that must be taken into account to obtain some specific patterns.

There have been introduced in the literature several models that describe the mechanical interactions of a huge number of cells. One of the most recent papers in this direction, that is probably the one that includes the currently available information

about the mechanical interactions of the cells in a more careful manner is [14]. These results provide some interesting insights on the mechanics of dense cell aggregates. Nevertheless the mathematical object that a specialist in partial differential equations would like to have is a system of continuum equations for the cell aggregates, with a solid basis in physics and chemistry that could play a role in tissues analogous to the one played by the Navier–Stokes equations in fluid mechanics. Actually the Navier–Stokes equations have been used to model the evolution of cell aggregates (cf. [11]) and there has been obtained numerically good qualitative agreements with the experimentally observed patterns (cf. [41]). However, the mechanical properties of dense cell aggregates are most likely rather different from the properties of newtonian fluids.

I will mention shortly another problem related to the aggregation of Dd yielding also partial differential equations problems. This is the process of transmission of chemical signals between cells that yield the aggregation process. In the Keller–Segel model it is assumed that the production of chemical is proportional to the cell density and that the cell velocity is proportional to the concentration of chemical. However, this assumptions are just a simplification of a rather complex process. A more realistic picture of the production of chemical is provided by the theory of excitable systems. According to this picture the cells, upon the arrival of a diffusive chemical wave produce some additional chemical that compensates in this way the effect of its spontaneous degradation. After this production the cell enters in a refractory state lasting a few minutes during which the cell is unable to release chemical. There exists a huge mathematical theory for reaction-diffusion systems whose dynamics has these ingredients (cf. for instance [32]). Systems having such dynamics exhibit a large class of patterns, like travelling waves, spiral waves and several others. Actually, the chemical signalling in Dd aggregates was one of the problems that motivated the development of the theory of dynamical systems. In recent decades there have been several papers introducing models for the cell signalling process that include more detailed information about the biochemical processes taking place in the cell. Some of the most popular models are the ones in [36] and [43]. These models are reaction-diffusion models that are able to reproduce some of the features observed in the experiments that measure the chemical produced by cell aggregates (cf. [44]). Recently, in the article [34] several analytic formulae for magnitudes like the wave velocity, the chemical concentrations and other related quantities were computed using asymptotic methods.

**Acknowledgements.** This paper was partially written during a sabbatical stay at the Max Planck Institute for the Mathematics in the Natural Sciences. The author is partially supported by a fellowship of the Humboldt foundation and by DGES Grant MTM2004-05634. I wish to thank S. Luckhaus for introducing me to the study of the Keller–Segel model. Several of the results described in this paper were obtained in collaboration with M. A. Herrero. I want to also acknowledge several illuminating discussions concerning chemotaxis and mathematical biology with A. Stevens.

# From topological field theory to deformation quantization and reduction

Alberto S. Cattaneo*

**Abstract.** This note describes the functional-integral quantization of two-dimensional topological field theories together with applications to problems in deformation quantization of Poisson manifolds and reduction of certain submanifolds. A brief introduction to smooth graded manifolds and to the Batalin–Vilkovisky formalism is included.

**Mathematics Subject Classification (2000).** Primary 81T45; Secondary 51P05, 53D55, 58A50, 81T70.

**Keywords.** Topological quantum field theory, BV formalism, graded manifolds, deformation quantization, formality, Poisson reduction, $L_\infty$- and $A_\infty$-algebras.

## 1. Introduction: a 2D TFT

**1.1. The basic setting.** Let $\Sigma$ be a smooth compact 2-manifold. On $\mathcal{M}_1 := \Omega^0(\Sigma) \oplus \Omega^1(\Sigma)$ one may define the following very simple action functional:

$$S(\xi, \eta) := \int_\Sigma \eta \, \mathrm{d}\xi, \quad \xi \in \Omega^0(\Sigma), \ \eta \in \Omega^1(\Sigma), \tag{1.1}$$

which is invariant under the distribution $0 \oplus \mathrm{d}\beta$, $\beta \in \Omega^0(\Sigma)$. If we take $\xi$ and $\eta$ as above as coordinates on $\mathcal{M}_1$, we may also write

$$\delta_\beta \xi = 0, \quad \delta_\beta \eta = \mathrm{d}\beta. \tag{1.2}$$

The critical points are closed 0- and 1-forms. As symmetries are given by exact forms, the space of solution modulo symmetries, to which we will refer as the moduli space of solutions, is $H^0(\Sigma) \oplus H^1(\Sigma)$, which is finite dimensional. Moreover, it depends only on the topological type of $\Sigma$. Actually, something more is true: the action of the group of diffeomorphisms connected to the identity is included in the symmetries restricted to the submanifold of critical points. In fact, for every vector field $Y$ on $\Sigma$, we have $\mathrm{L}_Y \xi = \iota_Y \mathrm{d}\xi$ and $\mathrm{L}_Y \eta = \iota_Y \mathrm{d}\eta + \mathrm{d}\iota_Y \eta$. So upon setting $\mathrm{d}\xi = \mathrm{d}\eta = 0$, we get $\mathrm{L}_Y = \delta_{\beta_Y}$ with $\beta_Y = \iota_Y \eta$. This is the simplest example of 2-dimensional topological field theory (TFT) that contains derivatives in the fields.[1]

*The author acknowledges partial support of SNF Grant No. 200020-107444/1.

[1]This example belongs to the larger class of the so-called $BF$ theories. This is actually a 2-dimensional abelian $BF$ theory.

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

One may also allow $\Sigma$ to have a boundary $\partial\Sigma$. If we do not impose boundary conditions, the variational problem yields the extra condition i) $\iota_{\partial\Sigma}^*\eta = 0$ where $\iota_{\partial\Sigma}$ denotes the inclusion map of $\partial\Sigma$ into $\Sigma$. So it makes sense to impose i) from the beginning. The second possibility is to impose the boundary condition ii) that $\xi_{|\partial\Sigma}$ should be constant. By translasting $\xi$, we may always assume this constant to be zero.[2] For the symmetries to be consistent with boundary conditions i), we have to assume that $\beta_{|\partial\Sigma}$ is constant, and again we may assume without loss of generality that this constant vanishes. So we consider the following two cases:

| | | |
|---|---|---|
| Neumann boundary conditions: | $\iota_{\partial\Sigma}^*\eta = 0, \quad \beta_{\|\partial\Sigma} = 0$ | (N) |
| Dirichlet boundary conditions: | $\xi_{\|\partial\Sigma} = 0,$ | (D) |

**1.2. Generalizations.** To make things more interesting, we may replicate $n$ times what we have done above. Namely, take $\mathcal{M}_n = \mathcal{M}_1^n$ and define

$$S(\{\xi\},\{\eta\}) := \int_\Sigma \sum_{I=1}^n \eta_I \,\mathrm{d}\xi^I, \quad \xi^I \in \Omega^0(\Sigma),\ \eta_I \in \Omega^1(\Sigma).$$

Identifying $\mathcal{M}_n$ with $\Omega^0(\Sigma,\mathbb{R}^n)\oplus\Omega^1(\Sigma,(\mathbb{R}^n)^*)$, we may also write

$$S(\xi,\eta) := \int_\Sigma \langle \eta, \mathrm{d}\xi\rangle, \quad \xi \in \Omega^0(\Sigma,\mathbb{R}^n),\ \eta \in \Omega^1(\Sigma,(\mathbb{R}^n)^*), \tag{1.3}$$

where $\langle\ ,\ \rangle$ denotes the canonical pairing. The symmetries are now defined by the addition to $\eta$ of an exact 1-form $\mathrm{d}\beta$, $\beta \in \Omega^1(\Sigma,(\mathbb{R}^n)^*)$. If $\Sigma$ has a boundary, we then choose N or D boundary conditions for each index $I$. Accordingly the boundary components of $\beta$ corresponding to N boundary conditions have to be set to zero.

We may also modify the action functional by adding a local term

$$S_\alpha(\xi,\eta) = \frac{1}{2}\int_\Sigma \alpha(\xi)(\eta,\eta), \tag{1.4}$$

where $\alpha$ is a smooth map $\mathbb{R}^n \to \Lambda^2\mathbb{R}^n$ or more generally an element of $\hat{S}(\mathbb{R}^n)^*\otimes\Lambda^2\mathbb{R}^n$, where $\hat{S}(\mathbb{R}^n)$ denotes the formal completion (i.e., the space of formal power series) of the symmetric algebra $S(\mathbb{R}^n)^*$. We will discuss in the following under which assumption on $\alpha$ and on the boundary conditions, this term may be added without breaking the symmetries of $S$.

A further generalization with a smooth $n$-manifold $M$ as target exists. The space $\mathcal{M}(M) := \{\text{bundle maps } T\Sigma \to T^*M\}$ fibers over $\mathrm{Map}(\Sigma, M)$ with fiber at a map $X$ the space of sections $\Gamma(T^*\Sigma\otimes X^*T^*M)$. Regarding $\mathrm{d}X$ as a section of $X^*TM$ and using the canonical pairing $\langle\ ,\ \rangle$ of $TM$ with $T^*M$, we define

$$S(X,\eta) := \int_\Sigma \langle \eta, \mathrm{d}X\rangle, \quad X \in \mathrm{Map}(\Sigma, M),\ \eta \in \Gamma(T^*\Sigma\otimes X^*T^*M). \tag{1.5}$$

[2] For simplicity, in this note we do not consider the case [16] when the boundary is divided into different components with different boundary conditions.

The critical points are now given by pairs of a constant map $X$ and a closed form $\eta \in \Omega^1(\Sigma, T^*_x M)$ with $x = X(\Sigma)$. The symmetries are given by translating $\eta$ by $\mathrm{d}\beta$ with $\beta \in \Gamma(X^*T^*M)$.[3] For the boundary conditions, one chooses a submanifold $C$ of $M$ and imposes $X(\partial\Sigma) \subset C$ and $\iota^*_{\partial\Sigma}\eta \in \Gamma(T^*\partial\Sigma \otimes X^*N^*C)$, where the conormal bundle $N^*C$ is by definition the annihilator of $TC$ as a subbundle of $T_C M$; viz.:

$$N^*_x C := \{\alpha \in T^*_x M : \alpha(v) = 0 \text{ for all } v \in T_x C\}, \quad x \in C. \tag{1.6}$$

Accordingly, we require $\iota^*_{\partial\Sigma}\beta \in \Gamma(X^*N^*C)$. Observe that the tangent space at a given solution (i.e., $X(\Sigma) = x$, $\eta$ closed), is isomorphic – upon choosing local coordinates around $x$ – to $\mathcal{M}_n$, just by setting $X = x + \xi$. Moreover, the action evaluated around a solution is precisely (1.3).

A global generalization of (1.4) is also possible. Namely, to every bivector field $\pi$ (i.e., a section of $\Lambda^2 TM$), we associate the term

$$S_\pi(X, \eta) = \frac{1}{2}\int_\Sigma \pi(X)(\eta, \eta). \tag{1.7}$$

If we work in the neighborhood of a solution $x$ and set $X = x + \xi$, then (1.7) reduces to (1.4) with $\alpha(v) = \pi(x+v), \xi \in \mathbb{R}^n \simeq T_x M$. Actually we are interested in working in a formal neighborhood, so we set $\alpha$ to be the Taylor expansion of $\pi$ around $x$ and regard it as an element of $\hat{S}(\mathbb{R}^n)^* \otimes \Lambda^2\mathbb{R}^n$.

**1.3. Functional-integral quantization.** The action functional (1.5) is not very interesting classically. Much more interesting is its quantization, by which we mean the evaluation of "expectation values", i.e., ratios of functional integrals

$$\langle \mathcal{O} \rangle_{\mathrm{cl}} := \frac{\int_{\mathcal{M}(M)} \mathrm{e}^{\frac{\mathrm{i}}{\hbar}S}\,\mathcal{O}}{\int_{\mathcal{M}(M)} \mathrm{e}^{\frac{\mathrm{i}}{\hbar}S}}, \tag{1.8}$$

where $\mathcal{O}$ is a function (which we assume to be a polynomial or a formal power series) on $\mathcal{M}(M)$. The evaluation of these functional integrals consists of an ordinary integration over the moduli space of solutions and of an "infinite-dimensional integral" which is operatively defined in terms of the momenta of the Gaussian distribution given by $S$.

The finite-dimensional integration is not problematic, though it requires choosing a measure on the moduli space of solution. The main assumption in this paper is that the first cohomology of $\Sigma$ with whatsoever boundary conditions is trivial. Actually, we assume throughout that $\Sigma$ is the 2-disk $D$. Up to equivalence then a solution is given by specifying the value $x$ of the constant map $X$. Thus, the moduli space of solution is $M$. We choose then a delta measure on $M$ at some point $x$.

The second integration, performed around a point $x$, is then over $\mathcal{M}_n$. The main problem is that the operator d defining the quadratic form in $S$ is not invertible. To

[3] The derivative of $\beta$ is computed by choosing any torsion-free connection on $M$.

overcome this problem and make sense of the integration, we resort to the so-called BV (Batalin–Vilkovisky [5]) formalism, which is reviewed in Section 3. Besides giving us an operative unambiguous definition of (1.8), the BV formalism will also provide us with relations among the expectation values, the so-called Ward identities (see 4.5). The latter computation is however less rigorous; one might think of this as a machinery suggesting relations that have next to be proven to hold. Moreover, the BV formalism leads naturally to the generalization when the target $M$ is a graded manifold (see Section 2). In this context there is an interesting duality (see 4.3 and 4.4) between different targets.

**Acknowledgment.** I thank F. Bonechi, D. Fiorenza, F. Helein, R. Mehta, C. Rossi, F. Schätz, J. Stasheff and M. Zambon for very useful comments.

## 2. Smooth graded manifolds

In this section we give a crash course in the theory of smooth graded manifolds. A graded manifold is a supermanifold with a $\mathbb{Z}$-refinement of the $\mathbb{Z}_2$-grading. As we work in the smooth setting, we can work with algebras of global functions and so avoid the more technical definitions in terms of ringed spaces. We begin with recalling some basic definitions and notations.

**2.1. Graded linear algebra.** A graded vector space $V$ is a direct sum over $\mathbb{Z}$ of vector spaces: $V = \oplus_{i\in\mathbb{Z}} V_i$. Elements of $V_i$ have by definition degree $i$. By $V[n]$, $n \in \mathbb{Z}$, we denote the graded vector space with the same components of $V$ but shifted by $n$; i.e., $V[n]_i := V_{i+n}$. A morphism $\phi\colon V \to W$ of graded vector spaces is a homomorphism that preserves degree: i.e., $\phi(V_i) \subset W_i$ for all $i$. A $j$-graded homomorphism $\phi\colon V \to W$ is a morphism $V \to W[j]$; i.e., $\phi(V_i) \subset W_{i+j}$. We denote by $\mathrm{Hom}_j(V, W)$ the space of $j$-graded homomorphisms. We may regard the vector space of homomorphisms as a graded vector space $\mathrm{Hom}(V, W) = \oplus_j \mathrm{Hom}_j(V, W)$. In particular, by regarding the ground field as a graded vector space concentrated in degree zero, the dual $V^*$ of a graded vector space $V$ is also naturally graded with $V_i^* := (V^*)_i$ isomorphic to $(V_{-i})^*$. Observe that $V[n]^* = V^*[-n]$. Tensor products of graded vector spaces are also naturally graded: $(V \otimes W)_i = \oplus_{r+s=i} V_r \otimes W_s$.

**2.1.1. Graded algebras.** A graded algebra $A$ is an algebra which is also a graded vector space such that the product is a morphism of graded vector spaces. The algebra is called graded commutative (skew-commutative) if $ab = (-1)^{ij}ba$ ($ab = -(-1)^{ij}ba$) for all $a \in A_i$, $b \in A_j$, $i, j \in \mathbb{Z}$. The symmetric algebra of a graded vector space is the graded commutative algebra defined as $S(V) = T(V)/I$, where $T(V)$ denotes the tensor algebra and $I$ is the two-sided ideal generated by $vw - (-1)^{ij}wv$, $v \in V_i$, $w \in V_j$. We denote by $\hat{S}(V)$ its formal completion consisting of formal power series.

A graded skew-commutative algebra is called a graded Lie algebra (GLA) if its product, denoted by $[\ ,\ ]$ satisfies the graded Jacobi identity: $[a,[b,c]] = [[a,b],c] + (-1)^{ij}[b,[a,c]]$, for all $a \in A_i$, $b \in A_j$, $c \in A$, $i, j \in \mathbb{Z}$.

**2.1.2. Graded modules.** A graded module $M$ over a graded algebra $A$ is a graded vector space which is a module over $A$ regarded as a ring such that the action $A \otimes M \to M$ is a morphism of graded vector spaces. If $M$ is a module, then so is $M[j]$ for all $j \in \mathbb{Z}$.

The tensor product $M_1 \otimes_A M_2$ over $A$ of a right $A$-module $M_1$ and a left $A$-module $M_2$ is defined as the quotient of $M_1 \otimes M_2$ by the subspace generated by $m_1 a \otimes m_2 - m_1 \otimes a m_2$, for all $a_{\in} A$, $m_i \in M_i$. Observe that if $M_1$ and $M_2$ are bimodules, then so is $M_1 \otimes_A M_2$.

Let $M$ be a left $A$-module. If $A$ is graded commutative (skew-commutative), we make $M$ into a bimodule by setting $ma := (-1)^{ij} am$ ($ma := -(-1)^{ij} am$) , $a \in A_i$, $m \in M_j$. We may regard $A \oplus M$ as a graded commutative (skew-commutative) algebra by setting the product of two elements in $M$ to zero. If $A$ is a GLA, then so is $A \oplus M$.

Let $A$ be graded commutative. For every $A$-module $M$, we define inductively the $A$-module $T_A^k(M)$ as $T_A^{k-1}(M) \otimes_A M$, with $T_A^0(M) := A$. So one gets the graded associative algebra $T_A(M) := \oplus_{j\in\mathbb{N}} T_A^j(M)$ which is also an $A$-bimodule. The symmetric algebra $S_A(M)$ is defined as the quotient of $T_A(M)$ by the two-sided ideal generated by $vw - (-1)^{ij} wv$, $v \in M_i$, $w \in M_j$. We denote by $\hat{S}_A(M)$ its formal completion.

**2.1.3. Derivations and multiderivations.** A $j$-graded endomorphism $D$ of a graded algebra $A$ is called a $j$-graded derivation if $D(ab) = D(a)b + (-1)^{ij} aD(b)$ for all $a \in A_i$, $i \in \mathbb{Z}$, and all $b \in A$. For example, if $A$ is a GLA, $[a,\ ]$ is an $i$-graded derivation for every $a \in A_i$. A differential is a derivation of degree 1 that squares to zero. A differential graded Lie algebra (DGLA) is a GLA with a differential.

We denote by $\mathrm{Der}_j(A)$ the space of $j$-graded derivations of a graded algebra $A$ and set $\mathrm{Der}(A) = \oplus_{j\in\mathbb{Z}} \mathrm{Der}_j(A)$. It is a GLA with bracket $[D_1, D_2] := D_1 D_2 - (-1)^{j_1 j_2} D_2 D_1$, $D_i \in \mathrm{Der}_{j_i}(A)$. Observe that $\mathrm{Der}(A)$ is a left $A$-module while $A$ is a left $\mathrm{Der}(A)$-module. Thus, for every $n$, we may regard $\mathrm{Der}(A) \oplus A[n]$ as a GLA with the property

$$\begin{aligned} &[X, fg] = (-1)^{jk} f[X, g] + [X, f]g, \\ &\text{for all } X \in \mathrm{Der}(A)_j,\ f \in A_k,\ g \in A. \end{aligned} \tag{2.1}$$

Given a graded commutative algebra $A$, we define the algebra $\hat{\mathrm{D}}(A, n)$ of $n$-shifted multiderivations by $\hat{\mathrm{D}}(A, n) := \hat{S}_A(\mathrm{Der}(A)[-n])$, and denote by $\mathrm{D}(A, n)$ its subalgebra $S_A(\mathrm{Der}(A)[-n])$. Observe that the GLA structure on $\mathrm{Der}(A) \oplus A[n]$ can be extended to $\mathrm{D}(A, n)[n]$ and to $\hat{\mathrm{D}}(A, n)[n]$ in a unique way, compatible with (2.1), such that

$$[D_1, D_2 D_3] = (-1)^{(j_1+n)j_2} D_2 [D_1, D_3] + [D_1, D_2] D_3, \quad D_i \in \mathrm{D}(A)_{j_i}.$$

By this property, $\hat{\mathrm{D}}(A,n)$ is a so-called $n$-Poisson algebra. For $n=0$, it is a graded Poisson algebra. A 1-Poisson algebra is also called a Gerstenhaber algebra. Since this case is particularly important, we will use the special notation $\hat{\mathrm{D}}(A)$ ($\mathrm{D}(A)$) for $\hat{\mathrm{D}}(A,1)$ ($\mathrm{D}(A,1)$). Elements of $\hat{\mathrm{D}}(A)$ are simply called multiderivations. More precisely, elements of $S^j_A(\mathrm{Der}(A)[-1])$ are called $j$-derivations, and a $j$-derivation is said to be of degree $k$ and of total degree $j+k$ if it belongs to $\hat{\mathrm{D}}(A)_{j+k}$.

Given an $n$-Poisson algebra $(P,\bullet,[\ ,\ ])$, one defines $\mathrm{ad}\colon P\to\mathrm{Der}(P)$ by $\mathrm{ad}_X Y := [X,Y]$, $X,Y\in P$. The $n$-Poisson algebra is said to be nondegenerate if ad is surjective (in other words, if the first Lie algebra cohomology of $P$ with coefficients in its adjoint representation is trivial).

**2.1.4. The Hochschild complex.** For a given a graded vector space $A$ one defines $\mathsf{Hoch}^{j,m}(A)=\mathrm{Hom}_j(A^{\otimes m},A)$, $\mathsf{Hoch}^n(A)=\bigoplus_{j+m=n}\mathsf{Hoch}^{j,m}(A)$, and the Hochschild complex $\mathsf{Hoch}(A)=\bigoplus_n\mathsf{Hoch}^n(A)$. One may compose elements of $\mathsf{Hoch}(A)$ as follows: given $\phi\in\mathsf{Hoch}^{j_1,m_1}$ and $\psi\in\mathsf{Hoch}^{j_2,m_2}$, one defines the nonassociative product

$$\phi\bullet\psi=(-1)^{(j_2+m_2-1)(m_1-1)}\sum_i(-1)^{i(m_2-1)}\phi\circ(1^{\otimes i}\otimes\psi\otimes 1^{\otimes(m_1-1-i)})$$
$$\in\mathsf{Hoch}^{j_1+j_2,m_1+m_2-1}.$$

It turns out that its associated bracket $[\phi,\psi]:=\phi\bullet\psi-(-1)^{(j_1+m_1-1)(j_2+m_2-1)}\psi\bullet\phi$ makes $\mathsf{Hoch}(A)[1]$ into a GLA. A product on $A$ is an element $\mu$ of $\mathsf{Hoch}^{0,2}(A)$. Define $b=[\mu,\ ]$. Then $b$ is a differential on $\mathsf{Hoch}(A)[1]$ iff the product is associative.

**2.1.5. Differential and multidifferential operators.** Given a graded associative algebra $A$ and graded derivations $\phi_i\in\mathrm{Der}(A)_{j_i}$, the composition $\phi_1\circ\cdots\circ\phi_k$ is an element of $\mathsf{Hoch}^{j_1+\cdots+j_k,1}$. A differential operator on $A$ is by definition a linear combination of homomorphisms of this form. A multidifferential operator is a linear combination of elements of $\mathsf{Hoch}(A)$ of the form $(a_1,\dots,a_n)\mapsto\phi_1(a_1)\dots\phi_n(a_n)$ where each $\phi_i$ is a differential operator. Denote by $\mathcal{D}(A)$ the Lie subalgebra of multidifferential operators in $\mathsf{Hoch}(A)[1]$. As the product is a multidifferential operator itself, $\mathcal{D}(A)$ is also a subcomplex of $(\mathsf{Hoch}(A)[1],b)$. For $A$ graded commutative, one defines the HKR map (Hochschild–Kostant–Rosenberg [26]) $\mathrm{HKR}\colon\mathrm{D}(A)\to\mathcal{D}(A)$ as the linear extension of

$$\phi_1\dots\phi_n\mapsto\Big(a_1\otimes\cdots\otimes a_n\mapsto\sum_{\sigma\in S_n}\mathrm{sign}(\sigma)\phi_{\sigma(1)}(a_1)\dots\phi_{\sigma(n)}(a_n)\Big),$$

where the $\phi_i$s are derivations and the sign is given by $\phi_{\sigma(1)}\dots\phi_{\sigma(n)}=\mathrm{sign}(\sigma)\phi_1\dots\phi_n$ in $\mathrm{D}(A)$. It turns out that HKR is a chain map $(\mathrm{D}(A),0)\to(\mathcal{D}(A),b)$. It is a classical result [26] that in certain cases (e.g., when $A$ is the algebra of smooth functions on a smooth manifold), HKR is a quasiisomorphism (i.e., it induces an isomorphism in cohomology).

**2.2. Graded vector spaces.** To fix notations, from now on we assume the ground field to be $\mathbb{R}$. For simplicity we consider only finite-dimensional vector spaces. We define the algebra of polynomial functions over a graded vector space $V$ as the symmetric algebra of $V^*$ and the algebra of smooth functions as its formal completion. We use the notations $\mathbf{C}^\infty(V) := S(V^*) \subseteq \hat{\mathbf{C}}^\infty(V) := \hat{S}(V^*)$. Elements of $S^0(V^*) \simeq \mathbb{R}$ will be called constants functions.

**2.2.1. Multivector fields.** A vector field on $V$ is by definition a linear combination of graded derivations on its algebra of functions. We use the notations $\mathfrak{X}(V) := \mathrm{Der}(\mathbf{C}^\infty(V))$, $\hat{\mathfrak{X}}(V) := \mathrm{Der}(\hat{\mathbf{C}}^\infty(V))$. Observe that we may identify $\mathfrak{X}(V)$ and $\hat{\mathfrak{X}}(V)$ with $\mathbf{C}^\infty(V) \otimes V$ and $\hat{\mathbf{C}}^\infty(V) \otimes V$, respectively. Elements of $S^0(V^*) \otimes V \simeq V$ will be called constant vector fields.

Multivector fields are by definition multiderivations. In particular, $k$-vector fields are $k$-multiderivations, and we define their degree and total degree correspondingly. We use the notations $\boldsymbol{\mathfrak{X}}(V) := \mathrm{D}(\mathbf{C}^\infty(V))$ and $\hat{\boldsymbol{\mathfrak{X}}}(V) := \hat{\mathrm{D}}(\hat{\mathbf{C}}^\infty(V))$ for the corresponding Gerstenhaber algebras. We also define the $n$-Poisson algebras $\boldsymbol{\mathfrak{X}}(V, n)$ and $\hat{\boldsymbol{\mathfrak{X}}}(V, n)$ of $n$-shifted multivector fields as $\mathrm{D}(\mathbf{C}^\infty(V), n)$ and $\hat{\mathrm{D}}(\hat{\mathbf{C}}^\infty(V), n)$. We have the following identifications:

$$\boldsymbol{\mathfrak{X}}(V, n) \simeq S(V^*) \otimes S(V[-n]) \simeq \mathbf{C}^\infty(V \oplus V^*[n]), \tag{2.2a}$$

$$\hat{\boldsymbol{\mathfrak{X}}}(V, n) \simeq \hat{S}(V^*) \hat{\otimes} \hat{S}(V[-n]) \simeq \hat{\mathbf{C}}^\infty(V \oplus V^*[n]). \tag{2.2b}$$

**2.2.2. Berezinian integration.** Let $V$ be an odd vector space (i.e., a graded vector space with nontrivial components only in odd degrees). By integration we simply mean a linear form on its space of functions $\mathbf{C}^\infty(V) = \hat{\mathbf{C}}^\infty(V)$, which is isomorphic, forgetting degrees, to $\Lambda V^*$.[4] So integration is defined by an element $\mu$ of $\Lambda V$. We use the notation $\int_V f\,\mu$ for the pairing $\langle f, \mu\rangle$. We call an element of $\Lambda V$ a Berezinian form if its component in $\Lambda^{\mathrm{top}} V$, top $= \dim V$, does not vanish. In this case integration has the property that its restriction to the space of functions of top degree is injective. A Berezinian form concentrated in top degree, i.e., an element of $\Lambda^{\mathrm{top}} V \setminus \{0\}$, is called pure and has the additional property that the corresponding integral vanishes on functions that are not of top degree. Observe that a pure Berezinian form $\rho$ establishes an isomorphism $\phi_\rho \colon \mathbf{C}^\infty(V) \simeq \Lambda V^* \xrightarrow{\sim} \Lambda V$, $g \mapsto \iota_g \rho$. If $\mu = \iota_g \rho$, then $\int_V f\,\mu = \langle f, \iota_g \rho\rangle = \int_V fg\,\rho$, so we simply write $g\rho$ instead of $\iota_g \rho$.

**Lemma 2.1.** *Given a pure Berezinian form $\rho$, for every Berezinian form $\mu$ there is a unique constant $c \neq 0$ and a unique function $\sigma \in \Lambda^{>0} V^*$ such that $\mu = c\mathrm{e}^\sigma \rho$.*

*Proof.* Set $g = \phi_\rho^{-1}(\mu)$. If $\mu$ is a Berezinian form, its component $c$ in $\Lambda^0 V^*$ is invertible. So we may write, $g = c(1 + h)$ with $h \in \Lambda^{>0} V^*$. Finally we define $\sigma = \log(1+h) = \sum_{k=1}^\infty (-1)^{k+1} h^k / k$ (observe that this is actually a finite sum). □

[4] By $\Lambda V$, we mean the usual exterior algebra of $V$ regarded as an ordinary vector space.

**Lemma 2.2.** *For every Berezinian form $\mu$, there is a map* $\mathrm{div}_\mu\colon \mathfrak{X}(V) \to \mathbf{C}^\infty(V)$ (*the divergence operator*) *such that*

$$\int_V X(f)\,\mu = \int_V f\,\mathrm{div}_\mu X\,\mu \quad \textit{for all } f \in \mathbf{C}^\infty(V).$$

*Moreover,* $\mathrm{div}_{c\mu} = \mathrm{div}_\mu$ *for every constant* $c \neq 0$. *In particular, all pure Berezinian forms define the same divergence operator.*

*Proof.* The map $f \mapsto \int_V X(f)\,\mu$ is linear. So there is a unique $\mu_X \in \Lambda V$ such that $\int_V X(f)\,\mu = \int_V f\,\mu_X$. Given a pure Berezinian form $\rho$, define $g_\mu = \phi_\rho^{-1}(\mu)$ and $g_X^\mu = \phi_\rho^{-1}(\mu_X)$. Thus, $\mu_X = g_X^\mu \rho = g_X^\mu g_\mu^{-1}\mu$. Then we define $\mathrm{div}_\mu X$ as $g_X^\mu g_\mu^{-1}\mu$. Observe that this does not depend on the choice of $\rho$. □

**2.3. Graded vector bundles.** A graded vector bundle is a vector bundle whose fibers are graded vector spaces and such that the transition functions are morphisms of graded vector spaces. All the constructions for graded vector spaces described above extend to graded vector bundles. In particular, given a graded vector bundle $E$, we may define the shifted graded vector bundles $E[n]$, the dual bundle $E^*$ (and $E[n]^* = E^*[-n]$), the symmetric algebra bundle $S(E)$ and its formal completion $\hat{S}(E)$. We also define the graded commutative algebras of functions (we restrict for simplicity to graded vector bundles of finite rank) accordingly in terms of sections $\mathbf{C}^\infty(E) := \Gamma(S(E^*)) \subseteq \hat{\mathbf{C}}^\infty(E) := \Gamma(\hat{S}(E^*))$. Elements of $\mathbf{C}^\infty(E)$ will be called polynomial functions.

**Remark 2.3.** In case the given vector bundle is the tangent or the cotangent bundle of a manifold $M$, it is customary to write the shift after the $T$ symbol; viz., one writes $T[n]M$ and $T^*[n]M$ instead of $TM[n]$ and $T^*M[n]$. According to the previous remark, we have in particular $\mathbf{C}^\infty(T[1]M) = \hat{\mathbf{C}}^\infty(T[1]M) = \Omega(M)$ and $\mathbf{C}^\infty(T^*[1]M) = \hat{\mathbf{C}}^\infty(T^*[1]M) = \mathcal{X}(M)$, where $\Omega(M) = \Gamma(\Lambda T^*M)$ and $\mathcal{X}(M) = \Gamma(\Lambda TM)$ denote the graded commutative algebras of differential forms and of multivector fields respectively. Observe that, in terms of graded vector spaces, we have

$$\Omega(M) = \bigoplus_{i=0}^{\dim M} \Omega^i(M)[-i], \quad \mathcal{X}(M) = \bigoplus_{i=0}^{\dim M} \mathcal{X}^i(M)[-i], \tag{2.3}$$

where $\Omega^i(M)$ and $\mathcal{X}^i(M)$ are regarded as ordinary vector spaces.

**2.3.1. Multivector fields.** A vector field on $E$ is a linear combination of graded derivations on its algebra of functions. We use the notations $\mathfrak{X}(E) := \mathrm{Der}(\mathbf{C}^\infty(E))$, $\hat{\mathfrak{X}}(E) := \mathrm{Der}(\hat{\mathbf{C}}^\infty(E))$. A vector field $X$ on $E$ is completely determined by its restrictions $X_M$ to $C^\infty(M)$ and $X_E$ to $\Gamma(E^*)$. Observe that $X_M$ is a $\hat{\mathbf{C}}^\infty(E)$-valued vector field on $M$. Picking a connection $\nabla$ on $E^*$, we set $X_E^\nabla(\sigma) := X(\sigma) - \nabla_{X_M}\sigma$,

for all $\sigma \in \Gamma(E^*)$. Since $X_E^\nabla$ is $C^\infty(M)$-linear, it defines a bundle map $E^* \to \hat{S}(E^*)$. The map $X \mapsto X_M \oplus X_E^\nabla$ is then an isomorphism from $\hat{\mathfrak{X}}(E)$ to $\Gamma(\hat{S}E^* \otimes (TM \oplus E))$.

**Remark 2.4.** We may extend $\nabla$ to the whole of $\hat{\mathbf{C}}^\infty(E)$ as a derivation. So $\nabla_{X_M}$, unlike $X_M$, is a vector field on $E$. The difference $X^\nabla := X - \nabla_{X_M}$, which we call the vertical component of $X$, is then also a vector field with the additional property that its restriction to $C^\infty(M)$ vanishes.

Multivector fields are by definition multiderivations. In particular, $k$-vector fields are $k$-multiderivations, and we define their degree and total degree correspondingly. By $\mathfrak{X}(E) := \mathrm{D}(\mathbf{C}^\infty(E))$, $\hat{\mathfrak{X}}(E) := \hat{\mathrm{D}}(\hat{\mathbf{C}}^\infty(E))$ we denote the corresponding Gerstenhaber algebras. More generally, the $n$-Poisson algebra $\hat{\mathfrak{X}}(E,n)$ ($\mathfrak{X}(E,n)$) of $n$-shifted (polynomial) multivector fields are defined as $\hat{\mathrm{D}}(\hat{\mathbf{C}}^\infty(E),n)$ ($\mathrm{D}(\mathbf{C}^\infty(E),n)$). Upon choosing a connection $\nabla$, we have the identifications

$$\mathfrak{X}(E,n) \simeq \Gamma(SE^*) \otimes \Gamma(S((TM \oplus E)[-n])) \simeq \mathbf{C}^\infty(E \oplus T^*[n]M \oplus E^*[n]),$$
$$\hat{\mathfrak{X}}(E,n) \simeq \Gamma(\hat{S}(E^*)) \hat{\otimes} \Gamma(\hat{S}(TM \oplus E)[-n]) \simeq \hat{\mathbf{C}}^\infty(E \oplus T^*[n]M \oplus E^*[n]).$$

**2.3.2. The Berezinian bundle.** We may easily extend the Berezinian integration introduced in 2.2.2 to every odd vector bundle $E \to M$ (i.e., a bundle of odd vector spaces). A section $\mu$ of the "Berezinian bundle" $\mathrm{BER}(E) := \Lambda E \otimes \Lambda^{\mathrm{top}} T^*M$, $\mathrm{top} = \dim M$, defines[5] a $C^\infty(M)$-linear map $\langle\ ,\mu\rangle\colon \mathbf{C}^\infty(E) \simeq \Gamma(\Lambda E^*) \to \Omega^{\mathrm{top}}(M)$. We set $\int_E f\,\mu := \int_M \langle f,\mu\rangle$. (For $M$ non compact, this of course makes sense only for certain functions.) Like in the case of odd vector spaces, we are interested in integrations that are nondegenerate on the subspace of functions of top degree. These are determined by sections of the Berezinian bundle whose top component is nowhere vanishing. We call such sections Berezinian forms. A pure Berezinian form $\rho$ is then by definition a Berezinian form concentrated in top degree, i.e., a nowhere vanishing section of the "pure Berezinian bundle" $\mathrm{Ber}(E) := \Lambda^{\mathrm{top}} E \otimes \Lambda^{\mathrm{top}} T^*M$ (with the first "top" the rank of $E$).

**Example 2.5.** Let $E = T^*[k]M$, with $k$ odd and with $M$ orientable and connected. Then $\mathrm{Ber}(E) = (\Lambda^{\mathrm{top}} T^*M)^{\otimes 2}$. So there is a two-to-one correspondence between volume forms on $M$ and pure Berezinian forms on $E$. Let $v$ be a volume form and $\rho_v$ the corresponding Berezinian form. If we identify functions on $T^*[k]M$ with multivector fields, we may then compute $\int_{T^*[k]M} X\,\rho_v = \int_M \phi_v(X)\,v$, with $\phi_v\colon \mathfrak{X}(M) \xrightarrow{\sim} \Omega(M)$, $X \mapsto \iota_X v$. As a further example, consider the graded vector bundle $L_C := N^*[k]C, k$ odd, where $C$ is a submanifold of $M$ and $N^*C$ its conormal bundle (defined in (1.6)). Now $\mathrm{Ber}\, L_C \simeq \Lambda^{\mathrm{top}} N^*C \otimes \Lambda^{\mathrm{top}} T^*C \simeq \Lambda^{\mathrm{top}} T^*_C M$, where $T^*_C M$ is the restriction of $T^*M$ to $C$. Thus, a volume form $v$ on $M$ also determines by restriction a pure Berezinian form on $L_C$ which we denote by $\sqrt{\rho_v}$ as the correspondence is now linear instead of quadratic. We may identify functions on $L_C$ with sections of the exterior

[5] We consider $M$ to be orientable, otherwise replace the space of top forms with the space of densities.

algebra of $NC$. We then have $\int_{L_C} X \sqrt{\rho_v} = \int_C \phi_v(\tilde{X})$, where $\tilde{X}$ is any multivector field on $M$ extending a representative of $X$ in $\Gamma(\Lambda T_C M)$. Finally, we have a canonically defined surjective morphism $\imath_C^* \colon \mathbf{C}^\infty(M) \to \mathbf{C}^\infty(C)$ obtained by restricting a multivector field to $C$ and modding out its tangent components. One should think of $L_C$ as a submanifold (actually, a Lagrangian submanifold) of $T^*[k]M$ with inclusion map denoted by $\imath_C$. We then have

$$\int_{L_c} \imath_C^*(X) \sqrt{\rho_v} = \int_C \phi_v(X) \quad \text{for all } X \in \Gamma(\Lambda T M) \simeq \mathbf{C}^\infty(T^*[k]M), \tag{2.4}$$

with the r.h.s. defined to be zero if form degree and dimension do not match.

A pure Berezinian form $\rho$ establishes an isomorphism $\phi_\rho \colon \mathbf{C}^\infty(E) \simeq \Gamma(\Lambda E^*) \xrightarrow{\sim} \Gamma(\mathrm{BER}(E))$, $g \mapsto \imath_g \rho$. If $\mu = \imath_g \rho$, then $\int_E f\,\mu = \int_M \langle f, \imath_g \rho \rangle = \int_E fg\,\rho$, so we simply write $g\rho$ instead of $\imath_g \rho$. Lemmata 2.1 and 2.2 generalize as follows:

**Lemma 2.6.** *Given a pure Berezinian form $\rho$, for every Berezinian form $\mu$ there is a unique nowhere vanishing function $f \in C^\infty(M)$ and a unique function $\sigma \in \Gamma(\Lambda^{>0} E^*)$ such that $\mu = f \mathrm{e}^\sigma \rho$. If $M$ is connected, there is a unique function $\sigma \in \mathbf{C}^\infty(E)$ such that $\mu = \mathrm{e}^\sigma \rho$ or $\mu = -\mathrm{e}^\sigma \rho$.*

**Lemma 2.7.** *Let $E \to M$ be an odd vector bundle with $M$ compact and orientable. Then, for every Berezinian form $\mu$, there is a map $\mathrm{div}_\mu \colon \mathfrak{X}(E) \to \mathbf{C}^\infty(E)$ (the divergence operator) such that*

$$\int_E X(f)\,\mu = \int_E f\,\mathrm{div}_\mu X\,\mu \quad \textit{for all } f \in \mathbf{C}^\infty(E).$$

*Moreover,* $\mathrm{div}_{c\mu} = \mathrm{div}_\mu$ *for every constant* $c \neq 0$.

The proof of Lemma 2.6 is exactly the same as the proof of Lemma 2.1. The proof of Lemma 2.7 goes as the proof of Lemma 2.2 if we may assume that the map $f \mapsto \langle X(f), \mu \rangle$ is $C^\infty(M)$-linear. This is the case only for a vertical vector field. By using Remark 2.4, we write $X$ as $\nabla_{X_M} + X^\nabla$, and $X^\nabla$ is vertical. By further writing $X_M$ as $\sum_i h_i X_M^i$, with $h_i \in \mathbf{C}^\infty(E)$ and $X_M^i \in \mathfrak{X}(M)$, and manipulating the integral carefully, we end up with terms which are $C^\infty(M)$-linear plus terms where we may apply the usual divergence theorem on $M$. The expression for $\mathrm{div}_\mu X$ is then easily seen not to depend on the choices involved in this argument.

**Remark 2.8.** One may easily see that for every vector field $X$ and every function $g$, the divergence of $gX$ is the sum (with signs) of $g\mathrm{div}_\mu X$ and $X(g)$.

Integration over an arbitrary graded vector bundle is defined by splitting it into its odd part (where Berezinian integration may be defined) and its even part (where the usual integration theory makes sense).

**2.4. Smooth graded manifolds.** We are now ready to define smooth graded manifolds. We call a graded commutative algebra a graded algebra of smooth (polynomial) functions if it is isomorphic to the algebra of (polynomial) functions of a graded vector bundle. Next we denote by $\widehat{\mathsf{GrSmFun}}$ ($\mathsf{GrSmFun}$) the category whose objects are graded algebras of smooth (polynomial) functions and whose morphisms are graded algebra morphisms. Finally, we define the category $\widehat{\mathsf{SmoothGr}}$ ($\mathsf{SmoothGr}$) of smooth graded manifolds as the dual of $\widehat{\mathsf{GrSmFun}}$ ($\mathsf{GrSmFun}$). In particular, graded vector spaces and graded vector bundles may be regarded as smooth graded manifolds, i.e., as objects in $\widehat{\mathsf{SmoothGr}}$ or $\mathsf{SmoothGr}$ depending on which algebra of functions we associate to them.

**Notation 2.9.** If $A$ is an object of $\mathsf{GrSmFun}$, we write $\mathrm{Spec}(A)$ for the same object in $\mathsf{SmoothGr}$. Vice versa, if we start with an object $\mathcal{M}$ of $\mathsf{SmoothGr}$, we denote by $\mathbf{C}^\infty(\mathcal{M})$ the same object in $\mathsf{GrSmFun}$. We use the notations $\widehat{\mathrm{Spec}}$ and $\hat{\mathbf{C}}^\infty$ for the hatted categories. We denote by $\widehat{\mathrm{Mor}}(\mathcal{M}, \mathcal{N})$ ($\mathrm{Mor}(\mathcal{M}, \mathcal{N})$) the space of morphisms from $\mathcal{M}$ to $\mathcal{N}$ in $\widehat{\mathsf{SmoothGr}}$ ($\mathsf{SmoothGr}$).

**Remark 2.10.** The spaces of morphisms $\widehat{\mathrm{Mor}}(\mathcal{M}, \mathcal{N})$ ($\mathrm{Mor}(\mathcal{M}, \mathcal{N})$) may actually be given the structure of a (possibly infinite-dimensional) smooth manifolds. In particular, for $\mathcal{N} = V$ a graded vector space, they may be regarded as (possibly infinite-dimensional) vector spaces:

$$\mathrm{Mor}(\mathcal{M}, V) \simeq (V \otimes \mathbf{C}^\infty(\mathcal{M}))_0, \quad \widehat{\mathrm{Mor}}(\mathcal{M}, V) \simeq (V \otimes \hat{\mathbf{C}}^\infty(\mathcal{M}))_0, \tag{2.5}$$

for $\mathbf{C}^\infty(V)$ is generated by $V^*$, so an algebra morphism from $\mathbf{C}^\infty(V)$ is determined by its restriction to $V^*$ as a morphism of graded vector spaces.

By our definition, every smooth graded manifold may actually be realized as a graded vector bundle though not in a canonical way. One often obtains new graded algebras of smooth functions by some canonical constructions, yet their realization as algebras of functions of graded vector bundles requires some choice.

**Example 2.11.** As we have seen at the end of 2.3.1, upon choosing a connection, we may identify the algebra $\hat{\mathfrak{X}}(E, n)$ of shifted multivector fields on $E$ with the graded algebra of smooth functions on $E \oplus T^*[n]M \oplus E^*[n]$. We write $T^*[n]E$ for $\mathrm{Spec}\, \hat{\mathfrak{X}}(E, n)$ and have, tautologically, $\hat{\mathbf{C}}^\infty(T^*[n]E) = \hat{\mathfrak{X}}(E, n)$ and, noncanonically, $T^*[n]E \simeq E \oplus T^*[n]M \oplus E^*[n]$.

Given two smooth graded manifolds $\mathcal{M}$ and $\mathcal{N}$, their Cartesian product $\mathcal{M} \times \mathcal{N}$ is defined as the smooth graded manifold having $\mathbf{C}^\infty(\mathcal{M}) \hat{\otimes} \mathbf{C}^\infty(\mathcal{N})$ as algebra of functions (respectively $\hat{\mathbf{C}}^\infty(\mathcal{M}) \hat{\otimes} \hat{\mathbf{C}}^\infty(\mathcal{N})$ in the hatted category).

**Remark 2.12** (Graded maps). Unlike in the category of manifolds, in general $\mathrm{Mor}(\mathcal{L} \times \mathcal{M}, \mathcal{N})$ is not the same as $\mathrm{Mor}(\mathcal{L}, \mathrm{Mor}(\mathcal{M}, \mathcal{N}))$ even allowing infinite-dimensional objects. However, one can show that, given $\mathcal{M}$ and $\mathcal{N}$, the functor defined by $\mathcal{L} \mapsto \mathrm{Mor}(\mathcal{L} \times \mathcal{M}, \mathcal{N})$ is representable by an infinite-dimensional

smooth graded manifold [44], [36] denoted by $\mathrm{Map}(\mathcal{M}, \mathcal{N})$; viz., $\mathrm{Mor}(\mathcal{L}\times\mathcal{M}, \mathcal{N}) = \mathrm{Mor}(\mathcal{L}, \mathrm{Map}(\mathcal{M}, \mathcal{N}))$. Similarly, there is a hatted version denoted by $\widehat{\mathrm{Map}}(\mathcal{M}, \mathcal{N}))$.

For $\mathcal{N} = V$ a graded vector space, one can use (2.5)[6] and realize the graded manifolds of maps as graded vector spaces. Namely, one can easily show that

$$\mathrm{Map}(\mathcal{M}, V) \simeq V \otimes \mathbf{C}^\infty(\mathcal{M}), \quad \widehat{\mathrm{Map}}(\mathcal{M}, V) \simeq V \otimes \hat{\mathbf{C}}^\infty(\mathcal{M}). \tag{2.6}$$

In particular, one has the useful identities $\mathbf{C}^\infty(\mathcal{M}) \simeq \mathrm{Map}(\mathcal{M}, \mathbb{R})$, $\mathrm{Mor}(\mathcal{M}, V) = \mathrm{Map}(\mathcal{M}, V)_0, \mathrm{Map}(\mathcal{M}, V[k]) = \mathrm{Map}(\mathcal{M}, V)[k], \mathrm{Map}(\mathcal{M}, V\oplus W) = \mathrm{Map}(\mathcal{M}, V)\oplus \mathrm{Map}(\mathcal{M}, W)$, and their hatted versions.

On a graded manifold we can then define the notions of vector fields, multivector fields, Berezinian integration, divergence operator. In particular, if $\mathcal{M}$ is a smooth graded manifold with algebra of functions isomorphic to $\hat{\mathbf{C}}^\infty(E)$ for some graded vector bundle $E$, we have that $\hat{\boldsymbol{\mathfrak{X}}}(\mathcal{M}, n) := \hat{\mathrm{D}}(\hat{\mathbf{C}}^\infty(\mathcal{M}), n)$ is isomorphic to $\hat{\boldsymbol{\mathfrak{X}}}(E, n)$, so it is a graded algebra of smooth functions. We denote $\mathrm{Spec}(\hat{\boldsymbol{\mathfrak{X}}}(\mathcal{M}, n))$ by $T^*[n]\mathcal{M}$ and have, tautologically,

$$\hat{\mathbf{C}}^\infty(T^*[n]\mathcal{M}) = \hat{\boldsymbol{\mathfrak{X}}}(\mathcal{M}, n), \tag{2.7}$$

and, noncanonically,

$$T^*[n]\mathcal{M} \simeq E \oplus T^*[n]M \oplus E^*[n]. \tag{2.8}$$

**Remark 2.13** (Multidifferential operators). Multidifferential operators may be defined as in 2.1.5. We will use the notations $\boldsymbol{\mathcal{D}}(\mathcal{M})$ and $\hat{\boldsymbol{\mathcal{D}}}(\mathcal{M})$ for the DGLAs $\mathcal{D}(\mathbf{C}^\infty(\mathcal{M}))$ and $\mathcal{D}(\hat{\mathbf{C}}^\infty(\mathcal{M}))$. The HKR maps $\boldsymbol{\mathfrak{X}}(\mathcal{M}) \to \boldsymbol{\mathcal{D}}(\mathcal{M})$ and $\hat{\boldsymbol{\mathfrak{X}}}(\mathcal{M}) \to \hat{\boldsymbol{\mathcal{D}}}(\mathcal{M})$ are quasiisomorphisms of differential complexes [17] (see also [18]).

**2.4.1. Poisson structures.** A smooth graded manifold $\mathcal{M}$ is called a graded Poisson manifold of degree $n$ if $\hat{\mathbf{C}}^\infty(\mathcal{M})$ is endowed with a bracket that makes it into an $n$-Poisson algebra. By (2.7), for every smooth graded manifold $\mathcal{M}$, $T^*[n]\mathcal{M}$ is a Poisson manifold of degree $n$ in a canonical way. As a Poisson bracket is a graded biderivation, an $n$-Poisson structure on $\hat{\mathbf{C}}^\infty(\mathcal{M})$ determines an element $\pi$ of $(S^2_{\hat{\mathbf{C}}^\infty(\mathcal{M})}(\mathrm{Der}(\hat{\mathbf{C}}^\infty(\mathcal{M}))[-1-n]))_{2+n}$. The Jacobi identity for the Poisson bracket is then equivalent to the equation $[\pi, \pi] = 0$. A bivector field of degree $-n$ satisfying this equation will be called an $n$-Poisson bivector field. The Poisson bracket of two functions $f$ and $g$ may then be recovered as the derived bracket

$$\{f, g\} = [[f, \pi], g], \tag{2.9}$$

where $f$ and $g$ are regarded on the r.h.s. as 0-vector fields.

[6] The equation holds also for an infinite-dimensional graded vector space $V$, if one works from the beginning in terms of coalgebras instead of algebras of functions so as to avoid taking double duals.

If the $n$-Poisson structure of a graded Poisson manifold is nondegenerate, we speak of a graded symplectic manifold of degree $n$.

So $T^*[n]M$ is a graded symplectic manifold of degree $n$ in a canonical way.[7] We call (anti)symplectomorphism between two graded symplectic manifolds a morphism of the underlying smooth graded manifolds that yields an (anti) isomorphism of the Poisson algebras of functions. We have the following fundamental

**Theorem 2.14** (Legendre mapping [34]). *Let $E$ be a graded vector bundle. Then $T^*[n]E$ is canonically antisymplectomorphic to $T^*[n](E^*[n])$ for all $n$.*

Observe that (2.8) implies that the two graded manifolds in the theorem are diffeomorphic. The additional statement is that there is a diffeomorphism preserving Poisson brackets up to a sign and that it is canonical (i.e., independent of the choice of connection used to prove (2.8)). For a proof, see [34].

**Remark 2.15.** The name "Legendre mapping" comes from the simplest instance [43] of this theorem in the category of manifolds, $T^*TM \simeq T^*T^*M$, which induces the usual Legendre transformation of functions. The generalization $T^*E \simeq T^*E^*$ is due to [32]. The explicit expression in coordinates of this map also suggests the name of "Fourier transformation" which is used in [17].

**2.5. Further readings.** In this short introduction we did not consider: local coordinates, the definition of graded manifolds as ringed spaces, differential and integral forms as well as a proper definition of graded submanifolds and of infinite-dimensional graded manifolds. We refer to [35] and references therein for further reading on graded manifolds. For supermanifolds, see also [4], [9], [21], [30], [44].

## 3. The BV formalism

We give here a presentation of the BV formalism [5], [23] (which is a generalization of the BRST [8], [42] formalism) based mainly on [38]. See also [2], [3], [13], [22], [24], [25].

**3.1. De Rham theory revisited.** Let $M$ be a smooth orientable manifold with a volume form $v$ and $\phi_v$ the isomorphism defined in Example 2.5. Define $\Delta_v := \phi_v^{-1} \circ \mathrm{d} \circ \phi_v$ where d is the exterior derivative. (Observe that $\Delta_v$ restricted to vector fields is just the divergence operator.) So $\Delta_v^2 = 0$. Since $\phi_v$ is not an algebra morphism, $\Delta_v$ is not a derivation; one can however show that

$$\Delta_v(XY) = \Delta_v(X)Y + (-1)^i X\Delta_v(Y) + (-1)^i[X, Y], \quad X \in \mathcal{X}^i(M),\ Y \in \mathcal{X}(M). \tag{3.1}$$

[7] It may be proved [38] that every graded symplectic manifold of degree $2k + 1$ is isomorphic to some $T^*[2k + 1]\mathcal{M}$ with canonical symplectic structure.

Since $\phi_v(X)$ is a differential form, it is natural to integrate it on a submanifold of the corresponding degree. Stokes' Theorem may then be reformulated by saying that the integral vanishes if $X$ is $\Delta_v$-exact, and that it is invariant under cobordisms if $X$ is $\Delta_v$-closed. Using the language of smooth graded manifolds as in Example 2.5, we then have the

**Theorem 3.1.** *Let $v$ be a volume form on $M$ and $X$ a function on $T^*[k]M$, $k$ odd. Then:*

1. $\int_{L_C} X\sqrt{\rho_v} = \int_{L_{C'}} X\sqrt{\rho_v}$ *for every two cobordant submanifolds $C$ and $C'$ of $M$ iff $X$ is $\Delta_v$-closed.*
2. $\int_{L_C} X\sqrt{\rho_v} = 0$ *for every $C$ iff $X$ is $\Delta_v$-exact.*

Let $Q_X := [X, \ ]$ denote the Hamiltonian vector field of $X \in \mathbf{C}^\infty(T^*[k]M) \simeq \mathfrak{X}(M, k)$, $k$ odd. Using (3.1) and Stokes' Theorem, one easily has the following characterization of $\Delta_v$ in terms of the canonical symplectic structure of $T^*[k]M$:

**Theorem 3.2.** $\Delta_v X = \frac{1}{2}\mathrm{div}_{\rho_v} Q_X$ *for every volume form $v$.*

By Lemma 2.6, we know that every Berezinian form on $T^*[k]M$ may be written, up to a constant, as $\mathrm{e}^\sigma \rho_v =: \rho_v^\sigma$ for some volume form $v$ and some function $\sigma$. We write $\sqrt{\rho_v^\sigma} := \mathrm{e}^{\frac{\sigma}{2}}\sqrt{\rho_v}$. By Theorem 3.1, $\int_{L_C}\sqrt{\rho_v^\sigma}$ is the same for all cobordant submanifolds iff $\mathrm{e}^{\frac{\sigma}{2}}$ is $\Delta_v$-closed. Assuming for simplicity $\sigma$ to be even, by Theorem 3.2 and Remark 2.8, one can show that this is the case iff

$$\Delta_v\sigma + \frac{1}{4}[\sigma, \sigma] = 0. \tag{3.2}$$

Given a solution $\sigma$ of this equation, one can define a new coboundary operator $\Omega_{v,\sigma} := \Delta_v + \frac{1}{2}Q_\sigma$. Remark that $\Omega X_{v,\sigma} = \mathrm{e}^{-\frac{\sigma}{2}}\Delta_v(\mathrm{e}^{\frac{\sigma}{2}}X)$. Thus, multiplication by $\mathrm{e}^{\frac{\sigma}{2}}$ is an invertible chain map $(\mathbf{C}^\infty(T^*[k]M), \Omega_{v,\sigma}) \to (\mathbf{C}^\infty(T^*[k]M), \Delta_v)$ and the two cohomologies are isomorphic. Moreover, Theorem 3.1 is still true if one replaces $(\rho_v, \sqrt{\rho_v}, \Delta_v)$ by $(\rho_v^\sigma, \sqrt{\rho_v^\sigma}, \Omega_{v,\sigma})$.

**3.2. The general BV formalism.** Even though the above setting is all we need in the present paper, for completeness we give an overview of the general results of [38]. For this one needs the notion of submanifold of a graded manifold as well as notions of symplectic geometry on graded manifolds which we are not going to introduce here.

**Theorem 3.3.** *Let $k$ be an odd integer. Then:*

1. *Theorem* 3.1 *holds if $M$ is a graded manifold and $v$ a Berezinian form.*
2. *Every graded symplectic manifold of degree $k$ is symplectomorphic to some $T^*[k]M$ with canonical symplectic form.*

3. *There is a canonical way* (*up to a sign*) *of restricting a Berezinian form* $\rho_v$ *on* $T^*[k]M$ *to a Berezinian form denoted by* $\sqrt{\rho_v}$ *on a Lagrangian submanifold.*

4. *Every Lagrangian submanifold* $L$ *of* $T^*[k]M$ *may be deformed to a Lagrangian submanifold of the form* $L_C$*, with* $C$ *a submanifold of* $M$.

5. *If* $X$ *is* $\Delta_v$*-closed, then* $\int_L X\sqrt{\rho_v} = \int_{L'} X\sqrt{\rho_v}$ *if* $L$ *may be deformed to* $L'$.

6. *If* $X$ *is* $\Delta_v$*-exact, then* $\int_L X\sqrt{\rho_v} = 0$ *for every Lagrangian submanifold* $L$.

**3.2.1. Generating functions.** To do explicit computations, it is useful to describe the Lagrangian submanifold in terms of generating functions. Generalizing concepts from symplectic geometry to graded manifolds, one sees that the graph of the differential of a function of degree $k$ on $M$ is a Lagrangian submanifold of $T^*[k]M$. Such a function is called a generating function. However, Lagrangian submanifolds of this form project onto $M$; so certainly a conormal bundle cannot be represented this way.

A slightly more general setting is the following. We assume here some knowledge of symplectic geometry (see e.g. [6]) and generalize a classical construction. Let $U$ be an auxiliary graded manifold, and let $f$ be a function of degree $k$ on $M \times U$. Let $\Sigma$ be the $U$-critical set of $f$; i.e., the subset $M \times U$ where the differential of $f$ along $U$ vanishes. Assume $\Sigma$ to be a submanifold and let $\phi\colon \Sigma \to T^*M$ be defined by $(x, u) \mapsto (x, \mathrm{d}f(x, u))$. Then $\phi$ is a Lagrangian immersion whose image we denote by $L(f)$.

For example, if $C$ is a submanifold of $M$ defined by global regular constraints $\phi_1, \ldots, \phi_r$, with $\phi_j$ of degree $n_j$, we may take $U := \bigoplus_{j=1}^r \mathbb{R}[n_j - k]$ and define $\Psi = \sum_j \beta^j \phi_j$, where $\beta_j$ is the coordinate on $\mathbb{R}[n_j - k]$. It turns then out that $L(\Psi) = N^*[k]C$.[8] We regard now $\Psi$ as a function on $\tilde{M} := M \times U \times U[-k]$ and denote by $L_\Psi$ the graph of its differential. On $U \times U[-k]$, we choose the Lebesgue measure for the even components and a pure Berezinian form for the odd ones. We denote by $\tilde{v}$ the Berezinian form on $\tilde{M}$ obtained by this times $\rho_v$. Finally, let $u$ be the pairing between $U$ and $U^*$ regarded as a function of degree zero on $U[-k] \times U^*[k]$ and hence, by pullback, on $T^*[k]\tilde{M}$. Then a simple computation (using the Fourier representation of the delta function) shows that

$$\int_{N^*[k]C} X\mathrm{e}^{\frac{\sigma}{2}}\sqrt{\rho_v} = \int_{L_\Psi} X\mathrm{e}^{\frac{\sigma}{2}+\mathrm{i}u}\sqrt{\rho_{\tilde{v}}}.$$

Observe that deforming $\Psi$ just deforms the Lagrangian submanifold (which in general will no longer be a conormal bundle) but leaves the result unchanged.

**3.3. BV notations.** The BV formalism consists of the above setting with $k = -1$ (for historical reasons). The $-1$-Poisson bracket is called BV bracket and usually denoted

[8] In the absence of global regular constraints, conormal bundles may be described by a further generalization of generating functions, the so-called Morse families. See, e.g., [6].

by $(\ ,\ )$. The coboundary operator $\Delta_v$ is called the BV Laplacian, has degree 1 and, as $v$ is fixed, is usually simply denoted by $\Delta$. A solution $\sigma$ to (3.2) is usually written as $\sigma = 2\frac{\mathrm{i}}{\hbar}\mathsf{S}$, where $\mathsf{S}$ is called the BV action and satisfies the so-called "quantum master equation" (QME) $(\mathsf{S},\mathsf{S}) - 2\mathrm{i}\hbar\Delta\mathsf{S} = 0$. Here $\hbar$ is a parameter and $\mathsf{S}$ is allowed to depend on $\hbar$. If $\mathsf{S}$ is of degree 0, as it is usually assumed, then $Q_{\mathsf{S}}$ is of degree 1. The coboundary operator $\Omega_{v,\sigma}$ is then also homogeneous of degree 1. Setting $\Omega := -\mathrm{i}\hbar\Omega_{v,\sigma}$, we have $\Omega = Q_{\mathsf{S}} - \mathrm{i}\hbar\Delta$. An $\Omega$-closed element $\mathcal{O}$ is called an observable, and its expectation value

$$\langle\mathcal{O}\rangle := \frac{\int_L \mathrm{e}^{\frac{\mathrm{i}}{\hbar}\mathsf{S}}\,\mathcal{O}\,\sqrt{\rho_v}}{\int_L \mathrm{e}^{\frac{\mathrm{i}}{\hbar}\mathsf{S}}\,\sqrt{\rho_v}} \tag{3.3}$$

is invariant under deformations of $L$. The choice of an $L$ goes under the name of gauge fixing.[9] Expectation values of $\Omega$-exact observables vanish, but they may lead to interesting relations called Ward identities.

**Remark 3.4.** One often assumes $\hbar$ to be "small." Actually, one even takes $\mathsf{S}$ to be a formal power series in $\hbar$, $\mathsf{S} = \sum_{i=0}^{\infty}\hbar^i\mathsf{S}_i$. Then $\mathsf{S}_0$ satisfies the "classical master equation" (CME) $(\mathsf{S},\mathsf{S}) = 0$ and $Q_{\mathsf{S}_0}$ is a coboundary operator (sometimes called the BRST operator). One may look for solutions of the QME starting from a solution $\mathsf{S}_0$ of the CME. One easily sees that there is a potential obstruction to doing this (the so-called anomaly) in the second cohomology group of $Q_{\mathsf{S}_0}$.

**Remark 3.5.** An observable $\mathcal{O}$ of degree zero may also be thought of as an infinitesimal deformation of the BV action, for $\mathsf{S} + \varepsilon\mathcal{O}$ then satisfies the CME up to $\varepsilon^2$. For this to be a finite deformation, we should also assume $(\mathcal{O},\mathcal{O}) = 0$.

**3.4. Applications.** Suppose that the integral of $\mathrm{e}^{\frac{\mathrm{i}}{\hbar}\mathsf{S}}$ along a Lagrangian submanifold $L$ is not defined, but that it is enough to deform $L$ a little bit for the integral to exist. Then one defines the integral along $L$ as the integral along a deformed Lagrangian submanifold $L'$. For a given cobordism class of deformations, the integral does not depend on the specific choice of $L'$ if $S$ is assumed to satisfy the QME. This is really analogous to the definition of the principal part of an integral [22].

The typical situation is the following: One starts with a function $S$ defined on some manifold $\mathcal{M}$. One assumes there is a (nonnecessarily integrable) distribution on $\mathcal{M}$ – the "symmetries" – under which $S$ is invariant. One then adds odd variables of degree 1 (the generators of the distribution, a.k.a. the ghosts) defining a graded manifold $\tilde{\mathcal{M}}$ which fibers over $\mathcal{M}$ and is endowed with a vector field $\delta$ that describes the distribution. Then one tries to extend $S$ to a solution $\mathsf{S}_0 \in \mathbf{C}^\infty(T^*[-1]\tilde{\mathcal{M}})$ of the CME such that $Q_{\mathsf{S}_0}$ and $\delta$ are related vector fields. Under the assumption that the original distribution is integrable on the subset (usually assumed to be a submanifold)

[9] This is usually done as explained in 3.2.1 by using an auxiliary space and a generating function $\Psi$ which is in this case of degree $-1$ and is called the gauge-fixing fermion.

of critical points of $S$, one can show that this is possible under some mild regularity assumptions [5]. The next step is to find a solution of the QME as in Remark 3.4 if there is no anomaly.

Because of the invariance of $S$, the integral of $\mathrm{e}^{\frac{\mathrm{i}}{\hbar}S}$ on $\mathcal{M}$ will diverge (if the symmetry directions are not compact). On the other hand, if we integrate over $\tilde{\mathcal{M}}$ we also have zeros corresponding to the odd directions which we have introduced and along which $S$ is constant. If we introduce all generators, we have as many zeros as infinities, so there is some hope to make this ill-defined integral finite. This is actually what happens if we find a solution of the QME as in the previous paragraph and integrate on a different Lagrangian submanifold of $T^*[-1]\tilde{\mathcal{M}}$ than its zero section $\tilde{\mathcal{M}}$.

Given a function $\mathcal{O}$ on $\mathcal{M}$, it makes sense to define its expectation value as in (3.3) if there is an observable $\boldsymbol{\mathcal{O}}$ whose restriction to $\mathcal{M}$ is $\mathcal{O}$.

**Remark 3.6** (Field theory). In field theory one considers integrals of the form (1.8) with $\mathcal{M}$ infinite dimensional. Integration around critical points is defined by expanding the non quadratic part of $S$ and evaluating Gaussian expectation values. If there are symmetries, the critical points are degenerate and one cannot invert the quadratic form. One then operates as above getting an integral with the quadratic part of the BV action nondegenerate, so one can start the perturbative expansion.[10] This is not the end of the story since two problems arise. The first is that the formal evaluation of the Gaussian expectation values leads to multiplying distributions. The consistent procedure for overcoming this problem, when possible, goes under the name of renormalization. The second problem is that, in the absence of a true measure, there is no divergence operator and thus no well-defined BV Laplacian $\Delta$. This is overcome by defining $\Delta$ appropriately in perturbation theory. On the other hand, the BV bracket is well-defined (on a large enough class of functions). In the present paper the field theory is so simple that renormalization is (almost) not needed, so we will not talk about it. On the other hand, it makes sense [14] to assume that $\Delta$ exists and vanishes on the local functionals we are going to consider, while on products thereof one uses (3.1).

## 4. BV 2D TFT

We go back now to our original problem described in the Introduction. This may also be regarded as a continuation of our presentation in [10, Part III].

**4.1. The BV action.** We start by considering the TFT with action (1.1) and symmetries (1.2). We promote the generators $\beta$ of the symmetries to odd variables of degree 1; i.e., we define $\tilde{\mathcal{M}}_1 = \mathcal{M}_1 \oplus \Omega^0(\Sigma)[1]$ and the vector field $\delta$ by its action on the linear function $\xi$, $\eta$ and $\beta$: $\delta\xi = 0$, $\delta\eta = \mathrm{d}\beta$, $\delta\beta = 0$. Using integration on $\Sigma$, we identify $T^*[-1]\tilde{\mathcal{M}}_1$ with $\tilde{\mathcal{M}}_1 \oplus \Omega^2(\Sigma)[-1] \oplus \Omega^1(\Sigma)[-1] \oplus \Omega^2(\Sigma)[-2]$ and denote

[10] In order to have Gaussian integration on a vector space, one defines integration along the chosen Lagrangian submanifold via a generating function as explained in 3.2.1 and in footnote 9.

the new coordinates, in the order, by $\xi^+$, $\eta^+$ and $\beta^+$. We introduce the "superfields" $\boldsymbol{\xi} = \xi + \eta^+ + \beta^+$, $\boldsymbol{\eta} = \beta + \eta + \xi^+$, and define

$$\mathsf{S}(\boldsymbol{\xi}, \boldsymbol{\eta}) := \int_\Sigma \boldsymbol{\eta}\, \mathrm{d}\boldsymbol{\xi}, \tag{4.1}$$

where by definition the integration selects the 2-form. It is not difficult to see that $\mathsf{S}$ satisfies the master equation and $\mathsf{S}_{|\mathcal{M}_1} = S$. Moreover, the action of $Q_\mathsf{S}$ on the coordinate functions may be summarized in

$$Q_\mathsf{S}\boldsymbol{\xi} = \mathrm{d}\boldsymbol{\xi}, \quad Q_\mathsf{S}\boldsymbol{\eta} = \mathrm{d}\boldsymbol{\eta}. \tag{4.2}$$

So $Q_\mathsf{S}$ and $\delta$ are related vector fields.

By (2.3), we may regard $\boldsymbol{\xi}$ as an element of $\Omega(\Sigma)$ and $\boldsymbol{\eta}$ as an element of $\Omega(\Sigma)[1]$. As $\Omega(\Sigma) = \mathbf{C}^\infty(T[1]\Sigma)$, by Remark 2.12 at the end we may further identify $\Omega(\Sigma)$ with $\mathrm{Map}(T[1]\Sigma, \mathbb{R})$ and $\Omega(\Sigma)[1]$ with $\mathrm{Map}(T[1]\Sigma, \mathbb{R}[1])$ or, equivalently, with $\mathrm{Map}(T[1]\Sigma, \mathbb{R}^*[1])$. The latter choice is more appropriate in view of (4.1) where we pair $\boldsymbol{\xi}$ with $\boldsymbol{\eta}$. By Remark 2.12 at the end again, we have eventually the identification $T^*[-1]\tilde{\mathcal{M}}_1 \simeq \mathrm{Map}(T[1]\Sigma, T^*[1]\mathbb{R})$, where we have identified $\mathbb{R} \oplus \mathbb{R}^*[1]$ with $T^*[1]\mathbb{R}$ (by the results of Example 2.11 with $E = \mathbb{R}$ as a vector bundle over a point). This is actually the viewpoint taken in [1] (see also [15]). Finally, observe that we may also regard $T^*[-1]\tilde{\mathcal{M}}_1$ as $\mathrm{Map}(T[1]\Sigma, T^*[1]\mathbb{R}[0])$ (which is actually a submanifold) if we wish to consider formal power series in the coordinate functions.

The ill-defined integration on $\tilde{\mathcal{M}}_1$ is now replaced by a well-defined (in the sense of perturbation theory) integration over another Lagrangian submanifold $L$ of $T^*[-1]\tilde{\mathcal{M}}[-1]$. For example, as in [14], we may take $L = N^*[-1]C$ where $C$ is the submanifold of $\tilde{\mathcal{M}}$ defined as the zero locus of $\mathrm{d} * \eta$, where the Hodge-star operator is defined upon choosing a volume form on $\Sigma$.

**4.2. The superpropagator.** The main object appearing in the explicit evaluation of expectation values of functions of $\boldsymbol{\xi}$ and $\boldsymbol{\eta}$ is the "superpropagator" $\langle \boldsymbol{\xi}(z)\boldsymbol{\eta}(w)\rangle$, where $z$ and $w$ are points in $\Sigma$. Independently of the choice of gauge fixing, we have the Ward identity

$$\begin{aligned} 0 &= \langle \Omega(\boldsymbol{\xi}(z)\boldsymbol{\eta}(w))\rangle = \langle Q_\mathsf{S}(\boldsymbol{\xi}(z)\boldsymbol{\eta}(w))\rangle - \mathrm{i}\hbar\langle \Delta(\boldsymbol{\xi}(z)\boldsymbol{\eta}(w))\rangle \\ &= \mathrm{d}\langle(\boldsymbol{\xi}(z))\boldsymbol{\eta}(w)\rangle - \mathrm{i}\hbar\langle(\boldsymbol{\xi}(z), \boldsymbol{\eta}(w))\rangle = \mathrm{d}\langle(\boldsymbol{\xi}(z))\boldsymbol{\eta}(w)\rangle - \mathrm{i}\hbar\delta(z, w), \end{aligned}$$

where we assumed $\Delta(\boldsymbol{\xi}(z)) = \Delta(\boldsymbol{\eta}(w)) = 0$ (which is consistent with perturbation theory) and $\delta$ denotes the delta distribution (regarded here as a distributional 2-form). Thus, we get the fundamental identity[11]

$$\mathrm{d}\langle(\boldsymbol{\xi}(z)\boldsymbol{\eta}(w)\rangle = \mathrm{i}\hbar\delta(z, w). \tag{4.3}$$

[11] This method for deriving properties of the superpropagator just in terms of Ward identities works also for the higher-dimensional generalization of this TFT [19].

The restriction of the superpropagator to the configuration space $C_2(\Sigma) := \{(z, w) \in \Sigma \times \Sigma : z \neq w\}$ is then a closed, smooth 1-form. Namely, we set $i\hbar\theta(z, w) := \langle \boldsymbol{\xi}(z)\boldsymbol{\eta}(w)\rangle$, $(z, w) \in C_2(\Sigma)$. Then $\theta \in \Omega^1(C_2(\Sigma))$ and $d\theta = 0$. We call it the propagator 1-form. The delta distribution in (4.3) implies that $\int_\gamma \theta = 1$ where $\gamma$ is generator of the singular homology of $C_2(\Sigma)$ (viz., $\gamma$ is a loop of $w$ around $z$ or vice versa). Observe that $\theta$ is defined up to an exact 1-form. Different choices of gauge fixing just correspond to different, but cohomologous, choices of $\theta$.

If $\partial\Sigma \neq \emptyset$, we have to choose boundary conditions. Repeating the considerations in the Introduction, we see that there are two possible boundary conditions compatible with (4.2); viz.:

$$\begin{aligned} &\text{Neumann boundary conditions:} && \iota^*_{\partial\Sigma}\boldsymbol{\eta} = 0, && \text{(N)}\\ &\text{Dirichlet boundary conditions:} && \iota^*_{\partial\Sigma}\boldsymbol{\xi} = 0, && \text{(D)} \end{aligned}$$

For $\partial\Sigma = \emptyset$, the BV action (4.1) is invariant under the exchange of $\boldsymbol{\eta}$ with $\boldsymbol{\xi}$. This implies that $\psi^*\theta = \theta$ with $\psi(z, w) = (w, z)$.[12] For $\partial\Sigma \neq \emptyset$, we denote by $\theta_N$ and $\theta_D$ the propagator 1-forms corresponding to N and D boundary conditions, respectively. These 1-forms have to satisfy in addition boundary conditions. Let $\partial_i C_2(\Sigma) = \{(z_1, z_2) \in C_2(\Sigma) : z_i \in \partial\Sigma\}$ and $\iota_i$ the inclusion of $\partial_i C_2(\Sigma)$ into $C_2(\Sigma)$. Then we have $\iota_1^*\theta_D = 0$ and $\iota_2^*\theta_N = 0$. These 1-forms are no longer invariant under the involution $\psi$ defined above; they are instead related by it: viz., $\psi^*\theta_N = \theta_D$.

**4.3. Duality.** Exchanging the superfields has a deeper meaning. Observe that the 0-form component $\xi$ of $\boldsymbol{\xi}$ is an ordinary function (of degree zero), while the 0-component form $\beta$ of $\boldsymbol{\eta}$ has been assigned degree 1 and has values in $\mathbb{R}^*$. So, when we make this exchange, we are actually exchanging, loosely speaking, a map $\xi\colon \Sigma \to \mathbb{R}[0]$ with a map $\beta\colon \Sigma \to \mathbb{R}^*[1]$. In exchanging the superfields, we are then actually performing the canonical symplectomorphism $\mathrm{Map}(T[1]\Sigma, T^*[1]\mathbb{R}[0]) \to \mathrm{Map}(T[1]\Sigma, T^*[1]\mathbb{R}^*[1])$ which is induced by the canonical symplectomorphism $T^*[1]\mathbb{R}[0] \to T^*[1]\mathbb{R}[1]$, a special case of the Legendre mapping of Theorem 2.14. If we now take the graded vector space $\mathbb{R}[k]$ as target, the superfield exchange is a symplectomorphism $\mathrm{Map}(T[1]\Sigma, T^*[1]\mathbb{R}[k]) \to \mathrm{Map}(T[1]\Sigma, T^*[1]\mathbb{R}^*[1-k])$. In conclusion, the TFT with target $\mathbb{R}[k]$ is equivalent to the TFT with target $\mathbb{R}^*[1-k]$ is $\Sigma$ has no boundary, whereas, if $\Sigma$ has a boundary, the TFT with target $\mathbb{R}[k]$ and N boundary conditions is equivalent to the TFT with target $\mathbb{R}^*[1-k]$ and D boundary conditions. Thus, upon choosing the target appropriately, one may always assume to have only N boundary conditions.

**4.4. Higher-dimensional targets.** We may allow a higher-dimensional target as in (1.3) or in (1.5), and it makes sense for it to be a graded vector space or a graded manifold $M$. Now the space of fields may be identified with $\mathrm{Map}(T[1]\Sigma, T^*[1]M)$. For

[12] The cohomology class of a propagator 1-form is necessarily $\psi$-invariant. The stronger condition is that it is $\psi$-invariant without passing to cohomology.

simplicity, assume the target to be a graded vector space $V$ (which is anyway the local version of the general case). Upon choosing a graded basis $\{e_I\}$ and its dual basis $\{e^I\}$, we may consider the components $\boldsymbol{\xi}^i$ and $\boldsymbol{\eta}_i$ of the superfields. The superpropagator may then be computed as $\langle \boldsymbol{\xi}^I(z)\boldsymbol{\eta}_J(w)\rangle = \mathrm{i}\hbar\theta(z,w)\delta^I_J$, $(z,w) \in C_2(\Sigma)$, where $\theta$ is the 1-form propagator of the TFT with target $\mathbb{R}$. Again we are allowed to exchange superfields, but we may decide to exchange only some of them. Let $V = W_1 \oplus W_2$. A superfield exchange corresponding to $W_2$-components establishes a symplectomorphism $\mathrm{Map}(T[1]\Sigma, T^*[1](W_1 \oplus W_2) \simeq \mathrm{Map}(T[1]\Sigma, T^*[1](W_1 \oplus W_2^*[1])$. If we have N boundary conditions on the $W_1$-components and D boundary conditions on the $W_2$-components, the exchange yields a theory with only N boundary conditions.

If we work with target a graded manifold $M$ and D boundary conditions on a graded submanifold $C$, the perturbative expansion actually sees as target the graded submanifold $N[0]C$ of $M$ (as a formal neighborhood of $C$). As a consequence of the previous considerations, this is the same as the TFT with target $N^*[1]C$ and N boundary conditions. This case has been studied in [16], [17].

**4.4.1. Assumptions.** From now on we assume that $\Sigma$ is the disk and that on its boundary $S^1$ we put N boundary conditions. We also choose a point $\infty \in S^1$ and fix the map $X$ to take the value $x \in M$ at $\infty$. By setting $X = x + \xi$ we identify the theory with target $M$ with the theory with target the graded vector space $T_x[0]M$. The superfield $\boldsymbol{\xi} \in \mathrm{Map}(T[1]\Sigma, T_x[0]M)$ is then assumed to vanish at $\infty$.

**4.5. Ward identities and formality theorem.** There exists a class of interesting observables associated to multivector fields on the target. For simplicity we assume the target to be a graded vector space $V$, make the identification (2.2) and use a graded basis. So, for a $k$-vector field $F \in \mathfrak{X}(V)$, we define

$$\mathsf{S}_F(\boldsymbol{\xi}, \boldsymbol{\eta}) = \frac{1}{k!}\int_\Sigma F^{i_1\dots i_k}(\boldsymbol{\xi})\boldsymbol{\eta}_{i_1}\dots\boldsymbol{\eta}_{i_k}. \tag{4.4}$$

Since $Q_{\mathsf{S}}\mathsf{S}_F = \frac{1}{k!}\int_{\partial\Sigma} F^{i_1\dots i_k}(\boldsymbol{\xi})\boldsymbol{\eta}_{i_1}\dots\boldsymbol{\eta}_{i_k}$., we have defined an observable unless $F$ is a 0-vector field (i.e., a function), for one may show [14] that it is consistent to assume $\Delta\mathsf{S}_F = 0$. We will call observables of this kind bulk observables. By linear extension, we may associate a bulk observable to every element $F \in \hat{\mathfrak{X}}(V)$. If $F$ is of total degree $f$, then $\mathsf{S}_F$ is of degree $f-2$. One may also show [14] (see also [15]) that $(\mathsf{S}_F, \mathsf{S}_G) = \mathsf{S}_{[F,G]}$ for any two multivector fields $F$ and $G$. Another interesting class of observables is associated to functions on the target. Given a function $f$ and a point $u \in \partial\Sigma$, we set $\boldsymbol{\mathcal{O}}_{f,u}(\boldsymbol{\xi}, \boldsymbol{\eta}) = f(\boldsymbol{\xi}(u)) = f(\xi(u))$. Since $Q_{\mathsf{S}}\boldsymbol{\mathcal{O}}_{f,u} = 0$ as $u$ is on the boundary, since the difference $\boldsymbol{\mathcal{O}}_{f,u} - \boldsymbol{\mathcal{O}}_{f,u'}$ is equal $Q_{\mathsf{S}}\int_u^{'u} f(\boldsymbol{\xi})$ and since one may consistently set to zero $\Delta$ applied to functions of $\boldsymbol{\xi}$ only, we have defined new observables, which we will call boundary observables, in which the choice of $u$ is immaterial.

A product of observables is in general not an observable (since $\Omega$ is not a derivation). A product which is however an observable is $\boldsymbol{\mathcal{O}}(F; f_1, \dots, f_k)_{u_1,\dots u_k} :=$

$\mathsf{S}_F\boldsymbol{\mathcal{O}}_{f_1,u_1}\dots\boldsymbol{\mathcal{O}}_{f_k,u_k}$, where $F$ is a $k$-vector field, $k>0$, the $f_i$s are functions and the $u_i$s are ordered points on the boundary. The expectation value may easily be computed [14] and one gets $\langle\boldsymbol{\mathcal{O}}(F;f_1,\dots,f_k)_{u_1,\dots u_k}\rangle = \mathrm{HKR}(F)(f_1\otimes\cdots\otimes f_k)$. More generally, one may define

$$\boldsymbol{\mathcal{O}}(F_1,\dots,F_m;f_1,\dots,f_k)_{u_1,\dots u_k} := \mathsf{S}_{F_1}\dots\mathsf{S}_{F_m}\boldsymbol{\mathcal{O}}_{f_1,u_1}\dots\boldsymbol{\mathcal{O}}_{f_k,u_k}.$$

One may show [14] that the expectation value of $\boldsymbol{\mathcal{O}}(F_1,\dots,F_m;f_1,\dots,f_k)_{u_1,\dots u_k}$ may be regarded as a multidifferential operator $U_m(F_1,\dots,F_m)$ acting on $f_1\otimes\cdots\otimes f_k$. This way one defines multilinear maps $U_m$s from $\boldsymbol{\mathcal{X}}$ to $\boldsymbol{\mathcal{D}}$. However, the explicit form of the multidifferential operators will depend on the chosen gauge fixing as $\boldsymbol{\mathcal{O}}(F_1,\dots,F_m;f_1,\dots,f_k)_{u_1,\dots u_k}$ is not an observable in general. One may get very interesting identities relating the $U_m$s by considering the Ward identities

$$0=\langle\Omega\boldsymbol{\mathcal{O}}(F_1,\dots,F_m;f_1,\dots,f_k)_{u_1,\dots u_k}\rangle. \tag{4.5}$$

One may show [14] that the various contribution of the r.h.s. correspond to collapsing in all possible ways some of the bulk observables together with some of the boundary observables (with consecutives $u$s). As a result one gets relations among the $U_m$s. To interpret them, we have to introduce some further concepts.

**Definition 4.1.** An $L_\infty$-algebra[13] [29], [41] is a graded vector space $V$ endowed with operations (called multibrackets) $L_k\in\mathrm{Hom}_1(S^kV,V)$, $k\in\mathbb{N}$, satisfying for all $n\geq 0$ and for all $v_1,\dots,v_n\in V$

$$\sum_{k+l=n}\ \sum_{\sigma\in(k,l)\text{-shuffles}}\mathrm{sign}(\sigma)L_{l+1}(L_k(v_{\sigma(1)},\dots,v_{\sigma(k)}),v_{\sigma(k+1)},\dots,v_{\sigma(n)})=0,$$

where a $(k,l)$-shuffle is a permutation on $k+l$ elements such that $\sigma(1)<\cdots<\sigma(k)$ and $\sigma(k+1)<\cdots<\sigma(k+l)$, while the sign of the permutation $\sigma$ is defined by $v_{\sigma(1)}\dots v_{\sigma(n)}=\mathrm{sign}(\sigma)v_1\dots v_n$ in $S^kV$. We call flat an $L_\infty$-algebra with $L_0=0$.

In a flat $L_\infty$-algebra, $L_1$ is a coboundary operator. We denote by $H(V)$ the $L_1$-cohomology. Observe that $H(V)[-1]$ acquires a DGLA structure.

For $V$ finite dimensional, we may identify $\mathrm{Hom}_1(SV,V)$ with $(SV^*\otimes V)_1$ and so with $\mathfrak{X}(V)_1$. An $L_\infty$-algebra on $V$ is then the same as the data of a "cohomological vector field" (i.e., a vector field of degree 1 that squares to zero). The same holds in the infinite-dimensional case if one defines things appropriately.

**Example 4.2.** A (D)GLA $\mathfrak{g}$ may be regarded as a flat $L_\infty$-algebra by setting $V=\mathfrak{g}[1]$ and defining $L_k$ to be the Lie bracket for $k=2$ (and the differential for $k=1$), while all other $L_k$s are set to zero.

One may introduce the category of $L_\infty$-algebras by defining an $L_\infty$-morphism from $V$ to $W$ to be a sequence of morphisms $SV\to W$ with appropriate relations between the two sets of multibrackets. We do not spell these relations here. They essentially state that there is a morphism $V\to W$ as (possibly infinite-dimensional) graded

[13] We follow here the sign conventions of [45].

manifolds such that the corresponding homological vector fields are related. We write $U\colon V \rightsquigarrow W$ for an $L_\infty$-morphisms with components $U_m \in \mathrm{Hom}_0(S^m V, W)$. An important properties of the definition is the following: If $V$ and $W$ are flat and $U_0 = 0$, then $U_1$ is a chain map. If $U_1$ induces an isomorphism in cohomology, one says that $U$ is an $L_\infty$-quasiisomorphism. If in addition $V$ has zero differential, $V[-1]$ is isomorphic as a GLA to $H(W)[-1]$, and one says that $W[-1]$ is formal. Finally we may interpret the Ward identities (4.5) in terms of the DGLAs $\hat{\boldsymbol{\mathcal{V}}}(M) := \hat{\boldsymbol{\mathcal{X}}}(M)[1]$ and $\hat{\boldsymbol{\mathcal{D}}}(M)$ as flat $L_\infty$-algebras:

**Theorem 4.3** (Formality Theorem). *There is an $L_\infty$-morphism $U\colon \hat{\boldsymbol{\mathcal{V}}}(M) \rightsquigarrow \hat{\boldsymbol{\mathcal{D}}}(M)$, with $U_1$ the HKR map. So $U$ is an $L_\infty$-quasiisomorphism and the DGLA $\hat{\boldsymbol{\mathcal{D}}}(M)$ is formal.*

The Ward identities are not a full proof of the theorem as all arguments using infinite-dimensional integrals have to be taken with care (e.g., we have always assumed that we can work with the BV Laplacian $\Delta$ which is actually not properly defined). They however strongly suggest that such a statement is true. One may check that this is the case by inspecting the finite-dimensional integrals (associated to the Feynman diagrams) appearing in the perturbative expansion. For $M$ an ordinary smooth manifold, the Formality Theorem has been proved by Kontsevich in [28]. For a proof when $M$ is a smooth graded manifold, see [17].

**4.6. Deforming the action: The Poisson sigma model.** As we observed in Remark 3.5, an observable of degree zero that commutes with itself may be used to deform the BV action. By considering bulk observables (4.4), we get a deformed BV action $\mathsf{S}_F^{\mathrm{def}} = \mathsf{S} + \varepsilon \mathsf{S}_F$ for every self-commuting $F = \sum_i F_i \in \boldsymbol{\mathcal{X}}(M)_2$, $F_i$ is an $i$-vector field, which does not contain a 0-vector field (i.e., $F_0 = 0$).

An element $x$ of degree one of a DGLA is called an MC (for Maurer–Cartan) element if $\mathrm{d}x + \frac{1}{2}[x, x] = 0$. So $F$ must be in particular an MC element in $\boldsymbol{\mathcal{V}}(M)$. A multivector field $F$ is completely characterized by its derived brackets

$$\begin{aligned}\lambda_i(a_1, \dots, a_i) &:= \mathrm{pr}\,([\,[\cdots[\,[F, a_1], a_2], \dots], a_i]) \\ &= [\,[\cdots[\,[F_i, a_1], a_2], \dots], a_i], \quad a_1, \dots, a_i \in \hat{\mathbf{C}}^\infty(M),\end{aligned}$$

where pr is the projection from $\hat{\boldsymbol{\mathcal{V}}}(M)$ onto the abelian Lie subalgebra $\hat{\mathbf{C}}^\infty(M)$. A consequence of the more general results in [45] is that $F$ is MC iff $(\hat{\mathbf{C}}^\infty(M), \lambda)$ is an $L_\infty$-algebra. The condition $F_0 = 0$ is precisely the condition that this $L_\infty$-algebra is flat. By construction the multibrackets $\lambda$ are multiderivations, so we call this $L_\infty$-algebra a $P_\infty$-algebra ($P$ for Poisson).

A particular case is when $F$ is a Poisson bivector field of degree zero. This is the only possibility if the target is an ordinary manifold. The only derived bracket is the Poisson bracket (2.9), and $\mathsf{S}_F^{\mathrm{def}}$ is the BV action of the so-called Poisson sigma model [27], [37]. Another particular case is when we start with an ordinary Poisson manifold $(P, \pi)$ and consider the Poisson sigma model with D boundary conditions

on a submanifold $C$. As discussed at the end of 4.4, this is the same as working with target $N^*[1]C$ and N boundary conditions. The Poisson bivector field $\pi$ induces, noncanonically, a Poisson bivector field $\tilde{\pi}$ on $N[0]C$ which in turns by the Legendre transform yields an MC element $F$ in $\hat{\boldsymbol{\mathcal{V}}}(N^*[1]C)$. As pointed out above, we need $F_0 = 0$. This is the case iff $C$ is a coisotropic submanifold [16]. A submanifold $C$ of a Poisson manifold $P$ is called coisotropic if its vanishing ideal $I$ is a Lie subalgebra of $(C^\infty(P), \{\ ,\ \})$.[14] The derived brackets on $\hat{\mathbf{C}}^\infty(N^*[1]C)$ yield the $L_\infty$-algebra studied in [33]. The zeroth $F_1$-cohomology group is the Poisson algebra $C^\infty(C)^I$ of $\{I,\ \}$-invariant functions on $C$. Hamiltonian vector fields of functions in $I$ define an integrable distribution on $C$. The leaf space $\underline{C}$ is called the reduction of $C$. If it is a manifold, $C^\infty(\underline{C}) = C^\infty(C)^I$.[15]

The expectation value of boundary observables in the deformed theory $\mathsf{S}_F^{\mathrm{def}}$ may easily be computed in perturbation theory by expanding $\exp(\varepsilon \mathsf{S}_F)$. As a result one has just to apply to the functions placed on the boundary the formal power series of multidifferential operator $U(\varepsilon F) := \sum_{k=1}^\infty \frac{\varepsilon^k}{k!} U_k(F, \dots, F)$.

If $\mathfrak{g}$ is a DGLA, by linearity one may extend the differential and the bracket to formal power series and so give $\varepsilon\mathfrak{g}[[\varepsilon]]$ the structure of a DGLA. If $x$ is an MC element in a GLA $\mathfrak{g}$, then $\varepsilon x$ is an MC element in $\varepsilon\mathfrak{g}[[\varepsilon]]$. An $L_\infty$-morphism $U\colon \mathfrak{g} \rightsquigarrow \mathfrak{h}$ between DGLAs $\mathfrak{g}$ and $\mathfrak{h}$ may be extended by linearity to formal power series as well. If $X$ is an MC element in $\varepsilon\mathfrak{g}[[\varepsilon]]$, then $U(X)$ is well defined in $\varepsilon\mathfrak{h}[[\varepsilon]]$ and it may be proved to be an MC element.

So $U(\varepsilon F)$ is an MC element in $\varepsilon\hat{\boldsymbol{\mathcal{D}}}(M)[[\varepsilon]]$. As shown in [17] such an MC element induces an $A_\infty$-structure on $\hat{\mathbf{C}}^\infty(M)[[\varepsilon]]$. This is the data of multibrackets $A_i$ (with $i$ arguments) satisfying relations analogous to those of an $L_\infty$-algebra but without symmetry requirements [40], [41]. If $A_0 = 0$, the $A_\infty$-algebra is called flat, $A_1$ is a differential for $A_2$, and the $A_1$-cohomology has the structure of an associative algebra. However, $A_0 = 0$ is not implied by $F_0 = 0$. In [17] it is proved that a potential obstruction to making the $A_\infty$-structure flat is contained in the second $F_1$-cohomology group. We call this potential obstruction the anomaly.

## 5. Applications

When the target $M$ is an ordinary manifold and $F$ is a Poisson bivector field, $C^\infty(M)$ is concentrated in degree zero, so the $A_\infty$-structure consists just of the bidifferential operator and is a genuine associative algebra structure. This is the original result by Kontsevich [28] that every Poisson bivector field defines a deformation quantization [7] of the algebra of functions.

[14] According to Dirac's terminology, $C$ is determined (locally) by first-class constraints.

[15] We discuss here deformations of the TFT $\mathsf{S}$, i.e, the Poisson sigma model with zero Poisson structure. If one drops the condition that the Poisson sigma model with D boundary conditions must be such a deformation, much more general submanifolds $C$ are allowed [11], [12].

A general method for studying certain submanifolds of so-called weak Poisson manifolds and their quantization has been suggested in [31]: one concocts a smooth graded manifold $M$ endowed with an MC element $F$, with $F_0 = 0$, to describe the problem, and then applies the $L_\infty$-quasiisomorphism $U$.

A particular case is the graded manifold $N^*[1]C$ associated to a coisotropic submanifold $C$, as described above. In the absence of anomaly, the method yields a deformation quantization of a Poisson subalgebra of $C^\infty(C)^I$ (or of the whole algebra if the first $F_1$-cohomology vanishes) [16], [17].

A second interesting case is that of a Poisson submanifold $P'$ of a Poisson manifold $P$. The inclusion map $\iota$ is then a Poisson map (i.e., $\iota^*$ is a morphism of Poisson algebras). One may then try to get deformation quantizations of $P$ and $P'$ together with a morphism of associative algebras that deforms $\iota^*$. The simpler case is when $P'$ is determined by regular constraints $\phi^1, \dots, \phi^k$. The Koszul resolution of $C^\infty(P')$ is obtained by introducing variables $\mu^1, \dots, \mu^k$ of degree $-1$ and defining a differential $\delta\mu^i = \phi^i$. We may interpret this differential as a cohomological vector field $Q$ on the graded manifold $M := P \times \mathbb{R}^k[-1]$. The Poisson bivector field $\pi$ on $P$ may also be regarded as a Poisson bivector field on $M$. We may put the two together defining $F = Q + \pi$, which is an MC element iff $[\pi, Q] = 0$, i.e., iff the $\phi^i$s are central. In this case $U(\varepsilon F)$ produces an $A_\infty$-algebra structure on $\mathbf{C}^\infty(M)[[\varepsilon]]$, which is flat since $\mathbf{C}^\infty(M)$ is concentrated in nonpositive degrees. Moreover, $\mathbf{C}^\infty(M)_0[[\varepsilon]] = C^\infty(P)[[\varepsilon]]$ inherits an algebra structure which turns out to give a deformation quantization of $P$. One may also verify that the zeroth $A_1$-cohomology group $H^0$ is a deformation quantization of $P'$ and that the projection $\mathbf{C}^\infty(M)_0[[\varepsilon]] \to H^0$, which is by construction an algebra morphism, is a deformation of $\iota^*$. By inspection of the explicit formulae, one may easily see that this construction is the same as the one proposed in [20], thus proving their conjecture. The more general case when the regular constraints $\phi^i$ are not central, may in principle be treated following [29] which shows the existence an MC element of the form $F = Q + \pi + O(\mu)$. Repeating the above reasoning does not solve the problem since in general the algebra $\mathbf{C}^\infty(M)_0[[\varepsilon]]$ is not associative. For this to be the case, one has to find corrections to $F$ such that in each term the polynomial degree in the $\mu^i$s is less or equal than the polynomial degree in the $\partial/\partial\mu^i$s.

A third interesting case is that of a Poisson map $J$ from a Poisson manifold $P$ to the dual of a Lie algebra $\mathfrak{g}$. Under certain regularity assumptions, $J^{-1}(0)$ is a coisotropic submanifold and may be quantized as described above. In practice, the formulae are not very explicit, even if $P$ is a domain in $\mathbb{R}^n$, for one has to choose adapted coordinates. A different approach is the following: First endow $P \times \mathfrak{g}^*$ with the unique Poisson structure which makes the projection $\mathrm{p}_1$ to $P$ Poisson, the projection $\mathrm{p}_2$ to $\mathfrak{g}^*$ anti-Poisson and such that $\{\mathrm{p}_2^* X, \mathrm{p}_1^* f\}_{P\times\mathfrak{g}^*} = p_1^*\{J_X, f\}_P$, for all $f \in C^\infty(P)$ and for all $X \in \mathfrak{g}$. The graph $G$ of $J$ is then a Poisson submanifold of $P \times \mathfrak{g}^*$, while $P \times \{0\}$ is coisotropic. Their intersection, diffeomorphic to $J^{-1}(0)$, turns out to be coisotropic in $G$. One then describes $G$ as the zero set of the regular constraints $\phi\colon P \times \mathfrak{g}^* \to \mathfrak{g}^*$, $(x, \alpha) \mapsto J(x) - \alpha$. Thus, applying the above construction,

one describes $G$ by an appropriate MC element $F$ on $M := P \times \mathfrak{g}^* \times \mathfrak{g}^*[-1]$ and realizes the quantization of $\underline{J^{-1}(0)}$ by the TFT with BV action $\mathsf{S}_F^{\mathrm{tot}}$ and D boundary conditions on $C := P \times \{0\} \times \mathfrak{g}^*[-1]$. Since we may identify $N^*[1]C$ with $\tilde{M} := P \times \mathfrak{g}[1] \times \mathfrak{g}^*[-1]$, we eventually have the TFT with target $\tilde{M}$ and BV action $\mathsf{S}_{\tilde{F}}^{\mathrm{tot}}$, where $\tilde{F}$ is the Legendre transform of $F$. If $P$ is a domain in $\mathbb{R}^n$, we may now use one coordinate chart and get explicit formulae. This construction turns out to be equivalent to the BRST method. It has a generalization, equivalent to the BV method, when we have a map $J\colon P \to \mathbb{R}^k$ such that $J^{-1}(0)$ is coisotropic.

All the above ideas may in principle be applied to the case when the Poisson manifold $P$ is an infinite-dimensional space of maps (or sections) as in field theory. An $(n+1)$-dimensional field theory on $M \times \mathbb{R}$ is a dynamical system on a symplectic manifold $\mathcal{M}$ of sections on $M$ (or a coisotropic submanifold thereof in gauge theories). The Poisson sigma model version then yields [39] an equivalent $(n+2)$-dimensional field theory on $M \times \Sigma$, with $\Sigma$ the upper half plane.

# Matrix ansatz and large deviations of the density in exclusion processes

Bernard Derrida*

**Abstract.** Exclusion processes describe a gas of particles on a lattice with hard core repulsion. When such a lattice gas is maintained in contact with two reservoirs at unequal densities, or driven by an external field, it exhibits a non-equilibrium steady state. In one dimension, a number of properties of this steady state can be calculated exactly using a matrix ansatz. This talk gives a short review on results obtained recently by this matrix ansatz approach.

**Mathematics Subject Classification (2000).** 60K35, 82C26.

**Keywords.** Non-equilibrium statistical mechanics, exclusion processes.

## 1. Introduction

Exclusion processes have been studied for a long time as microscopic models of fluids which satisfy at large scale hydrodynamic equations [2], [13], [27], [28], [36], [39], [47]. They give also some of the simplest examples of non-equilibrium steady state [38], [12], [15], [16], [44], [29]. Here I will try to review a number of recent results on exclusion processes which have been obtained using an exact matrix representation of the weights of microscopic configurations in the non-equilibrium steady state.

One of the simplest cases for which this can be done is the symmetric simple exclusion process defined in Section 2. The matrix ansatz is discussed in Section 3 and the large deviation function of the density is obtained in Section 5 (using an additivity property given in Section 4). Section 6 gives a short review of an alternative approach to calculate this large deviation function, the macroscopic fluctuation theory [3], [4], [5]. Section 7 gives the extension of the matrix ansatz to the asymmetric exclusion process from which one can calculate the phase diagram (Section 8) and the fluctuations of density (Section 9).

*The author thanks T. Bodineau, C. Enaud, M. Evans, V. Hakim, J. L. Lebowitz, V. Pasquier and E. R. Speer. All the results reported in this talk were obtained in a series of works done in collaboration with them.

## 2. The symmetric simple exclusion process

The symmetric simple exclusion process (SSEP) describes a lattice gas of particles diffusing on a lattice with an exclusion rule which prevents a particle to move to a site already occupied by another particle. Here we consider the one dimensional version with open boundaries. The lattice consists of $L$ sites, each site being either occupied by a single particle or empty. During every infinitesimal time interval $dt$, each particle has a probability $dt$ of jumping to the left if the neighboring site on its left is empty, $dt$ of jumping to the right if the neighboring site on its right is empty. At the two boundaries the dynamics is modified to mimic the coupling with reservoirs of particles: at the left boundary, during each time interval $dt$, a particle is injected on site 1 with probability $\alpha dt$ (if this site is empty) and a particle is removed from site 1 with probability $\gamma dt$ (if this site is occupied). Similarly on site $L$, particles are injected at rate $\delta$ and removed at rate $\beta$.

From the very definition of the SSEP, if $\tau_i = 0$ or 1 is a binary variable indicating whether site $i$ is occupied or empty, one can write the time evolution of the average occupation $\langle \tau_i \rangle$:

$$\begin{aligned} \frac{d\langle \tau_1 \rangle}{dt} &= \alpha - (\alpha + \gamma + 1)\langle \tau_1 \rangle + \langle \tau_2 \rangle, \\ \frac{d\langle \tau_i \rangle}{dt} &= \langle \tau_{i-1} \rangle - 2\langle \tau_i \rangle + \langle \tau_{i+1} \rangle \qquad \text{for } 2 \le i \le L-1, \\ \frac{d\langle \tau_L \rangle}{dt} &= \langle \tau_{L-1} \rangle - (1 + \beta + \delta)\langle \tau_L \rangle + \delta. \end{aligned} \tag{1}$$

The steady state density profile (obtained by writing that $\frac{d\langle \tau_i \rangle}{dt} = 0$) is [20]

$$\langle \tau_i \rangle = \frac{\rho_a \left( L + \frac{1}{\beta+\delta} - i \right) + \rho_b \left( i - 1 + \frac{1}{\alpha+\gamma} \right)}{L + \frac{1}{\alpha+\gamma} + \frac{1}{\beta+\delta} - 1} \tag{2}$$

where $\rho_a$ and $\rho_b$ are defined by

$$\rho_a = \frac{\alpha}{\alpha + \gamma}, \quad \rho_b = \frac{\delta}{\beta + \delta}. \tag{3}$$

For a large system size ($L \to \infty$) one can notice that $\langle \tau_1 \rangle \to \rho_a$ and $\langle \tau_L \rangle \to \rho_b$ indicating that $\rho_a$ and $\rho_b$ defined by (3) represent the densities of the left and right reservoirs. One can in fact show [19], [20] that the rates $\alpha, \gamma, \beta, \delta$ do correspond to the left and right boundaries being connected respectively to reservoirs at densities $\rho_a$ and $\rho_b$.

In a similar way one can write down the equations which govern the time evolution of the two point function or higher correlations. For example one finds [46], [23] in

the steady state for $1 \leq i < j \leq L$

$$\begin{aligned}\langle \tau_i \tau_i \rangle_c &\equiv \langle \tau_i \tau_j \rangle - \langle \tau_i \rangle \langle \tau_j \rangle \\ &= -\frac{\left(\frac{1}{\alpha+\gamma} + i - 1\right)\left(\frac{1}{\beta+\delta} + L - j\right)}{\left(\frac{1}{\alpha+\gamma} + \frac{1}{\beta+\delta} + L - 1\right)^2 \left(\frac{1}{\alpha+\gamma} + \frac{1}{\beta+\delta} + L - 2\right)} (\rho_a - \rho_b)^2.\end{aligned}$$

One can notice that for large $L$, if one introduces macroscopic coordinates $i = Lx$ and $j = Ly$, this becomes

$$\langle \tau_{Lx} \tau_{Ly} \rangle_c = -\frac{x(1-y)}{L} (\rho_a - \rho_b)^2$$

for $x < y$. These weak, but long range, correlations are characteristic of the steady state of non equilibrium systems [47], [23], [41].

The average current in the steady state is given by

$$\bar{j} = \langle \tau_i (1 - \tau_{i+1}) - \tau_{i+1}(1 - \tau_i) \rangle = \langle \tau_i - \tau_{i+1} \rangle = \frac{\rho_a - \rho_b}{L + \frac{1}{\alpha+\gamma} + \frac{1}{\beta+\delta} - 1}. \quad (4)$$

This shows that for large $L$, the current $\bar{j} \simeq \frac{\rho_a - \rho_b}{L}$ is proportional to the gradient of the density (with a coefficient of proportionality which is here simply 1) and therefore follows Fick's law.

## 3. The matrix ansatz for the SSEP

For the SSEP, one can write down the steady state equations satisfied by higher and higher correlation functions, but solving these equations becomes quickly inextricable.

The matrix ansatz gives an algebraic way of calculating exactly the weights of all the configurations in the steady state: in [16] it was shown that the probability of a microscopic configuration $\{\tau_1, \tau_2, \ldots, \tau_L\}$ can be written as the matrix element of a product of $L$ matrices

$$\text{Pro}(\{\tau_1, \tau_2, \ldots, \tau_L\}) = \frac{\langle W | X_1 X_2 \ldots X_L | V \rangle}{\langle W | (D + E)^L | V \rangle} \quad (5)$$

where the matrix $X_i$ depends on the occupation $\tau_i$ of site $i$,

$$X_i = \tau_i D + (1 - \tau_i) E, \quad (6)$$

and the matrices $D$ and $E$ satisfy the following algebraic rules:

$$\begin{aligned} DE - ED &= D + E, \\ \langle W | (\alpha E - \gamma D) &= \langle W |, \\ (\beta D - \delta E) | V \rangle &= | V \rangle. \end{aligned} \quad (7)$$

Let us check on a simple example that expression (5) does give the steady state weights: if one chooses the configuration where the first $p$ sites on the left are occupied and the remaining $L-p$ sites on the right are empty, the weight of this configuration is given by

$$\frac{\langle W|D^p E^{L-p}|V\rangle}{\langle W|(D+E)^L|V\rangle}. \tag{8}$$

For (5) to be the weights of all configurations in the steady state, one needs that the rate at which the system enters each configuration and the rate at which the system leaves it should be equal. In the case of the configuration we consider in (8), this means that the following steady state identity should be satisfied:

$$\begin{aligned}(\gamma+1+\delta)\frac{\langle W|D^p E^{L-p}|V\rangle}{\langle W|(D+E)^L|V\rangle} = \alpha\frac{\langle W|ED^{p-1}E^{L-p}|V\rangle}{\langle W|(D+E)^L|V\rangle} \\ + \frac{\langle W|D^{p-1}EDE^{L-p-1}|V\rangle}{\langle W|(D+E)^L|V\rangle} \\ + \beta\frac{\langle W|D^p E^{L-p-1}D|V\rangle}{\langle W|(D+E)^L|V\rangle}.\end{aligned} \tag{9}$$

This equality is easy to check by rewriting (9) as

$$\begin{aligned}\frac{\langle W|(\alpha E-\gamma D)D^{p-1}E^{L-p}|V\rangle}{\langle W|(D+E)^L|V\rangle} - \frac{\langle W|D^{p-1}(DE-ED)E^{L-p-1}|V\rangle}{\langle W|(D+E)^L|V\rangle} \\ + \frac{\langle W|D^p E^{L-p-1}(\beta D-\delta E)|V\rangle}{\langle W|(D+E)^L|V\rangle} = 0\end{aligned} \tag{10}$$

and by using (7). A similar reasoning allows one to prove that the corresponding steady state identity holds for any other configuration.

A priori one should construct the matrices $D$ and $E$ (which might be infinite-dimensional) and the vectors $\langle W|$ and $|V\rangle$ satisfying (7) to calculate the weights of the microscopic configurations. However these weights do not depend on the particular representation chosen and can be calculated directly from (7).

This can be easily seen by using the two matrices $A$ and $B$ defined by

$$\begin{aligned}A &= \beta D-\delta E,\\ B &= \alpha E-\gamma D,\end{aligned} \tag{11}$$

which satisfy

$$AB-BA = (\alpha\beta-\gamma\delta)(D+E) = (\alpha+\gamma)A+(\beta+\delta)B. \tag{12}$$

Each product of $D$'s and $E$'s can be written as a sum of products of $A$'s and $B$'s which can be ordered using (12) by pushing all the $A$'s to the right and all the $B$'s to the left. One gets that way a sum of terms of the form $B^p A^q$, the matrix elements of which can be evaluated easily ($\langle W|B^p A^q|V\rangle = \langle W|V\rangle$) from (7) and (11).

One can calculate that way the average density profile

$$\langle \tau_i \rangle = \frac{\langle W|(D+E)^{i-1} D (D+E)^{L-i}|V\rangle}{\langle W|(D+E)^{L}|V\rangle}$$

as well as all the correlation functions and one can recover that way (2).

One can also show that (equation (3.11) of [20])

$$\frac{\langle W|(D+E)^{L}|V\rangle}{\langle W|V\rangle} = \frac{1}{(\rho_a - \rho_b)^L} \frac{\Gamma(L + \frac{1}{\alpha+\gamma} + \frac{1}{\beta+\delta})}{\Gamma(\frac{1}{\alpha+\gamma} + \frac{1}{\beta+\delta})} \tag{13}$$

and using the fact that the average current between sites $i$ and $i+1$ is given by

$$\bar{j} = \frac{\langle W|(D+E)^{i-1}(DE-ED)(D+E)^{L-i-1}|V\rangle}{\langle W|(D+E)^{L}|V\rangle} = \frac{\langle W|(D+E)^{L-1}|V\rangle}{\langle W|(D+E)^{L}|V\rangle}$$

one recovers (4) (of course in the steady state the current does not depend on $i$).

**Remark.** When $\rho_a = \rho_b = r$, i.e. for $\alpha\delta = \beta\gamma$ (see (3)), the two reservoirs are at the same density and the steady state becomes the equilibrium (Gibbs state) of the lattice gas at this density $r$. In this case, the weights of the configurations are those of a Bernoulli measure at density $r$, that is

$$\mathrm{Pro}(\{\tau_1, \tau_2, \ldots, \tau_L\}) = \prod_{i=1}^{L} [r\tau_i + (1-r)(1-\tau_i)] \tag{14}$$

as steady state identities such as (9) can be checked directly for $r = \alpha/(\alpha+\gamma) = \delta/(\beta+\delta)$. All steady state properties can also be recovered by making all the calculations with the matrices (5), (7) for $\rho_a \neq \rho_b$ and by taking the limit $\rho_a \to \rho_b$ in the final expressions, as all the expectations, for a lattice of finite size $L$, are rational functions of $\rho_a$ and $\rho_b$.

## 4. Additivity

As in (5) the weight of each configuration is written as the matrix element of a product of $L$ matrices, one can try to insert at a position $L_1$ a complete basis in order to relate the properties of a lattice of $L$ sites to those of two subsystems of sizes $L_1$ and $L - L_1$.

To do so let us define the following left and right eigenvectors $\langle \rho_a, a|$ and $|\rho_b, b\rangle$ of the operators $\rho_a E - (1-\rho_a)D$ and $(1-\rho_b)D - \rho_b E$:

$$\begin{aligned} \langle \rho_a, a| \, [\rho_a E - (1-\rho_a)D] &= a \langle \rho_a, a|, \\ [(1-\rho_b)D - \rho_b E] \, |\rho_b, b\rangle &= b |\rho_b, b\rangle. \end{aligned} \tag{15}$$

It is easy to see, using the definition (3), that the vectors $\langle W|$ and $|V\rangle$ which appear in (7) are given by

$$\begin{aligned} \langle W| &= \langle \rho_a, (\alpha+\gamma)^{-1}|, \\ |V\rangle &= |\rho_b, (\beta+\delta)^{-1}\rangle. \end{aligned} \tag{16}$$

It is then possible to show, using simply the fact (7) that $DE - ED = D + E$ and the definition of the eigenvectors (15), that (for $\rho_b < \rho_a$)

$$\begin{aligned} &\frac{\langle \rho_a, a|Y_1 Y_2|\rho_b, b\rangle}{\langle \rho_a, a|\rho_b, b\rangle} \\ &= \oint_{\rho_b<|\rho|<\rho_a} \frac{d\rho}{2i\pi} \frac{(\rho_a-\rho_b)^{a+b}}{(\rho_a-\rho)^{a+b}(\rho-\rho_b)} \frac{\langle \rho_a, a|Y_1|\rho, b\rangle}{\langle \rho_a, a|\rho, b\rangle} \frac{\langle \rho, 1-b|Y_2|\rho_b, b\rangle}{\langle \rho, 1-b|\rho_b, b\rangle} \end{aligned} \tag{17}$$

where $Y_1$ and $Y_2$ are arbitrary polynomials of matrices $D$ and $E$. (To prove (17) it is sufficient to establish it when $Y_1$ and $Y_2$ are both of the form $E^n D^{n'}$ as any polynomial can be reduced to a sum of such terms by the relation $DE - ED = D + E$. One can also, and this is easier, prove (17) for $Y_1$ of the form $[\rho_a E - (1-\rho_a)D]^n [D+E]^{n'}$ and $Y_2$ of the form $[D+E]^{n''}[(1-\rho_b)D - \rho_b E]^{n'''}$ and show using $DE - ED = D + E$ that any polynomial $Y_1$ or $Y_2$ can be reduced to a finite sum of such terms).

## 5. Large deviation function of density profiles

If one divides a chain of $L$ sites into $n$ boxes of linear size $l$ (one has of course $n = L/l$ such boxes), one can try to determine the probability of finding a certain density profile $\{\rho_1, \rho_2, \ldots, \rho_n\}$, i.e. the probability of seeing $l\rho_1$ particles in the first box, $l\rho_2$ particles in the second box, $\ldots l\rho_n$ in the $n$th box. For large $L$ one expects the following $L$ dependence of this probability

$$\mathrm{Pro}_L(\rho_1, \ldots, \rho_n|\rho_a, \rho_b) \sim \exp[-L\mathcal{F}_n(\rho_1, \rho_2, \ldots, \rho_n|\rho_a, \rho_b)] \tag{18}$$

where $\mathcal{F}_n$ is a large deviation function. If one defines a reduced coordinate $x$ by

$$i = Lx \tag{19}$$

and if one takes the limit $l \to \infty$ with $l \ll L$ so that the number of boxes becomes infinite, one can define a functional $\mathcal{F}$ for an arbitrary density profile $\rho(x)$

$$\mathrm{Pro}_L(\{\rho(x)\}) \sim \exp[-L\mathcal{F}(\{\rho(x)\}|\rho_a, \rho_b)]. \tag{20}$$

For the SSEP (in one dimension), the functional $\mathcal{F}(\rho(x)|\rho_a, \rho_b)$ is given by the following exact expressions:

*At equilibrium,* i.e. for $\rho_a = \rho_b = r$

$$\mathcal{F}(\{\rho(x)\}|r, r) = \int_0^1 B(\rho(x), r)dx \tag{21}$$

where

$$B(\rho, r) = (1-\rho)\log\frac{1-\rho}{1-r} + \rho\log\frac{\rho}{r}. \tag{22}$$

This can be derived easily. When $\rho_a = \rho_b = r$, the steady state is a Bernoulli measure (14) where all the sites are occupied independently with probability $r$. Therefore if one divides a chain of length $L$ into $L/l$ intervals of length $l$, one has

$$\mathrm{Pro}_L(\rho_1, \ldots, \rho_n|r, r) = \prod_i^{L/l} \frac{l!}{[l\rho_i]!\ [l(1-\rho_i)]!}\, r^{l\rho_i}\ (1-r)^{l(1-\rho_i)} \tag{23}$$

and using Stirling's formula one gets (21), (22).

*For the non-equilibrium case,* i.e. for $\rho_a \neq \rho_b$, it was shown in [19], [4], [20] that

$$\mathcal{F}(\{\rho(x)\}|\rho_a, \rho_b) = \int_0^1 dx\ \left[B(\rho(x), F(x)) + \log\frac{F'(x)}{\rho_b - \rho_a}\right] \tag{24}$$

where the function $F(x)$ is the monotone solution of the differential equation

$$\rho(x) = F + \frac{F(1-F)F''}{F'^2} \tag{25}$$

satisfying the boundary conditions $F(0) = \rho_a$ and $F(1) = \rho_b$.

This expression shows that $\mathcal{F}$ is a *non-local* functional of the density profile $\rho(x)$ as $F(x)$ depends (in a non-linear way) on the profile $\rho(y)$ at all points $y$. For example if the difference $\rho_a - \rho_b$ is small, one can expand $\mathcal{F}$ and obtain an expression where the non-local character of the functional is clearly visible

$$\begin{aligned}
&\mathcal{F}(\{\rho(x)\}|\rho_a, \rho_b) \\
&\quad = \int_0^1 dx\ B(\rho(x), \bar\rho(x)) \\
&\qquad + \frac{(\rho_a - \rho_b)^2}{[\rho_a(1-\rho_a)]^2}\int_0^1 dx \int_x^1 dy\, x(1-y)(\rho(x) - \bar\rho(x))(\rho(y) - \bar\rho(y)) \\
&\qquad + O(\rho_a - \rho_b)^3.
\end{aligned}$$

Here $\bar\rho(x)$ is the most likely profile given by

$$\bar\rho(x) = (1-x)\rho_a + x\rho_b. \tag{26}$$

It would be too long to reproduce here the full derivation of (24), (25) from the matrix ansatz [19], [20]. The idea is to decompose the chain into $L/l$ boxes of $l$ sites

and to sum the weights given by the matrix ansatz (5), (7) over all the microscopic configurations for which the number of particles is $l\rho_1$ in the first box, $l\rho_2$ in the second box,..., $l\rho_n$ in the $n$th box.

A rather easy way to derive (24), (25) is to write (we do it here in the particular case where $a+b=1$, i.e. $\frac{1}{\alpha+\gamma}+\frac{1}{\beta+\delta}=1$, and $\rho_a<\rho_b$) from (17) and (13)

$$P_{nl}(\rho_1,\rho_2,\ldots,\rho_n|\rho_a\rho_b)=\frac{(kl)!((n-k)l)!}{(nl)!}\oint_{\rho_b<|\rho|<\rho_a}\frac{d\rho}{2i\pi}\times\frac{(\rho_a-\rho_b)^{nl+1}}{(\rho_a-\rho)^{kl+1}(\rho-\rho_b)^{(n-k)l+1}}\times P_{kl}(\rho_1,\ldots,\rho_n|\rho_a,\rho)P_{(n-k)l}(\rho_{k+1},\ldots,\rho_n|\rho,\rho_b). \tag{27}$$

Note that in (27) the density $\rho$ has become a complex variable. This is not a difficulty as all the weighs (and therefore the probabilities which appear in (27)) are rational functions of $\rho_a$ and $\rho_b$.

For large $nl$, if one writes $k=nx$, by evaluating (27) at the saddle point one gets

$$\begin{aligned}\mathcal{F}_n(\rho_1,\rho_2,\ldots,\rho_n|\rho_a,\rho_b)&=\max_{\rho_b<F<\rho_a}x\mathcal{F}_k(\rho_1,\ldots,\rho_k|\rho_a,F)\\&\quad+(1-x)\mathcal{F}_{n-k}(\rho_{k+1},\ldots,\rho_n|F,\rho_b)\\&\quad+x\log\left(\frac{\rho_a-F}{x}\right)+(1-x)\log\left(\frac{F-\rho_b}{1-x}\right)-\log(\rho_a-\rho_b).\end{aligned} \tag{28}$$

(Note that to estimate (27) by a saddle point method, one should find the value of $\rho$ which maximizes the integrand over the contour. As the contour is perpendicular to the real axis at their crossing point, this becomes a minimum when $\rho$ varies along the real axis).

If one repeats the same procedure $n$ times, one gets

$$\mathcal{F}_n(\rho_1,\rho_2,\ldots,\rho_n|\rho_a,\rho_b)=\max_{\rho_b=F_0<F_1<\cdots<F_n=\rho_a}\frac{1}{n}\sum_{i=1}^{n}\mathcal{F}_1(\rho_i|F_{i-1},F_i)+\log\left(\frac{(F_{i-1}-F_i)n}{\rho_a-\rho_b}\right). \tag{29}$$

For large $n$, as $F_i$ is monotone, the difference $F_{i-1}-F_i$ is small for almost all $i$ and one can replace $\mathcal{F}_1(\rho_i|F_{i-1},F_i)$ by its equilibrium value $\mathcal{F}_1(\rho_i|F_i,F_i)=B(\rho_i,F_i)$. Therefore (29) becomes (24) in the limit $n\to\infty$, with (25) being the equation satisfied by the optimal $F(x)$.

## 6. The macroscopic fluctuation theory

Bertini, De Sole, Gabrielli, Jona-Lasinio and Landim [3], [4], [5] have developped a different and more general theory to calculate this large deviation functional which

can be summarized as follows: one starts from the expression of the probability $Q(\{\rho(x,s),\, j(x,s)\})$ of observing a certain time dependent macroscopic density profile $\rho(x,s)$ and current profile $j(x,t)$ over a time interval $0 \leq s \leq L^2 t$

$$Q(\{\rho(x,s),\, j(x,s)\}) \sim \max_{\rho(x,s)} \exp\left\{-L \int_{-\infty}^{t} ds \int_0^1 dx \frac{[j + D(\rho)\frac{d\rho}{dx}]^2}{2\sigma(\rho)}\right\} \tag{30}$$

where the current $j(x,s)$ is related to the density profile $\rho(x,s)$ by the conservation law

$$\frac{d\rho(x,s)}{ds} = -\frac{dj(x,s)}{dx} \tag{31}$$

and the functions $D(\rho)$ and $\sigma(\rho)$ are characteristic of the diffusive system studied [9], [10].

Then to calculate the probability of observing a certain density profile $\rho(x)$ in the steady state, one has to find out how this fluctuation is produced. For large $L$, one has to find the optimal path $\rho(x,s)$ for $-\infty < s < t$ in the space of profiles which goes from the typical profile $\bar{\rho}(x)$ to the desired profile $\rho(x)$ and

$$\mathrm{Pro}_L(\{\rho(x)\}) \sim \max_{\rho(x,s)} Q(\{\rho(x,s),\, j(x,s)\}) \tag{32}$$

where the optimal path $\rho(x,s)$ satisfies

$$\rho(x,-\infty) = \bar{\rho}(x),$$
$$\rho(x,t) = \rho(x).$$

Finding this optimal path is usually a hard problem, and so far it has not been possible to find the explicit expression of the functional $\mathcal{F}$ for general $D(\rho)$ and $\sigma(\rho)$. For the SSEP [4], where $D(\rho) = 1$ and $\sigma(\rho) = 2\rho(1-\rho)$, this approach allows one nevertheless to derive (24), (25). It also leads to the same expression of $\mathcal{F}$ as found by the matrix approach [24] in the weakly asymmetric exclusion process and allowed one to calculate the large deviation function $\mathcal{F}$ for the KPM model [35], [7] for which no matrix approach or alternative derivation has been used so far.

The macroscopic fluctuation theory has also been successfully used recently to calculate the fluctuations and the large deviations of the current through diffusive systems [6], [9], [10], [33].

## 7. The matrix approach for the asymmetric exclusion process

The matrix ansatz of Section 3 (which gives the weights of the microscopic configurations in the steady state) has been generalized to describe the steady state of several other systems [1], [8], [11], [14], [18], [25], [30], [31], [32], [37], [40], [42], [43], [45], with of course modified algebraic rules for the matrices the vectors $\langle W|$ and $|V\rangle$.

For example for the asymmetric exclusion process (ASEP), for which the definition is the same as the SSEP of Section 2, except that particles jump at rate 1 to their right and at rate $q \neq 1$ to their left (it the target site is empty), one can show [16], [8], [42], [43] that in this case too, the weights are still given by (5) with the algebra (7) replaced by

$$DE - qED = D + E, \tag{33}$$

$$\langle W|(\alpha E - \gamma D) = \langle W|, \tag{34}$$

$$(\beta D - \delta E)|V\rangle = |V\rangle. \tag{35}$$

One should notice that for the ASEP, the direct approach of calculating the steady state properties by writing the time evolution does not work. Indeed (1) becomes

$$\begin{aligned}
\frac{d\langle\tau_1\rangle}{dt} &= \alpha - (\alpha+\gamma+1)\langle\tau_1\rangle + q\langle\tau_2\rangle + (1-q)\langle\tau_1\tau_2\rangle, \\
\frac{d\langle\tau_i\rangle}{dt} &= \langle\tau_{i-1}\rangle - (1+q)\langle\tau_i\rangle + q\langle\tau_{i+1}\rangle - (1-q)(\langle\tau_{i-1}\tau_i\rangle - \langle\tau_i\tau_{i+1}\rangle), \\
\frac{d\langle\tau_L\rangle}{dt} &= \langle\tau_{L-1}\rangle - (q+\beta+\delta)\langle\tau_L\rangle + \delta - (1-q)\langle\tau_{L-1}\tau_L\rangle,
\end{aligned} \tag{36}$$

and the equations which determine the one-point functions are no longer closed. Therefore all the correlation functions have to be determined at the same time and this is what the matrix ansatz does.

The large deviation function $\mathcal{F}$ of the density defined by (20) has been calculated for the ASEP [21], [22], [24] by an extension of the approach sketched in Sections 4 and 5.

## 8. The phase diagram of the totally asymmetric exclusion process

The last two sections (8 and 9) present two results which can be obtained in the totally asymmetric case (TASEP), i.e. for $q = 0$ (in the particular case where particles are injected only at the left boundary and removed only at the right boundary, i.e. when the input rates $\gamma = \delta = 0$). In this case the algebra (33) becomes

$$DE = D + E, \tag{37}$$

$$\langle W|\alpha E = \langle W|, \tag{38}$$

$$\beta D|V\rangle = |V\rangle. \tag{39}$$

As for the SSEP the average current is still given in terms of the vectors $\langle W|$, $V\rangle$ and of the matrices $D$ and $E$ by

$$\bar{j} = \frac{\langle W|(D+E)^{L-1}|V\rangle}{\langle W|(D+E)^{L}|V\rangle} \tag{40}$$

However as the algebraic rules have changed, the expression of the current is different for the SSEP and the ASEP. From the relation $DE = D + E$ it is easy to prove by recurrence that

$$DF(E) = F(1) + E\,\frac{F(E) - F(1)}{E - 1}$$

for any polynomial $F(E)$ and

$$(D + E)^N = \sum_{p=1}^{N} \frac{p(2N - 1 - p)!}{N!(N - p)!}(E^p + E^{p-1}D + \cdots + D^p).$$

Using the fact that

$$\frac{\langle W|E^m D^n|V\rangle}{\langle W|V\rangle} = \frac{1}{\alpha^m}\frac{1}{\beta^n},$$

one gets [16]

$$\frac{\langle W|(D + E)^N|V\rangle}{\langle W|V\rangle} = \sum_{p=1}^{N} \frac{p(2N - 1 - p)!}{N!(N - p)!}\,\frac{\dfrac{1}{\alpha^{p+1}} - \dfrac{1}{\beta^{p+1}}}{\dfrac{1}{\alpha} - \dfrac{1}{\beta}}. \tag{41}$$

For large $N$ this sum is dominated either by $p \sim 1$, or $p \sim N$ depending one the values of $\alpha$ and $\beta$ and one obtains

$$\frac{\langle W|(D + E)^N|V\rangle}{\langle W|V\rangle} \sim \begin{cases} 4^N & \text{if } \alpha > \frac{1}{2} \text{ and } \beta > \frac{1}{2}, \\ [\beta(1 - \beta)]^{-N} & \text{if } \beta < \alpha \text{ and } \beta < \frac{1}{2}, \\ [\alpha(1 - \alpha)]^{-N} & \text{if } \beta > \alpha \text{ and } \alpha < \frac{1}{2}. \end{cases} \tag{42}$$

This leads to three different expressions of the current (40) for large $L$ corresponding to the three different phases:

- the low density phase ($\beta > \alpha$ and $\alpha < \frac{1}{2}$) where $\bar{j} = \alpha(1 - \alpha)$
- the high density phase ($\alpha > \beta$ and $\beta < \frac{1}{2}$) where $\bar{j} = \beta(1 - \beta)$
- the maximal current phase ($\alpha > \frac{1}{2}$ and $\beta > \frac{1}{2}$) where $\bar{j} = \frac{1}{4}$

which is the exact phase diagram of the TASEP [38], [15], [16], [44]. The existence of phase transitions [26], [34] in these driven lattice gases is one of the most striking properties of non-equilibrium systems, as it is well known that one dimensional systems at equilibrium with short range interactions cannot exhibit phase transitions.

## 9. Correlation functions in the TASEP and Brownian excursions

For the TASEP, in the maximal current phase ($\alpha > \frac{1}{2}$ and $\beta > \frac{1}{2}$) one can show [17], using the matrix ansatz, that the correlation function of the occupations of $k$ sites at positions $i_1 = Lx_1$, $i_2 = Lx_2, \ldots, i_k = Lx_k$ with $(Lx_1 < Lx_2 < \cdots < Lx_k)$ are given for large $L$ by

$$\left\langle \left(\tau_{Lx_1} - \frac{1}{2}\right) \ldots \left(\tau_{Lx_k} - \frac{1}{2}\right) \right\rangle = \frac{1}{2^k} \frac{1}{L^{k/2}} \frac{d^k}{dx_1 \ldots dx_k} \langle y_1 \ldots y_k \rangle, \qquad (43)$$

where $y(x)$ is a Brownian excursion between 0 and 1 (a Brownian excursion is a Brownian path constrained to $y(x) > 0$ for $0 < x < 1$ with the boundaries $y(0) = y(1)$). The probability $P(y_1 \ldots y_k; x_1 \ldots x_k)$ of finding the Brownian excursion at positions $y_1 \ldots y_k$ for $0 < x_1 < \cdots < x_k < 1$ is

$$P(y_1 \ldots y_k; x_1 \ldots x_k) = \frac{h_{x_1}(y_1)\, g_{x_2 - x_1}(y_1, y_2) \ldots g_{x_k - x_{k-1}}(y_{k-1}, y_k)\, h_{1-x_k}(y_k)}{\sqrt{\pi}},$$

where $h_x$ and $g_x$ are defined by

$$\begin{cases} h_x(y) = \frac{2y}{x^{3/2}} e^{-y^2/x}, \\ g_x(y, y') = \frac{1}{\sqrt{\pi x}} (e^{-(y-y')^2/x} - e^{-(y+y')^2/x}). \end{cases}$$

One can derive easily (43) in the particular case $\alpha = \beta = 1$ using a representation of (37) which consists of two infinite dimensional bidiagonal matrices

$$D = \sum_{n \geq 1} |n\rangle\langle n| + |n\rangle\langle n+1| = \begin{pmatrix} 1 & 1 & 0 & 0 & 0 & 0 & \cdots \\ 0 & 1 & 1 & 0 & 0 & 0 & \cdots \\ 0 & 0 & 1 & 1 & 0 & 0 & \cdots \\ 0 & 0 & 0 & 1 & 1 & 0 & \cdots \\ & & & & \ddots & \ddots & \end{pmatrix}$$

and

$$E = \sum_{n \geq 1} |n\rangle\langle n+1| + |n\rangle\langle n| = \begin{pmatrix} 1 & 0 & 0 & 0 & 0 & 0 & \cdots \\ 1 & 1 & 0 & 0 & 0 & 0 & \cdots \\ 0 & 1 & 1 & 0 & 0 & 0 & \cdots \\ 0 & 0 & 1 & 1 & 0 & 0 & \cdots \\ & & & \ddots & \ddots & & \end{pmatrix}$$

with

$$\langle W| = \langle 1| = (1, 0, 0 \ldots),$$

$$\langle V| = \langle 1| = (1, 0, 0 \ldots).$$

With this representation one can write $\langle W|(D+E)^L|V\rangle$ as a sum over a set $\mathcal{M}_L$ of one dimensional random walks $w$ of $L$ steps which never come back to the origin. Each walk $w$ is defined by a sequence $(n_i(w))$ of $L-1$ heights ($n_i(w) \geq 1$) (with $n_0(w) = n_L(w) = 1$ at the boundaries and the constraint $|n_{i+1} - n_i| \leq 1$). One then has

$$\langle W|(D+E)^L|V\rangle = \sum_{w\in\mathcal{M}_L} \Omega(w),$$

where

$$\Omega(w) = \prod_{i=1}^{L} v(n_{i-1}, n_i) \quad \text{with } v(n,n') = \begin{cases} 2 & \text{if } |n-n'| = 0, \\ 1 & \text{if } |n-n'| = 1, \end{cases}$$

using the fact that $v(n,n') = \langle n|D+E|n'\rangle$ since $D+E$ can be written as

$$D+E = \begin{pmatrix} 2 & 1 & & (0) \\ 1 & \ddots & \ddots & \\ & \ddots & \ddots & 1 \\ (0) & & 1 & 2 \end{pmatrix}.$$

Then from the matrix expression one gets $\langle \tau_i \rangle$ and $\langle \tau_i \tau_j \rangle$:

$$\left\langle \left(\tau_{i_1} - \frac{1}{2}\right) \dots \left(\tau_{i_k} - \frac{1}{2}\right) \right\rangle = \frac{1}{2^k} \sum_w \nu(w)(n_{i_1} - n_{i_1-1}) \dots (n_{i_k} - n_{i_k-1}), \quad (44)$$

where $\nu(w)$ is the probability of the walk $w$ induced by the weights $\Omega$:

$$\nu(w) = \frac{\Omega(w)}{\sum'_w \Omega(w')}.$$

The expression (44) is the discrete version of (43). The result (43) can be extended [17] to arbitrary values of $\alpha$ and $\beta$ in the maximal current phase (i.e. for $\alpha > 1/2$ and $\beta > 1/2$).

From this link between the density fluctuations and Brownian excursions, one can show that, for a TASEP of $L$ sites, the number $N$ of particles between sites $Lx_1$ and $Lx_2$, has non-Gaussian fluctuations in the maximal current phase: if one defines the reduced density

$$\mu = \frac{N - L(x_2 - x_1)/2}{\sqrt{L}}$$

one can show [17] that for large $L$

$$P(\mu) = \int_0^\infty dy_1 \int_0^\infty dy_2 \, \frac{1}{\sqrt{2\pi(x_2 - x_1)}} \, \exp\left(-\frac{(2\mu + y_1 - y_2)^2}{x_2 - x_1}\right). \quad (45)$$

According to numerical simulations [17] this distribution (properly rescaled) of the fluctuations of the density remains valid for more general driven systems in their maximal current phase. Of course proving it in a more general case is an interesting open question.

# Correlation functions of the $XXZ$ Heisenberg spin chain: Bethe ansatz approach

Jean Michel Maillet*

**Abstract.** We review recent progress in the computation of correlation functions of the $XXZ$ spin-1/2 chain. We describe both finite and infinite chain results. Long distance asymptotic behavior is discussed. Our method is based on the resolution of the quantum inverse scattering problem in the framework of the algebraic Bethe ansatz.

**Keywords.** Quantum integrable models, algebraic Bethe ansatz, correlation functions.

## 1. Introduction

The main challenging problem in the theory of quantum integrable models [1], [2], [3], [4], [5], [6] besides computing their spectrum is to obtain exact and manageable representations for their correlation functions. This issue is of great importance not only from theoretical and mathematical view points but also for applications to relevant physical situations. Although several important advances have been obtained over the years, we are still looking for a general method that could give a systematic solution to this problem. The purpose of this article is to give a review of an approach to this problem elaborated in [7], [8], [9], [10] and in [11], [12], [13], [14], together with a brief account of the more recent progress obtained in [15], [16], [17], [18], [19].

In our search for a general method to compute correlation functions of quantum integrable models our strategy was to consider a simple but representative model where it is possible to develop new tools to solve this problem. Such an archetype of quantum integrable lattice models is provided by the $XXZ$ spin-$\frac{1}{2}$ Heisenberg [20] chain in a magnetic field. Indeed, Heisenberg spin chains play a prominent role in the theory of quantum integrable models: they were the first models for which Bethe ansatz [21], [22], [23], [24], [25] was invented and successfully applied to compute their spectrum. This method has been later used and generalized to solve a large variety of integrable models ranging from statistical mechanics to quantum field theories (see [1], [2], [3], [4], [5]).

*The author would like to thank N. Kitanine, N. Slavnov and V. Terras for their longstanding collaboration on the topics presented in this paper.

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

The $XXZ$ spin-$\frac{1}{2}$ Heisenberg chain in a magnetic field is a quantum interacting model defined on a one-dimensional lattice with Hamiltonian

$$H = H^{(0)} - hS_z; \tag{1}$$

$$H^{(0)} = \sum_{m=1}^{M} \left\{ \sigma_m^x \sigma_{m+1}^x + \sigma_m^y \sigma_{m+1}^y + \Delta(\sigma_m^z \sigma_{m+1}^z - 1) \right\}, \tag{2}$$

$$S_z = \frac{1}{2} \sum_{m=1}^{M} \sigma_m^z, \quad [H^{(0)}, S_z] = 0. \tag{3}$$

Here $\Delta$ is the anisotropy parameter, $h$ denotes the magnetic field, and $\sigma_m^{x,y,z}$ are the local spin operators (in the spin-$\frac{1}{2}$ representation) associated with each site $m$ of the chain. The quantum space of states is $\mathcal{H} = \otimes_{m=1}^{M} \mathcal{H}_m$, where $\mathcal{H}_m \sim \mathbb{C}^2$ is called local quantum space, with $\dim \mathcal{H} = 2^M$. The operators $\sigma_m^{x,y,z}$ act as the corresponding Pauli matrices in the space $\mathcal{H}_m$ and as the identity operator elsewhere. For simplicity, the length of the chain $M$ is chosen to be even and we assume periodic boundary conditions. Since the simultaneous reversal of all spins is equivalent to a change of sign of the magnetic field, it is enough to consider the case $h \geq 0$.

The first task to solve such a model is to describe the spectrum of its Hamiltonian (1). The method to compute eigenvectors and associated energy levels of the Heisenberg spin chains goes back to H. Bethe in 1931 [21], [22], [23], [25] and is known as the Bethe ansatz. An algebraic version of it has been invented in the late 70s by Faddeev, Sklyanin and Taktajan [26], [27].

The second problem is to compute matrix elements of spin operators $\sigma_m^{x,y,z}$ between two eigenvectors of $H$ and then all correlation functions of spin operators: at zero temperature they reduce to the average value of products of spin operators in the lowest energy level state (the ground state). Let us denote by $| \psi_g \rangle$ the normalized ground state vector. Let $E_m^{\epsilon'_m, \epsilon_m}$ be the elementary operators acting at site $m$ as the $2 \times 2$ matrices $E_{lk}^{\epsilon', \epsilon} = \delta_{l,\epsilon'} \delta_{k,\epsilon}$. Any $n$-point correlation function can be reconstructed as a sum of the following elementary blocks:

$$F_m(\{\epsilon_j, \epsilon'_j\},\ h) = \langle \psi_g | \prod_{j=1}^{m} E_j^{\epsilon'_j, \epsilon_j} | \psi_g \rangle. \tag{4}$$

The knowledge of such correlation functions was for a long time restricted to the free fermion point $\Delta = 0$, a case for which nevertheless tremendous works have been necessary to obtain full answers [28], [29], [30], [31], [32], [33]. For generic $\Delta$, in the thermodynamic limit, at zero temperature, and for zero magnetic field, multiple integral representation of the above elementary blocks of the correlation functions have been obtained from the $q$-vertex operator approach (also using corner transfer matrix technique) in the massive regime $\Delta \geq 1$ in 1992 [34] and conjectured in 1996 [35] for the massless regime $-1 \leq \Delta \leq 1$ (see also [6]).

These results together with their extension to non-zero magnetic field have been obtained in 1999 [8], [9] using the algebraic Bethe ansatz framework [26], [27], [4] and the actual resolution of the so-called quantum inverse scattering problem [8], [10]. This method allows for the computation of the matrix elements of the local spin operators and the above elementary blocks of the correlation functions for the finite chain. Hence, thermodynamic limit can be considered separately. Moreover, time or temperature dependent correlation functions can also be computed [15], [16], [36] using such techniques. Let us mention also recent advances using $q$-KZ equations [37], [38].

This article is meant to be a rather brief review of the problem of correlation functions. More detailed account of the results sketched here together with their proofs can be found in the original articles [7], [8], [9], [10], [11], [12], [13], [14], [15], [16], [17] and in [18], [19]. This article is organized as follows. The space of states of the Heisenberg spin chain will be described in the next section. It includes a brief introduction to the algebraic Bethe ansatz and to various tools of importance in the computation of correlation functions, like in particular the solution of the quantum inverse scattering problem and the determinant representations of the scalar products of states. Section 3 is devoted to the correlation functions of the finite chain. Correlation functions in the thermodynamic limit are studied in Section 4. In Section 5 we describe several exact and asymptotic results together with some open problems. Conclusions and some perspectives are given in the last section.

## 2. The space of states: algebraic Bethe ansatz

The space of states is of dimension $2^M$. As can be observed from the definition of the Hamiltonian in (1), the construction of its eigenvectors is rather non trivial. The purpose of this section is to briefly explain the basics of the knowledge of the space of states in the framework of the algebraic Bethe ansatz, leading in particular to the determination of the spectrum of (1).

**2.1. Algebraic Bethe ansatz.** The algebraic Bethe ansatz originated from the fusion of the original (coordinate) Bethe ansatz and of the inverse scattering method in its Hamiltonian formulation [26], [27], [4]. At the root of the algebraic Bethe ansatz method is the construction of the quantum monodromy matrix. In the case of the $XXZ$ chain (1) the monodromy matrix is a $2 \times 2$ matrix,

$$T(\lambda) = \begin{pmatrix} A(\lambda) & B(\lambda) \\ C(\lambda) & D(\lambda) \end{pmatrix}, \tag{5}$$

with operator-valued entries $A$, $B$, $C$ and $D$ which depend on a complex parameter $\lambda$ (spectral parameter) and act in the quantum space of states $\mathcal{H}$ of the chain. One of the main property of these operators is that the trace of $T$, namely $A + D$, commutes with the Hamiltonian $H$, while operators $B$ and $C$ can be used as creation operators

of respectively eigenvectors and dual eigenvectors of $A + D$ and hence of $H$ itself. The monodromy matrix is defined as the following ordered product:

$$T(\lambda) = L_M(\lambda) \dots L_2(\lambda) L_1(\lambda), \tag{6}$$

where $L_n(\lambda)$ denotes the quantum $L$-operator at the site $n$ of the chain,

$$L_n(\lambda) = \begin{pmatrix} \sinh(\lambda + \frac{\eta}{2}\sigma_n^z) & \sinh\eta\,\sigma_n^- \\ \sinh\eta\,\sigma_n^+ & \sinh(\lambda - \frac{\eta}{2}\sigma_n^z) \end{pmatrix}. \tag{7}$$

The parameter $\eta$ is related to the anisotropy parameter as $\Delta = \cosh\eta$. It follows from this definition that the monodromy matrix is an highly non local operator in terms of the local spin operators $\sigma_n^{x,y,z}$. However, the commutation relations between the operators $A$, $B$, $C$, $D$ can be computed in a simple way. They are given by the quantum $R$-matrix

$$R(\lambda, \mu) = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & b(\lambda,\mu) & c(\lambda,\mu) & 0 \\ 0 & c(\lambda,\mu) & b(\lambda,\mu) & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}, \tag{8}$$

where

$$b(\lambda, \mu) = \frac{\sinh(\lambda - \mu)}{\sinh(\lambda - \mu + \eta)}, \quad c(\lambda, \mu) = \frac{\sinh(\eta)}{\sinh(\lambda - \mu + \eta)}. \tag{9}$$

The $R$-matrix is a linear operator in the tensor product $V_1 \otimes V_2$, where each $V_i$ is isomorphic to $\mathbb{C}^2$, and depends generically on two spectral parameters $\lambda_1$ and $\lambda_2$ associated to these two vector spaces. It is denoted by $R_{12}(\lambda_1, \lambda_2)$. Such an $R$-matrix satisfies the Yang–Baxter equation,

$$R_{12}(\lambda_1, \lambda_2)\ R_{13}(\lambda_1, \lambda_3)\ R_{23}(\lambda_2, \lambda_3) = R_{23}(\lambda_2, \lambda_3)\ R_{13}(\lambda_1, \lambda_3)\ R_{12}(\lambda_1, \lambda_2). \tag{10}$$

It gives the following commutation relations among the operators entries of the monodromy matrix:

$$R_{12}(\lambda, \mu)\ T_1(\lambda)\ T_2(\mu) = T_2(\mu)\ T_1(\lambda)\ R_{12}(\lambda, \mu) \tag{11}$$

with the tensor notations $T_1(\lambda) = T(\lambda) \otimes \mathrm{Id}$ and $T_2(\mu) = \mathrm{Id} \otimes T(\mu)$. These commutation relations imply in particular that the transfer matrices, defined as

$$\mathcal{T}(\lambda) = \mathrm{tr}\, T(\lambda) = A(\lambda) + D(\lambda), \tag{12}$$

commute for different values of the spectral parameter $[\mathcal{T}(\lambda), \mathcal{T}(\mu)] = 0$ and also with $S_z$, $[\mathcal{T}(\lambda), S_z] = 0$. The Hamiltonian (2) at $h = 0$ is related to $\mathcal{T}(\lambda)$ by the 'trace identity'

$$H^{(0)} = 2\sinh\eta\ \frac{d\mathcal{T}(\lambda)}{d\lambda}\mathcal{T}^{-1}(\lambda)\big|_{\lambda=\frac{\eta}{2}} - 2M\cosh\eta. \tag{13}$$

Therefore, the spectrum of the Hamiltonian (1) is given by the common eigenvectors of the transfer matrices and of $S_z$.

For technical reasons, it is actually convenient to introduce a slightly more general object, the twisted transfer matrix

$$\mathcal{T}_\kappa(\lambda) = A(\lambda) + \kappa D(\lambda), \tag{14}$$

where $\kappa$ is a complex parameter. The particular case of $\mathcal{T}_\kappa(\lambda)$ at $\kappa = 1$ corresponds to the usual (untwisted) transfer matrix $\mathcal{T}(\lambda)$. It will be also convenient to consider an inhomogeneous version of the $XXZ$ chain for which

$$T_{1\dots M}(\lambda; \xi_1, \dots, \xi_M) = L_M(\lambda - \xi_M + \eta/2) \dots L_1(\lambda - \xi_1 + \eta/2). \tag{15}$$

Here, $\xi_1, \dots, \xi_M$ are complex parameters (inhomogeneity parameters) attached to each site of the lattice. The homogeneous model (1) corresponds to the case where $\xi_j = \eta/2$ for $j = 1, \dots, M$.

In the framework of algebraic Bethe ansatz, an arbitrary quantum state can be obtained from the vectors generated by multiple action of operators $B(\lambda)$ on the reference vector $|\,0\,\rangle$ with all spins up (respectively by multiple action of operators $C(\lambda)$ on the dual reference vector $\langle\,0\,|$),

$$|\,\psi\,\rangle = \prod_{j=1}^{N} B(\lambda_j)|\,0\,\rangle, \quad \langle\,\psi\,| = \langle\,0\,|\prod_{j=1}^{N} C(\lambda_j), \quad N = 0, 1, \dots, M. \tag{16}$$

**2.2. Description of the spectrum.** Let us consider here the subspace $\mathcal{H}^{(M/2-N)}$ of the space of states $\mathcal{H}$ with a fixed number $N$ of spins down. In this subspace, the eigenvectors $|\,\psi_\kappa(\{\lambda\})\,\rangle$ (respectively $\langle\,\psi_\kappa(\{\lambda\})\,|$) of the twisted transfer matrix $\mathcal{T}_\kappa(\mu)$ can be constructed in the form (16), where the parameters $\lambda_1, \dots, \lambda_N$ satisfy the system of twisted Bethe equations

$$\mathcal{Y}_\kappa(\lambda_j|\{\lambda\}) = 0, \quad j = 1, \dots, N. \tag{17}$$

Here, the function $\mathcal{Y}_\kappa$ is defined as

$$\mathcal{Y}_\kappa(\mu|\{\lambda\}) = a(\mu)\prod_{k=1}^{N}\sinh(\lambda_k - \mu + \eta) + \kappa\, d(\mu)\prod_{k=1}^{N}\sinh(\lambda_k - \mu - \eta), \tag{18}$$

and $a(\lambda)$, $d(\lambda)$ are the eigenvalues of the operators $A(\lambda)$ and $D(\lambda)$ on the reference state $|\,0\,\rangle$. In the normalization (7) and for the inhomogeneous model (15) we have

$$a(\lambda) = \prod_{a=1}^{M}\sinh(\lambda - \xi_a + \eta), \quad d(\lambda) = \prod_{a=1}^{M}\sinh(\lambda - \xi_a). \tag{19}$$

The corresponding eigenvalue of $\mathcal{T}_\kappa(\mu)$ on $|\,\psi_\kappa(\{\lambda\})\,\rangle$ (or on a dual eigenvector) is

$$\tau_\kappa(\mu|\{\lambda\}) = a(\mu)\prod_{k=1}^{N}\frac{\sinh(\lambda_k-\mu+\eta)}{\sinh(\lambda_k-\mu)} + \kappa\, d(\mu)\prod_{k=1}^{N}\frac{\sinh(\mu-\lambda_k+\eta)}{\sinh(\mu-\lambda_k)}. \quad (20)$$

The solutions of the system of twisted Bethe equations (17) have been analyzed in [39]. In general, not all of these solutions correspond to eigenvectors of $\mathcal{T}_\kappa(\mu)$.

**Definition 2.1.** A solution $\{\lambda\}$ of the system (17) is called *admissible* if

$$d(\lambda_j)\prod_{\substack{k=1\\k\neq j}}^{N}\sinh(\lambda_j-\lambda_k+\eta)\neq 0, \quad j=1,\ldots,N, \quad (21)$$

and *un-admissible* otherwise. A solution is called *off-diagonal* if the corresponding parameters $\lambda_1,\ldots,\lambda_N$ are pairwise distinct, and *diagonal* otherwise.

One of the main result of [39] is that, for generic parameters $\kappa$ and $\{\xi\}$, the set of the eigenvectors corresponding to the admissible off-diagonal solutions of the system of twisted Bethe equations (17) form a basis in the subspace $\mathcal{H}^{(M/2-N)}$. It has been proven in [16] that this result is still valid in the homogeneous case $\xi_j=\eta/2$, $j=1,\ldots,N$, at least if $\kappa$ is in a punctured vicinity of the origin (i.e. $0<|\kappa|<\kappa_0$ for $\kappa_0$ small enough). Note however that, for specific values of $\kappa$ and $\{\xi\}$, the basis of the eigenvectors in $\mathcal{H}^{(M/2-N)}$ may include some states corresponding to un-admissible solutions of (17) (in particular in the homogeneous limit at $\kappa=1$).

At $\kappa=1$, it follows from the trace identity (13) that the eigenvectors of the transfer matrix coincide, in the homogeneous limit, with the ones of the Hamiltonian (1). The corresponding eigenvalues in the case of zero magnetic field can be obtained from (13), (20):

$$H^{(0)}\,|\,\psi(\{\lambda\})\,\rangle = \Big(\sum_{j=1}^{N}E(\lambda_j)\Big)\cdot|\,\psi(\{\lambda\})\,\rangle, \quad (22)$$

where the (bare) one-particle energy $E(\lambda)$ is equal to

$$E(\lambda)=\frac{2\sinh^2\eta}{\sinh(\lambda+\frac{\eta}{2})\sinh(\lambda-\frac{\eta}{2})}. \quad (23)$$

**2.3. Drinfel'd twist and $F$-basis.** As already noted, the operators $A$, $B$, $C$, $D$ are highly non local in terms of local spin operators. There exists however an interesting description of these operators by means of a change of basis of the space of states. In particular, this basis will provide a direct access to the scalar products of states. The root of this new basis is provided by the notion of Drinfel'd twist [40] associated to the $R$-matrix of the $XXZ$ chain. It leads to the notion of factorizing $F$-matrices. To be essentially self-contained we briefly recall here their main properties and refer to [7] for more details and proofs.

**Definition 2.2.** For inhomogeneity parameters $\xi_j$ in generic positions and for any integer $n$ one can associate to any element $\sigma$ of the symmetric group $S_n$ on $n$ elements a unique $R$-matrix $R^{\sigma}_{1\ldots n}(\xi_1, \ldots, \xi_n)$, denoted for simplicity $R^{\sigma}_{1\ldots n}$, constructed as an ordered product (depending on $\sigma$) of the elementary $R$-matrices $R_{ij}(\xi_i, \xi_j)$.

We have the following property for an arbitrary integer $n$.

**Proposition 2.1.**

$$R^{\sigma}_{1\ldots n}\; T_{1\ldots n}(\lambda; \xi_1, \ldots, \xi_n) = T_{\sigma(1)\ldots\sigma(n)}(\lambda; \xi_{\sigma(1)}, \ldots, \xi_{\sigma(n)})\; R^{\sigma}_{1\ldots n}. \tag{24}$$

We can now define the notion of a factorizing $F$-matrix:

**Definition 2.3.** A factorizing $F$-matrix associated to a given elementary $R$-matrix is an invertible matrix $F_{1\ldots n}(\xi_1, \ldots, \xi_n)$, defined for an arbitrary integer $n$, satisfying the following relation for any element $\sigma$ of $S_n$:

$$F_{\sigma(1)\ldots\sigma(n)}(\xi_{\sigma(1)}, \ldots, \xi_{\sigma(n)})\; R^{\sigma}_{1\ldots n}(\xi_1, \ldots, \xi_n) = F_{1\ldots n}(\xi_1, \ldots, \xi_n). \tag{25}$$

In other words, such an $F$-matrix factorizes the corresponding $R$-matrix for arbitrary integers $n$. Taking into account the fact that the parameters $\xi_n$ are in one to one correspondence with the vector spaces $\mathcal{H}_n$, we can adopt simplified notations such that

$$F_{1\ldots n}(\xi_1, \ldots, \xi_n) = F_{1\ldots n},$$
$$F_{\sigma(1)\ldots\sigma(n)}(\xi_{\sigma(1)}, \ldots, \xi_{\sigma(n)}) = F_{\sigma(1)\ldots\sigma(n)}.$$

**Theorem 2.1** ([7]). *For the $XXZ$ model with inhomogeneity parameters $\xi_n$ in generic positions there exists a factorizing, triangular $F$-matrix. It is constructed explicitly from the $R$-matrix.*

This matrix has two important properties:

**Proposition 2.2** ([7]). *In the $F$-basis, the monodromy matrix $\widetilde{T}$,*

$$\widetilde{T}_{1\ldots M}(\lambda; \xi_1, \ldots, \xi_M) \;=\; F_{1\ldots M} T_{1\ldots M}(\lambda; \xi_1, \ldots, \xi_M)\; F^{-1}_{1\ldots M}, \tag{26}$$

*is totally symmetric under any simultaneous permutations of the lattice sites $i$ and of the corresponding inhomogeneity parameters $\xi_i$.*

The second property gives the explicit expressions of the monodromy matrix in the $F$-basis. For the $XXZ$-$\frac{1}{2}$ model, the quantum monodromy operator is a $2 \times 2$ matrix with entries $A, B, C, D$ which are obtained as sums of $2^{M-1}$ operators, which themselves are products of $M$ local spin operators on the quantum chain. As an example, the $B$ operator is given as

$$B_{1\ldots M}(\lambda) = \sum_{i=1}^{N} \sigma_i^- \;\Omega_i \;+\; \sum_{i\neq j\neq k} \sigma_i^- \;(\sigma_j^- \;\sigma_k^+)\; \Omega_{ijk} \;+\; \text{higher terms}, \tag{27}$$

where the matrices $\Omega_i$, $\Omega_{ijk}$, are diagonal operators acting respectively on all sites but $i$, on all sites but $i, j, k$, and the higher order terms involve more and more exchange spin terms like $\sigma_j^- \sigma_k^+$. It means that the $B$ operator returns one spin somewhere on the chain, this operation being however dressed non-locally and with non-diagonal operators by multiple exchange terms of the type $\sigma_j^- \sigma_k^+$.

So, whereas these formulas in the original basis are quite involved, their expressions in the $F$-basis simplify drastically:

**Proposition 2.3** ([7]). *The operators D, B and C in the F-basis are given by the formulas*

$$\widetilde{D}_{1\ldots M}(\lambda;\xi_1,\ldots,\xi_M) = \bigotimes_{i=1}^{M} \begin{pmatrix} b(\lambda,\xi_i) & 0 \\ 0 & 1 \end{pmatrix}_{[i]}, \tag{28}$$

$$\widetilde{B}_{1\ldots M}(\lambda) = \sum_{i=1}^{M} \sigma_i^- \, c(\lambda,\xi_i) \bigotimes_{j\neq i} \begin{pmatrix} b(\lambda,\xi_j) & 0 \\ 0 & b^{-1}(\xi_j,\xi_i) \end{pmatrix}_{[j]}, \tag{29}$$

$$\widetilde{C}_{1\ldots M}(\lambda) = \sum_{i=1}^{M} \sigma_i^+ \, c(\lambda,\xi_i) \bigotimes_{j\neq i} \begin{pmatrix} b(\lambda,\xi_j)\, b^{-1}(\xi_i,\xi_j) & 0 \\ 0 & 1 \end{pmatrix}_{[j]}, \tag{30}$$

*and the operator $\widetilde{A}$ can be obtained from quantum determinant relations.*

We wish first to stress that while the operators $\widetilde{A}$, $\widetilde{B}$, $\widetilde{C}$, $\widetilde{D}$ satisfy the same quadratic commutation relations as $A, B, C, D$, they are completely symmetric under simultaneous exchange of the inhomogeneity parameters and of the spaces $\mathcal{H}_n$. It really means that the factorizing $F$-matrices we have constructed solve the combinatorial problem induced by the non-trivial action of the permutation group $S_M$ given by the $R$-matrix. In the $F$-basis the action of the permutation group on the operators $\widetilde{A}$, $\widetilde{B}$, $\widetilde{C}$, $\widetilde{D}$ is trivial.

Further, it can be shown that the pseudo-vacuum vector is left invariant, namely, it is an eigenvector of the total $F$-matrix with eigenvalue 1; in particular, the algebraic Bethe ansatz can be carried out also in the $F$-basis. Hence, a direct computation of Bethe eigenvectors and of their scalar products in this $F$-basis is made possible, while it was a priori very involved in the original basis. There, only commutation relations between the operators $A, B, C, D$ can be used, leading (see [5]) to very intricate sums over partitions.

**2.4. Solution of the quantum inverse problem.** The very simple expressions of the monodromy matrix operators entries $D$, $B$, $C$ in the $F$-basis suggests that any local operator $E_j^{\epsilon'_j,\epsilon_j}$, acting in a local quantum space $\mathcal{H}_j$ at site $j$, can be expressed in terms of the entries of the monodromy matrix. This is the so-called quantum inverse scattering problem. The solution to this problem was found in [8], [10]:

**Theorem 2.2.**

$$E_j^{\epsilon_j',\epsilon_j} = \prod_{\alpha=1}^{j-1} \mathcal{T}(\xi_\alpha) \cdot T_{\epsilon_j,\epsilon_j'}(\xi_j) \cdot \prod_{\alpha=1}^{j} \mathcal{T}^{-1}(\xi_\alpha). \tag{31}$$

The proof of this theorem is elementary (see [8], [10]) and hence it can be obtained for a large class of lattice integrable models. It relies essentially on the property that the $R$-matrix $R(\lambda, \mu)$ reduces to the permutation operator for $\lambda = \mu$. An immediate consequence of this theorem is that the operators $A$, $B$, $C$, and $D$ generate the space of all operators acting in $\mathcal{H}$.

**2.5. Scalar products.** We give here the expressions for the scalar product of an eigenvector of the twisted transfer matrix with any arbitrary state of the form (16). These scalar products can be expressed as determinant of rather simple matrices. The root of all these determinants is in fact the determinant representation for the partition function of the 6-vertex model with domain wall boundary conditions [41]. Let us first define, for arbitrary positive integers $n, n'$ ($n \leq n'$) and arbitrary sets of variables $\lambda_1, \ldots, \lambda_n, \mu_1, \ldots, \mu_n$ and $\nu_1, \ldots, \nu_{n'}$ such that $\{\lambda\} \subset \{\nu\}$, the $n \times n$ matrix $\Omega_\kappa(\{\lambda\}, \{\mu\}|\{\nu\})$ as

$$\begin{aligned}(\Omega_\kappa)_{jk}(\{\lambda\}, \{\mu\}|\{\nu\}) = a(\mu_k)\, t(\lambda_j, \mu_k) \prod_{a=1}^{n'} \sinh(\nu_a - \mu_k + \eta) \\ - \kappa\, d(\mu_k)\, t(\mu_k, \lambda_j) \prod_{a=1}^{n'} \sinh(\nu_a - \mu_k - \eta),\end{aligned} \tag{32}$$

with

$$t(\lambda, \mu) = \frac{\sinh \eta}{\sinh(\lambda - \mu) \sinh(\lambda - \mu + \eta)}. \tag{33}$$

**Proposition 2.4** ([42], [8], [15]). *Let $\{\lambda_1, \ldots, \lambda_N\}$ be a solution of the system of twisted Bethe equations* (17)*, and let $\mu_1, \ldots, \mu_N$ be generic complex numbers. Then,*

$$\begin{aligned}\langle 0 | \prod_{j=1}^{N} C(\mu_j) | \psi_\kappa(\{\lambda\}) \rangle &= \langle \psi_\kappa(\{\lambda\}) | \prod_{j=1}^{N} B(\mu_j) | 0 \rangle \\ &= \frac{\prod_{a=1}^{N} d(\lambda_a) \prod_{a,b=1}^{N} \sinh(\mu_b - \lambda_a)}{\prod_{a>b}^{N} \sinh(\lambda_a - \lambda_b) \sinh(\mu_b - \mu_a)} \cdot \det_N \left( \frac{\partial}{\partial \lambda_j} \tau_\kappa(\mu_k | \{\lambda\}) \right)\end{aligned} \tag{34}$$

$$= \frac{\prod_{a=1}^{N} d(\lambda_a)}{\prod_{a>b}^{N} \sinh(\lambda_a - \lambda_b)\sinh(\mu_b - \mu_a)} \cdot \det_N \Omega_\kappa(\{\lambda\},\{\mu\}|\{\lambda\}). \quad (35)$$

These equations are valid for any arbitrary complex parameter $\kappa$, in particular at $\kappa = 1$. In this case we may omit the subscript $\kappa$ and denote $(\psi, \tau, \mathcal{Y}, \Omega) = (\psi_\kappa, \tau_\kappa, \mathcal{Y}_\kappa, \Omega_\kappa)\big|_{\kappa=1}$. If the sets $\{\lambda\}$ and $\{\mu\}$ are different, the eigenvector $|\, \psi_\kappa(\{\lambda\})\,\rangle$ is orthogonal to the dual eigenvector $\langle\, \psi_\kappa(\{\mu\})\,|$. Otherwise we obtain a formula for the norm of the corresponding vector [43], [44], [8],

$$\langle\, \psi_\kappa(\{\lambda\}) \,|\, \psi_\kappa(\{\lambda\})\,\rangle = \frac{\prod_{a=1}^{N} d(\lambda_a)}{\prod_{\substack{a,b=1\\ a\neq b}}^{N} \sinh(\lambda_a - \lambda_b)} \cdot \det_N \Omega_\kappa(\{\lambda\},\{\lambda\}|\{\lambda\})$$

$$= (-1)^N \frac{\prod_{a=1}^{N} d(\lambda_a)}{\prod_{\substack{a,b=1\\ a\neq b}}^{N} \sinh(\lambda_a - \lambda_b)} \cdot \det_N \left( \frac{\partial}{\partial \lambda_k} \mathcal{Y}_\kappa(\lambda_j|\{\lambda\}) \right).$$

**2.6. Action of operators $A$, $B$, $C$, $D$ on a general state.** An important step of the computation of the correlation function is to express the action of any product of local operators on any Bethe eigenvector. From the solution of the quantum inverse scattering problem, this is given by the successive action of $A$, $B$, $C$, $D$ operators on a vector constructed by action of $C$ operators on the reference vector. Action of $A$, $B$, $C$, $D$ on such a vector are well known (see for example [5]). They can be written in the following form:

$$\langle\, 0 \,|\, \prod_{k=1}^{N} C(\lambda_k)\, A(\lambda_{N+1}) = \sum_{a'=1}^{N+1} a(\lambda_{a'}) \frac{\prod_{k=1}^{N} \sinh(\lambda_k - \lambda_{a'} + \eta)}{\prod_{\substack{k=1\\ k\neq a'}}^{N+1} \sinh(\lambda_k - \lambda_{a'})} \langle\, 0 \,|\, \prod_{\substack{k=1\\ k\neq a'}}^{N+1} C(\lambda_k); \quad (36)$$

$$\langle\, 0 \,|\, \prod_{k=1}^{N} C(\lambda_k)\, D(\lambda_{N+1}) = \sum_{a=1}^{N+1} d(\lambda_a) \frac{\prod_{k=1}^{N} \sinh(\lambda_a - \lambda_k + \eta)}{\prod_{\substack{k=1\\ k\neq a}}^{N+1} \sinh(\lambda_a - \lambda_k)} \langle\, 0 \,|\, \prod_{\substack{k=1\\ k\neq a}}^{N+1} C(\lambda_k). \quad (37)$$

The action of the operator $B(\lambda)$ can be obtained similarly,

$$\begin{aligned}\langle 0 \mid \prod_{k=1}^{N} C(\lambda_k)\, B(\lambda_{N+1}) = \sum_{a=1}^{N+1} d(\lambda_a) \frac{\prod_{k=1}^{N} \sinh(\lambda_a - \lambda_k + \eta)}{\prod_{\substack{k=1 \\ k\neq a}}^{N+1} \sinh(\lambda_a - \lambda_k)} \\ \times \sum_{\substack{a'=1 \\ a'\neq a}}^{N+1} \frac{a(\lambda_{a'})}{\sinh(\lambda_{N+1} - \lambda_{a'} + \eta)} \frac{\prod_{\substack{j=1 \\ j\neq a}}^{N+1} \sinh(\lambda_j - \lambda_{a'} + \eta)}{\prod_{\substack{j=1 \\ j\neq a,a'}}^{N+1} \sinh(\lambda_j - \lambda_{a'})} \langle 0 \mid \prod_{\substack{k=1 \\ k\neq a,a'}}^{N+1} C(\lambda_k),\end{aligned} \tag{38}$$

and the action of $C$ is obvious.

## 3. Correlation functions: finite chain

To compute correlation functions of some product of local operators, the following successive problems have to be addressed: (i) determination of the ground state $\langle\, \psi_g \mid$, (ii) evaluation of the action of the product of the local operators on it, and (iii) computation of the scalar product of the resulting state with $\mid \psi_g \,\rangle$. Using the solution of the quantum inverse scattering problem together with the explicit determinant formulas for the scalar products and the norm of the Bethe state, one sees that matrix elements of local spin operators and correlation functions can be expressed as (multiple) sums of determinants [9]. It should be stressed that this result is purely algebraic and is valid for finite chains of arbitrary length $M$.

**3.1. Matrix elements of local operators.** We begin with the calculation of the one-point functions. These results follow directly from the solution of the quantum inverse scattering problem, the above action of operators $A$, $B$, $C$ and $D$, and the determinant representation of the scalar products. We consider

$$F_N^-(m, \{\mu_j\}, \{\lambda_k\}) = \langle 0 \mid \prod_{j=1}^{N+1} C(\mu_j)\, \sigma_m^- \prod_{k=1}^{N} B(\lambda_k) \mid 0 \,\rangle \tag{39}$$

and

$$F_N^+(m, \{\lambda_k\}, \{\mu_j\}) = \langle 0 \mid \prod_{k=1}^{N} C(\lambda_k)\, \sigma_m^+ \prod_{j=1}^{N+1} B(\mu_j) \mid 0 \,\rangle, \tag{40}$$

where $\{\lambda_k\}_n$ and $\{\mu_j\}_{n+1}$ are solutions of Bethe equations.

**Proposition 3.1.** *For two Bethe states with spectral parameters* $\{\lambda_k\}_N$ *and* $\{\mu_j\}_{N+1}$, *the matrix element of the operator* $\sigma_m^-$ *can be represented as a determinant,*

$$F_N^-(m,\{\mu_j\},\{\lambda_k\}) = \frac{\phi_{m-1}(\{\mu_j\})}{\phi_{m-1}(\{\lambda_k\})} \frac{\prod_{j=1}^{N+1} \sinh(\mu_j - \xi_m + \eta)}{\prod_{k=1}^{N} \sinh(\lambda_k - \xi_m + \eta)} \cdot \frac{\det_{N+1} H^-(m,\{\mu_j\},\{\lambda_k\})}{\prod_{N+1\geq k>j\geq 1} \sinh(\mu_k - \mu_j) \prod_{1\leq\beta<\alpha\leq N} \sinh(\lambda_\beta - \lambda_\alpha)}, \tag{41}$$

$$\phi_m(\{\lambda_k\}) = \prod_{k=1}^{N}\prod_{j=1}^{m} b^{-1}(\lambda_k,\xi_j), \tag{42}$$

*and the* $(N+1)\times(N+1)$ *matrix* $H^-$ *is defined as*

$$H_{ab}^-(m) = \frac{\varphi(\eta)}{\varphi(\mu_a - \lambda_b)}\Big(a(\lambda_b)\prod_{\substack{j=1\\ j\neq a}}^{N+1}\varphi(\mu_j - \lambda_b + \eta) - d(\lambda_b)\prod_{\substack{j=1\\ j\neq a}}^{N+1}\varphi(\mu_j - \lambda_b - \eta)\Big) \tag{43}$$

*for* $b < N+1$, *and*

$$H_{aN+1}^-(m) = \frac{\varphi(\eta)}{\varphi(\mu_a - \xi_m + \eta)\varphi(\mu_a - \xi_m)}. \tag{44}$$

*For the matrix element* $F_N^+(m,\{\lambda_k\},\{\mu_j\})$ *we get*

$$F_N^+(m,\{\lambda_k\},\{\mu_j\}) = \frac{\phi_m(\lambda_k)\,\phi_{m-1}(\lambda_k)}{\phi_{m-1}(\mu_j)\,\phi_m(\mu_j)} F_N^-(m,\{\mu_j\},\{\lambda_k\}). \tag{45}$$

The matrix elements of the operator $\sigma_m^z$ between two Bethe states have been obtained similarly [8].

**3.2. Elementary blocks of correlation functions.** In this section we consider a more general case of correlation functions: the ground state mean value of any product of the local elementary $2\times 2$ matrices $E_{lk}^{\epsilon',\epsilon} = \delta_{l,\epsilon'}\delta_{k,\epsilon}$:

$$F_m(\{\epsilon_j,\epsilon_j'\}) = \frac{\langle\,\psi_g\,|\prod_{j=1}^{m} E_j^{\epsilon_j',\epsilon_j}|\,\psi_g\,\rangle}{\langle\,\psi_g\,|\psi_g\rangle}. \tag{46}$$

An arbitrary $n$-point correlation function can be obtained as a sum of such mean values. Using the solution of the quantum inverse scattering problem, we reduce this

problem to the computation of the ground state mean value of an arbitrary ordered product of monodromy matrix elements,

$$F_m(\{\epsilon_j,\epsilon'_j\}) = \phi_m^{-1}(\{\lambda\})\frac{\langle\,\psi_g\,|T_{\epsilon_1,\epsilon'_1}(\xi_1)\dots T_{\epsilon_m,\epsilon'_m}(\xi_m)|\,\psi_g\,\rangle}{\langle\,\psi_g\,|\psi_g\rangle}. \tag{47}$$

To calculate these mean values we first describe generically the product of the monodromy matrix elements. For that purpose, one should consider the two following sets of indices, $\boldsymbol{\alpha}^+ = \{j : 1 \le j \le m,\ \epsilon_j = 1\}$, $\mathrm{card}(\boldsymbol{\alpha}^+) = s'$, $\max_{j\in\boldsymbol{\alpha}^+}(j) \equiv j'_{\max}$, $\min_{j\in\boldsymbol{\alpha}^+}(j) \equiv j'_{\min}$, and similarly $\boldsymbol{\alpha}^- = \{j : 1 \le j \le m,\ \epsilon'_j = 2\}$, $\mathrm{card}(\boldsymbol{\alpha}^-) = s$, $\max_{j\in\boldsymbol{\alpha}^-}(j) \equiv j_{\max}$, $\min_{j\in\boldsymbol{\alpha}^-}(j) \equiv j_{\min}$. The intersection of these two sets is not empty and corresponds to the operators $B(\xi_j)$. Consider now the action, $\langle\,0\,|\prod_{k=1}^N C(\lambda_k)T_{\epsilon_1,\epsilon'_1}(\lambda_{N+1})\dots T_{\epsilon_m,\epsilon'_m}(\lambda_{N+m})$, applying one by one the formulae (36)–(38). For all the indices $j$ from the sets $\boldsymbol{\alpha}^+$ and $\boldsymbol{\alpha}^-$ one obtains a summation on the corresponding indices $a'_j$ (for $j \in \boldsymbol{\alpha}^+$, corresponding to the action of the operators $A(\lambda)$ or $B(\lambda)$) or $a_j$ (for $j \in \boldsymbol{\alpha}^-$, corresponding to the action of the operators $D(\lambda)$ or $B(\lambda)$). As the product of the monodromy matrix elements is ordered these summations are also ordered and the corresponding indices should be taken from the following sets: $\boldsymbol{A}_j = \{b : 1 \le b \le N+m,\ b \ne a_k, a'_k,\ k < j\}$ and $\boldsymbol{A'}_j = \{b : 1 \le b \le N+m,\ b \ne a'_k,\ k < j,\ b \ne a_k,\ k \le j\}$. Thus,

$$\begin{aligned}\langle\,0\,|\prod_{k=1}^{N} C(\lambda_k)\,T_{\epsilon_1,\epsilon'_1}(\lambda_{N+1})\dots T_{\epsilon_m,\epsilon'_m}(\lambda_{N+m})\\ = \sum_{\{a_j,a'_j\}} G_{\{a_j,a'_j\}}(\lambda_1,\dots,\lambda_{N+m})\langle\,0\,|\prod_{b\in\boldsymbol{A}_{m+1}} C(\lambda_b).\end{aligned} \tag{48}$$

The summation is taken over the indices $a_j$ for $j \in \boldsymbol{\alpha}^-$ and $a'_j$ for $j \in \boldsymbol{\alpha}^+$ such that $1 \le a_j \le N+j$, $a_j \in \boldsymbol{A}_j$, $1 \le a'_j \le N+j$, $a'_j \in \boldsymbol{A'}_j$. The functions $G_{\{a_j,a'_j\}}(\lambda_1,\dots\lambda_{N+m})$ can then be easily obtained from the formulae (36)–(38) taking into acount that $\lambda_a = \xi_{a-N}$ for $a > N$:

$$\begin{aligned}G_{\{a_j,a'_j\}}(\lambda_1,\dots,\lambda_{N+m}) = \prod_{j\in\boldsymbol{\alpha}^-} d(\lambda_{a_j})\frac{\prod\limits_{\substack{b=1\\ b\in\boldsymbol{A}_j}}^{N+j-1}\sinh(\lambda_{a_j}-\lambda_b+\eta)}{\prod\limits_{\substack{b=1\\ b\in\boldsymbol{A'}_j}}^{N+j}\sinh(\lambda_{a_j}-\lambda_b)}\\ \times\prod_{j\in\boldsymbol{\alpha}^+} a(\lambda_{a'_j})\frac{\prod\limits_{\substack{b=1\\ b\in\boldsymbol{A'}_j}}^{N+j-1}\sinh(\lambda_b-\lambda_{a'_j}+\eta)}{\prod\limits_{\substack{b=1\\ b\in\boldsymbol{A}_{j+1}}}^{N+j}\sinh(\lambda_b-\lambda_{a'_j})}.\end{aligned} \tag{49}$$

Now to calculate the normalized mean value (47) we apply the determinant representation for the scalar product. It should be mentioned that the number of operators $C(\lambda)$ has to be equal to the number of the operators $B(\lambda)$, as otherwise the mean value is zero, and hence the total number of elements in the sets $\boldsymbol{\alpha}^+$ and $\boldsymbol{\alpha}^-$ is $s + s' = m$. Taking into account that in (47), for $b > N$, $\lambda_b = \xi_{b-N}$ one has to consider the following scalar products:

$$\frac{\langle 0 \mid \prod\limits_{b \in \boldsymbol{A}_{m+1}} C(\lambda_b) \prod\limits_{k=1}^{N} B(\lambda_k) \mid 0 \rangle}{\langle 0 \mid \prod\limits_{k=1}^{N} C(\lambda_k) \prod\limits_{k=1}^{N} B(\lambda_k) \mid 0 \rangle},$$

for all the permitted values of $a_j, a'_j$. Finally we obtain

$$F_m(\{\epsilon_j, \epsilon'_j\}) = \frac{1}{\prod\limits_{k<l} \sinh(\xi_k - \xi_l)} \sum_{\{a_j, a'_j\}} H_{\{a_j, a'_j\}}(\lambda_1, \ldots, \lambda_{N+m}), \tag{50}$$

the sum being taken on the same set of indices $a_j$, $a'_j$ as in (48). The functions $H_{\{a_j, a'_j\}}(\{\lambda\})$ can be obtained using (49) and the determinant representations for the scalar products.

**3.3. Two-point functions.** The method presented in the last section is quite straightforward and gives formally the possibility to compute any correlation function. However, it has been developed for the computation of the expectation values of the monomials $T_{a_1 b_1}(\xi_1) \ldots T_{a_m b_m}(\xi_m)$, leading to the evaluation of elementary building blocks, whereas the study of the two-point functions involves big sums of such monomials. Indeed, let us consider for example the correlation function $\langle \sigma_1^z \sigma_{m+1}^z \rangle$. Then, according to the solution of the inverse scattering problem (31), we need to calculate the expectation value

$$\langle \psi(\{\lambda\}) \mid (A - D)(\xi_1) \cdot \prod_{a=2}^{m} \mathcal{T}(\xi_a) \cdot (A - D)(\xi_{m+1}) \cdot \prod_{b=1}^{m+1} \mathcal{T}^{-1}(\xi_b) \mid \psi(\{\lambda\}) \rangle. \tag{51}$$

Since $\mid \psi(\{\lambda\}) \rangle$ is an eigenvector, the action of $\prod_{b=1}^{m+1} \mathcal{T}^{-1}(\xi_b)$ on this state merely produces a numerical factor. However, it is much more complicated to evaluate the action of $\prod_{a=2}^{m} \mathcal{T}(\xi_a)$. Indeed, we have to act first with $(A - D)(\xi_1)$ on $\langle \psi(\{\lambda\}) \mid$ (or with $(A - D)(\xi_{m+1})$ on $\mid \psi(\{\lambda\}) \rangle$), which gives a sum of states which are no longer eigenvectors of the transfer matrix, and on which the multiple action of $\mathcal{T}$ is not simple. In fact, the product $\prod_{a=2}^{m}(A + D)(\xi_a)$ would lead to a sum of $2^{m-1}$ elementary blocks. This is not very convenient, in particular at large distance $m$. Therefore, to obtain manageable expressions for such correlation functions, it is of great importance to develop an alternative and compact way to express the multiple

action of the transfer matrix on arbitrary states or, in other words, to make an effective re-summation of the corresponding sum of the $2^{m-1}$ terms. This can be achieved in the following way:

**Proposition 3.2.** *Let $\kappa$, $x_1, \dots, x_m$ and $\mu_1, \dots, \mu_N$ be generic parameters. Then the action of $\prod_{a=1}^{m} \mathcal{T}_\kappa(x_a)$ on a state of the form $\langle 0 | \prod_{j=1}^{N} C(\mu_j)$ can be formally written as*

$$\langle 0 | \prod_{j=1}^{N} C(\mu_j) \prod_{a=1}^{m} \mathcal{T}_\kappa(x_a) = \frac{1}{N!} \oint\limits_{\Gamma\{x\}\cup\Gamma\{\mu\}} \prod_{j=1}^{N} \frac{dz_j}{2\pi i} \cdot \prod_{a=1}^{m} \tau_\kappa(x_a|\{z\}) \cdot \prod_{a=1}^{N} \frac{1}{\mathcal{Y}_\kappa(z_a|\{z\})} \times \prod_{\substack{j,k=1 \\ j<k}}^{N} \frac{\sinh(z_j - z_k)}{\sinh(\mu_j - \mu_k)} \cdot \det_N \Omega_\kappa(\{z\}, \{\mu\}|\{z\}) \cdot \langle 0 | \prod_{j=1}^{N} C(z_j), \quad (52)$$

*where the integration contour $\Gamma\{x\} \cup \Gamma\{\mu\}$ surrounds the points*[1] *$x_1, \dots, x_m$ and $\mu_1, \dots, \mu_N$ and does not contain any other pole of the integrand.*

One of the simplest applications concerns the generating function of the two-point correlation function of the third components of spin, which is defined as the normalized expectation value $\langle\, Q^\kappa_{l,m} \,\rangle$ of the operator

$$Q^\kappa_{l,m} = \prod_{n=l}^{m} \left( \frac{1+\kappa}{2} + \frac{1-\kappa}{2} \cdot \sigma^z_n \right) = \prod_{j=1}^{l-1} \mathcal{T}(\xi_j) \cdot \prod_{j=l}^{m} \mathcal{T}_\kappa(\xi_j) \cdot \prod_{j=1}^{m} \mathcal{T}^{-1}(\xi_j), \quad (53)$$

where $|\, \psi(\{\lambda\}) \,\rangle$ is an eigenvector of $\mathcal{T}(\mu)$ in the subspace $\mathcal{H}^{(M/2-N)}$. The two-point correlation function of the third components of local spins in the eigenvector $|\, \psi(\{\lambda\}) \,\rangle$ can be obtained in terms of the second 'lattice derivative' and the second derivative with respect to $\kappa$ of the generating function $\langle\, Q^\kappa_{l,m} \,\rangle$ at $\kappa = 1$:

$$\langle\, \sigma^z_l \sigma^z_{l+m} \,\rangle = \langle\, \sigma^z_l \,\rangle + \langle\, \sigma^z_{l+m} \,\rangle - 1 + 2 \frac{\partial^2}{\partial \kappa^2} \langle\, Q^\kappa_{l,l+m} - Q^\kappa_{l,l+m-1} - Q^\kappa_{l+1,l+m} + Q^\kappa_{l+1,l+m-1} \,\rangle\big|_{\kappa=1}. \quad (54)$$

Due to the translational invariance of the correlation functions in the homogeneous model, we will simply consider the expectation value $\langle\, Q^\kappa_{1,m} \,\rangle$. For any given eigenvector, we obtain the following result:

**Theorem 3.1.** *Let $\{\lambda\}$ be an admissible off-diagonal solution of the system of untwisted Bethe equations, and let us consider the corresponding expectation value $\langle\, Q^\kappa_{1,m} \,\rangle$ in*

[1] More precisely, for a set of complex variables $\{\nu_1, \dots, \nu_l\}$, the notation $\Gamma\{\nu\}$ should be understood in the following way: $\Gamma\{\nu\}$ is the boundary of a set of poly-disks $\mathcal{D}_a(r)$ in $\mathbb{C}^N$, i.e. $\Gamma\{\nu\} = \cup_{a=1}^{l} \bar{\mathcal{D}}_a(r)$ with $\bar{\mathcal{D}}_a(r) = \{z \in \mathbb{C}^N : |z_k - \nu_a| = r, \quad k = 1, \dots, N\}$.

*the inhomogeneous finite XXZ chain. Then there exists* $\kappa_0 > 0$ *such that, for* $|\kappa| < \kappa_0$, *the following representations hold:*

$$\langle\, Q^{\kappa}_{1,m}\,\rangle = \frac{1}{N!}\oint\limits_{\Gamma\{\xi\}\cup\Gamma\{\lambda\}} \prod_{j=1}^{N}\frac{dz_j}{2\pi i}\cdot\prod_{a=1}^{m}\frac{\tau_\kappa(\xi_a|\{z\})}{\tau(\xi_a|\{\lambda\})}\cdot\prod_{a=1}^{N}\frac{1}{\mathcal{Y}_\kappa(z_a|\{z\})} \times \det_N \Omega_\kappa(\{z\},\{\lambda\}|\{z\})\cdot\frac{\det_N \Omega(\{\lambda\},\{z\}|\{\lambda\})}{\det_N \Omega(\{\lambda\},\{\lambda\}|\{\lambda\})}. \tag{55}$$

*The integration contours are such that the only singularities of the integrand which contribute to the integral are the points* $\xi_1,\ldots,\xi_m$ *and* $\lambda_1\ldots,\lambda_N$.

From this result we can extract a compact representation for the two-point function of $\sigma^z$ [15]. Similar expressions exists for other correlation functions of the spin operators, and in particular for the time dependent case [15], [16]. Moreover, this multiple contour integral representation permits to relate two very different ways to compute two point correlation functions of the type, $g_{12} = \langle\omega|\theta_1\theta_2|\omega\rangle$, namely,

(i) to compute the action of local operators on the ground state $\theta_1\theta_2|\omega\rangle = |\tilde{\omega}\rangle$ and then to calculate the resulting scalar product $g_{12} = \langle\omega|\tilde{\omega}\rangle$ as was explained in the previous sections;

(ii) to insert a sum over a complete set of states $|\omega_i\rangle$ (for instance, a complete set of eigenvectors of the Hamiltonian) between the local operators $\theta_1$ and $\theta_2$ and to obtain the representation for the correlation function as a sum over matrix elements of local operators,

$$g_{12} = \sum_i \langle\omega|\theta_1|\omega_i\rangle\cdot\langle\omega_i|\theta_2|\omega\rangle. \tag{56}$$

In fact the above representation as multiple contour integrals contains both expansions. Indeed there are two ways to evaluate the corresponding integrals: either to compute the residues in the poles inside $\Gamma$, or to compute the residues in the poles within strips of the width $i\pi$ outside $\Gamma$.

The first way leads to a representation of the correlation function $\langle\sigma^z_1\sigma^z_{m+1}\rangle$ in terms of the previously obtained [11] $m$-multiple sums. Evaluation of the above contour integral in terms of the poles outside the contour $\Gamma$ gives us the expansion (ii) of the correlation function (i.e. an expansion in terms of matrix elements of $\sigma^z$ between the ground state and all excited states). This relation holds also for the time dependent case [15], [16].

## 4. Correlation functions: infinite chain

In the thermodynamic limit $M \to \infty$ and at zero magnetic field, the model exhibits three different regimes depending on the value of $\Delta$ [1]. For $\Delta < -1$, the model is ferromagnetic, for $-1 < \Delta < 1$ the model has a non degenerated anti ferromagnetic

ground state, and no gap in the spectrum (massless regime), while for $\Delta > 1$ the ground state is twice degenerated with a gap in the spectrum (massive regime). In both cases, the ground state has spin zero. Hence the number of parameters $\lambda$ in the ground state vectors is equal to half the size $M$ of the chain. For $M \to \infty$, these parameters will be distributed in some continuous interval according to a density function $\rho$.

**4.1. The thermodynamic limit.** In this limit, the Bethe equations for the ground state, written in their logarithmic form, become a linear integral equation for the density distribution of these $\lambda$'s,

$$\rho_{\mathrm{tot}}(\alpha) + \int_{-\Lambda}^{\Lambda} K(\alpha-\beta)\rho_{\mathrm{tot}}(\beta)\,d\beta = \frac{p'_{0_{\mathrm{tot}}}(\alpha)}{2\pi}, \tag{57}$$

where the new real variables $\alpha$ are defined in terms of general spectral parameters $\lambda$ differently in the two domains. From now on, we only describe the massless regime (see [9] for the other case) $-1 < \Delta < 1$ where $\alpha = \lambda$. The density $\rho$ is defined as the limit of the quantity $\frac{1}{M(\lambda_{j+1}-\lambda_j)}$, and the functions $K(\lambda)$ and $p'_{0_{\mathrm{tot}}}(\lambda)$ are the derivatives with respect to $\lambda$ of the functions $-\frac{\theta(\lambda)}{2\pi}$ and $p_{0_{\mathrm{tot}}}(\lambda)$:

$$\begin{aligned} K(\alpha) &= \frac{\sin 2\zeta}{2\pi\ \sinh(\alpha+i\zeta)\sinh(\alpha-i\zeta)} \\ p'_0(\alpha) &= \frac{\sin\zeta}{\sinh\left(\alpha+i\frac{\zeta}{2}\right)\sinh\left(\alpha-i\frac{\zeta}{2}\right)} \end{aligned} \qquad \text{for } -1<\Delta<1,\ \zeta = i\eta, \tag{58}$$

with $p'_{0_{\mathrm{tot}}}(\alpha) = \frac{1}{M}\sum_{i=1}^{M} p'_0\left(\alpha-\beta_k-i\frac{\zeta}{2}\right)$, where $\beta_k = \xi_k$. The integration limit $\Lambda$ is equal to $+\infty$ for $-1 < \Delta < 1$. The solution for the equation (57) in the homogeneous model where all parameters $\xi_k$ are equal to $\eta/2$, that is the density for the ground state of the Hamiltonian in the thermodynamic limit, is given by the following function [24]:

$$\rho(\alpha) = \frac{1}{2\zeta\cosh(\frac{\pi\alpha}{\zeta})}.$$

For technical convenience, we will also use the function

$$\rho_{\mathrm{tot}}(\alpha) = \frac{1}{M}\sum_{i=1}^{M}\rho\left(\alpha-\beta_k-i\frac{\zeta}{2}\right).$$

It will be also convenient to consider, without any loss of generality, that the inhomogeneity parameters are contained in the region $-\zeta < \mathrm{Im}\beta_j < 0$. Using these results, for any $\mathcal{C}^\infty$ function $f$ ($\pi$-periodic in the domain $\Delta > 1$), sums over all the values of $f$ at the point $\alpha_j$, $1 \le j \le N$, parameterizing the ground state, can be replaced in the thermodynamic limit by an integral:

$$\frac{1}{M}\sum_{j=1}^{N} f(\alpha_j) = \int_{-\Lambda}^{\Lambda} f(\alpha)\rho_{\mathrm{tot}}(\alpha)\,d\alpha + O(M^{-1}).$$

Thus, multiple sums obtained in correlation functions will become multiple integrals. Similarly, it is possible to evaluate the behavior of the determinant formulas for the scalar products and the norm of Bethe vectors (and in particular their ratios) in the limit $M \to \infty$.

**4.2. Elementary blocks.** From the representations as multiple sums of these elementary blocks in the finite chain we can obtain their multiple integral representations in the thermodynamic limit. Let us now consider separately the two regimes of the $XXZ$ model. In the massless regime $\eta = -i\zeta$ is imaginary, the ground state parameters $\lambda$ are real and the limit of integration is infinity $\Lambda = \infty$. In this case we consider the inhomogeneity parameters $\xi_j$ such that $0 > \mathrm{Im}(\xi_j) > -\zeta$. For the correlation functions in the thermodynamic limit one obtains the following result in this regime.

**Proposition 4.1.**

$$F_m(\{\epsilon_j, \epsilon'_j\}) = \prod_{k<l} \frac{\sinh\frac{\pi}{\zeta}(\xi_k - \xi_l)}{\sinh(\xi_k - \xi_l)} \prod_{j=1}^{s'} \int_{-\infty - i\zeta}^{\infty - i\zeta} \frac{d\lambda_j}{2i\zeta} \prod_{j=s'+1}^{m} \int_{-\infty}^{\infty} i\frac{d\lambda_j}{2\zeta}$$

$$\prod_{a=1}^{m}\prod_{k=1}^{m} \frac{1}{\sinh\frac{\pi}{\zeta}(\lambda_a - \xi_k)} \prod_{j\in\boldsymbol{\alpha}^-} \Big(\prod_{k=1}^{j-1} \sinh(\mu_j - \xi_k - i\zeta) \prod_{k=j+1}^{m} \sinh(\mu_j - \xi_k)\Big)$$

$$\prod_{j\in\boldsymbol{\alpha}^+} \Big(\prod_{k=1}^{j-1} \sinh(\mu'_j - \xi_k + i\zeta) \prod_{k=j+1}^{m} \sinh(\mu'_j - \xi_k)\Big) \prod_{a>b} \frac{\sinh\frac{\pi}{\zeta}(\lambda_a - \lambda_b)}{\sinh(\lambda_a - \lambda_b - i\zeta)},$$

*where the parameters of integration are ordered in the following way:* $\{\lambda_1, \ldots \lambda_m\} = \{\mu'_{j'_{\max}}, \ldots, \mu'_{j'_{\min}}, \mu_{j_{\min}}, \ldots, \mu_{j_{\max}}\}$.

The homogeneous limit ($\xi_j = -i\zeta/2$, for all $j$) of the correlation function $F_m(\{\epsilon_j, \epsilon'_j\})$ can then be taken in an obvious way. We have obtained similar representations for the massive regime, and also in the presence of a non-zero magnetic field [9]. For zero magnetic field, these results agree exactly with the ones obtained by Jimbo and Miwa in [35], using in particular $q$-KZ equations. It means that for zero magnetic field, the elementary blocks of correlation functions indeed satisfy $q$-KZ equations. Recently, more algebraic representations of solutions of the $q$-KZ equations have been obtained that correspond to the above correlation functions [37], [38]. From the finite chain representation for the two-point function it is also possible to obtain multiple integral representations for that case as well, in particular for their generating function [11], [13]. They correspond different huge re-summations and symmetrization of the corresponding elementary blocks, as in the finite chain situation [11]. Moreover, the case of time dependent correlation functions as also been obtained [15], [16]. Finally, let us note that at the free fermion point, all the results presented here lead, in a very elementary way, to already know results [12], [17], [19].

## 5. Exact and asymptotic results

**5.1. Exact results at $\Delta = 1/2$.** Up to now, two exact results have been obtained for the case of anisotropy $\Delta = 1/2$: the exact value of the emptiness formation probability for arbitrary distance $m$ [13] and the two point function of the third component of spin [18]. These two results follow from the above multiple integral representations for which, due to the determinant structure of the integrand, the corresponding multiple integrals can be separated and hence explicitly computed for this special value of the anisotropy.

**5.1.1. The emptiness formation probability.** This correlation function $\tau(m)$ (the probability to find in the ground state a ferromagnetic string of length $m$) is defined as the following expectation value:

$$\tau(m) = \langle \psi_g | \prod_{k=1}^{m} \frac{1-\sigma_k^z}{2} | \psi_g \rangle, \tag{59}$$

where $|\psi_g\rangle$ denotes the normalized ground state. In the thermodynamic limit ($M \to \infty$), this quantity can be expressed as a multiple integral with $m$ integrations [34], [35], [6], [8], [9].

**Proposition 5.1.** *For* $\Delta = \cos\zeta$, $0 < \zeta < \pi$, $\tau(m) = \lim_{\xi_1,\dots\xi_m \to -\frac{i\zeta}{2}} \tau(m, \{\xi_j\})$, *where*

$$\tau(m, \{\xi_j\}) = \frac{1}{m!} \int_{-\infty}^{\infty} \frac{Z_m(\{\lambda\}, \{\xi\})}{\prod_{a<b}^{m} \sinh(\xi_a - \xi_b)} \det_m \left( \frac{i}{2\zeta \sinh \frac{\pi}{\zeta}(\lambda_j - \xi_k)} \right) d^m\lambda, \tag{60}$$

$$Z_m(\{\lambda\}, \{\xi\}) = \prod_{a=1}^{m} \prod_{b=1}^{m} \frac{\sinh(\lambda_a - \xi_b)\sinh(\lambda_a - \xi_b - i\zeta)}{\sinh(\lambda_a - \lambda_b - i\zeta)} \cdot \frac{\det_m \left( \frac{-i\sin\zeta}{\sinh(\lambda_j - \xi_k)\sinh(\lambda_j - \xi_k - i\zeta)} \right)}{\prod_{a>b}^{m} \sinh(\xi_a - \xi_b)}. \tag{61}$$

The proof is given in [11]. Due to the determinant structure of the integrand, the integrals can be separated and computed for the special case $\Delta = \frac{1}{2}$ ($\zeta = \pi/3$):

**Proposition 5.2.** *Let* $\xi_k = \varepsilon_k - i\pi/6$ *and* $\varepsilon_{ab} = \varepsilon_a - \varepsilon_b$. *Then we obtain*

$$\tau(m, \{\varepsilon_j\}) = \frac{(-1)^{\frac{m^2-m}{2}}}{2^{m^2}} \prod_{a>b}^{m} \frac{\sinh 3\varepsilon_{ba}}{\sinh \varepsilon_{ba}} \prod_{\substack{a,b=1 \\ a\neq b}}^{m} \frac{1}{\sinh \varepsilon_{ab}} \cdot \det_m \left( \frac{3\sinh \frac{\varepsilon_{jk}}{2}}{\sinh \frac{3\varepsilon_{jk}}{2}} \right) \tag{62}$$

*and*

$$\tau(m) = \left(\frac{1}{2}\right)^{m^2} \prod_{k=0}^{m-1} \frac{(3k+1)!}{(m+k)!}. \tag{63}$$

Observe that the quantity $A_m = \prod_{k=0}^{m-1}(3k+1)!/(m+k)!$ is the number of alternating sign matrices of size $m$. This result was conjectured in [45].

**5.1.2. The two point function of $\sigma^z$.** The two point functions can be obtained, as in the finite chain situation, from a generating function $\langle Q_\kappa(m)\rangle$; in the thermodynamic limit, we use the following multiple integral representation [18]:

$$\begin{aligned}\langle Q_\kappa(m)\rangle = \sum_{n=0}^{m} \frac{\kappa^{m-n}}{n!(m-n)!} \oint_{\Gamma\{-i\zeta/2\}} \frac{d^m z}{(2\pi i)^m} \int_{\mathbb{R}-i\zeta} d^n\lambda \int_{\mathbb{R}} d^{m-n}\lambda \cdot \prod_{j=1}^{m} \frac{\varphi^m(z_j)}{\varphi^m(\lambda_j)} \\ \times \prod_{j=1}^{n} \left\{ t(z_j,\lambda_j) \prod_{k=1}^{m} \frac{\sinh(z_j-\lambda_k-i\zeta)}{\sinh(z_j-z_k-i\zeta)} \right\} \\ \times \prod_{j=n+1}^{m} \left\{ t(\lambda_j,z_j) \prod_{k=1}^{m} \frac{\sinh(\lambda_k-z_j-i\zeta)}{\sinh(z_k-z_j-i\zeta)} \right\} \\ \times \prod_{j=1}^{m}\prod_{k=1}^{m} \frac{\sinh(\lambda_k-z_j-i\zeta)}{\sinh(\lambda_k-\lambda_j-i\zeta)} \cdot \det_m \left( \frac{i}{2\zeta \sinh\frac{\pi}{\zeta}(\lambda-z)} \right).\end{aligned} \tag{64}$$

Here,

$$\Delta = \cos\zeta, \quad t(z,\lambda) = \frac{-i\sin\zeta}{\sinh(z-\lambda)\sinh(z-\lambda-i\zeta)}, \quad \varphi(z) = \frac{\sinh(z-i\frac{\zeta}{2})}{\sinh(z+i\frac{\zeta}{2})}, \tag{65}$$

and the integrals over the variables $z_j$ are taken with respect to a closed contour $\Gamma$ which surrounds the point $-i\zeta/2$ and does not contain any other singularities of the integrand. The equation (64) is valid for the homogeneous $XXZ$ chain with arbitrary $-1 < \Delta < 1$. If we consider the inhomogeneous $XXZ$ model with inhomogeneities $\xi_1, \ldots, \xi_m$, then one should replace in the representation (64) the function $\varphi^m$ in the following way:

$$\varphi^m(z) \to \prod_{b=1}^{m} \frac{\sinh(z-\xi_b-i\zeta)}{\sinh(z-\xi_b)}, \quad \varphi^{-m}(\lambda) \to \prod_{b=1}^{m} \frac{\sinh(\lambda-\xi_b)}{\sinh(\lambda-\xi_b-i\zeta)}. \tag{66}$$

In order to come back to the homogeneous case, one should set $\xi_k = -i\zeta/2$, $k = 1, \ldots, m$ in (66). In the inhomogeneous model, the integration contour $\Gamma$ surrounds the points $\xi_1, \ldots, \xi_m$, and the integrals over $z_j$ are therefore equal to the sum of the residues of the integrand in these simple poles. It turns out that again for the special case $\Delta = \frac{1}{2}$ integrals can be separated and computed to give:

**Proposition 5.3.**

$$\langle Q_\kappa(m)\rangle = \frac{3^m}{2^{m^2}} \prod_{a>b}^{m} \frac{\sinh 3(\xi_a-\xi_b)}{\sinh^3(\xi_a-\xi_b)} \sum_{n=0}^{m} \kappa^{m-n} \sum_{\substack{\{\xi\}=\{\xi_{\gamma_+}\}\cup\{\xi_{\gamma_-}\}\\ |\gamma_+|=n}} \det_m \hat{\Phi}^{(n)}$$

$$\times \prod_{a\in\gamma_+}\prod_{b\in\gamma_-} \frac{\sinh(\xi_b-\xi_a-\frac{i\pi}{3})\sinh(\xi_a-\xi_b)}{\sinh^2(\xi_b-\xi_a+\frac{i\pi}{3})},$$

$$\hat{\Phi}^{(n)}(\{\xi_{\gamma_+}\},\{\xi_{\gamma_-}\}) = \left(\begin{array}{c|c} \Phi(\xi_j-\xi_k) & \Phi(\xi_j-\xi_k-\frac{i\pi}{3}) \\ \hline \Phi(\xi_j-\xi_k+\frac{i\pi}{3}) & \Phi(\xi_j-\xi_k) \end{array}\right),$$

$$\Phi(x) = \frac{\sinh\frac{x}{2}}{\sinh\frac{3x}{2}}.$$

*Here the sum is taken with respect to all partitions of the set $\{\xi\}$ into two disjoint subsets $\{\xi_{\gamma_+}\}\cup\{\xi_{\gamma_-}\}$ of cardinality $n$ and $m-n$ respectively. The first $n$ lines and columns of the matrix $\hat{\Phi}^{(n)}$ are associated with the parameters $\xi\in\{\xi_{\gamma_+}\}$. The remaining lines and columns are associated with $\xi\in\{\xi_{\gamma_-}\}$.*

Thus, we have obtained an explicit answer for the generating function $\langle Q_\kappa(m)\rangle$ of the inhomogeneous $XXZ$ model. It is also possible to check that the above sum over partitions remains indeed finite in the homogeneous limit $\xi_k\to 0$.

**5.2. Asymptotic results.** An important issue is the analysis of the multiple integral representations of correlation functions for large distances. There it means analyzing asymptotic behavior of $m$-fold integrals for $m$ large. An interesting example to study in this respect is provided by the emptiness formation probability. This correlation function reduces to a single elementary block. Moreover, we already described its exact value for an anisotropy $\Delta=\frac{1}{2}$ in the previous section. In fact, it is possible to obtain the asymptotic behavior of $\tau(m)$ using the saddle-point method for arbitrary values of the anisotropy $\Delta>-1$ . This was performed for the first time in [12] in the case of free fermions ($\Delta=0$), but it can be applied to the general case as well. We present here the results in the massless and massive regimes [14], [19].

To apply the saddle-point method to the emptiness formation probability, it is convenient to express its integral representation in the following form:

$$\tau(m) = \int_{\mathcal{D}} d^m\lambda\; G_m(\{\lambda\})\; e^{m^2 S_m(\{\lambda\})}, \tag{67}$$

with

$$\begin{aligned} S_m(\{\lambda\}) = &-\frac{1}{m^2}\sum_{a>b}^{m}\log[\sinh(\lambda_a-\lambda_b+\eta)\ \sinh(\lambda_a-\lambda_b-\eta)] \\ &+\frac{1}{m}\sum_{a=1}^{m}\log[\sinh(\lambda_a+\eta/2)\ \sinh(\lambda_a-\eta/2)] \\ &+\frac{1}{m^2}\lim_{\xi_1\ldots\xi_m\to\eta/2}\log\Big[\Big(\frac{-2i\pi}{\sinh\eta}\Big)^m\frac{\big(\det\rho(\lambda_j,\xi_k)\big)^2}{\prod\limits_{a\neq b}\sinh(\xi_a-\xi_b)}\Big] \end{aligned} \tag{68}$$

and

$$G_m(\{\lambda\}) = \lim_{\xi_1\ldots\xi_m\to\eta/2}\frac{\det_m\left[\frac{i}{2\pi}t(\lambda_j,\xi_k)\right]}{\det_m\rho(\lambda_j,\xi_k)}. \tag{69}$$

In (67), the integration domain $\mathcal{D}$ is such that the variables of integration $\lambda_1,\ldots,\lambda_m$ are ordered in the interval $\mathcal{C}=[-\Lambda_h,\Lambda_h]$ (i.e. $-\Lambda_h<\lambda_1<\cdots<\lambda_m<\Lambda_h$ in the massless case, and $-i\Lambda_h<i\lambda_1<\cdots<i\lambda_m<i\Lambda_h$ in the massive case).

The main problem in the saddle point analysis is that, a priori, we do not know any asymptotic equivalent of the quantity $G_m(\lambda)$ when $m\to\infty$. Nevertheless, in the case of zero magnetic field, it is still possible to compute the asymptotic behavior of (67) in the leading order, provided we make the following hypothesis: we assume that the integrand of (67) admits a maximum for a certain value $\lambda'_1,\ldots,\lambda'_m$ of the integration variables $\lambda_1,\ldots,\lambda_m$ such that, for large $m$, the distribution of these parameters $\lambda'_1,\ldots,\lambda'_m$ can be described by a density function $\rho_s(\lambda')$ of the form

$$\rho_s(\lambda'_j)=\lim_{m\to\infty}\frac{1}{m(\lambda'_{j+1}-\lambda'_j)} \tag{70}$$

on the symmetric interval $[-\Lambda,\Lambda]$, and that, at the leading order in $m$, we can replace the sums over the set of parameters $\{\lambda'\}$ by integrals weighted with the density $\rho_s(\lambda')$.

First, it is easy to determine the maximum of the function $S_m(\{\lambda\})$. Indeed, let $\{\tilde{\lambda}\}$ be solution of the system

$$\partial_{\lambda_j}S_m(\{\tilde{\lambda}\})=0,\quad 1\le j\le m. \tag{71}$$

In the limit $m\to\infty$, if we suppose again that the parameters $\tilde{\lambda}_1,\ldots,\tilde{\lambda}_m$ become distributed according to a certain density $\tilde{\rho}_s(\lambda)$ and that sums over the $\tilde{\lambda}_j$ become integrals over this density, the system (71) turns again into a single integral equation for $\tilde{\rho}_s$, that can be solved explicitly in the case of zero magnetic field. It gives the maximum of $S_m(\{\lambda\})$ when $m\to\infty$[2].

[2]At this main order in $m$, there exists a unique solution of the integral equation for $\tilde{\rho}_s$, and we know it corresponds to a maximum because $S_m(\{\lambda\})\to-\infty$ on the boundary of $\mathcal{D}$.

The second step is to show that the factor $G_m(\{\lambda\})$ gives always a negligible contribution compared to $S_m(\{\tilde{\lambda}\})$ at this order in $m$, at least for any distribution of the variables $\lambda_j$ satisfying the previous hypothesis of regularity. We obtain

$$\lim_{m\to\infty} \frac{1}{m^2} \log G_m(\{\lambda\}) = 0 \tag{72}$$

for any distribution of $\{\lambda\}$ with good properties of regularity, in particular for the saddle point. This means that, at the main order in $m$, the factor $G_m(\{\lambda\})$ does not contribute to the value of the maximum of the integrand.

Finally we obtain the following result concerning the asymptotic behaviour of $\tau(m)$ for $m \to \infty$ (see [14], [19]):

$$S^{(0)}(\Delta) = \lim_{m\to\infty} \frac{\log \tau(m)}{m^2}, \tag{73}$$

$$= -\frac{\zeta}{2} - \sum_{n=1}^{\infty} \frac{e^{-n\zeta}}{n} \frac{\sinh(n\zeta)}{\cosh(2n\zeta)}, \qquad (\Delta = \cosh\zeta > 1), \tag{74}$$

$$= \log\frac{\pi}{\zeta} + \frac{1}{2} \int_{\mathbb{R}-i0} \frac{d\omega}{\omega} \frac{\sinh\frac{\omega}{2}(\pi-\zeta)\cosh^2\frac{\omega\zeta}{2}}{\sinh\frac{\pi\omega}{2}\sinh\frac{\omega\zeta}{2}\cosh\omega\zeta}, \quad (-1 < \Delta = \cos\zeta < 1). \tag{75}$$

It coincides with the exact known results obtained in [46], [12] at the free fermion point and in [45], [13] at $\Delta = 1/2$, and is in agreement with the expected (infinite) value in the Ising limit. Similar techniques can be applied to the two point function. However, the result that has been extracted so far is only the absence of the gaussian term. Unfortunately, we do not know up to now how to extract the expected power law corrections to the gaussian behavior from this saddle point analysis. More powerful methods will certainly be needed to go further.

## Conclusion and perspectives

In this article, we have reviewed recent results concerning the computation of correlation functions in the $XXZ$ chain by the methods of the inverse scattering problem and the algebraic Bethe ansatz. In conclusion, we would like to discuss some perspectives and problems to be solved.

One of the most interesting open problems is to prove the conformal field theory predictions [47], [48], [49], [50] concerning the asymptotic behavior of the correlation functions. This is certainly a very important issue not only for physical applications but also from a theoretical view point. Moreover, it also would open the route towards the generalization of the methods presented here to quantum integrable models of field theory. We have seen that in particular cases, the multiple integral representations

enable for a preliminary asymptotic analysis. Nevertheless, this problem remains one of the main challenges in the topics that have been described in this article.

A possible way to solve this problem would be to find the thermodynamic limit of the master equations (like the one obtained for the two point correlation functions). It is natural to expect that, in this limit, one should obtain a representation for these correlation functions in terms of a functional integral, which could eventually be estimated for large time and distance.

Note that the master equation shows a direct analytic relation between the multiple integral representations and the form factor expansions for the correlation functions. It seems likely that similar representations exist for other models solvable by algebraic Bethe ansatz. It would be in particular very interesting to obtain an analogue of this master equation in the case of the field theory models, which could provide an analytic link between short distance and long distance expansions of their correlation functions.

# Gromov–Witten invariants and topological strings: a progress report

Marcos Mariño*

**Abstract.** In this talk I summarize recent progress in the theory of Gromov–Witten invariants from topological string theory and string dualities. On the one hand, large $N$ dualities have led to the theory of the topological vertex, which solves Gromov–Witten theory to all genera on toric, noncompact Calabi–Yau threefolds. On the other hand, heterotic/type II duality and the holomorphic anomaly equations can be used to analyze Gromov–Witten theory in some simple compact examples. I sketch the physical ideas behind these results and connect the results obtained in physics with the results obtained in algebraic geometry.

**Mathematics Subject Classification (2000).** Primary 00A05; Secondary 00B10.

**Keywords.** String theory, Gromov–Witten invariants.

## 1. Introduction

The theory of Gromov–Witten invariants was largely motivated by the study of string theory on Calabi–Yau manifolds, and has now developed into one of the most dynamic fields of algebraic geometry. During the last years there has been enormous progress in the development of the theory and of its computational techniques. Roughly speaking, and restricting ourselves to Calabi–Yau threefolds, we have the following mathematical approaches to the computation of Gromov–Witten invariants:

1. *Localization*. This was first proposed by Kontsevich, and requires torus actions in the Calabi–Yau in order to work. Localization provides *a priori* a complete solution of the theory on toric (hence non-compact) Calabi–Yau manifolds, and reduces the computation of Gromov–Witten invariants to the calculation of Hodge integrals in Deligne–Mumford moduli space. Localization techniques make also possible to solve the theory at genus zero on a wide class of compact manifolds, see [8], [14] for a review.

2. *Deformation and topological approach*. This has been developed more recently and relies on *relative* Gromov–Witten invariants [11], [24]. It provides a cut-and-paste approach to the calculation of the invariants and seems to be the most

*I am grateful to M. Aganagic, A. Klemm and C. Vafa for collaboration on the work reported here. I would also like to thank D. Maulik, G. Moore and R. Pandharipande for discussions.

Proceedings of the International Congress of Mathematicians, Madrid, Spain, 2006

powerful approach to higher genus Gromov–Witten invariants in the compact case.

3. *D-brane moduli spaces*. Gromov–Witten invariants can be reformulated in terms of the so-called Gopakumar–Vafa invariants (see [14], [21] for a summary of these). Heuristic techniques to compute these have been developed in [16], as Euler characteristics of moduli space of embedded surfaces, and one can recover to a large extent the original information of Gromov–Witten theory. The equivalence between these two invariants remains however conjectural, and a general, rigorous definition of the Gopakumar–Vafa invariants in terms of appropriate moduli spaces is still not known.

4. *Equivalence to Donaldson–Thomas invariants*. In [23] it was proposed that Gromov–Witten invariants are equivalent to Donaldson–Thomas invariants, which are associated to moduli spaces of sheaves. This equivalence remains largely conjectural and so far it has led to little computational progress, although it is currently an area of active research.

Gromov–Witten invariants are closely related to string theory. It turns out that type IIA theory on a Calabi–Yau manifold $X$ leads to a four-dimensional supersymmetric theory whose Lagrangian contains moduli-dependent couplings $F_g(t)$, where $t$ denotes the Kähler moduli of the Calabi–Yau. When these couplings are expanded in the large radius limit, they are of the form

$$F_g(t) = \sum_{Q \in H_2(X)} N_{g,Q}\, \mathrm{e}^{-Q\cdot t}, \tag{1}$$

where $N_{g,Q}$ are the Gromov–Witten invariants for the class $Q$ at genus $g$. It turns out that there is a simplified version of string theory, called topological string theory, which captures precisely the information contained in these couplings. Topological string theory comes in two versions, called the A and the B model (see [21], [14] for a review). Type A topological string theory is related to Gromov–Witten theory, and its free energy at genus $g$ is precisely given by (1). Type B topological string theory is related to the deformation theory of complex structures of the Calabi–Yau manifold. In the last years, various dualities of string theory have led to powerful techniques to compute these couplings, hence Gromov–Witten invariants:

1. *Mirror symmetry*. Mirror symmetry relates type A theory on a Calabi–Yau manifold $X$ to type B theory on the mirror manifold $\widetilde{X}$. When the mirror of the Calabi–Yau $X$ is known, this leads to a complete solution at genus zero in terms of variation of the complex structures of $\widetilde{X}$. For genus $g \geq 1$, mirror symmetry can be combined with the holomorphic anomaly equations of [5] to obtain $F_g(t)$. However, this does not provide the full solution to the model due to the so-called holomorphic ambiguity. On the other hand, mirror symmetry and the holomorphic anomaly equation are very general and work for both compact and non-compact Calabi–Yau manifolds.

2. *Large N dualities*. Large $N$ dualities lead to a computation of the $F_g(t)$ couplings in terms of correlation functions and partition functions in Chern–Simons theory. Although this was formulated originally only for the resolved conifold, one ends up with a general theory – the theory of the topological vertex, introduced in [2] – which leads to a complete solution on toric Calabi–Yau manifolds. The theory of the topological vertex is closely related to localization and to Hodge integrals, and it can be formulated in a rigorous mathematical way [19], [23].

3. *Heterotic duality*. When the Calabi–Yau manifold has the structure of a K3 fibration, type IIA theory often has a heterotic dual, and the evaluation of $F_g(t)$ restricted to the K3 fiber can be reduced to a one-loop integral in heterotic string theory [4], [22]. This leads to explicit, conjectural formulae for Gromov–Witten invariants in terms of modular forms.

In this progress report I will concentrate on two results: (1) I will summarize how large $N$ dualities lead to a complete solution of topological string theory on toric Calabi–Yau manifolds. (2) I will discuss what is probably the simplest, non-trivial compact Calabi–Yau manifold, the so-called Enriques Calabi–Yau manifold, which is very tractable both mathematically and physically, and might be the natural starting point to understand the compact case.

## 2. The toric case

In this section we give a rather brief summary of the results obtained in the context of topological string theory to compute Gromov–Witten invariants of toric geometries. This subject has been extensively reviewed in [20], [21], to which we refer for further information and/or references.

**2.1. The Gopakumar–Vafa duality.** The Gopakumar–Vafa duality [12] is an example of the string/gauge theory dualities which have been discovered in the last years. It relates a particular gauge theory – $U(N)$ Chern–Simons theory on the three-sphere with coupling $k$ – to a particular string theory – the type A topological string on the small resolution of the conifold singularity. This is a toric (hence non-compact) Calabi–Yau manifold which can be regarded as the total space of the bundle

$$\mathcal{O}(-1) \oplus \mathcal{O}(-1) \to \mathbb{P}^1. \tag{2}$$

It has a single Kähler parameter $t$ which gives the complexified area of the $\mathbb{P}^1$. The identification is such that the effective coupling constant of the gauge theory

$$g = \frac{2\pi \mathrm{i}}{k+N} \tag{3}$$

is identified to the string coupling constant $g_s$, while the 't Hooft parameter $gN$ is identified with the Kähler parameter $t$:

$$t = \frac{2\pi \mathrm{i} N}{k+N}. \tag{4}$$

In particular, the duality asserts that the free energy of Chern–Simons theory on $\mathbb{S}^3$ equals the total free energy of the topological string, which is defined by summing the topological string amplitudes to all genera,

$$F = \sum_{g=0}^{\infty} F_g(t) g_s^{2g-2}, \tag{5}$$

This can be checked explicitly since both quantities are known. The free energies $F_g(t)$ of topological string theory on the resolved conifold have been computed in various ways (see for example [7]), and the free energy of Chern–Simons theory on the sphere was computed by Witten and is given by

$$F = \log Z = \log\ S_{00}, \tag{6}$$

where

$$S_{00} = \prod_{j=1}^{N} \left( 2 \sin \frac{2\pi \mathrm{i} j}{k+N} \right)^{N-j} \tag{7}$$

is obtained from the theory of affine Lie algebras.

The duality of Gopakumar and Vafa gives some important information on Gromov–Witten theory, but it only deals with one particular Calabi–Yau manifold: the resolved conifold. From the point of view of topological string theory it would be extremely useful to have generalizations of the duality which cover other situations, and express the amplitude $F_g(t)$ in terms of gauge theoretic quantities. It turns out that this can be done in two different ways, which I consider in the next two subsections.

**2.2. Extensions to other geometries.** The first possibility to generalize the Gopakumar–Vafa duality consists on taking Chern–Simons theory on more general three-manifolds and search for Calabi–Yau duals. One obvious way to achieve this is to do a quotient of both sides of the duality by $\mathbb{Z}_p$ symmetry. On the gauge theory side one obtains Chern–Simons theory on the lens space $L(p, 1)$. The quotient of the resolved conifold leads to a toric geometry, the $A_{p-1}$ fibration over $\mathbb{P}^1$, which has $p$ Kähler parameters. For example, for $p = 2$ this leads to a duality between Chern–Simons theory on $\mathbb{RP}^3$ and topological string theory on the Calabi–Yau manifold given by the anticanonical bundle of $\mathbb{P}^1 \times \mathbb{P}^1$.

This generalization of the Gopakumar–Vafa duality was proposed in [1], where it was tested in detail for $p = 2$. One interesting aspect of it is that one has to consider

the Chern–Simons theory around an arbitrary reducible flat connection which breaks the gauge group

$$U(N) \to \prod_{i=1}^{p} U(N_i). \tag{8}$$

The $p$ Kähler parameters of the Calabi–Yau manifold, $t_i$, are identified with the partial 't Hooft parameters of the Chern–Simons theory with broken gauge symmetry:

$$t_i = g_s N_i, \quad i = 1, \cdots, p. \tag{9}$$

Unfortunately, it is not known if there are further generalizations of these results. However, it seems natural to state the following

**Conjecture 2.1.** Given a rational homology sphere $M$, there exists a Calabi–Yau manifold $X_M$ such that the free energy of Chern–Simons theory on $M$, expanded around a generic reducible flat connection, equals the total free energy of topological string theory on $X_M$.

**2.3. The cut-and-paste approach: the topological vertex.** The basic idea of the topological vertex is to regard a generic toric geometry as made out of pieces where one can use the duality of Gopakumar and Vafa between the resolved conifold and Chern–Simons theory. A first approach is then to cut the manifold into pieces that are locally like resolved conifolds, to associate a topological string amplitude to each of the pieces, and then to glue the results together. This program was developed in [3], [9]. It turns out that there is a natural way to cut the original manifold into pieces, and this is by introducing D-branes around Lagrangian submanifolds. The amplitude associated to each of the pieces is then, due to the presence of D-branes, an *open* topological string amplitude. Fortunately, the duality of Gopakumar and Vafa also holds in the open setting [26], and the open amplitudes are closely related to *Chern–Simons invariants of knots and links* in $\mathbb{S}^3$. One then finds a surprising relation between these invariants and Gromov–Witten invariants of toric Calabi–Yau threefolds.

This procedure was refined and generalized in [2]. In the approach of [3], [9], one has to divide the geometry into pieces which are like the resolved conifold, which in terms of toric diagrams can be regarded as a four-valent graph. However, the basic building block is in fact a *trivalent* vertex that corresponds to $\mathbb{C}^3$ with three sets of D-branes wrapping Lagrangian submanifolds. The open topological string amplitude associated to this graph is called the topological vertex, and it is denoted by

$$C_{R_1 R_2 R_3}, \tag{10}$$

where $R_i$ are representations of $U(\infty)$ (or, equivalently, Young tableaux) which correspond roughly to the Chan–Paton factors associated to the open strings ending on the branes. The topological vertex depends only on the string coupling $g_s$, and from

its power series expansion in $g_s$ one can extract open Gromov–Witten invariants of $\mathbb{C}^3$ with specified Lagrangian boundary conditions. These invariants do not have a rigorous mathematical definition, but they can be re-interpreted as *relative* Gromov–Witten invariants and computed by localization [19]. As shown in [2], one can use a subtle variant of the Gopakumar–Vafa duality to obtain an explicit expression for the topological vertex in terms of known quantum group invariants for arbitrary representations $R_i$. The final result is

$$C_{R_1R_2R_3} = q^{\frac{\kappa_{R_2}+\kappa_{R_3}}{2}} \sum_{Q_1,Q_3,Q} N_{QQ_1}^{R_1} N_{QQ_3}^{R_3^t} \frac{W_{R_2^tQ_1} W_{R_2Q_3}}{W_{R_2}}. \tag{11}$$

In this equation, $N_{R_1R_2}^R$ are Littlewood–Richardson coefficients, and $R^t$ denotes the transpose of the representation $R$. $\kappa_R$ is related to the second Casimir of $R$ as a representation of $U(N)$ and can be written as

$$\kappa_R = \ell(R) + \sum_i l_i^R (l_i^R - 2i), \tag{12}$$

where $\ell(R)$ is the number of boxes in the Young tableau of $R$ and $l_i^R$ is the number of boxes in the $i$-th row of $R$. Finally, $W_{R_1R_2}$ are related to quantum group invariants of the Hopf link and can be written in terms of Schur polynomials as

$$W_{R_1R_2}(q) = s_{R_2}\big(x_i = q^{-i+\frac{1}{2}}\big) s_{R_1}\big(x_i = q^{l_i^{R_2}-i+\frac{1}{2}}\big), \tag{13}$$

where $q = \mathrm{e}^{g_s}$.

In [2] it is shown on a physical basis that the all genus Gromov–Witten invariants of any toric Calabi–Yau manifold can be computed from (11) and some simple gluing rules. Essentially, one takes the toric diagram of the Calabi–Yau and decomposes it into trivalent vertices. To each of these vertices one assigns the amplitude (11), and then one glues them together according to simple instructions encoded in the diagram. The result is the partition function $Z = \exp F$, where $F$ is the free energy (5). One simple example is the so-called local $\mathbb{P}^2$ manifold, namely the total space of the bundle $\mathcal{O}(-3) \to \mathbb{P}^2$. The rules of [2] give

$$Z_{\mathbb{P}^2} = \sum_{R_1,R_2,R_3} (-1)^{\sum_i \ell(R_i)} e^{-\sum_i \ell(R_i)t} q^{-\sum_i \kappa_{R_i}} C_{0R_2^tR_3} C_{0R_1^tR_2} C_{0R_3^tR_1}. \tag{14}$$

The theory of the topological vertex developed in [2] and largely based on the ideas of string/gauge theory duality has been re-derived to a large extent on a rigorous mathematical basis in [19], by using relative Gromov–Witten invariants. This theory gives a full solution of topological string theory in the toric case. Let us now consider the compact case.

## 3. The compact case

**3.1. Heterotic duality.** As we already explained in the introduction, the main tool to compute Gromov–Witten invariants in the compact case is the combination of mirror symmetry and the holomorphic anomaly equation of [5]. This approach is very general, but it does not give a complete solution to the problem of computing the topological string amplitudes due to the holomorphic ambiguity. It turns out that if the Calabi–Yau manifold has the structure of a K3 fibration over $\mathbb{P}^1$, one can do better. The reason is that type IIA theory on such manifolds has a heterotic dual [15], and for Kähler classes in the K3 fiber, one can compute the $F_g(t)$ couplings by doing a one-loop computation in the heterotic string. This leads to close expressions for the topological string amplitudes in terms of modular forms [13], [22].

Let us consider for example the STU model first studied in [15]. This is a K3 fibration where the K3 fiber has two complexified Kähler parameters, $t = (t^+, t^-)$ with $\operatorname{Re} t^\pm > 0$. The Kähler classes are labelled by two integers $r = (n, m)$. These classes form a lattice $\Gamma^{1,1}$ with intersection form

$$H = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}, \tag{15}$$

which defines an inner product such that $r \cdot t = mt^+ + nt^-$ and $r^2 = 2nm$. An involved heterotic computation [22] leads to a topological string coupling $F_g(t)$ of the form

$$F_g(t) = \sum_{r>0} c_g(r^2/2)\mathrm{Li}_{3-2g}(\mathrm{e}^{-r\cdot t}). \tag{16}$$

In this formula, $r > 0$ means the following possibilities: $(n, m) = (1, -1)$, $n > 0$, $m > 0$, $n = 0$, $m > 0$, or $n > 0$. The coefficients $c(n)$ are defined by

$$\sum_n c_g(n)q^n = -\frac{2E_4(q)E_6(q)}{\eta^{24}(q)}\mathcal{P}_g(q), \tag{17}$$

where $E_4$, $E_6$ are Eisenstein series, $\eta$ is the Dedekind eta function, and the polynomials $\mathcal{P}_g(q)$ are given by

$$\left(\frac{2\pi\eta^3\lambda}{\vartheta_1(\lambda|\tau)}\right)^2 = \sum_{g=0}^{\infty}(2\pi\lambda)^{2g}\mathcal{P}_g(q), \tag{18}$$

and can be written as polynomials in the Eisenstein series $E_2$, $E_4$ and $E_6$ (see [22], [18] for more details on the modular forms involved).

Other examples of heterotic computations of topological string amplitudes can be found in [17], which also tested the predictions by using the holomorphic anomaly equations and extended them up to genus two by including the "missing" Kähler parameter on the base of the fibration.

**3.2. A very special example: the Enriques Calabi–Yau.** Although many techniques have been developed in order to compute topological string amplitudes in the compact case, typically the theory becomes intractable at high genus and/or degree. In this sense, it would be important to identify *the* compact CY manifold where topological string theory is most tractable.

There is a compact example where topological string theory is exactly solvable, namely $\mathrm{K3}\times\mathbb{T}^2$. The topological string amplitudes are however rather trivial in this case, and in particular they vanish for $g \geq 2$. Hence this example is too simple, and this is due to the extended $\mathcal{N} = 4$ supersymmetry of the corresponding type II theory, related in turn to the SU(2) holonomy. It is then natural to consider Calabi–Yau manifolds with holonomy $H$ which is intermediate between the SU(2) and the generic one SU(3). A Calabi–Yau manifold with intermediate holonomy $\mathrm{SU}(2)\times\mathbb{Z}_2$ has been constructed in [6], [27], [10] as an orbifold w.r.t. a free $\mathbb{Z}_2$ involution of $\mathrm{K3}\times\mathbb{T}^2$. The resulting space exhibits a K3 fibration with four fibers of multiplicity two over the four fixed points of the involution in the base. These fibers are Enriques surfaces. A good deal of the nontrivial geometry of this CY comes from the geometry of the Enriques fibers, and therefore this example has been called the *Enriques CY manifold*. The string model obtained by compactifying type II theory on the Enriques CY has $\mathcal{N} = 2$ supersymmetry and is known as the FHSV model. The Enriques CY seems to be the simplest CY compactification with nontrivial topological string amplitudes. Moreover it has a dual description as an asymmetric orbifold of the heterotic string [10].

A first step in order to determine the topological string amplitudes is then to compute the amplitudes on the fiber, by using the heterotic dual and techniques similar to those of [22]. In order to write down the result, we notice that the Enriques fiber has ten Kähler parameters $t = (t^+, t^-, \vec{t}\,)$. The Kähler classes belong to the cone $\Gamma_E = \Gamma^{1,1} \oplus E_8(-1)$, and will be parametrized by a vector of integer numbers $r = (n, m, \vec{q}\,)$. The topological string amplitudes on the Kähler cone are given by

$$F_g^E(t) = \sum_{r>0} c_g(r^2)\left\{2^{3-2g}\mathrm{Li}_{3-2g}(e^{-r\cdot t}) - \mathrm{Li}_{3-2g}(e^{-2r\cdot t})\right\}, \tag{19}$$

where

$$\sum_n c_g(n)q^n = -\frac{2}{q}\prod_{n=1}^{\infty}(1-q^{2n})^{-12}\mathcal{P}_g(q), \tag{20}$$

and $r^2 = 2mn - \vec{q}^{\,2}$. The restriction $r > 0$ means now that $n > 0$, or $n = 0, m > 0$, or $n = m = 0, \vec{q} > 0$. The superscript $E$ refers to the Enriques fiber.

The Enriques Calabi–Yau manifold has an extra Kähler class corresponding to the $\mathbb{P}^1$ in the base of the fibration. The perturbative heterotic string theory does not give information on the dependence of $F_g(t)$ on this parameter, and the only available technique to do that for the moment being is the holomorphic anomaly equation. It turns out, however, that the Enriques Calabi–Yau is particularly simple in that respect, and one can solve the holomorphic anomaly equation at low genera. In this way one

finds explicit expressions for $F_1$ and $F_2$ on the *total* Calabi–Yau. If we denote by $S$ the Kähler parameter of the base, one finds

$$\begin{aligned} F_1(t, S) &= F_1^E(t) - 12 \log\, \eta(q_S), \\ F_2(t, S) &= E_2(q_S) F_2^E(t), \end{aligned} \tag{21}$$

where $q_S = \mathrm{e}^{-S}$. Notice that, as $S \to \infty$, one recovers the results in the fiber. These results are surprisingly simple, and they have been verified in [25] by using the topological techniques in Gromov–Witten theory. This is the only compact manifold where the topological string amplitudes have been computed up to genus two *both* in the context of topological string theory and in the context of algebraic geometry. It seems to be the most accessible compact example and it provides a fruitful interaction between physical and mathematical techniques. Results for genus 3 and 4 including the Kähler parameter of the base have also been obtained in [18]. One important remaining question is: is the Enriques Calabi–Yau an exactly solvable example?

## 4. Conclusions

One obvious and general conclusion is that the interaction between topological string theory and Gromov–Witten theory and algebraic geometry has been extremely rich and rewarding for both fields. String dualities have led to the solution of many models and to sometimes surprising mathematical predictions, while rigorous mathematical techniques have confirmed many of the physical ideas underlying the predictions. This interplay has led so far to a rather complete solution of the problem in the toric case. Progress in the compact case has been also significant, although the problem seems to be much harder and we are lacking an effective strategy to address general models. For this reason, we have proposed in [18] to focus on relatively simple examples where the theory might have some simplifying features yet be rich enough to display the essential complexities of the problem. So far, the simplest nontrivial valley in the landscape of compact Calabi–Yau's seems to be the Enriques Calabi–Yau, which has been solved at low genera in [18], [25]. The main open problem is of course to find an organizing principle that makes possible to address the general compact case in an effective way.

# The Cauchy problem in General Relativity

Igor Rodnianski*

**Abstract.** The paper revisits some of the classical and recent results on the Cauchy problem in General Relativity. Special emphasis is put on the problems concerning existence of a Cauchy development, break-down criteria and stability. The author would like to make a disclaimer that despite its general title the paper is not intended as a comprehensible survey. Due to the space-time constraints many remarkable results and developments are either mentioned briefly or not discussed at all. Most notably this concerns various work on the Einstein equations with matter and symmetry reduced problems.

**Mathematics Subject Classification (2000).** Primary 83C05; Secondary 35L15.

**Keywords.** Einstein equations, existence, break-down, stability.

## 1. Introduction

A mathematical description of General Relativity consists of a $3+1$-dimensional Lorentzian manifold $M$ and a metric $g$ verifying the Einstein equations

$$R_{\alpha\beta}(g) - \frac{1}{2} g_{\alpha\beta} R(g) = 8\pi\, T_{\alpha\beta},$$

where $R_{\alpha\beta}$ and $R$ are respectively the Ricci tensor and scalar curvature of $g$ and $T_{\alpha\beta}$ is the energy-momentum tensor of matter. Among the most popular mathematical matter models are[1]

1. the vacuum equations, where $T \equiv 0$, and the Einstein equations simply require that $(M, g)$ is Ricci flat;
2. the Einstein-scalar field model, where $T_{\alpha\beta} = \partial_\alpha\phi\, \partial_\beta\phi - \frac{1}{2} g_{\alpha\beta}\, \partial^\mu\phi\, \partial_\mu\phi$ and $\phi$ is a real valued scalar field $\phi : M \to R$;
3. the Einstein–Maxwell equations, where $T_{\alpha\beta} = \frac{1}{4\pi}\left(F_\alpha^{\ \mu} F_{\beta\mu} - \frac{1}{4} g_{\alpha\beta} F_{\mu\nu} F^{\mu\nu}\right)$, and $F_{\alpha\beta}$ is the electromagnetic tensor;
4. perfect fluid matter model, where $T_{\alpha\beta} = (\rho + p) u_\alpha\, u_\beta + p\, g_{\alpha\beta}$, and $u^\alpha$ is the four-velocity vector, $p$ is the pressure and $\rho$ is the proper energy density of the fluid.

*The paper was written while the author was visiting the Department of Mathematics at MIT.

[1] In what follows we will use the standard conventions of raising and lowering tensorial indices with the help of the metric $g$ and summing over repeated indices.

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

The contracted Bianci identity $D^\alpha R_{\alpha\beta} = 2\partial_\beta R$ implies that the gravitational tensor $G_{\alpha\beta} = R_{\alpha\beta} - \frac{1}{2} g_{\alpha\beta} R$ is always divergence free, $D^\alpha G_{\alpha\beta} = 0$. As a consequence, evolution equations for the external fields in the models described above follow from the requirement that $D^\alpha T_{\alpha\beta} = 0$. In particular, in the scalar field model $\phi$ must satisfy the wave equation

$$\Box_g \phi = \frac{1}{\sqrt{|g|}} \partial_\alpha \big( g^{\alpha\beta} \sqrt{|g|} \partial_\beta \phi \big) = 0$$

on a curved background $(M, g)$. For the Einstein–Maxwell problem the electromagnetic field obeys the Maxwell equations

$$D^\alpha F_{\alpha\beta} = 0, \quad D_\mu F_{\alpha\beta} + D_\beta F_{\mu\alpha} + D_\alpha F_{\beta\mu} = 0.$$

Finally, for the perfect fluid model,

$$u^\alpha D_\alpha \rho + (\rho + P) D^\alpha u_\alpha = 0, \quad (P + \rho) u^\alpha D_\alpha u_\beta + (g_{\alpha\beta} + u_\alpha u_\beta) D^\alpha P = 0.$$

Mathematical problems in Classical General Relativity can be loosely divided into the following categories:

1. Construction of special solutions (e.g. Minkowski, Schwarzschild, Kerr, Friedman–Robertson–Walker).
2. Mathematics of constraint equations (e.g. construction of solutions, positive mass theorem, Riemannian Penrose inequality).
3. Causality and global properties (e.g. singularity theorems, black hole uniqueness, splitting theorems).
4. Cauchy problem (e.g. existence and uniqueness of solutions, break-down, stability).

The evolution (Cauchy) problem in General Relativity consists of constructing a spacetime $(M, g)$ with the property that for a given data set [2] $(\Sigma_0, g_0, k_0)$, a 3-dimensional Riemannian manifold $\Sigma_0$ with a Riemannian metric $g_0$ and a symmetric 2-tensor $k_0$, there exists an embedding $\Sigma_0 \subset M$ such that $g_0$ coincides with the restriction of $g$ to $\Sigma_0$ and $k_0$ is the second fundamental form of the embedding. Since physically one should not be able to distinguish between different coordinate systems, i.e., the Einstein equations are covariant, a solution of the Cauchy problem can be unique only modulo a diffeomorphism.

The equations are overdetermined and the initial data has to satisfy the constraint equations

$$R_0 - |k_0|^2 + (\operatorname{tr} k_0)^2 = 16\pi T_{00}, \quad \nabla^j k_{0ij} - \nabla_i \operatorname{tr} k_0 = 8\pi T_{0i}, \tag{1}$$

where $R_0$ is the scalar curvature of $g_0$ and $\nabla$ is its Levi-Civita covariant derivative.

[2] For simplicity we describe the Cauchy problem for the vacuum equations. In general, one also needs to add the data for the external fields on $\Sigma_0$.

A particular important class is the asymptotically flat initial data given by $(\Sigma_0, g_0, k_0)$ with the properties[3] that $\Sigma_0$ minus a compact set is diffeomorphic to $R^3$ minus a ball and that there exists a system of coordinates "near infinity" such that

$$g_{0ij} = \left(1 + \frac{M}{r}\right)\delta_{ij} + O(r^{-1-\alpha}), \quad k_{0ij} = O(r^{-2-\alpha})$$

for some $\alpha > 0$. In particular, Minkowski, Schwarzschild and Kerr solutions belong to this class.

## 2. Existence and uniqueness of a maximal Cauchy development

Existence of a maximal Cauchy development for any sufficiently smooth initial data was established by Choquet-Bruhat in [CB1]. The proof exploited the covariance of the Einstein equations and a special choice of gauge (harmonic coordinate system) in which the Einstein equation can be cast as a system of quasilinear wave equations for the metric components.

Harmonic coordinates $x^\alpha$, which appeared already in the work of A.Einstein, are determined by the conditions

$$\Box_g x^\alpha = 0, \quad \alpha = 0, \ldots, 3. \tag{2}$$

This, in turn, is equivalent to requiring that the components of the metric $g_{\alpha\beta}$ relative to this particular system of coordinates satisfy

$$\partial_\alpha\left(g^{\alpha\beta}\sqrt{|g|}\right) = 0. \tag{3}$$

The Einstein equations then reduce to

$$\Box_g g_{\alpha\beta} - N_{\alpha\beta}(g, \partial g) = T_{\alpha\beta}. \tag{4}$$

In harmonic coordinates, $\Box_g = g^{\mu\nu}\partial^2_{\mu\nu}$ and the nonlinear term $N_{\alpha\beta}(u, v)$ depends quadratically on the variable $v$. Equation (4) is obtained by expressing the Ricci tensor $R_{\alpha\beta}$ of $g$ in terms of the components of $g$ and its (first and second) derivatives. To verify that a solution of (4) gives an Einstein metric one also has to satisfy the condition (2) or (3). However, as was observed by Choquet-Bruhat, these conditions are satisfied automatically for solutions of (4) provided that they are satisfied initially on $\Sigma_0$ and $(\Sigma_0, g_0, k_0)$ obey the constraint equations (1). This fact is known as propagation of the harmonic gauge. Thus to complete the initial value problem set up in harmonic gauge we choose a local system of coordinates on $\Sigma_0$ in such a way that the harmonic coordinate condition is verified initially and express the initial values[4]

[3] The asymptotic flatness condition given here is more restrictive than necessary. In particular, it requires that $\Sigma_0$ has only one asymptotic end and that the linear momentum of initial data is equal to zero.

[4] We identify $t = x^0$ and assume that $\Sigma_0$ corresponds to $t = 0$.

for the components of the metric $g_{\mu\nu}|_{t=0}$ and their time derivatives $\partial_t g_{\mu\nu}|_{t=0}$ from the initial data $(g_0, k_0)$[5]. Restricting our analysis for simplicity to the case of the vacuum equations we obtain the following initial value problem

$$\begin{aligned} &\Box_g g_{\alpha\beta} = N_{\alpha\beta}(g, \partial g), \\ &g_{\alpha\beta}|_{t=0} = g^0_{\alpha\beta}, \quad \partial_t g_{\alpha\beta}|_{t=0} = g^1_{\alpha\beta}. \end{aligned} \tag{5}$$

The equations (5) constitute a system of quasilinear wave equations for the components $g_{\alpha\beta}$ on the background determined by the metric $g$. The problem (5) is then solved locally (using finite speed of propagation) on a small interval of time, the resulting metrics patched together to form a Cauchy development from given initial data. The above local solutions are constructed by iteration of the linear equations

$$\begin{aligned} &\Box_{g^n} g^{n+1}_{\alpha\beta} = N_{\alpha\beta}(g^n, \partial g^n), \\ &g^{n+1}_{\alpha\beta}|_{t=0} = g^0_{\alpha\beta}, \quad \partial_t g^{n+1}_{\alpha\beta}|_{t=0} = g^1_{\alpha\beta} \end{aligned} \tag{6}$$

with convergence guaranteed by estimates for (6) or alternatively a priori estimates for (5). The original approach of Choquet-Bruhat to (6) relied on the construction of a Kirchoff–Sobolev parametrix for an inhomogeneous scalar linear problem

$$\Box_g \phi = F, \quad \phi|_{t=0} = \phi^0, \quad \partial_t \phi|_{t=0} = \phi^1$$

but the method imposed high differentiability requirement on the initial data for (5). This was refined in the work of Dionne [Di], Fisher–Marsden [F-M] and Hughes–Kato–Marsden [H-K-M] via the energy method. The energy method, in which the equation (5) is multiplied by $\partial_t g$ and integrated by parts or differentiated required number of times, multiplied by the time derivative of the differentiated solution and then integrated by parts, applied to the problem (5) shows that the Sobolev norm $H^s$ of the solution $g(t)$ at time $t$ is controlled

$$\|g(t)\|_{H^s} + \|\partial_t g(t)\|_{H^{s-1}} \leq C \exp\left(\int_0^t \|\partial g(\tau)\|_{L^\infty} d\tau\right) \left(\|g^0\|_{H^s} + \|g^1\|_{H^{s-1}}\right).$$

The desired a priori estimate for (5) follows from the Sobolev embedding $H^s \subset L^\infty$ provided that $s > 5/2$. This analysis essentially establishes *well-posedness*[6] of the system (5) in the scale of Sobolev spaces $H^s$ for any $s > 5/2$.

An interesting phenomenon however occurs in passage from the system (5) to the original Einstein equations. The above construction leads to solutions $(M, g)$ arising from arbitrary $H^s$ initial data $(g_0, k_0) \in H^s \times H^{s-1}$, as long as $s > \frac{5}{2}$. These solutions remain in the space $H^s$ relative to a system of coordinates $(t, x)$ so that the metric components $g_{\alpha\beta} \in C([0, T]; H^s_x)$ and $\partial_t g_{\alpha\beta} \in C([0, T]; H^{s-1}_x)$ on a time interval $[0, T]$ with $T$ dependent on the $H^s \times H^{s-1}$ norm of the data. However,

[5] Similar procedure is applied to the initial values for the external fields.

[6] Existence, uniqueness and continuous dependence on the initial data.

to show that two solutions $(M, g)$ and $(M', g')$ arising from the same initial data $(\Sigma_0, g_0, k_0)$ are related by a diffeomorphism $\Phi : M \to M'$ so that $\Phi_* g' = g$, and thus geometrically and physically indistinguishable, actually requires one to consider data and thus solutions $(M, g)$ and $(M', g')$ from the Sobolev class $H^\sigma$ with $\sigma > 7/2$. This means that while uniqueness for (5) holds in the same class $H^s$ with $s > 5/2$ as the existence result, there is a potential loss of uniqueness for the Einstein equations unless more regular solutions are considered.

The existence result for the system (5) and consequently the (vacuum or scalar field) Einstein equations can be improved when the energy method is combined with the Strichartz estimates. This was first seen for scalar semilinear wave equations in [P-S],

$$\Box\phi = N(\phi, \partial\phi), \tag{7}$$

where the energy estimate

$$\|\partial\phi(t)\|_{H^s} \leq C \exp\left(\int_0^t \|\phi(\tau)\|_{L^\infty} d\tau\right) \left(\|\phi^0\|_{H^s} + \|\phi^1\|_{H^{s-1}}\right)$$

can be complemented by the Strichartz estimate

$$\|\partial\phi\|_{L^2_{[0,T]}L^\infty} \leq C\left(\|\phi^0\|_{H^s} + \|\phi^1\|_{H^{s-1}} + \|\Box\phi\|_{L^1_{[0,T]}H^{s-1}}\right), \tag{8}$$

which holds for any $s > 2$ and thus allows to establish the existence and uniqueness result for the equation (7) for solutions in the Sobolev space $H^s$ with $s > 2$.

In the case of general quasilinear wave equations of the form (5), however, the situation is far more difficult. One can no longer rely on the Strichartz inequality (8) for the flat D'Alembertian; we need instead its extension to the operator $\Box_g$,

$$\|\partial\phi\|_{L^2_{[0,T]}L^\infty} \leq C\left(\|\phi^0\|_{H^s} + \|\phi^1\|_{H^{s-1}} + \|\Box_g\phi\|_{L^1_{[0,T]}H^{s-1}}\right). \tag{9}$$

To be able to apply such an estimate to the problem (5) and improve upon the energy method one needs to establish (9) for some $s \leq 5/2$ and with a constant $C$ which itself depends on $g$ only through its $\|\partial g\|_{L^\infty_{[0,T]}H^{s-1}}$ and $\|\partial g\|_{L^2_{[0,T]}L^\infty}$ norms. This means that we have to confront the issue of proving Strichartz estimates for wave operators $\Box_g$ on a *rough* background $g$.

This issue was first addressed in the work of Smith [Sm], Bahouri–Chemin [B-C1], [B-C2] and Tataru [Ta1], [Ta2].

In [Sm] a precise analog of (8) was established for the wave operator $\Box_g$ under the assumption that the metric $g$ is at least $C^2$.

The results of Bahouri–Chemin and Tataru are based on establishing a Strichartz type inequality, *with a loss*, i.e. with $s > 2 + \sigma$, and are compatible with applications to the problem (5). The optimal result[7] in this regard, due to Tataru, see [Ta2], requires

[7] Recently Smith-Tataru [S-T1] have shown that the result of Tataru is indeed sharp.

a loss of $\sigma = \frac{1}{6}$. This led to a proof of local well posedness for systems of type (5)[8] with $s > 2 + \frac{1}{6}$.

To do better than that one needs to take into account the nonlinear structure of the equations. Both the classical work [CB1], [Di], [F-M], [H-K-M] and the Strichartz based results [B-C1], [B-C2], [Ta1], [Ta2] only used the fact that the background metric $g$ is Lorentzian and obeys regularity conditions compatible with the final desired result. The additional important piece of information that $g$ itself is a solution of (5) was not exploited.

In [K-R1] we were able to improve the result of Tataru by taking into account not only the expected regularity properties of the metric $g$ but also the fact that they are themselves solutions to a similar system of equations. This allowed us to improve the exponent $s$, needed in the proof of well posedness of equations of type (5) to $s > 2 + \frac{2-\sqrt{3}}{2}$. Our approach was based on a combination of the paradifferential calculus ideas, initiated in [B-C1] and [Ta2], with a geometric treatment of the actual equations introduced in [K4]. The main improvement was due to a gain of conormal differentiability for solutions to the eikonal equations

$$g_{<\lambda}^{\alpha\beta}\partial_\alpha u\,\partial_\beta u = 0 \tag{11}$$

with $g_{<\lambda}$ a smoothed out version of the original metric $g$ with the property that $|\nabla^k g_{<\lambda}| \leq C_k\lambda^k$ for any spatial derivative $\nabla$. Such smoothing can be constructed with the help of the standard Littlewood–Paley projections $P_{<\lambda}$ which smoothly remove Fourier frequencies $\geq \lambda$.

In [K-R2]–[K-R4] we developed the ideas of [K-R1] further in the context of the Einstein vacuum equations, i.e., equations (5) coupled with the condition that $R_{\alpha\beta}(g) = 0$. We make use of both the vanishing of the Ricci curvature of $g$ and the harmonic gauge condition (3). The other important new features are the use of energy estimates along the null hypersurfaces generated by the optical function $u$ and a deeper use of the conormal properties of the null structure equations.

**Theorem 1** ([K-R2]). *Consider the reduced equation* (5) *with initial data* $g^0_{\alpha\beta}, g^1_{\alpha\beta} \in H^s \times H^{s-1}$ *for some* $s > 2$ *satisfying the constraint equations* (1) *with* $T \equiv 0$ *and the harmonic gauge condition* (3). *Then there exists a time interval* $[0, T]$ *and unique* (*Lorentzian metric*) *solution* $g$ *such that* $g_{\alpha\beta} \in C^0([0, T]; H^s)$ *with* $T$ *depending only on the size of* $\|g^0_{\alpha\beta}\|_{H^s} + \|g^1_{\alpha\beta}\|_{H^{s-1}}$.

The results of Theorem 1 require that the initial data can be approximated by a smooth sequence of data satisfying the constraint equations. Using a conformal method a large class of such $(\Sigma_0, g_0, k_0)$ was constructed in [CB3] and [Ma].

[8] The above results actually apply to more general quasilinear equations of the form

$$\Box_{g(\phi)}\phi = N(\phi, \partial\phi), \tag{10}$$

where $g$ is a *given* metric smoothly dependent on a solution $\phi$. However, there is no substantial difference between the equations (5) and (10) unless of course one also uses the fact that a solution of (5) with initial data in harmonic gauge is a solution of the vacuum Einstein equations.

In [S-T2] H. Smith and D. Tataru obtained the parallel $H^s$, $s > 2$ local well posedness result for general quasilinear equations, as well as the new improved results in other dimensions rather than $n = 3$. Their approach is based on the construction of a wave packet approximation of a solution. The geometry of wave packets controls the desired Strichartz estimate. The construction relies on the foliation by the null planes. It uses a gain of differentiablity along each plane, which can be traced to the decomposition of the tangential components of the curvature in the spirit [K-R1], but avoids references to the regularity of the foliation in the direction transversal to the leafs (i.e. torsion of the foliation).

It is very likely that the results of Theorem 1 are not sharp and the Einstein vacuum equations can be solved in even lower degree of regularity. A very satisfactory result both from the analytic and geometric point of view would a resolution of the $L^2$ *curvature conjecture*, see [K3], according to which the time of existence for solutions of the Einstein vacuum equations should depend only on the $L^2$ norms of the Riemann curvature tensor of $g_0$ and the gradient of the second fundamental form $\nabla k_0$ and perhaps some other weaker geometric characteristics of $\Sigma_0$. Some geometric evidence in support of this conjecture is provided in the work [K-R5]–[K-R7] where it was shown that null hypersurfaces, level surfaces of the optical function solving the eikonal equation $g^{\alpha\beta}\partial_\alpha u\,\partial_\beta u = 0$, do not break down locally as long as the $L^2$ curvature flux along them is finite.

**2.1. Existence results in other gauges.** Existence results for the Einstein (vacuum) equations can be also established in other gauges than the harmonic coordinate gauge (2).

In [A-M1] application of the energy method yields a construction of the $H^s$ with $s > 5/2$ vacuum space-times in the constant mean curvature spatially harmonic gauge. To describe the evolution equations in this particular gauge we write the metric $g$ in the form

$$g = -N^2 dt^2 + \gamma_{ij}(dx^i + X^i dt)(dx^j + X^j dt),$$

where $N$ and $X$ are the lapse and shift of the $t$-foliation. The Einstein vacuum equations are written as a system of evolution equations for the metric $\gamma$ and the second fundamental form $k$ of the $t$-foliation coupled to the constraint equations, while the gauge condition generates elliptic equations for $N$ and $X$.

$$\partial_t \gamma_{ij} = -2Nk_{ij} + \mathcal{L}_X \gamma_{ij}, \tag{12}$$

$$\partial_t k_{ij} = -\nabla_i \nabla_j N + N({}^{(3)}R_{ij} + \operatorname{tr} k\, k_{ij} - 2k_{im}k_j^m) + \mathcal{L}_X k_{ij}. \tag{13}$$

Here $\mathcal{L}$ is the Lie derivative and ${}^{(3)}R_{ij}$ is the Ricci curvature of $\gamma$. The constant mean curvature condition is the requirement that on the hypersurface $t = \text{const}$ we have $\operatorname{tr} k = t$. Under this condition taking the trace in (13) and using the constraint equations we obtain an elliptic equation for the lapse $N$:

$$-\Delta_\gamma N + |k|^2 N = 1. \tag{14}$$

The constraint equations in this gauge also become

$$^{(3)}R = |k|^2 - t, \quad \nabla^j k_{ij} = 0. \tag{15}$$

We also fix the spatially harmonic gauge by requiring[9] that a system of coordinates $x^i$, $i = 1, 2, 3$ on each $t =$ constant is harmonic, i.e., satisfies the equation $\Delta_\gamma x^i = 0$. The Ricci curvature $^{(3)}R_{ij}$ can then be written on the form

$$^{(3)}R_{ij} = -\frac{1}{2}\Delta_\gamma \gamma_{ij} + N_{ij}(\gamma, \nabla\gamma),$$

where as before $N_{ij}(u, v)$ depends quadratically on $v$. Propagation of this gauge results in an elliptic equation for the shift so that (12), (13), (14), (15) form an elliptic-hyperbolic system.

A local existence result in the maximal gauge was also proved in [C-K]. This particular gauge corresponds to the choice $\operatorname{tr} k = X = 0$. The lapse and constraint equations take the form

$$-\Delta_\gamma N + |k|^2 N = 0,$$
$$^{(3)}R = |k|^2, \quad \nabla^j k_{ij} = 0$$

while the system (12), (13) describes the evolution of $\gamma$ and $k$. To see the hyperbolic character of (12), (13) without imposing a spatially harmonic gauge one has to take an additional time derivative of (13) and express $\partial_t^{(3)}R$ in terms of $\gamma$ and $k$.

Another interesting formulation of the Einstein (vacuum) equations arises by drawing an analogy between the Einstein equations and the Yang–Mills theory. In the Yang–Mills theory an electromagnetic field is represented by a Lie algebra valued 2-form $F_{\alpha\beta} = \partial_\alpha A_\beta - \partial_\beta A_\alpha + [A_\alpha, A_\beta]$ constructed from an electromagnetic potential $A_\alpha$. The Yang–Mills equations on Minkowski space $R^{3+1}$ for $F$ take the form

$$D^\beta F_{\alpha\beta} = 0, \quad D_\mu F_{\alpha\beta} + D_\beta F_{\mu\alpha} + D_\alpha F_{\beta\mu} = 0,$$

where the covariant derivative $D_\alpha = \partial_\alpha + [A_\alpha, \cdot]$ and the second equation is the Bianci identity for the curvature form $F$. Differentiating the second equation we arrive at the second order hyperbolic problem for $F$

$$\Box_A F_{\alpha\beta} = 2F_\beta^{\ \mu} F_{\mu\alpha},$$

where $\Box_A = m^{\alpha\beta} D_\alpha D_\beta$.

In General Relativity the Riemann curvature tensor $R_{\alpha\beta\mu\nu}$ satisfies the Bianci identities

$$D_\sigma R_{\alpha\beta\mu\nu} + D_\beta R_{\sigma\alpha\mu\nu} + D_\alpha R_{\beta\sigma\mu\nu} = 0 \tag{16}$$

[9]The actual general harmonic gauge is only slightly more complicated.

and, if the Ricci curvature of $g$ vanishes, i.e., $(M, g)$ is a vacuum space-time, also a version of the contracted Bianci identities

$$D^{\alpha} R_{\alpha\beta\mu\nu} = 0. \tag{17}$$

Differentiating the Bianci identity (16) and also using (17) we easily obtain the wave equation for the Riemann curvature tensor

$$\Box_g R_{\alpha\beta\mu\nu} = (R \star R)_{\alpha\beta\mu\nu}\,, \tag{18}$$

where $\star$ denotes a combination of various contractions.

**2.2. Large data problem in General Relativity.** While the result of Choquet-Bruhat and its subsequent refinements guarantee the existence and uniqueness of a (maximal) Cauchy development, they provide no information about its geodesic completeness and thus, in the language of partial differential equations, constitutes a local existence result. Singularities could develop to the future (past) of the Cauchy hypersurface $\Sigma_0$ or the maximal Cauchy development could have a regular boundary, Cauchy horizon, beyond which the space-time could be continued thus losing its predictability from the initial data. Schwarzschild space-time is an example of a geodesically incomplete asymptotically flat space-time while the Reissner–Nordström solution of the Einstein–Maxwell equations possesses a Cauchy horizon.

More generally, there are a number of conditions that will guarantee that the space-time will be geodesically incomplete. The first such result was the Penrose singularity theorem:

**Theorem 2** (Penrose). *A space-time*[10] $(M, g)$ *is necessarily incomplete if it admits a non-compact Cauchy surface and a trapped*[11] 2*-dimensional compact surface.*

According to the result of [S-Y2] sufficient amount of matter placed in a region will create a trapped surface.

In the language of partial differential equations this means an impossibility of a large data global existence result for all initial data in General Relativity. In the absence of such a result a number of conjectures about the structure of space-times arising from generic data had been put forward in the '60s by Penrose. Among them is the *Weak Cosmic Censorship* which predicts that for generic asymptotically flat data null infinity will be affine complete or alternatively that singularities have to be hidden inside black holes. On the other hand the *Strong Cosmic Censorship* predicts a generic absence of the Cauchy horizons. At the moment not much progress has been made on either of these problems in the general case with remarkable exceptions in some cases of symmetry reduced Einstein equations: the proof of weak

[10] The energy-momentum tensor $T_{\alpha\beta}$ of matter is only required to satisfy what is called a null convergence energy condition.

[11] Infinitesimally deformations of such surface along both null outgoing and null incoming directions decrease its area.

cosmic censorship for the Einstein-scalar field equations in spherical symmetry by Christodoulou [C2],[C3], the work of Dafermos [D] on strong cosmic censorship and stability of the Cauchy horizons for the Einstein–Maxwell-scalar field equations in spherical symmetry, the proof of strong cosmic censorship in polarized Gowdy by Chruściel–Isenberg–Moncrief [C-I-M] and $T^3$-Gowdy by Ringström [Ri].

**2.3. Break-down criteria in General Relativity.** In the absence of a completeness result for general large data Cauchy problem in General Relativity and a very non-quantitative nature of the singularity theorems it is desirable to develop a better understanding of local or semi-local analytic mechanisms for break-down of solutions. Already the local existence results mentioned above provide such criteria. In particular an $H^s$ local existence result in harmonic gauge guarantees that a solution can be extended as long as the $H^s$ norms of the metric components in harmonic gauge remain finite. Such results however are not ideal as break-down criteria for the reasons that they are not geometric and strongly tied to a particular coordinate gauge and that they arise as a consequence of stronger local well-posedness statements.

The first *geometric* criterion for breakdown of solutions $(M, g)$ of the vacuum Einstein equations

$$R_{\alpha\beta}(g) = 0 \tag{19}$$

appeared in the work of M. Anderson [A1]. To describe the problem we assume that a part of space-time $M_I \subset M$ is foliated by the level hypersurface $\Sigma_t$ of a time function $t$, monotonically increasing towards future in the interval $I \subset R$, with lapse $N$ and second fundamental form $k$ so that

$$g = -N^2 dt^2 + \gamma_{ij} dx^i dx^j, \quad \partial_t \gamma_{ij} = -2N k_{ij}.$$

The surfaces $\Sigma_t$ are compact, of Yamabe type $-1$, and of constant negative mean curvature, $\operatorname{tr} k = t$ with $t < 0$. Relative to a time foliation we can naturally associate a non-degenerate notion of a pointwise absolute value of a space-time tensor.

In [A1] it was shown that a break-down can be tied to the condition that

$$\limsup_{t \to t_*^-} \|R(t)\|_{L^\infty} = \infty,$$

where $R(t)$ denotes the Riemann curvature tensor of $g$ and the norm is measured relative to the above described $t$-foliation.

A work in progress [K-R7] addresses the problem of break-down of solutions to the Einstein vacuum equations under the assumption that $T = N^{-1}\partial_t$ is an approximate Killing field. More precisely, the desirable break-down condition is

$$\limsup_{t \to t_*^-} \|\mathcal{L}_T g(t)\|_{L^\infty} = \infty, \tag{20}$$

where $\mathcal{L}_T g$ is the deformation tensor of $T$, equal to zero if $T$ is Killing, and it can be expressed as

$$|\mathcal{L}_T g| = |k| + |\nabla \log N|.$$

This result would complement Anderson's criterion. It is clear however that the condition (20) is formally weaker as it refers only to the second fundamental form $k$ and the lapse $n$ and thus requires one degree less of differentiability than a condition on the Riemann curvature tensor. Moreover a condition on the boundedness of the $L^\infty$ norm of $R(t)$ covers all the dynamical degrees of freedom of the equations. Indeed, once we know that $\|R(t)\|_{L^\infty}$ is finite, one can find bounds for $n$, $\nabla n$ and $k$ on $\Sigma_t$ purely by elliptic estimates. This is not true in our case.

A geometric criterion of the type (20) for the Einstein equations could be compared to the well known Beale–Kato–Majda [B-K-M] criterion for breakdown of solutions of the incompressible Euler equation

$$\partial_t v + (v \cdot \nabla)v = -\nabla p, \quad \operatorname{div} v = 0,$$

with smooth initial data at $t = t_0$. A routine application of the energy estimates shows that solution $v$ blows up if and only if

$$\int_{t_0}^{t_*} \|\nabla v(t)\|_{L^\infty}\, dt = \infty. \tag{21}$$

The Beale–Kato–Majda work improves the blow up criterion by replacing it with the following condition on the vorticity $\omega = \operatorname{curl} v$:

$$\int_{t_0}^{t_*} \|\omega(t)\|_{L^\infty}\, dt = \infty. \tag{22}$$

The quantities $\nabla v$ and $\omega$ are related to each other via a singular integral operator, i.e., $\nabla v = P^0(\omega)$.

Although $P^0$ does not define a bounded map $L^\infty \to L^\infty$ it is sufficient to reduce the breakdown condition (21) to the more satisfying one (22), in terms of the vorticity alone.

Similarly, in the case of the Einstein equations energy estimates, expressed relative to a special system of coordinates (e.g. in harmonic gauge), show that break-down does not occur unless

$$\int_{t_0}^{t_*} \|\partial g(t)\|_{L^\infty}\, dt = \infty.$$

This condition however is not geometric as it depends on the choice of a full coordinate system. Observe that both the spatial derivatives of the lapse $\nabla n$ and the components of the second fundamental form, $k_{ij} = -\frac{1}{2}N^{-1}\,\partial_t g_{ij}$, can be interpreted as components of $\partial g$.

Note however that after prescribing $k$ and $\nabla n$ we are still left with many more degrees of freedom in determining $\partial g$. The fundamental difficulty that one needs to overcome is that of deriving bounds for $R$ using only bounds for $\|\nabla N(t)\|_{L^\infty} + \|k(t)\|_{L^\infty}$ and geometric informations on the initial hypersurface $\Sigma_0$. Clearly this cannot be done by elliptic estimates alone. Thus, as opposed to both the results of M.

Anderson and Beale–Kato–Majda, it is far less obvious that a condition such as (20) can cover all *dynamic* degrees of freedom of the Einstein equations.

The criterion (20) is motivated in part by the desire to adapt the Eardley–Moncrief argument [E-M1], [E-M2] for the large data global existence for the $3+1$ Yang–Mills equations to General Relativity, exploiting the analogy between the Einstein vacuum and the Yang–Mills equations.

The Eardley–Moncrief proof relies on two independent ingredients: conservation of energy and pointwise bounds on curvature, which are derived using the fundamental solution for $\Box$ in Minkowski space, and shown to depend only on the flux of curvature and initial data. Since the analog of the Yang–Mills energy in General Relativity (the Bel–Robinson energy) is not conserved one can only hope to reproduce the second part of the Eardley–Moncrief argument and prove a conditional regularity result which states, roughly, that smooth solutions of the Einstein equations, in vacuum, remain smooth, and can therefore be continued, as long as an integral quantity, we call the flux of curvature, remains bounded. The possibility of such a result was first pointed out by V. Moncrief.

However it is the fact that $T = \partial_t$ is a Killing field that is ultimately responsible for the conservation of energy in the Yang–Mills theory on Minkowski space. Similarly, in the extension [C-S] of the Eardley–Moncrief result to the Yang–Mills equations on a smooth globally hyperbolic background it is the fact that $T = \partial_t$ is an approximate Killing field that allows one to control the energy and the flux of curvature.

Thus in the context of General Relativity rather then imposing a direct condition on the finiteness of the Bel–Robinson energy and curvature flux we formulate conditions (perhaps more natural albeit more restrictive) which control the extent to which the energy is not conserved. These conditions, which form our breakdown criterion, involve uniform bounds on the second fundamental form $k$ and the lapse $N$.

In what follows we describe how the main ideas of the proof of the Eardley–Moncrief result for Yang–Mills could be adapted to General Relativity.

The curvature tensor $R$ of a $3+1$ dimensional vacuum spacetime $(M, g)$, see (19), verifies a wave equation of the form,

$$\Box_g R = R \star R. \tag{23}$$

The Bel–Robinson energy-momentum tensor

$$\mathcal{Q}[R]_{\alpha\beta\gamma\delta} = R_{\alpha\lambda\gamma\mu} R_{\beta\ \delta}^{\ \lambda\ \mu} + \star R_{\alpha\lambda\gamma\mu} \star R_{\beta\ \delta}^{\ \lambda\ \mu}$$

verifies $D^\delta \mathcal{Q}[R]_{\alpha\beta\gamma\delta} = 0$ and can thus be used to derive energy and flux estimates for the curvature tensor $R$. The approximate Killing condition is sufficient to derive bounds for both energy and flux associated to the curvature tensor $R$. The flux is an integral of a square of the components of the Riemann curvature tensor tangent to a null hypersurface $N^-(p)$, boundary of the causal point of point $p$, generated, at least locally, as a level hypersurface $u = 0$ of an optical function $u$, solution of the eikonal equation $g^{\alpha\beta}\partial_\alpha u\, \partial_\beta u = 0$.

As in the case of the Yang–Mills equations it is precisely the boundedness of the flux of curvature that plays a crucial role in our analysis. In General Relativity the flux takes on even more fundamental role as it is also needed to control the geometry of the very object it is defined on, i.e. the boundary $N^-(p)$ of the causal past of $p$. This boundary, unlike in the case of Minkowski space, are not determined a-priori but depend in fact on the space-time we are trying to control.

The main idea is to show that if the condition (20) does not hold, i.e.,

$$\limsup_{t \to t_*^-} \|\mathcal{L}_T g(t)\|_{L^\infty} < \infty, \tag{24}$$

it implies a uniform curvature bound

$$\limsup_{t \to t_*^-} \|R(t)\|_{L^\infty} < \infty \tag{25}$$

and the solution can be continued beyond $t_*$.

The curvature bound (25) relies on the parametrix construction for the equation (23). In the construction of a parametrix for (23) we cannot, in any meaningful way, approximate $\Box_g$ by the flat D'Alembertian $\Box$. One could instead proceed via a geometric optics construction of parametrices for $\Box_g$, as developed in [F]. Such an approach would require additional bounds on the background geometry, determined by the metric $g$, incompatible with the assumption (24) and the implied finiteness of the curvature flux.

We rely instead on a geometric version, which we develop in [K-R6], of the Kirchoff–Sobolev formula, similar to that used by Sobolev in [Sob] and Choquet-Bruhat in [CB1], see also [Mo]. Roughly, this can be obtained by applying to (23) the measure $A\delta(u)$, where $u$ is an optical function whose level set $u = 0$ coincides with $N^-(p)$ and $A$ is a 4-covariant 4-contravariant tensor defined as a solution of a transport equation along $N^-(p)$ with appropriate (blowing-up) initial data at the vertex $p$. After a careful integration by parts we arrive at the following analogue of the Kirchoff formula:

$$R(p) = -\int_{N^-(p;\delta_0)} A \cdot (R \star R) + R^0(p;\delta_0) + \int_{N^-(p;\delta_0)} \mathcal{E} \cdot R, \tag{26}$$

where $N^-(p;\delta_0)$ denotes the portion of the null boundary $N^-(p)$ in the time interval $[t(p) - \delta_0, t(p)]$ and the error term $\mathcal{E}$ depends only on the intrinsic geometry of $N^-(p;\delta_0)$. The term $R^0(p;\delta_0)$ is completely determined by the initial data on the hypersurface $\Sigma_{t(p)-\delta_0}$. As in the flat case[12], one can prove bounds for the sup-norm of $R^0(p;\delta_0)$ which depend only on uniform bounds for $R$ and its first covariant derivatives at values of $t' \le t(p) \le t - \delta$.

As in the Yang–Mills setting the structure of the term $R \star R$ allows us to estimate one of the curvature terms by the flux of curvature.

[12]This is by no means obvious as we need to rely once more on the Kirchoff–Sobolev formula.

To control the error term in (26) one needs estimates for tangential derivatives of $A$ and other geometric quantities associated to the null hypersurfaces $N^-(p)$. In particular, it requires showing that $N^-(p)$ remains a *smooth* (not merely Lipschitz) hypersurface in the time slab $(t(p) - \delta_0, t(p)]$ for some $\delta_0$ dependent only on the initial data and (24). Thus to prove the desired theorem one would have to show that all geometric quantities, arising in the parametrix construction, can be estimated only in terms of the flux of the curvature along $N^-(p)$ and the bound in (24). Yet, to start with, it is not even clear that we can provide a lower bound for the radius of injectivity of $N^-(p)$. In other words the congruence of null geodesics, initiating at $p$, may not be controllable[13] only in terms of the curvature flux. Typically, in fact, lower bounds for the radius of conjugacy of a null hypersurface in a Lorentzian manifold are only available in terms of the sup-norm of the curvature tensor $R$ along the hypersurface, while the problem of short, intersecting, null geodesics appears not to be fully understood even in that context. The situation is similar to that in Riemannian geometry, exemplified by the Cheeger's theorem, where pointwise bounds on sectional curvature are sufficient to control the radius of conjugacy but to prevent the occurrence of short geodesic loops one needs to assume in addition an upper bound on the diameter and a lower bound on the volume of the manifold.

In a sequence of papers, [K-R2]–[K-R4], we have been able to prove a lower bound, depending essentially only on the curvature flux, for the radius of conjugacy of null hypersurfaces[14] in a Lorentzian spacetime which verifies the Einstein vacuum equations. The methods used in these articles can be adapted to provide all the desired estimates, except a lower bound on the "size" of intersecting null geodesics which needs a separate argument. The lower bound on the radius of injectivity of the null hypersurfaces $N^-(p)$ has been established in [K-R5]

## 3. Stability problems in General Relativity

In the absence of a general "large data" result in General Relativity the problem of stability of special solutions becomes simultaneously more important and more tractable. Despite our best efforts however these stability questions appear to be quite difficult and still poorly understood. A singular achievement in this regard has been the proof of stability of Minkowski space-time, [C-K], [L-R2] and a semi-global version in [Fr1]. To this date this is the only global result in the category of the asymptotically flat space-times. In the realm of cosmological models stability of the de Sitter space has been shown in [Fr2], [A2]. Finally one should also mention the proof of stability in the expanding direction of a flat cone solution for spatially compact space-times [A-M2], [Re].

[13] Different null geodesics of the congruence may intersect, or the congruence itself may have conjugate points, arbitrarily close to $p$.

[14] together with many other estimates of various geometric quantities associated to $N^-(p)$.

**3.1. Stability of the Minkowski space-time.** The problem of stability of Minkowski space-time for the Einstein-vacuum equations can be described as follows:

*Show existence of a causally geodesically complete vacuum space-time asymptotically "converging" to the Minkowski space-time for an arbitrary set of smooth asymptotically flat initial data* $(\Sigma_0, g_{0ij}, k_{0ij})$ *with* $\Sigma_0 \approx R^3$,

$$g_{0ij} = \left(1 + \frac{M}{r}\right)\delta_{ij} + o(r^{-1-\alpha}), \quad k_{0ij} = o(r^{-2-\alpha}), \quad r = |x| \to \infty,\ \alpha > 0 \tag{27}$$

*where* $(g_0 - \delta)$ *and* $k_0$ *satisfy global smallness assumptions .*

A positive parameter $M$ in the asymptotic expansion for the metric $g_0$ is the ADM mass, positive according to [S-Y1], [W].

The stability of Minkowski space for the Einstein-vacuum equations was shown in a remarkable work of Christodouolou–Klainerman for strongly asymptotic initial data (the parameter $\alpha \geq 1/2$ in the asymptotic expansion (27)), [C-K] The approach taken in that work viewed the Einstein-vacuum equations as a system of equations

$$D^\alpha W_{\alpha\beta\gamma\delta} = 0, \quad D^\alpha * W_{\alpha\beta\gamma\delta} = 0$$

for the Weyl tensor $W_{\alpha\beta\gamma\delta}$ of the metric $g_{\alpha\beta}$ and used generalized energy inequalities associated with the Bel–Robinson energy-momentum tensor, constructed from components of $W$, and special geometrically constructed vector fields, designed to mimic the rotation and the conformal Morawetz vector fields of the Minkowski space-time, i.e., "almost conformally Killing" vector fields of the unknown metric $g$. The proof was manifestly invariant, in particular it did not use the harmonic coordinate gauge. This approach was later extended to the Einstein–Maxwell equations by N. Zipser [Z].

In [L-R2] we succeeded in developing a new relatively technically simple approach which allowed allowing us to prove stability of Minkowski space in harmonic coordinate gauge, for general asymptotically flat data, $\alpha > 0$, and simultaneously treat the case of the Einstein equations coupled to a scalar field,

$$R_{\alpha\beta}(g) = \partial_\alpha\phi\, \partial_\beta\phi, \quad \Box_g\phi = 0$$

where the scalar field requires a global smallness assumption on its initial data $(\phi_0, \phi_1)$, which obey the asymptotic expansion

$$\phi_0 = o(r^{-1-\alpha}), \quad \phi_1 = o(r^{-2-\alpha}). \tag{28}$$

**Theorem 3** ([L-R2]). *Let* $(\Sigma, g_0, k_0, \phi_0, \phi_1)$ *be initial data for the Einstein-scalar field equations. Assume that the initial time slice* $\Sigma$ *is diffeomorphic to* $R^3$ *and admits a global coordinate chart relative to which the data is close to the initial data for the Minkowski space-time. More precisely, we assume that the data* $(g_0, k_0, \phi_0, \phi_1)$ *is smooth asymptotically flat in the sense of* (27)–(28) *with mass* $M$ *and* $\alpha > 0$ *and satisfy a global smallness assumption as measured in the scale of weighted Sobolev spaces. Then the Einstein-scalar field equations possess a future causally geodesically*

*complete solution* $(g, \psi)$ *asymptotically converging to Minkowski space-time. In fact, there exists a global harmonic system coordinates relative to which the metric g remains close* (*and "converges"*) *to the Minkowski metric.*

The appeal of the harmonic gauge for the proof of stability of Minkowski space-time lies in the fact that the latter can be simply viewed[15] as a *small data global existence result* for the quasilinear system (5) (for vacuum equations),

$$\Box_g g_{\alpha\beta} = N_{\alpha\beta}(g, \partial g), \quad g_{\alpha\beta}|_{t=0} = g^0_{\alpha\beta}, \ \partial_t g_{\alpha\beta}|_{t=0} = g^1_{\alpha\beta}. \tag{29}$$

However, usefulness of the harmonic gauge in this context was questioned earlier and it was suspected that harmonic coordinates are "unstable in the large", [CB1]. The conclusion is suggested from the analysis of the iteration scheme for the system (29), which resembles an iteration scheme for the semilinear equation $\Box\phi = (\partial_t\phi)^2$ shown to blow up in finite time for arbitrarily small initial data by F. John, [J].

To describe some of the difficulties in establishing a small data global existence result for the system (29) consider a generic quasilinear system of the form

$$\Box\,\phi_i = \sum b_i^{jk\alpha\beta}\,\partial_\alpha\phi_j\,\partial_\beta\phi_k + \sum c_i^{jk\alpha\beta}\,\phi_j\,\partial_\alpha\partial_\beta\phi_k + \text{cubic terms}. \tag{30}$$

The influence of cubic terms is negligible while the quadratic terms are of two types, the *semilinear terms* and the *quasilinear terms*, each of which present their own problems. D. Christodoulou [C1] and S. Klainerman [K2] showed global existence for systems of the form (30) if the semilinear terms satisfy the *null condition* and the quasilinear terms are absent. The null condition, first introduced by S. Klainerman in [K1], was designed to detect systems for which solutions are asymptotically free and decay like solutions of a linear equation. It requires special algebraic cancellations in the coefficients $b_i^{jk\alpha\beta}$, e.g. $\Box\,\phi = (\partial_t\phi)^2 - |\nabla_x\phi|^2$. However, the semilinear terms for the Einstein equations do not satisfy the null condition, see [CB2]. The quasilinear terms is another source of trouble. The only non-trivial example of a quasilinear equation of the type (30), for which the small data global existence result holds, is the model equation $\Box\,\phi = \phi\,\Delta\phi$, as shown in [L1] (radial case) and [Al] (general case), see also [L2].

In [L-R1] we identified a criteria under which it is more likely that a quasilinear system of the form (30) has global solutions[16]. We said that a system of the form (30) satisfy the *weak null condition* if the corresponding *asymptotic system* (c.f. [H]) has global solutions. We showed that the Einstein equations in harmonic coordinates satisfy the weak null condition. In addition an additional cancellation mechanism was found for the Einstein equations in harmonic coordinates that makes it better than a

[15]This statement requires additional care since a priori there is no guarantee that obtained "global in time" solution $g_{\mu\nu}$ defines a causally geodesically complete metric. However, the latter can be established provided one has good control on the difference between $g_{\mu\nu}$ and the Minkowski metric $m_{\mu\nu}$.

[16]At this point, it is unclear whether this criteria is sufficient for establishing a "small data global existence" result for a *general* system of quasilinear hyperbolic equations.

general system satisfying the weak null condition. The system decouples to leading order, when decomposed relative to the Minkowski *null frame*. An approximate model that describes the semilinear terms has the form

$$\Box\,\phi_2 = (\partial_t \phi_1)^2, \quad \Box\,\phi_1 = 0.$$

While every solution of this system is global in time, the system fails to satisfy the classical null condition and solutions are not asymptotically free: $\phi_2 \sim \varepsilon t^{-1} \ln |t|$. The semilinear terms in Einstein's equations can be shown to either satisfy the classical null condition or decouple in the above fashion when expressed in a null frame. The quasilinear terms also decouple but in a more subtle way. The influence of quasilinear terms can be detected via asymptotic behavior of the characteristic surfaces of metric $g$. It turns out that the main features of the characteristic surfaces at infinity are determined by a particular *null* component of the metric. The asymptotic flatness of the initial data and the harmonic coordinate condition (3)

$$\partial_\beta\big(g^{\alpha\beta}\sqrt{|g|}\big) = 0 \tag{31}$$

give good control of this particular component, i.e., $\sim M/r$, which in turn implies that the light cones associated with the metric $g$ diverge only logarithmically $\sim M \ln t$ from the Minkowski cones. The main simplification in our approach comes from the fact the behavior of the system (29) coupled to the harmonic gauge (31) can be completely controlled by means of the generalized energy estimates exploiting only the *exact* symmetries of Minkowski space thus avoiding having to construct dynamically generators of the approximate symmetries of the space-time $(M, g)$.

The asymptotic behavior of null components of the Riemann curvature tensor $R_{\alpha\beta\gamma\delta}$ of metric $g$ – the so called "peeling estimates" – was discussed in the works of Bondi, Sachs and Penrose and becomes important in the framework of asymptotically simple space-times (roughly speaking, space-times which can be conformally compactified), see also the paper of Christodoulou [C4] for further discussion of such space-times. The work of [C-K] provided very precise, although not entirely consistent with peeling estimates, analysis of the asymptotic behavior of constructed global solutions. However, global solutions obtained by Klainerman–Nicolo [K-N1] in the problem of exterior[17] stability of Minkowski space were shown to possess peeling estimates for special initial data, [K-N2]. The work [L-R2] is less precise about the asymptotic behavior of the curvature components.

**3.2. Beyond stability of Minkowski space-time.** The simplest solutions of the Einstein vacuum equations of general relativity,

$$R_{\mu\nu} = 0, \tag{32}$$

[17] Outside of the domain of dependence of a compact set.

containing black holes are the one-parameter Schwarzschild family of solutions. In the exterior region ($r > 2M$) the Schwarzschild metric can be written in the form

$$g_s = -\left(1 - \frac{2M}{r}\right) dt^2 + \left(1 - \frac{2M}{r}\right)^{-1} dr^2 + r^2 d\sigma_{S^2}.$$

The Schwarzschild family is a sub-family of the two-parameter Kerr family which describe stationary rotating black holes. In its proper rigorous formulation, the problem of nonlinear stability of the Kerr family is one of the major open problems in general relativity. In particular, it is conjectured that perturbations of Schwarzschild initial data should evolve into a spacetime with complete null infinity whose past "suitably" approaches a nearby Kerr exterior. At the heuristic level, however, considerable progress has been made in the last 40 years towards an understanding of the issues involved. In particular, a very influential role was played by the work of R. Price [Pr] in 1972, who discovered a heuristic mechanism, known in the physics literature as the *red-shift effect*, allowing for the decay of scalar field linear perturbations on the Schwarzschild exterior, i.e., solutions of the linear wave equation

$$\Box_{g_s} \phi = 0.$$

Despite the abundance of heuristic and numerical arguments the nonlinear problem is still lacking proper mathematical understanding while some progress has been made recently on a problem of asymptotic behavior of the linear problem. The causal picture of the Schwarzschild space-time is very different from the one of the Minkowski space. In (a right quadrant of) Schwarzschild space-time in addition to the null infinity, parametrized by $(u, \omega) \in R \times S^2$ there is a special null hypersurface, the *event horizon*, parametrized by $(v, \omega) \in R \times S^2$, separating the exterior region from the black hole. It is the presence of the event horizon that is responsible for the red-shift effect in which the frequency of an observer leaving the exterior region gets shifted to the red as viewed by the second observer positioned to the future of the first one. The geometry of the Schwarzschild space-time also ultimately determines the behavior of linear waves. However, even uniform boundedness of solutions of linear scalar wave equations, almost trivial in Minkowski context, is by no means obvious and is termed as linear stability of Schwarzschild in the physics literature. This result was rigorously established in the work of Kay and Wald [K-W]. Decay for $\phi$, without a rate, was first proven in [Tw].

**Theorem 4** ([D-R2]). *Let $\phi$ be a sufficiently regular solution of the wave equation*

$$\Box_{g_s} \phi = 0 \tag{33}$$

*on the (maximally extended) Schwarzschild spacetime $(\mathcal{M}, g)$, decaying suitably at spatial infinity on an arbitrary complete asymptotically flat Cauchy surface $\Sigma$. Fix retarded and advanced Eddington–Finkelstein coordinates $u$ and $v$. We have the*

*following pointwise decay rates*

$$\begin{aligned} |\phi| &\leq C \max(1, v)^{-1} \quad \text{in } r \geq 2M \\ |r\phi| &\leq C_{\hat{R}}(1 + |u|)^{-\frac{1}{2}} \quad \text{in } \{r \geq \hat{R} > 2M\} \cap J^+(\Sigma). \end{aligned} \tag{34}$$

A variant of the problem considered here is also studied in [B-S].

In the spherically symmetric case, the above result follows from a very special case of [D-R1], where the so called Price law has been established. (See also [M-S].)

For the more general Kerr family, even uniform boundedness remains an open problem (see however [FKSY]).

The proof of Theorem (4) is based on the energy type estimates for (33) with vector fields adapted to different regions of space-times. An important role in this analysis is played by the "red-shift vector field", which has no equivalent in Minkowski space, constructed near the event horizon.

# Categorification and correlation functions in conformal field theory

Christoph Schweigert, Jürgen Fuchs, and Ingo Runkel*

**Abstract.** A modular tensor category provides the appropriate data for the construction of a three-dimensional topological field theory. We describe the following analogue for two-dimensional conformal field theories: a 2-category whose objects are symmetric special Frobenius algebras in a modular tensor category and whose morphisms are categories of bimodules. This 2-category provides sufficient ingredients for constructing all correlation functions of a two-dimensional rational conformal field theory. The bimodules have the physical interpretation of chiral data, boundary conditions, and topological defect lines of this theory.

**Mathematics Subject Classification (2000).** Primary 81T40; Secondary 18D10, 18D35, 81T45.

**Keywords.** (Rational) conformal field theory, topological field theory, tensor categories, categorification.

## 1. Quantum field theories as functors

In approaches to quantum field theory that are based on the concepts of fields and states, the utility of categories and functors is by now well-established. The following pattern has been recognized: There is a geometric category $\mathcal{G}$ which, for every concrete model, must be suitably "decorated". The decoration is achieved with the help of objects and morphisms from another category $\mathcal{C}$. For known classes of quantum field theories, the decoration category $\mathcal{C}$ typically has a representation-theoretic origin – the reader is encouraged to think of it as the representation category of some algebraic object, like a quantum group, a loop group, a vertex algebra, a net of observable algebras, etc. This way one obtains a decorated geometric category $\mathcal{G}_\mathcal{C}$. The quantum field theory can then be formulated as a (tensor) functor $qft_\mathcal{C}$ from $\mathcal{G}_\mathcal{C}$ to some category of vector spaces. In this contribution, we mainly consider cases for which this latter category is the tensor category of finite-dimensional complex vector spaces.

A prototypical example for this pattern is provided by topological quantum field theories (TFTs). For such theories, the geometric category $\mathcal{G}$ is based on a cobordism category: its objects are $d-1$-dimensional topological manifolds without boundary. It is convenient to include two types of morphisms [42]: homeomorphisms of $d-1$-dimensional manifolds, and cobordisms. A cobordism $\mathrm{M}\colon \mathrm{Y}_1 \to \mathrm{Y}_2$ is a $d$-dimen-

*C. S. is supported by the DFG project SCHW 1162/1-1, and J. F. by VR under project no. 621–2003–2385.

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

sional topological manifold M together with a parametrization of its boundary given by a homeomorphism $\partial M \xrightarrow{\cong} \overline{Y}_1 \sqcup Y_2$, where $\overline{Y}_1$ has the orientation opposite to the one of $Y_1$. The composition of morphisms is by concatenation, by gluing, and by changing the parametrization of the boundary, respectively. Cobordisms that coincide by a homeomorphism of the $d$-manifold M restricting to the identity on $\partial M$ must be identified.

In the simplest case, a topological field theory thus associates to a closed $d-1$-dimensional manifold X a vector space $qft_{\mathcal{C}}(X)$, and to a homeomorphism or a cobordism $M\colon Y_1 \to Y_2$ a linear map

$$qft_{\mathcal{C}}(M)\colon qft_{\mathcal{C}}(Y_1) \to qft_{\mathcal{C}}(Y_2).$$

The assignment $qft_{\mathcal{C}}$ is required to be a (strict) tensor functor. This requirement implies the usual axioms (cf. e.g. [43]) of naturality, multiplicativity, functoriality and normalization.

There also exists a path-integral approach to certain classes of topological field theories. Its relation to the categorical framework described above is as follows: One can think of the vector space $qft_{\mathcal{C}}(\partial_- M)$ as the space of (equivalence classes of) possible initial data for "fields" in the path integral, and of $qft_{\mathcal{C}}(\partial_+ M)$ as the possible final data. The matrix elements of the linear map $qft_{\mathcal{C}}(M)$ are then the transition amplitudes for fixed initial and final values of the fields.

This picture is still oversimplified. In particular, it turns out that it is natural to enrich also the geometric category $\mathcal{G}$ over the category of complex vector spaces. As a consequence, when studying functors on $\mathcal{G}$, one should then consider also projective functors. These issues, which are closely related to anomalies in quantum field theory will, however, be suppressed in this note.

A prominent class of examples of 3-dimensional topological field theories arises from Chern–Simons field theories. For $G$ a simple connected and simply-connected complex Lie group, consider holomorphic $G$-bundles on a closed two-manifold X of genus $g$ with complex structure. Pick a generator $\mathcal{L}$ for the Picard group of the moduli space $\mathcal{M}_X^G$ of such bundles. Upon changing the complex structure of X, the vector spaces $H^0(\mathcal{M}_X^G, \mathcal{L}^{\otimes k})$ fit together into a vector bundle with projectively flat connection over the moduli space $\mathcal{M}_g^G$ of curves of genus $g$. The complex modular functor [3] associates these bundles to X; these bundles and their monodromies provide a formalization of all aspects of the chiral level-$k$ Wess–Zumino–Witten (WZW) conformal field theory for $G$ that are needed for the discussions in the subsequent sections.

As a next step, it is natural to extend the formalism by allowing for marked points with additional structure on the two-manifolds. From a field theoretical point of view, this is motivated by the desire to account for insertions of fields. In the case of Chern–Simons theory, the additional structure amounts to specifying parabolic structures at the marked points. The marked points thus have to carry labels, which we will identify in a moment as objects of a decoration category $\mathcal{C}$.

This structure must be extended to the geometric morphisms: Maps of 2-dimensional manifolds are required to preserve marked points and the decoration in $\mathcal{C}$. The decoration of the 2-dimensional manifolds is extended to the 3-dimensional manifolds M underlying cobordisms by supplying them with oriented (ribbon) graphs ending on (arcs through) the marked points on $\partial_{\pm}$M. The ribbon graph is allowed to have vertices with a finite number of ingoing and outgoing ribbons. From the construction of invariants of knots and links, it is known that this enforces a categorification of the set of labels: $\mathcal{C}$ must be a ribbon category, i.e. a braided sovereign tensor category. In particular, the vertices of the graph are to be labeled by morphisms in the decoration category $\mathcal{C}$.

This approach has been very fruitful and has, in particular, made a rigorous construction of Chern–Simons theory possible [38], [43]. The extension from invariants of links in $\mathbb{R}^3$ to link invariants in arbitrary oriented three-manifolds has revealed an important subclass of tensor categories: modular tensor categories.

For the purposes of the present contribution, we adopt the following definition of a modular tensor category: it is an abelian, $\mathbb{C}$-linear, semi-simple ribbon category with a finite number of isomorphism classes of simple objects. The tensor unit $\mathbf{1}$ is required to be simple, and the braiding must be nondegenerate in the sense that the natural transformations of the identity functor on $\mathcal{C}$ are controlled by the fusion ring $K_0(\mathcal{C})$:

$$\mathrm{End}(\mathrm{Id}_{\mathcal{C}}) \cong K_0(\mathcal{C}) \otimes_{\mathbb{Z}} \mathbb{C}.$$

The relation between Chern–Simons theory and chiral Wess–Zumino–Witten theory [44] was a first indication that modular tensor categories also constitute the appropriate mathematical formalization of the chiral data [31], [16] of a conformal field theory. Recent progress in representation theory has made this idea much more precise; for the following classes of representation categories it has been established that they carry the structure of a modular tensor category:

- The representation category of a connected ribbon factorizable weak Hopf algebra over $\mathbb{C}$ (or, more generally, over an algebraically closed field $\Bbbk$) with a Haar integral [33].
- The category of unitary representations of the double of a connected $C^*$ weak Hopf algebra [33].
- The category of local sectors of a finite-index net of von Neumann algebras on the real line, if the net is strongly additive (which for conformal nets is equivalent to Haag duality) and has the split property [27].
  (In this example and in the previous one one obtains unitary modular tensor categories.)
- The representation category of a self-dual vertex algebra that obeys Zhu's $C_2$ cofiniteness condition and certain conditions on its homogeneous subspaces, provided that this category is semisimple [25].

The last two entries in this list correspond to two different mathematical formalizations of chiral conformal field theories. The results of [27] and [25] therefore justify the point of view that modular tensor categories constitute an œcumenic formalization of the chiral data of a conformal field theory.

## 2. Two-dimensional conformal field theories

Three-dimensional topological field theory will indeed appear as a tool in constructions below. Our main interest here is, however, in a different class of quantum field theories: full (and in particular local) two-dimensional conformal field theories, or CFTs, for short.

For these theories, the geometric category of interest is the category of two-dimensional conformal manifolds, possibly with non-empty boundary. This fact already indicates that full conformal field theories are different from the chiral conformal field theories that we encountered in the last section for the case of WZW theories. Morphisms in the category of conformal manifolds are maps respecting the conformal structure. Actually, there are two different types of full conformal field theories, corresponding to two different geometric categories: One considers either oriented conformal manifolds, leading to a category $\mathcal{G}^{\mathrm{or}}$, or unoriented manifolds, leading to a different geometric category $\mathcal{G}^{\mathrm{unor}}$. As morphisms, we admit maps that preserve the respective structure. (In the application of conformal field theory to string theory, $\mathcal{G}^{\mathrm{or}}$ plays a role in superstrings of "type II", while $\mathcal{G}^{\mathrm{unor}}$ appears in superstring theories of "type I".)

As in the case of topological field theories, the geometric category needs to be decorated. To find the appropriate decoration data, we first discuss a physical structure that is known to be present in specific classes of models and that our approach to conformal field theory should take into account:

- Whenever a two-manifold X has a boundary, one expects that it is necessary to specify boundary conditions. In a path integral approach, a boundary condition is a prescription for the boundary values of fields that appear in the Lagrangian. Here, a more abstract approach is adequate: we take the possible boundary conditions to be the objects of a decoration category $\mathcal{M}$. This constitutes again a categorification of the decoration data. It can be motivated further by the observation that insertions of boundary fields can change the boundary condition; they will be related to morphisms of the category $\mathcal{M}$.

A second structure, which in the literature has received much less attention than boundary conditions, turns out to provide crucial clues for the construction of full conformal field theories:

- Conformal field theories can have topological defect lines. Such defect lines have e.g. been known for the Ising model for a long time: This CFT describes

the continuum limit of a lattice model with $\mathbb{Z}_2$-valued variables at the vertices of a two-dimensional lattice and with ferromagnetic couplings along its edges. A defect line is obtained when one changes the couplings on all edges that intersect a given line in the lattice from ferromagnetic to antiferromagnetic.

In the continuum limit, such a defect line can be described by a condition on the values of bulk fields at the defect line. In particular, when crossing a defect line, the correlation function of a bulk field can acquire a branch cut. Indeed, the defect lines we are interested in behave very much like branch cuts: they are topological in the sense that their precise location does not matter. In a field theoretic language, this is attributed to the fact that the stress-energy tensor of the theory is required to be smooth across defect lines. As in the case of boundary conditions, in our framework it is not desirable to express defect lines through conditions on the values of fields. Instead, we anticipate again a categorification of the decoration data and label the possible types of defect lines by objects in yet another decoration category $\mathcal{D}$.

There is a natural notion of fusion of defect lines, see e.g. [36], [15]. Accordingly, $\mathcal{D}$ will be a tensor category. Also, to take into account the topological nature of defect lines, we assume that the tensor category $\mathcal{D}$ has dualities and that it is even sovereign. In contrast, there is no natural notion of a braiding of defect lines, so $\mathcal{D}$ is, in general, not a ribbon category.

The two decoration categories – $\mathcal{D}$ for the defects and $\mathcal{M}$ for the boundary conditions – are themselves related. One can fuse a defect line to a boundary condition, thereby obtaining another boundary condition; see e.g. [24]. This endows the category $\mathcal{M}$ of boundary conditions with the structure of a module category over $\mathcal{D}$, i.e. there is a bifunctor

$$\otimes\colon \mathcal{D} \times \mathcal{M} \to \mathcal{M}$$

which has (mixed) associativity constraints obeying a mixed pentagon identity.

The structure just unraveled – a tensor category $\mathcal{D}$ together with a module category $\mathcal{M}$ over $\mathcal{D}$ – calls for the following natural extension: One should also consider the category of module functors, i.e. the category $\mathcal{C}$ whose objects are endofunctors of $\mathcal{M}$ that are compatible with the structure of a module category over $\mathcal{D}$ and whose morphisms are natural transformations between such functors. The concatenation of functors naturally endows $\mathcal{C}$ with a product so that $\mathcal{C}$ is a tensor category.

A recent insight is the following: In the application to two-dimensional conformal field theory, the category $\mathcal{C}$ obtained this way is equivalent to the category of chiral data that we discussed in Section 1! There is a particularly amenable subclass of conformal field theories, called *rational* conformal field theories (*R*CFTs), which can be rigorously discussed on the basis of this idea. For these theories, the category $\mathcal{C}$ of chiral data has the structure of a modular tensor category. In this case the idea can be exploited to arrive at a construction of correlation functions (see Section 4) of rational conformal field theories that is based on three-dimensional topological field theory. This TFT approach to RCFT correlators will be presented in Section 5 below.

## 3. The 2-category of Frobenius algebras

In practice, one frequently takes an opposite point of view: Instead of obtaining $\mathcal{C}$ as a functor category, one starts from some knowledge about the chiral symmetries of a conformal field theory. This allows one to use the representation-theoretic results mentioned in Section 1 so as to get a modular tensor category $\mathcal{C}$ describing the chiral data of the theory. Afterwards one realizes that the category $\mathcal{M}$ of boundary conditions is also a (right-) module category over $\mathcal{C}$. General arguments involving internal Hom's [35] together with specific properties relevant to rational conformal field theories then imply that in the tensor category $\mathcal{C}$ there exists an associative algebra $A$ such that $\mathcal{M}$ is equivalent to the category $\mathcal{C}_A$ of left $A$-modules in $\mathcal{C}$. By similar arguments one concludes that the category $\mathcal{D}$ is equivalent to the category of $A$-bimodules. Additional constraints, in particular the non-degeneracy of the two-point functions of boundary fields on a disk, lead to further conditions on this algebra [17]: $A$ must be a symmetric special Frobenius algebra. Owing to these insights we are able to use a generalization[1] of the theory of Frobenius algebras to braided tensor categories as a powerful tool to analyze (rational) conformal field theory. The algebraic theory in the braided setting is, however, genuinely richer; see [14] for a discussion of some new phenomena.

A *Frobenius* algebra $A = (A, m, \eta, \Delta, \varepsilon)$ in $\mathcal{C}$ is, by definition, an object of $\mathcal{C}$ carrying the structures of a unital associative algebra $(A, m, \eta)$ and of a counital coassociative coalgebra $(A, \Delta, \varepsilon)$ in $\mathcal{C}$, with the algebra and coalgebra structures satisfying the compatibility requirement that the coproduct $\Delta\colon A \to A \otimes A$ is a morphism of $A$-bimodules (or, equivalently, that the product $m\colon A \otimes A \to A$ is a morphism of $A$-bi-comodules). A Frobenius algebra is called *special* iff the coproduct is a right-inverse to the product – this means in particular that the algebra is separable – and a nonvanishing multiple of the unit $\eta\colon \mathbf{1} \to A$ is a right-inverse to the counit $\varepsilon\colon A \to \mathbf{1}$. There are two isomorphisms $A \to A^\vee$ that are naturally induced by product, counit and duality; $A$ is called *symmetric* iff these two isomorphisms coincide.

Two algebras in a tensor category $\mathcal{C}$ are called Morita equivalent iff their representation categories are equivalent as module categories over $\mathcal{C}$. Since the algebra $A$ is characterized by the requirement that $\mathcal{C}_A$ is equivalent to the given decoration category $\mathcal{M}$, it is clear that only the Morita class of the algebra should matter. It is a non-trivial internal consistency check on the constructions to be presented in Section 5 that this is indeed the case.

Taking the modular tensor category $\mathcal{C}$ as the starting point, the following further generalization of the setup (compare also [32], [46], [28]) is now natural:[2] Consider the set of *all* (symmetric special) Frobenius algebras in $\mathcal{C}$. This gives rise to a *family* of full conformal field theories that are based on the same chiral data. And

[1] When $\mathcal{C}$ is the modular tensor category of finite-dimensional complex vector spaces, the CFT is a topological CFT. In particular, $A$ is then an ordinary Frobenius algebra. This case has served as a toy model for conformal field theories, see e.g. [40], [30].

[2] We are grateful to Urs Schreiber for discussions on this point.

again we categorify the structure: we introduce a 2-category $\mathcal{F}rob_{\mathcal{C}}$ whose objects are symmetric special Frobenius algebras in $\mathcal{C}$. The 1-morphisms $\mathcal{H}om(A, A')$ are given by the category of $A$-$A'$-bimodules. The 2-category $\mathcal{F}rob_{\mathcal{C}}$ has a distinguished object $I$: as an object of $\mathcal{C}$, $I$ is just the tensor unit, which is naturally a symmetric special Frobenius algebra. Because of the considerations in [8], the full conformal field theory corresponding to $I$ is often referred to as the "Cardy case"; for this case a construction of the correlators in the spirit of Section 4 was given in [11].

We are now in a position to attribute a physical interpretation to the morphisms of $\mathcal{F}rob_{\mathcal{C}}$. $\mathcal{H}om(I, I)$ is naturally identified with the tensor category $\mathcal{C}$ of chiral data. Further, for any $A$ the tensor category $\mathcal{H}om(A, A)$ describes topological defects in the full conformal field theory associated to $A$; more generally, the category $\mathcal{H}om(A, A')$ accounts for topological defect lines that separate two different conformal field theories which share the same chiral data. Finally, the category $\mathcal{H}om(I, A)$ also describes boundary conditions for the full conformal field theory labeled by $A$.

We have thus learned that the decoration data of a family of full rational conformal field theories based on the same chiral data are described by a 2-category. This nicely fits with insight gained in other contexts:

- 2-categories appear in recent approaches to elliptic objects [2], [42].
- Hermitian bundle gerbes, which appear naturally in a semi-classical description of WZW conformal field theories [23], form a 2-category [41].

Unfortunately, at the time of writing, a unified approach to conformal field theories based on 2-categories has not been established yet. For this reason, in the sequel we will not be able to use this language systematically.

We close this section with two further comments. First, so far we have discussed the decoration data relevant to the oriented geometric category $\mathcal{G}^{\mathrm{or}}$. For the unoriented geometric category $\mathcal{G}^{\mathrm{unor}}$, additional structure on the relevant Frobenius algebra is needed: $A$ must then be a *Jandl* algebra, that is, a symmetric special Frobenius algebra coming with an algebra isomorphism $A \xrightarrow{\cong} A^{\mathrm{opp}}$ that squares to the twist on $A$. This turns out to be the appropriate generalization of the notion of an algebra with involution to braided tensor categories. We refrain from discussing this issue in the present contribution, but rather refer to [18], [21] for details.

Second, the general situation encountered above – a module category $\mathcal{M}$ over a tensor category $\mathcal{C}$ – naturally appears in various other contexts as well:

- The left modules over a weak Hopf algebra $H$ form a tensor category $\mathcal{C} = H$-Mod. In a weak Hopf algebra, one can identify two subalgebras $H_s$ and $H_t$ that are each other's opposed algebras [6]. Forgetful functors thus endow any $H$-module with the structure of an $H_t$-bimodule; one even obtains a tensor functor from $H$-Mod to $H_t$-Bimod. The usual tensor product of a $H_t$-bimodule and an $H_t$-left module endows the category of $H_t$-modules with the structure of a module category over $H_t$-Bimod and thus over $H$-Mod.

Weak Hopf algebras have indeed been proposed [37] as a framework for rational conformal field theories. Unfortunately, such a description must cope with two problems: First, to account for a braiding on $\mathcal{C}$, one must work with an $R$-matrix on $H$; not too surprisingly, this is technically involved, and indeed not very much is known about $R$-matrices on weak Hopf algebras. Secondly, given a tensor category $\mathcal{C}$ (describing the chiral data), there does not exist a canonical weak Hopf algebra such that $H$-Mod is equivalent to $\mathcal{C}$. Rather, as an additional datum, a fiber functor to $H_t$-bimodules needs to be chosen. A physical interpretation of this datum is unclear. On the other hand, Hopf algebras are still useful in the analysis of full rational CFT: Their Hochschild cohomology was used [10] to compute the Davydov–Yetter cohomology of the pair $(\mathcal{C}, \mathcal{M})$; from the vanishing of this cohomology, rigidity properties of rational conformal field theories follow.

- Weak Hopf algebras also appear in the study of inclusions of subfactors. For a review and further references, we refer to Sections 8 and 9 of [34].
- The same category-theoretic structures have been recovered in the theory of vertex algebras from so-called open-string vertex algebras [26] which are, in particular, extensions of ordinary vertex algebras.

Not surprisingly, some of the structures that will be encountered in the rest of this paper also have counterparts in the context of weak Hopf algebras, of nets of subfactors, or of open-string vertex algebras.

## 4. Correlation functions

The observations made in the preceding section raise the question whether one can construct a full rational conformal field theory by using a modular tensor category $\mathcal{C}$ and the 2-category $\mathcal{F}rob_{\mathcal{C}}$ as an input. These data should then in particular encode information about the correlation functions of the conformal field theory.

To decide this question, it is helpful to reformulate first the geometric categories $\mathcal{G}^{\mathrm{or}}$ and $\mathcal{G}^{\mathrm{unor}}$. This is achieved with the help of a crucial aspect of complex geometry in *two* dimensions: a complex structure on a two-dimensional manifold is equivalent to a conformal structure and the choice of an orientation. The complex double $\widehat{\mathrm{X}}$ of a conformal manifold X is a two-sheeted cover of X whose points are pairs consisting of a point $p \in \mathrm{X}$ and a local orientation at $p$. In view of the previous comment, it is clear that $\widehat{\mathrm{X}}$ is a complex curve. We have thus associated to any object X of the geometric categories $\mathcal{G}^{\mathrm{unor}}$ and $\mathcal{G}^{\mathrm{or}}$ a complex curve $\widehat{\mathrm{X}}$ that comes with an orientation reversing involution $\sigma$ such that the quotient $\widehat{\mathrm{X}}/\langle\sigma\rangle$ is naturally isomorphic to X, and we have a canonical projection

$$\pi : \widehat{\mathrm{X}} \mapsto \mathrm{X} \cong \widehat{\mathrm{X}}/\langle\sigma\rangle.$$

The set of fixed points of $\sigma$ is just the preimage under $\pi$ of the boundary $\partial\mathrm{X}$.

To be able to use the tools of complex geometry, we therefore reformulate our geometric categories as follows: in the case of $\mathcal{G}^{\mathrm{unor}}$, the objects are pairs $(\widehat{\mathrm{X}}, \sigma)$ consisting of a complex curve $\widehat{\mathrm{X}}$ and an anticonformal involution $\sigma$ that implements the action of the Galois group of $\mathbb{C}/\mathbb{R}$. In the case of $\mathcal{G}^{\mathrm{or}}$, we fix a global section of $\pi$ as an additional datum.

Next, since we are interested in correlation functions depending on insertion points, it is natural to consider simultaneously the family $\mathcal{M}_{g,m}$ of all complex curves with marked points that have the same topological type (i.e., genus $g$ and number $m$ of marked points) as $\widehat{\mathrm{X}}$. It is convenient to treat the positions of the insertion points and the moduli of the complex structure on the same footing. The curves that admit an involution $\sigma$ of the same type as $\widehat{\mathrm{X}}$ and for which the marked points are related by $\sigma$ form a submanifold $\mathcal{M}^{\sigma}_{g,m}$ of $\mathcal{M}_{g,m}$. (To be precise, one obtains [7] such a relation for Teichmüller spaces, rather than for moduli spaces.)

Given the modular tensor category $\mathcal{C}$, the complex modular functor [3] provides us with a vector bundle $\mathcal{V}$ with projectively flat connection on $\mathcal{M}_{g,m}$. We can now formulate the 'principle of holomorphic factorization' (which for certain classes of conformal field theories follows from chiral Ward identities that can formally be derived from an action functional [45]). It states that, first of all, the conformal surface X should be decorated in such a way that the double $\widehat{\mathrm{X}}$ has the structure of an object in the decorated cobordism category for the topological field theory based on $\mathcal{C}$. It then makes sense to require, secondly, that the correlation function is a certain global section of the restriction of $\mathcal{V}$ to $\mathcal{M}^{\sigma}_{g,m}$.

At this point, it proves to be convenient to use the equivalence of the complex modular functor and the topological modular functor $tft_{\mathcal{C}}$ based on the modular tensor category $\mathcal{C}$ [3] so as to work in a topological (rather than complex-analytic) category. We are thereby lead to the description of a correlation function on X as a specific vector $\mathrm{Cor}(\mathrm{X})$ in the vector space $tft_{\mathcal{C}}(\widehat{\mathrm{X}})$ that is assigned to the double $\widehat{\mathrm{X}}$ by the topological modular functor $tft_{\mathcal{C}}$. These vectors must obey two additional axioms:

- *Covariance*: Given any morphism $f : \mathrm{X} \to \mathrm{Y}$ in the relevant decorated geometric category $\mathcal{G}_{\mathcal{C}}$, we demand

$$\mathrm{Cor}(\mathrm{Y}) = tft_{\mathcal{C}}(f)(\mathrm{Cor}(\mathrm{X})).$$

- *Factorization*: Certain factorization properties must be fulfilled.

  We refer to [12], [13] for a precise formulation of these constraints.

The covariance axiom implies in particular that the vector $\mathrm{Cor}(\mathrm{X})$ is invariant under the action of the mapping class group $\mathrm{Map}(\mathrm{X}) \cong \mathrm{Map}(\widehat{\mathrm{X}})^{\sigma}$. This group, also called the relative modular group [4], acts genuinely on $tft_{\mathcal{C}}(\widehat{\mathrm{X}})$.

## 5. Surface holonomy

To find solutions to the covariance and factorization constraints on the vectors $\mathrm{Cor}(\mathrm{X}) \in tft_{\mathcal{C}}(\widehat{\mathrm{X}})$ we use the three-dimensional topological field theory associated to the modular tensor category $\mathcal{C}$. Thus we look for a (decorated) cobordism $(\mathrm{M_X}, \emptyset, \widehat{\mathrm{X}})$ such that the vector $tft_{\mathcal{C}}(\mathrm{M_X}, \emptyset, \widehat{\mathrm{X}})1 \in tft_{\mathcal{C}}(\widehat{\mathrm{X}})$ is the correlator $\mathrm{Cor}(\mathrm{X})$.

The three-manifold $\mathrm{M_X}$ should better not introduce any topological information that is not already contained in X. This leads to the idea to use an interval bundle as a "fattening" of the world sheet. It turns out that the following quotient of the interval bundle on $\widehat{\mathrm{X}}$, called the connecting (three-) manifold, is appropriate [11]:

$$\mathrm{M_X} = (\,\widehat{\mathrm{X}} \times [-1, 1]\,)/\langle(\sigma, t \mapsto -t)\rangle.$$

This three-manifold is oriented, has boundary $\partial \mathrm{M_X} \cong \widehat{\mathrm{X}}$, and it contains X as a retract: the embedding $\iota$ of X is to the fiber $t = 0$, the retracting map contracts along the intervals.

The connecting manifold $\mathrm{M_X}$ must now be decorated with the help of the decoration categories $\mathcal{H}om(A, A')$. We will describe this procedure for the oriented case only. The conformal surface X is decomposed by defect lines (which are allowed to end on $\partial$X) into various two-dimensional regions. There are two types of one-dimensional structures: boundary components of X and defect lines. Defect lines, in general, form a network; they can be closed or have end points, and in the latter case they can end either on the boundary or in the interior of X. Both one-dimensional structures are partitioned into segments by marked "insertion" points. The end points of defect lines carry insertions, too. Finally, we also allow for insertion points in the interior of two-dimensional regions.

To these geometric structures, data of the 2-category $\mathcal{F}rob_{\mathcal{C}}$ are now assigned as follows. First, we attach to each two-dimensional region a symmetric special Frobenius algebra, i.e. an object of $\mathcal{F}rob_{\mathcal{C}}$. To a segment of a defect line that separates regions with label $A$ and $A'$, respectively, we associate a 1-morphism in $\mathcal{H}om(A, A')$, i.e. an $A$-$A'$-bimodule. Similarly, to a boundary segment adjacent to a region labeled by $A$, we assign an object in $\mathcal{H}om(I, A)$, i.e. a left $A$-module. Finally, zero-dimensional geometric objects are labeled with 2-morphisms of $\mathcal{F}rob_{\mathcal{C}}$; in particular, junctions of defect lines with each other or with a boundary segment are labeled by 2-morphisms from the obvious spaces.

Two types of points, however, still deserve more comments: those separating boundary segments on the one hand, and those separating or creating segments of defect lines or appearing in the interior of two-dimensional regions on the other. These are the *insertion points* that were mentioned above. An insertion point $p \in \partial$X that separates two boundary segments labeled by objects $M_1, M_2 \in \mathcal{H}om(I, A)$ has a single preimage under the canonical projection $\pi$ from $\widehat{\mathrm{X}}$ to X; to the interval in $\mathrm{M_X}$ that joins this preimage to the image $\iota(p)$ of $p$ under the embedding $\iota$ of X into $\mathrm{M_X}$, we assign an object $U$ of the category $\mathcal{C} = \mathcal{H}om(I, I)$ of chiral data. To the insertion

point itself, we then attach a 2-morphism in the morphism space $\mathrm{Hom}(M_1 \otimes U, M_2)$ in $\mathcal{H}om(I, A)$.

An insertion point in the interior of X has two preimages on $\widehat{\mathrm{X}}$; these two points are connected to $\iota(p)$ by two intervals. To each of these two intervals we assign to each of these two intervals an object $U$ and $V$, respectively, of the category $\mathcal{C}$ of chiral data. In the oriented case, the global section of $\pi$ is used to attribute the two objects $U$, $V$ to the two preimages. (For the unoriented case, the situation is more involved; in particular, the Jandl structure on the relevant Frobenius algebra enters the prescription.) We now first consider an insertion point separating a segment of a defect line labeled by an object $B_1 \in \mathcal{H}om(A, A')$ from a segment labeled by $B_2 \in \mathcal{H}om(A, A')$. We then use the left action $\rho_l$ of $A$ and the right action $\rho_r$ of $A'$ on the bimodule $B_1$ to define a bimodule structure on the object $U \otimes B_1 \otimes V$ of $\mathcal{C}$ by taking the morphisms $(\mathrm{id}_U \otimes \rho_l \otimes \mathrm{id}_V) \circ (c^{-1}_{U,A} \otimes \mathrm{id}_{B_1} \otimes \mathrm{id}_V)$ and $(\mathrm{id}_U \otimes \rho_r \otimes \mathrm{id}_V) \circ (\mathrm{id}_U \otimes \mathrm{id}_{B_1} \otimes c^{-1}_{A',V})$ as the action of $A$ and $A'$, respectively, where $c$ denotes the braiding isomorphisms of $\mathcal{C}$. The insertion point separating the defect lines is now labeled by a 2-morphism in $\mathrm{Hom}(U \otimes B_1 \otimes V, B_2)$, i.e. by a morphism of $A$-$A'$-bimodules.

To deal with insertion points in the interior of a two-dimensional region labeled by a Frobenius algebra $A$, we need to invoke one further idea: such a region has to be endowed with (the dual of) a triangulation $\Gamma$. To each edge of $\Gamma$ we attach the morphism $\Delta \circ \eta \in \mathrm{Hom}(\mathbf{1}, A \otimes A)$, and to each trivalent vertex of $\Gamma$ the morphism $\varepsilon \circ m \circ (m \otimes \mathrm{id}_A) \in \mathrm{Hom}(A \otimes A \otimes A), \mathbf{1})$. This pattern is characteristic for notions of surface holonomy. It has appeared in lattice topological field theories [22] and shows up in the surface holonomy of bundle gerbes as well. (For more details, references, and the relation to the Wess–Zumino term of WZW conformal field theories in a Lagrangian description, see [23].)

Now each of the insertion points $p$ that we still need to discuss is located inside a two-dimensional region labeled by some Frobenius algebra $A$ or creates a defect line. For the first type of points, we choose the triangulation such that an $A$-ribbon passes through $p$; to $p$ we then attach a bimodule morphism in $\mathrm{Hom}(U \otimes A \otimes V, A)$, with $U$ and $V$ objects of $\mathcal{C}$ as above. To a point $p$ at which a defect line of type $B$ starts or ends, we attach a bimodule morphism in $\mathrm{Hom}(U \otimes A \otimes V, B)$ and in $\mathrm{Hom}(U \otimes B \otimes V, A)$, respectively.

We have now obtained a complete labelling of a ribbon graph in the connecting manifold $\mathrm{M_X}$ with objects and morphisms of the modular tensor category $\mathcal{C}$; in other words, a cobordism from $\emptyset$ to $\widehat{\mathrm{X}}$ in the decorated geometric category $\mathcal{G}_{\mathcal{C}}$. Applying the modular functor for the tensor category $\mathcal{C}$ to this cobordism, we obtain a vector

$$\mathrm{Cor(X)} = tft_{\mathcal{C}}(\mathrm{M_X})\, 1 \in tft_{\mathcal{C}}(\widehat{\mathrm{X}}).$$

This is the prescription for RCFT correlation functions in the TFT approach. It follows from the defining properties of a symmetric special Frobenius algebra that Cor(X) does not depend on the choice of triangulation; for details see [12].

## 6. Results

On the basis of this construction one can establish many further results. Let us list some of them, without indicating any of their proofs:

[17] Of particular interest are the correlators for X being the torus or the annulus without field insertions, but possibly with defect lines. From these "one-loop amplitudes" one can derive concrete expressions for partition functions of boundary, bulk and defect fields.

The coefficients of these partition functions in the distinguished basis of the zero-point blocks on the torus that is given by characters can be shown to be equal to the dimensions of certain spaces of 2-morphisms of the 2-category $\mathcal{F}rob_{\mathcal{C}}$. Thus in particular they are non-negative integers.

In fact, one recovers expressions that had also been obtained in an approach based on subfactors [29], [5]. Moreover, these coefficients can be shown to satisfy other consistency requirements like forming so-called NIMreps of the fusion rules.

[18] To extend these results to unoriented (in particular, to unorientable) surfaces one must specify as additional datum a Jandl structure on the relevant Frobenius algebra. One can then e.g. compute the partition functions for the Möbius strip and Klein bottle. Their coefficients in the distinguished basis of zero-point torus blocks are integers, and for CFT models which serve as building blocks of type I string theories, these partition functions combine with the torus and annulus amplitudes in a way consistent with an interpretation in terms of state spaces of the string theory.

[19] The expressions for correlation functions can be made particularly explicit for conformal field theories of simple current type [39], which correspond to Frobenius algebras for which every simple subobject is invertible. Eilenberg–Mac Lane's [9] abelian group cohomology turns out to provide a crucial tool for analyzing this case.

It should be stressed, though, that the TFT approach to RCFT correlators treats the simple current case and other conformal field theories (i.e. those having an 'exceptional modular invariant' as their torus partition function) on an equal footing.

[20] By expressing some specific correlation functions for the sphere, the disk, and the real projective plane through the appropriate (two- or three-point) conformal blocks, one can derive explicit expressions for the coefficients of operator product expansions of bulk, boundary, and defect fields.

[12] For arbitrary topology of the surface X the correlators obtained in the TFT construction can be shown to satisfy the covariance and factorization axioms that were stated at the end of Section 4.

[15] The Picard group of the tensor category $\mathcal{H}om(A, A)$ describes symmetries of the full conformal field theory that is associated to $A$. The fusion ring $K_0(\mathcal{H}om(A, A))$ of that category contains information about Kramers–Wannier-like dualities as well.

## 7. Conclusions

The TFT approach to the construction of CFT correlation functions, which represents CFT quantities as invariants of knots and links in three-manifolds, relates a general paradigm of quantum field theory to the theory of (symmetric special) Frobenius algebras in (modular) tensor categories. It thereby constitutes a powerful algebraization of many questions that arise in the study of conformal field theory. As a result, one can both make rigorous statements about rational conformal field theories and set up efficient algorithms for the computation of observable CFT quantities.

A rich dictionary relating algebraic concepts and physical notions is emerging. It includes in particular the following entries:

- The classification of (oriented) full conformal field theories for given chiral data $\mathcal{C}$ amounts to the classification of Morita classes of Frobenius algebras in $\mathcal{C}$.
  As a special case, the classification of those theories whose torus partition function is "of automorphism type" amounts to determining the Brauer group of the category $\mathcal{C}$.

- The Picard group of the tensor category $\mathcal{H}om(A, A)$ acts as a symmetry group on the full conformal field theory associated to $A$, while the fusion ring of this tensor category contains information about Kramers–Wannier like dualities.

- Deformations of the conformal field theory are controlled by the Davydov–Yetter cohomology of the pair $(\mathcal{C}, \mathcal{C}_A)$.

The structure of this dictionary gives us confidence that some of the insights of the TFT approach – though, unfortunately, not most of the proofs – will still be relevant for the study of conformal field theories that are not rational any more.

# Soliton dynamics and scattering

Avy Soffer*

**Abstract.** A survey of results and problems of soliton dynamics in dispersive and hyperbolic nonlinear PDE's and the related spectral and scattering theory. I focus on the problem of large time behavior of the nonlinear Schrödinger equation, with both solitary and radiative waves appearing in the solution. The equations are nonintegrable in general and in arbitrary dimension. I will formulate the main conjectures relevant to soliton dynamics.

**Mathematics Subject Classification (2000).** Primary 35Qxx.

**Keywords.** Solitons, NLS, asymptotic-completeness, dispersive waves, asymptotic stability.

## 1. Introduction

The advances in spectral and scattering theory of the last 20 years, combined with the intense physical research based on nonlinear dispersive equations have led to major progress in nonlinear dynamics.

The goal of understanding the large time behavior of all solutions of nonlinear dispersive equations is now pursued on many levels: global existence theory, nonlinear scattering, new solutions, applications.

Furthermore, the new applications of NLPDE in physics generate a host of new research in the physics literature, e.g. experimental [12], [9], [30] and theoretical [57], [2], [29].

It is then fair to say that we are witnessing a new (golden) generation that focusses on complex collective systems behavior, the age of coherent structures.

Consider the following generic form of dispersive NLPDE:

$$i\,\partial_t u = Hu + F(u)u$$

with initial data in (say) some Hilbert space $\mathcal{H}$, typically (vector valued) Sobolev space.

$H$ is a self-adjoint (matrix) operator in general.

For example NLS (semilinear):

$$H = -\Delta, \quad F(u) \sim \sum_{i=1}^{N} \lambda_i |u|^{p_i},$$

$$\mathcal{H} = H^1(\mathbb{R}^n);$$

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

and the NLKG equation (hyperbolic type):

$$\partial_t \begin{pmatrix} u \\ \dot{u} \end{pmatrix} = \begin{pmatrix} 0 & 1 \\ H_m & 0 \end{pmatrix} \begin{pmatrix} u \\ \dot{u} \end{pmatrix} + \begin{pmatrix} 0 & 0 \\ F(u) & 0 \end{pmatrix} \begin{pmatrix} u \\ \dot{u} \end{pmatrix},$$

$$H_m = -\Delta + m^2.$$

In general we expect that if the $\lambda_i > 0$ and the $p_i$ are not too large/small that global existence holds, that uniqueness holds and scattering theory holds and all solutions disperse like free waves for large time [54]. When some $\lambda_i$ are negative $F$ is attractive and blow-up occurs in general, in finite time, for data not too small.

However a fundamental new phenomena appears: the dispersion by $H$ can be exactly cancelled by the focusing of $F$, to create a new type of localized in space solutions, smooth, uniformly in time. I shall refer to these solutions as *coherent structures or solitons*.

**Example 1.1.** NLS solitons, KG/SG kinks, vortices, monopoles, breathers, topological solitons, hedgehogs, skyrmions, blackholes, ... and the more recent more exotic coherent structures: compactons, peakons, noncommutative solitons. [31], [54], [53].

**Definition 1.1.** A localized solution/soliton/coherent structure is a solution of a dispersive equation satisfying

$$\lim_{R\to\infty} \left\{ \sup_t \|\chi(|x| > R)u(x,t)\|_{\mathcal{H}} \right\} = 0.$$

To understand how fundamental are coherent structures we have the following conjecture:

**Grand Conjecture** (Asymptotic Completeness). Generic asymptotic states are given by independently (freely) moving coherent structures and free radiation.

**Comments.** 1) The Grand Conjecture states that besides free waves only these coherent structures can emerge as $t \to \infty$.

2) We are very far from proving such a result for any interesting equation.

In making progress in this direction I will formulate another "simple" conjecture that I expect to play an important role:

**Petite Conjecture.** Localized solutions of NLS are almost periodic in time.

**Comments.** 1) I used "NLS" and not "dispersive" to avoid giving a rigorous definition of "dispersive".

2) This conjecture is a nonlinear analog of the geometric characterisation of bound states in linear theory originally proposed by Ruelle and developed as RAGE theorem.

It also states that coherent structures/solitons are the "bound states" of dispersive wave equations.

3) While such a result follows for data near a stable soliton solution of NLS [40], [37], [35], [10], [45], [46], [4], [5], [36] it is not known for even a single equation in such generality.

4) One can replace the localization assumption by the stronger condition

$$\sup_t \|\chi(|x| > R)u(x,t)\|_{\mathcal{H}} \leq cR^{-m}, \quad R > 1,$$

some $m > 0$, or even exponential decay in $R$ for many equations.

## 2. Asymptotic stability

The kind of problems we do understand are small perturbations of the putative asymptotic states described above. That is, we can prove that if the initial data is close to $N$ solitons moving independently and small perturbation it will propagate as expected when $t \to \infty$.

Next, I shall describe the developments and arguments leading to this result.

So consider the NLS in three or more dimensions, here we follow [40]:

$$i\frac{\partial \psi}{\partial t} = -\Delta\psi - F(|\psi|^2)\psi \quad x \in \mathbb{R}^n \text{ and } n \geq 3. \tag{1}$$

If $F$ has a negative (attractive) part the equation will have, in general, coherent structure solutions, such as solitons. To find (some of) them, we look for time periodic solutions

$$\psi = e^{i\omega t}\phi_\omega(x),$$

which gives

$$-\omega\phi_\omega = -\Delta\phi_\omega - F(|\phi_\omega|^2)\phi_\omega.$$

In general $\phi_\omega$ will be localized (at least as an $L^2$-function) for $\omega > 0$.

Thanks to the pioneering works of [8], [53], [3], [24], [32], [17] we know a great deal of information about such solitons: existence, decay at infinity, uniqueness of the positive solutions, symmetry and more.

By Galilean invariance

$$\psi_\sigma \equiv e^{i\vec{v}\cdot x - i\frac{1}{2}(|v|^2-\omega)t + i\gamma}\phi_\omega(x - \vec{v}t - \vec{a})$$

are all solutions of NLS;

$$\sigma = (\vec{u}, \gamma, \vec{a}, \omega) \in \mathbb{R}^n \times \mathbb{R} \times \mathbb{R}^n \times \mathbb{R}.$$

$\psi_\sigma$ are moving solitons, with velocity $\vec{v}$ localized at $\vec{a}$ (at time 0), with energy $\omega$ and phase $\gamma$. The general conjecture then states that generic solutions of NLS are

asymptotic to a sum of such moving solitons plus a free wave (a solution of the free Schrödinger equation corresponding to $F = 0$).

A weaker but useful result is orbital *stability* of solitons: we would like to know if a small perturbation of a soliton (as initial data) leads to a nearby, soliton (in $\sigma$ space) up to a phase, for all times [7], [13], [14], [18], [19], [20], [58], [59].

It turns out that in many cases stability follows from *linear stability* :

First we linearize the equation around a soliton:

$$\psi \equiv e^{i\theta}(\phi_\omega + R)$$

and deriving (the linear part of) the equation of $R$: since there will be both $R$ and $\bar{R}$ terms in the equation we complexify to get:

$$i\frac{\partial}{\partial t}\begin{pmatrix} R \\ \bar{R} \end{pmatrix} = \mathcal{H}\begin{pmatrix} R \\ \bar{R} \end{pmatrix},$$

$$\mathcal{H} \equiv \begin{pmatrix} L+ & W(x) \\ -W(x) & -L_+ \end{pmatrix},$$

$$L_+ = -\Delta + \omega - F(\phi_\omega^2) - F'(\phi_\omega^2)\phi_\omega^2,$$

$$W(x) = -F'(\phi_\omega^2)\phi_\omega^2.$$

Since $\mathcal{H}$ is not self-adjoint we do not have $L^2$ conservation under such $\mathcal{H}$. Linear stability states that on the complement of the root space of $\mathcal{H}$ the solutions are uniformly bounded in $L^2$:

$$\sup_t \|U(t)Pf\|_{L^2} \leq c\|f\|_{L^2}$$

where $P$ is the projection on $(N^*)^\perp$ and $N$ is the root space of $\mathcal{H}$,

$$N \equiv \bigcup_{\ell \geq 1} \ker \mathcal{H}^\ell.$$

Such analysis can be made for other coherent structures in a similar way [vortices, kinks, blackholes,. . . .].

To proceed with the problem of asymptotic stability and completeness we are going to need much more detailed spectral/scattering results for $e^{i\mathcal{H}t}P$. Proving such results for various types of $\mathcal{H}$ that appear in applications is in general difficult, and while there are many works in this direction from the last few years, a lot is left open, see the review [42].

We need to prove

a) Absence of embedded eigenvalues in the continuous spectrum of $\mathcal{H}$.

There are remarkably detailed and complete results for self-adjoint Schrödinger operators on $\mathbb{R}^n$ and manifolds [22], [41].

The extension to matrix operators such as $\mathcal{H}$ is still eluding us, and a general new approach would be of great interest to the field, see however [42].

b) Absence of threshold resonances. This is related to the next condition.

c) Dispersive estimates:

$$\|U(t)P\psi_0\|_{L^\infty} \lesssim t^{-n/2}\|\psi_0\|_{L^1}.$$

Weaker estimates are also of interest, such as

$$\|\langle x\rangle^{-\sigma}U(t)P\langle x\rangle^{-\sigma}\| \lesssim t^{-\sigma}, \quad t > 1.$$

The subject of dispersive estimates is another fast growing field of research inspired by soliton dynamics, see the latest review of Schlag [42].

Such $L^p$-dispersive estimates were proved for

$$H = -\Delta + V \text{ on } \mathbb{R}^n, \quad n \geq 3,$$

for a quite general class of $V$ in [23]. It was then extended (also to $L^p$ boundedness of wave operators) in [60]; further important new extension is due to [38]. For matrix operators see [39], [42]. All the results which are known require enough decay at $\infty$ of the potential perturbations. The decay is determined by the decay of the soliton.

NLS solitons decay exponentially and so they are included.

However other types of coherent structures like vortices, monopoles etc. lead to slowly decaying potentials, and so the dispersive theory for both Schrödinger and matrix operators is still lacking the generality needed.

What is more, the above stated decay also requires the knowledge of absence of threshold resonances, a difficult problem to solve for specific operators. In fact, in some situations (e.g. kink scattering) such resonances are present, and therefore the asymptotic stability theory of kinks requires as yet unknown modifications.

## 3. The method of modulation equations

Presently, the modulation equations approach is the only method that is used to prove asymptotic stability of solitons. The first step is the *Ansatz* and the associated *orthogonality condition*.

**Ansatz.**

$$\psi(t) = S_{\sigma(t)} + R(t).$$

Here $S_\sigma$ is a soliton with parameters $\sigma$.

**Orthogonality condition.** $R(t)$ belongs to the range of $P_t$ so it is orthogonal to the root space adjoint $N^*$.

**Remark 3.1.** When the soliton is small we can replace $P_t$ by $P_{t=0}$ [45], [46]. Under favorable conditions we can derive a closed system of equations for $R(t), \sigma(t)$. The equation for $\mathbb{R} \equiv (R(t), \bar{R}(t))$ then has the form

$$i\partial_t \mathbb{R}(t) = \mathcal{H}\mathbb{R}(t) + \mathcal{NL}(\mathbb{R}(t))$$

where $\mathcal{NL}(\mathbb{R}(t))$ is a sum of quadratic and higher order terms in $\mathbb{R}$, and terms of the form

$$O(\dot{\sigma}\mathbb{R}).$$

The $\sigma$-equation is a system of ODE's:

$$\dot{\sigma}(t) = \mathcal{K}(t)\sigma(t) + \mathcal{NL}(\mathbb{R}, \sigma).$$

The idea for solving such a system is based on bootstrap and smallness. Suppose that we can prove that the solutions of the PDE for $(\mathbb{R}(t))$ is indeed dispersive:

$$|||\mathbb{R}(t)||| = O(t^{-m})$$

where $|||\cdot|||$ is typically a sum of $L^P$ and local decay norms.

For example, for $p = \infty$, and three or more dimensions we expect $m = 3/2$ at least. Then, plugging this estimate for $\mathbb{R}(t)$ into the $\mathcal{NL}(\mathbb{R}, \sigma)$ terms of the ODE we shall be able to prove that

$$\dot{\sigma}(t) \text{ is in } L^1(dt) \text{ (excluding } \dot{\gamma})$$

and perhaps get some pointwise decay.

Then these estimates on $\dot{\sigma}$ should be sufficient to control the $O(\dot{\sigma}R)$ terms in the PDE. Smallness can then be used to close the above self-consistent system of estimates.

The key to implementing this procedure is proving sufficient decay estimates for the PDE, assuming the decay of $\dot{\sigma}$. This leads us to study the following general problem:

$$i\frac{\partial R}{\partial t} = \mathcal{H}PR + P\mathcal{NL}(R)$$

where $P$ is the projection on $(N^*)^{\perp}$.

When $R$ is small, we try to solve this problem by Duhamel type identities

$$R(t) = e^{-i\mathcal{H}Pt}R(0) - i\int_0^t e^{-i\mathcal{H}P(t-s)}P\mathcal{NL}(R(s)\,ds.$$

The starting point is then knowing the basic estimates for

$$e^{-i\mathcal{H}Pt}$$

which is the linear problem described before.

There are many situations where the range of $P$ includes, besides the continuous spectrum of $\mathcal{H}$, some point spectrum. In this case, further decomposition of the solution is needed.

This will be described in the next section.

So consider the case when $P = P_c(\mathcal{H})$. We need, besides the $L^p$ decay estimates for $\mathcal{H}$, to estimate the nonlinear terms.

When the nonlinearities are of sufficient power decay (near zero) this is not difficult.

However, notice that we always need to deal with a term of the form

$$\sum SR^2.$$

When the soliton $S$ is well localized, local decay pointwise in time plus some $L^p$ decay is sufficient. The complications arise in cases where there is not enough decay or when $S$ is not well localized. For example the kink problem leads to $S$ that is of order 1 at infinity! Hence all the decay should come from $R^2$, which is not possible in 1-dimension. For this and other equally subtle reasons the kink asymptotic stability is completely open. In particular, one needs to solve the *long range* nonlinear scattering problem. A lot of work was done on this problem by Ginibre–Velo–Naumkin [16], [21] and collaborators. Recently Delort [11] worked out the problem for NLKG in 1-dimension. A new simpler and general approach was very recently developed in [26], [27], [28] ]

In the simplest cases we end up with estimating

$$R(t) \sim c^{-i\mathcal{H}_c t} R(0) - i \int_0^t e^{-i\mathcal{H}_c(t-s)} O(\chi R^2(s) + R(s)^p + O(s^{-\alpha})R(s))ds$$

in $L^p$.

A particularly effective way of doing it, is to use the mixed norm $L^\infty + L^2$.

We then get

$$\|R(t)\|_{L^2+L^\infty} \leq C\|R(0)\|_{L^2+L^1}\langle t\rangle^{-n/2} + c\int_0^t \frac{ds}{\langle t-s\rangle^{n/2}}\|O(\cdot)\|_{L^2+L^1}\,ds.$$

In three or more dimensions, $n/2 > 1$.

Since for all $s$ large enough and any $\varepsilon > 0$,

$$\begin{aligned}&\|\mathcal{O}(\cdot)\|_{L^2+L^1}\\ &\quad\leq C\langle s\rangle^{-n/2}\sup_{0\leq s'\leq s}\{\|R(s')\|_{2+\infty}^2 + \|R(s')\|_{2+\infty}^{2+m} + \|R(s')\|_p^p + \varepsilon\|R(s')\|_{2+\infty}\}\end{aligned}$$

provided $\left(\frac{n}{2} - \frac{n}{p}\right)\cdot p \geq \frac{n}{2}$ implies $p \geq 3$. $\|R(t)\|_{L^2+L^\infty}$ is $O(t^{-n/2})$ for $R(o)$ small.

It is possible to improve the estimates to lower values of $p$, by proving only that $\|R\|_q \leq ct^{-1-\varepsilon}$ for

$$q \text{ such that } \frac{n}{2} - \frac{n}{q} = 1 + \varepsilon.$$

A different approach, which applied to nonlocalized perturbations of solitons is based on using Strichartz estimates instead of pointwise bounds. See [15].

## 4. Selection of the ground state, spurious eigenvalues

In general there is more than one (family of) localized states to the nonlinear equation.

Examples include

$$i\frac{\partial\psi}{\partial t} = (-\Delta + V(x))\psi + \lambda F(|\psi|)\psi \tag{2}$$

with $H = -\Delta + V(x)$ having more than one (negative) eigenvalue in its spectrum. Another example is the nonlinear wave equation analog of (2):

$$(\partial_t^2 - \Delta + V(x) + m^2)u = \lambda F(u)u \tag{3}$$

with $-\Delta + V(x) + m^2 > 0$, and having as before one or more eigenvalues.

Other examples include the NLS with excited state solitons etc., spurious eigenvalues, including embedded eigenvalues in the spectrum of the linearization. In these cases the grand conjecture is more complicated to state.

The generic behavior we expect is that the asymptotic states are combinations of ground state (families) solitons *only* plus free radiation.

This was proved for the NLWE (3) in the case of one bound state in 3-dimensions in [49]. The techniques developed in [49] will be briefly described below; they were used to deal with the more involved NLS (2) in the case of two bound states in [51], [56] and some results were obtained for more then two bound states in [55]. It also applied to the *linear* resonance problem in QM [47], [48], [50], [33], [34], [18], [6]. Very recently an experiment was done confirming the predictions below [30], [52].

We use modulation equations again. Consider the problem (2): Time periodic soliton solutions, nonlinear bound states, bifurcate from the linear eigenstates of $-\Delta + V(x)$. For each $E_i$, $i = 0, 1$, we solve

$$(-\Delta + V(x))\psi_{E_i} + \lambda F(|\psi_{E_i}|^2)\psi_{E_i} = E_i\psi_{E_i} \tag{4}$$

such that $E_i \to E_{i*}$ as $\lambda \to 0$, where $(i = 0, 1)$

$$(-\Delta + V(x))\psi_i = E_{*_i}\psi_i \ \|\psi_i\| = 1.$$

We assume the initial data is small in $H^s$, $(s \geq 2)$ and $2E_{1*} - E_{0*} > 0$.

We begin with the Ansatz $\phi(t) \equiv e^{-i\theta(t)}[\psi_0(t) + \psi_1(t) + \phi_2(t)]$ where $\psi_0(t) \equiv \psi_{E_0(t)}$ is a solution of the ground state eigenvalue equation with energy $E_0(t)$, at time $t$. $E_0(t)$ will be determined later by orthogonality conditions [Se 7, 5, 1]. Similarly $\psi_1(t)$ is an excited state eigenvector with eigenvalue $E_1(t)$. $\theta(t) \equiv \theta_0(t) + \tilde{\theta}(t)$; $\theta_0(t) = \int_0^t E_0(s)ds$. $\tilde{\theta}(t)$ will be chosen appropriately; it includes (logarithmic) divergent phase. Substitution of the above Ansatz for $\phi$ into (1), and complexifying the equations $[\phi_2 \to (\phi_2, \bar{\phi}_2) \equiv \Phi_2(t)$, $\psi_j \to (\psi_j, \bar{\psi}_j) \equiv \Psi_j(t)$ etc.] we derive

$$i\partial_t\Phi_2(t) = \mathcal{H}_0(t)\Phi_2(t) - i\partial_t\Psi_0 - \left[((E_0 - E_1) + \partial_t\tilde{\theta})\sigma_3 + i\partial_t\right]\Psi_1 + \vec{F}_{NL},$$

where $\vec{F}_{\mathcal{NL}}$ is nonlinear in $\Phi_2$, $\Psi_0$, $\Psi_1$, $\tilde{\theta}$ and $\mathcal{H}_0(t)$ is given by the matrix operator

$$\sigma_3 \begin{pmatrix} H - E_0(t) + 2\lambda|\psi_0(t)|^2 & \lambda\psi_0^2(t) \\ \lambda\bar{\psi}_0^2(t) & H - E_0(t) + 2\lambda|\psi_0(t)|^2 \end{pmatrix} \tag{5}$$

where $\sigma_3$ is the Pauli matrix diag$(1, -1)$. We consider the spectrum of $\mathcal{H}_0(t)$ for fixed $t$, and $|\psi_0| \equiv |\alpha_0|$ small: (a) The continuous spectrum extends from $-\mu$ to $-\infty$, and $\mu$ to $\infty$ where $\mu \equiv E_1 - E_0 + O(|\alpha_0|^2)$. The discrete spectrum is $\{0, -\mu, \mu\}$, with $0 < |\mu| < |E_0|$ by assumption. (b) Zero is a generalized eigenvalue of $\mathcal{H}_0$, with generalized eigenspace spanned by $\{\sigma_3\Psi_0, \partial_{E_0}\Psi_0\}$.

The discrete spectral subspace has dimension four. Therefore, $\Psi_2$ which lies in the continuous spectral part of $\mathcal{H}_0(t)$, is constrained by four orthogonality conditions. Furthermore $\partial_t\tilde{\theta}$ is chosen to remove divergent logarithmic phase contributions. In the weakly nonlinear (perturbative) regime, bound states have expressions $\psi_{E_j} = \alpha_j(\psi_{j*}(x) + g|\alpha_j|^2\psi_j^{(1)}(x) + \mathcal{O}(g^2|\alpha_j|^4))$ and $E_g = E_{j*} + \mathcal{O}(|\alpha_j|^2)$. The system for $\Phi_2$ and $\vec{\alpha} = (\vec{\alpha}_0, \vec{\alpha}_1)$ can be written in the form $i\partial_t\vec{\alpha} = \mathcal{A}(t)\vec{\alpha} + F_\alpha$, $i\partial_t\Phi_2 = \mathcal{H}(t)\Phi_2 + F_\Phi$ .

To proceed further we decompose $\Phi_2$ into its continuous spectral (dispersive) part, $\eta \in \mathcal{H}_0(T)$, and its components along the discrete modes. The latter are higher order and controllable. Thus NLS at low energy is equivalent to a system of the form:

$$\begin{aligned} i\partial_t\eta &= \mathcal{H}_0(T)\eta + \mathcal{F}_\eta(t; \alpha_0, \beta_1, \eta) + \sigma(t)\eta, \\ i\partial_t\beta_1 &= 2\lambda\langle\psi_{0*}, \psi_{1*}^3\rangle|\beta_1|^2\alpha_0 e^{i\lambda_+ t} \\ &\quad + 2\lambda\langle\psi_{0*}\psi_{1*}^2, \pi_1\Phi_2\rangle\bar{\beta}_1\alpha_0 e^{2i\lambda_+ t} + \mathcal{R}_0, \\ i\partial_t\alpha_0 &= \lambda\langle\psi_{0*}^2, \psi_{1*}^2\rangle e^{-2i\lambda_+ t}\beta_1^2\overline{\alpha}_0 \\ &\quad + \lambda\langle\psi_{0*}\psi_{1*}^2, \Phi_2\rangle\beta_1^2 e^{-2i\lambda_+ t} + \mathcal{R}_1, \end{aligned} \tag{6}$$

where $\mathcal{R}_j$ denotes corrections of a similar form and higher order.

The above system can be viewed as an infinite dimensional Hamiltonian system consisting of two subsystems: a finite dimensional subsystem governing "oscillators", $(\alpha_0, \beta_1)$, and an infinite dimensional subsystem governing the field, $\eta$.

The coupled system (6) can not be solved or understood by looking at the linear terms only. This is due to the fact that the asymptotic behavior is determined by a process, nonlinear, in which the excited state part of the solution decays into radiation and ground state part. We therefore need to derive effective equations for the ground and excited state parts, which include the dissipative effects due to coupling to radiation. see [49], [44] see also [43], [1], [25].

To arrive at the reduction, we solve the $\eta$-equation, making explicit all terms through second order in $g$, using the Green's function $G(t, t') = e^{-i\mathcal{H}_0(T)(t-t')}$. We focus on the key terms coming from the sources in $\mathcal{F}_\eta$ or the type $\alpha_0^i\alpha_1^j$, $0 \le i, j \le 2$

and having oscillatory phases $e^{im_{ij}t}$. Their contribution to $\eta$ is of the form

$$\sim \int_0^t e^{-i\mathcal{H}_0(T)(t-t')}|\chi\rangle e^{im_{ij}(t')}\alpha_0^i(t')\alpha_1^j(t')dt'$$

where $\alpha_0$, $\alpha_1$ is a component of either $\vec{\alpha}_0$ or $\vec{\alpha}_1$, where $|\chi\rangle$ is an (exponentially localized) function of position expressible in terms of $\psi_{0*}$ and $\psi_{1*}$. We insert this solution into the $\alpha_0$-, $\alpha_1$-equations, in place of $\Phi_2$. We obtain integro-differential equations for $\alpha_0$, $\alpha_1$, $(\beta_1)$. The resulting terms of the above form are solutions to a forced linear system and among the forcing terms there are (coupled) oscillatory terms with the frequency $\omega_*$, which is resonant with the continuous spectrum. Internal dissipation resulting in nonlinear resonant energy transfer from the excited state to the ground state and to dispersive radiation is derived from these resonant terms; see also the derivation of internal dissipation in both linear and nonlinear resonance theories recently developed by us [46], [44]. This dissipation coefficient is $\Gamma$, the rate of decoherence and relaxation. The above described scheme gives $i\partial_t\tilde{\alpha}_0 = (-\Lambda + i\Gamma) \times |\tilde{\beta}_1|^2\tilde{\alpha}_0 + \tilde{\mathcal{R}}_0(t)$, $i\partial_t\tilde{\beta}_1 = 2(\Lambda - i\Gamma)|\tilde{\alpha}_0|^2|\tilde{\beta}_1|^2\beta_1 + \tilde{\mathcal{R}}_1(t)$.

Introducing the squared projections of the system's state onto the ground state and excited states, $P_0 \equiv |\tilde{\alpha}_0|^2$, $P_1 \equiv |\tilde{\beta}_1|^2$ we obtain NLME. The system is analyzed in terms of renormalized powers $\mathcal{Q}_0$ and $\mathcal{Q}_1$, for which it is shown that there exist transition times $t_0$ and $t_1$, such that $\mathcal{Q}_0(t)$ decays rapidly on $[0, t_0]$, $\mathcal{Q}_0(t)/\mathcal{Q}_1(t)$, grows rapidly on $[t_0, t_1]$, and then finally on $[t_1, \infty)$ the following system governs: $\partial_t\mathcal{Q}_0 = 2\Gamma\mathcal{Q}_0\mathcal{Q}_1^2$, $\partial_t\mathcal{Q}_1 = -4\Gamma\mathcal{Q}_0Q_1^2$. This gives $Q_0 \uparrow Q_0(\infty)$ and $Q_1 \downarrow 0$ at rates discussed above.

$$\Gamma = \pi\lambda^2|(e_{\omega*}, \psi_{1*}^2\psi_{0*})|^2$$

for $F(|\psi|^2) \equiv |\psi|^2$. Here $e_{\omega*}$ is the generalized eigenvalue of $H_0$ at energy $\omega* = 2E_{1*} - E_{0*}$.

## 5. Concluding remarks

Nonlinear dispersive equations play a prominent role in many fields of physics, including BEC theory, nonlinear optics, large molecule dynamics (e.g. DNA) and more.

The mathematical aspects of such equations is remarkably rich, and contributed new, challenging directions for PDE, mathematical physics spectral and scattering theory and more. In particular, the problem of large time dynamics of interacting solitons and more general coherent structures is witnessing a major progress in the last 15–20 years. Yet, we are only at the beginning of developing the mathematical tools and theories to deal with the general aspects of soliton dynamics. Besides the many problems I listed in the previous sections, other topics worth mentioning are: systems of equations (e.g. coupled Maxwell–Dirac equations and BEC coupled to vapor at finite temperature), solitons dynamics on curved spaces, like arbirarily shaped optical fibre (monoples and other topological solitons), and discrete space modeles.

# Hypocoercive diffusion operators

Cédric Villani

**Abstract.** In many problems coming from mathematical physics, the association of a degenerate diffusion operator with a conservative operator may lead to dissipation in all variables and convergence to equilibrium. One can draw an analogy with the well-studied phenomenon of hypoellipticity in regularity theory, and actually both phenomena have been studied together. Now a distinctive theory of "hypocoercivity" is starting to emerge, with already some striking results, and several challenging open problems.

**Mathematics Subject Classification (2000).** Primary 35B40; Secondary 35K70, 76P05.

**Keywords.** Hypocoercivity, hypoellipticity, diffusion equations, spectral gap, logarithmic Sobolev inequalities, Fokker–Planck and Boltzmann equations, $H$ Theorem.

## Introduction

During the past decade, considerable progress has been achieved in the qualitative study of diffusion equations in large time, be it for linear or nonlinear models. Quantitative functional methods have become especially popular. Here are some of the keywords in the field: spectral gap (Poincaré) inequalities, logarithmic Sobolev inequalities, analysis of entropy production, gradient flows, rescalings. Most of the time, estimates on the rate of convergence are established in the end by means of some Gronwall-type inequality $dE/dt \leq -\Phi(E)$, where $E$ is a Lyapunov functional for the system. Among a large literature, I shall only quote some of my own works: entropy production estimates for the spatially homogeneous Boltzmann equation, in collaboration with Giuseppe Toscani [25], [26], [28]; and for certain nonlinear diffusion equations with a convex mean-field interaction, in collaboration with José Antonio Carrillo and Robert McCann [2].

While these subjects are still very active, in this text I shall focus on a newer direction of research which has emerged only a few years ago, and can be loosely described as "the role of the non-dissipative part in the dissipation process".

Indeed, it happens not so rarely that the dissipative properties of an equation are strongly influenced by some of the conservative terms in this equation. This statement in itself is nothing new, since it is almost obvious in the context of hydrodynamics (dissipativity in Navier–Stokes is certainly considerably more complex than in the heat equation). In the context of diffusion equations, the interaction between dissipative and conservative terms is also well-known, since it is at the basis of the phenomenon of

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

*hypoellipticity*. To make the discussion a bit more precise, let me recall a particularly simple theorem of hypoelliptic regularization, which is a direct consequence of Lars Hörmander's celebrated regularity theorem [20]. Let $A_1, \dots, A_k$ and $B$ be $C^\infty$ vector fields on $\mathbb{R}^N$, identified with derivation operators, and let $L = -\sum A_j^2 + B$. If the rank of $(A_1, \dots, A_k)$ is strictly less than $N$, then the operator $L$ is not elliptic, and there is no a priori reason why the semigroup $e^{-tL}$ would be regularizing in all variables. But if $-\sum [A_j, B]^2 - \sum A_j^2$ is elliptic, where $[A_j, B]$ is the Lie bracket between $A_j$ and $B$, then $e^{-tL}$ is regularizing in all variables, and the operator $L$ is said to be hypoelliptic. (This is not the classical definition of hypoellipticity, but it will do for the purpose of this presentation.) We see here how the "nondissipative" first-order operator $B$ interacts with the "dissipative part" of $L$, or more precisely the derivation operators $A_j$, to produce the missing directions of regularization. Possibly the most important instance of application is to the operator $L = -\Delta_v + v \cdot \nabla_x$, where $(x, v) \in \mathbb{R}^n \times \mathbb{R}^n$; in that case $A_j = \partial/\partial v_j$, $B = v \cdot \nabla_x$, $[A_j, B] = \partial/\partial x_j$. The corresponding evolution equation $\partial_t f + Lf = 0$ is degenerate, but still presents some of the typical features of a parabolic equation; the word "ultraparabolic" is sometimes used for it.

Hypoelliptic regularity has been the object of hundreds of works for the past four decades. But what was understood only very recently is that quite similar phenomena arise in the study of rates of convergence to equilibrium. To describe this, I shall use the word "hypocoercivity", which was suggested to me by Thierry Gallay. A typical hypocoercivity theorem will give sufficient conditions on an operator $L$ so that $e^{-tL}$ will converge to equilibrium at a certain rate, even though $L$ is not "coercive", in the sense that the kernel of its dissipative part is much larger than the set of equilibria.

Hypoellipticity and hypocoercivity are often found together, and have been actually studied together, by refined hypoelliptic techniques [6], [7], [15], [16], [19], and sometimes by probabilistic methods [8], [22], [23]. However, these two phenomena are distinct: Each of them can occur without the other; and the structures which underlie them are not exactly the same. This motivates the development of a separate theory of hypocoercivity. In the sequel, I shall present some of the first results in this direction.

**Acknowledgement.** The ideas exposed in the sequel have benefited from interactions with many people who are quoted within the text. Warm thanks are due to Martin Hairer, Frédéric Hérau and Clément Mouhot for their detailed comments on a preliminary version of these notes; and to Thierry Gallay for illuminating discussions.

## 1. Motivations

In this section I shall describe some concrete examples which motivate the study of hypocoercivity. All of them come from mathematical physics, and none of them is academic. Of course the list is far from exhaustive.

**The kinetic Fokker–Planck equation.** In stochastic analysis, Fokker–Planck equations are often encountered as equations satisfied by the time-dependent laws of solutions of first-order stochastic differential equations. In "real life" however, equations of motion are not first-order, but second-order. Consider for instance a particle in $\mathbb{R}^n$, following Newton's equations with a potential force $-\nabla V$, a white noise random forcing, and a linear friction with coefficient $\theta = 1$: Then its position $X_t$ at time $t$ satisfies the second-order stochastic differential equation

$$\frac{d^2X_t}{dt^2} = -\nabla V(X_t) + \sqrt{2}\,\frac{dB_t}{dt} - \frac{dX_t}{dt},$$

where $B_t$ is a standard Brownian motion. (Of course, the coefficient $\sqrt{2}$ is just a convenient normalization, and the writing is formal in the sense that $B_t$ is not differentiable.) To write the associated partial differential equation, define $f_t(x, v)$ as the density of the law of $(X_t, \dot{X}_t)$ in $\mathbb{R}^n \times \mathbb{R}^n$. Then $f$ is a solution of

$$\frac{\partial f}{\partial t} + v \cdot \nabla_x f - \nabla V(x) \cdot \nabla_v f = \Delta_v f + \nabla_v \cdot (fv), \tag{1}$$

where $\Delta_v$ and $\nabla_v \cdot$ respectively stand for the Laplace and divergence operators in velocity space. Equation (1) is *kinetic* in the sense that it involves not only the position, but also the velocity variable; it is one of the fundamental equations in gas dynamics. It admits many nonlinear variants, among which the Vlasov–Poisson–Fokker–Planck equation, which is accepted as one of the fundamental equations of stellar dynamics.

When $V$ is quadratic, the fundamental solution of (1) is explicit and Gaussian. Its examination shows that there is relaxation to a Gaussian equilibrium (in $x$ and $v$ variables) as $t \to \infty$, and this convergence is exponentially fast, with an explicit rate. Here we see a perfect illustration of the hypocoercivity phenomenon: The differential operator on the left-hand side of (1) is conservative (it describes the trajectories of a classical dynamical system in $\mathbb{R}^n \times \mathbb{R}^n$ with Hamiltonian $V(x) + |v|^2/2$), and the right-hand side alone is diffusive degenerate (it only acts on the velocity variable $v$, so cannot cause any relaxation to equilibrium with respect to the $x$ dependence); however, their combination leads to an exponential convergence to equilibrium.

For more general potentials, there is still a global equilibrium:

$$f_\infty(x, v) = \frac{e^{-\left[V(x) + \frac{|v|^2}{2}\right]}}{Z},$$

where $Z$ is a normalizing constant. Then it is an obviously natural question whether exponential convergence to $f_\infty$ holds true under adequate assumptions on the potential $V$, which go beyond the "trivial" quadratic case. Shockingly enough, the first such results were obtained only around 2002, by Frédéric Hérau and Francis Nier [19]. They used a quite sophisticated approach taking roots in Joseph Kohn's approach to hypoellipticity. Since then, their method has been very much simplified, as I shall describe later.

**About the choice of functional space.** The choice of functional space in which to study the large-time behavior of (1) is not innocent. From a probabilistic or physical point of view, it is most natural to assume that $f$ is an integrable density (or even a measure) with possibly rapid decay at infinity. However, in the majority of mathematical studies on the Fokker–Planck equation (kinetic or not), a different choice is made, namely

$$\int \frac{f^2}{f_\infty} < \infty. \tag{2}$$

The reason is simple: Perform a change of unknown in (1) by writing $h = f/f_\infty$ (from a probabilistic perspective, this amounts to considering the adjoint equation); then (1) turns into

$$\frac{\partial h}{\partial t} + v \cdot \nabla_x h - \nabla V(x) \cdot \nabla_v h = \Delta_v h - v \cdot \nabla_v h. \tag{3}$$

Now the operator appearing on the right-hand side is self-adjoint in the Hilbert space $L^2(f_\infty\, dx\, dv)$, so (3) might lend itself to a spectral treatment. Assumption (2) simply says that $h$ belongs to the above-mentioned Hilbert space.

Of course, formally, equations (1) and (3) are equivalent. But this is misleading, since the additional assumption (2) is a very strong restriction. In fact, it does happen that for certain potentials $V$, the convergence to equilibrium is exponential under the "$L^2$-type" assumption (2), but not under a more general "$L^1$-type" assumption (that is assuming just integrability, and maybe some moment bounds). In this sense, $L^1$ results are stronger than $L^2$ results. This is actually one of the reasons of the popularity of logarithmic Sobolev inequalities: They provide a natural functional tool to study convergence to equilibrium in $L^1$ spaces.

The moral of this discussion is that for physical relevance the discussion of convergence to equilibrium of solutions to (1) should not be limited to an $L^2$ framework, but also include more general $L^1$-type assumptions. In the sequel, I shall describe some results in this direction.

**Oscillator chains.** Even though Fourier's law of conduction of heat is one of the oldest partial differential equations, it is still extremely far from a rigorous theoretical understanding. Many models of statistical physics have been proposed to describe heat conduction. Here is one of them, described in [8]. Each atom in a solid body is labelled (for the sake of this discussion, we may assume that the dimension is 1, so atoms are labelled $0, 1, \dots, N$), and the unknowns are the displacements $X^0, \dots, X^N$ of the atoms with respect to their respective equilibrium positions. Each atom is bound to its equilibrium position with a "pinning potential" $V$, and it also interacts with its two neighbors by an interaction potential $W$, assumed to be symmetric ($W(z) = W(-z)$). So the equation for $X^k$ is just

$$\frac{d^2 X_t^k}{dt^2} = -\nabla V(X_t^k) - \nabla W(X_t^k - X_t^{k-1}) - \nabla W(X_t^k - X_t^{k+1}). \tag{4}$$

Of course these equations do not apply to the atoms that are at the extreme left ($k = 0$) and the extreme right ($k = N$) in the chain, since they have only one neighbor. But these extremal atoms are also *shaken* by some external bath, with a temperature of agitation $T^{(\ell)}$ on the left, and $T^{(r)}$ on the right. The corresponding equations for, say, $k = 0$, can be written

$$\begin{cases} \dfrac{d^2 X_t^0}{dt^2} = -\nabla V(X_t^0) - \nabla W(X_t^0 - X_t^1) + \ell, \\ \dfrac{d\ell}{dt} = \lambda^{(\ell)} \sqrt{2T^{(\ell)}}\, \dfrac{dB_t^{(\ell)}}{dt} - \ell + (\lambda^{(\ell)})^2 \ell\, \dfrac{dX_t^0}{dt}. \end{cases} \tag{5}$$

Here $\lambda^{(\ell)}$ is a coefficient describing the strength of the coupling between the particle and the heat bath.

Again, the law of this system is described by a linear partial differential equation in the variables $\ell, r, X^0, \dots, X^N, \dot{X}^0, \dots, \dot{X}^N$. It is very similar to the kinetic Fokker–Planck equation, except that it is much more degenerate, since the diffusion only acts on the variables $\ell$ and $r$.

There are now two difficult problems which naturally arise: (i) Show that the solution $f_t(\ell, r, x^0, \dots, x^N, v^0, \dots, v^N)$ approaches some stationary distribution as $t \to \infty$; (ii) Study the properties of this stationary distribution, and in particular the associated energy flux. (In this case, it is better to say "stationary distribution" rather than "equilibrium", precisely because the temperatures are not necessarily equal.) In particular, if $T^{(\ell)} > T^{(r)}$, in the asymptotic regime $N \to \infty$, is it true that energy flows from the left to the right, and what is the relation between the average flux and the difference of temperatures!?

When $T^{(\ell)} = T^{(r)}$, the equilibrium distribution is easy to write down explicitly, and problem (ii) is trivially solved. But as soon as these temperatures are different, the stationary solution is not explicit – except in the case when $V$ and $W$ are quadratic, but then the results are physically irrelevant!! It is conjectured that some anharmonicity is *necessary* to get the Fourier law (ironically enough, the heat equation, although one of the most basic *linear* models in science, needs some dose of microscopic nonlinearity to be explained). Then problem (ii) becomes incredibly difficult.

Even when the two temperatures are equal, problem (i) appears to be quite difficult. It is actually a typical hypocoercive situation: The diffusion on $\ell$ and $r$ should lead in the end to a relaxation to equilibrium in all variables.

Exponential convergence to the stationary distribution has been proved recently by several authors [8], [7], even for the case when $T^{(\ell)} \neq T^{(r)}$, under various assumptions on the potentials; but the dependence of the estimates upon the number of atoms is just terrible.

**The Boltzmann equation.** The Boltzmann equation is one of the basic partial differential equations in statistical mechanics. It is a kinetic model for the evolution of a rarefied gas of particles interacting via binary collisions. Historically, it has preceded

the Fokker–Planck equation; but the analytical problems that it raises are considerably more acute. A mathematically-oriented presentation of the Boltzmann equation can be found in my long review paper [27]. The classical Boltzmann equation in $n$ dimensions of space can be written

$$\frac{\partial f}{\partial t} + v \cdot \nabla_x f = Q(f, f), \quad x \in \Omega_x, \ v \in \mathbb{R}^n, \tag{6}$$

where $\Omega_x$ is a bounded connected open spatial domain, and $Q$ is the Boltzmann collision operator, defined by

$$Q(f, f) = \int_{\mathbb{R}^n} \int_{S^{n-1}} B(v - v_*, \sigma)\big[f(x, v')f(x, v'_*) - f(x, v)f(x, v_*)\big]\, d\sigma\, dv_*.$$

Here $\sigma$ is a variable unit vector in $\mathbb{R}^n$, $B(v - v_*, \sigma)$ is a collision kernel depending on the particular form of the interaction (for instance $B(v - v_*, \sigma) = |v - v_*|$), and the transform $(v, v_*) \to (v', v'_*)$ is computed by the rules of elastic collision:

$$v' = \frac{v + v_*}{2} + \frac{|v - v_*|}{2}\sigma, \quad v'_* = \frac{v + v_*}{2} - \frac{|v - v_*|}{2}\sigma.$$

This equation should of course be supplemented with boundary conditions. To simplify things, one can assume that $\Omega_x$ is just the $n$-dimensional torus $\mathbb{T}^n$ (periodic boundary conditions); another common choice is specular reflexion in a bounded open set.

In spite of hundreds of papers, the mathematical theory of the Boltzmann equation is far from complete; in particular there is still no theory of classical solutions in the large. However, strong regularity results have been obtained in a close-to-equilibrium regime. A complete theory can also be put together as long as there is a pointwise control of certain hydrodynamic fields (density in physical space, mean velocity, temperature, pressure tensor).

It was Boltzmann's beautiful observation that the $H$ functional (negative of the entropy),

$$H(f) = \int f \log f \, dx\, dv$$

is nonincreasing with time along solutions of the Boltzmann equation. Then there is a unique large-time equilibrium, which takes the form of a Maxwellian (Gaussian) distribution:

$$f_\infty(x, v) = \rho \, \frac{e^{-\frac{|v-u|^2}{2T}}}{(2\pi T)^{n/2}},$$

where $\rho \geq 0$ (total mass), $u \in \mathbb{R}^n$ (total mean momentum) and $T \geq 0$ (mean temperature) are constants. This equilibrium is obtained by maximizing the entropy given the conservation laws.

The problem of convergence to equilibrium for the Boltzmann equation is famous for historical reasons (it triggered a hot controversy in the nineteenth century) and also

for theoretical reasons (as a manifestation of irreversibility in the statistical description of a reversible mechanical system; and as the justification of the law of maximum entropy on a basic model). See my lecture notes [29] for an overview of this question.

Of course the complexity of the Boltzmann equation, and its nonlinearity are major difficulties in the study. But behind that, we can recognize once again a hypocoercive situation: The dissipation (collision) operator $Q$ on the right-hand side of (6) is very degenerate since is only acts on the velocity dependence, and it is only its association with the conservative transport operator $v \cdot \nabla_x$ on the left-hand side which can lead to convergence to equilibrium.

**Stability of Oseen's vortices.** The last example in this gallery comes from hydrodynamics and was brought to my attention by Thierry Gallay. It is a well-documented fact in turbulence theory that the vorticity of a two-dimensional incompressible flow tends to coalesce and form large vortices. Thierry Gallay and Eugene Wayne [11] have studied this phenomenon rigorously for a two-dimensional incompressible viscous fluid in the whole space: If $\omega = \omega_t(x)$ is the vorticity, the equation is just

$$\frac{\partial \omega}{\partial t} + \mathrm{BS}[\omega] \cdot \nabla \omega = \Delta \omega,$$

where $\mathrm{BS}[\omega]$ is the velocity field obtained from the vorticity $\omega$ via the Biot–Savart law:

$$\mathrm{BS}[\omega](x) = \frac{1}{2\pi} \int_{\mathbb{R}^2} \frac{(x-y)^\perp}{|x-y|^2}\, \omega(y)\, dy,$$

and $v^\perp$ is obtained from $v$ by rotation of angle $\pi/2$.

If $\omega_0 \in L^1(\mathbb{R}^2)$, then $\omega_t$ converges to 0 as $t \to \infty$, due to viscous dissipation. But a refined analysis shows that $\omega_t$ is asymptotically close to an explicit self-similar Gaussian solution, which physically corresponds to a unique large vortex, called Oseen's vortex. In fact, in suitably rescaled variables, the vorticity does converge to a stationary Gaussian distribution.

The linear stability analysis of this phenomenon reduces to the spectral analysis of the operator $S + \alpha B$ in $L^2(\mathbb{R}^2)$, where

$$\begin{cases} S\omega = -\Delta\omega + \dfrac{|x|^2}{16}\,\omega - \dfrac{\omega}{2}, \\ B\omega = \mathrm{BS}[G] \cdot \nabla\omega + 2\,\mathrm{BS}[G^{1/2}\omega] \cdot \nabla G^{1/2}. \end{cases} \tag{7}$$

Here $G$ is a Gaussian distribution: $G(x) = e^{-|x|^2/4}/(4\pi)$; and $\alpha$ is the value of the "circulation Reynolds number", which in the present set of conventions is just $\int \omega_0$.

The spectral study of $S + \alpha B$ turns out to be quite tricky. In the hope of getting a better understanding, one can decompose $\omega$ in Fourier series: $\omega = \sum_{n\in\mathbb{Z}} \omega_n(r) e^{in\theta}$, where $(r, \theta)$ are standard polar coordinates in $\mathbb{R}^2$. For each $n$, the operators $S$ and $B$

can be restricted to the vector space generated by $e^{in\theta}$, and can be seen as just operators on a function $\omega(r)$:

$$\begin{cases} (S_n\omega)(r) = -\partial_r^2\omega - \left(\frac{r}{2} + \frac{1}{r}\right)\partial_r\omega - \left(1 - \frac{n^2}{r^2}\right)\omega, \\ (B_n\omega)(r) = i\,n\,(\varphi\omega - g\Omega_n). \end{cases}$$

Here $g(r) = e^{-r^2/4}/4\pi$, $\varphi(r) = (1-e^{-r^2/4})/2\pi r^2$, and $\Omega_n(r)$ solves the differential equation

$$-(r\Omega')' + \frac{n^2}{r}\Omega = \frac{r}{2}\omega.$$

The regime $|\alpha| \to \infty$ is of physical interest and has already been the object of numerical investigations by physicists. There are two families of eigenvalues which are imposed by symmetry reasons; but apart from that, it seems that all eigenvalues converge to infinity as $|\alpha| \to \infty$, and for some of them the precise asymptotic rate of divergence $O(|\alpha|^{1/2})$ has been established by numerical evidence. If that is correct, this means that the "perturbation" of $S$ by $\alpha B$ is strong enough to send most eigenvalues to infinity as $|\alpha| \to \infty$. This is particularly striking when one realizes that $S$ is symmetric in $L^2(\mathbb{R}^2)$, while $B$ is antisymmetric. Obviously, this is again a manifestation of a hypocoercive phenomenon.

Let us simplify things just a bit by throwing away the nonlocal term $g\Omega_n$ in the expression of $B_n$. After a few manipulations, the problem reduces to the following

**Model Problem 1.1.** Identify sufficient conditions on $f : \mathbb{R} \to \mathbb{R}$, so that the real parts of the eigenvalues of

$$L_\alpha : \omega \longmapsto (-\partial_x^2\omega + x^2\omega - \omega) + i\alpha f\omega$$

in $L^2(\mathbb{R})$ go to infinity as $|\alpha| \to \infty$, and estimate this rate.

So far this problem has been solved only partially, by Isabelle Gallagher and Thierry Gallay; I shall describe their results later on.

## 2. A dynamical approach

Together with Laurent Desvillettes [3], [5], I have developed a method to study quite general hypocoercive situations. The method ultimately relies on the analysis of a *system* of coupled differential inequalities of first and second order (instead of just one first-order differential inequality as in Gronwall's lemma). The method was devised with the aim of proving convergence to equilibrium for *uniformly smooth* solutions of the Boltzmann equation, so I shall explain its principle on that particular example. Complete proofs [5] are quite long and technical, so my goal here is only to isolate the main ideas in a sketchy way.

**First and second order differential inequalities.** As we know, Boltzmann's $H$ functional goes down in time along solutions of (6). A more precise analysis shows that the total entropy production, $-dH/dt$, is always strictly positive, unless $f_t$ is a *hydrodynamical state*:

$$f_t(x, v) = \rho_t(x) \frac{e^{-\frac{|v-u_t(x)|^2}{2T_t(x)}}}{(2\pi T_t(x))^{n/2}}.$$

In words, a hydrodynamical state is a kinetic distribution which is in Maxwellian equilibrium with respect to the velocity variable, but not with respect to the position variable; so it only depends on the fields of local density ($\rho$), mean velocity ($u$) and local temperature ($T$).

With a much more refined analysis, one can establish a *quantitative lower bound* on the entropy production, under adequate (very strong) smoothness, decay and positivity assumptions on $f$: For any $\varepsilon > 0$ there is a constant $K_\varepsilon > 0$ such that

$$-\frac{d}{dt}[H(f) - H(M)] \geq K_\varepsilon \big[H(f) - H(M^f_{\rho\, u\, T})\big]^{1+\varepsilon}, \tag{8}$$

where $M$ is the global equilibrium, which is a Maxwellian distribution, $M^f_{\rho\, u\, T}$ is the hydrodynamical state with the same (local) density, mean velocity and temperature as $f$, and the dependence of $f$, $\rho$, $u$ and $T$ on time is implicit. (The quantity in the right-hand side of (8) is nonnegative.)

Inequality (8) gives a good lower bound on the entropy production, as long as the unknown $f$ *stays away from hydrodynamical states*. But if $f$ decides to become hydrodynamic, or very close to, then the entropy production vanishes and there is nothing that we can deduce about the convergence to equilibrium. This is where the antisymmetric part of the Boltzmann equation has to help us.

Now the second differential inequality is obtained by introducing a suitable functional measuring the distance of $f$ to the space of hydrodynamical states. On one hand it should be controlled by the quantity $H(f) - H(M^f_{\rho\, u\, T})$; but on the other hand it should be simple enough to make explicit computations. A natural choice is $\mathcal{E}_1(f) = \|f - M^f_{\rho\, u\, T}\|^2_{L^2}$; note that this functional depends on $f$ in a strongly nonlinear way, via $\rho$, $u$ and $T$. The point now is to give a *lower bound on the second-order time-derivative* of this new functional.

Differentiating a functional once along the Boltzmann equation is already complicated, but differentiating it twice is a horrendous task; so it better be well motivated. There are in fact two main reasons to consider the second derivative. The first is that the second derivative in time gives a measure of how fast the distance between $f$ and $M^f_{\rho\, u\, T}$ will increase again if it ever vanishes, or becomes very close to. The second reason is that by applying twice the Boltzmann equation, we let the first-order operator $v \cdot \nabla_x$ act twice, and then the resulting computations are somewhat similar to those that would have been obtained by letting a second-order operator *in the $x$ variable* act once. So in this second-order time derivative one will find some of the

terms that would have appeared in a first-order computation along the heat equation in the $x$ variable.

So, after many calculations one can show that for $\delta_1$ small enough,

$$\frac{d^2}{dt^2}\|f - M^f_{\rho\, u\, T}\|^2_{L^2} \geq K_1 \left[\int_{\Omega_x} |\nabla T(x)|^2\, dx + \int_{\Omega_x} |\{\nabla u(x)\}|^2\, dx\right] - \frac{C_1}{{\delta_1}^{1-\varepsilon}}\left(\|f - M^f_{\rho\, u\, T}\|^2_{L^2}\right)^{1-\varepsilon} - \delta_1[H(f) - H(M)], \tag{9}$$

where $K_1$ and $C_1$ are constants which only depend on some a priori smoothness and positivity estimates on $f$, and $\{\nabla u\}$ is the traceless part of the symmetric part of the matrix-valued field $\nabla u$.

To understand what has been achieved, assume for a moment that $f$ becomes hydrodynamical at some time $t_0$, and forget the error term with $\delta_1$. Then we have $(d^2/dt^2)\|f - M^f_{\rho\, u\, T}\|^2_{L^2} \geq K_1\|\nabla T\|^2_{L^2}$. In particular, $\|f - M^f_{\rho\, u\, T}\|^2$ is strictly convex, as a function of $t$, unless $\nabla T$ is equal to 0, and will grow quadratically for a short time. So this second equation gives us some information about the inhomogeneities in the temperature field $T$. In a geometric language, what we have shown, more or less, is that the Boltzmann flow is "transverse" to the space of hydrodynamical states, in presence of heterogeneities of the temperature.

Combining this with the first inequality (8), we see that we have some information about how far $f$ is to the space of hydrodynamical states with constant temperature. There is still something missing, but now we can repeat the procedure: Introduce a new functional measuring the distance of $f$ to that space, for instance $\mathcal{E}_2(f) = \|f - M^f_{\rho\, u\, \langle T\rangle}\|^2_{L^2}$, where $M^f_{\rho\, u\, \langle T\rangle}$ is the hydrodynamical state which has the same density $\rho$ and velocity fields $u$ as $f$, and a constant temperature whose value is computed by averaging the temperature $T$ of $f$ against the density $\rho$. Then differentiate twice again. New computations yield a result which is very similar to the one in (9), except that the terms $\|\nabla T\|^2$ and $\|\{\nabla u\}\|^2$ are replaced by $\|\nabla^{\mathrm{sym}} u\|^2$, the square $L^2$ norm of the complete symmetric part of $\nabla u$.

As a general principle (Korn's inequality), a control of the symmetric part of $\nabla u$ implies a control on the whole of $\nabla u$, under suitable boundary conditions. In fact the boundary conditions here are not standard, at least for specular reflexion, so the desired estimates do not follow from the classical theory of Korn inequalities; but let us forget this for the moment and assume that we have indeed a good control on the inhomogeneities of the velocity field.

So far there is still no control on the inhomogeneities of the density, but at this stage the reader has probably understood the sequel of the method: Introduce a suitable functional $\mathcal{E}_3$ measuring the distance of $f$ to the space of hydrodynamical states with constant temperature and constant velocity field, and differentiate this expression twice in time. It is possible to choose $\mathcal{E}_3(f) = \|f - M^f_{\rho\, 0\, 1}\|^2_{L^2}$, where $M^f_{\rho\, 0\, 1}$ has the same density as $f$, the same average temperature and the same total momentum; and then in the resulting computations pops up the desired term $\|\nabla\rho\|^2$.

**Closing the system.** At this stage we have a system of four differential inequalities (one of first order, and three of second order). To close the system, one can use:

- A *physical input*: The total entropy is the sum of a purely kinetic entropy and a purely hydrodynamical entropy, which controls inhomogeneities of all fields $\rho$, $u$ and $T$.
- An *analytical input*: In presence of smoothness bounds, all the norms appearing in the computations are "almost equivalent". More precisely, if $\|f\|_1$ and $\|f\|_2$ are any two Lebesgue, or Sobolev norms, then for any $\varepsilon > 0$ one can find a constant $C_\varepsilon$, only depending on some smoothness estimates on $f$, such that $\|f\|_1 \leq C_\varepsilon \|f\|_2^{1-\varepsilon}$. This step, obviously based on elementary interpolation theory, is crucial to "get the exponents right"; without it, one would get disastrous rates of convergence, or just no rate at all. This way of *trading smoothness for exponents* is one of the reasons why the method is so greedy in regularity.
- A *geometric/analytical input*: Certain norms of differential quantities ($\|\nabla T\|$, $\|\nabla^{\mathrm{sym}} u\|$, $\|\nabla \rho\|$) imply a control on the departure of the corresponding fields to their mean value. The shape of the domain (connectedness, rotational symmetry, etc.) plays a crucial role here; all of this can be expressed *quantitatively* with some functional inequalities of Poincaré or Korn type (see in particular [4]).

**Study of the differential system.** Not all the hard job has been done at this stage. The result is a system of first and second-order differential inequalities, coupled together in a quite intricate way, from which one wants to extract estimates about the rates of relaxation. This can be done with the help of the following (definitely not obvious) lemma:

**Lemma 2.1.** *Let $h(t) \geq 0$ satisfy*

$$h''(t) + A h(t)^{1-\varepsilon} \geq \alpha > 0 \quad \text{for all } t \in (t_1, t_2)$$

*for some $\varepsilon < 0.1$. Then,*

*– either $t_2 - t_1$ is small:*

$$t_2 - t_1 \leq 50\, \frac{\alpha^{\frac{\varepsilon}{2(1-\varepsilon)}}}{A^{\frac{1}{2(1-\varepsilon)}}};$$

*– or $h$ is large on the average:*

$$\frac{1}{t_2 - t_1} \int_{t_1}^{t_2} h(t)\, dt \geq \frac{\alpha^{\frac{1}{1-\varepsilon}}}{100}\ \inf\left(\frac{1}{A}, \frac{1}{A^2}\right).$$

With a repeated use of Lemma 2.1, one can show in the end that the system of differential inequalities implies relaxation to equilibrium at a rate $O(t^{-\infty})$, that is, faster than any inverse power of time. All in all, one can get the following result, which is stated here in a slightly sketchy way (see [5] for more precise statements):

**Theorem 2.2.** *Let $(f_t)_{t\geq 0}$ be a smooth solution of the Boltzmann equation* (6)*, such that all the derivatives of $f$ are uniformly bounded, and all the moments of $f$ are bounded, uniformly in time. Further assume that $f$ satisfies a pointwise lower bound of the form $f_t(x,v) \geq K_0 e^{-A_0|v|^{q_0}}$. Then, under adequate boundary conditions, $f_t$ converges to global equilibrium as $t \to \infty$, at least as fast as $O(t^{-\kappa})$ for all $\kappa > 0$.*

**Further comments.** More information about the implementation of this program in the context of the Boltzmann equation can be found in the original research paper [5], or, in a lighter form, in the lecture notes [30], [29]. Before being used on the Boltzmann equation, the dynamical approach had been tried on the Fokker–Planck equation [3] and on some other linear models [1], [9]. It is quite robust and adapted to equations with very little structure.

One of its appealing features is that it seems to provide a good physical intuition of what is going on: The system approaches hydrodynamical state under the influence of collisions, then it is driven out of hydrodynamical state by the influence of the transport, etc. Numerical simulations have corroborated this qualitative analysis surprisingly well. In the diagram below, computed numerically by Francis Filbet, one sees very clearly that the solution of the Boltzmann equation oscillates between states

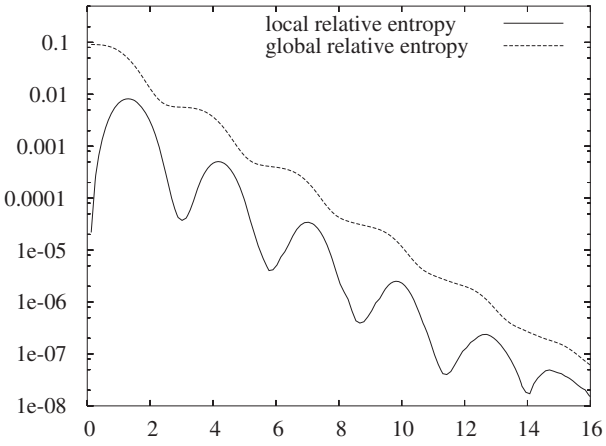

Figure 1. The upper curve is the $H$ functional as a function of time, in semi-log plot; the lower curve is the purely kinetic part of the $H$ functional. When the two curves are far away, the distribution is almost in hydrodynamical state; when they are very close, it is almost homogeneous.

where it is close to hydrodynamical, and states where it is close to homogeneous. In particular, contrary to a widespread belief, the approach to hydrodynamical regime is not faster than the approach to global equilibrium. (All of this is valid only on scales of time on which the Knudsen number is of order 1.)

From the point of view of physics, the discovery of these oscillations may be one of the most noticeable outcomes of the program of hypocoercivity applied to

the Boltzmann equation. (No doubt that one day there will be a simpler analytical way to explain them.) They are not easy to observe, and have even been used as a "benchmark" to test the accuracy of certain numerical schemes (see e.g. [10]).

However, the dynamical method suffers from the complexity of its practical application, and its heavy computational cost. In the next section, I shall describe another method which may be less appealing from the physical point of view, and requires a bit more structure, but has the advantage to be much lighter.

Also, I emphasize that Theorem 2.2 requires strong regularity and decay estimates on the solutions. As discussed in [5], all these estimates can be proven in the *close-to-equilibrium* regime, but remain a major open problem for solutions in the large. Even in a close-to-equilibrium regime, decay estimates based on a linearization method are quite hard to obtain, and were not available at the time when [5] was published; since then this gap has been filled in a series of important works by Yan Guo and Robert Strain [13], [14].

## 3. A functional approach

In the previous method the resolution of the main degeneracy problem was done via the time-differentiation of certain (relatively) simple functionals. Now the idea is to put as much as possible of the difficulty in a careful choice of the functional; and more precisely to add "correction terms" which are negligible in size, but contribute in an important way to the time-derivative of the functional. This will be more easily explained on the example of the Fokker–Planck equation, in the form (3).

Suppose you want to get a Gronwall inequality for some well-chosen functional, applied to the Fokker–Planck equation. First try the $L^2$ norm. With the notation $\mu(dx\,dv) = f_\infty(x,v)\,dx\,dv$, and omitting once again the dependence upon time, one has

$$\frac{d}{dt}\int h^2\,d\mu = -\int |\nabla_v h|^2\,d\mu.$$

Since the derivatives in the right-hand side involve only the velocity variables, there is no way to dominate the integral in the left-hand side by the right-hand side (choose $h = h(x)$, then the right-hand side vanishes).

So go to a higher order norm, involving gradients of $h$. After a bit of work, under suitable assumptions on $V$, one can find constants $a, c, K > 0$ such that

$$\begin{aligned}\frac{d}{dt}\left(\int h^2\,d\mu + a\int |\nabla_x h|^2\,d\mu + c\int |\nabla_v h|^2\,d\mu\right)\\ \leq -K\left(\int |\nabla_v h|^2\,d\mu + \int |\nabla_v\nabla_x h|^2\,d\mu + \int |\nabla_v\nabla_v h|^2\,d\mu\right).\end{aligned} \tag{10}$$

Again, the right-hand side is not sufficient to control the expression in brackets on the left-hand side. So still nothing!

But now correct the functional on the left-hand side by adding an innocent-looking term $2b \int \nabla_x h \cdot \nabla_v h \, d\mu$. If $b < \sqrt{ac}$, this term does not play any noticeable role in the value of the functional, since

$$\left| 2b \int \nabla_x h \cdot \nabla_v h \, d\mu \right| \leq (1 - \delta) \left[ a \int |\nabla_x h|^2 \, d\mu + c \int |\nabla_v h|^2 \, d\mu \right]$$

for some positive constant $\delta$. However, if $a$, $b$ and $c$ are properly chosen, then we have a differential inequality which is much better than (10):

$$\begin{aligned} &\frac{d}{dt} \left( \int h^2 \, d\mu + a \int |\nabla_x h|^2 \, d\mu + 2b \int \nabla_x h \cdot \nabla_v h \, d\mu + c \int |\nabla_v h|^2 \, d\mu \right) \qquad (11) \\ &\leq -K \left( \int |\nabla_x h|^2 \, d\mu + \int |\nabla_v h|^2 \, d\mu + \int |\nabla_v \nabla_x h|^2 \, d\mu + \int |\nabla_v \nabla_v h|^2 \, d\mu \right). \end{aligned}$$

Now it very easy to close this differential inequality: It suffices that $\mu$ satisfies a Poincaré inequality (in the $x$ and $v$ variables).

**The algebraic core.** I started to work on this approach while struggling to understand the results of Frédéric Hérau and Francis Nier [19], without resorting to the technical hypoelliptic machinery used in their work. After deciding that there should be an elementary approach based on integration by parts and chain rule, I was still flooded by the complex calculations. Then I decided that there should be an even simpler approach with no analysis at all. After going to an abstract formulation of the problem, I found out that there was indeed an extremely simple "algebraic core" which can be presented as follows. Take two operators $A$ and $B$ on a Hilbert space (in the present case $A$ would be the vector-valued differential operator $\nabla_v$, while $B$ would be $v \cdot \nabla_x - \nabla V(x) \cdot \nabla_v$), with $B^* = -B$. Then, at least formally, the time-derivative of

$$\langle Ah, [A, B]h \rangle$$

along the influence of $B$ can be written as

$$\langle ABh, [A, B]h \rangle + \langle Ah, [A, B]Bh \rangle.$$

Pretend that $B$ commutes with $[A, B]$; then the previous expression is

$$\langle ABh, [A, B]h \rangle + \langle Ah, B[A, B]h \rangle,$$

and since $B^* = -B$, this can be rewritten as

$$\langle ABh, [A, B]h \rangle - \langle BAh, [A, B]h \rangle = \langle [A, B]h, [A, B]h \rangle. \qquad (12)$$

In the example of the Fokker–Planck equation, $[A, B] = \nabla_x$, so $\langle Ah, [A, B]h \rangle = \int \nabla_v h \cdot \nabla_x h \, d\mu$, and the right-hand side of (12) is the desired term in $\|\nabla_x h\|^2$.

The advantage to input terms with "mixed derivatives" such as $\int \nabla_x h \cdot \nabla_v h$ had been actually noted before in studies of global in time propagation of the smoothness

for kinetic equations, most notably by Denis Talay [24] and Yan Guo [12]. The simple algebraic core presented above explains why this trick also applies to problems of convergence to equilibrium.

The rest of this section will be devoted to a presentation of some results which have been obtained by pushing further this approach. All the results quoted below are extracted from two preprints by the author [31], [32], and another preprint by Clément Mouhot and Lukas Neumann [21]. There is also an independent series of works by Frédéric Hérau [18], [17], which is based on quite similar tools.

**The basic theorem.** Two important features of the next theorem are that

– it applies to a general abstract framework: $\mathcal{H}$ is a Hilbert space (think of $\mathcal{H}$ as $L^2(\mu)$, where $\mu$ is the equilibrium measure); and $\mathcal{V}$ another Hilbert space (think of $\mathcal{V}$ as $\mathbb{R}^n$, the space of velocities); then $A$ is an unbounded operator $\mathcal{H} \to \mathcal{H} \otimes \mathcal{V}$, and $B$ is an unbounded operator $B \to B$ with $B^* = -B$;

– it considers a linear operator $L$ which is in (abstract) *Hörmander form*, that is $L = A^*A + B$ for some operators $A$, $B$ as above.

Assume that the semigroup $e^{-tL}$ is well defined and that there is no problem to differentiate the square norms, etc. Systematic tensorization with the identity operator will be used to make sense of notation such as $[A, B] = AB - (B \otimes I)A$. The scalar product in $\mathcal{H}$ will be denoted by $\langle \cdot, \cdot \rangle$, the norm in $\mathcal{H}$ by $\| \cdot \|$, and an operator $S$ will be said to be bounded respectively to a family of operators $T_1, \dots, T_k$ if there is a constant $C$ such that $\|Sy\| \le C(\|T_1 y\| + \cdots + \|T_k y\|)$. The symbol $\Re$ stands for real part.

**Theorem 3.1.** *With the above notation, write* $[A, B] = C$*, and assume that*

(i) $[A, C] = 0$, $[A^*, C] = 0$;

(ii) $[A, A^*]$ *is bounded relatively to* $I$ *and* $A$;

(iii) $[B, C]$ *is bounded relatively to* $A$, $A^2$, $C$ *and* $AC$.

*Further assume that*

(H) $A^*A + C^*C$ *is coercive.*

*Then for a suitable choice of constants* $a, b, c$ *one has the differential inequality*

$$\frac{d}{dt}\mathcal{F}(e^{-tL}h) \le -K\,\mathcal{F}(e^{-tL}h),$$

*where*

$$\mathcal{F}(h) = \|h\|^2 + a\,\|Ah\|^2 + 2b\,\Re\,\langle Ah, Ch\rangle + c\,\|Ch\|^2,$$

*and* $K$ *is a positive constant which only depends on the constants appearing implicitly in assumptions* (ii)*,* (iii) *and* (H).

**Remark 3.2.** The assumption (H) is obviously an analog in this context of Lars Hörmander's bracket condition.

This theorem applies to the Fokker–Planck equation (3) under simple assumptions on the potential $V$, and yields exponential convergence to equilibrium for initial data $h_0$ satisfying $\|\nabla_x h_0\|^2 + \|\nabla_v h_0\|^2 < +\infty$. The latter restriction can finally be removed by an independent study of hypoelliptic regularity [16], [31]. (This is not a standard hypoelliptic estimate since it is global; there would be much to say about it, but this would take us too far.) In the end, one obtains the following theorem, which generalizes and improves the results of [19], [16]. Recall that a measure $\nu$ is said to satisfy a Poincaré inequality if one has a functional inequality of the form $\|\nabla h\|_{L^2(\nu)} \geq P\|h - \langle h\rangle\|_{L^2(\nu)}$, $P > 0$, where $\langle h\rangle$ is the average value of $h$ with respect to $\nu$.

**Theorem 3.3.** *Let $V \in C^2(\mathbb{R}^n)$ with $\inf V > -\infty$, such that*

(a) $|\nabla^2 V| \leq C(1 + |\nabla V|)$;

(b) *the reference measure $\nu(dx) = e^{-V(x)}\,dx$ satisfies a Poincaré inequality with constant $P$.*

*Let $\mu(dx\,dv) = e^{-(V(x)+|v|^2/2)}\,dx\,dv/Z$, where $Z$ is a normalizing constant. Then there are constants $\lambda > 0$ and $C'$, explicitly computable in terms of $C$ and $P$, such that solutions of the Fokker–Planck equation* (3) *satisfies*

$$\|h_t - \langle h_0\rangle\|_{L^2(\mu)} \leq C' e^{-\lambda t}\,\|h_0 - \langle h_0\rangle\|_{L^2(\mu)}.$$

Theorem 3.1, or more precisely its proof, was also used by Isabelle Gallagher and Thierry Gallay to provide a first solution to the Model Problem 1.1, as follows. Set $\mathcal{H} = L^2(\mathbb{R};\mathbb{C})$, $A = \partial_x\omega + x\omega$, $B\omega = (i\alpha f)\omega$. Then $C\omega = i\alpha f'\omega$, so the operator $A^*A + C^*C$ is of Schrödinger type:

$$(A^*A + C^*C)\,\omega = (-\partial_x^2\omega + x^2\omega - \omega) + \alpha^2 f'^2\omega,$$

and the spectrum of $A^*A + C^*C$ can be studied via standard semi-classical techniques. For instance, if $f'(x)^2 = x^2/(1+x^2)^k$, $k \in \mathbb{N}$, then the spectral gap of $A^*A + C^*C$ is bounded below like $O(|\alpha|^{2\nu})$, with $\nu = \min(1, 2/k)$. Then a careful examination of the proof of Theorem 3.1 yields a lower bound like $O(|\alpha|^{\nu})$ on the real part of the spectrum of $A^*A + B$.

**Multiple commutators.** As in Lars Hörmander's hypoellipticity theorem, multiple commutators are also allowed in hypocoercivity results. But as an important difference, it seems that one only needs to consider commutators with the antisymmetric part. Here is such a theorem:

**Theorem 3.4.** *With the same notation as before, assume the existence of (possibly unbounded) operators $C_0, C_1, \ldots, C_{N_c+1}$, $R_1, \ldots, R_{N_c+1}$, and $Z_1, \ldots, Z_{N_c+1}$ such that*

$$C_0 = A, \quad [C_j, B] = Z_{j+1}C_{j+1} + R_{j+1} \ \ (0 \leq j \leq N_c), \quad C_{N_c+1} = 0,$$

*and, for all* $k \in \{0, \dots, N_c\}$,

(i) $[A, C_k]$ *is bounded relatively to* $\{C_j\}_{0\le j\le k}$ *and* $\{C_j A\}_{0\le j\le k-1}$;

(ii) $[A^*, C_k]$ *is bounded relatively to* $I$ *and* $\{C_j\}_{0\le j\le k}$;

(iii) $R_k$ *is bounded relatively to* $\{C_j\}_{0\le j\le k-1}$ *and* $\{C_j A\}_{0\le j\le k-1}$;

(iv) $Z_j$ *is bounded relatively to* $I$, *and* $I$ *is bounded relatively to* $Z_j$;

(H) $\sum_{j=0}^{N_c} C_j^* C_j$ *is coercive.*

*Then one can choose constants* $a_k$ *and* $b_k$ *in such a way that the functional*

$$\mathcal{F}(h) = \|h\|^2 + \sum_{k=0}^{N_c} \big( a_k \|C_k h\|^2 + 2 b_k \, \Re \, \langle C_k h, C_{k+1} h \rangle \big)$$

*satisfies the differential inequality*

$$\frac{d}{dt} \mathcal{F}(e^{-tL} h) \le -K \mathcal{F}(e^{-tL} h)$$

*for some constant* $K$ *which can be computed explicitly in terms of the constants appearing implicitly in* (i)–(iv) *and* (H).

This result generalizes Theorem 3.1 in several ways: Multiple commutators are allowed; a remainder $R_{j+1}$, and a multiplier $Z_j$ are allowed in the identity defining $C_{j+1}$ in terms of $C_j$; and the various directions $C_k$ are not assumed to commute.

As a simple application of Theorem 3.4, it is possible to prove exponential convergence to equilibrium for the oscillator chain described by equations (4)–(5), under the assumption that $V$ and $W$ are uniformly convex and have a bounded Hessian, *and that the temperatures on the left and on the right are equal*, that is $T^{(\ell)} = T^{(r)}$. Interestingly enough, bounded Hessians are not covered by the results of Jean-Pierre Eckmann and Martin Hairer [7], who impose a superquadratic growth at infinity. Conversely, it is not clear whether Theorem 3.4 can be used to recover the results in [7]. Still some work is required to clarify the situation about these assumptions on the potentials. I shall also come back in the end of these notes to the very unsatisfactory restriction $T^{(\ell)} = T^{(r)}$.

**$L \log L$ estimates.** Now it is not so difficult to adapt the previous $L^2$ theory to an $L \log L$ framework, replacing $L^2$ square norms by *entropies and Fisher informations*. For this I shall have to leave the framework of abstract Hilbert spaces, and replace it by functional spaces on, say, $\mathbb{R}^N$ (or a differentiable manifold). Then the operators $A_1, \dots, A_m$ and $B$ will be vector fields, identified with differentiation operators, the notation $A$ will stand for the vector-valued differential operator $A = (A_1, \dots, A_m)$, and I shall now say that $S$ is bounded relatively to $T_1, \dots, T_k$ if there is a constant $C$ such that $|S(x)| \le C(|T_1(x)| + \cdots + |T_k(x)|)$, where $S(x)$ stands for the value of the vector field $S$ at $x$. The equilibrium measure will be assumed to take the form $\mu(dX) = e^{-E} \, dX$, where $E$ is a smooth function, $dX$ is the Lebesgue measure in

$\mathbb{R}^N$, and $E$ is normalized so that $\int e^{-E} = 1$. The notation $S^*$ will stand for the adjoint of $S$ *in* $L^2(\mu)$. The linear equation under study will still be $\partial_t h + Lh = 0$, where $L = A^*A + B$ and the unknown is the probability density $f = he^{-E}$.

**Theorem 3.5.** *With the above conventions, assume that all the assumptions in Theorem* 3.4 *are satisfied, up to the following reinforcements:*

(i′) $[A, C_k]$ *is bounded relatively to* $A$;

(ii′) $[A, C_k^*]$ *and* $[A, C_k]^*$ *are bounded relatively to* $A$ *and* $I$;

(iii′) $R_k$ *is bounded relatively to* $\{C_j\}_{0\le j\le k-1}$.

*Further assume that there is a positive constant* $\lambda$ *such that* $\sum_k C_k^* C_k \ge \lambda I_N$, *pointwise on* $\mathbb{R}^N$, *and that* $\mu$ *satisfies a logarithmic Sobolev inequality. Then there are quadratic forms* $x \to S(x)$, *uniformly positive definite, such that the functional*

$$\mathcal{I}(f) = \int f(\log f + E) + \int f\big\langle S\,\nabla(\log f + E), \nabla(\log f + E)\big\rangle$$

*satisfies*

$$\frac{d}{dt}\,\mathcal{I}\big((e^{-tL}h)e^{-E}\big) \le -K\,\mathcal{I}\big((e^{-tL}h)e^{-E}\big),$$

*for some explicitly computable constant* $K$.

The most noticeable novelty in the assumptions of Theorem 3.5 is that now the reference measure is not required to satisfy a Poincaré inequality, but a logarithmic Sobolev inequality, i.e. for any probability density $f$ one should have

$$\int f\,(\log f + E) \le (2P)^{-1} \int f\,|\nabla(\log f + E)|^2,$$

where $P$ is a positive constant. (The normalization here is such that $e^{-E}$ automatically satisfies a Poincaré inequality with constant $P$.)

Apart from this, Theorem 3.5 looks very similar to Theorem 3.4. In fact, by writing densities in the form $f = (1+\varepsilon h)e^{-E}$ and letting $\varepsilon \to 0$, one can recover the conclusion of Theorem 3.4 as a perturbative limit regime. Still, there are some subtle things going on, as indicated by the reinforced assumptions (i')–(iii'). In fact there are some tricky additional computations underlying the proof, with rather miraculous simplifications, suggesting that an adequate formalism is still to be found.

Here is an application of Theorem 3.5:

**Theorem 3.6.** *Let* $V$ *be a* $C^\infty$ *potential on* $\mathbb{R}^n$; *assume that there are positive constants* $k$, $C$, $\{C_j\}_{j\in\mathbb{N}}$ *such that*

(a) $|\nabla^j V(x)| \le C_j$ *for all* $j \ge 2$;

(b) $e^{-V}$ *satisfies a logarithmic Sobolev inequality.*

*Then for any initial datum* $f_0(x, v)$ *with finite moments of all orders, the solution of the Fokker–Planck equation* (1) *converges to equilibrium exponentially fast in the sense of relative entropy and* $L^1$ *norm, with a rate of exponential convergence that does not depend on* $f_0$.

This result is obtained by combining Theorem 3.5 with a global hypoelliptic regularization theorem for $L^1$ initial data. (This again is a highly nonstandard framework for regularization, but I shall not develop this here.)

**Beyond the Hörmander form.** All the examples treated so far were dealing with linear operators in the form $L = A^*A + B$, where $B$ is antisymmetric. In theory, any operator can of course be cast in this form, but this might be a terrible thing to do in practise; for instance, if the symmetric part of $L$ is an integral operator then $A$ would look horrendous. So it is desirable to prove results under alternative structure assumptions.

It would be illusory to hope for a gain based on commutators like $[L, B]$. Instead, one can introduce an adequate auxiliary operator $A$ into the estimates, in such a way that (i) $A^*A + [A, B]^*[A, B]$ is coercive, and (ii) $A$ "almost commutes" with $L$.

Recently, Clément Mouhot and Lukas Neumann [21] have derived such a hypocoercivity theorem in the particular framework of kinetic equations; more precisely, $A = \nabla_v$, $B = v \cdot \nabla_x$, $C = \nabla_x$, and

$$L = v \cdot \nabla_x - \mathcal{L}, \quad \mathcal{L} = K - \Lambda, \tag{13}$$

where $K$ and $\Lambda$ only act on the velocity variable, $-\Lambda$ is "damping" (for instance a multiplication operator) and $K$ is "regularizing" (for instance an integral operator). These assumptions cover many interesting cases in kinetic theory [21]. Here I state the results in a slightly more precise (although not yet fully rigorous) way:

**Theorem 3.7.** *Let $\mathcal{L}$ be an unbounded operator on $L^2(\mathbb{R}^n_v)$, taking the form $\mathcal{L} = K - \Lambda$, and assume that there exists a Hilbert norm $\|\cdot\|_\Lambda$, with $\|\cdot\|_\Lambda \geq \|\cdot\|_{L^2}$, and constants $\kappa, C > 0$ such that*

(i) $\kappa \, \|h\|_\Lambda^2 \leq \langle \Lambda h, h\rangle_{L^2} \leq C \|h\|_\Lambda^2$;

(ii) $\langle \mathcal{L} h, g\rangle \leq C \|h\|_\Lambda \|g\|_\Lambda$;

(iii) *for all $\delta > 0$ there exists $C_\delta > 0$ such that $\langle \nabla_v K h, \nabla_v h\rangle_{L^2} \leq C_\delta \|h\|_{L^2}^2 + \delta \|\nabla_v h\|_{L^2}^2$ for all $h$*;

(iv) $\langle \nabla_v \Lambda h, \nabla_v h\rangle_{L^2} \geq \kappa \|\nabla_v h\|_{L^2}^2 - C \|h\|_{L^2}^2$;

(C) $\langle \mathcal{L} h, h\rangle_{L^2} \leq -\kappa \, \|h - \Pi h\|_{L^2}^2$, *where $\Pi$ is the orthogonal projection onto the kernel of $\mathcal{L}$, assumed to be finite-dimensional.*

*Then the operator $L = -v \cdot \nabla_x + \mathcal{L}$ is hypocoercive in $L^2(\mathbb{T}^n_x \times \mathbb{R}^n_v)$. There are constants $a, b, c, \lambda > 0$ such that the functional defined by*

$$\mathcal{F}(h) = \|h\|_{L^2}^2 + a \, \|\nabla_v h\|_{L^2}^2 + 2b \, \langle \nabla_v h, \nabla_x h\rangle_{L^2} + c \, \|\nabla_x h\|_{L^2}^2$$

*satisfies*

$$\frac{d}{dt} \mathcal{F}(e^{-tL} h) \leq -\lambda \, \mathcal{F}(e^{-tL} h)$$

*for all $h \in L^2(\mathbb{R}^n_x \times \mathbb{R}^n_v) / \operatorname{Ker} L$.*

Some comments on the assumptions: Assumption (i) implies the damping nature of $-\Lambda$, and assumption (iii) is a very weak way to state the regularizing property of $K$. Assumption (iv) is some way to express the fact that $\nabla_v$ and $\Lambda$ satisfy good commutation relations: The estimate would be trivial if $\nabla_v \Lambda$ were replaced by $\Lambda \nabla_v$. Finally, assumption (C) expresses the coercivity of the operator $\mathcal{L}$ when applied to functions which only depend on the velocity variable.

Theorem 3.7 applies for instance to the linearized Boltzmann equation, or many other linear Boltzmann-type models. (There is also an independent study by Frédéric Hérau [17] which analyzes the hypocoercivity of some such operators with very similar tools.)

By combining Theorem 3.7 with a linearization analysis and some global bounds derived by Yan Guo, Clément Mouhot and Lukas Neumann were able to recover a simple proof of the following theorem of convergence to equilibrium for the *nonlinear* Boltzmann equation. In the next statement, $H^k$ stands for the standard $L^2$-Sobolev space of order $k$ on the domain $\mathbb{T}^n_x \times \mathbb{R}^n_v$.

**Theorem 3.8.** *Consider the Boltzmann equation* (6) *in* $\mathbb{T}^n_x \times \mathbb{R}^n_v$*, with the collision kernel* $|v - v_*|$*. Let* $f_0$ *be a* $C^\infty$ *initial density with associated global equilibrium* $f_\infty(x, v) = M(v) = e^{-|v|^2/2}/(2\pi)^{n/2}$*. If*

$$\|M^{-1/2}(f_0 - M)\|_{H^k} \leq \varepsilon,$$

*for some* $k$ *large enough and some* $\varepsilon > 0$ *small enough, then the corresponding solution of the Boltzmann equation converges to equilibrium exponentially fast:*

$$\|M^{-1/2}(f_t - M)\|_{L^2} = O(e^{-\lambda t}).$$

**Nonlinear equations.** To conclude this section, I shall show how to recover fully nonlinear hypocoercivity estimates by a variant of the approach developed above. For general nonlinear operators, it is probably hopeless to try to get anywhere unless one assumes some strong assumptions of smoothness and decay at infinity, to make sure that all norms involved are "almost comparable" (that is, they are comparable if one allows them to be raised to powers that are arbitrarily close to 1). So I will assume that $(f_t)_{t \geq 0}$ satisfies uniform bounds in a scale of weighted Sobolev spaces $(X^s)_{s \in \mathbb{R}}$ of arbitrarily high smoothness and decay, that are in interpolation. (For instance, $X^s$ might be defined as the space of functions $f$ such that $(I - \Delta_v - \Delta_x)^{s/2} f(x, v)(1 + |x|^2 + |v|^2)^{s/2}$ lies in $L^2$.) Then all the nonlinear operators involved will be assumed to be Lipschitz when restricted on balls of $X^s$, with values in some higher order space $X^{s+k}$. In practise, this means that our nonlinearities are not worse than polynomial, with coefficients that do not increase faster than polynomial. Then I shall denote the functional derivative of a functional $\mathcal{F}$ at function $f$ by just $\mathcal{F}'_f$. I shall further assume that there is a unique equilibrium $f_\infty$, and a Lyapunov functional $\mathcal{E}$ satisfying

$$\mathcal{E}(f_t) - \mathcal{E}(f_\infty) \geq K \, \|f_t - f_\infty\|_s^{2(1+\varepsilon)}$$

for some suitable $s = s(\varepsilon)$, $K = K(\varepsilon)$, where $\varepsilon$ is arbitrarily small. In words, this means that $\mathcal{E}$ essentially controls the square of the distance to equilibrium.

**Theorem 3.9.** *With the above notation, let*

$$L = B - \mathcal{C}$$

*be a nonlinear differential operator, such that $B$ preserves the Lyapunov functional $\mathcal{E}$ (that is, $\mathcal{E}'_f \cdot Bf = 0$), let $(f_t)_{t\geq 0}$ solve $\partial_t f + Lf = 0$, and let $(\Pi_j)_{1\leq j\leq J}$ be nonlinear operators satisfying*

$$\Pi_j \circ \Pi_k = \Pi_{\max(j,k)}, \tag{14}$$

*such that, for all $t \geq 1$,*

(i) $\mathcal{C} \circ \Pi_1 = 0$; $-\mathcal{E}'_{f_t} \cdot (\mathcal{C} f_t) \geq K_\varepsilon [\mathcal{E}(f) - \mathcal{E}(\Pi_1 f)]^{1+\varepsilon}$;

(ii) $K_\varepsilon \|\Pi_1 f_t - f_\infty\|^{2+\varepsilon} \leq \mathcal{E}(\Pi_1 f) - \mathcal{E}(f_\infty) \leq C_\varepsilon \|\Pi_1 f_t - f_\infty\|^{2-\varepsilon}$;

(iii) $\Pi_J f = f_\infty$; $Bf_\infty = 0$;

(H) $\|(\mathrm{Id} - \Pi_j)'_{\Pi_j f} \cdot (B \Pi_j f)\|^2 \geq K_\varepsilon \|(\Pi_j - \Pi_{j+1}) f\|^{2+\varepsilon}$ *for all* $j \in \{1, \dots, J-1\}$.

*Then* $\|f_t - f_\infty\| = O(t^{-\infty})$.

This theorem may seem particularly abstract and confusing, so I should give some explanations. First, $B$ plays the role of the antisymmetric part, but this shows only in the assumption that it does not contribute to the decay of $\mathcal{E}$; on the contrary, $\mathcal{C}$ should be thought of as the symmetric, or collisional part, and it does make the Lyapunov functional decay.

Next, the operators $\Pi_j$ act as a family of "nested projections". The first one, $\Pi_1$, sends $f$ to the kernel of the "collision operator" $\mathcal{C}$; then the second one sends $f$ to a smaller subspace, and then each $\Pi_j$ takes values in a smaller subspace until finally one reaches $f_\infty$. The "concrete" examples are the maps $f \to M^f_{\rho\, u\, T}$, $f \to M^f_{\rho\, u\, \langle T\rangle}$, $f \to M^f_{\rho\, 0\, 1}$, $f \to f_\infty$ which we considered in Section 2 (so for the Boltzmann equation we need four such nonlinear projections).

Finally, the key hypocoercivity condition is (H): It ensures basically that the effect of the "antisymmetric part" $B$ is strong enough to get us out of the image of $\Pi_j$, unless we are in the image of $\Pi_{j+1}$.

Theorem 3.9 leads to a simplified proof of Theorem 2.2, which does not involve any second-order differential inequality, but just variants of Gronwall's lemma. Once again, the key point is to add a correction to the Lyapunov functional $\mathcal{E}$ into another functional $\mathcal{F}$. The correction is small enough that the value of $\mathcal{F}$ is very close to the value of $\mathcal{E}$; but its structure is such that $\mathcal{F}$ satisfies (almost) a Gronwall-type estimate. More explicitly,

$$\mathcal{F}(f) = \big[\mathcal{E}(f) - \mathcal{E}(f_\infty)\big] + \sum_{j=1}^{J-1} a_j \big\langle (\mathrm{Id} - \Pi_j) f,\ (\mathrm{Id} - \Pi_j)'_f \cdot (Bf) \big\rangle, \tag{15}$$

where $\langle \cdot, \cdot \rangle$ denotes the scalar product in, say, $X^0$, and $\varepsilon > 0, a_j > 0\,(1 \le j \le J-1)$ are small numbers depending on the smoothness of $f_t$, on $\delta$, and on estimates on the distance of $f$ to $f_\infty$ (in general $1 \gg a_1 \gg \cdots \gg a_{J-1}$).

If the reader thinks that I am being too abstract and formal here, I invite him or her to write down explicitly what (15) is for the Boltzmann equation: Take $\mathcal{E}(f) = \int f \log f$, $f_\infty = M(v)$, $\Pi_1 f = M^f_{\rho\, u\, T}$, $\Pi_2 f = M^f_{\rho\, u\, \langle T \rangle}$, $\Pi_3 f = M^f_{\rho\, 0\, 1}$, $\Pi_4 f = f_\infty$, and $Bf = v \cdot \nabla_x f$; then the expression of $\mathcal{F}(f)$ would fill up basically a whole page. Expression (15) is not only quite general, it is also the best way to conduct calculations.

Let me conclude this section with another theorem that can be derived from Theorem 3.9: convergence to equilibrium for the nonlinear Vlasov–Fokker–Planck interaction with moderate interaction and small coupling.

**Theorem 3.10.** *Let $W \in C^\infty(\mathbb{T}^n)$ be an even smooth function with* $\sup W - \inf W$ *small enough, and let $f_0$ be a probability density on $\mathbb{T}^n_x \times \mathbb{R}^n_v$, with all moments finite. Then there is a unique solution $(f_t)_{t \ge 0}$ to the partial differential equation*

$$\frac{\partial f}{\partial t} + v \cdot \nabla_x f - \nabla_x (W * \rho) \cdot \nabla_v f = \Delta_v f + \nabla_v \cdot (f v), \quad \rho_t(x) = \int f_t(x, v)\, dv;$$

*and it does converge to a uniquely determined equilibrium distribution $f_\infty$, with*

$$\| f_t - f_\infty \|_{L^1} = O(t^{-\infty}).$$

This theorem also follows directly from Theorem 3.9, now by choosing just $\Pi_1 f = \rho M$, $\Pi_2 f = f_\infty$, where the equilibrium $f_\infty$ is the unique minimizer of the energy functional $H(f) + (1/2) \int \rho(x)\, \rho(y)\, W(x - y)\, dx\, dy$. The assumption on $W$ being smooth and small enough guarantees the uniqueness of the minimizer (it implies that we stay away from phase transitions) and allows to develop a very strong regularity theory for the equation.

## 4. Perspectives

There seems to be a whole mathematical world to explore behind the hypocoercivity phenomenon, both in nonlinear and linear partial differential equations.

Obvious remaining open problems concern the nonlinear equations such as Boltzmann's equation, for which the convergence to equilibrium is proven only under strong conditional smoothness assumptions; however, Theorem 2.2 says that, in some sense, it all amounts to a good understanding of the Cauchy problem. The situation is more subtle for coupled equations, such as the Vlasov–Fokker–Planck model: Theorem 3.10 solves the problem only for smooth *small enough* potentials, leaving completely open the issue of phase transition for large potentials. Realistic models such as the Vlasov–Poisson–Fokker–Planck equation require further thoughts.

But within the range of linear equations, where one is more demanding about conclusions, there is even much more to say. First, one would like to get a qualitative description of the convergence to equilibrium, and in particular of the oscillations described in the discussion of the Boltzmann equation. As discussed in [29], these oscillations appear in many models, but not always, and their presence or absence should be related to some spectral analysis of the linearized operator, involving conservation laws and hydrodynamical approximations. Recently, Francis Filbet, Clément Mouhot and Lorenzo Pareschi [10] have made some progress on this issue, by combining numerical simulations, linearization and asymptotic analysis; they suggest that for large domains the period of oscillations is given by the imaginary part of the eigenvalues of the linearized compressible Euler system, while the asymptotic rate of decay is determined by the real parts of the eigenvalues of the compressible linearized Navier–Stokes system. For small enough domains, the situation is completely different, and hydrodynamic effects should be negligible. Actually, numerical simulations in small domains show that the gas distribution first becomes spatially homogeneous, and then converges to equilibrium like a solution of the spatially homogeneous Boltzmann equation – a scenario which is somehow opposite to the ideas that seemed to be prevailing among physicists and mathematicians.

Another issue is about the quantitative relevance of the estimates. All the estimates derived from the hypocoercivity theorems in this text are explicit, but this does not mean that they have the correct order of magnitude. For simple equations like the Fokker–Planck equation, the rates of convergence predicted by my method seem to be off the true value by a factor of about $10^2$, which is not so bad (and much better than previous estimates). But the rates obtained for the oscillator chain have an incredibly bad dependence on the number of oscillators, leaving motivation for quantitative improvement.

It is important to note that the analysis of operators of the form $A^*A + B$ involved a systematic comparison with the symmetric operator $A^*A + [A, B]^*[A, B]$, or more complicated symmetric operators constructed from brackets with $B$. The same is true of the hypoelliptic method by Bernard Helffer and Francis Nier [16]. This might look satisfactory, but might also give wrong orders of magnitude. For instance, in the Model Problem 1.1, we have seen that if the eigenvalues for $A^*A + [A, B]^*[A, B]$ grow like $|\alpha|^{2\nu}$, then the real parts of the eigenvalues for $A^*A + B$ grow at least like $|\alpha|^{\nu}$. This behavior is optimal for some forms of the function $f$, but not for other ones, as pointed out to me by Thierry Gallay. Indeed, if $f(x) = 1/(1 + x^2)$, then $\nu = 1/4$, but numerical simulations suggest that the growth is like $|\alpha|^{1/2}\ldots$. This might indicate a fundamental limitation of present techniques, and motivate the development of a refined analysis.

In the example of the oscillator chain, the application of Theorem 3.4 is so far restricted to the oversimplified case when $T^{(\ell)} = T^{(r)}$. In fact, Theorem 3.4 could be applied if we had some basic qualitative information about the non-explicit equilibrium measure: For instance, some bounds on the Hessian of the logarithm of its density; and a Poincaré inequality. This leads to another challenging topic: deriving

qualitative *global* information about stationary solutions of linear partial differential equations.

Finally, the links and analogies between hypoellipticity and hypocoercivity need to be further explored. The interplay goes in both directions: It is possible to adapt some of the tricks presented here, into elementary methods for the study of hypoelliptic regularization. While these do not apply with such generality as the classical techniques introduced by Lars Hörmander and later by Joseph Kohn, they are quite flexible, in particular to get global estimates, or estimates from $L^1$ data. The same discovery has been made independently by Frédéric Hérau. Hopefully, all this agitation will lead to a new look at the old field of hypoelliptic regularity.

# Metastability: a potential theoretic approach

Anton Bovier*

**Abstract.** Metastability is an ubiquitous phenomenon of the dynamical behaviour of complex systems. In this talk, I describe recent attempts towards a model-independent approach to metastability in the context of reversible Markov processes. I will present an outline of a general theory, based on careful use of potential theoretic ideas and indicate a number of concrete examples where this theory was used very successfully. I will also indicate some challenges for future work.

**Mathematics Subject Classification (2000).** Primary 60J45; Secondary 82C26.

**Keywords.** Metastability, Markov processes, potential theory, capacity, spectral theory.

## 1. Introduction

Metastability is a physical phenomenon that is observed in a large variety of situations in nature. The classical school-book example is the time delay in the evaporation of overheated water, resp. the delayed freezing of under-cooled water. Generally speaking, metastability is related to the existence of multiple, well separated time-scales: at a short time-scale, the systems *appears* to be in an equilibrium state, but really explores only a confined section of its available phase space, while, at much larger time scales, it undergoes transitions *between* such *metastable* states. The main mathematical task we want to discuss it the analysis of such system at these very long time-scales.

The mathematical description of metastable systems began in the 1930s and 1940s and is linked to the names of Eyring [15] and Kramer [26], who were interested in metastability in the context of chemical reactions. Kramer, in particular, introduced a one-dimensional diffusion process in a double-well potential as a model of a metastable system which is still used today in many applications. This work set the way to study metastability as a phenomenon that takes place in *stochastic processes*, and, in particular, in *Markov processes*, which is the setting that we will consider in this talk.

The mathematically rigorous analysis of metastability phenomena in the context of stochastic dynamics goes back essentially to the work of Freidlin and Wentzell in the early 1970s (see their seminal book [16]). They considered mainly the setting

*Support by the German Research Council (DFG) and by the European Science Foundation in the programme RDSES is gratefully acknowledged.

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

of finite dimensional dynamical systems perturbed by weak additive noise. In the simplest case, this would be driven by Brownian motion, but alternative settings, such as Levy-processes, were also considered. Metastability arises in this context if the unperturbed systems possesses several stable attractors. In this case, on short time-scales, the trajectories of the system will track those of the unperturbed system, and hence will converge towards one of the attractors. On much longer time-scales, however, the random perturbation allow the system to perform transitions between these stable attractors. The method to analyse the occurrence of such transitions introduced by Freidlin and Wentzell in this context was *large deviation theory* on path-space. This allows to control the probability of an "atypical" trajectory $\gamma(t)$ over some time interval $[T_1, T_2]$ in terms of an *action functional* $S(\gamma, T_1, T_2)$, which can be written as

$$S(\gamma, T_1, T_2) = \int_{T_1}^{T_2} \mathcal{L}(\gamma(t), \gamma'(t), t)\, dt \tag{1.1}$$

in the sense that

$$\lim_{\epsilon \downarrow 0} \epsilon \ln \mathbb{P}\left(X_\epsilon(t) \sim \gamma(t), \quad t \in [T_1, T_2]\right) = S(\gamma, T_1, T_2), \tag{1.2}$$

where $\epsilon$ is a parameter controlling the strength of the random perturbation, and $\mathcal{L}$ is a *Lagrangian* in the sense of classical mechanics. Clearly, such results allow to compute probabilities, and hence expected times, of the occurrence of transitions between attractors. We will refer to estimates of the type (1.2) as *logarithmic equivalence*. While these are in some sense rather crude estimates, the large deviation method has proven very useful due to its rather universal applicability. It has, in fact, dominated the field on the mathematical side, and large deviations and metastability are often seen as almost synonymous (see e.g. the recent monograph [35]).

Besides the large deviation estimates, Freidlin and Wentzell introduced a very interesting and useful way of looking at metastable systems by associating to it what they called a *Markov chain with exponentially small transition probabilities*. Here they associate to the original system a finite state Markov chain whose states label the different attractors of the underlying dynamical system. The transition probabilities of this new chain are then computed by finding the probability of the most likely trajectory linking two such attractors; by the foregoing discussion, this probability will be exponentially small. The long-time behaviour of the system, viewed on the coarse-grained level, will then be well-described by that of the associated finite Markov chain. It was later noted that such Markov chains arise also in other contexts, notably in stochastic dynamics of interacting particle systems at very low temperatures, and they have become a subject of intensive investigation in their own right ([33], [34], [10], [9]), initially again mainly through large deviation techniques.

In the physics literature, very early on more precise results than those provided by large deviation theory were sought. The modelling context here was mostly that of stochastic differential equations with small noise, i.e. the multi-dimensional extension of Kramer's approach. However, while in the one-dimensional case essentially

exact solutions are available, the multi-dimensional setting leads to partial differential equations that are not explicitly solvable, and those asymptotic analysis encountered considerable analytic difficulties. Several authors strove to overcome those and to derive asymptotic expansions in the parameter $\epsilon$ using methods similar to those used in the study of quantum mechanical tunneling (WKB-method); these results remained, however, on the formal level, as no error estimates could be proven. We will not enter the details of this development here, but refer to the excellent account given in [27]. Very recently, there has been renewed progress on this issue in the case of the reversible diffusions that we will comment on below [18], [19], [20].

Independent of the issue of rigour, the analytic approach has the disadvantage that it is applicable to a very limited class of models. Thus, more robust techniques that would still give precise results are sought for. Spectral theory for the generator of the Markov process appears as a natural tool, since long-term dynamical properties should find their encoding in the nature of the spectrum. In fact, the analysis of the *spectral gap* between the zero eigenvalue and the next-smallest eigenvalue of the generator has been a prominent topic in the theory of Markov processed, mainly as a tool to control convergence to equilibrium. Let us cite, from the vast body of literature, the papers [24], [31], [30]. The characterisation of metastability in terms of spectral properties was initiated in early work of Davies [11], [12], [13], and more recently continued by Gaveau and Schulman [17]. In view of numerical applications in dynamics of large bio-molecules, this issue was also addressed recently by Huisinga et al. [25].

Our own interest in the issue of metastability form the study of Gibbs distributions of disordered systems, and in particular the Hopfield model of neural networks. Here one is interested in the dynamical behaviour of Markov process on some high-dimensional state space, mostly chosen to be reversible with respect to a *Gibbs measure*. Considerable effort is invested in the analysis of the properties of these Gibbs measures in the limit of infinite dimensions. The question that then arises is what can be learned from these Gibbs measures, or, what do we need to know about the Gibbs measures in order to understand the long-term properties of the dynamics? This question can be seen as the leitmotiv behind our work. Other than that, we were aiming for an approach that would be to a large extend model independent, and that at the same time would provide finer estimates than those obtainable with large deviation methods. Our approach thus makes deliberate use of knowledge of the invariant measure, and, moreover, will always assume that the dynamics is reversible. This certainly leaves many interesting situations out of the reach of our methods, but still covers a range of important applications.

**Acknowledgements.** The work reported here is based on a joint effort with Véronique Gayrard, Michael Eckhoff, and Markus Klein to understand metastability. Applications of these ideas in concrete models have been worked out with Gerard Ben Arous, Alessandra Faggionato, Frank den Hollander, Francesco Manzo, and Francesca Nardi. I am deeply indebted to all these collaborators for their immense contributions.

## 2. Characterisations of metastability

The most general setting we will consider can be described as follows. We consider a Markov process $X_t$ on a measure space $\Gamma \supset X_t$ with discrete or continuous time $t$. We will usually assume that the process is uniquely ergodic with invariant measure $\mathbb{Q}$. We will denote the law of this process by $\mathbb{P}$. Moreover, we will denote by $\mathbb{P}_x$ the law of the process conditioned on $X_0 = x$. We will denote by $\tau_D$, $D \subset \Gamma$, the first entrance time of $X_t$ in $D$, i.e.

$$\tau_D \equiv \inf\{t > 0,\ X(t) \in D\}. \tag{2.1}$$

An intuitively appealing definition of metastability could be the following:

*A family of Markov processes is called metastable, if there exists a collection of disjoint sets $B_i \subset \Gamma$, such that*

$$\frac{\sup_{x \notin \cup_i B_i} \mathbb{E}_x \tau_{\cup_i B_i}}{\inf_{x \in \cup_i B_i} \mathbb{E}_x \tau_{\cup_{k \neq i} B_k}} = o(1). \tag{2.2}$$

Here $o(1)$ should be thought of as an intrinsic small parameter that characterises the "degree" of metastability. Often we will have to do with a family of processes indexed by a parameter, that allows to make (2.2) as small as we like.

Intuitively, this definition says that our process lingers around one of the subsets $B_i$ for a long time (resp. returns to $B_i$ many times) before it visits another of these sets, and so on. This can be re-expressed in a number of ways, e.g. in terms of the behaviour of empirical distributions, but we will not go into this.

This definition characterizes metastability in terms of physical properties, namely hitting times, of the system. The problem is that it is not immediately verifiable, since it involves mean hitting times, that are nor easy to compute. It would thus be desirable to have an equivalent definition involving more manageable quantities.

A further goal will be to derive further general properties of metastable systems. Since the definition implies frequent returns to the small starting set $B_i$ before transit to another set $B_j$, this suggests an exponential law for the transit times. This also suggests that we may expect to describe the process of successive visits to distinct $B_i$ asymptotically as a Markov process. The most fundamental result we want to achieve in this context is a characterization of the spectrum of the generator, resp. the transition matrix of a metastable process.

## 3. Markov processes and potential theory

Our approach to metastability relies heavily on some elementary potential theory for Markov processes. Let us briefly recall some basic facts and definitions. We will consider the case of discrete space and discrete time, but the same holds with obvious changes in the continuous setting.

Thus let $\Gamma$ be a discrete set, $\mathbb{Q}$ be a positive measure on $\Gamma$, and $P$ a stochastic matrix on $\Gamma$. We will denote by $-L$ the generator of the process in the case of continuous time, and set $L = \mathbb{1} - P$ in the case of discrete time[1]. We assume that $L$ is symmetric on the space $L^2(\Gamma, \mathbb{Q})$.

**Green's function.** Let $\Omega \subset \Gamma$. Consider for $\lambda \in \mathbb{C}$ and $g$ a real valued function on $\Omega$ the Dirichlet problem

$$\begin{aligned} (L-\lambda) f(x) &= g(x), \qquad x \in \Omega, \\ f(x) &= 0, \qquad x \in \Omega^c. \end{aligned} \tag{3.1}$$

Whenever $\lambda$ is such that the problem has a unique solution, then it can be expressed in terms of the Dirichlet Green's function $G^{\lambda}_{\Omega}(x, y)$ as $(L-\lambda)^{\Omega}$, i.e. for any $g \in C_0(\Omega)$,

$$f(x) = \sum_{y \in \Omega} G^{\lambda}_{\Omega}(x, y) g(y). \tag{3.2}$$

Recall that the spectrum of $L$ (more precisely the Dirichlet spectrum of the restriction of $L$ to $\Omega$, which we will sometimes denote by $L^{\Omega}$), is the complement of the set of values $\lambda$ for which $G^{\lambda}_{\Omega}$ defines a bounded operator.

**Equilibrium potential and equilibrium measure.** Let $A, D \subset \Gamma$. Then the $\lambda$-equilibrium potential $h^{\lambda}_{A,D}$ (of the capacitor $(A, D)$) is defined as the solution of the Dirichlet problem

$$\begin{aligned} (L-\lambda) h^{\lambda}_{A,D}(x) &= 0, \quad x \in (A \cup D)^c, \\ h^{\lambda}_{A,D}(x) &= 1, \quad x \in A, \\ h^{\lambda}_{A,D}(x) &= 0, \quad x \in D. \end{aligned} \tag{3.3}$$

Note that (3.3) has a unique solution provided $\lambda$ is not in the spectrum of $L^{(A \cup B)^c}$.

The equilibrium measure $e^{\lambda}_{A,D}$ is defined as the unique measure on $A$ such that

$$h^{\lambda}_{A,D}(x) = \sum_{y \in A} G^{\lambda}_{D^c}(x, y) e^{\lambda}_{A,D}(y). \tag{3.4}$$

(3.4) may also be written as

$$e^{\lambda}_{A,D}(y) = (L-\lambda) h^{\lambda}_{A,D}(y). \tag{3.5}$$

**Capacity.** We now restrict our attention to the case $\lambda = 0$. We write $h \equiv h^0$ and $e \equiv e^0$. The *capacity* of the capacitor $(A, D)$ is defined as

$$\operatorname{cap}(A, D) \equiv \sum_{y \in A} \mathbb{Q}(y) e_{A,D}(y). \tag{3.6}$$

[1] The choice of the sign is made so that $L$ is a positive definite operator.

Using (3.5) one derives after some algebra that

$$\mathrm{cap}(A, D) = \frac{1}{2}\sum_{x,y} \mathbb{Q}(y)p(x, y)\|h_{A,D}(x) - h_{A,D}(y)\|^2 \equiv \Phi(h_{A,D}), \tag{3.7}$$

where $p(x, y)$ are the transition probabilities (in discrete time) respectively transition rates (in discrete time). $\Phi$ is called the Dirichlet form (or energy) for the operator $L$.

A fundamental consequence of (3.7) is the variational representation of the capacity, namely

$$\mathrm{cap}(A, D) = \inf_{h\in\mathcal{H}_{A,D}} \Phi(h), \tag{3.8}$$

where $\mathcal{H}_{A,D}$ denotes the set of functions

$$\mathcal{H}_{A,D} \equiv \{h\colon \Gamma \to [0, 1] : h(x) = 0,\ x \in D,\ h(x) = 1,\ x \in A\}. \tag{3.9}$$

**Probabilistic interpretation.** If $\lambda = 0$, the equilibrium potential has a natural probabilistic interpretation in terms of hitting probabilities of this process, namely

$$h_{A,D}(x) = \mathbb{P}_x[\tau_A < \tau_D]. \tag{3.10}$$

The equilibrium measure has a nice interpretation in the discrete time case if $A = \{y\}$ is a single point:

$$e_{y,D}(y) = \mathbb{P}_y[\tau_D < \tau_y]. \tag{3.11}$$

If $\lambda \neq 0$, the equilibrium potential still has a probabilistic interpretation in terms of the Laplace transform of the hitting time $\tau_A$ of the process starting in $x$ and killed in $D$. Namely, we have for general $\lambda$ that

$$h^{\lambda}_{A,D}(x) = \mathbb{E}_x e^{\lambda\tau_A}\mathbb{1}_{\tau_A<\tau_D} \tag{3.12}$$

for $x \in (A \cup D)^c$, whenever the right-hand side is finite.

Note that (3.12) implies that

$$\frac{d}{d\lambda}h^{\lambda=0}_{A,D}(x) = \mathbb{E}_x\tau_A\mathbb{1}_{\tau_A<\tau_D}. \tag{3.13}$$

Differentiating the defining equation of $h^{\lambda}_{A,D}$ reveals that the function

$$w_{A,D}(x) = \begin{cases} \mathbb{E}_x\tau_A\mathbb{1}_{\tau_A<\tau_D}, & x \in (A \cup D)^c \\ 0, & x \in A \cup D \end{cases} \tag{3.14}$$

solves the inhomogeneous Dirichlet problem

$$Lw_{A,D}(x) = h_{A,D}(x), \quad x \in (A \cup D)^c, \tag{3.15}$$

$$w_{A,D}(x) = 0, \quad x \in A \cup D. \tag{3.16}$$

Therefore, the mean hitting time in $A$ of the process killed in $D$ can be represented in terms of the Green's function as

$$\mathbb{E}_x \tau_A \mathbb{1}_{\tau_A < \tau_D} = \sum_{y \in (A \cup D)^c} G_{(A\cup D)^c}(x, y) h_{A,D}(y). \tag{3.17}$$

Note that in the particular case when $D = \emptyset$, we get the familiar Dirichlet problem

$$L w_A(x) = 1, \quad x \in A^c, \tag{3.18}$$

$$w_A(x) = 0, \quad x \in A, \tag{3.19}$$

and the representation

$$\mathbb{E}_x \tau_A = \sum_{y \in A^c} G_{A^c}(x, y). \tag{3.20}$$

The full beauty of all this comes out when combining (3.4) with (3.17), resp. (3.20). Namely,

$$\begin{aligned} \mathbb{Q}(z)\mathbb{E}_z \tau_A e_{z,A}(z) &= \sum_{y \in A^c} \mathbb{Q}(y) G_{A^c}(y, z) e_{z,A}(z) \\ &= \sum_{y \in A^c} \mathbb{Q}(y) h_{z,A}(y) \end{aligned} \tag{3.21}$$

or

$$\mathbb{E}_z \tau_A = \frac{1}{\operatorname{cap}(z, A)} \sum_{y \in A^c} \mathbb{Q}(y) h_{z,A}(y) \tag{3.22}$$

**Remark 3.1.** Equation (3.22) relies explicitly on the discrete structure on the state space, or more precisely that for any $x \in \Gamma$, $\mathbb{Q}(x) > 0$. In the case of continuous state space, such formulas do not hold in the strict sense, or are not useful, but suitable "integral versions", involving integrals over suitably chosen small neighborhoods of e.g. the points $z$ in (3.22) are still valid, and can be used to more or less the same effect as the exact relations in the discrete case. This entails, however, some extra technical difficulties. In these notes we will therefore restrict our attention to the discrete case, where the principle ideas can be explained without being obscured by technicalities.

## 4. Capacitary characterization of metastability

The relation (3.22) between mean hitting times and capacities suggests an alternative characterisation of metastability through capacities. We will see that this entails many advantages.

**Definition 4.1.** Assume that $\Gamma$ is a discrete set. Then a Markov processes $X^t$ is $\rho$-metastable with respect to the set of points $\mathcal{M} \subset \Gamma$ if

$$\frac{\sup_{x \in \mathcal{M}} \operatorname{cap}(x, \mathcal{M}\backslash x)/\mathbb{Q}(x)}{\inf_{y \notin \mathcal{M}} \operatorname{cap}(y, \mathcal{M})/\mathbb{Q}(y)} \leq \rho \ll 1. \tag{4.1}$$

**Remark 4.2.** Definition 4.1 is useful since it involves quantities that are either "known", or expected to be easily controllable. It becomes intuitively more appealing if we notice that it can be written alternatively as

$$\frac{\sup_{x\in\mathcal{M}} \mathbb{P}_x[\tau_{\mathcal{M}\setminus x} < \tau_x]}{\inf_{y\notin\mathcal{M}} \mathbb{P}_y[\tau_{\mathcal{M}} < \tau_y]} \leq \rho \ll 1. \tag{4.2}$$

**Renewal estimates.** The estimation of the equilibrium through capacities is based on a renewal argument, that in the case of discrete state space is very simple.

**Lemma 4.3.** *Let $A, D \subset \Gamma$ be disjoint sets, and let $x \notin A \cup D$. Then*

$$h_{A,D}(x) \leq \min\left(\frac{\mathrm{cap}(x, A)}{\mathrm{cap}(x, D)}, 1\right). \tag{4.3}$$

**Remark 4.4.** Note that the power of Lemma 4.3 is more than doubled by judicious use of the elementary fact that $h_{A,D}(x) = 1 - h_{D,A}(x)$.

**Ultrametricity.** An important fact that allows to obtain general results under our definition of metastability is the fact that it implies approximate ultrametricity of capacities. This has been noted in [5].

**Lemma 4.5.** *Assume that $x, y \in \Gamma$ and $D \subset \Gamma$. If $\mathrm{cap}(y, D) \leq \delta \mathrm{cap}(y, x)$ for $0 < \delta < \frac{1}{2}$, then*

$$\frac{1-2\delta}{1-\delta} \leq \frac{\mathrm{cap}(x, D)}{\mathrm{cap}(y, D)} \leq \frac{1}{1-\delta}. \tag{4.4}$$

*Proof.* The proof of this lemma given in [5] is probabilistic and uses splitting and renewal ideas. It should be possible to prove this result with purely analytic arguments. □

Lemma 4.5 has the following immediate corollary, which is the version of the ultrametric triangle inequality we are looking for:

**Corollary 4.6.** *Let $x, y, z \in \mathcal{M}$. Then*

$$\mathrm{cap}(x, y) \geq \frac{1}{3} \min\left(\mathrm{cap}(x, z), \mathrm{cap}(y, z)\right) \tag{4.5}$$

In the sequel it will be useful to have the notion of a "valley" or "attractor" of a point in $\mathcal{M}$. We set for $x \in \mathcal{M}$,

$$A(x) \equiv \{z \in \Gamma \mid \mathbb{P}_z[\tau_x = \tau_{\mathcal{M}}] = \sup_{y\in\mathcal{M}} \mathbb{P}_z[\tau_x = \tau_{\mathcal{M}}]\} \tag{4.6}$$

Note that valleys may overlap, but from Lemma 4.5 it follows easily that the intersection has a vanishing invariant mass. The notion of a valley in the case of a diffusion process coincides with the intuitive notion.

**Mean times.** A very pleasant feature of the definition of metastability in terms of capacities is that it allows to relate some key capacities to mean hitting times in a very simple way.

**Theorem 4.7.** *Let $x \in \mathcal{M}$ and $J \subset \mathcal{M}\backslash x$ be such a that for all $m \notin J \cup x$ either $\mathbb{Q}(m) \ll \mathbb{Q}(x)$ or $\mathrm{cap}(m, J) \gg \mathrm{cap}(m, x)$. Then*

$$\mathbb{E}_x \tau_J = \frac{\mathbb{Q}(A(x))}{\mathrm{cap}(x, J)} (1 + o(1)) . \tag{4.7}$$

Finally we want to compute the mean time to reach $\mathcal{M}$ starting from a general point.

**Lemma 4.8.** *Let $z \notin \mathcal{M}$. Let $a \equiv \sup_{y \notin \mathcal{M}} \frac{\mathbb{Q}(y)}{\mathrm{cap}(y, \mathcal{M})}$. Then*

$$\mathbb{E}_z \tau_{\mathcal{M}} \leq a^{-2} |\Gamma|. \tag{4.8}$$

**Remark 4.9.** If $\Gamma$ is finite, the above estimate combined with Theorem 4.7 shows that the two definitions of metastability we have given in terms of mean times rep. capacities are equivalent. On the other hand, in the case of infinite state space $\Gamma$, we cannot expect the supremum over $\mathbb{E}_z \tau_{\mathcal{M}}$ to be finite, which shows that our first definition was somewhat naive. Note however that this case the estimate (4.8) can be improved by placing $|\Gamma|$ with $\sum_{y:\mathbb{Q}(y \leq \mathbb{Q}(z)} \mathbb{Q}(y)/\mathbb{Q}(z) + \sum_{y:\mathbb{Q}(y) > \mathbb{Q}(z)} 1$.

## 5. Spectral characterisation of metastability

We now turn to the characterisation of metastability through spectral data. We will show that Definition 4.1 implies that the spectrum of the generator decomposes into a cluster of $|\mathcal{M}|$ very small real eigenvalues that are separated by a gap from the rest of the spectrum.

**A priori estimates.** The first step of our analysis consists in showing that the matrix $L^{\mathcal{M}^c}$ (i.e. with Dirichlet conditions in all the points of $\mathcal{M}$) has a minimal eigenvalue that is not smaller than $O(a)$. This result needs sometimes some improvement, but is shows the basic twist. This is a simple application of a Donsker–Varadhan argument.

**Lemma 5.1.** *Let $\lambda^0$ denote the infimum of the spectrum of $L^{\mathcal{M}^c}$. Then*

$$\lambda^0 \geq \frac{1}{\sup_{x \in \Gamma} \mathbb{E}_z \tau_{\mathcal{M}}}. \tag{5.1}$$

**Remark 5.2.** Lemma 5.1 links the fast time scale to the smallest eigenvalue of the Dirichlet operator, as should be expected. Note that the relation is not very precise. We will soon derive a much more precise relation between times and eigenvalues for the cluster of small eigenvalues. As stated, it is useless in the case of infinite state

space. It can, however, be improved to give useful bounds under tightness conditions on $\mathbb{Q}$ [5].

**Characterization of small eigenvalues.** We will now obtain a representation formula for all eigenvalues that are smaller than $\lambda^0$. It is clear that there will be precisely $|\mathcal{M}|$ such eigenvalues. This representation was first exploited in [5], but already in 1973 Wentzell put forward very similar ideas.

The basic idea is to use the fact that the solution of the Dirichlet problem

$$\begin{aligned} (L-\lambda)f(x) &= 0, \qquad x \notin \mathcal{M}, \\ f(x) &= \phi_x, \qquad x \in \mathcal{M}, \end{aligned} \tag{5.2}$$

already solves the eigenvalue equation $L\phi(x) = \lambda\phi(x)$ everywhere except possibly on $\mathcal{M}$. The question if whether an appropriate choice of boundary conditions and the right choice of the value of $\lambda$ will actually lead to a solution. This is indeed the case.

**Lemma 5.3.** *Assume that $\lambda < \lambda^0$ is an eigenvalue of $L$ and $\phi(x)$ is the corresponding eigenfunction. Then the unique solution of* (5.2) *with $\phi_x = \phi(x)$, $x \in \mathcal{M}$, satisfies $f(y) = \phi(y)$, for all $y \in \Gamma$.*

Let us denote by $\mathcal{E}_{\mathcal{M}}(\lambda)$ the $|\mathcal{M}| \times |\mathcal{M}|$-matrix with elements

$$(\mathcal{E}_{\mathcal{M}}(\lambda))_{xy} \equiv e^{\lambda}_{z,\mathcal{M}\setminus z}(x). \tag{5.3}$$

**Lemma 5.4.** *A number $\lambda < \lambda^0$ is an eigenvalue of the matrix $L$ if and only if*

$$\det \mathcal{E}_{\mathcal{M}}(\lambda) = 0. \tag{5.4}$$

Anticipating that we are interested in small $\lambda$, we want to re-write the matrix $\mathcal{E}_{\mathcal{M}}$ in a more convenient form. To do so let us set

$$h^{\lambda}_x(y) \equiv h_x(y) + \psi^{\lambda}_x(y). \tag{5.5}$$

Then $\mathcal{E}(\lambda)$ can be written in the form

$$\begin{aligned} (\mathcal{E}_{\mathcal{M}}(\lambda))_{xz} = \mathbb{Q}(x)^{-1}\Bigg(&\frac{1}{2}\sum_{y\neq y'} \mathbb{Q}(y')p(y',y)[h_z(y') - h_z(y)][h_x(y') - h_x(y)] \\ &- \lambda \sum_y \mathbb{Q}(y)\left(h_z(y)h_x(y) + h_x(y)\psi^{\lambda}_z(y)\right)\Bigg) \end{aligned} \tag{5.6}$$

where the term involving $\psi^{\lambda}$ can be viewed as a more or less irrelevant

We are now in a position to relate the small eigenvalues of $L$ to the eigenvalues of the classical capacity matrix. Let us denote by $\|f\|_2$ the $\ell^2$-norm with respect to the measure $\mathbb{Q}$, i.e. $\|f\|_2^2 = \sum_y \mathbb{Q}(y)f(y)^2$.

**Theorem 5.5.** *If $\lambda < \lambda^0$ is an eigenvalue of $L$, then there exists an eigenvalue $\mu$ of the $|\mathcal{M}| \times |\mathcal{M}|$-matrix $\mathcal{K}$ whose matrix elements are given by*

$$\mathcal{K}_{zx} = \frac{\frac{1}{2}\sum_{y \neq y'} \mathbb{Q}(y')p(y', y)[h_z(y') - h_z(y)][h_x(y') - h_x(y)]}{\|h_z\|_2 \|h_x\|_2} \tag{5.7}$$

*such that $\lambda = \mu\,(1 + O(\rho(\epsilon))$.*

The computation of the eigenvalues of the capacity matrix is now in principle a finite, though in general not trivial problem. The main difficulty is of course the computation of the capacities and induction coefficients.

In fact we will prove the following theorem.

**Theorem 5.6.** *Assume that there exists $x \in \mathcal{M}$ such that for some $\delta \ll 1$*

$$\frac{\mathrm{cap}_x(\mathcal{M}\backslash x)}{\|h_x\|_2^2} \geq \delta \max_{z \in \mathcal{M}\backslash x} \frac{\mathrm{cap}_z(\mathcal{M}\backslash z)}{\|h_z\|_2^2}. \tag{5.8}$$

*Then the largest eigenvalue of $L$ is given by*

$$\lambda_x = \frac{\mathrm{cap}_x(\mathcal{M}\backslash x)}{\|h_x\|_2^2}(1 + O(\delta)) \tag{5.9}$$

*and all other eigenvalues of $L$ satisfy*

$$\lambda \leq C\delta\lambda_x. \tag{5.10}$$

*Moreover, the eigenvector $\phi$ corresponding to the largest eigenvalues normalized such that $\phi_x = 1$ satisfies $\phi_z \leq C\delta$, for $z \neq x$.*

Theorem 5.6 has the following simple corollary, that allows in many situations a complete characterization of the small eigenvalues of $L$.

**Corollary 5.7.** *Assume that we can construct a sequence of metastable sets $\mathcal{M}_k \supset \mathcal{M}_{k-1} \supset \cdots \supset \mathcal{M}_2 \supset \mathcal{M}_1 = x_0$, such that, for any $i$, $\mathcal{M}_i \backslash \mathcal{M}_{i-1} = x_i$ is a single point, and that each $\mathcal{M}_i$ satisfies the assumptions of Theorem* 5.6. *Then $L$ has $k$ eigenvalues*

$$\lambda_i = \frac{\mathrm{cap}_{x_i}(\mathcal{M}_{i-1})}{\mathbb{Q}(A(x_i))}\,(1 + O(\delta))\,. \tag{5.11}$$

*The corresponding normalized eigenfunction is given by*

$$\psi_i(y) = \frac{h_{x_i}(y)}{\|h_{x_i}\|_2} + O(\delta). \tag{5.12}$$

## 6. Variational principles and bounds for capacities

While the characterisation of metastability in terms of properties of mean first entrance times did not seem immediately verifiable in a given model, (3.22) already suggests a close relation between these times to capacities. In fact, the key idea in our approach will be to express all quantities of interest ultimately to capacities, and to exploit the fact that these can be estimated remarkably well by exploiting the variational principle (3.8). This observation is not new; in fact, it is the basis of the "electric network" approach to Markov chains (see e.g. the excellent account in Doyle and Snell [14]). The fact that this approach is very useful for metastable systems appears to have been overlooked.

Let us briefly comment on the use of these variational principles and explain why they are efficient. While the specifics of their exploitation are model-dependent, some basic principles are quite general follow directly from the fact that one is considering a metastable system.

**Upper bound.** Upper bounds on capacities can be gotten readily by judicious choices of a test-function $h$. Inspecting the Dirichlet form will often suggest rather good choices. There are two major advantages in this variational principle: there are no constraints on the test function except boundary conditions, and the minimizers has a very clear probabilistic interpretation. This is quite different from the situation of the Rayleigh–Ritz variational principle for the spectral gap, which is therefore more difficult to handle. The fact that a system is metastable suggests that there will be rather large regions, surrounding the metastable points, where the equilibrium potential is constant, and only its behaviour on the (often small) connecting sets has to be guessed with greater care.

**Lower bound.** A lower bound appears at first sight less obvious; however, the fact that $\Phi(h)$ is monotone in the variables $p(x, y)$ suggests an immediate lower bound in terms of the capacities of a chain there some (or even many) $p(x, y)$ are set to zero (known as Rayleigh's cut method [14]), hoping of course that the resulting chain will be so simple that explicit computations of the capacities are possible. This idea can, however, be extended considerably. To this end, consider a countable set $I$, and a let $\mathcal{G} \equiv \{g_{xy}, x, y \in \Gamma\}$, be a collection of sub-probability measures on $I$, i.e. for each $(x, y)$, $g_{xy}(\alpha) \geq 0$, and $\sum_{\alpha\in I} g_{xy}(\alpha) \leq 1$. Then

$$\begin{aligned}
\mathrm{cap}(A, B) &= \inf_{h\in\mathcal{H}_{A,D}} \sum_{\alpha\in I} \frac{1}{2} \sum_{x,y} \mathbb{Q}(y) g_{xy}(\alpha) p(x, y) \|h_{A,D}(x) - h_{A,D}(y)\|^2 \\
&\geq \sum_{\alpha\in I} \inf_{h\in\mathcal{H}_{A,D}} \sum_{\alpha\in I} \frac{1}{2} \sum_{x,y} \mathbb{Q}(y) g_{xy}(\alpha) p(x, y) \|h_{A,D}(x) - h_{A,D}(y)\|^2 \\
&\equiv \sum_{\alpha\in I} \inf_{h\in\mathcal{H}_{A,D}} \Phi^{\mathcal{G}(x)}(h) \equiv \sum_{\alpha\in I} \mathrm{cap}^{\mathcal{G}(\alpha)}(A, D).
\end{aligned} \tag{6.1}$$

As this it true for all $\mathcal{G}$, we get the variational principle

$$\operatorname{cap}(A, D) = \sup_{\mathcal{G}} \sum_{\alpha \in I} \operatorname{cap}^{\mathcal{G}(a)}(A, D). \tag{6.2}$$

Note that this may look trivial, as of course the supremum is realised for the trivial case $I = \{1\}$, $g_{xy}(1) = 1$, for all $(x, y)$. The interest in the principle arises from the fact that there may be other choices that still realise the supremum (or at least come very close to it). If we denote by $h_{A,D}^{\mathcal{G}(\alpha)}$ the minimizer of $\Phi^{\mathcal{G}(x)}(h)$, then $\mathcal{G}$ realises the supremum whenever

$$h_{A,D}^{\mathcal{G}(\alpha)}(x) = h_{A,D}(x), \quad \text{for all } x \text{ with } g(xy)(\alpha) \neq 0. \tag{6.3}$$

Of course we do not know $h_{A,D}(x)$, but this observation suggest a very good strategy to prove lower bounds, anyhow: guess a plausible test function $h$ for the upper bound, then try to construct $\mathcal{G}$ such that the minimizers, $h^{\mathcal{G}(\alpha)}$, are computable, and are similar to $h$! If this succeeds, the resulting upper and lower bounds will be at least very close. Remarkably, this strategy actually does work in many cases.

## 7. Applications 1. Low-temperature dynamics of spin systems

The somehow simplest example where the general approach outlined above works very well and with remarkable ease is stochastic dynamics of discrete spin systems in the low temperature limit.

Here we have a finite spin-space $\mathcal{S}$, a finite subset $\Lambda$ of $Z^d$, and a Hamiltonian function $H_\Lambda \colon \mathcal{S}^\Lambda \to \mathbb{R}$. The Markov processes one is interested in are reversible (discrete or continuous time) Markov chains on $\mathcal{S}^\Lambda$ that are reversible with respect to the *Gibbs measure*,

$$\mu_\beta(\sigma) = \frac{e^{-\beta H_\sigma(\sigma)}}{Z_{\beta,\Lambda}}, \tag{7.1}$$

where $\beta$ will play the rôle of a large parameter and $\mathbb{Z}_{\beta,\Lambda}$ is a normalisation constant, called partition function. To complete the description of the dynamics, one defines a graph $\Gamma = (\mathcal{S}^\Lambda, \mathcal{E}^\Lambda)$ on $\mathcal{S}^\Lambda$ whose edges determine the allowed transitions. One may then choose transition probabilities

$$p(\sigma, \sigma') = \frac{1}{C_\sigma} e^{-\beta[H_\Lambda(\sigma') - H_\Lambda(\sigma)]_+} \quad \text{if } (\sigma, \sigma') \in \mathcal{E}^\Lambda, \tag{7.2}$$

where $C_\sigma$ denotes the coordination number of the vertex $\sigma$ in $\Gamma$ and $[f]_+$ is the positive part of $f$; all other transitions have zero probability, except of course the probability to stay at $\sigma$, which is determined by the requirement that $p$ be a stochastic matrix. Such a dynamics is usually called a Metropolis algorithm.

Metastability occurs in such dynamics whenever the Hamiltonian has more than one local minimum, if $\beta$ is large. Our methods allow a full analysis of such dynamics,

provided we understand the function $H_\Lambda$ well enough to know its minima and saddle points. This latter problem is rather non-trivial in general and involves complicated discrete optimisation problems. In the Ising model, these have been studied in great detail by Alonso and Cerf [1]

The two most prominent examples in this class of models are the Glauber dynamics in the Ising spin model and Kawasaki dynamics in the Ising lattice gas.

**Ising model under Glauber dynamics.** Here the state space is $\mathcal{S} = \{-1, 1\}$, and the Hamiltonian is

$$H_\Lambda(\sigma) = -\sum_{x,y\in\Lambda,\|x-y\|=1} \sigma_x\sigma_y - h\sum_{x\in\Lambda}\sigma_x. \tag{7.3}$$

The edges of the graph $\Gamma$ of allowed transitions consists of all pairs $\sigma, \sigma'$) such that $\sigma$ and $\sigma'$ differ in exactly one coordinate, i.e. the Hamming distance between $\sigma$ and $\sigma'$ equals to 1. A detailed analysis of the structure of this Hamiltonian was given in [1], [9]. Here, if $h > 0$, the configurations $+\mathbf{1} \equiv \{\sigma_x \equiv +1 \text{ for all } x \in \Lambda\}$, and $-\mathbf{1} \equiv \{\sigma_x \equiv -1 \text{ for all } x \in \Lambda\}$, correspond to the deepest, resp. second-deepest minima. One can verify that the set $\mathcal{M} \equiv \{-\mathbf{1}, +\mathbf{1}\}$ is a set of metastable points in the sense of our definition. This dynamics was investigated in particular in [32] ($d = 2$) and [9] ($d = 2, 3$) using large deviation methods, and logarithmic asymptotics (in the regime $\Lambda$ fixed, $\beta \uparrow \infty$) were obtained, together with a description of the most probable exit path. In [4] we showed that the methods outlined above are readily applicable here and give a radical improvement on the precision of the results. We cite the main theorem of [4] to give a flavour of the type of results one can get.

**Theorem 7.1.** *Consider the Ising model with Metropolis dynamics in dimension $d = 2$ or $d = 3$ in a torus $\Lambda^d(l)$ with diameter $l$. Let $0 < h < 1$ such that $2/h$ and (in $d = 3$) $(h/2\lceil 4/h\rceil(4/h + 1 - \lceil 4/h\rceil)$ is not an integer. Then there exists $\delta > 0$, independent of $\beta$, such that the following hold.*

- *In dimension 2, let $h$ be such that $2/h$ is not an integer. Let $\ell_2 := \lceil \frac{2}{h} \rceil$ and $\Gamma_2 := 4\ell_2 - h(\ell_2^2 - \ell_2 + 1)$ be the diameter and the activation energy of the "critical droplet", respectively. Then*

$$\begin{aligned}\mathbb{E}\tau(-\mathbf{1}) &= \frac{3}{8}\frac{1}{\ell_2 - 1}e^{\beta\Gamma_2}(1 + O(e^{-\beta\delta}) \\ &= \frac{3}{16}he^{\beta\Gamma_2}(1 + O(h) + O(e^{-\beta\delta})).\end{aligned} \tag{7.4}$$

- *In dimension 3, let $h$ be such that $2/h$ and $(h/2\ \lceil 4/h\rceil\ (4/h + 1 - \lceil 4/h\rceil))$ are not integer. Let $\ell_3 := \lceil \frac{4}{h} \rceil$ and $a := \lceil h/2\ \lceil 4/h\rceil\ (4/h + 1 - \lceil 4/h\rceil)\rceil$ (notice that $a$ can take the value 1 or 2). The activation energy of the "critical droplet" is*

$$\begin{aligned}\Gamma_3 := (&6\ell_3^2 - (12 - 4a)\ell_3 + 4\ell_2 + 4 - 2a) \\ &- h(\ell_3^3 - (3 - a)\ell_3^2 + (2 - a) + \ell_2^2 - \ell_2 + 1).\end{aligned} \tag{7.5}$$

*Then*

$$\mathbb{E}\tau(-\mathbf{1}) = \frac{a}{16}\frac{1}{(\ell_3-\ell_2+1)(\ell_3-\ell_2+a-1)(\ell_2-1)}e^{\beta\Gamma_3}(1+O(e^{-\beta\delta})) = \frac{a}{128}h^3e^{\beta\Gamma_3}(1+O(h)+O(e^{-\beta\delta})). \tag{7.6}$$

*Moreover, the distribution of* $\tau(-\mathbf{1})/\mathbb{E}\tau(-\mathbf{1})$ *converges to the exponential distribution as* $\beta \uparrow \infty$.

**Local Kawasaki dynamics with open boundary conditions.** Kawasaki dynamics is most conveniently thought of a taking place on the configuration space $\{0,1\}^\Lambda$, where dynamics variable $\eta_x(t)$ is thought of as the number of particles at site $x$ at time $t$. In contrast to Glauber dynamics, Kawasaki dynamics is *conservative*, i.e. the total number of particles is fixed. In several papers, den Hollander et al. [21], [22] introduced a local version of this dynamics in a finite box where particle number of conserved by transitions within the box, but where particles may appear or disappear at the boundary. This dynamics was introduced as a local approximation of a true Kawasaki dynamics in infinite volume.

The Hamiltonian is written in these variables as

$$H_\Lambda(\eta) = -U\sum_{x,y\in\Lambda;\|x-y\|=1}\eta_x\eta_y - \Delta\sum_{x\in\Lambda}\eta_x. \tag{7.7}$$

Again the dynamics is chosen reversible with respect to the corresponding Gibbs measureand this time transition are possible between configurations $\eta, \eta'$ such that (i) either two nearest neighbor sites $x$, $y$ exchange their particle numbers, or (ii) the particle number of one site in the boundary of $\Lambda$ is increased from 0 to 1, or decreased from 1 to 0. This dynamics differs from Glauber dynamics essentially only in the structure of the graph of admissible transitions, but this has rather noticeable consequences.

From the point of view of metastability, the main new feature is that now the saddle points form Gauber dynamics have to be replaced by 'plateaus': there is a set of critical configurations where a "critical droplet" has been formed and a free particle has entered the box at the boundary. The droplet will become supercritical if this new particle attaches itself to the droplet. Therefore, in the computation of the capacities, the probability that a simple random walker starting at the boundary of a box $\Lambda$ will reach some set in the interior before exiting will play a crucial rôle and will in fact modify the prefactor of the nucleation time in a $\Lambda$ and dimension dependent way. Results analogous to those described in Section 7 have been obtained for Kawasaki dynamics in [8].

## 8. Applications 2. Diffusion processes

In the preceding sections we have explained our approach in the context of discrete Markov chains. A natural challenge was the extension of the methods to the classical examples of the theory of Freidlin and Wentzell, at least in the reversible case, and to consider stochastic differential equations of the type

$$dX_\epsilon(t) = -\nabla F(X_\epsilon(t))dt + \sqrt{2\epsilon}dW(t) \tag{8.1}$$

on a domain in $\mathbb{R}^d$, where $W$ is a $d$-dimensional Brownian motion, and $F$ a potential function (that shall satisfy suitable smoothness and boundary conditions). Note that this process is reversible with respect to the measure $\mathbb{Q}(dx) \equiv \exp(-F(x)/\epsilon)dx$.

The difficulties to overcome in this case is that, in dimension greater than 1, the process will not hit given points in finite time, and thus Definition 4.1 cannot be used. A viable alternative turns out to be:

**Definition 8.1.** Consider a diffusion process on a set $\Omega \subset \mathbb{R}^d$. The processes $X^t$ is $\rho$-metastable with respect to the set of points $\mathcal{M} \subset \Omega$ if

$$\frac{\sup_{x\in\mathcal{M}} \mathrm{cap}\,(B_\epsilon(x), \mathcal{M}\backslash x)\,/\mathbb{Q}\,(B_\epsilon(x))}{\inf_{z\in\Omega} \mathrm{cap}\,(B_\epsilon(z), \cup_{x\in\mathcal{M}}(B_\epsilon(x))\,/\mathbb{Q}\,((B_\epsilon(z)))} \leq \rho \ll 1, \tag{8.2}$$

where $B_\epsilon(x)$ denotes the Euclidean ball of radius $\epsilon$ around $x$.

Note that, if $F$ has finitely many local minima, one may chose the $\mathcal{M}$ as the set of local minima and $\rho = \exp(-c/\epsilon)$ for some $F$-dependent constant $a$.

This definition works, and in fact most of the approach of the discrete setting can be carried over to the diffusion case due to a-priori estimates on regularity properties of harmonic functions with respect to the generator of this process, which is the elliptic operator

$$-L_\epsilon \equiv -\epsilon\Delta - \nabla F(x)\cdot\nabla. \tag{8.3}$$

Elliptic regularity theory for local solutions of equation $L_\epsilon h = f$ implies that these tend to be Hölder continuous with constants those dependence on the small parameter can be controlled; typically they imply that the oscillation of such functions over balls of size $\epsilon$ is bounded by some positive power of $\epsilon$.

The estimates of capacities in the diffusion setup are again rather easily performed, and one obtains rigorous estimates of the prefactor of exit times from metastable sets as well as sharp asymptotics of the set of exponentially small eigenvalues associated with the local minima of $F$, under some non-degeneracy conditions (degenerate cases can in principle also be treated, but require special case by case analysis). The following result was proven in [6]:

**Theorem 8.2.** *Let $x_i$ be a minimum of $F$ and let $D$ be any closed subset of $\mathbb{R}^d$ such that:*

(i) *If $\mathcal{M}_i \equiv \{y_1, \ldots, y_k\} \subset \mathcal{M}$ enumerates all those minima of $F$ such that $F(y_j) \leq F(x_i)$, then $\cup_{j=1}^k B_\epsilon(y_j) \subset D$, and*

(ii) $\mathrm{dist}\,(\mathcal{S}(\mathrm{x_i}, \mathcal{M}_\mathrm{i}), \mathrm{D}) \geq \delta > 0$ *for some $\delta$ independent of $\epsilon$. Then*

$$\mathbb{E}_{x_i}\tau_D = \frac{2\pi\, e^{[F(z^*)-F(x_j)]/\epsilon}}{\sqrt{\det(\nabla^2 F(x_i))}\,\frac{|\lambda_1^*(z^*)|}{\sqrt{|\det(\nabla^2 F(z^*))|}}}\left(1 + O(\sqrt{\epsilon}|\ln\epsilon|)\right). \tag{8.4}$$

Here $z^*$ denotes the "minimal saddle point" between $x_i$ and the set $D$ (assumed unique), and $\lambda_i(z^*)$ denote the eigenvalues of the Hessian matrix of $\nabla^2 F(z^*)$ (assumed non-degenerate), $\lambda_1(z^*)$ being the unique negative one.

The following result on the small eigenvalues of $L_\epsilon$ is taken form [7]:

**Theorem 8.3.** *Assume that $F$ has $n$ local minima, $x_1, \ldots, x_n$ and that for some $\theta > 0$ the minima $x_i$ of $F$ can be labeled in such a way that, with $\mathcal{M}_k \equiv \{x_1, \ldots, x_k\}$ and $\mathcal{M}_0 \equiv \Omega^c$,*

$$F(z^*(x_k, \mathcal{M}_{k-1})) - F(x_k) \leq \min_{i<k}\left(F(z^*(x_i, \mathcal{M}_k \backslash x_i)) - F(x_i)\right) - \theta \tag{8.5}$$

*holds for all $k = 1, \ldots, n$. We will set $B_i \equiv B_\epsilon(x_i)$ and $\mathcal{S}_k \equiv \bigcup_{i=1}^k B_i$, and $h_k(y) \equiv h_{B_k, \mathcal{S}_{k-1}}(y)$. Assume moreover that all saddle points $z^*(x_k, \mathcal{M}_{k-1})$ are unique, and that the Hessian of $F$ is non-degenerate at all these saddle points and at all local minima. Then there exists $\delta > 0$ such that the $n$ exponentially small eigenvalues $\lambda_1 < \lambda_2 < \cdots < \lambda_n$ of $L_\epsilon$ satisfy*

$$\lambda_1 = 0, \tag{8.6}$$

*and for $k = 2, \ldots, n$,*

$$\begin{aligned}
\lambda_k &= \frac{\mathrm{cap}_{B_k}(\mathcal{S}_{k-1})}{\|h_k\|_2^2}(1 + O(e^{-\delta/\epsilon})) \\
&= \frac{1}{\mathbb{E}_{x_k}\tau_{\mathcal{S}_{k-1}}}(1 + O(e^{-\delta/\epsilon})) \\
&= \frac{|\lambda_1^*(z^*(x_k, \mathcal{M}_{k-1}))|}{2\pi}\sqrt{\frac{\det(\nabla^2 F(x_k))}{|\det(\nabla^2 F(z^*(x_k, \mathcal{M}_{k-1})))|}}\, e^{-[F(z^*(x_k, \mathcal{M}_{k-1}))-F(x_k)]/\epsilon} \\
&\quad \times \left(1 + O(\epsilon^{1/2}|\ln\epsilon|)\right)
\end{aligned} \tag{8.7}$$

*where $\lambda_1^*(z^*)$ denotes the unique negative eigenvalue of the Hessian of $F$ at the saddle point $z^*$.*

**Remark 8.4.** After the results of [7] appeared, Helffer and Nier [19] reconsidered earlier work of Helffer and Sjösstrand concerning spectral asymptotics of Schrödinger operators with multi-well potentials. In two papers [18], [20] they showed that using the so-called Witten complex, it is possible to derive similar spectral results and even extend them to complete asymptotic expansions, provided $F$ is assumed smooth. This is an interesting alternative approach, that for the time being has the disadvantage to be limited to the diffusion setting.

## 9. Challenges

The main challenges to the approach to metastability outlined in this talk are models in very high, respectively infinite, dimensions. The most interesting examples here are stochastic dynamics of spin systems beyond the low-temperature regime and in large or infinite volume. There are two major difficulties that present themselves. The first one is the estimation of capacities, and more precisely the lower bounds. The second problem is that of proving some a priori regularity properties, similar to the case of diffusion processes. Both issues seem at the moment quite open and will probably require the analysis of model problems. If these problems can be understood, we would feel that metastability is rather well understood in the context of reversible Markov processes. An altogether different and wide open issue is metastability in non-reversible systems. Here, the theory of Freidlin and Wentzell remains the only generally applicable tool, and finding ways to get estimates of higher precision than those obtainable from large deviation theory remains, at least in general, unsolved.

# On Ising droplets

Raphaël Cerf

**Abstract.** One of the fundamental goals of statistical mechanics is to understand the macroscopic effects induced by the random forces acting at the microscopic level. Some satisfactory results are now available for the Ising model at equilibrium in the phase coexistence regime in any dimension: it is rigorously proved that the most likely shapes of the macroscopic droplets of one pure phase floating in the other pure phase are close to the Wulff crystal of the model. However, the dynamical processes leading to the emergence of a droplet are far from being understood. We formulate a classical conjecture: the scaling limit of the Glauber microscopic dynamics should be an anisotropic motion by mean curvature.

**Keywords.** Ising model, Wulff crystal, Glauber dynamics, mean curvature motion.

## 1. Water and oil

Let us consider a volume of water in absence of gravity at ordinary temperature. We start to pour a very small quantity of oil into the water. First, nothing noticeable happens on the macroscopic scale, i.e., the oil is perfectly dissolved throughout the water and the oil molecules are homogeneously spread within the water: by observing the liquid at the macroscopic level, we cannot even tell that it is a mixture of two distinct types of particles, which nevertheless have the tendency to repel each other. Let us keep pouring oil into the water. We know that the solubility of oil in water is not infinite; at some density threshold (which increases with the temperature), we obtain a solution of water saturated with oil. This solution is still a pure phase, completely homogeneous on the macroscopic level, and it realizes a perfect tradeoff between entropy and energy; we call it the water phase. Let us pour in some more oil. The excess of oil is not dissolved any more and it precipitates: macroscopic droplets of oil emerge. These droplets are not regions where there are only oil molecules, rather in these regions we observe the symmetric pure phase consisting of oil saturated with water, which we call the oil phase. The droplets are delimited by an abrupt change of the local density of water and oil molecules. We wish to understand the law governing the evolution and the shapes of these droplets.

The classical phenomenological theory asserts the existence of a macroscopic surface free energy $\mathcal{I}$ and that the droplets evolve so as to minimize $\mathcal{I}$. For instance, at equilibrium, in case $\mathcal{I}$ is isotropic, one observes a unique spherical droplet of the

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

oil phase floating in the sea of the water phase. Our aim is to confirm the predictions of the phenomenological theory starting from a truly microscopic model. We wish to understand how the random forces acting at the atomic level, more precisely the probabilistic repulsive effect between the two types of particles, can induce such deterministic macroscopic effects. One of the most famous results in probability theory is the law of large numbers: If $(X_n)_{n\in\mathbb{N}}$ is a sequence of independent identically distributed random variables with mean $m$, then, with probability one,

$$\lim_{n\to\infty} \frac{1}{n}(X_1 + \cdots + X_n) = m.$$

What we have in mind is a generalization of the law of large numbers, but in a fundamentally new context, which we could state informally as follows:

$$\lim_{\text{number of particles}\to\infty} \begin{pmatrix} \text{global effect of the random} \\ \text{microscopic repulsive forces} \end{pmatrix} = \text{single droplet.}$$

The limiting deterministic object is the shape of the droplet at equilibrium and the problem is intrinsically geometric; we deal with spatially dependent random variables and we leave radically and definitively the independent framework. Hence the geometry enters the problem in a decisive way, in the random interactions and in the formulation of the result itself.

Let us try to set up a simple model of our experiment with water and oil. A convenient choice is a lattice model: each site of the lattice is occupied either by a water particle or by an oil particle, which we indicate respectively by $+$ or $-$. The interaction between different particles is repulsive and occurs when the substances are in immediate contact. Hence a repulsive nearest neighbour interaction is a sensible choice. Since we focus only on the repulsive interaction between different molecules, we can assume that the two substances are symmetric and that their self-interactions are of equal magnitude, or equivalently, equal to zero. We do not assume that the self-interactions between two particles of the same type are negligible compared to the repulsive effect; rather, we say that because of the symmetry, the global effect of the self-interactions cancels out. Thus the total energy of a configuration should be simply the number of all nearest neighbour pairs with different signs. We end up exactly with the Hamiltonian of the famous Ising model (to be defined precisely in the next section). In our experiment the density of oil is fixed, therefore we have a constraint on the possible configurations: the proportion of pluses and minuses has to be fixed. This situation amounts to considering the Ising model with plus boundary conditions (guaranteeing the water dominance) conditioned on the event that the average magnetization is equal to a fixed value smaller than the spontaneous magnetization at the given temperature.

## 2. Definition of the Ising model

For reasons of technical simplicity, it is easier to build our model on a lattice. We will work with the lattice $\mathbb{Z}^d$; each site of the lattice is occupied by one of the two types of particles that we denote by $-$ and $+$. Let $\Lambda \subset \mathbb{Z}^d$ be a cubic box. A configuration in $\Lambda$ is a map $\sigma : \Lambda \to \{-, +\}$ and for $x \in \Lambda$, we denote by $\sigma(x)$ the type of the particle present at $x$. The energy or Hamiltonian $H_\Lambda(\sigma)$ of the configuration $\sigma$ in $\Lambda$ is, up to a constant, twice the number of interfaces between the minuses and the pluses, that is,

$$H_\Lambda(\sigma) = -\frac{1}{2} \sum_{\substack{x,y\in\Lambda \\ |x-y|=1}} \sigma(x)\sigma(y) = - \sum_{\substack{\{x,y\}\in\Lambda^2 \\ |x-y|=1}} \sigma(x)\sigma(y).$$

We use the standard rules to multiply signs: $++ = -- = +$, $-+ = +- = -$. The first sum is above ordered pairs (whence the factor $1/2$) while the second is above unordered pairs. We need also a mechanism to ensure the dominance of one type of particles. This is achieved through boundary conditions. We consider only two types of boundary conditions, by putting either a layer of pluses or of minuses around the box $\Lambda$. The energy or Hamiltonian $H^*_\Lambda(\sigma)$ with boundary conditions $*$ (where $*$ stands for $-$ or $+$) is defined as above for the configurations $\sigma$ such that $\sigma(x) = *$ for all the sites $x$ in $\Lambda$ which are at a distance less than or equal to 1 from the complement of $\Lambda$ and $H^*_\Lambda(\sigma) = +\infty$ otherwise. Next we add some randomness in the model. Let $T > 0$ be the temperature. We build a probability law on the space $\{-, +\}^\Lambda$ of the configurations. This space is huge but finite, hence to define the law we need to specify the individual probability of each possible configuration. The natural way to do this is to use the Boltzmann factor. So, the Gibbs measure $\mu^*_{\Lambda,T}$ in $\Lambda$ at temperature $T$ with boundary conditions $*$ is given by

$$\mu^*_{\Lambda,T}(\sigma) = \frac{1}{Z^*_{\Lambda,T}} \exp -\frac{H^*_\Lambda(\sigma)}{T} \quad \text{for all } \sigma \in \{-, +\}^\Lambda,$$

where the normalizing factor $Z^*_{\Lambda,T}$, called the partition function, is equal to

$$Z^*_{\Lambda,T} = \sum_{\sigma\in\{-,+\}^\Lambda} \exp -\frac{H^*_\Lambda(\sigma)}{T}.$$

Whenever the superscript $*$ is absent, the boundary conditions are not specified and we have the Ising Gibbs measure $\mu_{\Lambda,T}$ with free boundary conditions, associated to the Hamiltonian $H_\Lambda$. Let us take a closer look at this formula. The elements $\Lambda$, $T$, $* \in \{-, +\}$ being fixed, the most likely configurations are those having a small energy, i.e., those for which the contacts between the minuses and the pluses are reduced. Thus we have built a complex probability law with strong spatial correlations. We shall next play a bit with the elements controlling the Gibbs measures $\mu^\pm_{\Lambda,T}$ in order to get some feeling for their influence.

**First asymptotics.** Imagine that we fix the box $\Lambda$ and that we set the boundary conditions to $+$. If we send $T$ to 0, then the measure $\mu^+_{\Lambda,T}$ concentrates on the configuration which realizes the global minimum of the Hamiltonian $H^+_\Lambda$, in this case the configuration where all the sites are pluses. On the contrary, if we send $T$ to $\infty$, the value of the Hamiltonian becomes irrelevant and $\mu^+_{\Lambda,T}$ converges towards the Bernoulli product law where all the sites are independent. The case of $\mu^-_{\Lambda,T}$ being symmetric, we see that

$$\begin{array}{rcccl} \text{Dirac mass at ``all pluses''} & \longleftarrow & \mu^+_{\Lambda,T} & \longrightarrow & \text{i.i.d. Bernoulli} \\ & T \downarrow 0 & & T \uparrow \infty & \\ \text{Dirac mass at ``all minuses''} & \longleftarrow & \mu^-_{\Lambda,T} & \longrightarrow & \text{i.i.d. Bernoulli} \end{array}$$

Something remarkable has already happened: as $T \uparrow \infty$, the boundary conditions are forgotten, while as $T \downarrow 0$, they completely determine the limit. However, we wish to work at a fixed positive temperature $T$. In order to observe a sharp mathematical phenomenon, we consider another kind of limit, namely the thermodynamic limit where the number of particles goes to infinity. This is achieved by letting the box $\Lambda$ grow and invade the whole lattice $\mathbb{Z}^d$. As $\Lambda$ increases to $\mathbb{Z}^d$, the expectation $\mu^+_{\Lambda,T}(\sigma(0))$ decreases and converges towards a limiting quantity $m^*(T)$:

$$\lim_{\Lambda \uparrow \mathbb{Z}^d} \mu^+_{\Lambda,T}(\sigma(0)) = m^*(T) = -\lim_{\Lambda \uparrow \mathbb{Z}^d} \mu^-_{\Lambda,T}(\sigma(0)).$$

Here is a heuristic explanation for this monotone convergence. Let us consider a huge box $\Lambda$ and the site at the center of the box $\Lambda$. With free boundary conditions, the law of $\sigma(0)$ under $\mu_{\Lambda,T}$ is symmetric, hence it is the one of a fair coin, i.e.,

$$\mu_{\Lambda,T}(\sigma(0) = +) = 1/2 = \mu_{\Lambda,T}(\sigma(0) = -).$$

If we put $+$ boundary conditions, these boundary conditions start to influence positively the sites at distance 1 from the boundary of the box, which themselves influence the sites at distance 2 from the boundary. This effect propagates and reaches the origin, so that the law of $\sigma(0)$ under $\mu^+_{\Lambda,T}$ is slightly biased towards $+$:

$$\mu^+_{\Lambda,T}(\sigma(0) = +) \; > \; 1/2 \; > \; \mu^+_{\Lambda,T}(\sigma(0) = -).$$

The larger the box $\Lambda$ is, the smaller is the resulting effect at the origin, hence the influence of the boundary conditions decreases as the box increases and the following monotone limit exists:

$$m^*(T) = \lim_{\Lambda \uparrow \mathbb{Z}^d} \mu^+_{\Lambda,T}(\sigma(0)).$$

The fundamental and basic question is whether something of the influence of the boundary conditions still remains after we have sent them to infinity. Equivalently, is $m^*(T)$ equal to 0?

The quantity $m^*(T)$ is called the spontaneous magnetization at temperature $T$. This terminology stems from the fact that the Ising model was originally introduced

as a model of ferromagnetism: under some adequate conditions, a magnet submitted to the influence of a magnetic field will remember the sign of the field even after it has disappeared (see [24] and the references therein for a serious physical introduction to the Ising model).

**Phase transition.** We say that there is a phase transition at temperature $T$ if $m^*(T) > 0$. The first fundamental result concerning the phase transition in the Ising model is the following.

**Theorem 2.1.** *In any dimension $d \geq 2$, there exists a positive and finite critical temperature $T_c(d)$ such that the Ising model exhibits a phase transition for $T < T_c(d)$ and it does not for $T > T_c(d)$.*

It is also possible to take the thermodynamic limit of the finite volume Gibbs measure $\mu^+_{\Lambda,T}$, and not only of the expected value $\mu^+_{\Lambda,T}(\sigma(0))$. As $\Lambda$ increases to $\mathbb{Z}^d$, the measure $\mu^+_{\Lambda,T}$ decreases stochastically and converges weakly towards the infinite volume Gibbs measure $\mu^+_T$, which is a probability measure on the space of infinite volume configurations $\{-,+\}^{\mathbb{Z}^d}$. Similarly, $\mu^-_{\Lambda,T}$ increases weakly towards a measure $\mu^-_T$:

$$\lim_{\Lambda\uparrow\mathbb{Z}^d} \mu^-_{\Lambda,T} = \mu^-_T, \quad \lim_{\Lambda\uparrow\mathbb{Z}^d} \mu^+_{\Lambda,T} = \mu^+_T.$$

The spontaneous magnetization $m^*(T)$ is equal to the expected value of $\sigma(0)$ under $\mu^+_T$ and there is a phase transition at temperature $T$ if and only if $\mu^-_T$ and $\mu^+_T$ are distinct. In other words, we have

$$m^*(T) > 0, \quad \mu^-_T \neq \mu^+_T \qquad \text{for all } T < T_c(d),$$

whereas for $T > T_c(d)$, we have $m^*(T) = 0$ and $\mu^-_T = \mu^+_T$.

## 3. The Wulff crystal

We shall mimic mathematically the initial experiment of Section 1 with the help of the Ising model. Let us consider a box $\Lambda(n)$ of diameter $n$ full of pluses. We take $n$ very large, of the order of the Avogadro number $6.02 \times 10^{23}$. We start deleting pluses and replacing them by minuses, first a small quantity of minuses. It is possible to build a stochastic dynamics in the box which is conservative (i.e., the total numbers of minuses and pluses remain unchanged or equivalently the empirical magnetization $n^{-d}\sum_{x\in\Lambda(n)}\sigma(x)$ remains constant) and whose final equilibrium is the Gibbs measure $\mu^+_{\Lambda(n),T}$ conditioned to have the initial fixed magnetization. The simplest such dynamics is the so-called Kawasaki dynamics: at random exponential times, a pair of neighbouring particles might be exchanged according to a simple local probabilistic rule (see Section 4). As long as the empirical magnetization is larger than $m^*(T)$, the configuration in $\Lambda(n)$ at equilibrium is expected to be spatially homogeneous. If

we keep pouring minuses into the box and removing pluses, we soon reach the value $m^*(T)$, and at this point we obtain the saturated pure phase $\mu_T^+$, i.e., the configuration in $\Lambda(n)$ looks like a finite sample of the infinite volume Gibbs measure $\mu_T^+$. We finally add some more minuses and we cross the threshold $m^*(T)$. We wish to understand the response of the system and the most likely configurations inside the box when there is an excess of minuses.

It turns out that this simple model indeed confirms the prediction of the phenomenological theory. At equilibrium, with probability tending to 1 as $n$ goes to $\infty$, a region emerges inside the box $\Lambda(n)$ where the configuration statistically looks like the minus phase $\mu_T^-$, surrounded by a region filled with the plus phase $\mu_T^+$. When rescaled by a factor $n$, the shape of this region converges as $n$ goes to $\infty$ towards a deterministic shape, called the Wulff crystal of the Ising model. This crystal is convex, it depends on the temperature and on the initial lattice $\mathbb{Z}^d$; it bears the name of Wulff, who studied it one century ago [33].

In order to detect conveniently the Wulff region, we rescale the box $\Lambda(n)$ by a factor $n$ and we send it onto the $d$-dimensional unit cube $[-1/2, 1/2]^d$. Let $\sigma$ be a spin configuration in $\Lambda(n)$. To $\sigma$ we associate a measure $\sigma_n$ on $[-1/2, 1/2]^d$ by setting

$$\sigma_n = \frac{1}{n^d} \sum_{x \in \Lambda(n)} \sigma(x)\, \delta_{x/n}$$

where $\delta_{x/n}$ is the Dirac mass at $x/n$. We call $\sigma_n$ the empirical magnetization. The expectation $b_n$ of $\sigma_n$ is

$$b_n = \frac{1}{n^{d+1}} \sum_{x \in \Lambda(n)} \sigma(x) x.$$

We denote by $\mathcal{L}^d$ or simply by $dx$ the $d$-dimensional Lebesgue measure.

**Theorem 3.1.** *Let $d \geq 2$ and let $T < T_c(d)$. There exists a bounded, closed, convex set $\mathcal{W}$ containing 0 in its interior, called the Wulff crystal of the Ising model such that the following holds.*

*Let $m < m^*$ be close enough to $m^*$ so that the rescaled Wulff crystal*

$$\mathcal{W}(m) = \left(\frac{m^* - m}{2m^*}\right)^{1/d} \frac{\mathcal{W}}{\mathcal{L}^d(\mathcal{W})^{1/d}}$$

*fits into the unit cube $[-1/2, 1/2]^d$. Let $w_n$ be the random measure defined by*

$$w_n(x)\, dx = \Big(1_{[-1/2,1/2]^d}(x) - 2 \cdot 1_{\mathcal{W}(m)}\Big(\frac{b_n}{m^* - m} + x\Big)\Big) m^*\, dx.$$

*This is the measure having density $-m^*$ on $-b_n/(m^* - m) + \mathcal{W}(m)$ and $m^*$ on the complement. Under the conditional probability*

$$\mu_n(\cdot) = \mu^+_{\Lambda(n),T}\Big(\,\cdot\,\Big|\frac{1}{n^d} \sum_{x \in \Lambda(n)} \sigma(x) \leq m\Big)$$

*the difference between the random measures $\sigma_n$ and $w_n$ converges weakly in probability towards* 0*, i.e., for any continuous function* $f : [-1/2, 1/2]^d \to \mathbb{R}$*,*

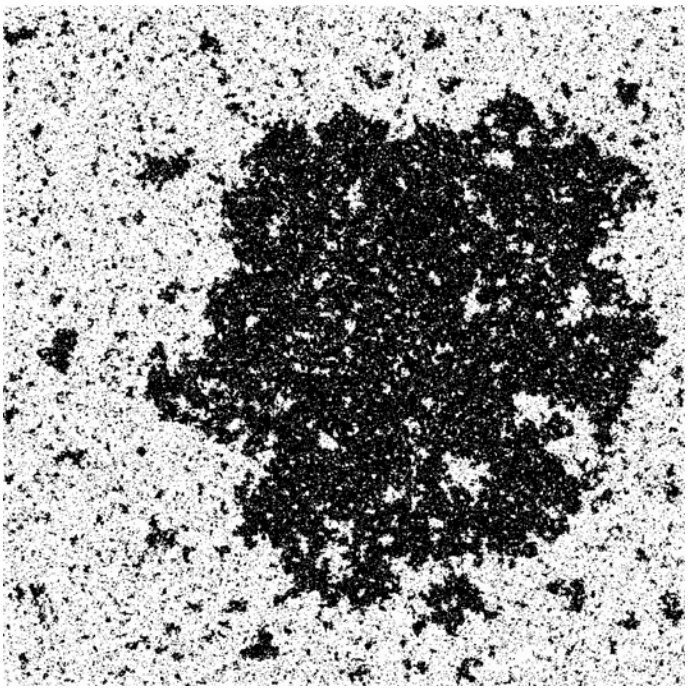
$$\lim_{n\to\infty} \mu_n\big(|\sigma_n(f) - w_n(f)| \geq \varepsilon\big) = 0 \quad \textit{for all } \varepsilon > 0.$$

*The probabilities of the deviations are of order* $\exp -cn^{d-1}$.

The last sentence of the theorem means the following. For any continuous function $f : [-1/2, 1/2]^d \to \mathbb{R}$, any $\varepsilon > 0$, there exist positive constants $b, c$ depending on $d$, $T$, $f$, $\varepsilon$ such that

$$\mu_n\Big(\Big|\frac{1}{n^d} \sum_{x\in\Lambda(n)} \sigma(x)\, f\Big(\frac{x}{n}\Big) + \int_{\mathcal{W}(m)} 2m^* f\Big(-\frac{b_n}{m^* - m} + x\Big)\, dx - \int_{[-1/2,1/2]^d} m^* f(x)\, dx\Big| > \varepsilon\Big) \leq b \exp(-cn^{d-1}).$$

The main assertion of the theorem is that the left-hand quantity goes to 0 for any continuous function $f$ and $\varepsilon > 0$. The objects appearing in the statement, namely the spontaneous magnetization $m^*$ and the Wulff crystal $\mathcal{W}$, are built as the thermodynamic limit of finite volume quantities. These objects can equivalently be defined with the help of the infinite volume Gibbs measure $\mu_T^+$.



Simulation of the Ising Wulff crystal at $T = 2.26$ after 69 days on a 1 Ghz PC.

Theorem 3.1 in dimension 2 is a consequence of the much finer results of Dobrushin, Kotecký, Shlosman [23] and Pfister [29] for low temperatures and Ioffe and Schonmann [25] for all subcritical temperatures. In dimensions 3 and higher, they were proven by Bodineau [7] for low temperatures and by Cerf and Pisztora [17] until the slab percolation threshold for temperatures such that the associated infinite volume FK measure is unique. Recently, Bodineau proved that this slab percolation threshold coincides with the true critical point [8] and that for any subcritical temperature, the associated infinite volume FK measure is indeed unique [9].

In two dimensions the Wulff droplet can be identified with a random region surrounded by a minus spin cluster. Its external boundary is therefore a large contour separating plus and minus spins which follows closely the boundary of the Wulff crystal in the sense of the Hausdorff metric [23], [25]. In dimension $d \geq 3$, it is widely believed that for low temperatures, the Wulff droplet can still be defined by a microscopic contour. However for temperatures close to $T_c$, a fundamentally new situation is expected. The dominant minus spin cluster of the Wulff droplet should percolate all the way to the boundary of the box. More precisely, there should exist two big spin clusters, one of pluses and one of minuses, and they should both be omnipresent in the entire box; the densities of these clusters should undergo an abrupt change at the boundary of the Wulff droplet. In this case the phase boundaries cannot be described directly with contours.

Let us mention the most recent works on the Wulff crystal. The low temperature expansion of the 3D Wulff crystal is computed in [14]. Alexander succeeded recently in deriving cube root fluctuations of the random curve around the Wulff crystal in the FK model in two dimensions [1], [4]. Couronné and Messikh provide a two dimensional version of Pisztora's coarse graining estimates [22]. Messikh analyzes the phase coexistence phenomenon in the 2D Ising model close to criticality: the Wulff crystal then becomes a circle [16], [27] (see also [28] for an application to image segmentation). Couronné has shown that the statistical repartition of the large finite clusters in the FK percolation model can be approximated by a Poisson process [21]. He has also studied the Wulff crystal for oriented percolation in dimension $d \geq 3$ [20]. In this model, the Wulff crystal has a singular point. Bodineau, Schonmann and Shlosman investigate the question of the flatness of the Wulff crystal [12]. Biskup, Chayes and Kotecky study the formation/dissolution of equilibrium droplets in the context of the 2D Ising model [5] and they derive the Gibbs–Thomson formula in the droplet formation regime [6]. Alexander, Biskup and Chayes devise an Ising-based model of a solvent-solute system [2], [3] and they study the associated phase separation phenomenon. The book [13] contains the proof of Theorem 3.1 and the corresponding statements in percolation.

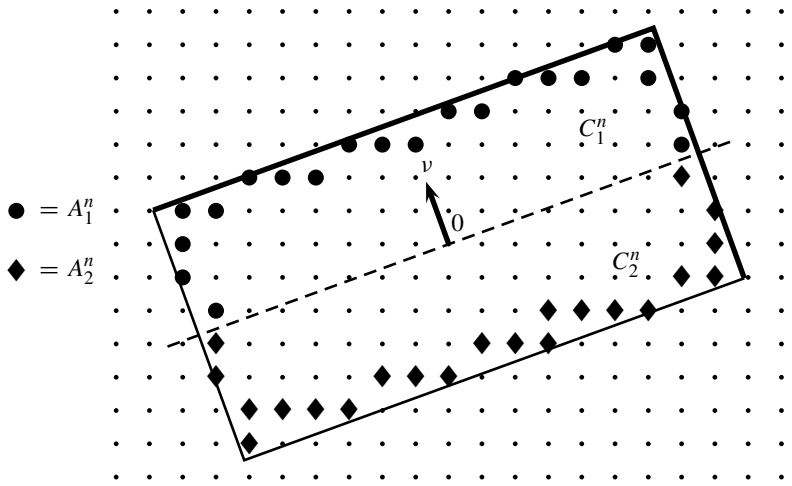
**The Wulff construction.** The Wulff crystal $\mathcal{W}$ appearing in Theorem 3.1 can be defined constructively. First we define the surface tension of the Ising model as follows. Let $\nu \in S^{d-1}$ be a unit vector in $\mathbb{R}^d$ and let $A$ be a unit hypersquare

orthogonal to $\nu$. Let $D_n$ be the cylinder

$$D_n = \{na + t\nu : a \in A,\ |t| \le n\}.$$

The set $D_n \setminus nA$ has two connected components, which we denote by $C_1^n$ and $C_2^n$. For $i = 1, 2$ and $n \in \mathbb{N}$, let $A_i^n$ be the set of the points of $C_i^n \cap \mathbb{Z}^d$ which have a nearest neighbour in $\mathbb{Z}^d \setminus D_n$:

$$A_i^n = \{x \in C_i^n \cap \mathbb{Z}^d : \text{there exists } y \in \mathbb{Z}^d \setminus D_n \text{ such that } |x - y| = 1\}.$$



The Ising Hamiltonian in $D_n$ is

$$H_n(\sigma) = -\frac{1}{2} \sum_{\substack{x,y \in D_n \\ |x-y|=1}} \sigma(x)\sigma(y) \quad \text{for all } \sigma \in \{-,+\}^{D_n}.$$

Let $\mathcal{E}_n$ be the set of the spin configurations $\sigma$ inside $D_n$ such that $\sigma(x) = +$ for $x \in A_1^n \cup A_2^n$. Let $\mathcal{F}_n$ be the set of the spin configurations $\sigma$ inside $D_n$ such that $\sigma(x) = -$ for $x \in A_1^n$ and $\sigma(x) = +$ for $x \in A_2^n$. The partition functions $Z_n^+$, $Z_n^{-,+}$ corresponding to pure $+$ and mixed $-, +$ boundary conditions at temperature $T$ are

$$Z_n^+ = \sum_{\sigma \in \mathcal{E}_n} \exp -\frac{H_n(\sigma)}{T}, \quad Z_n^{-,+} = \sum_{\sigma \in \mathcal{F}_n} \exp -\frac{H_n(\sigma)}{T}.$$

Let $T > 0$. The limit

$$\tau(\nu) = \lim_{n \to \infty} -\frac{1}{n^{d-1}} \ln \frac{Z_n^{-,+}}{Z_n^+}$$

exists in $[0, \infty]$. The function $\tau$ is called the surface tension of the Ising model. It satisfies the weak simplex inequality, it is continuous and invariant under the isometries which leave $\mathbb{Z}^d$ invariant. Moreover $\tau$ is positive in the regime $T < T_c$. The Wulff crystal $\mathcal{W}$ appearing in Theorem 3.1 is the Wulff shape associated to the surface tension $\tau$, called also the crystal of $\tau$, defined by

$$\mathcal{W} = \{x \in \mathbb{R}^d : x \cdot w \leq \tau(w) \text{ for all } w \text{ in } S^{d-1}\}.$$

**Large deviations.** The way to prove Theorem 3.1 is rather long. The key is the analysis of the deviations of the average magnetization from its typical value. We have first a weak law of large numbers:

$$\lim_{n\to\infty} \mu^+_{\Lambda(n),T}\Big(\frac{1}{n^d}\sum_{x\in\Lambda(n)}\sigma(x)\Big) = m^*(T) \quad \text{for all } T > 0.$$

The large deviations from above are similar in nature to what happens for a sum of independent identically distributed random variables.

**Theorem 3.2.** *Let $d \geq 2$ and let $T > 0$. For any $\alpha \in [-1, 1]$, the limit*

$$J(\alpha) = \lim_{n\to\infty} -\frac{1}{n^d} \ln \mu^+_{\Lambda(n),T}\Big(\frac{1}{n^d}\sum_{x\in\Lambda(n)}\sigma(x) \geq \alpha\Big)$$

*exists and is finite. The map $\alpha \in [-1, 1] \mapsto J(\alpha) \in \mathbb{R}^+$ is convex continuous. It vanishes on $[-1, m^*(T)]$ and it is strictly positive on $]m^*(T), 1]$.*

The deviations from above are of volume order. The function $J$ appearing in Theorem 3.2 vanishes on $[0, m^*[$ because on this interval the large deviations are of surface order. As we are in the phase coexistence regime, a new large deviation principle on the surface scale emerges.

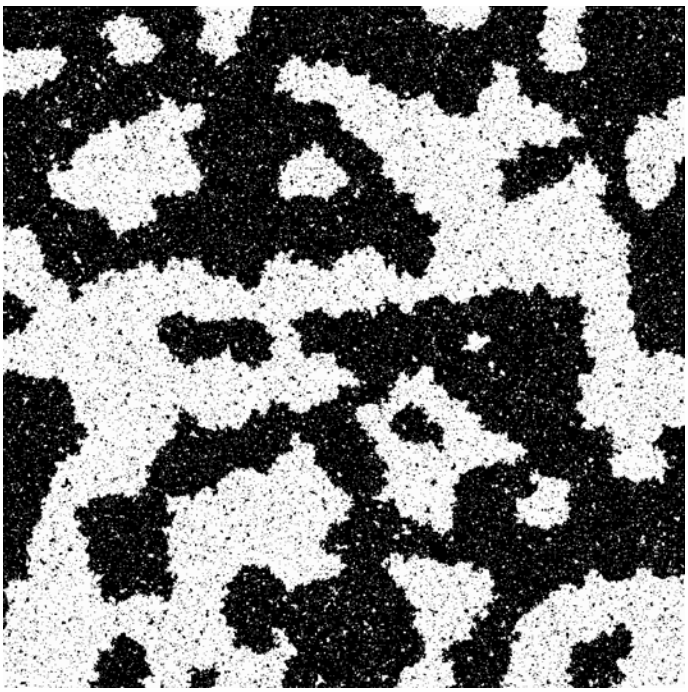
**Theorem 3.3.** *Let $d \geq 2$ and let $T < T_c(d)$. For $m < m^*$ close enough to $m^*$, so that the rescaled Wulff crystal $\mathcal{W}(m)$ fits into the unit cube $[-1/2, 1/2]^d$, we have*

$$\lim_{n\to\infty} \frac{1}{n^{d-1}} \ln \mu^+_{\Lambda(n),T}\Big(\frac{1}{n^d}\sum_{x\in\Lambda(n)}\sigma(x) \leq m\Big) = -d\left(\frac{m^* - m}{2m^*}\right)^{\frac{d-1}{d}} \mathcal{L}^d(\mathcal{W})^{\frac{1}{d}}.$$

Theorems 3.2 and 3.3 provide a complete picture of the large deviation behavior of the average magnetization. The emergence of a droplet is responsible for the asymptotic formula of Theorem 3.3. The full proofs of Theorems 3.2 and 3.3 can be found in the book [13].

## 4. Dynamics

Another very interesting topic is of course the dynamics. One should try to understand the dynamical mechanism leading to the creation of a Wulff crystal. It is naturally expected that several reasonable choices of microscopic dynamics induce the macroscopic dynamics associated to the motion by mean curvature. For instance it seems to be the case for the non-conservative Glauber dynamics, which is relevant for the beautiful theory of metastability (see [30], [31]). However the full understanding of these dynamics seems currently out of reach and only partial results are available [11], [15], [18], [19], [26], [32].



Phase separation under the Glauber dynamics at $T = 2.1$.

Let $d \geq 2$ and let $\Lambda \subset \mathbb{Z}^d$ be a cubic box. We wish to build a stochastic dynamics on the configuration space $\{-,+\}^\Lambda$ which models the microscopic repulsive forces between the particles. The interaction being microscopic, only one site or two neighbouring sites can be altered at each step. For $\sigma : \Lambda \to \{-,+\}$ and $x \in \Lambda$, we denote

$$S(\sigma, x) = \sum_{y:|x-y|=1} \sigma(y)$$

the sum of the spins of the neighbours of $x$.

Let $T > 0$ be a positive temperature. We consider two dynamics, which are built as discrete time Markov chains $(\sigma(k))_{k\geq 0}$ with state space $\{-,+\}^{\Lambda}$. We describe next the transition mechanisms of each dynamics.

**Glauber dynamics.** We suppose that $\sigma(k)$ is known and we explain how to build $\sigma(k+1)$. We first choose a site $x \in \Lambda$ randomly with the uniform law on $\Lambda$. We then compute $\Delta = 2\sigma(k,x)S(\sigma(k),x)$.

- If $\Delta < 0$, we flip the spin at $x$.
- If $\Delta \geq 0$, we flip the spin at $x$ with probability $\exp -(\Delta/T)$.

With the Glauber dynamics, at most one spin is changed at each time step.

**Kawasaki dynamics.** We suppose that $\sigma(k)$ is known and we explain how to build $\sigma(k+1)$. We first choose two neighbouring sites $x, y \in \Lambda$ randomly with the uniform law on the pairs of neighbours in $\Lambda$. We then compute $\Delta = (\sigma(k,x) - \sigma(k,y))(S(\sigma(k),x) - S(\sigma(k),y))$.

- If $\Delta < 0$, we exchange the spins of the sites at $x$ and $y$.
- If $\Delta \geq 0$, we exchange the spins of $x$ and $y$ with probability $\exp -(\Delta/T)$.

With the Kawasaki dynamics, at most two spins are changed at each time step.

A fundamental problem is to understand the scaling limits of these dynamics. For the Glauber dynamics, the adequate scaling is expected to converge to an anisotropic motion by mean curvature. More precisely, to the Markov chain $(\sigma(k))_{k\geq 0}$ we associate a process $(\sigma_n(t))_{t\geq 0}$ taking its values in the space of the Borel measures on $[-1/2,1/2]^d$ by setting

$$\sigma_n(t) = \frac{1}{n^d} \sum_{x\in\Lambda(n)} \sigma(\lfloor n^2 t \rfloor, x)\, \delta_{x/n} \quad \text{for all } t > 0,$$

where $\delta_{x/n}$ is the Dirac mass at $x/n$. We call $\sigma_n(t)$ the stochastic empirical magnetization.

Let $A$ be a subset of $[-1/2,1/2]^d$ having smooth boundary. We take as initial condition at step $n$ the configuration defined by

$$\sigma(0,x) = 1 - 2\cdot 1_{nA}(x) \quad \text{for all } x \in \mathbb{Z}^d.$$

Let $\mu$ be a function defined on the unit sphere $S^{d-1}$ of $\mathbb{R}^d$ with values in $\mathbb{R}^+$. Let $(A(t))_{t\geq 0}$ be the anisotropic mean curvature motion starting from $A$ associated to the function $\mu$, that is the solution (in some weak sense) of the equation:

$$v(x) = -\mu(\nu(x))\,\kappa(x)\,\nu(x) \quad \text{for all } t > 0,\ x \in \partial A(t),$$

where $v(x)$ is the speed at $x$, $\nu(x)$ is the normal vector to $A(t)$ at $x$ and $\kappa(x)$ is the curvature of $A(t)$ at $x$. Let $(w(t,x)\,dx)_{t\geq 0}$ be the measure valued process defined by

$$w(t,x)\,dx = m^*\big(1 - 2\cdot 1_{A(t)}(x)\big)\,dx \quad \text{for all } t \geq 0.$$

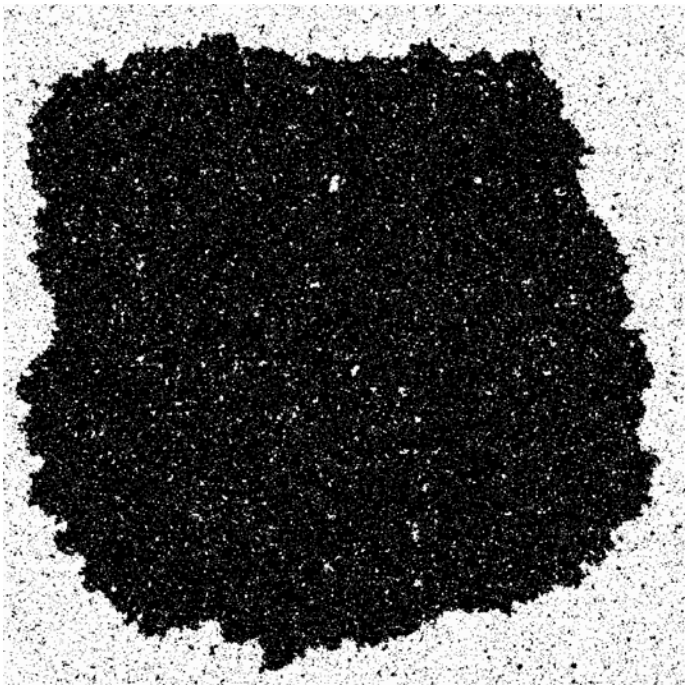
The big conjecture is that there exists a function $\mu\colon S^{d-1} \to \mathbb{R}^+$ such that the stochastic empirical magnetization $\sigma_n(t)$ converges weakly to the anisotropic mean curvature motion associated to $\mu$: there exists $T > 0$ such that, for any continuous function $f\colon [-1/2, 1/2]^d \to \mathbb{R}$,

$$\lim_{n\to\infty} P\big(|\sigma_n(t)(f) - w_n(t)(f)| \geq \varepsilon\big) = 0 \quad \text{for all } t \in [0,T],\ \varepsilon > 0.$$

We are still very far from the proof of such a result. In the two dimensional case at zero temperature, some specific computations [15], [32] show that, if this conjecture is correct, then the function $\mu$ governing the anisotropic motion by mean curvature must be equal to

$$\mu(x) = \frac{1}{2(|\cos\theta| + |\sin\theta|)^2},$$

where $\theta$ is the angle between the horizontal axis and the tangent to the boundary at $x$. The scaling limit of the conservative Kawasaki dynamics seems even more challenging to understand.



Evolution of a square droplet under Glauber dynamics at $T = 2.1$.

# Simple random covering, disconnection, late and favorite points

Amir Dembo

**Abstract.** We review recent advances in the study of the fractal nature of certain random sets, the key to which is a multi-scale truncated second moment method. We focus on some of the fine properties of the sample path of the most basic stochastic processes such as the simple random walk and the Brownian motion. As we shall see, probability on trees inspires many of our proofs, with trees used to model the relevant correlation structure. Along the way we also mention a few open problems.

**Mathematics Subject Classification (2000).** Primary 60J15; Secondary 28A80, 60G17, 60J65, 82C41.

**Keywords.** Random walk, Brownian motion, Gaussian free field, cover time, late points, favorite points, thick points, multi-fractal analysis, disconnection, intersection local time.

## 1. Introduction

The simple random walk (SRW) on a graph $G = (V, E)$ of finite degrees tracks the movement on the set $V$ of vertices by a particle which at each time step jumps with equal probability to any one of the nearest neighbors of its current position, independently of all previous positions. In particular, the SRW on $\mathbb{Z}^d$ is a fundamental object in probability theory. More than forty years ago, Erdős and Taylor posed in [ET60] the following problem about the SRW on $\mathbb{Z}^2$: What is the maximal number of visits by the walk to one lattice site during its first $n$ steps? More formally, denote by $L_n(x)$ the number of visits to $x$ by the SRW during its first $n$ steps, and set $L_n^* := \max_{x\in\mathbb{Z}^2} L_n(x)$. Then, it was conjectured in [ET60, (3.11)] and proved in [DPRZ01] that with probability one,

$$\lim_{n\to\infty} \frac{L_n^*}{(\log n)^2} = \frac{1}{\pi}. \tag{1.1}$$

As illustrated in Section 3, the key to proving (1.1) is a multi-scale truncated second moment method, inspired by the study of the corresponding problem for SRW on finite, regular trees. As detailed in Section 2, the same approach provides information about the location in $\mathbb{Z}^2$ where $L_n^*$ is attained, the number of sites $x \in \mathbb{Z}^2$ for which $L_n(x)$ is exceptionally large, and the fractal dimension of the corresponding object for the sample path of the planar Brownian motion.

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

The *cover time* $C_G$ for a SRW on a finite graph $G$ is the number of steps till the walk has visited all sites of $G$ at least once. It has been studied intensively by probabilists, statistical physicists, combinatorialists and computer scientists (e.g. [Ald89], [Bro90], [BH91], [NCF91], [MP94]). In particular, the SRW on a finite graph is a time-reversible Markov chain and the asymptotics of $C_G$ is an important aspect of the general theory of reversible Markov chains, see [AF01]. The problem of determining the asymptotics of the cover time $C_n := C_{\mathbb{Z}_n^2}$ for the two dimensional lattice torus $\mathbb{Z}_n^2 = \mathbb{Z}^2/n\mathbb{Z}^2$ of side length $n$ was posed by Wilf, see [Wil89], and more formally by Aldous, who conjectured in [Ald89] that

$$\lim_{n\to\infty} \frac{C_n}{(n\log n)^2} = \frac{4}{\pi} \quad \text{in probability,} \tag{1.2}$$

and proved the upper bound of $4/\pi$ in (1.2). A lower bound $2/\pi$ was later proved in [Law92] and the conjecture (1.2) resolved in [DPRZ04]. Whereas the general theory of reversible Markov chains provides the correct growth order of $C_n$ it fails to provide the multiplying constant in (1.2). As described in Section 4, the proof of (1.2) relies on the same multi-scale truncated second moment method used en-route to (1.1). Further, this approach provides information about the number and spatial distribution of the sites in $\mathbb{Z}_n^2$ for which the time of first visit by the SRW is of the order of the cover time. In addition, it allows us to answer the following questions of Révész about (discrete) discs covered by the random walk on $\mathbb{Z}^2$ till time $n$, namely, where every site of the lattice within the disc is visited by the walk at least once.

- What is the radius $\rho_n$ of the largest disc, centered at the origin that is covered during the first $n$ steps of the walk? It is shown in [DPRZ04] that

$$\lim_{n\to\infty} \mathbb{P}\Big( \frac{(\log \rho_n)^2}{\log n} \geq y \Big) = e^{-4y}, \tag{1.3}$$

  for all $y > 0$ (in 1989 Révész derived upper and lower bounds for (1.3) with non-matching constants 120 and $1/4$; these have been improved to 4 and 2 in [Law92] which also quotes (1.3) as a conjecture of Kesten).

- What is the radius $R_n$ of the largest disc (of arbitrary center) that is covered during the first $n$ steps of the walk? It is shown in [DPR07] that with probability one,

$$\lim_{n\to\infty} \frac{\log R_n}{\log n} = \frac{1}{4} \tag{1.4}$$

  (non-matching bounds for (1.4) with constants other than $1/4$ are given in [Rév93] where the existence of the limit is also conjectured).

In Section 5 we detail additional results for intersection local times and for the two dimensional Gaussian free field that have been obtained by the same approach we review here.

Statements such as (1.1) and (1.2) are easier to handle for the SRW on $\mathbb{Z}^d$, $d \geq 3$ whose transience enables us to effectively localize the relevant occupation measures, in contrast with the case of $d = 2$.

Let $G_n = \mathbb{Z}_n^d \times \mathbb{Z}$ denote the infinite discrete cylinder based on the $d$-dimensional discrete torus of side length $n$. We say that a finite subset $\Gamma$ disconnects $G_n$ if, for large $r$ the sets $\mathbb{Z}_n^d \times [r, \infty)$ and $\mathbb{Z}_n^d \times (-\infty, -r]$ are contained in two distinct connected components of $G_n \setminus \Gamma$. Consider the time $D_n$ till the range of the SRW on $G_n$ disconnects the cylinder. Clearly, the *disconnection time* $D_n$ is between the cover time $C_n$ of the base $\mathbb{Z}_n^d$ by the projection of the SRW and the cover time $\widehat{C}_n$ of the slice $\mathbb{Z}_n^d \times \{0\}$ by the SRW on $G_n$. It was shown in [DS06] that

$$\lim_{n\to\infty} \frac{\log D_n}{\log n} = \lim_{n\to\infty} \frac{\log \widehat{C}_n}{\log n} = 2d \quad \text{in probability.} \tag{1.5}$$

That is, the disconnection time is roughly of order $n^{2d}$ and comparable to $\widehat{C}_n$, but in contrast to the case of $d = 1$, when $d \geq 2$ it is substantially larger than the cover time $C_n$ (which is roughly of order $n^{\max(d,2)}$, up to logarithmic correction terms). We outline in Section 6 the geometric argument which is the key to the proof of (1.5) and explain in what sense (1.5) implies for $d \geq 2$ a massive clogging of the truncated cylinders of height $n^{d-\varepsilon}$ by the SRW before it disconnects the infinite cylinder. See also [Szn06] for recent universality results about the asymptotic of the disconnection time for the SRW on $H_n \times \mathbb{Z}$ (under mild conditions on the finite graph $H_n$).

For earlier surveys of parts of this body of work see [Per03], [Dem05], [Shi06]. Many additional interesting examples of random fractals as well as numerous references to earlier works on such problems are provided in the survey [Tay86]. See also [LeG92] for more about the planar Brownian path and [Lyo05] for probability on trees.

## 2. Favorite and thick points

**2.1. Favorite points for SRW on $\mathbb{Z}^d$.** Erdős and Révész in [ER84] call a site $x \in \mathbb{Z}^d$ for which $L_n(x) = L_n^*$ a *favorite point* of the SRW. In a similar manner, for any $0 < \alpha < 1$ we say that $x \in \mathbb{Z}^2$ is an *$\alpha$-favorite point* of the walk if $L_n(x) \geq (\alpha/\pi)(\log n)^2$. The size of the set $\mathcal{F}_n(\alpha)$ of $\alpha$-favorite points can be estimated by the same approach leading to (1.1). More precisely, it is shown in [DPRZ01] that for each $\alpha \in (0, 1]$,

$$\lim_{n\to\infty} \frac{\log |\mathcal{F}_n(\alpha)|}{\log n} = 1 - \alpha \quad \text{a.s.} \tag{2.1}$$

In other words, the $n^\beta$-most visited point during the first $n$ steps of the walk is visited approximately $\frac{1-\beta}{\pi}(\log n)^2$ times. This is in contrast with typical points on the path of the walk, each of which has order $\log n$ visits.

It is also shown in [DPRZ01] that any random sequence $\{x_n\}$ in $\mathbb{Z}^2$ such that $L_n(x_n)/L_n^* \to 1$ must satisfy

$$\lim_{n\to\infty} \frac{\log \|x_n\|}{\log n} = \frac{1}{2} \quad \text{a.s.} \tag{2.2}$$

In particular, the favorite points, i.e. those $x_n^*$ where $L_n^*$ is attained, are consistently located near the frontier of the set of visited points, at least on a logarithmic scale.

For the SRW on $\mathbb{Z}$ the analog of the statement (2.2) is contained in the results of Bass and Griffin [BG85]. See also [Rév05, page 160] for a list of unsolved problems about favorite points of the SRW on $\mathbb{Z}$, taken from [ER84]. Tóth provided recently a partial answer to one of these questions, showing that the SRW on $\mathbb{Z}$ has for sufficiently large time $n$ at most three different favorite points $x_n^*$ (cf. [Tót01] for this result and its history). However, not much is known about $x_n^*$. For example,

**Open Problem 2.1.**
• Determine for which $d \geq 1$ the SRW on $\mathbb{Z}^d$ has with probability one at most two favorite points $x_n^*$ for all $n$ sufficiently large.
• Describe the evolution of $n \mapsto x_n^*$ in any dimension $d \geq 2$.
• How is the growth of time between the first and last visits to $x_n^*$ prior to $n$, affected by the dimension $d$?

**2.2. Thick points for planar Brownian motion.** Let $w^{(m)}(t) = \sqrt{d/m}\, S_{\lfloor mt \rfloor}$ denote a time-space rescaled image of the SRW $(S_k, k \geq 0)$ on $\mathbb{Z}^d$. Donsker's functional CLT tells us that the distribution of $(w^{(m)}(t), t \geq 0)$ converges as $m \to \infty$, to that of the Brownian motion $(w(t), t \geq 0)$. The latter is a continuous in time, $\mathbb{R}^d$-valued Gaussian stochastic process, of independent coordinates, each starting at zero and having zero mean increments of variance $|t - s|$.

It is thus not surprising that the continuous time analogs of (1.1) and (2.1) can be expressed in terms of the Brownian *occupation measure*

$$\mu_t^w(A) = \int_0^t \mathbf{1}_A(w(s))ds, \quad \text{for all } A \subseteq \mathbb{R}^d \text{ Borel}, \tag{2.3}$$

in the planar case, that is, when $d = 2$. To this end, let $D(x, r)$ denote the open disc in $\mathbb{R}^2$, centered at $x$ and of radius $r$, and let $\bar{\theta} = \inf\{t \geq 0 : \|w(t)\| \geq 1\}$ be the exit time of the planar Brownian motion from the unit disc $D(0, 1)$. Since $w([0, \bar{\theta}]) := \{w(t) : 0 \leq t \leq \bar{\theta}\}$ is a compact set, it follows that $\mu_{\bar{\theta}}^w(D(x, r)) = 0$ for any $x \notin w([0, \bar{\theta}])$ and all $r$ small enough. Further, it is not hard to show that for almost all Brownian paths, the pointwise Hölder exponent of the random measure $\mu_{\bar{\theta}}^w$, namely,

$$\lim_{r\to 0} \frac{\log \mu_{\bar{\theta}}^w(D(x, r))}{\log r},$$

takes the same value 2 for all points $x \in w([0, \bar{\theta}])$ (see also [Ray63, Theorem 1] for the precise lim sup decay rate of $\mu_{\bar{\theta}}^w(D(0, r))$ when $r \to 0$). Therefore, standard

multi-fractal analysis must be refined in order to capture the delicate fluctuations of the Brownian occupation measure and obtain a non-degenerate dimension spectrum. Indeed, it is shown in [DPRZ01] that for any $0 < a \leq 2$,

$$\dim\{x : \lim_{r\to 0} \frac{\mu^w_{\bar\theta}(D(x,r))}{r^2(\log r)^2} = a\} = 2 - a \quad \text{a.s.} \tag{2.4}$$

(where throughout $\dim(A)$ denotes the Hausdorff dimension of the set $A$). For a typical $x$ on the Brownian path $\mu^w_{\bar\theta}(D(x,r)) \asymp r^2|\log r|$ (e.g. see [DPRZ01, Lemma 2.1]), so the *a-thick points*, i.e. those in the set considered in (2.4), correspond to unusually large occupation measure.

The identity (2.4), together with the appropriate upper bound, yields that

$$\lim_{r\to 0} \sup_{x\in\mathbb{R}^2} \frac{\mu^w_{\bar\theta}(D(x,r))}{r^2(\log r)^2} = 2 \quad \text{a.s.} \tag{2.5}$$

as conjectured by Perkins and Taylor. It is not hard to show then that both (2.4) and (2.5) hold when $\bar\theta$ is replaced by any deterministic $0 < T < \infty$ and it is in the latter form that (2.5) was stated as [PT87, Conjecture 2.4]. As shown in [DPRZ02, Theorem 1.2], both (2.4) and (2.5) apply even when the discs $D(x,r) = x + rD(0,1)$ are replaced by the sets $x + rK$, provided the set $K$ is normalized to have area (Lebesgue measure) $\pi$ and its boundary has zero Lebesgue measure.

See also [PPPY01] for the application of (2.5) to the problem of reconstructing the range of spatial Brownian motion from the occupation measure projected to the sphere.

**2.3. From Brownian motion to SRW.** The passage from (2.5) and (2.4) to the corresponding results (1.1) and (2.1) for the discrete setting is based on the celebrated strong approximation theorem of Komlós, Major and Tsunády [KMT75] which constructs in an enlarged probability space a one dimensional Brownian motion $w$ and a SRW $(S_k, k \geq 0)$ on $\mathbb{Z}$ such that $\mathbb{P}(\sup_{t\leq 1}|w(t) - w^{(n)}(t)| \geq c(\log n)/\sqrt{n}) \to 0$ when $n \to \infty$. A simple geometric argument extends this conclusion to the SRW on $\mathbb{Z}^2$. Further, applying Einmahl's multidimensional version of this strong approximation theorem, the same argument allows [DPRZ01, Theorem 5.1] to establish (1.1), (2.1) and (2.2) for a wide collection of two-dimensional lattice valued random walks whose increments are of zero mean and finite moments. Here is an outline of such an argument, revealing the source of the factor $2\pi$ between (1.1) and (2.5). Taking $r = r(n) = n^{\eta-1/2}$ for fixed $\eta > 0$ small, and fixing $0 < a < 2$, one predicts from (2.4) that there are about $r^{a-2}$ discs of radius $r$, which are $r$-separated of each other, each having a Brownian occupation measure of about $ar^2(\log r)^2$. By strong approximation a similar result applies for the occupation measure of $w^{(n)}$. Since $t \mapsto w^{(n)}(t)$ is piecewise constant on intervals of length $1/n$, this translates to $nar^2(\log r)^2$ visits by $w^{(n)}$ to discs whose radius is approximately $r$. Further, with each of these discs having about $\pi r^2 n/2$ of the sites of $\sqrt{2/n}\mathbb{Z}^2$, we see that to these discs correspond

distinct (random) points in $\mathbb{Z}^2$ having at least $2a(\log r)^2/\pi$ visits during the first $n$ steps of the SRW. So, for $\alpha = 2a(1/2-\eta)^2$ these $r^{a-2} = n^{1-2\eta-\alpha/(1-2\eta)}$ points are $\alpha$-favorite, and considering first $n \to \infty$ then $\eta \to 0$ gives the lower bound in (2.1) and consequently also in (1.1).

As shown in [Ros05], (2.1) and (1.1) can also be proved without reference to the Brownian motion results, by directly applying the multi-scale truncated second moment approach of Section 3 to the SRW on $\mathbb{Z}^2$.

## 3. The multi-scale truncated second moment

Fixing a positive integer $b \geq 2$ let $\Gamma_h$ denote the $b$-ary rooted regular tree of height $h$, that is, the degree of each vertex of $\Gamma_h$ is $b+1$, except for the root, denoted $\mathbf{o}$, whose degree is $b$ and the $b^h$ leaves of this tree, each of whom has degree one. Starting a SRW $(X_i)$ on $\Gamma_h$ at its left-most leaf let $\tau_{\mathbf{o}} = \inf\{i \geq 0 : X_i = \mathbf{o}\}$ denote the hitting time of the root of $\Gamma_h$ and $L_x$ the number of visits to $x \in \Gamma_h$ by $\{X_i, i \leq \tau_{\mathbf{o}}\}$. Fixing $0 < \alpha < 1$ we call a leaf $x$ of $\Gamma_h$ *$\alpha$-favorite* if $L_x \geq \alpha h^2 \log b$ and let $\mathcal{F}_h(\alpha)$ denote the set of $\alpha$-favorite leaves. In Subsection 3.1 we outline the multi-scale truncated second moment method in the context of proving that

$$\lim_{h\to\infty} \frac{1}{h} \log |\mathcal{F}_h(\alpha)| = (1-\alpha)\log b \quad \text{in probability.} \tag{3.1}$$

As demonstrated in Subsection 3.2, this is the core of the computations leading to (2.4) and (2.5), thereby also to (1.1), (2.1) and (2.2), where the trees $\Gamma_h$ serve in revealing the hidden correlation structure across scale (i.e., the radius of discs), and space (i.e., their centers).

**3.1. Favorite points for SRW on regular trees.** Let $\partial\Gamma_h$ denote the set of leaves of $\Gamma_h$ and $\mathbf{o} \leftrightarrow x$ denote the shortest path in $\Gamma_h$ between $\mathbf{o}$ and $x \in \partial\Gamma_h$, also called the ray of $x$. Fixing $x$ and projecting the SRW on its ray, we see that $L_x$ has the same law as the number of visits to a reflecting boundary at $h$ prior to absorption at 0, for a SRW $(Y_i)$ on $\{0, 1, \ldots, h\}$. In particular, $\mathbb{P}(L_x \geq t) \leq \left(1 - \frac{1}{h}\right)^{t-1}$ for any $x \in \partial\Gamma_h$, $t \geq 1$. Taking $t = t_h$ for $t_h := \alpha h^2 \log b$ yields the upper bound in (3.1) by an application of the first moment bound $\mathbb{P}(Z \geq 1) \leq \mathbb{E}Z$ for $Z = Z_h = b^{-\beta h}|\mathcal{F}_h(\alpha)|$ and $\beta > 1-\alpha$. With a little more work we find that as $h \to \infty$ also $\mathbb{E}(Z_h) \to \infty$ for $\beta < 1-\alpha$, supporting the validity of (3.1). To take advantage of diverging expectations one usually relies on the second moment method. That is, applying the classical bound $\mathbb{P}(Z \geq \delta \mathbb{E}Z) \geq (1-\delta)^2(\mathbb{E}Z)^2/\mathbb{E}Z^2$ for some $0 < \delta < 1$ and the preceding $Z = Z_h$. However, at least for $\alpha > 1/2$ this approach fails to work here. Indeed, as shown in [Dem05, Lemma 4.2], then $\mathbb{E}Z_h^2/(\mathbb{E}Z_h)^2 \to \infty$ since for such $\alpha$ and any $0 < \xi < 2\alpha - 1$ there exists $\eta = \eta(\alpha, \xi) > 0$ such that for large enough $h$

$$b^{-2(1-\alpha)h} \sum_{(x,y)\in\partial_\xi\Gamma_h} \mathbb{P}(L_x \geq t_h, L_y \geq t_h) \geq b^{\eta h}, \tag{3.2}$$

where $\partial_\xi \Gamma_h$ denote the collection of pairs $x, y \in \partial\Gamma_h$ for which $\mathbf{o} \leftrightarrow x$ and $\mathbf{o} \leftrightarrow y$ separate at distance $\xi h$ from $\mathbf{o}$.

Starting the SRW $\{Y_i\}$ at $Y_0 = h$ and assuming $t_h$ returns to $h$ prior to its absorption at 0, the expected number of excursions between $k-1$ and $k$ till the $t_h$-th return to $h$ is about $\alpha k^2 \log b$ when $k \gg 1$ and $h - k \gg 1$ (cf. [Dem05, Lemma 4.3]). This suggests that for a typical $x \in \mathcal{F}_h(\alpha)$ the SRW $(X_i)$ has prior to $\tau_{\mathbf{o}}$ about $\alpha k^2 \log b$ visits to a vertex on $\mathbf{o} \leftrightarrow x$ which is at distance $k$ from $\mathbf{o}$. The analysis leading to (3.2) reveals also that the main contribution of the collection $\partial_\xi \Gamma_h$ to the second moment of $|\mathcal{F}_h(\alpha)|$ is via the rare events of having prior to $\tau_{\mathbf{o}}$ a sufficiently excessive number of SRW excursions between the vertex $z$ where $\mathbf{o} \leftrightarrow x$ and $\mathbf{o} \leftrightarrow y$ separate and the leaves of the sub-tree rooted at $z$. The typical number of such excursions for $\alpha$-favorite leaves is only a fraction of what these events require, so they contribute little to $\mathbb{E}Z_h$ when $h$ is large. However, the occurrence of such rare event yields too many $\alpha$-favorite leaves at the sub-tree rooted at $z$, hence resulting with the excessive growth of the second moment of $Z_h$.

Since this problem occurs for any separation height $\xi h$, $\xi < 2\alpha - 1$, one should pursue a multi-scaling truncation strategy. That is, apply the second moment method for $Z_h = b^{-\beta h}|\mathcal{S}_h(\alpha)|$, replacing $\mathcal{F}_h(\alpha)$ by a subset $\mathcal{S}_h(\alpha)$ of leaves along the rays of which various excursion counts are kept within a relatively small distance from the typical excursion count profile for an $\alpha$-favorite leaf. Of course we are to do so while not changing much the mean of $Z_h$, that is, keeping

$$\mathbb{P}(x \in \mathcal{S}_h(\alpha)) = b^{-\alpha h(1+o(1))} \tag{3.3}$$

for all $x \in \partial\Gamma_h$. To attain (3.3) only $o(h)$ excursion counts are to be controlled along each ray of $\Gamma_h$. Specifically, fixing $c > 0$ large enough, we set heights $h_0 = 0$, $h_1 = 1$ and $h_k = [ck \log k]$ for $k = 2, \ldots, m$, taking $h = h_m$, and consider the number $N_k^x$ of complete excursions between vertices $x_{k-1}$ and $x_k$ at distances $h_{k-1}$ and $h_k$ from $\mathbf{o}$ along $\mathbf{o} \leftrightarrow x$ which occur between the first visit of the SRW to $x_1$ and its first successive visit to $x_0 = \mathbf{o}$. Recall that for a typical $\alpha$-favorite leaf $x$, the SRW $(X_i)$ makes about $\alpha h_k^2 \log b$ visits to $x_k$ during this time interval. With $\Delta_k = h_k - h_{k-1} = c \log k(1 + o(1))$ for large $k$, this translates to $N_k^x$ being near $n_k = \alpha h_k^2 \log b/(c \log k)$ for a typical $x \in \mathcal{F}_h(\alpha)$. Consequently, we take as $\mathcal{S}_h(\alpha)$ those $x \in \partial\Gamma_h$ such that $|N_k^x - n_k| \le k$ for $k = 2, \ldots, m$. Per $x \in \partial\Gamma_h$, the sequence $(N_k^x, k = 1, \ldots, m)$ is the realization of a non-homogeneous Markov chain on $\mathbb{Z}_+$, starting at $N_1^x = 1$. The transition probabilities of this chain are given by explicit hyper-geometric distributions. As $n_{k+1} = n_k(1 + 2/k)(1 + o(1))$, for large $k$ one gets by normal approximation that the probability of the transition from $N_k^x = [n_k]$ to $N_{k+1}^x = [n_{k+1}]$ is about $p_k = b^{-\alpha\Delta_k}/\sqrt{n_k}$. With $k/\sqrt{n_k} \to 0$, further analysis shows that for some finite constant $C$ which depends only on $(\alpha, b, c)$ and for any $|\ell_k - n_k| \le k$ and $|\ell_{k+1} - n_{k+1}| \le k + 1$, the probability of the transition from $N_k^x = \ell_k$ to $N_{k+1}^x = \ell_{k+1}$ is between $C^{-1}p_k$ and $Cp_k$ (cf. [Dem05, Lemma 4.6]). Note that $q_m = \mathbb{P}(x \in \mathcal{S}_{h_m}(\alpha))$ is the same for any $x \in \partial\Gamma_{h_m}$. Also, in the definition of the event $\{x \in \mathcal{S}_{h_m}(\alpha)\}$, for each $k$, the random variable $N_k^x$ can take any one of

$2k+1$ possible values. Hence, by the preceding analysis $m^{-1}\log\left(q_m/\left[\prod_{k=1}^{m-1} kp_k\right]\right)$ is bounded. Moreover, as $n_k = \zeta k^2 \log k$ for some positive constant $\zeta$, it follows that $kp_k = b^{-\alpha\Delta_k(1+o(1))}$ and with $m = o(h_m)$, it is now easy to verify that (3.3) holds (cf. [Dem05, Proposition 4.4]).

We turn next to study the correlation structure of $\{x \in \mathcal{S}_{h_m}(\alpha)\}$ across $x \in \partial\Gamma_{h_m}$. Specifically, let $B_{l,x} = \{|N_k^x - n_k| \le k, l < k \le m\}$ for $l = 1, \ldots, m-1$, noting that $B_{1,x} = \{x \in \mathcal{S}_{h_m}(\alpha)\}$, so the second moment of $|\mathcal{S}_{h_m}(\alpha)|$ is the sum of $\mathbb{P}(B_{1,x} \cap B_{1,y})$ over $x, y \in \partial\Gamma_{h_m}$. Let $q_{m,l}$ denote the maximum of these probabilities over pairs $(x, y)$ such that $x_1 = y_1$ and the rays $\mathbf{o} \leftrightarrow x$ and $\mathbf{o} \leftrightarrow y$ separate at a vertex $z$ whose distance from $\mathbf{o}$ is between $h_{l-1}$ and $h_l$. Since $B_{1,y} \subseteq B_{l,y}$, it thus suffices for us to get an upper bound on $\mathbb{P}(B_{1,x} \cap B_{l,y})$. To this end, note that given the value of $N_{l+1}^y$, the event $B_{l,y}$ is independent of $B_{1,x}$. Consequently,

$$q_{m,l} \le q_m \sum_{|\ell - n_{l+1}| \le l+1} \mathbb{P}(B_{l,y} | N_{l+1}^y = \ell).$$

By a similar reasoning,

$$q_m \ge q_{l+1} \inf_{|\ell - n_{l+1}| \le l+1} \mathbb{P}(B_{l,y} | N_{l+1}^y = \ell).$$

As we have already seen, the above terms $\mathbb{P}(B_{l,y}|N_{l+1}^y = \ell)$ are almost constant (up to a factor $C^2$) with respect to $\ell$, leading to the bound

$$q_{m,l} \le C^2(2l+3)\frac{q_m^2}{q_{l+1}} \tag{3.4}$$

(cf. [Dem05, Lemma 4.8]). This is effectively the same correlation structure as for independent percolation on the tree $\Gamma_{h_m}$ projected to skeleton heights $\{h_k\}$ and with level depending edge probabilities that are about $p_k$. In particular, using the bound of (3.4) leads to $\mathbb{E}[|\mathcal{S}_h(\alpha)|^2] \le K(\mathbb{E}|\mathcal{S}_h(\alpha)|)^2$ for some $K = K(\alpha)$ finite and any $h \in \{h_k\}_{k=1}^{\infty}$ (cf. [Dem05, Lemma 4.9]). Combining this with the first moment estimate of (3.3), an application of the second moment method yields that the probability of ${h_m}^{-1}\log|\mathcal{S}_{h_m}(\alpha)| \ge (1-\alpha)\log b(1+o(1))$ is bounded away from zero (being about $1/K$).

It remains to improve this result to one that holds with probability approaching one, and to connect the fact that $N_m^x$ is near $n_m$ with the event $\{x \in \mathcal{F}_{h_m}(\alpha)\}$. To this end, for $h \in [h_{m+1}, h_{m+2})$ and any vertex $v \in \Gamma_h$ of height $h - h_m + 1$ let $\mathcal{S}_{h_m}^v(\alpha)$ be defined in analogy to $\mathcal{S}_{h_m}(\alpha)$, but for the subtree rooted at the ancestor of $v$ and consisting of those $u \in \Gamma_h$ with $v$ on the shortest path from $u$ to $\mathbf{o}$. Next let $\mathcal{S}_h^*(\alpha)$ be the union of the sets $\mathcal{S}_{h_m}^v(\alpha)$ over the $R_h$ vertices $v$ of height $h - h_m + 1$ that the SRW on $\Gamma_h$ visits by time $\tau_{\mathbf{o}}$. The preceding bound applies for the SRW within any regular subtree of depth $h_m$, hence for each of the sets $\mathcal{S}_{h_m}^v(\alpha)$. Thus, as $R_h \to \infty$ with high probability, and the restrictions of the SRW to within the subtrees of $\Gamma_h$ rooted at these

vertices are independent of each other and of $R_h$, it follows that

$$\lim_{h\to\infty} \frac{1}{h} \log |\mathcal{S}_h^*(\alpha)| = (1-\alpha)\log b \quad \text{in probability}$$

(cf. [Dem05, Lemma 4.11]). Finally, a simple concentration argument shows that during $n_m - m$ excursions between $x \in \partial\Gamma_h$ and a vertex on its ray at distance $\Delta_m$ from $x$, the SRW visits $x$ less than $n_m\Delta_m(1-\delta)$ times with probability that decays to zero exponentially in $n_m$ (cf. [Dem05, Lemma 4.7]). This leads for any $\beta < \alpha$ to $\mathbb{P}(\mathcal{S}_h^*(\alpha) \subseteq \mathcal{F}_h(\beta)) \to 1$ and consequently completes the proof of (3.1).

**3.2. From trees to Brownian motion.** The approach of [DPRZ01] in proving (2.4) and (2.5), which goes back to [Ray63], is to control Brownian occupation measures using excursions between concentric discs. Specifically, fixing $R' > R > r$, the total occupation measure of $D(x, r)$ during the first $N$ excursions of the sample path between $D(x, R)$ and the complement of $D(x, R')$ is of the form $\sum_{i=1}^{N} \tau_i$, where $\tau_i$ denotes the occupation measure of $D(x, r)$ accumulated during the $i$-th such excursion. Since these Brownian excursions are independent of each other, so are the random variables $\{\tau_i\}$. Further, the events of interest here involve exceptionally large occupation measures that translate into having numerous excursions around the same point. Consequently, for the range of $N$ values relevant here, the resulting total occupation measure is highly concentrated around its mean $N\mathbb{E}\tau_1$.

From the corresponding elliptic PDE we have that $\mathbb{E}\tau_1 = r^2\log(R'/R)$ which by the strong Markov property of the Brownian motion implies also that $\mathbb{P}(\tau_1 \geq t[r^2\log(R'/r) + 1])$ decays exponentially in $t$ (cf. [Dem05, Lemma 5.5]). The statement (2.5) can be shown to concern the maximum of the occupation measures $\mu_{\bar{\theta}}^w(D(x_j, r))$ for a suitable non-random discrete net of about $r^{-2}$ points $x_j \in D(0, 1)$. To upper bound such maximum, we take $R' = 2$ in which case $\mu_{\bar{\theta}}^w(D(x, r)) \leq \tau_1$. Hence, for $a > 2$, we see from the tail probabilities of $\tau_1$ (at $t = a\log(1/r)$), that the expected number of discs with centers in this net and occupation measure exceeding $ar^2(\log r)^2$ decays to zero at rate $r^{a-2}$. By the first moment method we get the upper bound in (2.5), where the almost sure statement is attained by using the monotonicity of $r \mapsto \mu_{\bar{\theta}}^w((D(x, r))$ to interpolate between radii $r_n$ such that $\sum_n r_n^{a-2}$ is finite.

The same argument shows that the expected number of such discs with occupation measure exceeding $t_r = ar^2(\log r)^2$ diverges at rate $r^{a-2}$ when $a < 2$, supporting the validity of (2.5). Unfortunately, the second moment method fails to work here since the recurrence of the planar Brownian motion precludes a fast decay of the correlation between the events $\{\mu_{\bar{\theta}}^w((D(x, r)) \geq t_r\}$ even for $x$ and $y$ of distance $r^\delta$ of each other (and $\delta$ a fixed small positive constant). A natural truncation of the second moment is by localizing the occupation measures. For example, considering only the Brownian occupation measure of $D(x, r)$ during the interval between the first hitting time of this disc by the Brownian path and its successive exit of $D(x, R)$. For a suitable $R(r) \to 0$ such that $R(r)/r \to \infty$ the second moment of the number of discs with localized occupation measures exceeding $t_r$ is much smaller than the corresponding

second moment for $\mu_{\bar\theta}^w(D(x,r))$. However, it comes at the cost of a substantial drop in the corresponding first moment, so this strategy results with non-matching lower and upper bounds (cf. [PT87]).

We note in passing that the same problem arises in the context of the SRW on $\mathbb{Z}^2$, that is, in [ET60] treatment of (1.1), and more generally in all statements we make in this paper.

We mitigate this problem by employing a multi-scale truncation, as done in Subsection 3.1. To this end, recall that the counts of Brownian excursions between concentric discs of radii $\{e^{-j}\}$ have the same law as the bond occupation measure for the SRW on $\mathbb{Z}$, which plays a key role in proving (3.1). Indeed, for $x \notin D(0,r_1)$ taking $r_k = r_1 e^{-h_k}$ for $h_k = [ck\log k]$, $k = 2,\ldots,m$, the numbers $N_k^x$ of Brownian excursions from $\partial D(x,r_{k-1})$ to $\partial D(x,r_k)$ till hitting $\partial D(x,r_0)$ have the same joint law as the random variables $N_k^x$ for the SRW on the regular tree $\Gamma_{h_m}$ (to make this precise, take $r_0 = er_1$). Thus, setting $n_k = ah_k^2/(c\log k)$ and partitioning the square $S(1,1) = [2r_1, 4r_1]^2$ into $e^{2h_m}$ non-overlapping squares $S(m,i)$ of edge length $2r_m$ each, we now consider the random set $\mathcal{S}_{h_m}(a)$ that consists of centers $x = x_{m,i}$ of squares $S(m,i)$ for which $|N_k^x - n_k| \le k$, $k = 2,\ldots,m$. As explained above, the estimate (3.3) applies here (with $\alpha = a$, $b = e$ and $h = h_m$), resulting with $\mathbb{E}|\mathcal{S}_{h_m}(a)| = e^{(2-a)h_m(1+o(1))}$. We can further uniformly bound correlation terms of the form $\mathbb{P}(B_{1,x} \cap B_{l,y})$ for $x = x_{m,i}$ and $y = x_{m,j}$ such that $|x-y| \in (2r_l, 2r_{l-1}]$ in a similar manner to that for the SRW on regular trees, apart from two complications. First, to assure that $\partial D(x,r_k)$ does not intersect $\partial D(y,r_l)$ we have to exclude $k = l-1$. That is, remove from $B_{1,x}$ the constraints on the values of $N_{l-1}^x$ and $N_l^x$. Even after this is done, given $N_{l+1}^y = \ell$, the event $B_{l,y}$ still depends on $B_{1,x}$ via the locations of the initial and final points of the $\ell$ Brownian excursions from $\partial D(y,r_{l+1})$ to $\partial D(y,r_l)$. Using the Poisson kernel for the density of the exit location at $z \in \partial D(y,R')$ for a Brownian path starting at some $z' \in D(y,R')$, it can be shown that the probability of $B_{l,y}$ given $N_{l+1} = \ell$ *and the terminal points* of these $\ell$ excursions is at most $(1+\kappa r_{l+1}/r_l)^\ell \mathbb{P}(B_{l,y}|N_{l+1}^y = \ell)$ (cf. [DPRZ01, Lemma 7.4]). Taking $c$ sufficiently large ($c = 3$ will do), provides enough separation for $n_{l+1} \ll r_l/r_{l+1}$ resulting with a bound of the form of (3.4), apart from replacing $C^2(2l+3)$ by a larger polynomial factor (cf. [DPRZ01, Lemma 8.1]). This is enough for deducing that $\mathbb{E}[|\mathcal{S}_{h_m}(a)|^2] \le K(\mathbb{E}|\mathcal{S}_{h_m}(a)|)^2$, for some $K = K(a)$ and all $m$. Since $\mathbb{E}|\mathcal{S}_{h_m}(a)| \to \infty$, by the second moment method also $\liminf_m \mathbb{P}(\mathcal{S}_{h_m}(a) \neq \emptyset) \ge 1/K$. By Fatou's lemma, this implies the existence with positive probability of some random $m(j) \to \infty$ and $y_j \in \mathcal{S}_{h_{m(j)}}(a)$. By compactness of $S(1,1)$, the sequence $y_j$ has at least one limit point $y_* \in S(1,1)$.

Let $M_{x,r} = \mu_{\bar\theta}^w(D(x,r))/[r^2(\log r)^2]$. We claim that $M_{y_*,r} \to a$ for $r \to 0$. That is, $y_*$ is an $a$-thick point, see (2.4). To this end, recall that for $R' = r_{k-1}$ and $R = r = r_k$ we have $\mathbb{E}\tau_1 = r_k^2\Delta_k$, whereas $n_k\Delta_k$ is about $ah_k^2 = a(\log r_k)^2$. With $\{\tau_i\}$ of exponential tail probabilities, it follows that $\mathbb{P}(|M_{x,r_k} - a| > \eta, |N_k^x - n_k| \le k) \le e^{-\gamma n_k}$ for any $\eta > 0$, some $\gamma = \gamma(a,\eta) > 0$, all $k$ and $x \in S(1,1)$. By the monotonicity of the non-negative measure $\mu_{\bar\theta}^w$ and the almost sure continuity properties of $M_{x,r}$

in $x$ and $r$, we further deduce the existence of $\delta(r, w) \to 0$ such that with probability one, if $x \in S(1, 1)$ and $|N_k^x - k| \le n_k$ for all $k \le \ell$, then $|M_{x,r} - a| \le \delta(r)$ for all $r \ge r_\ell$ (cf. [DPRZ01, Section 6]). Recall that for any fixed $\ell$, if $j$ is sufficiently large then $|N_k^{y_j} - n_k| \le k$ for $k = 2, \ldots, \ell$. Consequently, $\limsup_j |M_{y_j,r} - a| \le \delta(r)$ for any $r > 0$. Since $|y_j - y_*| \to 0$, the monotonicity of $\mu_{\bar\theta}^w$ leads to $|M_{y_*,r} - a| \le \delta(r)$, and so we deduce that with some positive probability there exists an $a$-thick point.

Fixing $\beta < 2 - a$, by a slightly more involved argument, the squares $S(m, i)$ whose centers are in $\mathcal{S}_{h_m}(a)$ support the density with respect to Lebesgue measure of a random measure $\nu_m$ such that a non-zero weak limit point $\nu_\infty$ of $\{\nu_m\}$ is supported on a closed set of $a$-thick points and has a finite $\beta$-energy

$$\mathcal{E}_\beta(\nu_\infty) := \int |x - y|^{-\beta} d\nu_\infty(x) d\nu_\infty(y) \tag{3.5}$$

(cf. [DPRZ01, Section 3]). This in turns implies that with positive probability the dimension of the set of $a$-thick points is at least $\beta$. Using Brownian scaling, it follows by Blumenthal's zero-one law that the latter property holds with probability one, establishing the stated lower bound in (2.4) and hence also that of (2.5).

## 4. Fractal geometry: late points and covered discs

**4.1. Cover times and covered discs.** For $0 \le \gamma < 1$ let $C_n(\gamma)$ denote the time it takes until the largest disc unvisited by the SRW on the two dimensional lattice torus $\mathbb{Z}_n^2$ has radius $n^\gamma$. It is shown in [DPRZ04] that

$$\lim_{n\to\infty} \frac{C_n(\gamma)}{(n \log n)^2} = \frac{4}{\pi}(1 - \gamma)^2 \quad \text{in probability,} \tag{4.1}$$

with (1.2) corresponding to the special case of $\gamma = 0$. In other words, at time $\beta C_n$ the radius of the largest disc within the set unvisited by the SRW is $n^{(1-\sqrt{\beta})(1-o(1))}$.

In [PR04], Peres and Revelle deduce from (4.1) that the total variation convergence to the stationary measure for the SRW on the lamplighter group over $\mathbb{Z}_n^2$ requires at least $(4/\pi)(n \log n)^2(1 + o(1))$ steps. This is based on their observation that starting at a zero lamp configuration, the lamps remain identically zero on the sites of $\mathbb{Z}_n^2$ which the lamplighter did not visit, while under the stationary (uniform) measure of this SRW the probability of having a disc of radius $\log n$ in $\mathbb{Z}_n^2$ with a zero lamp configuration tends to zero with $n$. By general considerations, the asymptotic growth in $n$ of the total variation mixing time for the SRW on the lamplighter group over $\mathbb{Z}_n^d$, $d \ge 2$, is between $\mathbb{E}C_{\mathbb{Z}_n^d}$ and half its value, but it is not known whether this upper bound is tight also for $d \ge 3$ (see [PR04]).

Let $\{w_{\mathbb{T}^2}(t)\}$ denotes a Brownian motion on the two dimensional unit torus $\mathbb{T}^2$, with the corresponding hitting times, $\tau(x, \varepsilon) = \inf\{t > 0 : w_{\mathbb{T}^2}(t) \in D_{\mathbb{T}^2}(x, \varepsilon)\}$, and the $\varepsilon$-cover time,

$$\boldsymbol{C}_\varepsilon = \sup_{x\in\mathbb{T}^2} \{\tau(x, \varepsilon)\}. \tag{4.2}$$

Equivalently, $\boldsymbol{C}_r$ is the amount of time needed for the Wiener sausage of radius $r$ to completely cover $\mathbb{T}^2$. It is shown in [DPRZ04] that

$$\lim_{r\to 0} \frac{\boldsymbol{C}_r}{(\log r)^2} = \frac{2}{\pi} \quad \text{a.s.} \tag{4.3}$$

Similarly to the argument we outline in Subsection 2.3, (4.1) is an immediate consequence of (4.3). Indeed, we identify the vertices of $n^{-1}\mathbb{Z}_n^2$ with the corresponding subset of $\mathbb{T}^2$, noting that up to scaling by $n$, distances in $\mathbb{Z}_n^2$ match the corresponding distances in $\mathbb{T}^2$. Further identifying the latter with $[0,1)^2$, we represent $w_{\mathbb{T}^2}(t)$ as the image of the planar Brownian motion $w(t)$ via the non-expansive mapping $x \mapsto x \bmod \mathbb{Z}^2$. Similarly, if $S_k$ denotes the SRW on $\mathbb{Z}^2$, then $X_k = (n^{-1}S_k) \bmod \mathbb{Z}^2$ is the SRW on $n^{-1}\mathbb{Z}_n^2$. By Einmahl's [Ein89, Theorem 1] multidimensional version of KMT strong approximation theorem, we can construct $\{S_k\}$ and $\{w(t)\}$ on the same probability space such that with probability approaching one as $n \to \infty$, the distance in $\mathbb{T}^2$ between $w_{\mathbb{T}^2}(t)$ and $X_{\lfloor mt \rfloor}$ is for $m = 2n^2$ and $t \le 2(\log n)^2$ at most $\delta_n = (\log m)^3/\sqrt{m}$. Fixing $\gamma > 0$, since $\delta_n \ll n^{\gamma-1} = \varepsilon_n$ and $w_{\mathbb{T}^2}$ completely misses some disc $D_{\mathbb{T}^2}(x, \varepsilon_n)$ in $\mathbb{T}^2$ till time $\boldsymbol{C}_{\varepsilon_n}$, we deduce that $(X_k)$ completely misses a disc whose radius is about $\varepsilon_n$ till time $2n^2\boldsymbol{C}_{\varepsilon_n}$. That is, $C_n(\gamma)$ is about $2n^2\boldsymbol{C}_{\varepsilon_n}$. Taking $\gamma \to 0$ then provides the lower bound in (1.2). The matching upper bound on $C_n$ is easily obtained upon considering the expected number of sites that are unvisited during the first $\alpha(4/\pi)(n\log n)^2$ steps of the SRW on $\mathbb{Z}_n^2$, with $\alpha > 1$ fixed and $n \to \infty$.

The derivation of (1.3) follows a similar path, where setting $\varepsilon_m = m^{\gamma-1}$ for $\gamma > 0$ one first checks that the lower bound in (4.3) applies also for the $\varepsilon_m$-cover time of the disc $D_{\mathbb{T}^2}(0, br_m)$ when $r_m = c(\log m)^{-3}$ (with $b$, $c$ fixed and $m$ large). For $R > 0$ sufficiently small, the expected time it takes $w_{\mathbb{T}^2}$ to complete an excursion between the discs of radii $r_m$ and $R$, centered at the origin, is about $(1/\pi)\log(R/r_m)$. By a concentration argument the number of such excursions made by $w_{\mathbb{T}^2}$ till its $\varepsilon_m$-cover time of $D_{\mathbb{T}^2}(0, br_m)$ is thus about $(2/\pi)(\log \varepsilon_m)^2/[(1/\pi)(\log R/r_m)]$. For $1/2 < b < 1$ and $c < R/b$ this implies by a strong approximation argument that with high probability the planar SRW makes at least $(1-\gamma)^3 2(\log m)^2/(3\log\log m)$ excursions between the discs of radii $m(\log m)^3$ and $2m$, centered at the origin, till it covers the concentric disc of radius $m$ (cf. [DPRZ04, Lemma 5.1]). A similar argument leads to the matching upper bound. The limit distribution of (1.3) then follows upon studying the tail probabilities for the time it takes the planar SRW to complete one such excursion for large value of $m$ (cf. [Law92]). By a similar technique, [HP06] establishes the law of the iterated logarithm which corresponds to (1.3). That is,

$$\limsup_{n\to\infty} \frac{(\log \rho_n)^2}{\log n \log_3 n} = \frac{1}{4}, \quad \text{a.s.}$$

(where $\log_3$ denotes three iterations of the log function).

Jonasson and Schramm proved in [JS00] that if $G = (V, E)$ is a planar graph of maximal degree $D$ then there are constants $k_D$ and $K_D$ depending only on $D$ such

that $k_D|V|(\log|V|)^2 \le \mathbb{E}[C_G] \le K_D|V|^2$. As illustrated already, (1.2) is a direct consequence of (4.3), with the same argument applicable for finding the asymptotics of the cover time for SRW on different planar lattices. As explained in [DPRZ04, Section 9], this leads to

**Open Problem 4.1.** Is the lattice $\mathbb{Z}^2$ asymptotically the easiest to cover when $D = 4$? That is, does $\liminf \mathbb{E}[C_G]/(|V|(\log|V|)^2) = 1/\pi$, where the lim inf is over all planar graphs $G = (V, E)$ of maximal degree $D = 4$ and for $|V| \to \infty$?

The limit distribution of the cover time $C_n$ for the SRW on the lattice torus $\mathbb{Z}_n^2$ and similar random fluctuations are likely related to behavior such as that of branching Brownian motion, and hence to KPP-type partial differential equations (cf. [Ald91], [Bra83], [Bra86], [McK75]). However, very little is known about it. For example,

**Open Problem 4.2.** Does there exist a non-random sequence $b_n$ such that $b_n(\sqrt{C_n} - \mathrm{Med}\{\sqrt{C_n}\})$ converges in distribution to a non-degenerate random variable, and if so what is the limit distribution?

Even the existence of a non-random normalizing sequence $b_n$ that results with a tight, yet non-degenerate collection, is not obvious. See [BZ06] for a proof of tightness for the simpler problem in the context of SRW on the regular trees $\Gamma_h$.

For any $0 < \alpha < 1$, let $R_n(\alpha)$ denote the radius of the largest disc (of arbitrary center) consisting of $\alpha$-favorite points for the SRW on $\mathbb{Z}^2$. The proof of (1.4) combines the ideas behind the proofs of (1.1) and (1.2). Similarly, based on (2.1) and (4.1), it is also shown in [DPR07] that for any $0 < \alpha < 1$, with probability one,

$$\lim_{n\to\infty} \frac{\log R_n(\alpha)}{\log n} = \frac{1-\sqrt{\alpha}}{4}. \tag{4.4}$$

Indeed, with $h_k = [ck \log k]$ and $r_k = e^{h_k}$, it takes about $r_m^2$ steps for the SRW to first exit $D(0, r_m)$. Hence, taking $r_{m,k} = e^{h_m - h_k}$, (4.4) follows by showing that with probability one, if $\zeta = (b\beta - \sqrt{\alpha})/(1-\beta) > 1$ for some $b < 1$ and $m$ is large enough, there exists $x \in D(0, r_m)$ such that each $z \in D(x, r_{m,\beta m})$ is visited at least $(4\alpha/\pi)h_m^2$ times prior to the first exit of the SRW from $D(0, r_m)$, whereas no such $x$ exists if $\zeta < 1$ for some $b > 1$. To this end, for each $a < 2$, by strong approximation and the outline of the proof of the lower bound for (2.5), we have that for some $x \in D(0, r_m)$ and $n_k(a) = ah_k^2/(c \log k)$, prior to exiting $D(0, r_m)$ the SRW completes at least $n_k(a) - k$ excursions between $D(x, r_{m,k})$ and the complement of $D(x, r_{m,k-1})$. Thus, considering $k = \beta m - 1$ and $b < \sqrt{a/2}$ for which $\zeta = \zeta(b, \beta, \alpha) > 1$, for $m$ large enough and any $z \in D(x, r_{m,\beta m})$, the SRW completes at least $K = 2(b\beta)^2 h_m^2/(c \log m)$ excursions between $D(z, R)$ and the complement of $D(z, R')$ prior to exiting $D(0, r_m)$ (say, for $R = 2r_{m,\beta m-1}$ and $R' = 0.5r_{m,\beta m-2}$). Let $\widehat{\mathcal{L}}_K(\alpha)$ denote the collection of lattice sites $z \in D(x, r_{m,\beta m})$ visited less than $(4\alpha/\pi)h_m^2$ times during the first $K$ excursions of the SRW between $D(z, R)$ and the

complement of $D(z, R')$. Since there are only $\exp(2(1-\beta)h_m(1+o(1)))$ lattice sites in $D(x, r_{m,\beta m})$, upon showing that

$$\mathbb{P}(z \in \widehat{\mathcal{L}}_K(\alpha)) \le e^{-2(1-\beta)h_m\zeta^2(1+o(1))}, \tag{4.5}$$

it follows that $\mathbb{E}|\widehat{\mathcal{L}}_K(\alpha)| \to 0$ as $m \to \infty$ sufficiently fast to produce the lower bound in (4.4).

The bound (4.5) is obtained by a large deviations estimate of the following type. If $T_i$ are i.i.d. random variables, such that $\mathbb{P}(T_1 > t) \le Qe^{-t/M}$ for all $t > 0$, then for $\gamma < 1$ and $\lambda = (\gamma^{-1} - 1)/M > 0$,

$$\mathbb{P}\Big(\sum_{i=1}^{K} T_i \le \gamma^2 KQM\Big) \le e^{\lambda\gamma^2 KQM}\mathbb{E}[e^{-\lambda T_1}]^K \le e^{-(1-\gamma)^2 KQ}. \tag{4.6}$$

The $K$ excursions of the SRW between $D(z, R)$ and the complement of $D(z, R')$ are approximately independent of each other. Further, by potential theory estimates for the SRW (cf. [Law91]), the probability $Q$ that during such an excursion the SRW visits $z$ is about $(\log(R'/R))/\log R'$ which in turn is about $(c\log m)/((1-\beta)h_m)$. By similar reasoning, upon visiting $z$ at least once, the mean number of returns to $z$ by the SRW during such an excursion, denoted $M$ is about $\frac{2}{\pi}\log R'$, and the number $T_i$ of such returns to $z$ during the $i$-th excursion is such that $\mathbb{P}(T_i > t) \le Qe^{-t(1+o(1))/M}$ for all $t > 0$. Thus, with $KQ$ being about $2(b\beta)^2 h_m/(1-\beta)$ and $KQM$ about $(4(b\beta)^2/\pi)h_m^2$, setting $\gamma = \sqrt{\alpha}/(b\beta) < 1$ in (4.6) leads to (4.5).

As for the matching upper bound in (4.4), by the preceding reasoning, for each $a > 2$, with probability that is fast approaching one (in $m$) for every $x \in D(0, r_m)$ the SRW completes fewer than $n_k(a)$ excursions between $D(x, r_{m,k})$ and the complement of $D(x, r_{m,k-1})$ by the time it exits $D(0, r_m)$. Further, if $\zeta < 1$ for some $b > 1$ then for $k = \beta m - 1$ the expected size of the set $\widehat{\mathcal{L}}_K(\alpha)$ of $z \in D(x, r_{m,k+1})$ with less than $(4\alpha/\pi)h_m^2$ visits by the SRW during its first $K = n_k(2b^2)$ excursions between $D(x, r_{m,k})$ and the complement of $D(x, r_{m,k-1})$ diverges as $m \to \infty$. A truncated multi-scale second moment argument similar to that of Subsection 4.2 then allows us to deduce that for each fixed $x$, with probability approaching one (in $m$), the set $\widehat{\mathcal{L}}_K(\alpha)$ is non-empty, thus completing the proof of (4.4).

**4.2. Late points for SRW on regular trees.** The cover time problem (4.3) is, in a sense, dual of (2.5), in that it replaces "extremely large" occupation measure by "extremely small" occupation measure. Indeed, the derivation in [DPRZ04] of the lower bound for (4.3) is based on another toy problem involving the SRW on a regular tree. In this case it is the asymptotics of the number $\widetilde{C}_h$ of returns to $\mathbf{o}$ by the SRW on $\Gamma_h$, starting at $\mathbf{o}$, till it visits all leaves of the tree.

Both [Ald91] and [Per03] show that $\mathbb{E}\widetilde{C}_h = h^2 b(1+o(1))\log b$ as $h \to \infty$. However, these proofs rely on an embedded branching process argument exploiting the tree structure of $\Gamma_h$ and as such are not suitable to deal with the corresponding

Brownian result (4.3). We explain next how the multi-scale truncated second-moment provides another derivation of the asymptotic of $\widetilde{C}_h$ which is *robust enough* to be adapted in [DPRZ04] to deal with the Brownian motion setting of (4.3).

Turning to deal with $\widetilde{C}_h$, fixing $\alpha > 0$ we say that a leaf $x$ of $\Gamma_h$ is $\alpha$-*late* if the number $\widetilde{R}_x$ of returns to $\mathbf{o}$ by the SRW on $\Gamma_h$ till its first visit to $x \in \partial\Gamma_h$ is at least $\alpha h^2 b \log b$. Starting at $\mathbf{o}$, the probability that the SRW visits a specific leaf $x$ before returning to $\mathbf{o}$ is $1/(bh)$. Hence $\mathbb{P}(\widetilde{R}_x \geq t) = \left(1 - \frac{1}{bh}\right)^t$, yielding the first moment estimate

$$\mathbb{E}(|\mathcal{L}_h(\alpha)|) = b^{h(1-\alpha)(1+o(1))},$$

for the set $\mathcal{L}_h(\alpha)$ of $\alpha$-late leaves of $\Gamma_h$. By the first moment method, this shows that for any $\alpha > 1$ the set $\mathcal{L}_h(\alpha)$ is empty with high probability. Since $\widetilde{C}_h$ is the maximum of $\widetilde{R}_x$ over $x \in \partial\Gamma_h$, we deduce that $\widetilde{C}_h$ is about $h^2 b \log b$ upon showing that for each $0 < \alpha < 1$,

$$\lim_{h\to\infty} \frac{1}{h} \log |\mathcal{L}_h(\alpha)| = (1-\alpha)\log b \quad \text{in probability.} \tag{4.7}$$

As in the derivation of the asymptotic (3.1) for the number of $\alpha$-favorite leaves, the second moment of $|\mathcal{L}_h(\alpha)|$ is much larger than $b^{2h(1-\alpha)(1+o(1))}$. Let $h_k = [ck \log k]$ and $n_k = \alpha h_k^2 \log b/(c \log k)$. Then, adapting the approach taken in Subsection 3.1, the appropriate way of truncating $\mathcal{L}_h(\alpha)$ is by considering for $h \in [h_{m+\rho}, h_{m+\rho+1})$ and $v \in \Gamma_h$ of height $h - h_m + 1$, the subset $\mathcal{S}^v_{h_m}(\alpha)$ of leaves $x$ in the subtree rooted at $v$ such that $N_2^x = 0$ and $|N_k^x - n_k| \leq k$ for $k = 3, \ldots, m-1$. In duality with the case of $\alpha$-favorite leaves, here we set $x_1 = x$ and for $k = 2, \ldots, m$ the vertex $x_k$ is at distance $h_k - 1$ from the *leaf* $x$ along the ray $v \leftrightarrow x$ (so that now $x_m = v$). We then have $N_k^x$ count the number of complete excursions between $x_{k-1}$ and $x_k$ which occur during the first $n_m$ excursions of the SRW between vertices $x_{m-1}$ and $x_m$.

Omitting the detailed computations for this case, we note in passing that similarly to the derivation of (3.3), here $\bar{q}_m = \mathbb{P}(x \in \mathcal{S}^v_{h_m}(\alpha)) = b^{-\alpha h_m(1+o(1))}$, yielding the desired asymptotic growth of $\mathbb{E}(|\mathcal{S}^v_{h_m}(\alpha)|)$. Further, similarly to the derivation of (3.4), here we have that

$$\bar{q}_{m,l} := \sup_{x_{l-1} \neq y_{l-1}} \mathbb{P}\big(x \in \mathcal{S}^v_{h_m}(\alpha) \text{ and } y \in \mathcal{S}^v_{h_m}(\alpha)\big) \leq C l \bar{q}_m \bar{q}_{l-1},$$

for some $C < \infty$ and $l = 2, \ldots, m$ (with the convention of $\bar{q}_1 = \bar{q}_2 = 1$). Although $m \mapsto \mathbb{E}(|\mathcal{S}^v_{h_m}(\alpha)|^2)/\mathbb{E}(|\mathcal{S}^v_{h_m}(\alpha)|)^2$ is now unbounded, its polynomial growth is easily accommodated by considering the sum $|\mathcal{S}^*_h(\alpha)|$ of the $b^{h-h_m+1}$ i.i.d. random variables $|\mathcal{S}^v_{h_m}(\alpha)|$, provided $\rho$ is large enough.

To complete the derivation of (4.7) it thus remains only to show that with high probability $\mathcal{S}^*_h(\alpha) \subseteq \mathcal{L}_h(\beta)$ for $\beta < \alpha$. To this end, recall that the condition $N_2^x = 0$ guarantees that $x \in \mathcal{S}^v_{h_m}(\alpha)$ is not visited by the SRW during its first $n_m$ excursions between the vertex $v$ at level $h - h_m + 1$ and a specific descendent $u = u(x)$ of $v$ which is $\Delta_m$ levels further from $\mathbf{o}$. A concentration argument similar to that of

[Dem05, Lemma 4.7] shows that the probability that the number of returns to $\mathbf{o}$ during the first $n_m$ excursions between such pair $v$ and $u$ is less than $(1-\delta)n_m b\Delta_m$, decays exponentially in $n_m$. Since $n_m b\Delta_m = \alpha b h^2(1+o(1))\log b$ it follows that $\mathbb{P}(\mathcal{S}_h^*(\alpha) \subseteq \mathcal{L}_h(\beta)) \to 1$ for any $\beta < \alpha$ and $h \to \infty$, as required.

**4.3. Clustering of late points on $\mathbb{Z}_n^2$.** Simulations of the SRW on $\mathbb{Z}_n^2$ reveal that the points that are visited late by the walk appear in clumps of various sizes. Motivated by [BH91], the geometric characteristics of these clumps are studied in [DPRZ06]. More precisely, with $\tau_x$ denoting the first hitting time of $x$ by the SRW on $\mathbb{Z}_n^2$, it is shown in [DPRZ06] that for $\alpha \in (0,1]$ the set

$$\mathcal{L}_n(\alpha) = \{x \in \mathbb{Z}_n^2 : \ \tau_x \geq \alpha(4/\pi)(n\log n)^2\},$$

of *$\alpha$-late points* for the SRW has typical size $n^{2(1-\alpha)+o(1)}$ and that for any fixed $x$ in $\mathbb{Z}_n^2$ and $0 < \beta < 1$,

$$\lim_{n\to\infty} \frac{\log|\mathcal{L}_n(\alpha) \cap D(x, n^\beta)|}{\log n} = 2\beta - 2\alpha/\beta \quad \text{in probability} \tag{4.8}$$

(with $D(x, n^\beta)$ the disc of radius $n^\beta$, centered at $x \in \mathbb{Z}_n^2$). If the points of $\mathcal{L}_n(\alpha)$ were approximately evenly spread out in $\mathbb{Z}_n^2$, then the number of $\alpha$-late points in $D(x, n^\beta)$ would be $n^{2\beta-2\alpha+o(1)}$, whereas (4.8) shows that there are significantly less of them (as $2\beta - 2\alpha/\beta < 2\beta - 2\alpha$). The clustering pattern of $\mathcal{L}_n(\alpha)$ is confirmed by another result of [DPRZ06], showing that for any $0 < \alpha, \beta < 1$, if $Y_n$ is chosen uniformly in $\mathcal{L}_n(\alpha)$ then,

$$\lim_{n\to\infty} \frac{\log|\mathcal{L}_n(\alpha) \cap D(Y_n, n^\beta)|}{\log n} = 2\beta(1-\alpha) \quad \text{in probability.} \tag{4.9}$$

Counting pairs of late points one is tempted to apply the approximations

$$\begin{aligned}
&\mathbb{E}[\#\text{ of pairs of } \alpha\text{-late points within distance } n^\beta \text{ of each other}] \\
&\quad \simeq n^2 n^{2\beta}\mathbb{P}(x,\ y \ \text{ are } \alpha\text{-late when } |x-y| \simeq n^\beta) \\
&\quad \simeq (\text{Typical value of such number of pairs}) \\
&\quad \simeq (\#\text{ discs in } n^\beta \text{ grid with } \alpha\text{-late points}) \\
&\qquad \times (\text{Typical value of } |\mathcal{L}_n(\alpha) \cap D(x, n^\beta)| \text{ when } x \text{ is } \alpha\text{-late})^2.
\end{aligned} \tag{4.10}$$

However, as seen in [DPRZ06], such approximations fail to hold and these three quantities exhibit different power growth exponents.

All preceding results about the clustering of $\alpha$-late points are derived in [DPRZ06] by the same truncated multi-scale second moment method as in Subsection 4.2. In contrast to the results of [DPRZ04] about cover times and covered discs, the derivation of (4.9) requires conditioning upon the first hitting time at a *point* $x \in \mathbb{Z}_n^2$ for which strong approximation theorems are ineffective. This is handled in [DPRZ06] by

appealing to potential theory estimates for SRW (cf. [Law91]) and relying on the fact that only rough approximations of the probability that $|N_k^x - n_k| \le k$ are required. The derivation of the power growth exponent for (4.10) is more technically challenging since the mean of this object is already off its typical value. Further, the dominant contribution is from pairs of $\alpha$-late points having significantly less excursions between discs at the intermediate scale $n^\beta$ (in comparison with the typical excursion count profile for $\alpha$-late points), forcing an accumulation of many $\alpha$-late points inside such a disc. Thus, the evaluation of this power growth exponent is by a large deviations analysis of various excursion counts, similar in spirit to that of (4.5).

Not much else is known about the late points. For example,

**Open Problem 4.3.**
• In [DPRZ06] the power growth exponent of pairs of $\alpha$-late points within distance $n^\beta$ of each other is computed. Extend this to a "full multi-fractal analysis". For example, find the power growth exponent of triplets $(x_1, x_2, x_3)$ of $\alpha$-late points, such that $x_i$ is within distance $n^\beta$ of $x_j$ for $i, j = 1, 2, 3$.
• What is the distribution of the distance between the last two points to be covered by the SRW in $\mathbb{Z}_n^2$? In particular, does the chance that they are adjacent go to zero as $n$ grows?

**Open Problem 4.4.** Adapting the proof of (4.3) one can show that for any $a \le 2$,

$$\dim\left\{x \in \mathbb{T}^2 : \limsup_{\varepsilon\to 0} \frac{\tau(x,\varepsilon)}{(\log\varepsilon)^2} = \frac{a}{\pi}\right\} = 2 - a \quad \text{a.s.} \tag{4.11}$$

It is not clear what to do when the lim sup in (4.11) is replaced by a limit or a lim inf, since in this case we can no longer avoid considering the stochastic behavior of $\tau(x, \varepsilon)$ across different scales (i.e. $\varepsilon$ values) which are highly dependent when the scales are close to each other.

## 5. Intersection local times and Gaussian free fields

**5.1. Intersections and processes with jumps.** While having the Markov property is of much help for the results described here, [DPRZ02] deals with thick points for intersection of planar sample path, whereby it is partially lost. For example, [DPRZ02, Theorem 1.4] provides the analog of (2.4), showing that for any $0 < a \le 1$,

$$\dim\left\{x : \lim_{r\to 0} \frac{\mathcal{I}_{\bar\theta,\bar\theta'}(D(x,r))}{r^2(\log r)^4} = a^2\right\} = 2 - 2a \quad \text{a.s.} \tag{5.1}$$

where $\mathcal{I}_{T,T'}(A)$ denotes the projected intersection local time of two independent planar Brownian motions $(w(t), 0 \le t \le T)$ and $(w'(t'), 0 \le t' \le T')$, normalized by factor $\pi$ (see [LeG92, Chapter VIII] for more on $\mathcal{I}_{T,T'}(\cdot)$ and its properties). By strong approximation this leads to the analogs of (1.1) and (2.1) for the intersections of

two independent SRW on $\mathbb{Z}^2$ (cf. [DPRZ02, Theorem 1.1]). The lower bound in (5.1) is proved by first constructing for $\beta < 2-a$, along the lines of Subsection 3.2, a non-zero random measure $\nu'_\infty$ of finite $\beta$-energy (cf. (3.5)), that is supported on a closed set of $a$-thick points for $w'([0,\bar\theta'])$. The same construction is then repeated for $w([0,\bar\theta])$, now using the squares $S(m,i)$ whose centers are in $\mathcal{S}_{h_m}(a)$ to define the density of the random measure $\nu_m$ with respect to $\nu'_\infty$, instead of with respect to Lebesgue measure. Fixing $\gamma < \beta - a < 2-2a$, the non-zero weak limit point of $\{\nu_m\}$ is then of finite $\gamma$-energy and shown in [DPRZ02, Section 4.1] to be supported on a closed subset of the *$a^2$-thick intersection points* of (5.1). This strategy works since $\mathcal{I}_{\bar\theta,\bar\theta'}(A)$ is a continuous additive functional for $w([0,\bar\theta])$ with Revuz measure $\pi\rho$ such that $\rho(B) = \mu^{w'}_{\bar\theta'}(A\cap B)$; for almost every path $w'([0,\bar\theta'])$, the accumulation on $D(x,r)$ of such an additive functional during one excursion of $w(t)$ between $D(x,R)$ and the complement of $D(x,R')$ has a mean value $\rho(D(x,r))\log(R'/R) \pm Cr^2(\log r)^2$ and exponentially decaying tail probabilities (cf. [DPRZ02, Lemma 2.3]).

With a slightly different approach of directly controlling the excursion counts for two random walks, [DPR07, Theorem 1.3] shows that the radius of the largest discrete disc in the intersection of the sample path of two independent SRW on $\mathbb{Z}^2$, each run for $n$ steps, is $R_{n,2} = n^{1/(2+2\sqrt{2})+o(1)}$. However,

**Open Problem 5.1.** The growth rate of the diameter $D_{n,2}$ of the largest connected component of the intersection of two independent planar simple random walk path, each run for $n$ steps, is not known. A related open problem is to determine whether the intersection of two independent planar Brownian motion path, each run for a unit time, is almost surely a totally disconnected set.

The results described here depend mostly on the local properties of the stochastic processes considered. They are thus not limited to Brownian motion or to random walks. In particular, sample path continuity is not essential. For instance, Daviaud [Dav05] considers the Cauchy process on $\mathbb{R}$, that is, a stochastic process $X(t)$ with $X(0) = 0$ and stationary independent increments $X(t+s) - X(t)$ each of whom has the Cauchy density $s/(\pi(s^2+x^2))$ with respect to Lebesgue measure. This is a recurrent process, whose Green's function has a logarithmic behavior, similar to that of the planar Brownian motion (cf. [Dav05, Proposition 1.3]), but which has infinitely many jumps. In analogy with (2.4), [Dav05] shows that for $0 \le a \le 1$,

$$\dim\{x : \lim_{r\to 0} \frac{\mu^X_{\bar\theta}(D(x,r))}{r(\log r)^2} = \frac{2}{\pi}a\} = 1-a \quad \text{a.s.}$$

where $D(x,r)$ is an interval of radius $r$ and center $x \in \mathbb{R}$ and $\bar\theta = \inf\{t : |X(t)| \ge 1\}$. To avoid the technical difficulties due to jumps, [Dav05] relies on the representation of the Cauchy process $X(t)$, up to a well understood time change, as the intersection of the planar Brownian motion $w(t)$ and, say, the $x$-axis, thereby adapting the strategy of [DPRZ02] to the case at hand.

**5.2. The Gaussian free field.** The discrete $d$-dimensional Gaussian free field (abbreviated GFF) on the square $V_n = \{1, \dots, n\}^d \subset \mathbb{Z}^d$ is a Gaussian random vector $(\phi_x,\ x \in V_n)$ of zero mean and covariance given by the Green's function of the SRW restricted to $V_n$. That is, $\mathbb{E}[\phi_x \phi_y]$ is the expected number of visits to $y$ by the SRW on $\mathbb{Z}^d$, starting at $x$ and run till its first exit from $V_n$. The GFF (also called the harmonic crystal) is a special case of the *solid on solid* model used in statistical physics to describe the effective interface between two phases at low temperature (cf. [Gia01], [Fun05] and the references therein).

In this context, the presence of a hard wall is manifested by the *entropic repulsion* conditioning on the non-negativity constraint $\Omega^+_{n,\varepsilon} = \{\phi_x \geq 0 : x \in V_{n,\varepsilon}\}$, for small $\varepsilon > 0$, where $V_{n,\varepsilon}$ denotes the subset of points in $V_n$ of distance at least $n\varepsilon$ to the boundary of $V_n$. For $d \geq 3$ it is well known that entropic repulsion pushes the GFF far from the wall, while asymptotically making no other changes to its law (cf. [Gia01, Chapter 3] and the references therein). Both [BDG01] and [Dav06] consider the effect of entropic repulsion on the two dimensional GFF. To this end, [BDG01, Theorem 2] shows that $\max_{x \in V_n} \phi_x$ grows with $n$ like $g_n = 2\sqrt{2/\pi} \log n$, from which they deduce that upon conditioning on $\Omega^+_{n,\varepsilon}$, the GFF is shifted by $g_n$, that is, $g_n^{-1}\phi_x \to 1$ uniformly on $V_{n,\varepsilon}$.

Theorem 2 of [BDG01] is derived by a multi-scale truncated second moment approach which is motivated by the similarity between the GFF and a branching random walk type model on regular trees. Whereas the profile of excursion counts along each ray is the key object of study in Section 3.1, the approach of [BDG01] is to consider a notion of success shared by all vertices of $\Gamma_h$ at a given height (i.e. distance from $\mathbf{o}$). Adapted to the context of (3.1), the $h_k$-th level of $\Gamma_h$ is successful if for enough vertices $x_k$ of $\Gamma_h$ at height $h_k$, the SRW completed by time $\tau_{\mathbf{o}}$ at least $n_k - k$ excursions between $x_k$ and its ancestor $x_{k-1}$ (at height $h_{k-1}$). Starting at distance $\delta h$ from $\mathbf{o}$ with enough independence to have sufficiently many such vertices at distance $h_2$ further from $\mathbf{o}$, the success of the $h_k$-th level propagates (in $k$) by counting the excursions to vertices at height $h_{k+1}$ during the first $n_k - k$ excursions between their ancestors at heights $h_{k-1}$ and $h_k$. By controlling the union over the probabilities of failure at the different steps $k = 2, 3, \dots, m$ of this process, one concludes that with high probability, the last step, consisting of $\partial\Gamma_h$, is successful.

Pursuing the same approach, [Dav06] goes further in relating the conditioned GFF with the shifted GFF by deriving in this context the analogs of the results of [DPRZ06] and [DPR07]. For example, it is shown in [Dav06, Theorem 1.1] that conditioned on $\Omega^+_{n,\varepsilon}$, the largest disc within $V_{n,\varepsilon}$ for which all values of $\phi_x$ are below $\eta g_n$ is of radius $n^{\eta/2(1+o(1))}$. Indeed, for the unconditional GFF this is the radius of the largest disc for which all values of $\phi_x$ exceed $(1-\eta)g_n$ (see [Dav06, Theorem 1.7]), a result which is the analog of (4.4). The transformation $\eta = \sqrt{\alpha}$ between the two has to do with the isomorphism between $\phi_x^2/2$ and the local time at $x$ of a continuous time planar SRW.

**Open Problem 5.2.** The results of [Dav06] suggest the possibility of simpler proofs in the SRW world by proving the corresponding results for the GFF and applying an isomorphism theorem. Can you find such a proof for (1.1)?

We note in passing that "level lines" of the continuous two dimensional GFF are intimately related to the conformally invariant Schramm–Loewner evolution (abbreviated SLE). See [She06] for a survey of the continuous GFF, [Wer04] for the SLE and its application for computing intersection exponents of independent Brownian motions and [SS06] for the convergence of the zero level interface of an interpolated GFF with appropriate boundary values to variants of the SLE(4) process. However, though the path of the planar Brownian motion is also conformally invariant, we do not know of any direct relation between the results presented here and the SLE.

## 6. Disconnection of cylinders by random walks

Let $(X_k)$ denote the SRW on the infinite discrete cylinder $G_n = \mathbb{Z}_n^d \times \mathbb{Z}$ (endowed with its natural graph structure), which starts at $X_0 = 0$. As $X_k$ is an irreducible, recurrent Markov chain, it is easy to see that the disconnection time $D_n = \inf\{k \geq 0 : \ X_{[0,k]}$ disconnects $G_n\}$ is almost surely finite. Further, $C_n \leq D_n \leq \widehat{C}_n$, where $C_n$ denotes the first time the projection of $X_\cdot$ has visited all points of the base $\mathbb{Z}_n^d$ and $\widehat{C}_n$ denotes the cover time of the slice $\mathbb{Z}_n^d \times \{0\}$ by the SRW on $G_n$. When $d = 1$, it is straightforward to argue that $D_n$ is roughly of order $n^2$ and comparable to $C_n$ (and to $\widehat{C}_n$). Indeed, by the general theory of Markov chains one knows that for any $d \geq 1$, the sequence $\log C_n / \log n$ converges in probability to $\max(d, 2)$ (as we have seen already, much more in known about $C_n$). From (1.5) we see a different behavior for $d \geq 2$ in which case $D_n = n^{2d+o(1)}$ is much larger than $C_n$.

The upper bound in (1.5) is quite simple to prove. It is based on the fact that $D_n \leq \widehat{C}_n$ and a relatively crude upper bound on the cover time $\widehat{C}_n$ of the slice $\mathbb{Z}_n^d \times \{0\}$. Indeed, fixing $\beta > d - 1$, though the hitting times of the sites on this slice are of infinite mean, the first moment method works for the number $Z_n$ of non-visited sites on it during the first $n^\beta$ excursions of the SRW between the truncated cylinders $\mathbb{Z}_n^d \times [-n, n]$ and $\mathbb{Z}_n^d \times [-2n, 2n]$. For large $n$ it gives with high probability an upper bound on $\widehat{C}_n$ by the time it takes the walk to make these $n^\beta$ excursions, which in turn is bounded above by $n^\gamma$ for fixed $\gamma > 2(\beta + 1)$.

Somewhat surprisingly, this rather primitive strategy of replacing $D_n$ by $\widehat{C}_n$ captures the correct rough order of magnitude of $D_n$. However, the lower bound is more delicate because a direct enumeration over the huge collection of possible disconnecting subsets of $G_n$ seems to lead nowhere. Instead, we find a robust geometric property that every disconnecting $\Gamma \subseteq G_n$ must have, then show that with high probability $X_{[0,n^{2d-\delta}]}$ lacks this property. More precisely, [DS06, Lemma 2.4] shows that for $\gamma \in (0, 1)$ fixed and any $n$ large enough, if $\Gamma$ disconnects $G_n$ then there exists a box of side length $n^\gamma$ in $G_n$ that contains at least order of $n^{d\gamma}$ points of $\Gamma$. This

is a purely combinatorial argument, based on the following isoperimetric inequality [DP96, (A.3)]:

For any $\varepsilon > 0$ and finite box $B \subset \mathbb{Z}^{d+1}$,

$$|A \cap B| \le (1-\varepsilon)|B| \implies |\partial_B(A \cap B)| \ge \delta |A \cap B|^{d/(d+1)}, \tag{6.1}$$

where $\partial_B(U)$ denotes the points of $B \setminus U$ within distance one of $U$ and the positive constant $\delta$ depends only on $\varepsilon$ and $d \ge 1$. As shown in [DP96], the inequality (6.1) is a direct consequence of the Loomis–Whitney inequality bounding the size of any finite set $A \subset \mathbb{Z}^{d+1}$ by the $d$-th root of the product of sizes of the $(d+1)$ projections of $A$ on the hyperplanes perpendicular to the coordinate axes (cf. [LW49, Theorem 2]).

The preceding combinatorial argument is complemented by a probabilistic analysis involving the excursions between two concentric boxes of side length $n^\gamma$ and $2n^\gamma$. Fixing $1 > \delta > 3(d-1)\gamma > 0$, it shows that for some finite $c_0$ the probability that during its first $n^{2d-\delta}$ steps the SRW makes more than $c_0 \log n$ such excursions for some pair of boxes, decays to zero as $n \to \infty$. Scaling the occupation measure of the smaller box during one such excursion by $n^{-2\gamma}$ yields a random variable whose moment generating function is bounded uniformly in $n$ and the excursion's starting point. Consequently, for some finite $c_1$ depending only on $\delta$ and $\gamma$, during its first $n^{2d-\delta}$ steps, the number of visits by the SRW to any box of side length $n^\gamma$ does not exceed $c_1(\log n)\, n^{2\gamma}$. For $d \ge 3$ and large $n$, this is substantially less than the order of $n^{d\gamma}$ points that the walk must have visited for at least one such box by time $D_n$ (since by definition $X_{[0,D_n]}$ disconnects $G_n$), producing in this case the lower bound on $D_n$ as stated in (1.5).

Though the argument for $d = 2$ is of a similar flavor, it requires a considerable refinement in order to utilize the much smaller differences, of only a logarithmic growth in $n$, that we have here. To this end, by similar isoperimetric controls, [DS06, Lemma 2.5] shows that for some finite, positive constants $c_i$, $i = 2, 3, 4$, and $n$ large enough, if $\Gamma$ disconnects $G_n$, then for one of the three two-dimensional coordinate projections there exists a box of side length $n^\gamma$ and a collection of $c_2(\log n)^{2\alpha}$ disjoint sub-boxes, each of side length $\ell_n = n^\gamma (\log n)^{-\alpha}$, whose centers lie on a common $c_3\ell_n$-sub-grid of this box, such that the projection of the intersection of $\Gamma$ with any of these sub-boxes, contains at least $c_4 \ell_n^2$ points. The stated lower bound on $D_n$ in case $d = 2$ is thus the result of a more careful probabilistic analysis which shows that for $\gamma$ small and $\alpha < 3/4$ the probability that the set $\Gamma = X_{[0,n^{4-\delta}]}$ has this property, tends to zero as $n \to \infty$.

One consequence of (1.5) is that when $d \ge 2$ and $n$ is large, by the time $D_n$ the walk pretty much fills up the truncated cylinders of height $n^{d-\varepsilon}$. More precisely, with $\rho(x, A)$ denoting the minimal length of a nearest neighbor path from $x \in G_n$ to $A \subseteq G_n$, for any $d \ge 2$, $\varepsilon > 0$ and $\eta > 0$,

$$\lim_{n\to\infty} n^{-\eta} \max_{x \in \mathbb{Z}_n^d \times [-n^{d-\varepsilon}, n^{d-\varepsilon}]} \rho(x, X_{[0,D_n]}) = 0 \quad \text{in probability.} \tag{6.2}$$

This is in contrast with the situation when $d = 1$, where with non-vanishing prob-

ability there are points in such a truncated cylinder which are at distance $n$ from $X_{[0,D_n]}$. The clogging effect of (6.2) is a direct consequence of the lower bound $n^{2d-\delta}$ on $D_n$, due to (1.5), as one can show that within $n^{2d-\delta}$ steps, in a uniform fashion for $\mathbb{Z}_n^d \times [-n^{d-\varepsilon}, n^{d-\varepsilon}]$, the walk comes "often enough" within distance $n$ of $x$, giving it each time an opportunity to come even closer to $x$.

**Acknowledgment.** I thank Yuval Peres, Jay Rosen and Ofer Zeitouni, for valuable feedback on a preliminary version of this manuscript, and the National Science Foundation for funding the research on which it is based.

# Modelling genes: mathematical and statistical challenges in genomics

Peter Donnelly

**Abstract.** The completion of the human and other genome projects, and the ongoing development of high-throughput experimental methods for measuring genetic variation, have dramatically changed the scale of information available and the nature of the questions which can now be asked in modern biomedical genetics. Although there is a long history of mathematical modelling in genetics, these developments offer exciting new opportunities and challenges for the mathematical sciences. We focus here on the challenges within human population genetics, in which data document molecular genetic variation between different people. The explosion of data on human variation allows us to study aspects of the underlying evolutionary processes and the molecular mechanisms behind them; the patterns of genetic variation in different geographical regions and the ancestral histories of human populations; and the genetic basis of common human diseases. In each case, sophisticated mathematical, statistical, and computational tools are needed to unravel much of the information in the data, with many of the best methods combining complex stochastic modelling and modern computationally-intensive statistical methods. But the rewards are great: key pieces of scientific knowledge simply would not have been available by other means.

**Keywords.** Genetics, problems related to evolution, Monte Carlo methods.

## 1. Introduction

We begin with a brief review of the basic concepts and terminology from genetics. The full picture is both more complicated and richer than we need, and we present only a very high-level overview.

Genetic information is transmitted from parents to offspring, and carried in the nucleus of each cell, in DNA (deoxyribonucleic acid). To a mathematician, DNA can be thought of as a very long word over the four letter alphabet $\{A, C, G, T\}$, with each letter representing one of the four chemical bases, or nucleotides, which are arranged effectively linearly along the DNA molecule. It is the order in which the bases appear which conveys the information. Some parts of the molecule are "read" by molecular machinery, and the relevant part of the DNA is used as a template to make a particular protein. These parts of the DNA are called genes. The totality of an organism's DNA is called its genome. The human genome consists of about $3 \times 10^9$ bases, and contains around 25,000 genes, but most of the DNA in the human genome appears to have no

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

function. The genomes of different organisms differ in size, with some much smaller and some substantially larger than the human genome. Like many other organisms, humans are diploid, in that we carry two copies of our genome, one inherited from our mother, and one from our father. Human DNA is packaged into 23 pairs of chromosomes, with one copy of each chromosome inherited from each parent.

Each human sperm or egg (collectively referred to as germ cells) contains a single copy of each of the 23 chromosomes. For what follows, we need to understand a little about the process during which germ cells are formed, called meiosis. Focus on a particular human chromosome. The individual (progenitor) producing the germ cell will have two (slightly different) copies of this chromosome. Think of the process which produces the chromosome for the germ cell as starting on one of the chromosomes in the progenitor and copying from it along the chromosome. Occasionally, and for our purposes randomly, the copying process will "cross over" to the other chromosome in the progenitor, and then copy from that, perhaps later jumping back and copying from the original chromosome, and so on. The chromosome in the germ cell will thus be made up as a mosaic of the two chromosomes in the progenitor. The crossings over are referred to as recombination events. In a typical human meiosis, there will be only a few recombination events per chromosome. In addition to the process of recombination, there will be very occasional mutations: positions where the nucleotide in the offspring is different from that in the progenitor chromosome from which it is being copied. To give an idea of the scale of these effects in humans, the probability of a mutation in any particular nucleotide position is of order $10^{-8}$ per meiosis, and the average probability of a recombination event in a particular position is of the same order. Mutation and recombination are two of the fundamental evolutionary forces. Mutation introduces new variants into a population. (Some of these will make the resulting chromosome better at doing its job than the progenitor chromosome). The effect of recombination is more subtle, but equally important. Recombination allows the shuffling of variants between different backgrounds: when a mutation arises it occurs on a particular chromosome with a particular DNA sequence. Over generations, recombination events near this mutation allow it to be swapped onto different backgrounds.

In effect, the human genome project read one copy of the human genome ([12], [26]) – actually a mosaic made up of the genome from many individuals. The human genome sequence is available on the web, along with annotations which show, for example, which parts correspond to known and predicted genes, or regions which regulate the expression of genes, or appear to be highly conserved across species. The genomes of many other organisms are also now available, with more being completed each month. In each case a major challenge within the science is to better understand the function of, and interactions between, different parts of each of these genomes.

We can think of the human genome project as focussing on the aspects of our genome which we all share: the things that make us human. But there are also differences between people, in appearance, nature, abilities, and susceptibility to different diseases. Some of these differences have a genetic component, resulting

from differences in the DNA sequence between individuals. If we compared two human chromosomes in the same region then they would differ at about 1 place in 1000. (As a comparison, the human genome sequence differs from that of the chimpanzee at about 1 position in 100.)

Following on from the human genome project, there was a major effort in a public-private partnership to discover many of the positions at which human chromosomes differ. While there are a number of interesting ways in which DNA sequences can differ, the most common is when at a particular position, or nucleotide, some chromosomes in the population carry one letter (or base) while others carry a different letter (base). Such positions are called single nucleotide polymorphisms, or SNPs (pronounced "snips"). These SNPs are catalogued in public databases (e.g. http://www.bioinfo.org.cn/relative/dbSNP%20Home%20Page.htm). Over the current decade the number of SNPs known in humans has grown from hundreds to more than 8 million. Nonetheless, many remain undiscovered. For example it is estimated that there are 10 million "common" SNPs, that is SNPs where the rarer variant has a population frequency of at least 5% [11]. As noted above, the mutation rate at any particular nucleotide position is very small ($10^{-8}$). On the other hand the human genome is large ($3 \times 10^9$ nucleotides). SNPs can be thought of as positions at which mutations happen to have occurred in the genome, where the chromosome carrying the mutation has spread through the population. It is extremely rare for there to be more than two variants present at a particular SNP.

Having read one copy of the human genome sequence, then catalogued many of the DNA sequence variations present in human populations, a natural next step was to understand the patterns in which these variants occur in different populations. This has recently been undertaken by the International HapMap Consortium, a collaboration involving five different countries (Canada, China, Japan, UK, USA), at a cost of about $100M. Largely completed, the project typed around 3.5M SNPs in samples from four populations around the world: 90 Caucasians from Utah, 90 Yorubans from Ibadan, Nigeria, 45 Han Chinese from Beijing, and 45 Japanese from Tokyo. The first phase of the project, involving just over 1M SNPs, was reported in [11].

It turns out that the variants present at SNPs close to each other on the same chromosome are often correlated. That is, if at one SNP some chromosomes in the population carry an $A$ and others a $G$, while at a nearby SNP the two variants are $T$ and $C$, it might be that chromosomes which carry an $A$ at the first SNP are more likely to carry a $T$ at the second SNP than those with a $G$ at the first SNP. This kind of correlation is known in population genetics as linkage disequilibrium (LD). The correlations can be very strong (for example the extreme case where all chromosomes carry either $A$ and $T$ or $G$ and $C$, is not unusual) and as we will see below, are very important for studies of the genetics of human disease. Amongst other things, the HapMap project characterized patterns of linkage disequilibrium in the samples it studied.

The reasons for linkage disequilibrium are apparent when one thinks about the history of novel mutations. In the example above, suppose the mutation giving rise

to the first SNP ($A/G$) occurred further into the past than that giving rise to the second SNP, and suppose that at the second SNP the $C$ variant (variants are often called alleles in genetics) was the one present originally. The mutation creating a $T$ and giving rise to the second SNP will have occurred on a single chromosome in a particular generation. Suppose it occurred on a chromosome carrying an $A$ at the first SNP. Then it is immediate that when it arose, a $T$ at the second SNP would occur with an $A$ at the first SNP. Over subsequent generations, the number of copies of the chromosome carrying the $T$ is likely to have grown (otherwise it would not be present today) and unless there is a recombination event between the two SNP positions on one of these chromosomes, it will remain the case that a $T$ at the second SNP would always occur with an $A$ at the first SNP. This association will only be broken down by recombination events, and the extent of this will depend on two things: (i) how many nucleotides separate the two SNPs on the chromosome (the closer together, on average, the smaller is the chance of a recombination between them); and (ii) the number of generations since the mutation giving rise to the second SNP (since a larger number of generations will allow a greater chance for a recombination event). In general, the observed patterns of LD depend on a number of factors, including chance past recombination events, and the demographic history of the population concerned.

## 2. Mathematical models

The arguments in the previous section were entirely qualitative. While helpful, they do not allow quantitative assessments of the way in which various aspects of genetic variation depend on the underlying evolutionary forces or demographic effects. To do so requires the development and analysis of mathematical models of the evolutionary process.

There has been a long history of mathematical modelling in population genetics, dating back to Fisher and Wright early last century. For most questions of interest, stochastic effects are important and the principal models are probabilistic. For most of the period over which these models have been studied, empirical data against which to compare the models have been sparse. Typically, what data there were came from so-called model organisms (particular species of flies and worms for example). Over the last few years, there has been an explosion of data documenting genetic variation in humans, to the extent that our own species provides the richest setting in which to apply these models.

We aim here only to give a brief flavour of the stochastic models which arise in population genetics. The most basic models are finite Markov chains which describe the way in which the genetic composition of the population changes over time. In most cases, these models are not tractable, and interest moves to their limiting behaviour as the population size grows large, under suitable re-scalings of time. When examined forward in time, this leads to a nice family of measure-valued diffusions, called

Fleming–Viot processes. In a complementary, and for many purposes more powerful approach, one can instead look backwards in time, and focus on the genealogical tree relating sampled chromosomes. In the large population limit, these (random) trees converge to a particular process called the coalescent.

One simple discrete model for population demography is the Wright–Fisher model. Consider a population of fixed size $N$ chromosomes which evolves in discrete generations. (For many purposes it turns out that we can ignore the fact that chromosomes occur in pairs in individuals, and we do so here.) The random mechanism for forming the next generation is as follows: each chromosome in the next generation chooses a chromosome in the current generation (uniformly at random) and copies it, with the choices made by different chromosomes being independent. An equivalent description is that each chromosome in the current generation gives rise to a random number of copies in the next generation, with the joint distribution of these "offspring numbers" being symmetric multinomial. Under an assumption of genetic neutrality, all variants in a population are equally fit. In this case, one can first generate the demography of the population using, say, the Wright–Fisher model, and then independently superimpose the genetic type for each chromosome, and the details of the (stochastic) mutation process which may change types. The extent to which this neutrality assumption applies is rather controversial in general, and for humans in particular, but it seems likely that it provides a reasonable description for many parts of the genome. Recombination (and if needed natural selection) can be naturally added to the model. Where a recombination event occurs, the offspring chromosome will be made up from two chromosomes in the current population. Although we have described it in terms of chromosomes, it is natural only to apply the Wright–Fisher model to small regions of a chromosome. In this case, the probabilities of mutation and recombination in a copying event are both very small, and these events are rare.

The Wright–Fisher model may also be extended to allow for more realistic demographic effects, including variation in population size, and geographical spatial structure in the population (so that offspring chromosomes are more likely to be located near to their parents). We will not describe these here. Somewhat surprisingly, it transpires that the simple model described above, (constant population size, random mating, and neutrality – the so-called "standard neutral" model), or rather its large population limit, captures many of the important features of human evolution. There is an aphorism in statistics that "all models are false, but some are useful". The standard neutral model has proved to be extremely useful.

In a Wright–Fisher or any other model, we could describe the genetic composition of the population at any point in time by giving a list of the genetic types currently present, and the proportion of the population currently of each type. Such a description corresponds to giving a probability measure on the set $E$ of possible types. It is sometimes helpful to think of this measure as the distribution of the type of an individual picked at random from the population. In this framework, when we add details of the mutation process and recombination to the Wright–Fisher model, we obtain a discrete time (probability) measure-valued Markov process. As $N$ becomes

large a suitable rescaling of the process converges to a diffusion limit: time is measured in units of $N$ generations, and mutation and recombination probabilities are scaled as $N^{-1}$. For general genetic systems, the limit is naturally formulated as a measure-valued process, called the Fleming–Viot diffusion. The classical so-called Wright–Fisher diffusion is a one dimensional diffusion on $[0, 1]$ which arises when there are only two genetic types and one tracks the population frequency of one of the types. This is a special case of the Fleming–Viot diffusion, in which we can identify the value of the classical diffusion, $p \in [0, 1]$ with a probability measure on a set with just two elements. The beauty of the more general, measure-valued, formulation is that it allows much more complicated genetic types, which could track DNA sequences, or more exotically even keep track of the time since particular mutations arose in the population.

The Fleming–Viot process can thus be thought of as an approximation to a large population evolving according to the Wright–Fisher model. For the Wright–Fisher model, time is measured in units of $N$ generations in this approximation (and the approximation applies when mutation and recombination probabilities are of order $N^{-1}$). In fact the Fleming–Viot process arises as the limit of a wide range of demographic models, (and we refer to such models as being within the domain of attraction of the Fleming–Viot process) although the appropriate time scaling can differ between models. (See, for example, [5].) For background, including explicit formulations of the claims made above, see for example [2], [3] [4], [5], [6]. Donnelly and Kurtz ([2], [3]) give a discrete construction of the Fleming–Viot process. As a consequence, the process can actually be thought of as describing the evolution of a hypothetically infinite population, and it explicitly includes the demography of that population.

There has been considerable recent interest in looking backwards in time to study the genealogy of population genetics models. This is simplest in the absence of recombination. Consider again the discrete Wright–Fisher model. If we consider two different chromosomes in the current generation, they will share an ancestor in the previous generation with probability $1/N$. If not, they retain distinct ancestries, and will share an ancestor in the previous generation with probability $1/N$. The number of generations until they share an ancestor is thus geometrically distributed with success probability $1/N$ and mean $N$. In the limit for large $N$, with time measured in units of $N$ generations, this geometric random variable will converge to an exponential random variable with mean 1.

More generally, if we consider $k$ chromosomes, then for fixed $k$ and large $N$, they will descend from $k$ distinct ancestors in the previous generation with probability

$$1 - \binom{k}{2}\frac{1}{N} + O(N^{-2}).$$

Exactly two will share a common ancestor in the previous generation with probability $\binom{k}{2}\frac{1}{N} + O(N^{-2})$ and more than a single pair will share a common ancestor with probability $O(N^{-2})$. In the limit as $N \to \infty$, with time measured in units of $N$ generations, the time until any of the $k$ share an ancestor will be exponentially distributed

with mean $\binom{k}{2}^{-1}$, after which time a randomly chosen pair of chromosomes will share an ancestor.

Thus, in the large population limit, with time measured in units of $N$ generations, the genealogical history of a sample of size $n$, may be described by a random binary tree. The tree initially has $n$ branches, for a period of time $T_n$, after which a pair of branches (chosen uniformly at random independently of all other events) will join, or coalesce. More generally, the times $T_k$, $k = n, n-1, \ldots, 2$ for which the tree has $k$ branches are independent exponential random variables with

$$\mathrm{E}(T_k) = \binom{k}{2}^{-1},$$

after which a pair of branches (chosen uniformly at random independently of all other events) will join, or coalesce. The resulting random tree is called the $n$-coalescent, or often just the coalescent.

In a natural sense the tree describes the important part of the genealogical history of the sample, in terms of their genetic composition. It captures their shared ancestry, due to the demographic process. A key observation is that in neutral models the distribution of this ancestry is independent of the genetic types which happen to be carried by the individuals in the population. Probabilistically, one can thus sample the coalescent tree and then superimpose genetic types: first choose a type for the most recent common ancestor of the population (the type at the root of the coalescent tree) according to the stationary distribution of the mutation process, and then track types forward through the tree from the common ancestor, where they will possibly be changed by mutation.

The preceding recipe gives a simple means of simulating the genetic types of a sample of size $n$ from the population. Note that this is an early example of what has recently come to be termed "exact simulation": a finite amount of simulation producing a sample with the exact distribution given by the stationary distribution of a Markov process. In addition, it is much more computationally efficient than simulating the entire population forward in time for a long period and then taking a sample from it. Finally, it reveals the complex structure of the distribution of genetics models at stationarity – the types of each of the sampled chromosomes are (positively) correlated, exactly because of their shared ancestral history.

We motivated the coalescent from the Wright–Fisher model, but the same limiting genealogical tree arises for any of the large class of demographic models in the domain of attraction of the Fleming–Viot diffusion. Moreover, the way in which the tree shape changes under different demographic scenarios (e.g. changes in population size, geographical population structure) is well understood.

The discrete construction of the Fleming–Viot process described above actually embeds the coalescent and the forward diffusion in the same framework, so that one can think of the coalescent as describing the genealogy of a sample from the diffusion.

There is even a natural limit, as $n \to \infty$ of the $n$-coalescents. This can be thought of as the limit of the genealogy of the whole population, or as the genealogy of

the infinite population described by the Fleming–Viot process, although the analysis underlying the relevant limiting results is much more technical than that outlined above for the fixed-sample-size case. It is easiest to describe this tree from the root, representing the common ancestor of the population, forward to the tips, each of which represents an individual alive at the reference time. The tree has $k$ branches for a random period of time $T_k$, after which a branch, chosen uniformly at random, independently for each $k$, splits to form two branches. The times $T_k$, $k = 2, 3, \ldots$, are independent exponential random variables, and independent of the topology of the tree, with

$$\mathrm{E}(T_k) = \binom{k}{2}^{-1}.$$

Write

$$T = \sum_{k=1}^{\infty} T_k$$

for the total depth of the tree, or equivalently for the time back until the population first has a common ancestor. Note that $T$ is a.s. finite. In fact $\mathrm{E}(T) = 2$.

Now we return to the case where recombination is allowed. The simplest way to conceptualise this more general situation is that there is a genealogical tree, marginally distributed as the coalescent, associated with each nucleotide position. As one moves along the DNA sequence, these trees for different positions are highly positively correlated. In fact, two neighbouring positions will have the same tree iff there is no recombination event between those positions since their joint most recent common ancestor, on a lineage leading to the current sample. If there is such a recombination, the trees for the two positions will be identical back to that point, but (in general) different before it. The correlation structure between the trees for different positions is complex, and for example regarded as a process on trees as one moves along the sequence, it is not Markov. But it is straightforward to simulate from the relevant joint distribution of trees, and hence of sampled sequences. The trees for each position can be embedded in a more general probabilistic object (this time a graph rather than a tree) called the ancestral recombination graph ([8], [9]).

## 3. Disease mapping

One major current analytical challenge in the field is the development of statistical methods in genetic studies of human disease. A common study design is case-control: a (typically large) set of individuals with a particular disease (cases) and a set of healthy individuals (controls) are typed at a (large) set of SNPs. If one variant at a particular SNP predisposes individuals to (respectively protects them against) the disease in question then the frequency of that variant should be higher (lower) in the cases than the controls. The signal one looks for then is a difference in allele frequency between cases and controls at a particular SNP.

As one contemporary example, the Wellcome Trust Case Control Consortium is a large UK-based study in which 2000 cases for each of 8 common diseases (Type 1 and Type 2 Diabetes, Hypertension, Coronary Heart Disease, Crohn's Disease, Bipolar Disorder, Rheumatoid Arthritis, and Tuberculosis) will be compared with 3000 controls at around 500,000 SNPs. This size of study is becoming more common, and although expensive, is within reach of major biomedical research budgets. (For example, the study just described will cost around US$15M.)

Some human disorders have a simple genetic component. In these, a single gene will be involved, and mutations in that gene cause individuals to be affected. In some cases, such as Huntington's disease, individuals will be affected if either of their chromosomes carries the mutation. (The inheritance is said to be dominant.) In others, such as Cystic Fibrosis, individuals will be affected only if both their chromosomes carry mutations at the gene in question. (The inheritance is said to be recessive.) In these cases there is effectively a deterministic relationship between carrying mutated copies of the gene in question and having the disease. These so-called simple genetic diseases are typically rare, and often very debilitating. In a large number of cases the exact genes involved are now known.

Most or all of the common human diseases also have a genetic component, but one which acts in a more subtle, and complicated, way. We are some way from understanding the full story, but for these common human diseases, it is thought that mutations in genes may slightly increase (or decrease) the probability of the individual developing the disease, rather than deterministically predicting it. Disease susceptibility may well also involve the interaction between mutations in different genes, and/or interactions between genes and environmental or lifestyle factors.

One major issue with case-control studies involves the need for cases and controls to be as similar as possible apart from their disease status. A particular, genetic, concern relates to geographical population structure. Most human populations differ genetically – individuals from nearby geographical locations are more likely to be genetically similar than those from distant locations. This is well documented in comparisons between the major continental regions of the world. But the same effect pertains, to a lesser extent, within continental or even national regions. Suppose for simplicity that a population is actually made up of two subpopulations which differ genetically at a particular genetic marker (say the $A$ allele is more common in subpopulation 1 than in subpopulation 2), and that in addition, perhaps for environmental reasons, the disease is more common in subpopulation 1. Then a random sample of cases from the population as a whole will tend to include more individuals from subpopulation 1 than will a random sample of controls, and in turn the sample of cases will have a higher frequency of $A$ than will the controls. A naive analysis, which ignores the population substructure, might wrongly conclude that the $A$ variant at this SNP played a role in disease susceptibility.

This tendency for geographical population structure to lead to false positives in association studies actually led to the case-control design being largely ignored for many years. More recently a range of statistical approaches has been developed to

correct the problem. One class of approach uses all the markers typed to correct the null distribution of the usual test statistics. Another uses the markers to infer the underlying structure and assign individuals to subpopulations, with the comparisons between cases and controls being made only within subpopulations. Perhaps counter-intuitively, it is also the case that the problems caused by substructure increase with the size of the study: even the small amounts of structure within national populations might cause problems for the large studies currently being undertaken. See [19] for further discussion and additional references.

If an association study directly tests a SNP causatively involved in disease susceptibility, then we would expect to see frequency differences between cases and controls at that SNP. For common diseases the effect of carrying one variant is typically small, which will lead to only a small difference in the frequency of that variant between cases and controls. The large sample sizes of current studies are needed to ensure statistical power to detect small frequency differences.

Even were an investigator to restrict attention only to variants which occur at appreciable frequency (e.g. so-called "common variants", where the less common, or "minor" allele has frequency $> 5\%$), these cannot all be tested in an association study. It is estimated that there are probably around 10 million such variants in the human genome [11]. Firstly, many of these variants are not known, and secondly, the cost of checking all known variants is prohibitive (even at levels of current biomedical research funding).

Here, the correlations between alleles described above (recall the discussion of linkage disequilibrium) is very helpful. In an extreme case, suppose variants at two SNPs are perfectly correlated: each chromosome carrying an $A$ at the first SNP carries a $T$ at the second, and chromosomes with a $G$ at the first SNP carry a $C$ at the second. In this case, when an association study types one of the SNPs it effectively also types the other. Put another way, if one of the two SNPs were causatively involved in the disease, and a study typed the other SNP, then there should still be a signal.

In fact, this "extreme" case, of perfect correlation, is not uncommon. For example, it is estimated that in a Caucasian population, 60% of common SNPs have the property that there are at least three other SNPs with which they are perfectly correlated, and 20% are perfectly correlated with more than 20 other SNPs; only around 20% are not perfectly correlated with any other SNPs [11]. (There is in general less correlation between SNPs in samples from African populations.) The reasons for this are now well understood. They follow from properties of coalescent trees, and recently discovered facts about the human recombination process. Two SNPs will be perfectly correlated iff they occur on the same branch of the coalescent tree. The branches near the root of the tree are relatively long, thus allowing time for a number of mutations to occur. In addition, as we discuss in more detail below, it turns out that in humans, recombination events do not occur uniformly along the chromosome, but instead cluster into small regions, called recombination hotspots, which are typically widely separated. Between these regions there will often be effectively a single coalescent tree for all nucleotide positions, and the placement of mutations

on branches of this tree induces the correlations between SNPs.

Often two SNPs may be well correlated but not perfectly so. In this case, if one is causative and the other is typed, it may still be possible to see a signal, and hence to detect the untyped causative SNP. Under a simple disease model, this effect depends simply on the correlation coefficient, $r^2$, between the SNPs. If a sample size of $n$ were needed at given power to detect the SNP in a study in which it is typed directly, then a sample size of $n/r^2$ will be needed for the same power if only the correlated SNP were typed.

The major point of the HapMap project was to describe these correlations between SNPs in human populations. As a consequence, association studies can carefully choose which SNPs to type so as to minimize the number of SNPs involved. For example, it is estimated that in a Caucasian sample, genotyping a set of 300,000 SNPs will capture around 80% of all common SNPs with $r^2 > 0.8$ [11].

Whatever strategy is chosen to select SNPs for typing in an association study, the analytical challenge is how best to analyse the data. This can helpfully be thought of as a statistical missing data problem. We have data at a set of SNPs in cases and controls. For these SNPs we can directly test the possibility that their variants are related to disease susceptibility in a variety of ways (e.g. by simple chi-squared tests for differences in genotype frequencies, or by fitting say logistic regression models relating genotype to disease status). If we had data at the SNPs not typed in the study we could apply the same tests at those SNPs. Thinking of the data at the untyped SNPs as missing data, the challenge then is to learn about the missing data from the data we actually have. Some of the most promising approaches to this problem make use of the mathematical models described above, (or approximations to them). Informally, the models can be used to predict, or impute, data at the untyped SNPs from the data at the SNPs actually typed, and then this imputed data is used to test for a disease effect. The approach can be applied either at the positions of known SNPs not included in the study, or more generally at arbitrary positions in the genome. It combines the empirical information available from surveys such as HapMap, inferences as to recombination rates in the human genome, and population genetics models.

## 4. Human recombination

Recall that recombination is the process by which germ cells are constructed to contain part of each of the chromosomes in their progenitor. It has long been known that recombination events do not happen uniformly along the human chromosomes. (The rates of recombination even differ between males and females.) Over large scales, this can be seen in pedigree (or family) studies: effectively through localising the genomic positions of recombination events in comparisons between parents and their children.

But pedigree studies have limited resolution for estimating recombination rates. The average recombination rate across 10 million basepairs – 10 megabases (Mb) –

is $10^{-1}$. Reliable estimation of probabilities of order $10^{-1}$ requires many tens, or hundreds of observations. While this is realistic in human pedigree studies, the average recombination rate across 1Mb is an order of magnitude lower, and requires an order of magnitude more observations for accurate estimation, taking it effectively beyond the limit of practicability for pedigree studies. As a consequence, our understanding of the variation in human recombination rates based on pedigree studies does not go below the megabase scale.

So what do recombination rates look like over finer scales. Two recent lines of evidence suggested that the picture may be surprising and very interesting. The first was the direct observation of recombination hotspots: small (typically 2 kilobase, or kb) regions in which recombination events cluster, and for which the local recombination rate is much higher than in the surrounding DNA. These observations typically involved studies of human sperm. Although realistic pedigree studies are uninformative over these scales, clever and careful experimentation does allow detection of sperm with recombination events in particular small regions, from which recombination rates (in males) can be estimated over the region studied.

The second clue came from patterns of linkage disequilibrium (LD) in human populations. Contrary to the predictions of simple models, human linkage disequilibrium extended over much larger regions than expected, and in addition, the patterns showed regions of extended LD interrupted by short regions of LD breakdown. Although both the initial observations and the suggested causes were controversial, this pattern is now well documented in humans [11]. One natural explanation was that recombination events were not uniformly distributed but instead clustered into hotspots.

As we saw above, the patterns of genetic variation in human populations have been shaped by a number of effects, including recombination. In principle then, such data contain information about the underlying recombination rates. Armed with an understanding of the stochastic models of section 2, we could then treat this as a statistical problem, and try to use data to infer some of the parameters of the models, in particular the recombination rates.

It turns out that this is a challenging inference problem, for a number of reasons. In either classical or Bayesian statistical inference, a central role is played by the likelihood: the probability of the observed data as a function of model parameters. Although the stochastic models are well understood, and for example easy to simulate from, no explicit expressions are available for probabilities of interest, such as the stationary distribution. In the statistical context, this means that the likelihood associated with the model is not available analytically. One way of conceptualising the difficulty is as follows: for a given genealogical tree (or graph in the context of recombination) one could calculate the likelihood for given parameter values. The actual likelihood could then be obtained by averaging this quantity over all possible underlying trees or graphs. Herein lies the problem: the space of trees/graphs is so large that this averaging is impracticable.

Various clever computational approaches have been developed in modern statistics to overcome this type of problem, and there has been particular attention to these

in the population genetics context (see for example [25]). A general observation is that sophisticated understanding of the stochastic models allows big improvements in the quality and efficiency of the statistical inference. For example, for inference of recombination rates assumed constant across the region of interest, the best available methods are more efficient then their predecessors by up to four orders of magnitude [7].

But even the best available statistical methods based on the coalescent are impracticable for estimating recombination rates of interest for a different reason: the sheer size of available data sets. The Phase I HapMap data, for example, documents genetic variation at 1M SNPs in 269 individuals. Two different approaches have recently been developed to address this issue. In essence, each takes the view that the coalescent model is itself an approximation to reality, so why not make further judicious approximations in order to achieve tractability. One approach, pioneered by Li and Stephens [18] involves an alternative model for genetic data with a hidden Markov structure. (See [1] for application to the estimation of fine-scale recombination rates.) We concentrate here on the other approach, introduced by Hudson [10] in the context of constant recombination rates, and developed by McVean and colleagues for variable recombination rates [20], [21].

This approach retains the original coalescent model, and uses its exact likelihood for data at a pair of SNPs, as a function of the recombination rate between them. But rather than using the correct joint distribution for a set of more than two SNPs, the approximation assumes each pair of SNPs to be independent. In this way, a so-called pairwise composite likelihood is constructed as the product of the exact coalescent likelihoods across all pairs of SNPs in the data. In the setting of variable recombination rate, the parameter of interest is a piecewise constant function specifying the recombination rate between each pair of SNPs (so the function only changes value at the positions of SNPs). McVean *et al.* [21] adopt a Bayesian approach to inference. The prior distribution (here on function space) encourages smoothness in the rate function and reversible jump Markov chain Monte Carlo, using the pairwise composite likelihood, is used to explore the posterior distribution on recombination rates. One attractive feature of the prior distribution putting weight on smooth functions is that the approach "borrows" information from nearby SNPs – the estimated rate between a pair of SNPs will be influenced by data at nearby SNPs. Another positive consequence is the tendency to avoid overfitting: maximum likelihood estimation with the same likelihood function would fit a different recombination rate between each pair of SNPs. The paper also develops a formal likelihood ratio test for the presence of a recombination hotspot, based on the composite likelihood (with significance levels determined by appropriate simulation). Tests on real and simulated data show these methods to perform remarkably well. In spite of the approximations (firstly to give the coalescent and secondly of the coalescent) involved, the models appear to be capturing key features of the real world remarkably well.

These new statistical methods, applied to recent genome-wide variation data sets such as the HapMap, have enormously extended our knowledge of human recombi-

nation. For the first time, fine-scale estimates of recombination rates are available across the human genome. These so-called genetic maps have resolution 2-3 orders of magnitude finer than their predecessors from pedigree studies. They show striking variation in rates, by up to four orders of magnitude, over kilobase scales, and provide a powerful tool in studies of human disease. We now know that recombination hotspots are a ubiquitous feature of the human genome: whereas around 15-20 hotspots had been previously characterised, around 30,000 have been detected from the new approach, with an estimated average density of one hotspot per 50kb. The approach has demonstrated, also for the first time, that recombination hotspots are definitively a feature of female recombination, and more generally that the fine-scale recombination landscape appears similar between males and females. Contrary to previous reports, recombination rates are systematically lower within genes, but interestingly, systematically higher close to genes [11], [22].

One common general tool in genetics studies involves comparisons between species, and this has proved informative for recombination as well. Two comparisons between humans and our closest neighbouring species, the chimpanzee, revealed that recombination hotspots are a feature of chimpanzee recombination as well. But whereas human and chimpanzee DNA sequences agree at about 99% of nucleotide positions, the studies surprisingly found that the positions of recombination hotspots do not match between the two species, suggesting that they have evolved rapidly over evolutionary times [29], [23]. Comparisons between the time-averaged recombination rates estimated from population data and those in contemporary sperm suggest an even more rapid evolution of recombination hotspots, with substantial changes even over the half a million or so years over which human genetic variation has accumulated [13].

Perhaps the best example of mathematical and statistical approaches adding substantially to scientific knowledge in this area comes from studies of motifs associated with recombination hotspots. The question of why some parts of the DNA sequence act as recombination hotspots and some do not has been a major focus of research attention, and remains little understood. No clear pattern was available from the 15 hotspots directly characterised from human sperm typing. But by first identifying, and then studying, 25,000 hotspots, Myers *et al.* [22] were able to identify several short DNA sequence motifs associated with hotspots. (In fact the analysis was not straightforward, essentially because most hotspots are localised only to within 5-10kb by statistical methods. The key was to focus only on those hotspots containing specific sequences of several hundred basepairs – many such so-called repetitive elements abound in the human genome – and to compare them with the same sequences outside hotspots.) Although also an exciting ongoing story, this approach was the first to identify sequence motifs (one important example is the collection $CCTCCCT$ of eight basepairs) associated with human hotspots, and amongst the first to be identified for any organism.

## 5. Conclusion

In addition to explaining some of the science, our aim has been to give a sense of the central role being played in modern genomics by mathematical modelling and statistical methods. The Human Genome Project provided the foundation for a new generation of genetics research. As we build on that foundation, in our understanding of basic biology, of the genetic basis for disease susceptibility, and in the use of this information to develop new therapies and preventions for human disease, it is clear that the mathematical and computational sciences will continue to play a vital role.

# Geometric stochastic analysis on path spaces

K. David Elworthy and Xue-Mei Li*

**Abstract.** An approach to analysis on path spaces of Riemannian manifolds is described. The spaces are furnished with 'Brownian motion' measure which lies on continuous paths, though differentiation is restricted to directions given by tangent paths of finite energy. An introduction describes the background for paths on $\mathbb{R}^m$ and Malliavin calculus. For manifold valued paths the approach is to use 'Itô' maps of suitable stochastic differential equations as charts. 'Suitability' involves the connection determined by the stochastic differential equation. Some fundamental open problems concerning the calculus and the resulting 'Laplacian' are described. A theory for more general diffusion measures is also briefly indicated. The same method is applied as an approach to getting over the fundamental difficulty of defining exterior differentiation as a closed operator, with success for one and two forms leading to a Hodge–Kodaira operator and decomposition for such forms. Finally there is a brief description of some related results for loop spaces.

**Mathematics Subject Classification (2000).** Primary 58B10, 58J65; Secondary 58A14, 60H07, 60H10, 53C17, 58D20, 58B15.

**Keywords.** Path space, Hodge–Kodaira theory, infinite dimensions, connection, de Rham cohomology, stochastic differential equations, Malliavin calculus, Sobolev spaces, abstract Wiener spaces, differential forms.

## 1. Introduction

**1.1. Analysis with Gaussian measures.** Classical differential and geometric analysis is based on Lebesgue measure. The non-existence of an analogue of Lebesgue measure in infinite dimensions is demonstrated by the following theorem:

**Theorem 1.1.** *If $\mu$ is a locally finite Borel measure on a separable Banach space $E$ such that translations by every element of $E$ preserve sets of measure zero, then either $\mu = 0$ or $E$ is finite dimensional.*

'Local finiteness' here means that every point of $E$ has a neighbourhood with finite measure. The theorem is a special case of more general results, e.g. see Theorem 17.2 of [62]. In a sense it is behind many of the mathematical difficulties in 'path integration' and has meant that infinite dimensional differential and geometric analysis has had to develop its own techniques.

*Xue-Mei Li (-Hairer) has benefited from a Royal Society Leverhulme senior research fellowship.

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

The analysis proposed by Gross was based on his notion of *abstract Wiener spaces*. These are triples $\{i, H, E\}$ where $i\colon H \to E$ is a continuous linear injective map, with dense range, of a Hilbert space $(H, \langle\,,\,\rangle_H)$ into a separable Banach space $E$. (Throughout this article *all the linear spaces considered will be real*.) The defining property is that there is a Borel measure $\gamma$, say, on $E$ whose Fourier transform $\hat{\gamma}$ is given by

$$\hat{\gamma}(l) := \int_E e^{\sqrt{-1}l(x)}\, d\mu(x) = e^{-\frac{|j(l)|_H^2}{2}}$$

for all $l \in E^*$ where $j\colon E^* \to H$ is the adjoint of $i$. This was a generalisation of *classical Wiener space* where some analysis had been previously investigated, particularly by Cameron & Martin e.g. see [8], and also was influenced by Irving Segal's work. It was shown later that all, centred and strictly positive, so-called 'Gaussian measures' on a separable Banach space $E$ arise from an essentially unique abstract Wiener space structure on $E$, e.g. see [14].

Classical Wiener space can be considered as the special case when $E$ is the space $C_0([0, T]; \mathbb{R}^m)$ of continuous maps of a fixed interval $[0, T]$ into $\mathbb{R}^m$ which start at the origin, and $H$, sometimes called the *Cameron–Martin space*, is the space of finite energy paths $L_0^{2,1}([0, T]; \mathbb{R}^m)$, i.e. those paths in $C_0([0, T]; \mathbb{R}^m)$ which have distributional derivatives in $L^2$. The map $i$ is the inclusion. The norm for $H$ is given by $|h|_H^2 = \int_0^t |\dot{h}(t)|^2 dt$, and the measure on $E$ is the classical Wiener measure constructed by Wiener, so that the canonical process $[0, T] \times C_0([0, T]; \mathbb{R}^m) \to \mathbb{R}^m$ given by evaluation, is the standard model of Brownian motion. Denote that measure by $\boldsymbol{P}$.

The starting point for Gross's analysis was his extension of Cameron & Martin's quasi-invariance theorem to the case of abstract Wiener spaces and their measures $\gamma$:

**Theorem 1.2.** *Translation by an element $v$ of $E$ preserves sets of measure zero if and only if $v$ lies in the image of $H$. Moreover, for $h \in H$ and integrable $f\colon E \to \mathbb{R}$ we have for any $t \in \mathbb{R}$:*

$$\int_E f(x)\, d\gamma = \int_E f(x + ti(h)) \exp\Big( - t\mathcal{P}(h) - \frac{t^2}{2}|h|_H^2 \Big)\, d\gamma, \tag{1}$$

*where $\mathcal{P}\colon H \to L^2(E; \mathbb{R})$ is the* Paley–Wiener *map.*

The Paley–Wiener map is an isometry into $L^2$ defined as the $L^2$-limit of any sequence, $\{l_n\}_{n\geq 1}$ of elements in $E^*$ for which $\{j(l_n)\}_{n\geq 1}$ converges in $H$ to $h$. For classical Wiener space it is written as $\sigma \mapsto \int_0^T \langle \dot{h}(s), d\sigma(s)\rangle$ and called the *Paley–Wiener* (*stochastic*) *integral*. If $E = H = \mathbb{R}^n$ then $\mathcal{P}(h)(x) = \langle h, x\rangle_H$ which accounts for the notation $\langle h, x\rangle\tilde{}_H$ sometimes used for it in general.

The Gross–Cameron–Martin formula was given here with a parameter $t$ in order to obtain an integration by parts formula from it by differentiating with respect to $t$ at $t = 0$. If $f$ is sufficiently regular, for example Fréchet differentiable and bounded with bounded derivative $Df : E \to E^*$, this yields:

**Corollary** (Integration by parts). *For all* $h \in H$

$$\int_E Df(x)(i(h))\, d\gamma(x) = -\int_E f(x)\, \mathrm{div}(h)(x)\, d\gamma(x) \tag{2}$$

*where* $\mathrm{div}(h) = -\mathcal{P}(h)$.

Diffeomorphisms of the form $x \mapsto x + ij\alpha(x)$ between open subsets of $E$ where $\alpha$ is a $C^1$ map into $E^*$ were shown by H.-H. Kuo to also preserve sets of measure zero. This led him, starting in his thesis, and then others, to the study of *abstract Wiener manifolds*: Banach manifolds modelled on the space $E$ of an abstract Wiener space whose interchange of charts were of Kuo's form, [42]. Such manifolds have a natural class of Borel measures, locally equivalent to $\gamma$, and many of the usual constructions and results of the finite dimensional situation go over to them, [43], [20], [18], [55].

For any abstract Wiener space the map $i$ is compact. It follows that the derivatives of transformations of Kuo's type are linear maps which differ from the identity by a compact operator. This implies that abstract Wiener manifolds are Fredholm manifolds, [18]. For a wide class of Banach spaces $E$ the theory and classification of such manifold structures showed that every separable metrisable manifold $M$ modelled on $E$ can be given the structure of an abstract Wiener manifold, with the K-theory of $M$ playing the major role in their classification, [17].

It soon became clear that although interesting manifolds, such as path and loop spaces on finite dimensional manifolds admit these structures, in most interesting cases there is no natural one. Exceptions are finite codimensional submanifolds of abstract Wiener spaces, such as the space of paths from one submanifold embedded in $\mathbb{R}^m$ to another. Also see [32]. More general transformations preserving sets of measure zero were described, notably by Ramer in 1974, and then using Malliavin calculus by Kusuoka in 1982, and for flows of a class of vector fields on classical Wiener space by Driver, [12]. However the form of these transformations is not so different from those of Kuo, though the identity map in the decomposition may be replaced by a 'rotation'. See [61]. This together with the advent of Malliavin calculus, in 1976, with emphasis on mappings determined by stochastic differential equations, led to a move away from this approach, or at least a major modification of it [44], [45].

In [36] Gross shows that for any abstract Wiener space $\{i, H, E\}$ there is an abstract Wiener space $\{i', H, E'\}$ and a compact linear map $k\colon E' \to E$ such that $i = k \circ i'$. In other words, in the infinite dimensional case the measure $\gamma$ can be considered to lie in a smaller space than $E$; (however $H$ itself has measure zero). In the classical case this is demonstrated by the fact that the space of continuous functions can be replaced by the closure of $L_0^{2,1}$ in the space of Hölder continuous functions of exponent $\alpha$ for any $0 < \alpha < 1/2$. In Malliavin calculus on these linear spaces the space $E$ loses its importance, and in some treatments essentially disappears, e.g. see [39], and [50]. In the latter it is the Paley–Wiener functions, $\{\mathcal{P}(h) : h \in H\}$ which play the dominant role, returning to Segal's 'weak distribution' theory, [57]. However in the non-linear case of diffusion measures on path spaces of manifolds it seems necessary, at least at

the moment, to deal with the actual manifold on which the measures sit, though this could be taken to be Hölder continuous paths rather than continuous paths if that is more convenient. The treatment of Malliavin calculus below is organised with this in mind.

**1.2. Malliavin calculus on $E$.** From Gross's work, especially [35], it was clear that the basic differentiation operator on an abstract Wiener space should be the *$H$-derivative*. This could be defined on a basic domain, $\mathrm{Dom}(d_H)$, of functions $f\colon E \to \mathbb{R}$ consisting of a set of Fréchet differentiable functions which is dense in $L^p$ and whose $H$-derivatives: $d_H f\colon E \to H^*$ given by $d_H f_x(h) = Df(x)(i(h))$ lie in $L^p$, for all $1 \le p < \infty$. The integration by parts formula, equation (2), implies that $d_H$ is closable as a map between $L^p$ spaces with closure a closed linear map

$$d\colon \mathrm{Dom}(d) \subset L^p(E;\mathbb{R}) \to L^p(E;H^*).$$

Let $\mathbb{D}^{p,1}$ denote $\mathrm{Dom}(d)$ with its graph norm.

Our Paley–Wiener functionals, $\mathcal{P}(h)$, are easily seen to be in $\mathbb{D}^{p,1}$ for all $1 \le p < \infty$ with $d\mathcal{P}(h)_x(k) = \langle h, k\rangle_H$ for all $x \in E$ and $k \in H$, despite their lack of continuity in $E$. In fact the main point of the theory is that, for classical Wiener space, more general stochastic integrals and solution maps of stochastic differential equations, as described below, all lie in these Sobolev spaces.

The following characterisation of $\mathbb{D}^{p,1}$ for $1 < p < \infty$ was given by Sugita:

**Theorem 1.3** ([60]). *If $f \in L^p(E;\mathbb{R})$ then $f \in \mathbb{D}^{p,1}$ if and only if both of the following hold.*

1. *For each $h \in H$ there is a function $f_h\colon E \times \mathbb{R} \to \mathbb{R}$ which is absolutely continuous in the second variable and has $f_h(x,t) = f(x+th)$, for almost all $x \in E$, for each $t \in \mathbb{R}$.*
2. *There exists $df \in L^p(E;H^*)$ such that for any $h \in H$, $\frac{1}{t}(f(x+th) - f(x))$ converges in measure to $df_x(h)$ as $t \to 0$.*

From this we see that the spaces $\mathbb{D}^{p,1}$, for $1 < p < \infty$ are independent of any reasonable choice of initial domain $\mathrm{Dom}(d_H)$. A comforting fact; but one which is still open in the corresponding situation for paths on curved spaces, as will be described below.

For functions with values in a separable Hilbert space $G$ the spaces $\mathbb{D}^{p,1}(E;G)$ are defined in the analogous way, with the derivative $df$ now mapping $E$ into $\mathcal{L}_2(H;G)$, the space of Hilbert–Schmidt operators of $H$ into $G$. This is a Hilbert space often identified with the completed tensor product $G \otimes H$. It occurs because a basic property of an abstract Wiener space is that any continuous linear map from $E$ to a Hilbert space $G$, such as $Df(x)$ if $f\colon E \to G$ is Fréchet differentiable, gives a Hilbert–Schmidt operator when composed with $i$, e.g. see Thm 17.3 in [62]. We can iterate this procedure to obtain higher order Sobolev spaces.

As usual the gradient can be defined for functions in $\mathbb{D}^{p,1}$, $1 < p < \infty$, by $\langle \nabla f(x), h\rangle_H = df_x(h)$ to give an *H-vector field*, $\nabla f : E \to H$. It is a closed operator between the $L^p$ spaces with the negative of its adjoint denoted by div, a closed operator from Dom(div) in $L^q(E; H)$ to $L^q(E; \mathbb{R})$, where $q$ is the conjugate of $p$. Similar we have the adjoint $d^*$ of $d$. From this we get the analogue of the (Witten) Laplacian, or the 'Ornstein–Uhlenbeck operator', $\mathcal{L} = \operatorname{div} \nabla = -d^*d$. In the case $E = H = \mathbb{R}^n$ this is given by

$$\mathcal{L}(f)(x) = \Delta f(x) - Df(x)(x)$$

for $\Delta$ the usual Laplacian (with negative spectrum) of $\mathbb{R}^n$.

The Ornstein–Uhlenbeck operator acting on $L^2$ is the well known operator whose spectrum consists of 0 as unique ground state, together with the negative integers as eigenvalues of infinite multiplicity, corresponding to the homogeneous chaos decomposition of $L^2(E; \mathbb{R})$, and conjugate to the number operator of mathematical physics acting on the real symmetric Fock space. For example from above we see that for $h \in H$ the map $\mathcal{P}(h)$ is an eigenvector of eigenvalue minus one (so giving the 'one-particle' space). For more, see for example [37], [53], or [38].

For classical Wiener space an H-vector field $V : C_0 \to L_0^{2,1}$ is said to be *non-anticipating* if for each time t its value $V(\sigma)_t$ at the path $\sigma$ depends only on the restriction of $\sigma$ to the interval $[0, T]$. If this holds and it is in $L^2$, then it is in the domain of the divergence operator and $\operatorname{div}(V)(\sigma)$ is precisely the negative of the *Itô stochastic integral*, $\int_0^T \dot{V}(\sigma)_t \, d\sigma(t)$, as shown by Gaveau. This is the integral which is the basis of stochastic calculus. In the anticipating case it is the *Skorohod*, or *Ramer–Skorohod integral*, now by definition: although here the word 'integral' can be misleading since, as in finite dimensions, differentiation may be involved, [53].

An $L^2$-deRham and Hodge–Kodaira theory was given in this context by Shigekawa [58]. The $k$-forms were '$H$-forms', i.e. maps from $E$ into $\wedge^k H$ where $\wedge^k$ denotes the Hilbert space completion of the $k$-th exterior power, with the exterior derivative being a closed operator derived from our $H$-derivative $d$. The Hodge decomposition was just as in finite dimensional, standard, $L^2$-theory, and Shigekawa proved a vanishing theorem, implying the expected triviality of the deRham cohomology. A theory of finite co-dimensional forms was proposed by Ramer in his Thesis, in the context of abstract Wiener manifolds; further developments were made by Kusuoka, [46], but more is needed to develop the theory, even on domains in these linear spaces.

## 2. Scalar analysis on paths in *M*

**2.1. Brownian motion measure and Bismut tangent spaces.** Consider a smooth manifold $M$. For a fixed time $T > 0$, and a fixed $x_0 \in M$ let $C_{x_0}([0, T]; M)$, or simply $C_{x_0}$, denote the space of continuous paths $\sigma : [0, T] \to M$ starting at $x_0$, together with its usual $C^\infty$ Banach manifold structure, e.g. see [19] or [54]. The

tangent space $T_\sigma C_{x_0}$ to $C_{x_0}$ at a point $\sigma$ can be identified with the space of continuous paths $v\colon [0,T] \to TM$ into the tangent bundle to $M$, such that $v(0) = 0$ and $v(t) \in T_{\sigma(t)}M$ for $0 \le t \le T$. For a complete Riemannian manifold the *Brownian motion measure*, $\mu_{x_0}$, on $C_{x_0}$ is the unique Borel measure for which

$$\begin{aligned}\mu_{x_0}(\{\sigma \in C_{x_0} : \sigma(t_j) \in A_j,\, j = 1, 2, \dots, k\}) \\ = \int_{A_1}\int_{A_2}\cdots\int_{A_n} \prod_{j=0}^{j=k-1} p_{t_{j+1}-t_j}(x_j; dx_{j+1})\end{aligned} \tag{3}$$

where $0 = t_0 < t_1 < \cdots < t_k \le T$, the $A_j$ are Borel subsets of $M$, and the measures $p_t(x, dy)$ are the heat kernel measures: $p_t(x, dy) = p_t(x, y)dy$ for $p_t(x, y)$ the fundamental solution of the heat equation $\frac{\partial f}{\partial t} = \frac{1}{2}\Delta$ for $\Delta$ the Laplace Beltrami operator, div grad, of $M$.

For simplicity we shall assume that $M$ is compact. Let its dimension be $n$.

From the successes of the flat space case it was expected that, to do analysis on the path space $C_{x_0}$ using Brownian motion measure, the differentiation should only take place in a special set of directions. In the case of Gaussian measures on linear space a natural choice was given, as described above, by the linear structure together with the measure: but there are other choices as we see in Section 2.3 below and it is not clear if the measure plus the differential structure does determine a special one, cf. [21]. Nevertheless a natural choice for Brownian motion measure is the *Bismut tangent spaces*. These are Hilbert spaces, $\mathcal{H}_\sigma$, of tangent vectors, defined for almost all $\sigma \in C_{x_0}$ by

$$\mathcal{H}_\sigma = \{v \in T_\sigma C_{x_0} : (/\!/_\cdot)^{-1} v(\,\cdot\,) \in L^{2,1}([0,T]; T_{x_0}M)\} \tag{4}$$

where $/\!/_t$ denotes parallel translation along $\sigma$ using the Levi-Civita connection.

Because our paths $\sigma$ are typically so irregular, e.g. almost surely $\alpha$-Hölder continuous only for $\alpha < 1/2$, the parallel translation has to be constructed by stochastic differential equations and so is only defined along almost all paths. However if we set $\mathcal{H} = \cup_\sigma \mathcal{H}_\sigma \subset TC_{x_0}$ we will see that it has the rudiments of a bundle structure. We will call its sections $H$-vector fields, and the sections of its dual bundle $\mathcal{H}^*$ will be called $H$-one-forms, cf. [40].

In [12], Driver extended Cameron–Martin's theorem and the formulae (1), and (2) to this situation, showing that if $V^h$ is the $H$-vector field whose value at $\sigma$ is obtained by parallel translation of a fixed element $h \in L^{2,1}([0,T]; T_{x_0}M)$ along $\sigma$ then this measurable vector field has a solution flow which preserves sets of $\mu_{x_0}$-zero, with consequent analogues of equations (1) and (2).

As for flat space the integration by parts formula gives closability of the $H$-derivative $d_H\colon \mathrm{Dom}(d_H) \to L^2\Gamma\mathcal{H}^*$ from its domain in $L^2$ into the $L^2$-$H$-one-forms. It works for the $L^p$-spaces but we shall only mention $L^2$ from now on for simplicity. A natural, essentially the smallest natural, domain to choose is to let $\mathrm{Dom}(d_H)$ be the space $\mathrm{Cyl}(M)$ of smooth cylinder functions: those maps of the form

$\sigma \mapsto F(\sigma(t_i), \ldots, \sigma(t_k))$ for some smooth $F$ defined on the $k$-fold product of $M$, some $0 \leq t_1 < \cdots < t_k \leq T$, any natural number $k$. Other choices include the space of (Fréchet) $C^1$- functions which are bounded together with their derivatives, using the natural Finsler metric on $C_{x_0}$. However this time we do not know if these lead to the same domain for the closure of $d_H$, see [26], [27].

We must make a choice, and will choose $\mathrm{Cyl}(M)$ as basic domain. With this choice let $\mathbb{D}^{2,1}(C_{x_0})$, or $\mathbb{D}^{2,1}$, denote the domain of the $L^2$-closure of $d_H$ with its graph norm, with $\mathbb{D}^{2,1}(C_{x_0}; G)$ for the corresponding space of $G$-valued functions, $G$ a separable Hilbert space. Let $d$ denote the closure of $d_H$, so if $f : C_{x_0} \to G$ is in $\mathbb{D}^{2,1}(C_{x_0}; G)$ then $df$ is an $L^2$-section of $\mathcal{L}_2(\mathcal{H}; G)$ the 'bundle' with fibre at $\sigma$ the space of Hilbert–Schmidt maps of $\mathcal{H}_\sigma$ into $G$, sometimes denoted by $\mathcal{G} \otimes \mathcal{H}$.

With this we get a closed operator $\nabla$ as usual, mapping its domain $\mathbb{D}^{2,1}$ into $H$-vector fields, with adjoint the negative of a closed operator div. As usual we have a self adjoint 'Laplacian', or 'Ornstein–Uhlenbeck' operator $\mathcal{L}$ acting on functions, defined by $\mathcal{L} = \operatorname{div} \nabla = -d^* d$. The associated Dirichlet forms and processes have been studied, e.g. [13], [15]. Norris devised a stochastic partial differential equation to construct associated 'Brownian motions' or 'Ornstein–Uhlenbeck processes' on these path spaces, treating them as two parameter $M$-valued processes, [52]. The existence of a spectral gap for $\mathcal{L}$ was proved by S. Fang, and Log Sobolev inequalities independently by E. Hsu and Aida & Elworthy, see [37], [22]. However little, if anything, appears to be known else about its spectrum.

To discuss higher derivatives it is convenient to have a 'connection' on $\mathcal{H}$ in order to differentiate its sections. The most obvious choice is to use the trivialisation of $\mathcal{H}$ obtained simply by parallel translating every element in each $\mathcal{H}_\sigma$ back to an element of $L^{2,1}([0, T]; T_{x_0}M)$, so that $H$-vector fields can be considered as maps of $C_{x_0}$ into $L^{2,1}([0, T]; T_{x_0}M)$ to which we may try to apply our closed derivative operator $d$. This approach was used effectively, for example in [47]. However it does not conserve the $C_{\mathrm{Id}}([0, T]; \mathrm{GL}(n))$-structure of our path space, nor as Cruziero& Malliavin pointed out, does it fit well with the underlying 'Markovianity' of our set up. This led them to the 'Markovian' connection, see [11], a modification of which we will describe below.

**2.2. Itô maps and the stochastic development.** The stochastic development map $\mathcal{D} : C_0([0, T]; T_{x_0}M) \to C_{x_0}$ is an almost surely defined version of the Cartan development, describing 'rolling without slipping' along smooth paths. Its inverse is given by $\mathcal{D}^{-1}(\sigma)(t) = \int_0^t (/\!\!/_t)^{-1} \circ d\sigma(t)$, where the integral is a Stratonovitch stochastic integral, and $/\!\!/_t$ refers to parallel translation along the path $\sigma$, (defined for almost all paths). Reformulating Gangolli, [33], [18], it was shown by Eells & Elworthy that it sends Wiener measure to the Brownian motion measure. A fundamental result of Malliavin calculus is that, for each time $t$ the map can be $H$-differentiated infinitely often in the Sobolev sense. This was used by Driver to transfer his results about flows of vector fields, and integration by parts formulae, from flat space to $C_{x_0}$, see [12] where background details are included. However the use of $\mathcal{D}$ as a chart was lim-

ited because its $H$-derivative does not map $L_0^{2,1}([0,T];T_{x_0}M)$ to the Bismut tangent spaces. Furthermore from [49] it now seems that, unless $M$ is flat, composition with $\mathcal{D}$ will not pull elements in $\mathbb{D}^{2,1}(C_{x_0})$ back to elements in the domain of $d$: there will be a loss of differentiability.

An alternative technique is to use the solution maps, *Itô maps*, of more simple stochastic differential equations as replacements for charts. For this take a (Stratonovich) stochastic differential equation

$$dx_t = X(x_t) \circ dB_t + A(x_t)dt \tag{5}$$

on $M$. Here $A$ is a smooth vector field and $X$ gives linear maps $X(x)\colon \mathbb{R}^m \to T_xM$, smooth in $x \in M$. Also $B$ is the canonical Brownian motion given by $B_t\colon C_0([0,T];\mathbb{R}^m) \to \mathbb{R}^m$ with $B_t(\omega) = \omega(t)$ for $C_0([0,T];\mathbb{R}^m)$ furnished with its Wiener measure, which we shall now denote by $\boldsymbol{P}$.

The solution $x_t\colon C_0([0,T];\mathbb{R}^m) \to M$ to such an equation, starting from $x_0$, can be obtained by 'Wong–Zakai approximation': taking piecewise linear approximations $B_t^\Pi$ to the Brownian motion, for each partition $\Pi$ of $[0,T]$, and solving the family of ordinary differential equations

$$\frac{dx^\Pi(\omega)}{dt} = X(x_t^\Pi(\omega))\frac{dB^\Pi(\omega)}{dt} + A(x_t^\Pi(\omega))$$

starting at $x_0$, for each $\omega$. The required solution $x_t$ is given by $x_t(\omega) = \mathcal{I}(\omega)_t$ for $\mathcal{I}$ the limit in probability of $x^\Pi\colon C_0([0,T];\mathbb{R}^m) \to C_{x_0}$ as the mesh of $\Pi$ goes to zero. The map $\mathcal{I}$ is the *Itô map*. To be precise we have to choose it as a representative from an almost sure equivalence class of measurable maps. However, as with the stochastic development these maps can be differentiated arbitrarily many times in the sense of Malliavin calculus. In particular for almost all $\omega$ there is a linear $H$-derivative $T_\omega\mathcal{I}\colon H \to T_{\mathcal{I}(\omega)}C_{x_0}$.

The solutions to equation (5) form a Markov process with generator $\mathcal{A}$ where

$$\mathcal{A} = \frac{1}{2}\sum_{j=1}^{m} \mathcal{L}_{X^j}\mathcal{L}_{X^j} + \mathcal{L}_A. \tag{6}$$

For them to be Brownian motions we need $\mathcal{A} = \frac{1}{2}\Delta$ which requires each mapping $X(x)\colon \mathbb{R}^m \to T_xM$ to be surjective and induce the given Riemannian metric on the tangent space, or equivalently for the adjoint $Y_x\colon T_xM \to \mathbb{R}^m$ of $X(x)$ to be a right inverse of $X(x)$. Given that, we may choose the vector field $A$ appropriately. Then $\mathcal{I}$ will map the flat Wiener measure $\boldsymbol{P}$ to our Brownian motion measure $\mu_{x_0}$. In general the dimension, $m$, of the space on which the driving Brownian motion runs, will be larger than that of $M$ so that $\mathcal{I}$ will not be injective. The disadvantage of this can be reduced by 'filtering out the redundant noise' and to do this successfully we need to note that our SDE for Brownian motion determines a metric connection, $\breve{\nabla}$ on $TM$ by using $X$ to project the trivial connection on the trivial $\mathbb{R}^m$-bundle onto $TM$: for

a vector field $U$ and tangent vector $v \in T_xM$ the covariant derivative of $U$ in the direction $v$ is given by

$$\check{\nabla}_v U = X(x)(d[y \mapsto Y_y U(y)]_x(v)). \tag{7}$$

It follows from Narasimhan & Ramanan's theory of universal connections that every metric connection on $TM$ can be obtained by a suitable choice of $X$, see [22], or [56] for a direct proof. To obtain the Levi-Civita connection we can use Nash's theorem to take an isometric embedding $j\colon M \to \mathbb{R}^m$ for some $m$ and then set $X(x) = (dj)^*_x$, the adjoint of $(dj)_x$. With $A = 0$ the resulting 'gradient' SDE has Brownian motions as solutions as required. For Riemannian symmetric spaces it may be useful to use the homogeneous space structure; for example if $M$ is a compact Lie group with bi-invariant metric we may take $\mathbb{R}^m$ to be a copy of the direct sum $\mathfrak{g} \oplus \mathfrak{g}$ of the Lie algebra, $\mathfrak{g} = T_{\mathrm{Id}}M$, of $M$ with itself and define $X(x)(e, e') = TR_x(e) - TL_x(e')$ with $A = 0$, where $TR_x$ and $TL_x$ are the derivatives of left and right translation by $x$, [22].

One basic result, extending estimates in [4], which contrasts with the stochastic development is the following.

**Theorem 2.1** ([27]). *Suppose the connection $\check{\nabla}$ induced by the SDE is the Levi-Civita connection. The the pull back by $\mathcal{I}$ of cylindrical one-forms on $C_{x_0}$ extends to a continuous linear map $\mathcal{I}^*\colon L^2\mathcal{H}^* \to L^2(C_0([0,T];\mathbb{R}^m); H^*)$ of $L^2$ $H$-one-forms on $C_{x_0}$ to those on the flat path space.*

Here for a cylindrical, or other one form, $\phi$, on $C_{x_0}$, the pull-back $H$-form $\mathcal{I}^*(\phi)$ is given by $\mathcal{I}^*(\phi)_\omega(h) = \phi(T_\omega\mathcal{I}(h))$ for $h \in H$. However, in general the $H$-derivative $T\mathcal{I}$ does not map $H$ into the Bismut tangent spaces and so for $H$-one-forms $\phi$ the pullback does not have a classical meaning, though it does have an expression as an Itô integral under our condition on $\check{\nabla}$. If $\check{\nabla}$ were not the Levi-Civita connection this integral would be a Skorohod integral with a consequent loss of differentiability expected, as for the stochastic development map in [49]. There is an important equivalent dual, or 'co-joint', version to this result. For this suppose $\alpha\colon C_{x_0} \to H$ is an $H$-vector field in $L^2$. For almost all $\sigma \in C_{x_0}$ we can 'integrate over the fibre of $\mathcal{I}$' at $\sigma$ to obtain $\overline{T\mathcal{I}(\alpha)}_\sigma \in T_\sigma C_{x_0}$. Mathematically that is achieved by taking the conditional expectation with respect to the $\sigma$-algebra $\mathcal{F}^{x_0}$ on $C_{x_0}$ generated by $\mathcal{I}$:

$$\overline{T\mathcal{I}(\alpha)}_\sigma = \mathbb{E}\{T\mathcal{I}(\alpha(-)) \mid \mathcal{I}(-) = \sigma\}.$$

**Theorem 2.2** ([27]). *Suppose the connection $\check{\nabla}$ induced by the SDE is the Levi-Civita connection. Then for all $H$-vector fields $\alpha$ in $L^2$, we have $\overline{T\mathcal{I}(\alpha)}_\sigma \in \mathcal{H}_\sigma$ almost surely, giving a continuous linear map $\overline{T\mathcal{I}(-)}\colon L^2(C_{x_0}; H) \to L^2\mathcal{H}$.*

When $\alpha$ is constant, with value $h$ say, we write $\overline{TI}_\sigma(h)$ for $\overline{T\mathcal{I}(\alpha)}_\sigma$. This map was known earlier, [22], to map $H$ isomorphically onto $\mathcal{H}_\sigma$, with our assumption on $\check{\nabla}$. In fact it has the explicit expression

$$\overline{TI}_\sigma(h)_t = \boldsymbol{W}(X(\sigma(-))\dot{h}), \tag{8}$$

where $\boldsymbol{W}\colon L^2([0,T];TM) \to \mathcal{H}$ is an isomorphism of the Bismut tangent 'bundle', where defined, with the $L^2$-tangent bundle $L^2TC_{x_0}$ of $C_{x_0}$ given by

$$L^2T_\sigma C_{x_0} = \Big\{ v\colon [0,T] \to TM \text{ such that } v(t) \in T_{\sigma(t)}M,\, 0 \leqslant t \leqslant T \text{ and } \int_0^T |v(t)|^2_{\sigma(t)}\, dt < \infty \Big\}.$$

The isomorphism is the inverse of the 'damped derivative' along the paths of $C_{x_0}$:

$$\frac{\mathbb{D}}{dt} = \frac{D}{dt} + \frac{1}{2}\,\mathrm{Ric}^{\#}\colon \mathcal{H} \to L^2TC_{x_0}, \tag{9}$$

where $\mathrm{Ric}^{\#}\colon TM \to TM$ corresponds to the Ricci curvature.

It is convenient to give $\mathcal{H}$ the Riemannian metric and bundle structure it inherits from this isomorphism with the bundle of $L^2$ 'tangent vectors'. The latter is a smooth Hilbert bundle over $C_{x_0}$ with structure group $C_{\mathrm{Id}}([0,T];O(n))$. It also has a natural metric, 'Levi-Civita', connection, the 'pointwise connection' induced from the Levi-Civita connection on $M$, [19]. Moving this to $\mathcal{H}$ by $\boldsymbol{W}$ gives a metric connection which is easily seen to be that projected onto $\mathcal{H}$ by $\overline{T\mathcal{I}}$, in the same way as we defined $\check{\nabla}$. This connection agrees with the 'damped Markovian' connection of Cruzeiro & Fang, see [9], referred to above. It can be used to define higher order derivative operators and Sobolev spaces, and Sobolev spaces of sections of $\mathcal{H}$, e.g. $\mathbb{D}^{2,1}\mathcal{H}$, the domain of the $L^2$-closure of the covariant $H$-derivative acting on sections of $\mathcal{H}$. The latter is shown to be in the domain of div in [27]: a result proved by M. & P. Kree for classical Wiener measure in 1983.

We can define an $L^2$-function $f\colon C_{x_0} \to \mathbb{R}$ to be *weakly differentiable* if it is in the domain of the adjoint of the restriction of div to $\mathbb{D}^{2,1}\mathcal{H}$. Let $W^{2,1}$ denote the space of such functions with its graph norm. Thus for $f \in W^{2,1}$ there exists $\widetilde{df} \in L^2\mathcal{H}^*$ such that if $V \in \mathbb{D}^{2,1}\mathcal{H}$ then

$$\int_{C_{x_0}} f(\sigma)\,\mathrm{div}(V(\sigma))\,d\mu_{x_0} = -\int_{C_{x_0}} \widetilde{df}(V(\sigma))\,d\mu_{x_0}.$$

For paths on $\mathbb{R}^m$ it follows from [60] that weak differentiability implies differentiability, in our Sobolev sense.

We have the following intertwining result:

**Theorem 2.3** ([27]). *Suppose the connection $\check{\nabla}$ induced by the SDE is the Levi-Civita connection. Then $f \in W^{2,1}$ if and only if $f \circ \mathcal{I} \in \mathbb{D}^{2,1}C_0([0,T];\mathbb{R}^m)$ and composition with $\mathcal{I}$ gives a continuous linear map of $W^{2,1}$ onto the space $\mathbb{D}^{2,1}_{\mathcal{F}^{x_0}}$ of those elements in $\mathbb{D}^{2,1}C_0([0,T];\mathbb{R}^m)$ which are $\mathcal{F}^{x_0}$-measurable. Moreover for $f \in W^{2,1}$ we have*

$$d(f \circ \mathcal{I}) = \mathcal{I}^*\widetilde{df}.$$

Preliminary versions of some of the above results were given in [24]. A fundamental question is whether $W^{2,1} = \mathbb{D}^{2,1}$. Applying results of Eberle, [15], it is shown in [27] that this equality holds if and only if *Markov uniqueness* holds for the operator $\mathcal{L}$ defined above but with domain $\mathrm{Cyl}(M)$. Markov uniqueness is a weaker notion than essential self-adjointness. Probabilistically it relates to uniqueness of solutions to the martingale problem, and it essentially means that there is a unique extension which generates a Markov semigroup. Equality would also imply the independence of $\mathbb{D}^{2,1}$ from the choice of initial domain $\mathrm{Dom}(d_H)$. We do not know of any non-flat manifolds $M$ for which an answer is known to these questions. A positive answer would follow from a positive answer to the following.

*If* $f \in \mathbb{D}^{2,1}C_0([0,T];\mathbb{R}^m)$*, is its conditional expectation* $\mathbb{E}\{f|\mathcal{F}^{x_0}\}$ *also in* $\mathbb{D}^{2,1}$?

This is described concisely in [26], and in detail in [27], describing some partial results and correcting claims made in our 2004 Comptes-Rendues note. A discussion somewhat related to the above question, by Airault, Malliavin & Ren, is in [5].

**2.3. More general diffusion measures.** Let $\mathcal{A}$ be a smooth diffusion generator on $M$ i.e. it is a semi-elliptic second order differential operator with no zero order term, acting on real valued functions on $M$. Essentially as for the case $\mathcal{A} = \frac{1}{2}\Delta$, there is an induced measure $\mu_{x_0}^{\mathcal{A}}$ on $C_{x_0}$.

To extend the previous results to do analysis with such a measure we will suppose the principal symbol $\sigma^{\mathcal{A}}\colon T^*M \to TM$ of $\mathcal{A}$ has constant rank, and so has image in a sub-bundle $E$ of $TM$. This is equivalent to requiring that $\mathcal{A}$ has a Hormander form, as equation (6), with the vector fields $X^j$ being sections of $E$.

In general there is now no obvious choice of a connection with which to define 'Bismut tangent' spaces. We therefore choose any metric connection on $E$ and as before, using Narasimhan & Ramanan's theorem, take a stochastic differential equation (5) for which the induced connection $\breve{\nabla}$ on $E$ is that chosen one, and for which (6) holds. To define the Bismut tangent spaces it is convenient to use the *adjoint semi-connection*, $\widehat{\nabla}$, which allows differentiation of all smooth vector fields, but only in $E$-directions. It is defined by

$$\widehat{\nabla}_{U(x)}V = \breve{\nabla}_{V(x)}U + [U,V](x) \in T_xM$$

for $U$ a section of $E$ and $V$ a vector field on $M$, [22].

Adjoint connections were used in a similar way in order to use different Bismut tangent spaces for Brownian measures, by Driver in [12]. The adjoint of the Levi-Civita connection is itself; that of the flat left invariant connection on a Lie group is a flat right invariant connection. For more examples see [22]. Semi-connections are also called 'partial connections' or '$E$-connections'.

We now define $\mathcal{H}_\sigma$ to be the set of those $v \in T_\sigma C_{x_0}$ for which $\frac{\hat{\mathbb{D}}}{dt}(v) \in L^2([0,T];E)$ where

$$\frac{\hat{\mathbb{D}}}{dt} = \frac{\hat{D}}{dt} + \frac{1}{2}\,\check{\mathrm{Ric}}^{\#} - \breve{\nabla}_{-}A \tag{10}$$

where the covariant differentiation is done using the semi-connection while $\check{\mathrm{Ric}}^{\#}\colon TM \to E$ corresponds to the Ricci curvature for $\check{\nabla}$. If $A$ does not take values in $E$ then this operator needs special interpretation, [22]. Since $L^2([0,T];E)\bigcap L^2TC_{x_0}$ is a smooth Hilbert bundle, as for the case $E = TM$, with pointwise connection induced from $\check{\nabla}$, we can induce all this structure, at least almost surely, on $\mathcal{H}$. When there is a metric on $TM$ to which the semi-connection $\widehat{\nabla}$ is adapted, the theory goes essentially as before, [27]. If not there may be some loss of integrability in the intertwining, for example, but the operator $\mathcal{L}$ has a spectral gap; indeed there is a Log Sobolev inequality, [22]. The Dirichlet forms which arise in this situation are discussed in [28].

## 3. Towards an $L^2$-deRham–Hodge–Kodaira theory

**3.1. The spaces of $H$-forms.** Following Shigekawa's rather complete $L^2$-deRham theory for $H$-forms on abstract Wiener spaces it would be natural to base such a theory on sections of the dual bundles to the exterior products $\wedge^k\mathcal{H}$ of the Bismut tangent bundle, using the Hilbert space completion of the exterior powers of each $\mathcal{H}_\sigma$. However this runs into difficulties even at defining the exterior derivative of an $H$ one-form, $\phi$, say: Recall that the standard formula for the exterior derivative $d\phi$ is

$$d\phi\big(U(x)\wedge V(x)\big) = \mathcal{L}_U\big(\phi(V(-))\big)(x) - \mathcal{L}_V\big(\phi(U(-))\big)(x) - \phi\big([U,V](x)\big)$$

for vector fields $U$ and $V$. However if $U$ and $V$ are $H$-vector fields their bracket need not be and so if $\phi$ is an $H$-form the last term in the expression above will not in general be defined. One way round this is to interpret this final term as a stochastic integral, in general a Skorohod integral. This was carried through by Léandre in [47] where he obtained a deRham complex in this situation and for loop spaces, proving that the resulting deRham cohomology agrees with the topological real cohomology. However this was not really an $L^2$ theory and did not include a version of the Hodge–Kodaira Laplacian.

A proposal made in [24] was to modify the definitions of $k$-forms by replacing the spaces $\wedge^k\mathcal{H}$ by Hilbert spaces $\mathcal{H}^{(k)}$, for $k = 1, 2, \ldots$, continuously included in the projective exterior powers $\wedge^k TC_{x_0}$. For the 'projective exterior powers' the completion is made using the largest cross norm and the usual, geometric, differential forms are sections of the dual bundles $(\wedge^k TC_{x_0})^*$. Our $H$-$k$-forms will be sections of the dual bundles $\mathcal{H}^{(k)*}$.

To define $\mathcal{H}^{(k)}$, for simplicity we will deal only with the case of Brownian motion measures and Levi-Civita connections. The more general situation is touched upon in [25]; for details of the following see [23]. Take an SDE as in Section 2.2 with corresponding Itô map $\mathcal{I}$. It is shown that the map $h_1\wedge\cdots\wedge h_k \mapsto T_\omega\mathcal{I}(h_1)\wedge\cdots\wedge T_\omega(h_k)$ determines a continuous linear map $\wedge^k T_\omega\mathcal{I}\colon \wedge^k H \to \wedge^k T_{\mathcal{I}(\omega)}C_{x_0}$ from Hilbert space to Banach space. As done in Section 2.2 integrate over the fibres

of $\mathcal{I}$ to define

$$\overline{\wedge T\mathcal{I}}_\sigma : \wedge^k H \to \wedge^k T_\sigma C_{x_0}$$

for almost all $\sigma \in C_{x_0}$, by the conditional expectation:

$$\overline{\wedge T\mathcal{I}}_\sigma(\underline{h}) = \mathbb{E}\{\wedge^k T\mathcal{I}(\underline{h})|\mathcal{I} = \sigma\}$$

for $\underline{h} \in \wedge^k H$. We then let $\mathcal{H}_\sigma^{(k)}$ be the image of $\overline{\wedge T\mathcal{I}}_\sigma$ with its quotient Hilbert space structure. Thus $\mathcal{H}^{(1)} = \mathcal{H}$. As with the case $k = 1$ these spaces depend only on the Riemannian structure of $M$, not on the choice of SDE we used to construct them (provided $\breve{\nabla}$ is the Levi-Civita connection).

For $k = 2$ there is a detailed description. For this let $\boldsymbol{R}: \wedge^2 TC_{x_0} \to \mathbb{L}(\mathcal{H}; \mathcal{H})$ be the curvature operator of the damped Markovian connection on $\mathcal{H}$, see Section 2.2, and let $\mathbb{T}: \mathcal{H} \times \mathcal{H} \to \mathcal{H}$ be its torsion. We have

$$\mathcal{H}^{(2)} = \{U \in \wedge^2 TC_{x_0} : U - \boldsymbol{R}(U) \in \wedge^2 \mathcal{H}\}$$

with inner product having the norm $|U|_{\mathcal{H}^2} = |U - \boldsymbol{R}(U)|_{\wedge^2\mathcal{H}}$. Alternatively, inverting $\mathrm{Id} - \boldsymbol{R}$, we have

$$\mathcal{H}^{(2)} = \{V + \boldsymbol{Q}(V) : V \in \wedge^2 \mathcal{H}\}$$

where the linear map $\boldsymbol{Q}$ can be expressed in terms of the curvature of $M$ and involves a 'damped translation' of 2-vectors on $M$ where the damping is by the second Weitzenbock curvature, just as the first, the Ricci curvature, appears in equation (9). It turns out that '$\mathrm{div}$' $\boldsymbol{Q}(u \wedge v) = \frac{1}{2}\mathbb{T}(u, v)$ for any bounded *adapted* $H$-vector fields $u$ and $v$ in the sense that for any smooth cylindrical one-form $\phi$ on $C_{x_0}$ we have

$$\int_{C_{x_0}} d\phi(\boldsymbol{Q}(u \wedge v)d\mu_{x_0} = -\frac{1}{2}\int_{C_{x_0}} \phi(\mathbb{T}(u, v))d\mu_{x_0}.$$

This relates to a result of Cruzeiro–Fang, [10], that for suitable $u$ and $v$ the torsion $\mathbb{T}(u, v)$ has 'divergence' zero, in the corresponding sense.

If we define the exterior $H$-derivative as usual on cylindrical one forms $\phi$ but restrict the resulting $(d_H\phi)_\sigma : \wedge^2 T_\sigma C_{x_0} \to \mathbb{R}$ to $\mathcal{H}_\sigma^{(2)}$ we obtain a map, with domain the smooth cylindrical one forms, into the $L^2$ $H$ two-forms, $L^2\ \mathcal{H}^{(2)*}$. The cylindrical one forms when restricted to $\mathcal{H}^*$ form a dense subspace of $L^2\mathcal{H}^*$ and it turns out that this map is closable as an operator on $L^2\mathcal{H}^*$. We obtain a closed exterior derivative operator

$$d^1 : \mathrm{Dom}(d) \subset L^2\mathcal{H}^* \to L^2\mathcal{H}^{(2)*}$$

with a dual operator $\mathrm{div}: \mathrm{Dom}(\mathrm{div}) \subset L^2\mathcal{H}^{(2)} \to L^2\mathcal{H}$.

The covariant derivative determined by the damped Markovian connection on $\mathcal{H}$ can be considered as a closed operator $\nabla$ from its domain, $\mathbb{D}^{2,1}\mathcal{H}$, in $L^2\mathcal{H}$ to $L^2(\mathcal{H} \otimes \mathcal{H})$ and so has an adjoint $\nabla^*$. The following suggests that our construction is a natural one, but the condition of adaptedness on the vector fields is essential:

**Proposition 3.1** ([23]). *Let $u$ and $v$ be bounded and adapted $H$-vector fields on $C_{x_0}$. Suppose $u, v \in \mathbb{D}^{2,1}\mathcal{H}$ then $u \wedge v \in \mathrm{Dom}\,\nabla^*$ and*

$$\nabla^*(u \wedge v) = \mathrm{div}((\mathrm{Id} + \boldsymbol{Q})(u \wedge v)).$$

It turns out that the exterior product $\phi^1 \wedge \phi^2$ of two $H$-one-forms can be considered as an $H$-two-form in a consistent way. Essentially this is because although an element in some $\mathcal{H}_\sigma^{(2)}$ is not in $\mathcal{H}_\sigma \otimes \mathcal{H}_\sigma$, a space which can be identified with the Hilbert–Schmidt maps on $\mathcal{H}_\sigma$, it can be identified with a bounded linear map on $\mathcal{H}_\sigma$, and elements of the uncompleted tensor product of $\mathcal{H}_\sigma$ with itself act as linear functionals on the bounded linear maps. We have then:

**Proposition 3.2** ([23]). *Suppose $f \in \mathbb{D}^{2,1}(C_{x_0}; \mathbb{R})$ and $\phi$ is a bounded $H$-one-form which is in the domain of the exterior derivative, and is bounded together with $d\phi$. Then $f\phi$ is in the domain of the exterior derivative and*

$$d^1(f\phi) = df \wedge \phi + f d^1\phi.$$

**3.2. A Hodge–Kodaira decomposition for one and two forms.** The key step to prove closability of the exterior derivative on these $H$-$k$-forms is to prove an analogue of Theorem 2.2. We would like a rich set of $L^2$ maps $\underline{h}\colon C_{x_0} \to \wedge^k\mathcal{H}$ such that

$$\overline{\wedge^k T\mathcal{I}(\underline{h})}_\sigma := \mathbb{E}\{\wedge^k T\mathcal{I}(\underline{h}) | \mathcal{I} = \sigma\} \in \mathcal{H}_\sigma^{(k)}$$

almost surely. For $k = 1$ this holds for all such $\underline{h}$ by Theorem 2.2. For $k = 2$ it is claimed for an adequately rich family in [23], for all relevant Itô maps, and for all $\underline{h}$ if the Itô map is defined via a symmetric space structure. It is unknown for higher $k$ largely because of the apparently complicated algebraic structure of the spaces $\mathcal{H}^{(k)}$ for higher $k$. (On the other hand in [25] it is shown that an important class of $k$-vector fields, defined for $k = 1, \ldots, n-1$ are $L^2$ sections of $\mathcal{H}^{(k)}$ when $k = 1, 2$: these are important in the sense that they give integration by parts results, or generalised 'Bismut-formulae', for the finite dimensional exterior derivatives $dP_t\phi$ of the heat semigroup on forms on $M$ in terms of a path integral of $\phi$ itself.)

From these results for $k = 1, 2$ we have now closed operators

$$d^k\colon \mathrm{Dom}(d^k) \subset L^2\Gamma\mathcal{H}^{(k)} \to L^2\Gamma\mathcal{H}^{(k+1)}$$

for $k = 1, 2$ with $d^2d^1 = 0$. This leads to the Hodge–Kodaira decomposition:

$$L^2\Gamma\mathcal{H}^k = \overline{\mathrm{Im}(d^{(k-1)})} \oplus \overline{\mathrm{Im}((d^k)^*)} \oplus (\ker d^k \cap \ker(d^{(k-1)})^*) \tag{11}$$

for $k = 1, 2$, as given for $k = 1$ in [24], and for $k = 2$ in [23]. Here $d^0$ refers to $d$, and in the case $k = 1$ the image of $d$ is closed by Fang's theorem, e.g. see the Clark–Ocone formula in [22]. Moreover we have self-adjoint operators $(d^k)^*d^k + d^{(k-1)}(d^{(k-1)})^*$ acting on the spaces of $L^2$ $H$-$k$-forms for $k = 1, 2$. For $k = 1$ the decomposition plus Fang's theorem shows that the space of $L^2$ harmonic one-forms represents the $L^2$-deRham cohomology group of $H$-one-forms.

**3.3. Lie groups with flat connection.** At present we have no information about even the first $L^2$ deRham group for non-flat manifolds. However in [31], Fang & Franchi considered the case where $M$ is a compact Lie group $G$ with bi-invariant metric. For the Bismut tangent spaces coming from a right invariant flat connection, the natural Itô map to use is that of a left invariant SDE, $dx_t = TL_{x_t} \circ dB_t$, for $B_\cdot$ a Brownian motion on the Lie algebra $\mathfrak{g}$. There is no 'redundant noise' and the derivative of the Itô map maps the Cameron–Martin space into the Bismut tangent spaces, and its exterior powers onto those of the Bismut spaces. There is no problem with the definition of the exterior derivative and they showed that the Itô map can be used to transfer Shigekawa's results for classical Wiener space, determining a Hodge–Kodaira decomposition, and giving the vanishing of $L^2$ harmonic forms and so of the corresponding deRham cohomology groups.

## 4. Loop spaces

We have not extended the Itô map techniques described above in any systematic way to the case of loop spaces, (but see [1]), and here will only briefly describe the basic set up and some relevant results. The surveys [48] and [2] give more information and references. Special motivation for the development of analysis on these spaces has come from the loop space approach to index theorems, as in [7], and the Hohn–Stolz conjecture, [59]. However note that this theory is based on tangent spaces of vectors which are in some sense in $L^{2,1}$ and it is not clear that this is always what is relevant to some physical or topological situations, e.g. see [32].

On the space of based loops, or more generally on the spaces $C_{x_0,y_0}$ of continuous paths $\sigma : [0, T] \to M$ with $\sigma(0) = x_0$ and $\sigma(1) = y_0$, for $y_0 \in M$, a natural measure to take is the *Brownian Bridge measure*, $\mu_{x_0,y_0}$, obtained by conditioning Brownian motion from $x_0$ to be at $y_0$ at time $T$. If equation (5) has solutions which are Brownian motions then the equation:

$$db_t = X(b_t) \circ dB_t + A(b_t)dt + \nabla \log p_{T-t}(b_t; y_0)dt \tag{12}$$

will have Itô map which sends Wiener measure to $\mu_{x_0,y_0}$. Here $p_t(x, y)$ is the heat kernel as in Section 2.1.

For the space $L(M)$ of free loops, i.e. of continuous $\sigma : S^1 \to M$, there is Bismut's measure, $\mu_L$, which can be defined as $\int_M p_T(y, y)\mu_{y,y}\, dy$ with $T = 2\pi$, [7]. This measure is invariant under the action of $S^1$. A variant of this when $M$ is a Lie group is to average using normalised Haar measure rather than the heat kernel. Either of these loop spaces could be furnished with a *heat kernel measure*, $\mu_h$. This is defined by choosing a base point, e.g. a constant loop, and constructing a 'Brownian motion' on the loop space starting at that point, running it for some fixed time, $\tau$ say, and using its probability distribution as $\mu_h$. This will depend on $\tau$ and for free loops an extra averaging over the initial base point to retain $S^1$-invariance is needed. The

construction of such Brownian motions goes back to Baxendale, see [6] and Gaveau & Mazet, [34] but has been most developed for loop groups, [51]. For based paths on a compact simply connected Lie group this measure has been shown to be equivalent to the Brownian Bridge measure, [3].

In these contexts, by results of several people including M. P. & P. Malliavin, Driver, Hsu, Leandre, Enchev & Stroock, and Aida there are integration by parts formulae and associated Sobolev spaces based on Bismut tangent spaces defined similarly to those above, though for Lie groups flat connections are often used to define the Bismut tangent spaces. For the Brownian bridge and Bismut measures there are cohomology results: using stochastic Chen forms in [40], 'Sobolev differential forms' [47], and more recently 'Chen–Souriau cohomology' defined via a 'stochastic diffeology', see [48]. In general the resulting cohomology agrees with the usual singular real cohomology. We refer the reader to MathScinet to see the variety of constructions in these and related situations by R. Leandre.

For compact Lie groups with bi-invariant metrics, and with Bismut tangent spaces defined by flat left, or right, invariant connections, Fang & Franchi were able to extend their results for path spaces to based loops defining Hodge–Kodaira operators on forms and giving a 'Weitzenbock formulae' for them, [30]. This formula rather clearly shows the form of these operators as 'Witten' or 'Bismut' Laplacians where the 'perturbing' vector field is not an $H$-vector field, and gives rise to stochastic integrals in the formulae. The curvature part of the formulae has a Ricci term, which requires a careful summation, as in [32].

One striking result for the Brownian bridge measure is the following by Eberle:

**Theorem 4.1** ([16]). *Suppose the compact manifold $M$ has a closed geodesic for which there is a neighbourhood in $M$ of constant negative curvature. Then on the loop spaces $C_{x_0,x_0}$ with Brownian bridge measure, and $L(M)$ with Bismut measure, the self-adjoint operator $\mathcal{L} = -d^*d$ does not have a spectral gap.*

Spectral gaps for the Hodge–Kodaira 'Laplacians' are important in Hodge theory since they correspond to the (exterior) derivative operators having closed range in $L^2$. At present it is unknown if there is ever a spectral gap for $\mathcal{L}$ for these measures for loops on non-flat manifolds, e.g. on spheres. However for heat kernel measures on compact Lie groups with bi-invariant metrics Driver & Lohrenz proved the existence of a Log Sobolev inequality and so of a spectral gap for $\mathcal{L}$, see [29].

An alternative approach to based loops has been to represent them by 'submanifolds' of classical Wiener space by choosing a suitable (i.e. a quasi-continuous) version of the stochastic development and considering the inverse image $\widetilde{C}$, say, under it, of the based loops on $M$. This construction is dependent on 'quasi-sure' analysis, see [50], where our measure theoretic concepts are refined potential theoretically, so that $\widetilde{C}$ can be defined up to sets of capacity zero. To a certain extent this allows $\widetilde{C}$ to be treated as a submanifold of co-dimension the dimension of $M$, with a differential form theory and Weitzenbock formula, see [41], and [45].

# Statistical challenges with high dimensionality: feature selection in knowledge discovery

Jianqing Fan and Runze Li*

**Abstract.** Technological innovations have revolutionized the process of scientific research and knowledge discovery. The availability of massive data and challenges from frontiers of research and development have reshaped statistical thinking, data analysis and theoretical studies. The challenges of high-dimensionality arise in diverse fields of sciences and the humanities, ranging from computational biology and health studies to financial engineering and risk management. In all of these fields, variable selection and feature extraction are crucial for knowledge discovery. We first give a comprehensive overview of statistical challenges with high dimensionality in these diverse disciplines. We then approach the problem of variable selection and feature extraction using a unified framework: penalized likelihood methods. Issues relevant to the choice of penalty functions are addressed. We demonstrate that for a host of statistical problems, as long as the dimensionality is not excessively large, we can estimate the model parameters as well as if the best model is known in advance. The persistence property in risk minimization is also addressed. The applicability of such a theory and method to diverse statistical problems is demonstrated. Other related problems with high-dimensionality are also discussed.

**Keywords.** AIC, BIC, LASSO, bioinformatics, financial econometrics, model selection, oracle property, penalized likelihood, persistent, SCAD, statistical learning.

## 1. Introduction

Technological innovations have had deep impact on society and on scientific research. They allow us to collect massive amount of data with relatively low cost. Observations with curves, images or movies, along with many other variables, are frequently seen in contemporary scientific research and technological development. For example, in biomedical studies, huge numbers of magnetic resonance images (MRI) and functional MRI data are collected for each subject with hundreds of subjects involved. Satellite imagery has been used in natural resource discovery and agriculture, collecting thousands of high resolution images. Examples of these kinds are plentiful in computational biology, climatology, geology, neurology, health science, economics,

Proceedings of the International Congress of Mathematicians, Madrid, Spain, 2006

and finance among others. Frontiers of science, engineering and the humanities differ in the problems of their concerns, but nevertheless share one common theme: massive and high-throughput data have been collected and new knowledge needs to be discovered using these data. These massive collections of data along with many new scientific problems create golden opportunities and significant challenges for the development of mathematical sciences.

The availability of massive data along with new scientific problems have reshaped statistical thinking and data analysis. Dimensionality reduction and feature extraction play pivotal roles in all high-dimensional mathematical problems. The intensive computation inherent in these problems has altered the course of methodological development. At the same time, high-dimensionality has significantly challenged traditional statistical theory. Many new insights need to be unveiled and many new phenomena need to be discovered. There is little doubt that the high dimensional data analysis will be the most important research topic in statistics in the 21st century [19].

Variable selection and feature extraction are fundamental to knowledge discovery from massive data. Many variable selection criteria have been proposed in the literature. Parsimonious models are always desirable as they provide simple and interpretable relations among scientific variables in addition to reducing forecasting errors. Traditional variable selection such as $C_p$, AIC and BIC involves a combinatorial optimization problem, which is NP-hard, with computational time increasing exponentially with the dimensionality. The expensive computational cost makes traditional procedures infeasible for high-dimensional data analysis. Clearly, innovative variable selection procedures are needed to cope with high-dimensionality.

Computational challenges from high-dimensional statistical endeavors forge cross-fertilizations among applied and computational mathematics, machine learning, and statistics. For example, Donoho and Elad [20] and Donoho and Huo [21] show that the NP-hard best subset regression can be solved by a penalized $L_1$ least-squares problem, which can be handled by a linear programming, when the solution is sufficiently sparse. Wavelets are widely used in statistics function estimation and signal processing [1], [14], [17], [23], [24], [64], [65], [71]. Algebraic statistics, the term coined by Pistone, Riccomagno, Wynn [73], uses polynomial algebra and combinatorial algorithms to solve computational problems in experimental design and discrete probability [73], conditional inferences based on Markovian chains [16], parametric inference for biological sequence analysis [72], and phylogenetic tree reconstruction [78].

In high-dimensional data mining, it is helpful to distinguish two types of statistical endeavors. In many machine learning problems such as tumor classifications based on microarray or proteomics data and asset allocations in finance, the interests often center around the classification errors, or returns and risks of selected portfolios rather than the accuracy of estimated parameters. On the other hand, in many other statistical problems, concise relationship among dependent and independent variables are needed. For example, in health studies, we need not only to identify risk factors, but also to assess accurately their risk contributions. These are needed for prognosis and understanding the relative importance of risk factors. Consistency results are

inadequate for assessing the uncertainty in parameter estimation. The distributions of selected and estimated parameters are needed. Yet, despite extensive studies in classical model selection techniques, no satisfactory solutions have yet been produced.

In this article, we address the issues of variable selection and feature extraction using a unified framework: penalized likelihood methods. This framework is applicable to both machine learning and statistical inference problems. In addition, it is applied to both exact and approximate statistical modeling. We outline, in Section 2, some high-dimensional problems from computational biology, biomedical studies, financial engineering, and machine learning, and then provide a unified framework to address the issues of feature selection in Sections 3 and 4. In Sections 5 and 6, the framework is then applied to provide solutions to some problems outlined in Section 2.

## 2. Challenges from sciences and humanities

We now outline a few problems from various frontiers of research to illustrate the challenges of high-dimensionality. Some solutions to these problems will be provided in Section 6.

**2.1. Computational biology.** Bioinformatic tools have been widely applied to genomics, proteomics, gene networks, structure prediction, disease diagnosis and drug design. The breakthroughs in biomedical imaging technology allow scientists to monitor large amounts of diverse information on genetic variation, gene and protein functions, interactions in regulatory processes and biochemical pathways. Such technology has also been widely used for studying neuron activities and networks. Genomic sequence analysis permits us to understand the homologies among different species and infer their biological structures and functionalities. Analysis of the network structure of protein can predict the protein biological function. These quantitative biological problems raise many new statistical and computational problems. Let us focus specifically on the analysis of microarray data to illustrate some challenges with dimensionality.

DNA microarrays have been widely used in simultaneously monitoring mRNA expressions of thousands of genes in many areas of biomedical research. There are two popularly-used techniques: c-DNA microarrays [5] and Affymetrix GeneChip arrays [61]. The former measures the abundance of mRNA expressions by mixing mRNAs of treatment and control cells or tissues, hybridizing with cDNA on the chip. The latter uses combined intensity information from 11-20 probes interrogating a part of the DNA sequence of a gene, measuring separately mRNA expressions of treatment and control cells or tissues. Let us focus further on the cDNA microarray data.

The first statistical challenge is to remove systematic biases due to experiment variations such as intensity effect in the scanning process, block effect, dye effect, batch effect, amount of mRNA, DNA concentration on arrays, among others. This is collectively referred to as normalization in the literature. Normalization is critical

for multiple array comparisons. Statistical models are needed for estimation of these systematic biases in presence of high-dimensional nuisance parameters from treatment effects on genes. See, for example, lowess normalization in [26], [83], semiparametric model-based normalization by [36], [37], [50], and robust normalization in [63]. The number of significantly expressed genes is relatively small. Hence, model selection techniques can be used to exploit the sparsity. In Section 6.1, we briefly introduce semiparametric modeling techniques to issues of normalization of cDNA microarray.

Once systematic biases have been removed, the statistical challenge becomes selecting statistically significant genes based on a relatively small sample size of arrays (e.g. $n = 4, 6, 8$). Various testing procedures have been proposed in the literature. See, for example, [30], [37], [50], [83], [84]. In carrying out simultaneous testing of orders of hundreds or thousands of genes, classical methods of controlling the probability of making one falsely discovered gene are no longer relevant. Therefore various innovative methods have been proposed to control the false discovery rates. See, for example, [2], [22], [25], [27], [44], [57], [77]. The fundamental assumption in these developments is that the null distribution of test statistics can be determined accurately. This assumption is usually not granted in practice and new probabilistic challenge is to answer the questions how many simultaneous hypotheses can be tested before the accuracy of approximations of null distributions becomes poor. Large deviation theory [45], [46], [53] is expected to play a critical role in this endeavor. Some progress has been made using maximal inequalities [55].

Tumor classification and clustering based on microarray and proteomics data are another important class of challenging problems in computational biology. Here, hundreds or thousands of gene expressions are potential predictors, and the challenge is to select important genes for effective disease classification and clustering. See, for example, [79], [82], [88] for an overview and references therein.

Similar problems include time-course microarray experiments used to determine the expression pathways over time [79], [80] and genetic networks used for understanding interactions in regulatory processes and biochemical pathways [58]. Challenges of selecting significant genes over time and classifying patterns of gene expressions remain. In addition, understanding genetic network problems requires estimating a huge covariance matrix with some sparsity structure. We introduce a modified Cholesky decomposition technique for estimating large scale covariance matrices in Section 6.1.

**2.2. Health studies.** Many health studies are longitudinal: each subject is followed over a period of time and many covariates and responses of each subject are collected at different time points. Framingham Heart Study (FHS), initiated in 1948, is one of the most famous classic longitudinal studies. Documentation of its first 50 years can be found at the website of National Heart, Lung and Blood Institute (http://www.nhlbi.nih.gov/about/framingham/). One can learn more details about this study from the website of American Heart Association. In brief, the FHS follows a representative sample of 5,209 adult residents and their offspring aged 28–62 years in

Framingham, Massachusetts. These subjects have been tracked using (a) standardized biennial cardiovascular examination, (b) daily surveillance of hospital admissions, (c) death information and (d) information from physicians and other sources outside the clinic.

In 1971 the study enrolled a second-generation group to participate in similar examinations. It consisted of 5,124 of the original participants' adult children and their spouses. This second study is called the Framingham Offspring Study.

The main goal of this study is to identify major risk factors associated with heart disease, stroke and other diseases, and to learn the circumstances under which cardiovascular diseases arise, evolve and end fatally in the general population. The findings in this studies created a revolution in preventive medicine, and forever changed the way the medical community and general public view on the genesis of disease. In this study, there are more than 25,000 samples, each consisting of more than 100 variables. Because of the nature of this longitudinal study, some participant cannot be followed up due to their migrations. Thus, the collected data contain many missing values. During the study, cardiovascular diseases may develop for some participants, while other participants may never experience with cardiovascular diseases. This implies that some data are censored because the event of particular interest never occurred. Furthermore, data between individuals may not be independent because data for individuals in a family are clustered and likely positively correlated. Missing, censoring and clustering are common features in health studies. These three issues make data structure complicated and identification of important risk factors more challenging. In Section 6.2, we present a penalized partial likelihood approach to selecting significant risk factors for censored and clustering data. The penalized likelihood approach has been used to analyze a data subset of Framingham study in [9].

High-dimensionality is frequently seen in many other biomedical studies. For example, ecological momentary assessment data have been collected for smoking cessation studies. In such a study, each of a few hundreds participants is provided a hand-held computer, which is designed to randomly prompt the participants five to eight times per day over a period of about 50 days and to provide 50 questions at each prompt. Therefore, the data consist of a few hundreds of subjects and each of them may have more than ten thousand observed values [60]. Such data are termed intensive longitudinal data. Classical longitudinal methods are inadequate for such data. Walls and Schafer [86] presents more examples of intensive longitudinal data and some useful models to analyze this kind of data.

**2.3. Financial engineering and risk management.** Technological revolution and trade globalization have introduced a new era of financial markets. Over the last three decades, an enormous number of new financial products have been created to meet customers' demands. For example, to reduce the impact of the fluctuations of currency exchange rates on corporate finances, a multinational corporation may decide to buy options on the future of exchange rates; to reduce the risk of price fluctuations of a commodity (e.g. lumbers, corns, soybeans), a farmer may enter

into a future contract of the commodity; to reduce the risk of weather exposures, amusement parks and energy companies may decide to purchase financial derivatives based on the weather. Since the first options exchange opened in Chicago in 1973, the derivative markets have experienced extraordinary growth. Professionals in finance now routinely use sophisticated statistical techniques and modern computing power in portfolio management, securities regulation, proprietary trading, financial consulting, and risk management. For an overview, see [29] and references therein.

Complex financial markets [51] make portfolio allocation, asset pricing and risk management very challenging. For example, the price of a stock depends not only on its past values, but also its bond and derivative prices. In addition, it depends on prices of related companies and their derivatives, and on overall market conditions. Hence, the number of variables that influence asset prices can be huge and the statistical challenge is to select important factors that capture the market risks. Thanks to technological innovations, high-frequency financial data are now available for an array of different financial instruments over a long time period. The amount of financial data available to financial engineers is indeed astronomical.

Let us focus on a specific problem to illustrate the challenge of dimensionality. To optimize the performance of a portfolio [10], [12] or to manage the risk of a portfolio [70], we need to estimate the covariance matrix of the returns of assets in the portfolio. Suppose that we have 200 stocks to be selected for asset allocation. There are 20,200 parameters in the covariance matrix. This is a high-dimensional statistical problem and estimating it accurately poses challenges.

Covariance matrices pervade every facet of financial econometrics, from asset allocation, asset pricing, and risk management, to derivative pricing and proprietary trading. As mentioned earlier, they are also critical for studying genetic networks [58], as well as other statistical applications such as climatology [54]. In Section 6.1, a modified Cholesky decomposition is used to estimate huge covariance matrices using penalized least squares approach proposed in Section 2. We will introduce a factor model for covariance estimation in Section 6.3.

**2.4. Machine learning and data mining.** Machine learning and data mining extend traditional statistical techniques to handle problems with much higher dimensionality. The size of data can also be astronomical: from grocery sales and financial market trading to biomedical images and natural resource surveys. For an introduction, see the books [47], [48]. Variable selections and feature extraction are vital for such high-dimensional statistical explorations. Because of the size and complexity of the problems, the associated mathematical theory also differs from the traditional approach. The dimensionality of variables is comparable with the sample size and can even be much higher than the sample size. Selecting reliable predictors to minimize risks of prediction is fundamental to machine learning and data mining. On the other hand, as the interest mainly lies in risk minimization, unlike traditional statistics, the model parameters are only of secondary interest. As a result, crude consistency results suffice for understanding the performance of learning theory. This eases considerably

the mathematical challenges of high-dimensionality. For example, in the supervised (classification) or unsupervised (clustering) learning, we do not need to know the distributions of estimated coefficients in the underlying model. We only need to know the variables and their estimated parameters in the model. This differs from high-dimensional statistical problems in health sciences and biomedical studies, where statistical inferences are needed in presence of high-dimensionality. In Sections 4.2 and 6.4, we will address further the challenges in machine learning.

## 3. Penalized least squares

With the above background, we now consider the variable selection in the least-squares setting to gain further insights. The idea will be extended to the likelihood or pseudo-likelihood setting in the next section. We demonstrate how to directly apply the penalized least squares approach for function estimation or approximation using wavelets or spline basis, based on noisy data in Section 5. The penalized least squares method will be further extended to penalized empirical risk minimization for machine learning in Section 6.4.

Let $\{\boldsymbol{x}_i, y_i\}$, $i = 1, \ldots, n$, be a random sample from the linear regression model

$$y = \boldsymbol{x}^T \boldsymbol{\beta} + \varepsilon, \tag{3.1}$$

where $\varepsilon$ is a random error with mean 0 and finite variance $\sigma^2$, and $\boldsymbol{\beta} = (\beta_1, \ldots, \beta_d)^T$ is the vector of regression coefficients. Here, we assume that all important predictors, and their interactions or functions are already in the model so that the full model (3.1) is correct.

Many variable selection criteria or procedures are closely related to minimize the following penalized least squares (PLS)

$$\frac{1}{2n} \sum_{i=1}^{n} (y_i - \boldsymbol{x}_i^T \boldsymbol{\beta})^2 + \sum_{j=1}^{d} p_{\lambda_j}(|\beta_j|), \tag{3.2}$$

where $d$ is the dimension of $\boldsymbol{x}$, and $p_{\lambda_j}(\cdot)$ is a penalty function, controlling model complexity. The dependence of the penalty function on $j$ allows us to incorporate prior information. For instance, we may wish to keep certain important predictors in the model and choose not to penalize their coefficients.

The form of $p_{\lambda_j}(\cdot)$ determines the general behavior of the estimator. With the entropy or $L_0$-penalty, namely, $p_{\lambda_j}(|\beta_j|) = \frac{1}{2}\lambda^2 I(|\beta_j| \neq 0)$, the PLS (3.2) becomes

$$\frac{1}{2n} \sum_{i=1}^{n} (y_i - \boldsymbol{x}_i^T \boldsymbol{\beta})^2 + \frac{1}{2}\lambda^2 |M|, \tag{3.3}$$

where $|M| = \sum_j I(|\beta_j| \neq 0)$, the size of the candidate model. Among models with $m$ variables, the selected model is the one with the minimum residual sum of squares

(RRS), denoted by $\mathrm{RSS}_m$. A classical statistical method is to choose $m$ by maximizing the adjusted $R^2$, given by

$$R_{\mathrm{adj},m} = 1 - \frac{n-1}{n-m}\frac{\mathrm{RSS}_m}{\mathrm{RSS}_1},$$

or equivalently by minimizing $\mathrm{RSS}_m/(n-m)$, where $\mathrm{RSS}_1$ is the total sum of squares based on the null model (using the intercept only). Using $\log(1+x) \approx x$ for small $x$, it follows that

$$\log\{\mathrm{RSS}_m/(n-m)\} \approx (\log\sigma^2 - 1) + \sigma^{-2}\left\{\frac{1}{n}\mathrm{RSS}_m + \frac{1}{n}m\sigma^2\right\}. \tag{3.4}$$

Therefore, maximization of $R_{\mathrm{adj},m}$ is asymptotically equivalent to minimizing the PLS (3.3) with $\lambda = \sigma/\sqrt{n}$. Similarly, generalized cross-validation (GCV) given by

$$\mathrm{GCV}(m) = \mathrm{RSS}_m/\{n(1-m/n)^2\}$$

is asymptotically equivalent to the PLS (3.3) with $\lambda = \sqrt{2}\sigma/\sqrt{n}$ and so is the cross-validation (CV) criterion.

Many popular variable selection criteria can be shown asymptotically equivalent to the PLS (3.3) with appropriate values of $\lambda$, though these criteria were motivated from different principles. See [69] and references therein. For instance, RIC [38] corresponds to $\lambda = \sqrt{2\log(d)}(\sigma/\sqrt{n})$. Since the entropy penalty function is discontinuous, minimizing the entropy-penalized least-squares requires exhaustive search, which is not feasible for high-dimensional problem. In addition, the sampling distributions of resulting estimates are hard to derive.

Many researchers have been working on minimizing the PLS (3.2) with $L_p$-penalty for some $p > 0$. It is well known that the $L_2$-penalty results in a ridge regression estimator, which regularizes and stabilizes the estimator but introduces biases. However, it does not shrink any coefficients directly to zero.

The $L_p$-penalty with $0 < p < 2$ yields bridge regression [39], intermediating the best-subset ($L_0$-penalty) and the ridge regression ($L_2$-penalty). The non-negative garrote [8] shares the same spirit as that of bridge regression. With the $L_1$-penalty specifically, the PLS estimator is called LASSO in [81]. In a seminal paper, Donoho and Elad [20] show that penalized $L_0$-solution can be found by using penalized $L_1$-method for sparse problem. When $p \leq 1$, the PLS automatically performs variable selection by removing predictors with very small estimated coefficients.

Antoniadis and Fan [1] discussed how to choose a penalty function for wavelets regression. Fan and Li [33] advocated penalty functions with three properties:

**a.** *Sparsity:* The resulting estimator should automatically set small estimated coefficients to zero to accomplish variable selection.

**b.** *Unbiasedness:* The resulting estimator should have low bias, especially when the true coefficient $\beta_j$ is large.

**c.** *Continuity:* The resulting estimator should be continuous to reduce instability in model prediction.

To gain further insights, let us assume that the design matrix $\boldsymbol{X} = (\boldsymbol{x}_1, \ldots, \boldsymbol{x}_n)^T$ for model (3.1) is orthogonal and satisfies that $\frac{1}{n}\boldsymbol{X}^T\boldsymbol{X} = I_d$. Let $\boldsymbol{z} = (\boldsymbol{X}^T\boldsymbol{X})^{-1}\boldsymbol{X}^T\boldsymbol{y}$ be the least squares estimate of $\boldsymbol{\beta}$. Then (3.2) becomes

$$\frac{1}{2n}\|\boldsymbol{y} - \boldsymbol{X}\boldsymbol{z}\| + \frac{1}{2}\|\boldsymbol{z} - \boldsymbol{\beta}\|^2 + \sum_{j=1}^{d} p_{\lambda_j}(|\beta_j|).$$

Thus the PLS reduces to a componentwise minimization problem:

$$\min_{\beta_j}\left\{\frac{1}{2}(z_j - \beta_j)^2 + p_{\lambda_j}(|\beta_j|)\right\}, \quad \text{for } j = 1, \ldots, d,$$

where $z_j$ is the $j$-th component of $\boldsymbol{z}$. Suppress the subscript $j$ and let

$$Q(\beta) = \frac{1}{2}(z - \beta)^2 + p_\lambda(|\beta|). \tag{3.5}$$

Then the first order derivative of $Q(\beta)$ is given by

$$Q'(\beta) = \beta - z + p'_\lambda(|\beta|)\mathrm{sgn}(\beta) = \mathrm{sgn}(\beta)\{|\beta| + p'_\lambda(|\beta|)\} - z.$$

Antoniadis and Fan [1] and Fan and Li [33] derived that the PLS estimator possesses the following properties:

(a) *sparsity* if $\min_\beta\{|\beta| + p'_\lambda(|\beta|)\} > 0$;

(b) *unbiasedness* $p'_\lambda(|\beta|) = 0$ for large $|\beta|$;

(c) *continuity* if and only if $\mathrm{argmin}_\beta\{|\beta| + p'_\lambda(|\beta|)\} = 0$.

The $L_p$-penalty with $0 \le p < 1$ does not satisfy the continuity condition, the $L_1$ penalty does not satisfy the unbiasedness condition, and $L_p$ with $p > 1$ does not satisfy the sparsity condition. Therefore, none of the $L_p$-penalties satisfies the above three conditions simultaneously, and $L_1$-penalty is the such penalty that is both convex and produces sparse solutions. Of course, the class of penalty functions satisfying the aforementioned three conditions are infinitely many. Fan and Li [33] suggested the use of the smoothly clipped absolute deviation (SCAD) penalty defined as

$$p_\lambda(|\beta|) = \begin{cases} \lambda|\beta|, & \text{if } 0 \le |\beta| < \lambda; \\ -(|\beta|^2 - 2a\lambda|\beta| + \lambda^2)/\{2(a-1)\}, & \text{if } \lambda \le |\beta| < a\lambda; \\ (a+1)\lambda^2/2, & \text{if } |\beta| \ge a\lambda. \end{cases}$$

They further suggested using $a = 3.7$. This function has similar feature to the penalty function $\lambda|\beta|/(1 + |\beta|)$ advocated in [71]. Figure 1 depicts the SCAD, $L_{0.5}$-penalty,

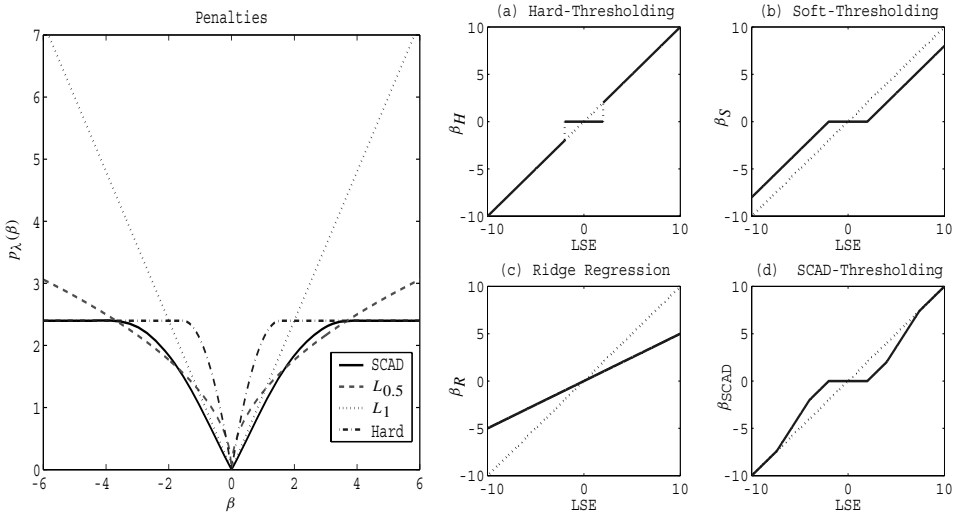

Figure 1. Penalty functions (left panel) and PLS estimators (right panel).

$L_1$-penalty, and hard thresholding penalty (to be introduced) functions. These four penalty functions are singular at the origin, a necessary condition for sparsity in variable selection. Furthermore, the SCAD, hard-thresholding and $L_{0.5}$ penalties are nonconvex over $(0, +\infty)$ in order to reduce the estimation bias.

Minimizing the PLS (3.5) with the entropy penalty or hard-thresholding penalty $p_\lambda(\beta) = \lambda^2 - (\lambda - |\beta|)_+^2$ (which is smoother) yields the hard-thresholding rule [23] $\hat{\beta}_H = zI(|z| > \lambda)$. With the $L_1$-penalty, the PLS estimator is $\hat{\beta}_S = \text{sgn}(z)(|z| - \lambda)_+$, the soft-thresholding rule [3], [23]. The $L_2$-penalty results in the ridge regression $\hat{\beta}_R = (1 + \lambda)^{-1} z$ and the SCAD penalty gives the solution

$$\hat{\beta}_{\text{SCAD}} = \begin{cases} \text{sgn}(z)(|z| - \lambda)_+, & \text{when } |z| \le 2\lambda; \\ \{(a-1)z - \text{sgn}(z)a\lambda\}/(a-2), & \text{when } 2\lambda < |z| \le a\lambda; \\ z, & \text{when } |z| > a\lambda. \end{cases}$$

These functions are also shown in Figure 1. The SCAD is an improvement over the $L_0$-penalty in two aspects: saving computational cost and resulting in a continuous solution to avoid unnecessary modeling variation. Furthermore, the SCAD improves bridge regression by reducing modeling variation in model prediction. Although similar in spirit to the $L_1$-penalty, the SCAD also improves the $L_1$-penalty by avoiding excessive estimation bias since the solution of the $L_1$-penalty could shrink all regression coefficients by a constant, e.g., the soft thresholding rule.

## 4. Penalized likelihood

PLS can easily be extended to handle a variety of response variables, including binary response, counts, and continuous response. A popular family of this kind is called generalized linear models. Our approach can also be applied to the case where the likelihood is a quasi-likelihood or other discrepancy functions. This will be demonstrated in Section 6.2 for analysis of survival data, and in Section 6.4 for machine learning.

Suppose that conditioning on $\boldsymbol{x}_i$, $y_i$ has a density $f\{g(\boldsymbol{x}_i^T\boldsymbol{\beta}), y_i\}$, where $g$ is a known inverse link function. Define a penalized likelihood as

$$Q(\boldsymbol{\beta}) = \frac{1}{n}\sum_{i=1}^{n} \log f\{g(\boldsymbol{x}_i^T\boldsymbol{\beta}), y_i\} - \sum_{j=1}^{d} p_{\lambda_j}(|\beta_j|). \tag{4.1}$$

Maximizing the penalized likelihood results in a penalized likelihood estimator. For certain penalties, such as the SCAD, the selected model based on the nonconcave penalized likelihood satisfies $\beta_j = 0$ for certain $\beta_j$'s. Therefore, parameter estimation is performed at the same time as the model selection.

**Example** (*Logistics Regression*). Suppose that given $\boldsymbol{x}_i$, $y_i$ follows a Bernoulli distribution with success probability $P\{y_i = 1|\boldsymbol{x}_i\} = p(\boldsymbol{x}_i)$. Take $g(u) = \exp(u)/(1 + \exp(u))$, i.e. $p(\boldsymbol{x}) = \exp(\boldsymbol{x}^T\boldsymbol{\beta})/\{1 + \exp(\boldsymbol{x}^T\boldsymbol{\beta})\}$. Then (4.1) becomes

$$\frac{1}{n}\sum_{i=1}^{n}[y_i(\boldsymbol{x}_i^T\boldsymbol{\beta}) - \log\{1 + \exp(\boldsymbol{x}_i^T\boldsymbol{\beta})\}] - \sum_{j=1}^{d} p_{\lambda_j}(|\beta_j|).$$

Thus, variable selection for logistics regression can be achieved by maximizing the above penalized likelihood.

**Example** (*Poisson Log-linear Regression*). Suppose that given $\boldsymbol{x}_i$, $y_i$ follows a Poisson distribution with mean $\lambda(\boldsymbol{x}_i)$. Take $g(\cdot)$ to be the log-link, i.e. $\lambda(\boldsymbol{x}) = \exp(\boldsymbol{x}^T\boldsymbol{\beta})$. Then (4.1) can be written as

$$\frac{1}{n}\sum_{i=1}^{n}\{y_i(\boldsymbol{x}_i^T\boldsymbol{\beta}) - \exp(\boldsymbol{x}_i^T\boldsymbol{\beta})\} - \sum_{j=1}^{d} p_{\lambda_j}(|\beta_j|)$$

after dropping a constant. Thus, maximizing the above penalized likelihood with certain penalty functions yields a sparse solution for $\boldsymbol{\beta}$.

**4.1. Oracle properties.** Maximizing a penalized likelihood selects variables and estimates parameters simultaneously. This allows us to establish the sampling properties of the resulting estimators. Under certain regularity conditions, Fan and Li [33] demonstrated how the rates of convergence for the penalized likelihood estimators

depend on the regularization parameter $\lambda_n$ and established the oracle properties of the penalized likelihood estimators.

In the context of variable selection for high-dimensional modeling, it is natural to allow the number of introduced variables to grow with the sample sizes. Fan and Peng [35] have studied the asymptotic properties of the penalized likelihood estimator for situations in which the number of parameters, denoted by $d_n$, tends to $\infty$ as the sample size $n$ increases. Denote $\boldsymbol{\beta}_{n0}$ to be the true value of $\boldsymbol{\beta}$. To emphasize the dependence of $\lambda_j$ on $n$, we use notation $\lambda_{n,j}$ for $\lambda_j$ in this subsection. Define

$$a_n = \max\{p'_{\lambda_{n,j}}(|\beta_{n0j}|) : \beta_{n0j} \neq 0\} \quad \text{and} \quad b_n = \max\{|p''_{\lambda_{n,j}}(|\beta_{n0j}|)| : \beta_{n0j} \neq 0\}. \tag{4.2}$$

Fan and Peng [35] showed that if both $a_n$ and $b_n$ tend to 0 as $n \to \infty$, then under certain regularity conditions, there exists a local maximizer $\hat{\boldsymbol{\beta}}$ of $Q(\boldsymbol{\beta})$ such that

$$\|\hat{\boldsymbol{\beta}} - \boldsymbol{\beta}_{n0}\| = O_P\{\sqrt{d_n}(n^{-1/2} + a_n)\}. \tag{4.3}$$

It is clear from (4.3) that by choosing a proper $\lambda_{n,j}$ such that $a_n = O(n^{-1/2})$, there exists a root-$(n/d_n)$ consistent penalized likelihood estimator. For example, for the SCAD, the penalized likelihood estimator is root-$(n/d_n)$ consistent if all $\lambda_{n,j}$'s tend to 0.

Without loss of generality assume that, unknown to us, the first $s_n$ components of $\boldsymbol{\beta}_{n0}$, denoted by $\boldsymbol{\beta}_{n01}$, are nonzero and do not vanish and the remaining $d_n - s_n$ coefficients, denoted by $\boldsymbol{\beta}_{n02}$, are 0. Denote by

$$\Sigma = \operatorname{diag}\bigl\{p''_{\lambda_{n,1}}(|\beta_{n01}|), \ldots, p''_{\lambda_{n,s_n}}(|\beta_{n0s_n}|)\bigr\}$$

and

$$\boldsymbol{b} = \bigl(p'_{\lambda_{n,1}}(|\beta_{n01}|)\operatorname{sgn}(\beta_{n01}), \ldots, p'_{\lambda_{n,s_n}}(|\beta_{n0s_n}|)\operatorname{sgn}(\beta_{n0s_n})\bigr)^T.$$

**Theorem 1.** *Assume that as* $n \to \infty$, $\min_{1\le j\le s_n} |\beta_{n0j}|/\lambda_{n,j} \to \infty$ *and that the penalty function* $p_{\lambda_j}(|\beta_j|)$ *satisfies*

$$\liminf_{n\to\infty} \liminf_{\beta_j \to 0+} p'_{\lambda_{n,j}}(\beta_j)/\lambda_{n,j} > 0. \tag{4.4}$$

*If* $\lambda_{n,j} \to 0$, $\sqrt{n/d_n}\lambda_{n,j} \to \infty$ *and* $d_n^5/n \to 0$ *as* $n \to \infty$, *then with probability tending to* 1, *the root* $n/d_n$ *consistent local maximizers* $\hat{\boldsymbol{\beta}} = (\hat{\boldsymbol{\beta}}_{n1}^T, \hat{\boldsymbol{\beta}}_{n2}^T)^T$ *must satisfy:*

(i) *Sparsity:* $\hat{\boldsymbol{\beta}}_{n2} = \mathbf{0}$;

(ii) *Asymptotic normality: for any* $q \times s_n$ *matrix* $\boldsymbol{A}_n$ *such that* $\boldsymbol{A}_n\boldsymbol{A}_n^T \to \boldsymbol{G}$, *a* $q \times q$ *positive definite symmetric matrix,*

$$\sqrt{n}\boldsymbol{A}_n\boldsymbol{I}_1^{-1/2}\{\boldsymbol{I}_1 + \Sigma\}\bigl\{\hat{\boldsymbol{\beta}}_{n1} - \boldsymbol{\beta}_{n10} + (\boldsymbol{I}_1 + \Sigma)^{-1}\boldsymbol{b}\bigr\} \xrightarrow{\mathcal{D}} N(\mathbf{0}, \boldsymbol{G})$$

*where* $\boldsymbol{I}_1 = \boldsymbol{I}_1(\boldsymbol{\beta}_{n10}, \mathbf{0})$, *the Fisher information knowing* $\boldsymbol{\beta}_{n20} = \mathbf{0}$.

The theorem implies that any finite set of elements of $\hat{\boldsymbol{\beta}}_{n1}$ are jointly asymptotically normal. For the SCAD, if all $\lambda_{j,n} \to 0$, $a_n = 0$. Hence, when $\sqrt{n/d_n}\lambda_{n,j} \to \infty$, its corresponding penalized likelihood estimators possess the oracle property, i.e., perform as well as the maximum likelihood estimates for estimating $\boldsymbol{\beta}_{n1}$ knowing $\boldsymbol{\beta}_{n2} = \mathbf{0}$. That is, with probability approaching to 1,

$$\hat{\boldsymbol{\beta}}_{n2} = 0, \quad \text{and} \quad \sqrt{n}\boldsymbol{A}_n \boldsymbol{I}_1^{1/2}(\hat{\boldsymbol{\beta}}_{n1} - \boldsymbol{\beta}_{n10}) \to N(\mathbf{0}, \boldsymbol{G}).$$

For the $L_1$-penalty, $a_n = \max_j \lambda_{j,n}$. Hence, the root-$n/d_n$ consistency requires that $\lambda_{n,j} = O(\sqrt{d_n/n})$. On the other hand, the oracle property in Theorem 2 requires that $\sqrt{n/d_n}\lambda_{n,j} \to \infty$. These two conditions for LASSO cannot be satisfied simultaneously. It has indeed been shown that the oracle property does not hold for the $L_1$-penalty even in the finite parameter setting [90].

**4.2. Risk minimization and persistence.** In machine learning such as tumor classifications, the primary interest centers on the misclassification errors or more generally expected losses, not the accuracy of estimated parameters. This kind of properties is called persistence in [42], [43].

Consider predicting the response $Y$ using a class of model $g(\boldsymbol{x}^T\boldsymbol{\beta})$ with a loss function $\ell\{g(\boldsymbol{X}^T\boldsymbol{\beta}), Y)$. Then the risk is

$$L_n(\boldsymbol{\beta}) = E\ell\{g(\boldsymbol{X}^T\boldsymbol{\beta}), Y\},$$

where $n$ is used to stress the dependence of dimensionality $d$ on $n$. The minimum risk is obtained at $\boldsymbol{\beta}_n^* = \operatorname{argmin}_{\boldsymbol{\beta}} L_n(\boldsymbol{\beta})$. In the likelihood context, $\ell = -\log f$. Suppose that there is an estimator $\hat{\boldsymbol{\beta}}_n$ based on a sample of size $n$. This can be done by the penalized empirical risk minimization similarly to (4.1):

$$n^{-1}\sum_{i=1}^{n} \ell\{g(\boldsymbol{x}_i^T\boldsymbol{\beta}), y_i\} + \sum_{j=1}^{d} p_{\lambda_j}(|\beta_j|), \tag{4.5}$$

based on a set of training data $\{(\boldsymbol{x}_i, y_i), i = 1, \ldots, n\}$. The persistence requires

$$L_n(\hat{\boldsymbol{\beta}}_n) - L_n(\boldsymbol{\beta}_n^*) \xrightarrow{P} 0, \tag{4.6}$$

but not necessarily the consistency of $\hat{\boldsymbol{\beta}}_n$ to $\boldsymbol{\beta}_n^*$. This is in general a much weaker mathematical requirement. Greenshtein and Ritov [43] show that if the non-sparsity rate $s_n = O\{(n/\log n)^{1/2}\}$ and $d_n = n^\alpha$ for some $\alpha > 1$, LASSO (penalized $L_1$ least-squares) is persistent under the quadratic loss. Greenshtein [42] extends the results to the case where $s_n = O\{n/\log n\}$ and more general loss functions. Meinshausen [66] considers a case with finite non-sparsity $s_n$ but with $\log d_n = n^\xi$, with $\xi \in (0, 1)$. It is shown there that for the quadratic loss, LASSO is persistent, but the rate to persistency is slower than a relaxed LASSO. This again shows the bias problems in LASSO.

**4.3. Issues in practical implementation.** In this section, we address practical implementation issues related to the PLS and penalized likelihood.

**Local quadratic approximation (LQA).** The $L_p$, $(0 < p < 1)$, and SCAD penalty functions are singular at the origin, and they do not have continuous second order derivatives. Therefore, maximizing the nonconcave penalized likelihood is challenging. Fan and Li [33] propose locally approximating them by a quadratic function as follows. Suppose that we are given an initial value $\boldsymbol{\beta}^0$ that is close to the optimizer of $Q(\boldsymbol{\beta})$. For example, take initial value to be the maximum likelihood estimate (without penalty). Under some regularity conditions, the initial value is a consistent estimate for $\boldsymbol{\beta}$, and therefore it is close to the true value. Thus, we can locally approximate the penalty function by a quadratic function as

$$p_{\lambda_n}(|\beta_j|) \approx p_{\lambda_n}(|\beta_j^0|) + \frac{1}{2}\{p'_{\lambda_n}(|\beta_j^0|)/|\beta_j^0|\}(\beta_j^2 - \beta_j^{02}), \quad \text{for } \beta_j \approx \beta_j^0. \tag{4.7}$$

To avoid numerical instability, we set $\hat{\beta}_j = 0$ if $\beta_j^0$ is very close to 0. This corresponds to deleting $x_j$ from the final model. With the aid of the LQA, the optimization of penalized least-squares, penalized likelihood or penalized partial likelihood (see Section 6.2) can be carried out by using the Newton–Raphson algorithm. It is worth noting that the LQA should be updated at each step during the course of iteration of the algorithm. We refer to the modified Newton–Raphson algorithm as the LQA algorithm.

The convergence property of the LQA algorithm was studied in [52], whose authors first showed that the LQA plays the same role as the E-step in the EM algorithm [18]. Therefore the behavior of the LQA algorithm is similar to the EM algorithm. Unlike the original EM algorithm, in which a full iteration for maximization is carried out after every E-step, we update the LQA at each step during the iteration course. This speeds up the convergence of the algorithm. The convergence rate of the LQA algorithm is quadratic which is the same as that of the modified EM algorithm [56].

When the algorithm converges, the estimator satisfies the condition

$$\partial \ell(\hat{\boldsymbol{\beta}})/\partial \beta_j + n p'_{\lambda_j}(|\hat{\beta}_j|)\operatorname{sgn}(\hat{\beta}_j) = 0,$$

the penalized likelihood equation, for non-zero elements of $\hat{\boldsymbol{\beta}}$.

**Standard error formula.** Following conventional techniques in the likelihood setting, we can estimate the standard error of the resulting estimator by using the sandwich formula. Specifically, the corresponding sandwich formula can be used as an estimator for the covariance of the estimator $\hat{\boldsymbol{\beta}}_1$, the non-vanishing component of $\hat{\boldsymbol{\beta}}$. That is,

$$\widehat{\operatorname{cov}}(\hat{\boldsymbol{\beta}}_1) = \{\nabla^2 \ell(\hat{\boldsymbol{\beta}}_1) - n\Sigma_\lambda(\hat{\boldsymbol{\beta}}_1)\}^{-1} \widehat{\operatorname{cov}}\{\nabla \ell(\hat{\boldsymbol{\beta}}_1)\}\{\nabla^2 \ell(\hat{\boldsymbol{\beta}}_1) - n\Sigma_\lambda(\hat{\boldsymbol{\beta}}_1)\}^{-1}, \tag{4.8}$$

where $\widehat{\operatorname{cov}}\{\nabla \ell(\hat{\boldsymbol{\beta}}_1)\}$ is the usual empirically estimated covariance matrix and

$$\Sigma_\lambda(\hat{\boldsymbol{\beta}}_1) = \operatorname{diag}\{p'_{\lambda_1}(|\hat{\beta}_1|)/|\hat{\beta}_1|, \ldots, p'_{\lambda_{s_n}}(|\hat{\beta}_{s_n}|)/|\hat{\beta}_{s_n}|\}$$

and $s_n$ the dimension of $\hat{\boldsymbol{\beta}}_1$. Fan and Peng [35] demonstrated the consistency of the sandwich formula:

**Theorem 2.** *Under the conditions of Theorem* 1*, we have*

$$\boldsymbol{A}_n \widehat{\mathrm{cov}}(\hat{\boldsymbol{\beta}}_1)\boldsymbol{A}_n^T - \boldsymbol{A}_n \Sigma_n \boldsymbol{A}_n^T \xrightarrow{P} 0 \quad \text{as } n \to \infty$$

*for any matrix* $\boldsymbol{A}_n$ *such that* $\boldsymbol{A}_n \boldsymbol{A}_n^T = \boldsymbol{G}$*, where* $\Sigma_n = (\boldsymbol{I}_1 + \Sigma)^{-1}\boldsymbol{I}_1^{-1}(\boldsymbol{I}_1 + \Sigma)^{-1}$.

**Selection of regularization parameters.** To implement the methods described in previous sections, it is desirable to have an automatic method for selecting the thresholding parameter $\lambda$ in $p_\lambda(\cdot)$ based on data. Here, we estimate $\lambda$ via minimizing an approximate generalized cross-validation (GCV) statistic in [11]. By some straightforward calculation, the effective number of parameters for $Q(\boldsymbol{\beta})$ in the last step of the Newton–Raphson algorithm iteration is

$$e(\boldsymbol{\lambda}) \equiv e(\lambda_1, \ldots, \lambda_d) = \mathrm{tr}[\{\nabla^2 \ell(\hat{\boldsymbol{\beta}}) - n\Sigma_\lambda(\hat{\boldsymbol{\beta}})\}^{-1}\nabla^2 \ell(\hat{\boldsymbol{\beta}})].$$

Therefore the generalized cross-validation statistic is defined by

$$\mathrm{GCV}(\boldsymbol{\lambda}) = -\ell(\hat{\boldsymbol{\beta}})/[n\{1 - e(\boldsymbol{\lambda})/n\}^2]$$

and $\hat{\boldsymbol{\lambda}} = \mathrm{argmin}_{\boldsymbol{\lambda}}\{\mathrm{GCV}(\boldsymbol{\lambda})\}$ is selected.

To find an optimal $\boldsymbol{\lambda}$, we need to minimize the GCV over a $d_n$-dimensional space. This is an unduly onerous task. Intuitively, it is expected that the magnitude of $\lambda_j$ should be proportional to the standard error of the maximum likelihood estimate of $\beta_j$. Thus, we set $\boldsymbol{\lambda} = \lambda \mathrm{se}(\hat{\boldsymbol{\beta}}_{\mathrm{MLE}})$ in practice, where $\mathrm{se}(\hat{\boldsymbol{\beta}}_{\mathrm{MLE}})$ denotes the standard error of the MLE. Therefore, we minimize the GCV score over the one-dimensional space, which will save a great deal of computational cost. The behavior of such a method has been investigated recently.

## 5. Applications to function estimation

Let us begin with one-dimensional function estimation. Suppose that we have noisy data at possibly irregular design points $\{x_1, \ldots, x_n\}$:

$$y_i = m(x_i) + \varepsilon_i,$$

where $m$ is an unknown regression and $\varepsilon_i$'s are iid random error following $N(0, \sigma^2)$. Local modeling techniques [31] have been widely used to estimate $m(\cdot)$. Here we focus on global function approximation methods.

Wavelet transforms are a device for representing functions in a way that is local in both time and frequency domains [13], [14], [64], [65]. During the last decade, they have received a great deal of attention in applied mathematics, image analysis, signal

compression, and many other fields of engineering. Daubechies [17] and Meyer [68] are good introductory references to this subject. Wavelet-based methods have many exciting statistical properties [23]. Earlier papers on wavelets assume the regular design points, i.e, $x_i = \frac{i}{n}$ (usually $n = 2^k$ for some integer $k$) so that fast computation algorithms can be implemented. See [24] and references therein. For an overview of wavelets in statistics, see [87].

Antoniadis and Fan [1] discussed how to apply wavelet methods for function estimation with irregular design points using penalized least squares. Without loss of generality, assume that $m(x)$ is defined on [0, 1]. By moving nondyadic points to dyadic points, we assume $x_i = n_i/2^J$ for some $n_i$ and some fine resolution $J$ that is determined by users. To make this approximation errors negligible, we take $J$ large enough such that $2^J \geq n$. Let $\boldsymbol{W}$ be a given wavelet transform at all dyadic points $\{i/2^J :, i = 1, \ldots, 2^J - 1\}$. Let $N = 2^J$ and $\boldsymbol{a}_i$ be the $n_i$-th column of $\boldsymbol{W}$, an $N \times N$ matrix, and $\boldsymbol{\beta} = \boldsymbol{W}\boldsymbol{m}$ be the wavelet transform of the function $m$ at dyadic points. Then it is easy to see that $m(x_i) = \boldsymbol{a}_i^T \boldsymbol{\beta}$. This yields an overparameterized linear model

$$y_i = \boldsymbol{a}_i^T \boldsymbol{\beta} + \varepsilon_i, \tag{5.1}$$

which aims at reducing modeling biases. However, one cannot find a reasonable estimate of $\boldsymbol{\beta}$ by using the ordinary least squares method since $N \geq n$. Directly applying penalized least squares, we have

$$\frac{1}{2n} \sum_{i=1}^{n} (y_i - \boldsymbol{a}_i^T \boldsymbol{\beta})^2 + \sum_{j=1}^{N} p_{\lambda_j}(|\beta_j|). \tag{5.2}$$

If the sampling points are equally spaced and $n = 2^J$, the corresponding design matrix of linear model (5.1) becomes a square orthogonal matrix. From the discussion in Section 3, minimizing the PLS (5.2) with the entropy penalty or the hard-thresholding penalty results in a hard-thresholding rule. With the $L_1$ penalty, the PLS estimator is the soft-thresholding rule. Assume that $p_\lambda(\cdot)$ is nonnegative, nondecreasing, and differentiable over $(0, \infty)$ and that function $-\beta - p'_\lambda(\beta)$ is strictly unimodal on $(0, \infty)$, $p'_\lambda(\cdot)$ is nonincreasing and $p'_\lambda(0+) > 0$. Then Antoniadis and Fan [1] showed that the resulting penalized least-squares estimator that minimizes (5.2) is adaptively minimax within a factor of logarithmic order as follows. Define the Besov space ball $B^r_{p,q}(C)$ to be

$$B^r_{p,q}(C) = \left\{ m \in L_p : \textstyle\sum_j (2^{j(r+1/2-1/p)} \|\boldsymbol{\theta}_{j\cdot}\|_p)^q < C \right\},$$

where $\boldsymbol{\theta}_{j\cdot}$ is the vector of wavelet coefficients of function $m$ at the resolution level $j$. Here $r$ indicates the degree of smoothness of the regression functions $m$.

**Theorem 3.** *Suppose that the regression function $m(\cdot)$ is in a Besov ball with $r + 1/2 - 1/p > 0$. Then the maximum risk of the PLS estimator $\hat{m}(\cdot)$ over $B^r_{p,q}(C)$ is of rate $O(n^{-2r/(2r+1)} \log(n))$ when the universal thresholding $\sqrt{2\log(n)/n}$ is used. It also achieves the rate of convergence $O\{n^{-2r/(2r+1)} \log(n)\}$ when the minimax thresholding $p_n/\sqrt{n}$ is used, where $p_n$ is given in* [1].

We next consider multivariate regression function estimation. Suppose that $\{\boldsymbol{x}_i, y_i\}$ is a random sample from the regression model

$$y = m(\boldsymbol{x}) + \varepsilon,$$

where, without loss of generality, it is assumed that $\boldsymbol{x} \in [0, 1]^d$. Radial basis and neural-network are also popular for approximating multi-dimensional functions. In the literature of spline smoothing, it is typically assumed that the mean function $m(\boldsymbol{x})$ has a low-dimensional structure. For example,

$$m(\boldsymbol{x}) = \mu_0 + \sum_j m_j(x_j) + \sum_{k<l} m_{kl}(x_k, x_l).$$

For given knots, a set of spline basis functions can be constructed. The two most popular spline bases are the truncated power spline basis $1, x, x^2, x^3, (x - t_j)_+^3$, $(j = 1, \ldots, J)$, where $t_j$'s are knots, and the B-spline basis (see [6] for definition). The $B$-spline basis is numerically more stable since the multiple correlation among the basis functions is smaller, but the power truncated spline basis has the advantage that deleting a basis function is the same as deleting a knot.

For a given set of 1-dimensional spline bases, we can further construct a multivariate spline basis using tensor products. Let $\{B_1, \ldots, B_J\}$ be a set of spline basis functions on $[0, 1]^d$. Approximate the regression function $m(\boldsymbol{x})$ by a linear combination of the basis functions, $\sum \beta_j B_j(\boldsymbol{x})$, say. To avoid a large approximation bias, we take a large $J$. This yields an overparameterized linear model, and the fitted curve of the least squares estimate is typically undersmooth. Smoothing spline suggested penalizing the roughness of the resulting estimate. This is equivalent to the penalized least squares with a quadratic penalty. In a series of work by Stone and his collaborators (see [76]), they advocate using regression splines and modifying traditional variable selection approaches to select useful spline subbases. Ruppert *et al.* [75] advocated penalized splines in statistical modeling, in which power truncated splines are used with the $L_2$ penalty. Another kind of penalized splines method proposed by [28] shares the same spirit of [75].

## 6. Some solutions to the challenges

In this section, we provide some solutions to problems raised in Section 2.

**6.1. Computational biology.** As discussed in Section 2.1, the first statistical challenge in computational biology is how to remove systematic biases due to experiment variations. Thus, let us first discuss the issue of normalization of cDNA-microarrays. Let $Y_g$ be the log-ratio of the intensity of gene $g$ of the treatment sample over that of the control sample. Denote by $X_g$ the average of the log-intensities of gene $g$ at the treatment and control samples. Set $r_g$ and $c_g$ be the row and column of the block

where the cDNA of gene $g$ resides. Fan *et al.* [37] use the following model to estimate the intensity and block effect:

$$Y_g = \alpha_g + \beta_{r_g} + \gamma_{c_g} + f(X_g) + \varepsilon_g, \quad g = 1, \ldots, N \tag{6.1}$$

where $\alpha_g$ is the treatment effect on gene $g$, $\beta_{r_g}$ and $\gamma_{c_g}$ are block effects that are decomposed into the column and row effect, $f(X_g)$ represents the intensity effect and $N$ is the total number of genes. Based on $J$ arrays, an aim of microarray data analysis is to find genes $g$ with $\alpha_g$ statistically significantly different from 0. However, before carrying multiple array comparisons, the block and treatment effects should first be estimated and removed. For this normalization purpose, parameters $\alpha_g$ are nuisance and high-dimensional (recall $N$ is in the order of tens of thousands). On the other hand, the number of significantly expressed genes is relatively small, yielding the sparsity structure of $\alpha_g$.

Model (6.1) is not identifiable. Fan *et al.* [37] use within-array replicates to infer about the block and treatment effects. Suppose that we have $I$ replications for $G$ genes, which could be a small fraction of $N$. For example, in [37], only 111 genes were repeated at random blocks ($G = 111$, $I = 2$), whereas in [63], all genes were repeated three times, i.e. $I = 3$ and $N = 3G$, though both have about $N \approx 20,000$ genes printed on an array. Using $I$ replicated data on $G$ genes, model (6.1) becomes

$$Y_{gi} = \alpha_g + \beta_{r_{gi}} + \gamma_{c_{gi}} + f(X_{gi}) + \varepsilon_{gi}, \quad g = 1, \ldots, G, \ i = 1, \ldots, I. \tag{6.2}$$

With estimated coefficients $\hat{\beta}$ and $\hat{\gamma}$ and the function $\hat{f}$, model (6.1) implies that the normalized data are $Y_g^* = Y_g - \hat{\beta}_{r_g} - \hat{\gamma}_{c_g} - \hat{f}(X_g)$ even for non-repeated genes.

Model (6.2) can be used to remove the intensity effect array by array, though the number of nuisance parameters is very large, a fraction of total sample size in (6.2). To improve the efficiency of estimation, Fan *et al.* [36] aggregate the information from other microarrays (total $J$ arrays):

$$Y_{gij} = \alpha_g + \beta_{r_{gi},j} + \gamma_{c_{gi},j} + f_j(X_{gij}) + \varepsilon_{gi}, \quad j = 1, \ldots, J, \tag{6.3}$$

where the subscript $j$ denotes the array effect.

The parameters in (6.2) can be estimated by the profile least-squares method using the Gauss–Seidel type of algorithm. See [36] for details. To state the results, let us write model (6.2) as

$$Y_{gi} = \alpha_g + \boldsymbol{Z}_{gi}^T \boldsymbol{\beta} + f(X_{gi}) + \varepsilon_{gi}, \tag{6.4}$$

by appropriately introducing the dummy variable $\boldsymbol{Z}$. Fan *et al.* [36] obtained the following results.

**Theorem 4.** *Under some regularity conditions, as $n = IG \to \infty$, the profile least-squares estimator of model* (6.4) *has*

$$\sqrt{n}(\hat{\boldsymbol{\beta}} - \boldsymbol{\beta}) \xrightarrow{\mathcal{D}} N\Big(0, \frac{I}{I-1}\sigma^2 \Sigma^{-1}\Big),$$

*where* $\Sigma = E\{\mathrm{Var}(\mathbf{Z}|X)\}$ *and* $\sigma^2 = \mathrm{Var}(\varepsilon)$. *In addition,* $\hat{f}(x) - f(x) = O_P(n^{-2/5})$.

**Theorem 5.** *Under some regularity conditions, as* $n = IG \to \infty$, *when* $X$ *and* $\mathbf{Z}$ *are independent, the profile least-squares estimator based on* (6.3) *possesses*

$$\sqrt{n}(\hat{\boldsymbol{\beta}}_j - \boldsymbol{\beta}_j) \xrightarrow{\mathcal{D}} N\Big(0, \frac{I(J-1)+1}{J(I-1)}\,\sigma^2\Sigma^{-1}\Big).$$

The above theorems show that the block effect can be estimated at rate $O_P(n^{-1/2})$ and intensity effect $f$ can be estimated at rate $O_P(n^{-2/5})$. This rate can be improved to $O_P(n^{-1/2} + N^{-2/5})$ when data in (6.1) are all used. The techniques have also been adapted for the normalization of Affymetrix arrays [30]. Once the arrays have been normalized, the problem becomes selecting significantly expressed genes using the normalized data

$$Y^*_{gj} = \alpha_g + \varepsilon_{gj}, \quad g = 1, \ldots, N,\ j = 1, \ldots, J, \tag{6.5}$$

where $Y^*_{gj}$ is the normalized expression of gene $g$ in array $j$. This is again a high-dimensional statistical inference problem. The issues of computing P-values and false discovery are given in Section 2.1.

Estimation of high-dimensional covariance matrices is critical in studying genetic networks. PLS and penalized likelihood can be used to estimate large scale covariance matrices effectively and parsimoniously [49], [59]. Let $\boldsymbol{w} = (W_1, \ldots, W_d)^T$ be a $d$-dimensional random vector with mean zero and covariance $\Sigma$. Using the modified Cholesky decomposition, we have $\boldsymbol{L}\Sigma\boldsymbol{L}^T = \boldsymbol{D}$, where $\boldsymbol{L}$ is a lower triangular matrix having ones on its diagonal and typical element $-\phi_{tj}$ in the $(t, j)$th position for $1 \le j < t \le d$, and $\boldsymbol{D} = \mathrm{diag}\{\sigma_1^2, \ldots, \sigma_d^2)^T$ is a diagonal matrix. Denote $\boldsymbol{e} = \boldsymbol{L}\boldsymbol{w} = (e_1, \ldots, e_d)^T$. Since $\boldsymbol{D}$ is diagonal, $e_1, \ldots, e_d$ are uncorrelated. Thus, for $2 \le t \le d$

$$W_t = \sum_{j=1}^{t-1} \phi_{tj} W_j + e_t. \tag{6.6}$$

That is, the $W_t$ is an autoregressive (AR) series, which gives an interpretation for elements of $L$ and $D$, and allows us to use PLS for covariance selection. We first estimate $\sigma_t^2$ using the mean squared errors of model (6.6). Suppose that $\boldsymbol{w}_i$, $i = 1, \ldots, n$, is a random sample from $\boldsymbol{w}$. For $t = 2, \ldots, d$, covariance selection can be achieved by minimizing the following PLS functions:

$$\frac{1}{2n}\sum_{i=1}^{n}\Big(W_{it} - \sum_{j=1}^{t-1}\phi_{tj}W_{ij}\Big)^2 + \sum_{j=1}^{t-1} p_{\lambda_{t,j}}(|\phi_{tj}|). \tag{6.7}$$

This reduces the non-sparse elements in the lower triangle matrix $\boldsymbol{L}$. With estimated $\boldsymbol{L}$, the diagonal elements can be estimated by the sample variance of the components in $\hat{L}\boldsymbol{w}_i$. The approach can easily be adapted to estimate the sparse precision matrix $\Sigma^{-1}$. See [67] for a similar approach and a thorough study.

**6.2. Health studies.** Survival data analysis has been a very active research topic because survival data are frequently collected from reliability analysis, medical studies, and credit risks. In practice, many covariates are often available as potential risk factors. Selecting significant variables plays a crucial role in model building for survival data but is challenging due to the complicated data structure. Fan and Li [34] derived the nonconcave penalized partial likelihood for Cox's model and Cox's frailty model, the most commonly used semiparametric models in survival analysis. Cai *et al.* [9] proposed a penalized pseudo partial likelihood for marginal Cox's model with multivariate survival data and applied the proposed methodology for a subset data in the Framingham study, introduced in Section 2.2.

Let $T$, $C$ and $\boldsymbol{x}$ be respectively the survival time, the censoring time and their associated covariates. Correspondingly, let $Z = \min\{T, C\}$ be the observed time and $\delta = I(T \leq C)$ be the censoring indicator. It is assumed that $T$ and $C$ are conditionally independent given $\boldsymbol{x}$, that the censoring mechanism is noninformative, and that the observed data $\{(\boldsymbol{x}_i, Z_i, \delta_i) : i = 1, \ldots, n\}$ is an independently and identically distributed random sample from a certain population $(\boldsymbol{x}, Z, \delta)$. The Cox model assumes the conditional hazard function of $T$ given $\boldsymbol{x}$

$$h(t|\boldsymbol{x}) = h_0(t)\exp(\boldsymbol{x}^T\boldsymbol{\beta}), \tag{6.8}$$

where $h_0(t)$ is an unspecified baseline hazard function. Let $t_1^0 < \cdots < t_N^0$ denote the ordered observed failure times. Let $(j)$ provide the label for the item failing at $t_j^0$ so that the covariates associated with the $N$ failures are $\boldsymbol{x}_{(1)}, \ldots, \boldsymbol{x}_{(N)}$. Let $R_j$ denote the risk set right before the time $t_j^0 : R_j = \{i : Z_i \geq t_j^0\}$. Fan and Li [34] proposed the penalized partial likelihood

$$Q(\boldsymbol{\beta}) = \sum_{j=1}^{N}\Big[\boldsymbol{x}_{(j)}^T\boldsymbol{\beta} - \log\Big\{\sum_{i\in R_j}\exp(\boldsymbol{x}_i^T\boldsymbol{\beta})\Big\}\Big] - n\sum_{j=1}^{d} p_{\lambda_j}(|\beta_j|). \tag{6.9}$$

The penalized likelihood estimate of $\boldsymbol{\beta}$ is to maximize (6.9) with respect to $\boldsymbol{\beta}$.

For finite parameter settings, Fan and Li [34] showed that under certain regularity conditions, if both $a_n$ and $b_n$ tend to 0, then there exists a local maximizer $\hat{\boldsymbol{\beta}}$ of the penalized partial likelihood function in (6.9) such that $\|\hat{\boldsymbol{\beta}} - \boldsymbol{\beta}_0\| = O_P(n^{-1/2} + a_n)$. They further demonstrated the following oracle property.

**Theorem 6.** *Assume that the penalty function $p_{\lambda_n}(|\beta|)$ satisfies condition* (4.4). *If $\lambda_{n,j} \to 0$, $\sqrt{n}\lambda_{n,j} \to \infty$ and $a_n = O(n^{-1/2})$, then under some mild regularity conditions, with probability tending to* 1, *the root n consistent local maximizer $\hat{\boldsymbol{\beta}} = (\hat{\boldsymbol{\beta}}_1^T, \hat{\boldsymbol{\beta}}_2^T)^T$ of $Q(\boldsymbol{\beta})$ defined in* (6.9) *must satisfy*

$$\hat{\boldsymbol{\beta}}_2 = \mathbf{0}, \quad \textit{and} \quad \sqrt{n}(I_1 + \Sigma)\big\{\hat{\boldsymbol{\beta}}_1 - \boldsymbol{\beta}_{10} + (I_1 + \Sigma)^{-1}\boldsymbol{b}\big\} \xrightarrow{\mathcal{D}} N\big\{\mathbf{0}, I_1(\boldsymbol{\beta}_{10})\big\},$$

*where $I_1$ is the first $s \times s$ submatrix of the Fisher information matrix $I(\boldsymbol{\beta}_0)$ of the partial likelihood.*

Cai *et al.* [9] investigated the sampling properties of penalized partial likelihood estimate with a diverging number of predictors and clustered survival data. They showed that the oracle property is still valid for penalized partial likelihood estimation for the Cox marginal models with multivariate survival data.

**6.3. Financial engineering and risk management.** There are many outstanding challenges of dimensionality in diverse fields of financial engineering and risk management. To be concise, we focus only on the issue of covariance matrix estimation using a factor model.

Let $Y_i$ be the excess return of the $i$-th asset over the risk-free asset. Let $f_1, \ldots, f_K$ be the factors that influence the returns of the market. For example, in the Fama–French 3-factor model, $f_1$, $f_2$ and $f_3$ are respectively the excessive returns of the market portfolio, which is the value-weighted return on all NYSE, AMEX and NASDAQ stocks over the one-month Treasury bill rate, a portfolio constructed based on the market capitalization, and a portfolio constructed based on the book-to-market ratio. Of course, constructing factors that influence the market itself is a high-dimensional model selection problem with massive amount of trading data. The $K$-factor model [15], [74] assumes

$$Y_i = b_{i1} f_1 + \cdots + b_{iK} f_K + \varepsilon_i, \quad i = 1, \ldots, d, \tag{6.10}$$

where $\{\varepsilon_i\}$ are idiosyncratic noises, uncorrelated with the factors, and $d$ is the number of assets under consideration. This an extension of the famous Capital Asset Pricing Model derived by Sharpe and Lintner (See [10], [12]). Putting it into the matrix form, we have $\boldsymbol{y} = \boldsymbol{B}\boldsymbol{f} + \boldsymbol{\varepsilon}$ so that

$$\Sigma = \mathrm{Var}(\boldsymbol{B}\boldsymbol{f}) + \mathrm{Var}(\boldsymbol{\varepsilon}) = \boldsymbol{B}\,\mathrm{Var}(\boldsymbol{f})\boldsymbol{B}^T + \Sigma_0, \tag{6.11}$$

where $\Sigma = \mathrm{Var}(\boldsymbol{y})$ and $\Sigma_0 = \mathrm{Var}(\boldsymbol{\varepsilon})$ is assumed to be diagonal.

Suppose that we have observed the returns of $d$ stocks over $n$ periods (e.g., 3 years daily data). Then, applying the least-squares estimate separately to each stock in (6.10), we obtain the estimates of coefficients in $\boldsymbol{B}$ and $\Sigma_0$. Now, estimating $\mathrm{Var}(\boldsymbol{f})$ by its sample variance, we obtain a substitution estimator $\widehat{\Sigma}$ using (6.11). On the other hand, we can also use the sample covariance matrix, denoted by $\widehat{\Sigma}_{\mathrm{sam}}$, as an estimator.

In the risk management or portfolio allocation, the number of stocks $d$ can be comparable with the sample size $n$ so it is better modeled as $d_n$. Fan *et al.* [32] investigated thoroughly when the estimate $\widehat{\Sigma}$ outperforms $\widehat{\Sigma}_{\mathrm{sam}}$ via both asymptotic and simulation studies. Let us quote some of their results.

**Theorem 7.** *Let $\lambda_k(\Sigma)$ be the $k$-th largest eigenvalue of $\Sigma$. Then, under some regularity conditions, we have*

$$\max_{1\le k\le d_n} |\lambda_k(\widehat{\Sigma}) - \lambda_k(\Sigma)| = o_P\{(\log n\, d_n^2/n)^{1/2}\} = \max_{1\le k\le d_n} |\lambda_k(\widehat{\Sigma}_{\mathrm{sam}}) - \lambda_k(\Sigma)|.$$

*For a selected portfolio weight $\boldsymbol{\xi}_n$ with $\mathbf{1}^T\boldsymbol{\xi}_n = 1$, we have*

$$\left|\boldsymbol{\xi}_n^T\widehat{\Sigma}\boldsymbol{\xi}_n - \boldsymbol{\xi}_n^T\Sigma\boldsymbol{\xi}_n\right| = o_P\{(\log n\, d_n^4/n)^{1/2}\} = \left|\boldsymbol{\xi}_n^T\widehat{\Sigma}_{\text{sam}}\boldsymbol{\xi}_n - \boldsymbol{\xi}_n^T\Sigma_n\boldsymbol{\xi}_n\right|.$$

*If, in addition, the all elements in $\boldsymbol{\xi}_n$ are positive, then the latter rate can be replaced by $o_P\{(\log n\, d_n^2/n)^{1/2}\}$.*

The above result shows that for risk management where the portfolio risk is $\boldsymbol{\xi}_n^T\Sigma\boldsymbol{\xi}_n$, no substantial gain can be realized by using the factor model. Indeed, there is no substantial gain for estimating the covariance matrix even if the factor model is correct. These have also convincingly been demonstrated in [32] using simulation studies. Fan *et al.* [32] also gives the order $d_n$ under which the covariance matrix can be consistently estimated.

The substantial gain can be realized if $\Sigma^{-1}$ is estimated. Hence, the factor model can be used to improve the construction of the optimal mean-variance portfolio, which involves the inverse of the covariance matrix. Let us quote one theorem of [32]. See other results therein for optimal portfolio allocation.

**Theorem 8.** *Under some regularity conditions, if $d_n = n^\alpha$, then for $0 \le \alpha < 2$,*

$$d_n^{-1}\text{tr}(\Sigma^{-1/2}\widehat{\Sigma}\Sigma^{-1/2} - I_{d_n})^2 = O_P(n^{-2\beta})$$

*with $\beta = \min(1/2, 1-\alpha/2)$, whereas for $\alpha < 1$, $d_n^{-1}\text{tr}(\Sigma^{-1/2}\widehat{\Sigma}_{\text{sam}}\Sigma^{-1/2} - I_{d_n})^2 = O_P(d_n/n)$. In addition, under the Frobenius norm*

$$d_n^2\|\widehat{\Sigma}^{-1} - \Sigma^{-1}\|^2 = o(d_n^4\log n/n) = \|\widehat{\Sigma}_{\text{sam}}^{-1} - \Sigma^{-1}\|^2.$$

**6.4. Machine learning and data mining.** In machine learning, our goal is to build a model with the capability of good prediction of future observations. Prediction error depends on the loss function, which is also referred to as a divergence measure. Many loss functions are used in the literature. To address the versatility of loss functions, let us use the device introduced by [7]. For a concave function $q(\cdot)$, define a $q$-class of loss function $\ell(\cdot,\cdot)$ to be

$$\ell(y,\hat{m}) = q(\hat{m}) - q(y) - q'(\hat{m})(\hat{m} - y) \tag{6.12}$$

where $\hat{m} \equiv \hat{m}(\boldsymbol{x})$, an estimate of the regression function $m(\boldsymbol{x}) = E(y|\boldsymbol{x})$. Due to the concavity of $q$, $\ell(\cdot,\cdot)$ is non-negative.

Here are some notable examples of $\ell$-loss constructed from the $q$-function. For binary classification, $y \in \{-1, 1\}$. Letting $q(m) = 0.5\min\{1-m, 1+m\}$ yields the misclassification loss, $\ell_1(y,\hat{m}) = I\{y \ne I(\hat{m} > 0)\}$. Furthermore, $\ell_2(y,\hat{m}) = [1 - y\text{sgn}(\hat{m})]_+$ is the hinge loss if $q(m) = \frac{1}{4}\min\{1-m, 1+m\}$. The function $q_3(m) = \sqrt{1-m^2}$ results in $\ell_3(y,\hat{m}) = \exp\{-0.5y\log\{(1+\hat{m})/(1-\hat{m})\}$, the exponential loss function in AdaBoost [40]. Taking $q(m) = cm - m^2$ for some constant $c$ results in the quadratic loss $\ell_4(y,\hat{m}) = (y-\hat{m})^2$.

For a given loss function, we may extend the PLS to a penalized empirical risk minimization (4.5). The dimensionality $d$ of the feature vectors can be much larger than $n$ and hence the penalty is needed to select important feature vectors. See, for example, [4] for an important study in this direction.

We next make a connection between the penalized loss function and the popularly used support vector machines (SVMs), which have been successfully applied to various classification problems. In binary classification problems, the response $y$ takes values either 1 or $-1$, the class labels. A classification rule $\delta(\boldsymbol{x})$ is a mapping from the feature vector $\boldsymbol{x}$ to $\{1, -1\}$. Under the 0–1 loss, the misclassification error of $\delta$ is $P\{y \neq \delta(\boldsymbol{x})\}$. The smallest classification error is the Bayes error achieved by $\text{argmin}_{c\in\{1,-1\}} P(y = c|\boldsymbol{x})$. Let $\{\boldsymbol{x}_i, y_i\}$, $i = 1, \ldots, n$ be a set of training data, where $\boldsymbol{x}_i$ is a vector with $d$ features, and the output $y_i \in \{1, -1\}$ denotes the class label. The 2-norm SVM is to find a hyperplane $\boldsymbol{x}^T\boldsymbol{\beta}$, in which $x_{i1} = 1$ is an intercept and $\boldsymbol{\beta} = (\beta_1, \boldsymbol{\beta}_{(2)}^T)^T$, that creates the biggest margin between the training points from class 1 and $-1$ [85]:

$$\max_{\boldsymbol{\beta}} \frac{1}{\|\boldsymbol{\beta}_{(2)}\|^2} \quad \text{subject to } y_i(\boldsymbol{\beta}^T\boldsymbol{x}_i) \geq 1 - \xi_i, \text{ for all } i, \xi_i \geq 0, \sum \xi_i \leq B, \quad (6.13)$$

where $\xi_i$ are slack variables, and $B$ is a pre-specified positive number that controls the overlap between the two classes. Due to its elegant margin interpretation and highly competitive performance in practice, the 2-norm SVM has become popular and has been applied for a number of classification problems. It is known that the linear SVM has an equivalent hinge loss formulation [48]

$$\hat{\boldsymbol{\beta}} = \text{argmin}_{\boldsymbol{\beta}} \sum_{i=1}^{n} [1 - y_i(\boldsymbol{x}_i^T\boldsymbol{\beta})]_+ + \lambda \sum_{j=2}^{d} \beta_j^2.$$

Lin [62] shows that the SVM directly approximates the Bayes rule without estimating the conditional class probability because of the unique property of the hinge loss. As in the ridge regression, the $L_2$-penalty helps control the model complexity to prevent over-fitting.

Feature selection in the SVM has received increasing attention in the literature of machine learning. For example, the last issue of volume 3 (2002-2003) of *Journal of Machine Learning Research* is a special issue on feature selection and extraction for SVMs. We may consider a general penalized SVM

$$\hat{\boldsymbol{\beta}} = \text{argmin}_{\boldsymbol{\beta}} \sum_{i=1}^{n} [1 - y_i(\boldsymbol{x}_i^T\boldsymbol{\beta})]_+ + \sum_{j=1}^{d} p_{\lambda_j}(|\beta_j|).$$

The 1-norm (or LASSO-like) SVM has been used to accomplish the goal of automatic feature selection in the SVM ([89]). Friedman *et al.* [41] shows that the 1-norm SVM is preferred if the underlying true model is sparse, while the 2-norm SVM performs better if most of the predictors contribute to the response. With the SCAD penalty, the penalized SVM may improve the bias properties of the 1-norm SVM.

# Random matrices and enumeration of maps

Alice Guionnet

**Abstract.** We review recent developments in random matrix theory related with the enumeration of connected oriented graphs called maps. In particular, we show that the long standing use of matrix integrals in physics to tackle such issues can be made rigorous and discuss some applications. This talk is based on joint works with E. Maurel-Segala and O. Zeitouni.

**Mathematics Subject Classification (2000).** Primary 15A52, 05C30.

**Keywords.** Random matrices, map enumeration.

## 1. Introduction

A map is a connected oriented diagram which can be embedded into a surface. Its genus $g$ is by definition the smallest genus of a surface in which it can be embedded in such a way that edges do not cross and the faces of the graph (which are defined by following the boundary of the graph) are homeomorphic to a disc. One has the formula for the Euler characteristic $\chi$:

$$\chi = 2 - 2g = \sharp \text{ vertices} + \sharp \text{ faces} - \sharp \text{ edges}.$$

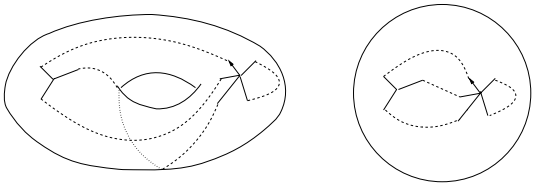

Figure 1. Examples of maps with 2 vertices of degree 3 and 5 respectively, with $g = 1$ and $g = 0$.

In the sequel, we shall be interested in the enumeration of maps up to equivalence classes, namely up to homeomorphisms of the oriented surface. This amounts to consider the purely combinatorial problem of enumerating the possible arrangements of the edges of graphs with prescribed vertices and genus. A dual point of view goes as follows. We can replace each vertex with valence $k$ by a face whose boundary is made of $k$ edges (each of them crossing a different edge adjacent to the vertex). The problem can then be reformulated as the enumeration of possible tilings of a surface

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

of given genus by a given number of faces with prescribed degree (the degree of the face is the number of edges that border the face). For some problems (for instance related with statistical mechanics), one would like eventually to color the edges or the vertices of the map and impose additional constraints for the gluing of edges/vertices of different colors.

The problem of enumerating maps was first tackled in the sixties by W. Tutte [34], [35] who was motivated by combinatorial problems such as the four color problem (see [26] or [4] for combinatorial motivations and problems). Tutte considered *rooted* planar maps. The root of a map is a distinguished oriented edge. Fixing a root allows to reduce the number of symmetries of the problem; enumerating rooted maps is equivalent to count maps with labelled edges. Tutte showed that diverse 'chirurgical' operations on rooted planar maps allow to obtain equations for the generating functions of the numbers of these maps with a given number of faces, each face having the same fixed degree. One of the examples of the maps which were exactly enumerated by Tutte are triangulations (i.e maps with faces of degree 3); he proved [34] that the number of rooted triangulations with $2n$ faces is given by $2^{n+1}(3n)!/(2n+2)!n!$ (see e.g. E. Bender and E. Canfield [5] for generalizations). In general, the equations obtained by Tutte's approach are not exactly solvable; their analysis was the subject of subsequent developments (see e.g. [19]).

Because this last problem is in general difficult, a bijective approach was developed after the work of R. Cori and B. Vauquelin [13] and G. Schaeffer's thesis (see e.g. [32]). It was shown that planar triangulations and quadrangulations can be encoded by labelled trees, which are much easier to count. This idea proved to be very fruitful in many respects. It allows not only to study the number of maps but also part of their geometry; P. Chassaing and G. Schaeffer [12] could prove that the diameter of uniformly distributed quadrangulations with $n$ vertices behaves like $n^{\frac{1}{4}}$. This technique was first applied to triangulations or quadrangulations, but soon generalized to other maps, see e.g. [10] or [9]. The case of planar bi-colored maps related to the so-called Ising model on random planar graphs could also be studied [7]. Further, it allows also to tackle maps with higher genus, an avenue recently opened by M. Marcus and G. Schaeffer. In general, this approach give more complete results than the other methods. However, it yet can not cover all the models which were analysed in physics by the so-called matrix models approach and when it does, the solution for the enumeration problem has the same flavour than the solution obtained with matrix models (see [9]).

The question of enumerating maps has been studied intensively in physics for more than thirty years. One of the first motivation came in QCD (which stands for Quantum Chromodynamics) with a large number $N$ of colors; 't Hooft [33] noticed in the seventies that as $N$ is large, physical quantities can be expanded, via Feynamnn diagrams, as sums over maps. This fundamental remark allowed the connection between quantum field theory and the problem of enumerating maps, and in particular led to the use of matrix integrals to count maps (In [11], this technique was used to

enumerate planar maps with vertices of degree 4). The interest in enumerating maps was revived by quantum gravity in the eighties; random triangulations could be used for instance to approximate fluctuating geometries. As a side product, people got interested by statistical models defined on random graphs. Such models should in fact be related at criticality with the corresponding model on $\mathbb{Z}^2$ (see [28]). Maps were also used to approximate low-dimensional string theory (see e.g. the review [15]). Although recently the methods introduced by R. Cori, B. Vauquelin and G. Scheaffer began to be developed in physics too (by P. Di Francesco et al.), the most common approach has been to use matrix models, a rather indirect but quite powerful method that we shall describe in this survey (see also A. Zvonkin [36]). It is based on the particular form of Gaussian moments as given by Wick formula; if $(G_1, \ldots, G_{2n})$ is a centered Gaussian vector, then Wick formula asserts that

$$\mathbb{E}[G_1 G_2 \ldots G_{2n}] = \sum_{\substack{1 \le s_1 < s_2 \ldots < s_n \le 2n \\ r_i > s_i}} \prod_{j=1}^{n} \mathbb{E}[G_{s_j} G_{r_j}].$$

Alternatively, this formula can be represented by Feynman diagrams. Let us now consider matrices from the Gaussian Unitary Ensemble (GUE). For a fixed dimension $N$, let $\mathcal{H}_N$ be the set of $N \times N$ Hermitian matrices. The law of the GUE is then given as the Gaussian law on $\mathcal{H}_N$

$$\mu_N(dA) = \frac{1}{Z_N} e^{-\frac{N}{2}\operatorname{tr}(A^2)} dA.$$

In other words, $A_{lk} = \bar{A}_{kl}$ for $1 \le k < l \le N$ and

$$A_{kl} = (2N)^{-\frac{1}{2}}(g^1_{kl} + i g^2_{kl}) \quad \text{for } k < l, \qquad A_{kk} = N^{-\frac{1}{2}} g^1_{kk},$$

where the $(g^1_{kl}, g^2_{kl}, k \le l)$ are independent identically distributed standard Gaussian variables. One can then observe that Wick formula implies that for all integer numbers $p_i$, $1 \le i \le k$, all $k \in \mathbb{N}$, $N \in \mathbb{N}$,

$$\int \prod_{i=1}^{k} (N \operatorname{tr}(A^{p_i}))\, d\mu_N(A) = \sum_{F \ge 0} N^{F+k-\frac{\sum p_i}{2}}\, G((p_i)_{1 \le i \le k}, F) \tag{1}$$

with

$$G((p_i)_{1 \le i \le k}, F) = \sharp\{\text{oriented graphs with } F \text{ faces and } 1 \text{ vertex of degree } p_i, 1 \le i \le k\}.$$

In $G((p_i)_{1 \le i \le k}, F)$, the edges of the graph are labelled. One should notice that the number $F + k - \frac{\sum p_i}{2}$ corresponds to $2 - 2g$, with $g$ the genus of the surface on which a connected oriented graph with $F$ faces and one vertex of degree $p_i$ for $1 \le i \le k$

can be embedded, since such a graph has $k$ vertices and $2^{-1}\sum p_i$ edges. Hence, if we see the dimension $N$ of the matrices as a parameter, the expectation of the trace of moments of matrices from the GUE can be seen as a generating function for the number of oriented graphs with a given genus and a given number of vertices with prescribed degree. Laplace transforms of traces of matrices from the GUE should therefore be generating functions for maps. In fact, we find, by expanding the exponential and using (1) that, with $\boldsymbol{t} = (t_1, \dots, t_k)$,

$$\log Z_N(\boldsymbol{t}) := \log \int e^{-\sum_{i=1}^k t_i N \operatorname{tr}(A^{p_i})}\, d\mu_N(A) = \sum_{g\geq 0} N^{2-2g} F_g(\boldsymbol{t}) \tag{2}$$

with

$$F_g(\boldsymbol{t}) := \sum_{n_1,\dots,n_k\in\mathbb{N}^k} \prod_{i=1}^k \frac{(-t_i)^{k_i}}{k_i!} M((p_i, n_i)_{1\leq i\leq k}; g)$$

the generating function for the number $M((p_i, n_i)_{1\leq i\leq k}; g)$ of maps with genus $g$ and $n_i$ vertices of degree $p_i$ for $i \in \{1, \dots, k\}$. Note here that we now count maps, and so oriented graphs that are connected, due to the fact that we took the logarithm. Formula (2) is only formal, i.e means that all the derivatives of the functions on each side of the equality match at $(t_1, \dots, t_k) = (0, \dots, 0)$.

An interesting feature of the relation (1) is that it can be generalized to several matrices, corresponding then to the enumeration of colored-edges maps. Namely, let us introduce a bijection between non-commutative monomials and oriented vertices with colored half-edges and a distinguished half-edge as follows; to the letters $(X_1, \dots, X_m)$ we associate half-edges with $m$ different colors $c_1, \dots, c_m$, and to a monomial $q(X_1, \dots, X_m) = X_{i_1} \dots X_{i_k}$ a clockwise oriented vertex with first half-edge (which is distinguished) of color $c_{i_1}$, second of color $c_{i_2}$ till the last half-edge of color $c_{i_k}$. We call such a vertex, equipped with its colored half-edges, orientation and distinguished edge, a star of type $q$. It defines a bijection between monomials and stars. We then can generalize (2) as follows; let $(q_1, \dots, q_k)$ be $k$ non-commutative monomials of $m$ indeterminates, then

$$\begin{aligned}\int \prod_{i=1}^k (N \operatorname{tr}(q_i(A_1, \dots, A_m))\, d\mu_N(A_1) \dots d\mu_N(A_m) \\ = \sum_{F\geq 0} N^{k+F-\frac{\sum p_i}{2}} G_c((q_i)_{1\leq i\leq k}, F),\end{aligned} \tag{3}$$

with $G_c((q_i)_{1\leq i\leq k}, F)$ the number of oriented graphs with $F$ faces and one star of type $q_i$, $1 \leq i \leq k$, the gluing between half-edges of different colors being forbidden. (2) also generalizes to this multi-matrix setting and we find that

$$\log Z_N(\boldsymbol{t}) = \log \int e^{-N\sum_{i=1}^k t_i \operatorname{tr}(q_i(A_1,\dots,A_m))} \prod_{i=1}^m d\mu_N(A_i) \tag{4}$$

expends formally as a generating function of colored maps (here $M((p_i, n_i), 1 \leq i \leq k; g)$ has to be replaced by the number $M_c((q_i, n_i), 1 \leq i \leq k; g)$ of maps with genus $g$ and $n_i$ stars of type $q_i$, the gluing between half-edges of different colors being forbidden.)

As we said before, these considerations have been intensively used in physics to analyze various combinatorial models via their representations in terms of matrices. It is no surprise that mathematicians end up wondering what physicists are doing or come to cross the same lines of thoughts. In the last ten years, progress in the theory of random matrices led to a better mathematical understanding of this approach. The first natural question is to find a reasonable domain of the parameters $(t_1, \ldots, t_n)$ where the expansion (2) or (4) are not only formal. Because the right hand side is a priori a diverging series, this expansion can not be obtained analytically in a neighborhood of the origin, but we would like to show that equality holds up to some error term $N^{-2k}$ provided the parameters belong to some neighborhood of the origin. Once this question is settled, one can try to 'solve'(and then in which sense?) the combinatorial problem by estimating the matrix integral.

As we shall see in the next section, the first goal has received a rather complete answer in the last few years. For the second question and one matrix setting, it turns out that at least the first order asymptotics of the left-hand-side of (2) can be computed by using standard saddle point (or large deviations) techniques. The answer is yet not very transparent since it is given by a variational formula and we shall review part of its analysis. In the multi-matrix setting, very few results have been obtained so far, a few of which we shall describe.

## 2. Expansion of the free energy of matrix models

**2.1. One matrix integrals.** In the case of one matrix, the free energy of the matrix model can be expressed as an integral over the eigenvalues of the random matrix. It is well known (see [30]) that the law of the eigenvalues of the GUE can be described by a Coulomb gas law;

$$d\sigma_N(\lambda_1, \ldots, \lambda_N) = \frac{1}{Z_N} \prod_{i<j} |\lambda_i - \lambda_j|^2 e^{-\frac{N}{2}\sum_{i=1}^N (\lambda_i)^2} \prod d\lambda_i$$

with $Z_N$ the normalizing constant. It therefore turns out that (2) is given by

$$Z_N(\boldsymbol{t}) = Z_N^{-1} \int e^{-N\sum_{i=1}^N [V_{\boldsymbol{t}}(\lambda_i) + \frac{1}{2}(\lambda_i)^2]} \prod_{i<j} |\lambda_i - \lambda_j|^2 \prod d\lambda_i \tag{5}$$

with $V_{\boldsymbol{t}}(x) = \sum_{i=1}^k t_i x^{p_i}$. To make sure that $Z_N(\boldsymbol{t})$ is finite for each $N \in \mathbb{N}$, we shall assume that $p_k = \max_{l \leq k} p_l$ is even and $t_k > 0$. It was conjectured by Bessis, Itzykson and Zuber [6] that $\log Z_N(\boldsymbol{t})$ can be expanded in the vicinity of the origin. It

was only twenty years later that this question met its complete mathematical treatment in [17] (see also [2], [1] for previous advances in the subject). It was indeed shown in [17], Theorem 1.1, that if we let

$$\mathbb{T}(T,\gamma)=\left\{\boldsymbol{t}\in\mathbb{R}^k : \sum_{i=1}^k |t_i|\le T,\ t_k>\gamma\sum_{i=1}^{k-1}|t_i|\right\},$$

then the following result holds:

**Theorem 2.1.** *For all $k\in\mathbb{N}$, there is $T>0$ and $\gamma>0$ so that for $\boldsymbol{t}\in\mathbb{T}(T,\gamma)$, for all $k\in\mathbb{N}$, one has the expansion*

$$N^{-2}\log Z_N(\boldsymbol{t})=\sum_{l=0}^{k}N^{-2l}F_l(\boldsymbol{t})+O(N^{-2k-2}).$$

*Moreover,*

$$F_l(\boldsymbol{t})=\sum_{n_1,\dots,n_k\in\mathbb{N}^n}\prod_{l=1}^{k}\frac{(-t_i)^{n_i}}{n_i!}M((p_i,n_i),1\le i\le k;g)$$

*with $M((p_i,n_i)_{1\le i\le k};g)$ the number of maps with genus $g$ and $n_i$ vertices of degree $p_i$ for $1\le i\le k$.*

This result is based on an expansion for the mean empirical density of the eigenvalues under the associated Gibbs measure

$$d\sigma_{\boldsymbol{t}}^N(\lambda_1,\dots,\lambda_N)=Z_N(\boldsymbol{t})^{-1}e^{-N\sum_{i=1}^N V_t(\lambda_i)}\prod_{i<j}|\lambda_i-\lambda_j|^2e^{-\frac{N}{2}\sum_{i=1}^N(\lambda_i)^2}\prod d\lambda_i.$$

Indeed, if we set $\mu_{\boldsymbol{t}}^N$ to be the probability measure on $\mathbb{R}$ given for any bounded measurable test function $f$ by

$$\int f(x)d\mu_{\boldsymbol{t}}^N(x)=\int\frac{1}{N}\sum_{i=1}^N f(\lambda_i)\,d\sigma_{\boldsymbol{t}}^N(\lambda_1,\dots,\lambda_N),$$

it is proved in [17], Theorem 1.3, that

**Theorem 2.2.** *For all $k\in\mathbb{N}$, there is $T>0$ and $\gamma>0$ so that for $\boldsymbol{t}\in\mathbb{T}(T,\gamma)$, for all $k\in\mathbb{N}$, one has the expansion*

$$\int f(x)d\mu_{\boldsymbol{t}}^N(x)=\sum_{g=0}^{k}N^{-2g}f_g(\boldsymbol{t})+O(N^{-2k-2})$$

*for any smooth function $f$ which grows no faster than a polynomial at infinity. Moreover, for all $p\in\mathbb{N}$, if $f(x)=x^p$,*

$$f_g(\boldsymbol{t})=\sum_{n_1,\dots,n_k\in\mathbb{N}^n}\prod_{l=1}^{k}\frac{(-t_i)^{n_i}}{n_i!}M((p,1),(p_i,n_i)_{1\le i\le k};g).$$

Note that this second theorem implies the first since for all $l$,

$$\partial_{t_l} \log Z_N(\boldsymbol{t}) = \mu_{\boldsymbol{t}}^N(x^{p_l})$$

gives

$$\log \frac{Z_N(\boldsymbol{t})}{Z_N(\boldsymbol{0})} = \sum_{l=1}^{k} \int_0^{t_l} \mu^N_{(0,\dots,0,s,t_{l+1},\dots,t_k)}(x^{p_l})\, ds.$$

The proof of these results are based on orthogonal polynomials; because the interaction between the eigenvalues $(\lambda_1, \dots, \lambda_N)$ are given in terms of the square of a Vandermonde determinant, the density of the law $\mu_{\boldsymbol{t}}^N$ can be expressed in terms of orthogonal polynomials, whose limits are well known (since they are completely integrable). The theory of integrable systems allowed many important breakthroughs in the theory of matrix models, but we want to argue in the next section that the large $N$ expansion of matrix models can be obtained by more direct arguments.

**2.2. Many matrix integrals.** In [22], [23], [29], following (3), we considered the multi-matrix integral defined, for $k$ non-commutative monomials of $m$ indeterminates $(q_1, \dots, q_k)$, by

$$Z_N(\boldsymbol{t}) = \int e^{-N \sum_{i=1}^k t_i \operatorname{tr}(q_i(A_1,\dots,A_m))}\, d\mu_N(A_1) \dots d\mu_N(A_m). \tag{6}$$

To make this integral finite and not oscillatory, we assume the following. Let $*$ be the involution on polynomial functions of $m$ non-commutative integrals given by

$$(zX_{i_1} \dots X_{i_p})^* = \bar{z} X_{i_p} \dots X_{i_1}$$

for any $p \in \mathbb{N}$ and any $i_j \in \{1, \dots, m\}$. Then, to avoid possible oscillations, we assume that $V_{\boldsymbol{t}}(X_1, \dots, X_m) = \sum_{i=1}^k t_i q_i(X_1, \dots, X_m)$ is self-adjoint, i.e. $V_{\boldsymbol{t}} = V_{\boldsymbol{t}}^*$. To bound the integral, we assume that there exists $c > 0$ so that $V_{\boldsymbol{t}}$ is $c$-convex, i.e $W(X_1, \dots, X_m) = V_{\boldsymbol{t}}(X_1, \dots, X_m) + \frac{(1-c)}{2} \sum_{i=1}^k X_i^2$ is convex in the sense that for any $N \in \mathbb{N}$, the application

$$(X_1, \dots, X_m) \in \mathcal{H}_N^m \to \operatorname{tr}(W(X_1, \dots, X_m))$$

is a convex function of the entries of $(X_1, \dots, X_m)$. Observe that, by Klein's lemma, if $V$ is a convex function of one real variable, $V$ is convex in the above sense and therefore our condition includes all $V_{\boldsymbol{t}}$ of the form

$$V_{\boldsymbol{t}}(X_1, \dots, X_m) = \sum V_i(\sum \kappa_i^j X_j) + \sum \beta_{jl} X_i X_j$$

with $V_i$ convex functions of one variable, real numbers $\kappa_i^j$ and $\beta_{jl}$ small enough constant (depending on $c$). This assumption generalizes that of Theorem 2.2 since if $\gamma$ is large enough and $T$ small enough, for $\boldsymbol{t} \in \mathbb{T}(T, \gamma)$, the potential $V_{\boldsymbol{t}}(x) =$

$\sum_{i=1}^k t_i x^{p_i} + 2^{-1}(1-c)x^2$ is strictly convex. In [22], [23], [29], the analogue of Theorems 2.1 and 2.2 were obtained for a range of parameters which are small enough and so that $V_{\boldsymbol{t}}$ stays uniformly $c$-convex for some $c > 0$. For the analogue of Theorem 2.2, $\mu_{\boldsymbol{t}}^N$ is generalized into the linear form on non-commutative polynomials given by

$$\mu_{\boldsymbol{t}}^N(P) = \frac{1}{Z_N(\boldsymbol{t})} \int \frac{1}{N} \operatorname{tr}(P(A_1, \ldots, A_m)) e^{-N \sum_{l=1}^k t_i \operatorname{tr}(q_i(A_1,\ldots,A_m))} \prod d\mu_N(A_i).$$

The techniques are complectly different from those of [17] (in fact, orthogonal polynomial techniques are unknown for general multi-matrix models) and rely on combinatorial interpretations of non-commutative differential operators. For instance, for the first order expansion, it can be shown under our hypothesis that for any non-commutative polynomial $P$, $\mu_{\boldsymbol{t}}^N(P)$ converges towards some quantity $\tau(P)$. Furthermore, $\tau$ satisfies some 'non-commutative differential equation', called the Schwinger–Dyson equation, which says that for all polynomials $P$,

$$\tau((X_i + D_i V_{\boldsymbol{t}})P) = \tau \otimes \tau(\partial_i P), \quad \tau(1) = 1 \tag{7}$$

with $\partial_i$ (resp. $D_i$) the non-commutative derivative (resp. the cyclic derivative) given on a monomial $P$ by

$$\partial_i P = \sum_{P = P_1 X_i P_2} P_1 \otimes P_2, \quad D_i P = \sum_{P = P_1 X_i P_2} P_2 P_1$$

where the sums run over all the possible decomposition of the monomial $P$ into $P_1 X_i P_2$. It turns out that in our range of parameters, there is only one solution to (7) (which satisfies some boundedness properties that the limit points of $\mu_{\boldsymbol{t}}^N$ share), which corresponds to the generating function for planar maps. This last identification comes out because $\partial_i$ and $D_i$ have very simple combinatorial interpretations; if you think of $\tau$ as the generating function of maps, you will see that $\partial_i$ consists in the operation of splitting your map into two disjoint maps when two edges of the color $c_i$ of one vertex are glued together, whereas $D_i$ will consist in the operation of erasing one edge when two different vertices are connected via an edge of the color $c_i$, then obtaining a single bigger vertex (see [22]). Amazingly, it turns out that these non-commutative derivatives play exactly the same role than the surgery initially introduced by Tutte. One could then wonder what matrix models brought so far. At least a funny remark; the limit $\tau$, whose moments are generating functions for maps, is a tracial state. In particular, in the one matrix case, it is a probability measure. Another remark is that the higher orders in the expansion of matrix integrals can be expressed in terms of $\tau$ and the differential operators defined by the $\partial_i$ and the $D_i$. Thus the expansion describes, without further thinking, the operations that one can do on a map of genus $g$ to enumerate it in terms of lower genus maps. In the next section, we shall therefore concentrate on planar maps and the analysis of the limiting state $\tau$.

## 3. Estimating matrix integrals

We shall focus in this section on the first order of matrix integrals, that is on planar maps.

**3.1. One matrix integrals.** It is easily seen by a saddle point method (or large deviations, see e.g. [3]) that with $Z_N(\boldsymbol{t})$ given by (5) and $V_{\boldsymbol{t}}(x) = \sum_{i=1}^k t_i x^{p_i}$, we have

$$\lim_{N\to\infty} \frac{1}{N^2} \log Z_N(\boldsymbol{t}) = \sup_{\mu\in\mathcal{P}(\mathbb{R})} \left\{ \int \log|x-y|\, d\mu(x) d\mu(y) - \int \left( V_{\boldsymbol{t}}(x) + \frac{x^2}{2} \right) d\mu(x) \right\} \tag{8}$$

up to a universal constant coming from the limit of $N^{-2}\log Z_N$. Moreover, the above supremum is achieved at a unique probability measure $\mu_{\boldsymbol{t}}$ and we have for all bounded continuous function,

$$\lim_{N\to\infty} \mu_{\boldsymbol{t}}^N(f) = \mu_{\boldsymbol{t}}(f).$$

In particular, at least for $\boldsymbol{t} \in \mathbb{T}(T,\gamma)$ as in Theorem 2.2, for all integer $p$, $\mu_{\boldsymbol{t}}(x^p)$ is a generating function for maps with one vertex of degree $p$ and so at least formally,

$$\begin{aligned} G\mu_{\boldsymbol{t}}(z) &:= \int \frac{1}{z-x}\, d\mu_{\boldsymbol{t}}(x) \\ &= \frac{1}{z} \sum_{l\geq 0} z^{-l} \sum_{n_1,\dots,n_k} \prod_{i=1}^k \frac{(-t_i)^{n_i}}{n_i!} M((l,1),(p_i,n_i)_{1\leq i\leq k};0) \end{aligned}$$

is a generating function for maps too. In [14] (see also [17]), the solution to the variational problem (8) has been studied. It turns out that in the small range of parameters we are considering, we have the following characterization of $\mu_{\boldsymbol{t}}$;

$$\mu_{\boldsymbol{t}}(dx) = \frac{1_{[\alpha(\boldsymbol{t}),\beta(\boldsymbol{t})]}}{2\pi} \sqrt{(x-\alpha(\boldsymbol{t}))(\beta(\boldsymbol{t})-x)}\, h_{\boldsymbol{t}}(x) dx$$

with $h_{\boldsymbol{t}}$ a polynomial given explicitly in terms of $V_{\boldsymbol{t}}$ and $\alpha(\boldsymbol{t})$, $\beta(\boldsymbol{t})$ determined by the set of equations

$$\int_{\alpha(\boldsymbol{t})}^{\beta(\boldsymbol{t})} \frac{(V_{\boldsymbol{t}}'(s)+s)}{\sqrt{(s-\alpha(\boldsymbol{t}))(\beta(\boldsymbol{t})-s)}} ds = 0, \quad \int_{\alpha(\boldsymbol{t})}^{\beta(\boldsymbol{t})} \frac{s(V_{\boldsymbol{t}}'(s)+s)}{\sqrt{(s-\alpha(\boldsymbol{t}))(\beta(\boldsymbol{t})-s)}} ds = 2\pi.$$

$\alpha(\boldsymbol{t})$, $\beta(\boldsymbol{t})$ are analytic functions of $\boldsymbol{t} \in \mathbb{T}(T,\gamma)$. This however does not give a very explicit formula for $G\mu_{\boldsymbol{t}}$. When $V_{\boldsymbol{t}}$ is a monomial, more detailed analysis were performed in [14]. It turns out that when $V_{\boldsymbol{t}}$ is even (see [9]), the analysis is more simple and, in the case $V_{\boldsymbol{t}} = tx^4$, can be pushed to obtain explicit formulas (see [11]).

**3.2. Many matrix integrals.** The problem of enumerating colored, or decorated, maps is much more challenging. In combinatorics, only the so-called Ising model on random quadrangulations could be tackled so far (see [7]). The list of models which could be 'solved' in physics is slightly longer; it includes for instance the so called Potts model, induced QCD, $ABAB$ model, dually weighted graphs (see e.g. [20] and references therein). Basically, all these models can be written in terms of quadratic interaction models, either by definition or by using character expansions. Thus, they are closely related with the Ising model we shall describe below. The Ising model is given by the partition function

$$Z_N(\boldsymbol{t}, c) = \int e^{-N\,\mathrm{tr}(V_{\boldsymbol{t}}^1(A))-N\,\mathrm{tr}(V_{\boldsymbol{t}}^2(B))-Nc\,\mathrm{tr}(AB)}\, d\mu_N(A) d\mu_N(B)$$

with $V_{\boldsymbol{t}}^1$ and $V_{\boldsymbol{t}}^2$ two polynomials of one real variable with coefficients depending on parameters $\boldsymbol{t}$. By paragraph 2.2, if $V_{\boldsymbol{t}}^1$, $V_{\boldsymbol{t}}^2$ are convex, for small enough parameters $(\boldsymbol{t}, c)$, the free energy $\log Z_N(\boldsymbol{t})$ expands into a generating function for two-colored maps with vertices prescribed by $V_{\boldsymbol{t}}^1$ and $V_{\boldsymbol{t}}^2$. The interaction $AB$ serves to generate edges between vertices of different colors. Thus, when $V_{\boldsymbol{t}}^1(x) = V_{\boldsymbol{t}}^2(x) = tx^4$, the model really looks like a generalization of the standard Ising model, with spins lying on a random quadrangulation rather than on $\mathbb{Z}^2$. Indeed, we have for small enough parameters $t, c$,

$$\frac{1}{N^2}\log Z_N(t, c) = (1-c^2)^{-1} \sum_{g=0}^{k} \frac{1}{N^{2g}} \sum_{k,\ell} \frac{1}{k!} \left(\frac{-t}{(1-c^2)^2}\right)^k \frac{(-c)^\ell}{\ell!} C(k, \ell, g) + o(N^{-2k})$$

with $C(k, \ell, g)$ the number of maps with genus $g$ with $k$ vertices of valence 4 being assigned the sign $+1$ or $-1$, with exactly $\ell$ edges between vertices of different signs. This formula is reminiscent of the standard grand canonical partition function for the Ising model in $\mathbb{Z}^2$, where $C(k, \ell, g)$ is simply replaced by the number of configurations on a subset of $\mathbb{Z}^2$ rather than on random graphs. The genus is then related with the boundary conditions. In this case, where $V_t^1(x) = V_t^2(x) = tx^4$, an explicit formula for the limiting free energy was obtained in [31] from which important information such as phase transition could be derived [8] (these results were recovered in [7] by a purely combinatorial approach). For more general potentials, variational formulas generalizing those of the one matrix setting were obtained in [20]. A more detailed analysis of these limits is under study. The basic ingredient for these general potentials estimates is based on the remark that under $\mu_N$, $A = UDU^*$ with $U$ a unitary matrix following the Haar measure and $D$ a diagonal matrix, independent of $U$. Therefore, the interaction in the Ising model is given by the spherical, or Itzykson–Zuber–Harish-Chandra, integral

$$I(D_1, D_2) = \int e^{Nc\,\mathrm{tr}(D_1 U D_2 U^*)}\, dU$$

with $D_1$ and $D_2$ the diagonal matrices of the eigenvalues of $A$, $B$ and $dU$ the Haar measure on the set of $N \times N$ unitary matrices. In [25], we obtained the large $N$ asymptotics of spherical integrals. Namely, take a sequence of diagonal matrices $(D_1^N, D_2^N)$ so that the empirical measures $N^{-1}\sum_{i=1}^N \delta_{D_j^N(ii)}$ converges weakly towards a probability measures $\mu_j$ for $j = 1, 2$. Then, if we set

$$I(\mu) = -\frac{1}{2}\iint \log|x-y| d\mu(x) d\mu(y) + \frac{1}{2}\int x^2 d\mu(x),$$

we have, if $I(\mu_1) < \infty$, $I(\mu_2) < \infty$,

$$\lim_{N\to\infty} \frac{1}{N^2} \log I(D_1^N, D_2^N)$$
$$= -\frac{1}{2} \inf \left\{ \int_0^1 \int u_t(x)^2 \rho_t(x) dx dt + \frac{\pi^2}{3} \int_0^1 \int \rho_t(x)^3 dx dt \right\} + I(\mu_1) + I(\mu_2).$$

The above infimum is taken over $(\rho, u)$ on $(0, 1) \times \mathbb{R}$ so that $v_t(dx) = \rho_t(x)dx$ is a probability measure on $\mathbb{R}$ for all $t \in (0, 1)$, $t \to v_t$ is continuous with limit as t goes to zero (resp. one) given by $\mu_1$ (resp. $\mu_2$) and for all $t \in (0, 1)$, all $x \in \mathbb{R}$,

$$\partial_t \rho_t(x) + \partial_x(\rho_t(x) u_t(x)) = 0.$$

In [20] it was shown that the infimum is taken at a couple $(\rho, u)$ so that $f = u + i\pi\rho$ satisfies the complex Burgers equation

$$\partial_t f_t(x) + f_t(x)\partial_x f_t(x) = 0.$$

These formulae are proved by large deviation estimates for $N$ non-intersecting Brownian motions evaluated at extremely small time $N^{-1}$. Complex Burgers equation also appears in discrete analogous settings coming from tiling, see e.g. [27]. Spherical integrals are rather fundamental objects since they are related with the characters of the symmetric group; the above limits give asymptotics of Schur functions, cf. [21].

## 4. Conclusion: Matrix models input in combinatorics

Even though rather indirect, the matrix model approach to the enumeration of maps have proved to be powerful since it permits to consider quite general maps. For general type of vertices, the formulas obtained by this method are often not so much explicit, but this should be no surprise. When possible, the bijective approach provides more detailed information, such as the diameter of the graph with a given number of vertices (an information which was never grasped by the matrix model approach so far). The matrix model approach shows that some (maybe) unexpected tools can be used to solve these combinatorial problems; let us cite characters expansions (see [24] and references therein), Brownian motion and stochastic calculus (see [25]). We believe

also that the description of the generating functions $\mu_t(x^p)$ as the expectation under a probability measure, or tracial state, is a rather powerful remark. It allows to give some information on Tutte's solutions to the equations for generating functions of maps, seen as a solution to Schwinger–Dyson's equation (7). For instance, it was shown in [16] that the generating function $\tau(z - A)^{-1}$ for the Ising model with general polynomial potentials satisfies an algebraic equation.

This field has experienced quite a lot of developments in the last few years, attracting the interests of theoretical physicists and of mathematicians from diverse fields such as combinatorics, integrable systems or probability. Central in the problem of the enumeration of maps is the Schwinger–Dyson equation (7) which encodes most of the induction relations satisfied by the numbers of interest. The study of its solution is the heart of the problem of enumerating maps and, at least in the multi-matrix model, also attracted the attention of free probabilists. Indeed, in free probability, the reverse question (i.e. given a tracial state, find a potential $V_t$ so that (7) is satisfied) serves to define the so-called conjugate variables which are central in free entropy questions. However, most issues in free probability are not related with small perturbative potentials as considered in this survey but on the contrary with very strong potentials. The understanding of matrix models is then extremly limited, since even the question of the convergence of the free energy is still unsettled.

# The weak/strong survival transition on trees and nonamenable graphs

Steven P. Lalley*

**Abstract.** Various stochastic processes on nonamenable graphs and manifolds of exponential volume growth exhibit phases that do not occur in the corresponding processes on amenable graphs. Examples include: (1) *branching diffusion* and random walk on hyperbolic space, which for intermediate branching rates may survive globally but not locally; (2) *contact processes* on homogeneous trees, which likewise can survive globally while dying out locally; and (3) *percolation* on Cayley graphs of nonamenable groups, where for certain parameter values infinitely many infinite percolation clusters may coincide. This article surveys some of what is known about the intermediate phases and the upper phase transitions for these processes.

**Mathematics Subject Classification (2000).** Primary 00A05; Secondary 00B10.

**Keywords.** Weak survival, nonamenable graph, contact process, percolation, branching Brownian motion, hyperbolic plane, Fuchsian group.

## 1. Branching Brownian motion and random walk

**B.B.M. in the hyperbolic plane.** Branching Brownian motion in the hyperbolic plane $\mathbb{H}$ is perhaps the simplest process exhibiting the weak/strong survival transition. It evolves as follows: At time 0, a single particle located at a specific point $x_0 \in \mathbb{H}$ begins a Brownian motion. At random exponentially distributed times with mean $1/\lambda$, independent of the motion, the particle undergoes *binary fission*, in which a replicate particle is created at the current location of the fissioning particle. The offspring particles behave as their parents, executing Brownian motions from the places of their births and undergoing further binary fissions at exponentially distributed random times; their behavior is completely independent of their parents' and other particles' behaviors, except for the locations of their births.

The behavior of the branching Brownian motion is controlled by the fission parameter $\lambda$. The size $N_t$ of the population at times $t$ is a simple continuous-time Galton–Watson process with $EN_t = e^{\lambda t}$. If a particle is chosen at random from the $N_t$ particles in existence at time $t$, the distribution of its position has as its density the heat kernel $p_t(x, \cdot)$. This is known to behave asymptotically as $t \to \infty$ like

$$p_t(x, y) \sim C_{x,y} t^{-3/2} \exp\{-t/8\} \tag{1}$$

*Research supported by NSF Grant DMS-0405102.

Proceedings of the International Congress of Mathematicians, Madrid, Spain, 2006

for constants $0 < C_{x,y} < \infty$ varying smoothly with $x, y$. Thus, the mean number of particles located in a bounded neighborhood $U$ of $y$ grows/decays roughly as $\exp\{(\lambda - 1/8)t\}$. It is not difficult to deduce the following.

**Proposition 1.** *For $\lambda \le 1/8$, branching Brownian motion survives weakly, that is, for every bounded region $U$ the number of particles located in $U$ is eventually 0, w.p.1. For $\lambda > 1/8$ it survives strongly, that is, for every open set $U$ the number of particles located in $U$ converges to $\infty$ as $t \to \infty$, w.p.1.*

In the weak survival phase, all particle trajectories tend to the boundary circle $\partial\mathbb{H}$ of the hyperbolic plane. Define $\Lambda$ to be the set of all accumulation points of particle trajectories in $\partial\mathbb{H}$. With probability 1, $\Lambda$ is a nonempty, compact subset of $\partial\mathbb{H}$.

**Theorem 2** ([14]). *For $\lambda \in (0, 1/8]$, the limit set $\Lambda$ is, with probability 1, a Cantor set of Hausdorff dimension*

$$\delta = \delta(\lambda) = \frac{1}{2}(1 - \sqrt{1 - 8\lambda}). \tag{2}$$

Observe that as $\lambda \to 1/8$ from below, the Hausdorff dimension approaches $1/2$, not 1 (the dimension of the ambient boundary $\partial\mathbb{H}$), as one might at first suspect. In the strong survival phase $\lambda > 1/8$ the limit set $\Lambda$ is the entire boundary $\partial\mathbb{H}$, so Theorem 2 shows that the Hausdorff dimension behaves discontinuously at the critical parameter $\lambda = 1/8$. Moreover, it shows that the *critical exponent* for $\delta(\lambda)$ at the transition is $1/2$. This, as it turns out, is closely related to the exponent $3/2$ appearing in the asymptotic formula (1) for the heat kernel.

Theorem 2 has been generalized to branching Brownian motion and certain other isotropic branching random walks on higher-dimensional hyperbolic spaces $\mathbb{H}^d$ by Karpelevich, Pechersky, and Suhov [8]: they prove that, for branching Brownian motion in $\mathbb{H}^d$, the Hausdorff dimension $\delta(\lambda)$ of the limit set $\Lambda$ converges up to $(d-1)/2$ as $\lambda$ approaches the critical point from below.

**Branching random walk on $\mathbb{T}^d$.** The existence of a weak survival phase for B.B.M. in $\mathbb{H}$ is a consequence of the exponential decay (1) of the heat kernel. A fundamental theorem of Kesten [9], [10] asserts that exponential decay of random walk transition probabilities is characteristic of nonamenable groups. Thus, branching random walk in any nonamenable group must also have a weak survival phase.

The transition from weak survival to strong survival is understood only for branching random walk on the homogeneous tree $\mathbb{T}^d$ of degree $d \ge 3$ (the Cayley graph of the free product $\Gamma^d := (\mathbb{Z}_2)^{*d}$). Let $\{p_i\}_{i \in A \cup \{1\}}$ be a positive probability distribution on $A \cup \{1\}$ where $A$ is the set of generators of $\Gamma^d$, and denote by $p_n(x, y)$ the $n$-step transition probabilities of the random walk with step distribution $\{p_i\}$. The branching random walk associated with the probability distribution $\{p_i\}$ is constructed as follows: At time $n = 0$, the process is initiated by a single particle located at the site 1 (the root of the tree). The population $X_{n+1}$ of each subsequent generation $n + 1$

is obtained from $X_n$ in two steps: First, each particle $\zeta$ in $X_n$ reproduces, creating a random number $N_\zeta \geq 1$ of replica particles, all located at the same vertex of $\mathbb{T}^d$ as $\zeta$. The distribution of the offspring count $N_\zeta$ is geometric+1 with mean $\lambda > 1$. Second, each particle moves to a randomly chosen neighboring vertex, according to the distribution $\{p_i\}$.

Let $R > 1$ be the spectral radius of the base random walk, that is,

$$R^{-1} := \lim_{n\to\infty} p_n(x, y)^{1/n}. \tag{3}$$

Just as for B.B.M. in $\mathbb{H}$, if the mean offspring number $\lambda$ exceeds $R$ then the number of particles located at the root vertex 1 will explode almost surely. However, if $\lambda \leq R$, then the branching random walk survives only weakly: although the total population size grows exponentially at rate $\lambda$, the number of particles located at any particular vertex will eventually be zero, w.p.1. (That the B.R.W. survives only weakly at the critical point $\lambda = R$ follows because the base random walk is $R$-transient: see [24].) Thus, for $\lambda \leq R$, particle trajectories converge to the space $\partial\mathbb{T}^d$ of ends of the tree. Hence, we may define

$$\Lambda := \{\text{ends in which the BRW survives}\}. \tag{4}$$

The Hausdorff dimension $\delta_H(\Lambda)$, computed with respect to the natural metric[1] on $\partial\mathbb{T}^d$, is a natural measure of the growth of the B.R.W. in the weak survival phase, for the following reason: If $M_m$ is the number of vertices of $\mathbb{T}^d$ at distance $m$ from the root that are ever visited by particles of the B.R.W., then with probability one,

$$\lim_{m\to\infty} M_m^{1/m} = \theta(\lambda) \tag{5}$$

where [7],

$$\delta_H(\Lambda) = \frac{\log\theta(\lambda)}{\log 2}. \tag{6}$$

Denote by $G_x(\lambda)$ the Green's function and $F_x(\lambda)$ the first-passage generating function of the base random walk, that is,

$$\begin{aligned} G_x(\lambda) &= \sum_{n=0}^{\infty} p_n(1, x), \\ F_x(\lambda) &= G_x(\lambda)/G_1(\lambda). \end{aligned} \tag{7}$$

**Theorem 3** ([7]). *The Malthusian parameter $\theta(\lambda)$ is the unique positive number such that*

$$\sum_{i\in A} \frac{F_i(\lambda)}{F_i(\lambda) + \theta(\lambda)} = 1. \tag{8}$$

[1]The natural metric $d$ is defined by $d(\alpha, \beta) = 2^{-N(\alpha,\beta)}$, where $N(\alpha, \beta)$ denotes the number of common edges in the geodesic segments from the root to $\alpha$ and from the root to $\beta$.

*This parameter has critical exponent* $1/2$ *at the critical point* $\lambda = R$*: that is, there exists a constant* $C > 0$ *such that as* $\lambda \to R$ *from below,*

$$\theta(R) - \theta(\lambda) \sim C\sqrt{R - \lambda}. \tag{9}$$

*Furthermore,*

$$\theta(\lambda) \le \sqrt{d-1} \tag{10}$$

*and equality holds if and only if the step distribution* $\{p_i\}$ *is isotropic.*

The formula (8) makes it clear that the critical exponent $1/2$ in (9) is related to the exponent $3/2$ occurring in the power law

$$p_n(1, x) \sim C_x R^{-n} n^{-3/2} \tag{11}$$

for the base random walk transition probabilities [24]. This is because (11) is determined by the singularity of the Green's function $G_x(\lambda)$ at $\lambda = R$, by standard Tauberian theorems, and this in turn has the same singular asymptotics as the first-passage generating functions $F_x(\lambda)$. It is conjectured that the local limit theorem (11) holds more generally for random walks on nonelementary Fuchsian groups (discrete groups of isometries of the hyperbolic plane), but this has been proved only for Fuchsian groups containing free groups as subgroups of finite index. It is natural to expect that branching random walks on such groups will have weak/strong survival transitions of the same type as on homogeneous trees.

## 2. Contact processes

**Weak survival.** Let $G = (V, E)$ be the Cayley graph of a finitely generated group $\Gamma$, with edges labeled by elements of the generating set $A$, and let $\mathcal{P} = \{p_a\}_{a \in A}$ be a probability distribution on $A$. The *contact process* with intensity parameter $\lambda > 0$ and infection rates $\mathcal{P}$ is a Markov process on the configuration space $\{0, 1\}^V$ (here $0 =$ "healthy" and $1 =$ "infected") that evolves as follows: (A) Infected vertices "recover" (become healthy) at rate 1. (B) Healthy vertices $x$ become infected at rate

$$\lambda \sum_{j \in A : xj \in \xi_t} p_j$$

where $\xi_t$ is the set of vertices that are infected at time $t$. If the probability distribution $\mathcal{P}$ is uniform on $A$, the contact process is said to be *isotropic*. If the generating set $A$ and the rates $\mathcal{P}$ are symmetric (that is, $a \in A$ implies $a^{-1} \in A$ and $p_a = p_{a^{-1}}$) then the contact process is said to be *symmetric*. The default initial condition is $\xi_0 = \{1\}$, where 1 denotes the group identity. The contact process is said to survive weakly if $\xi_t \neq \emptyset$ for all $t > 0$ but $\xi_t \cap F = \emptyset$ eventually for every finite set $F \subset V$. It survives strongly if for every nonempty set $F \subset V$, the intersection $\xi_t \cap F$ is nonempty at indefinitely large times $t$.

Most of what is known about existence of weak and strong survival phases for contact processes is restricted to groups $\Gamma$ whose associated Cayley graphs $G$ are trees.

**Theorem 4** ([20], [18], [23], [25]). *Assume that $G$ is the homogeneous tree $\mathbb{T}^d$ of degree $d \geq 3$. Then for the isotropic contact process there exist constants $0 < \lambda_c < \lambda_u < \infty$ (depending on $d$) so that*

(a) $\lambda \leq \lambda_c \Longrightarrow$ *ultimate extinction with probability* 1.

(b) $\lambda_c < \lambda \leq \lambda_u \Longrightarrow$ *weak survival with positive probability.*

(c) $\lambda > \lambda_u \Longrightarrow$ *strong survival with positive probability.*

Unlike the corresponding results for branching random walks and branching Brownian motion on hyperbolic spaces, Theorem 4 is surprisingly difficult (at least for small $d$). The proofs in [20], [18], and [23] rely heavily on both isotropy and the absence of cycles in the graph. The following result weakens the isotropy requirement.

**Theorem 5** ([16]). *Assume that $G$ is a homogeneous tree of degree $d \geq 3$. Assume further that the rates $\mathcal{P}$ are symmetric and* weakly isotropic *in the sense that there are generators $a, b$ with $a \neq b^{\pm 1}$ so that $p_a = p_b$. Then the contact process with rates $\mathcal{P}$ has a weak survival phase, that is, there exist $0 < \lambda_c < \lambda_u < \infty$ so that conclusions* (a)*,* (b)*, and* (c) *of Theorem* 4 *are valid.*

Alan Stacey (unpublished) has recently shown that the weak isotropy hypothesis is unnecessary.

**Size of the limit set.** Consider now the isotropic contact process on a homogeneous tree $\mathbb{T}^d$ of degree $d \geq 3$. By Theorem 4, there is a nontrivial weak survival phase $\lambda_c < \lambda < \lambda_u$. By definition of weak survival, any finite set of vertices must eventually be vacated, with probability 1. Therefore, the set of occupied vertices must recede to $\partial\mathbb{T}^d$ as $t \to \infty$. As for branching random walk in $\mathbb{T}^d$, define the *limit set* $\Lambda$ to be the set of ends in which the contact process survives.

**Theorem 6** ([15]). *For the isotropic contact process in the weak survival phase, the Hausdorff dimension $\delta_H(\Lambda)$ of the limit set $\Lambda$ is a.s. constant on the event of survival, and satisfies the inequality*

$$\delta_H(\Lambda) \leq \frac{1}{2}\delta_H(\partial\mathbb{T}^d). \tag{12}$$

*Furthermore, $\delta_H(\Lambda)$ is continuous* [22] *and strictly increasing* [12] *in the parameter $\lambda$, and equality in* (12) *holds at $\lambda = \lambda_u$.*

The inequality (12) holds for essentially the same reason as for branching random walk: If $\delta_H(\Lambda)$ were greater than $(1/2)\delta_H(\partial\mathbb{T}^d)$ then there would be particle trajectories extending from the root vertex to vertices far from the root and then back to

the root, contradicting weak survival. As for branching random walk on a homogeneous tree, the inequality (12) remains valid for nonisotropic but *symmetric* contact processes.

The Hausdorff dimension of the limit set $\Lambda$ is simply related to a hitting probability associated to the contact process. Let $x \in V$ be a vertex at distance $n$ from the root vertex 1, and define

$$u_n = P\{x \in \xi_t \text{ for some } t > 0\} \tag{13}$$

to be the probability that the vertex $x$ is ever infected. By isotropy, this probability is the same for all vertices $x$ at distance $n$ from 1. It is apparent that $u_{m+n} \geq u_m u_n$, and so

$$\lim_{n\to\infty} u_n^{1/n} := \beta = \beta(\lambda) \tag{14}$$

exists and is $\leq 1$.

**Theorem 7** ([15]).

$$\delta_H(\Lambda) = -\frac{\log(d-1)\beta}{\log 2}. \tag{15}$$

**Critical exponent.** For the isotropic contact process on the tree $\mathbb{T}^d$ of degree $d \geq 3$, the Hausdorff dimension $\delta(\lambda) := \delta_H(\Lambda)$ varies continuously with the intensity $\lambda$ for $\lambda \leq \lambda_u$ [22], and increases *strictly* with $\lambda$ in the interval $\{\lambda : \delta(\lambda) < 1/2\delta_H(\partial\mathbb{T}^d)\}$ [12]. Define

$$\lambda_* = \sup\{\lambda : \delta(\lambda) < 1/2\delta_H(\partial\mathbb{T}^d)\}. \tag{16}$$

**Conjecture 8.** $\lambda_* = \lambda_u$.

Recall that the critical exponent at the upper critical point for branching random walk on $\mathbb{T}^d$ is $1/2$, by formula (9). It is believed that the phase transition for the contact process is of the same type as the corresponding phase transition for branching random walk, and so it is natural to conjecture that the critical exponent is again $1/2$:

**Conjecture 9.**

$$\lim_{\lambda\to\lambda_*} \frac{\log(\delta_H(\partial\mathbb{T}^d) - 2\delta(\lambda))}{\lambda_* - \lambda} = \frac{1}{2}.$$

Further evidence for the truth of this conjecture is provided by the main result of [17], which we now describe. Consider the isotropic contact process $\xi_t$ on $\mathbb{T}^d$ in the weak survival phase $\lambda \in (\lambda_c, \lambda_u]$. For any site $x$, the total infection time

$$J(x) := \int_0^\infty \mathbf{1}\{x \in \xi_t\}\, dt \tag{17}$$

is finite with probability 1. It is known [12] that if $\lambda < \lambda_*$ then $P\{x \in \xi_t\}$ is exponentially decaying in $t$, and so $EJ(x) < \infty$. Because the hitting probability $u_n$ decays exponentially in $n$ even at the critical point $\lambda = \lambda_*$, it is natural to expect that the conditional expectation of $J(x)$ given $J(x) > 0$ is finite.

**Conjecture 10.** There exists a constant $C = C_d$ depending only on the degree $d$ of the tree $\mathbb{T}^d$ such that, for every vertex $x$ and all $\lambda \leq \lambda_*$,

$$E(J(x) \mid J(x) > 0) \leq C. \tag{18}$$

The analogous statement is known to be true for branching random walk. For the contact process, it is at least as plausible as Conjecture 9.

**Theorem 11** ([17]). *If Conjecture* 10 *is true then there is a finite constant* $C = C_d$ *so that for all* $\lambda < \lambda_*$,

$$\frac{1}{2}\delta_H(\partial\mathbb{T}^d) - \delta(\lambda) \leq C\sqrt{\lambda_* - \lambda}. \tag{19}$$

Thus, if Conjecture 10 is true, and if there is a critical exponent, then it cannot be less than $1/2$. The proof of Theorem 11 in [17] also suggests that $1/2$ is the correct value, as the inequalities in the proof are very likely approximate equalities.

## 3. Percolation

**Coexistence of infinite clusters.** In *Bernoulli site* (*resp., bond*) *percolation* on a graph $G$, vertices (resp., edges) are colored blue or red independently, blue with probability $p$, red with probability $1 - p$. For brevity we shall discuss only site percolation; however, most of the results and conjectures have natural analogues for bond percolation.

In site percolation, interest focuses on the connected clusters of blue vertices, and in particular on the existence/uniqueness and geometry of infinite blue clusters. *Percolation* is said to occur if there is an infinite blue cluster. For any infinite graph there exists a unique threshold $p_c \in [0, 1]$ for the Bernoulli parameter $p$ above which percolation occurs with positive probability, and below which it occurs with probability zero. Burton and Keane [5] showed that if the ambient graph $G$ is the Cayley graph of a finitely generated, amenable group, then infinite blue clusters, if they exist, are unique w.p.1. Grimmett and Newman [6] showed that uniqueness of infinite clusters need not hold in nonamenable graphs: in particular, they showed that Bernoulli percolation on $\mathbb{Z} \times \mathbb{T}^d$ has infinitely many infinite clusters for certain values of $p$, provided the degree $d$ is sufficiently large.

A graph is called *transitive* if its automorphism group acts transitively on the vertex set, and is called *nonamenable* if there exists a constant $\varepsilon > 0$ such that for any finite set $V_0$ of vertices, $|\partial V_0| > \varepsilon |V_0|$. (Here $\partial V_0$ denotes the set of vertices not in $V_0$ that are connected by edges to vertices of $V_0$.)

**Conjecture 12** ([1]). If $G$ is a transitive, nonamenable graph, then there exists a nonempty interval $I = (p_c, p_u)$ such that for all $p \in I$, Bernoulli-$p$ site percolation has infinitely many infinite blue clusters.

In full generality, this remains unresolved. However, two important results have been obtained:

**Theorem 13** ([2]). *Let $G$ be a transitive, nonamenable, planar graph with one end. Then there exist constants $0 < p_c < p_u < 1$ such that*

(a) $p \le p_c \Longrightarrow$ *no infinite blue clusters;*

(b) $p_c < p < p_u \Longrightarrow$ *infinitely many infinite blue clusters;*

(c) $p_u \le p \Longrightarrow$ *one infinite blue cluster.*

A connected, transitive graph is said to have one end if the subgraph obtained by deleting any finite set of vertices remains connected. Observe that the theorem asserts uniqueness of the infinite cluster at the upper transition point $p_u$: this contrasts with the analogous transition on $\mathbb{Z} \times \mathbb{T}^d$, where it is known [21] that at least for large $d$ there are infinitely many infinite clusters at $p_u$. See [3], [4] fr discussion of related issues.

**Theorem 14** ([19]). *For every finitely generated, nonamenable group there is a Cayley graph for which Conjecture* 12 *is true.*

**Percolation clusters in hyperbolic tessellations.** A *Fuchsian group* is a discrete group of isometries of the hyperbolic plane $\mathbb{H}$. Let $\Gamma$ be a co-compact Fuchsian group with finite, symmetric generating set $A$, and let $G$ be the Cayley graph. Then $G$ may be naturally embedded in $\mathbb{H}$ in such a way that edges are geodesic segments in $\mathbb{H}$, and so that any compact subset of $\mathbb{H}$ contains only finitely many vertices of $G$. Denote by $x_0 \in \mathbb{H}$ the vertex of $G$ corresponding to the group identity $1 \in \Gamma$.

Consider Bernoulli-$p$ site percolation on $G$, and let $K$ be the connected blue cluster containing $x_0$. On the event that $K$ is infinite, vertices in $K$ will accumulate at the boundary circle $\partial\mathbb{H}$: define $\Lambda$ to be the (closed) set of accumulation points.

**Theorem 15** ([11]). *If $p_c < p < p_u$ then on the event that $K$ is infinite the limit set $\Lambda$ is a Cantor set of Lebesgue measure* 0.

Recall that for the contact process on a homogeneous tree, the Hausdorff dimension of the limit set is discontinuous at the transition from weak to strong survival. It is natural to ask how the Hausdorff dimension of the limit set $\Lambda$ of a percolation cluster in $\mathbb{H}$ behaves as $p \to p_u$ from below.

**Theorem 16** ([13]). *For each $p \in (p_c, p_u)$ the Hausdorff dimension $\delta(p)$ of the limit set $\Lambda$ in Bernoulli-$p$ site percolation is almost surely constant. The function $p \mapsto \delta(p)$ is continuous and strictly increasing in $p$, with limit* 1 *as $p \to p_u$.*

Thus, the nature of the phase transition for Bernoulli percolation seems to be different from that for contact processes and branching random walks.

The use of $\delta(p)$ as a measure of the size of percolation clusters is not unreasonable for Fuchsian hyperbolic groups, but a more natural measure might be the volume growth rate

$$\varrho = \varrho(p) = \lim_{R\to\infty} R^{-1} \log \operatorname{card} K_R \tag{20}$$

where $K_R$ denotes the intersection of the cluster $K$ with the ball of radius $R$ centered at the root $x_0$. (For Fuchsian groups, it can be shown that $\varrho(p) = \delta(p)$.) Whereas $\delta(p)$ depends for its definition on the existence of a geometric boundary of the ambient space, $\varrho(p)$ can in principle be used for an arbitrary infinite group, using the graph metric to measure volume growth (existence of the limit must be proved, of course).

**Conjecture 17.** Assume that $G$ is a transitive, nonamenable graph with nonempty coexistence phase $(p_c, p_u)$. If there is a unique infinite cluster a.s. at $p = p_u$, then $\varrho(p)$ converges, as $p \to p_u$ from below, to the volume growth rate of the ambient graph $G$.

The proof of Theorem 16 leads to an interesting variational formula for the Hausdorff dimension $\delta(p)$ of percolation clusters in co-compact Fuchsian groups. Define the *connectivity function* $\tau : \Gamma \to [0, 1]$ as follows:

$$\tau(x) = \tau(x; p) = P_p\{x \in K\}. \tag{21}$$

By the FKG inequality, $\tau$ satisfies a log-subadditivity inequality on $\Gamma$:

$$\tau(xy) \geq \tau(x)\tau(y). \tag{22}$$

The function $\tau$ may be extended to a function on the entire hyperbolic plane $\mathbb{H}$ by setting $\tau(w) = \tau(x)$ where $x$ is the vertex of the Cayley graph $G$ nearest $w$ (with some convention for ties). Now consider the geodesic flow $\Phi_t$ on the unit tangent bundle of $\mathbb{H}/\Gamma$: geodesics may be lifted to $\mathbb{H}$, and so by (21) the log-connectivity function evaluated along geodesics is subadditive for the geodesic flow. Therefore, by Kingman's subadditive ergodic theorem, for any ergodic, invariant probability measure $\mu$ for the flow $\Phi_t$, there exists a constant $\beta(\mu) = \beta(\mu; p)$ so that $\mu$-almost surely, the connectivity function $\tau$ decays at rate $\beta(\mu)$ along geodesics, that is,

$$\lim_{t\to\infty} t^{-1} \log \tau \circ \Phi_t = \beta(\mu). \tag{23}$$

Denote by $\mathcal{I}$ the set of all invariant probability measures for the geodesic flow, and by $h(\mu)$ the Kolmogorov–Sinai entropy of the geodesic flow relative to the invariant measure $\mu$.

**Theorem 18** ([13]). *The decay rate function is jointly continuous in $\mu$ and $p$, and for each $\mu$ is strictly increasing in $p$ for $p \in (p_c, p_u)$. Moreover, $\beta(\mu; p) = 0$ for all $\mu \in \mathcal{I}$ and all $p \geq p_u$. For every $p$ the Hausdorff dimension $\delta(p)$ of the limit set $\Lambda$ is, $P_p$-almost surely on the event $|K| = \infty$, given by*

$$\delta(p) = \max_{\mu\in\mathcal{I}} (h(\mu) + \beta(\mu; p)). \tag{24}$$

Although it is by no means obvious, this is the natural analogue of formula (8) for the H.D. of the limit set of a branching random walk on $\mathbb{T}^d$. Formula (24) has further implications for the geometry of percolation clusters. Recall that $K_R$ is the intersection of the percolation cluster $K$ with the (hyperbolic) ball of radius $R$ centered at $x_0$. The cardinality of $K_R$ grows exponentially, at rate $\delta(p)$ (see (20)), and most of the vertices in $K_R$ are at distance nearly $R$ from $x_0$. Suppose that one of these is chosen at random: then the geodesic ray from $x_0$ through the randomly chosen vertex of $K_R$ will be approximately $\mu$-generic, where $\mu$ is the maximizing measure in (24).

# New developments in stochastic dynamics

Yves Le Jan

**Abstract.** Flows of random coalescing maps or flows of random transition probabilities can arise from simple stochastic differential equations when Ito's theory of strong solutions ceases to apply.

**Mathematics Subject Classification (2000).** 60H10, 60H40, 60G51, 76F05.

**Keywords.** Stochastic differential equations, stochastic flows, coalescing flows, noise.

## Introduction

A stationary motion on the real line with independent increments is described by a Levy process, or equivalently by a convolution semigroup of probability measures. This naturally extends to "rigid" motions represented by Levy processes on Lie groups. If one assumes the continuity of the paths, a convolution semigroup on a Lie group $G$ is determined by an element of the Lie algebra $\mathfrak{g}$ (the drift) and a scalar product on $\mathfrak{g}$ (the diffusion matrix). We call them the local characteristics of the convolution semigroup. We will be interested in stationary "fluid" random evolutions which have independent increments. They can be modelled by stochastic differential equations driven by Wiener processes. These have been studied for more than fifty years. In particular, it was shown that stochastic flows driven by smooth Brownian vector fields on a compact manifold define flows of diffeomorphisms. This is also true on non compact manifolds under appropriate conditions of non explosion ([7]). Such flows can be viewed as infinitely divisible limits of products of i.i.d. (independant and indentically distributed) random diffeomorphisms, and the theory is at least formally very similar to the theory of Brownian motion on Lie groups ([14], [19], [12]). Their laws can be viewed as convolution semigroups of probability measures on the group of diffeomorphisms. They are characterized by two functions: the covariance of the Brownian vector field, or equivalently its auto reproducing space, which plays the role of a metric on the Lie algebra and a drift vector field. One can similarly extend the notion of Levy processes by introducing Poisson measures on the group itself. A remarkable result of Tsirelson (cf. [24]) shows that there is essentially no other way to define a process $X_t$ with stationary independent increments on the unitary group of the Hilbert space. The *noise* defined by the increments of the flow, i.e. the family of $\sigma$-fields $\mathcal{F}_{s,t} = \sigma\{X_v X_u^{-1}, s \leq u \leq v \leq t\}$ is classical, i.e. generated by additive

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

increments of Wiener and (or) Poisson processes. But in recent years it appeared that this picture was not complete: indeed flows of non invertible transformations, and as well of transition probabilities, appear to play an important role in the theory.

To be more precise, on a compact manifold let $V_0, V_1, \dots, V_n$ be vector fields and $B^1, \dots, B^n$ be independent Brownian motions. Consider the SDE

$$dX_t = \sum_{k=1}^{n} V_k(X_t) \circ dB_t^k + V_0(X_t)\, dt, \tag{1}$$

which equivalently can be written as

$$df(X_t) = \sum_{k=1}^{n} V_k f(X_t) dB_t^k + \frac{1}{2} Af(X_t) dt \tag{2}$$

for every smooth function $f$ and $Af = \sum_{k=1}^{n} V_k(V_k f) + V_0 f$. Observe that $Af^2 - 2fAf = \sum_{k=1}^{n} (V_k f)^2$. Then strong solutions of this SDE produce a flow of maps $\varphi_t$ such that, for every $x$, $\varphi_t(x)$ is a strong solution of the SDE with $\varphi_0(x) = x$. When the vector fields are smooth, strong solutions are known to exist and to be unique. The framework can be extended to include flows of maps driven by vector field valued Brownian motions, which means essentially that $n = \infty$ (see for example [3], [12], [14], [19], [23]).

In a joint paper ([15]) with Olivier Raimond this was extended again to include flows of Markovian operators $S_t$ which are solutions of the SPDE

$$dS_t f = \sum_{k=1}^{\infty} S_t(V_k f) dB_t^k + \frac{1}{2} S_t(Af) dt, \tag{3}$$

assuming that the covariance function $C = \sum_{k=1}^{\infty} V_k \otimes V_k$ of the Brownian vector field $\sum_{k=1}^{\infty} V_k B^k$ is compatible with $A$, namely that

$$Af^2 - 2fAf \geq \sum_{k=1}^{\infty} (V_k f)^2. \tag{4}$$

Existence and uniqueness of a flow of Markovian operators $S_t$, which is a Wiener solution of the previous SPDE in the sense that $S_t$ is a function of the Brownian paths $(B^i)_{i \geq 1}$ up to time $t$, hold under rather weak assumptions.

The local characteristics of these flows are given by $A$ and the covariance function $C$, and they determine the SDE or the SPDE. Under Lipschitz conditions we actually get strong solutions of stochastic differential equations. These solutions are of a regular type, namely:

(a) The probability that two points thrown in the fluid at the same time and at distance $\varepsilon$, separate at distance one in one unit of time tends to 0 as $\varepsilon$ tends to 0.

(b) Such points will never hit each other.

But it was shown in [15] that covariance functions which are not smooth on the diagonal (e.g. covariance associated with Sobolev norms of order between $d/2$ and $(d+2)/2$, $d$ being the dimension of the space) can produce Wiener solutions which define random evolutions of different types:

– turbulent evolutions where (a) is not satisfied, which means that two points thrown initially at the same place separate, even when there is no pure diffusion, i.e. that $Af^2 - 2fAf = \sum_{k=1}^{\infty}(V_k f)^2$;

– coalescing evolutions where (b) does not hold.

That paper was motivated by the works of physicists working on the Kraichnan model for turbulent advection (cf., for example, [9], [10], [4], [6]).

In a subsequent paper [16] we adopted a more general approach based on consistent systems of $n$-point Markovian Feller semigroups which can be viewed as determining the law of the motion of $n$ indivisible points thrown into the fluid. Regular and coalescing evolutions are represented by flows of maps, and turbulent evolutions by flows of probability kernels $K_{s,t}(x, dy)$ describing how a point mass (made of a continuum of indivisible points) in $x$ at time $s$ is spread at time $t$. (Note that in this case, the motion of an indivisible point is not fully determined by the flow.)

Among turbulent evolutions, we can distinguish the intermediate ones where two points thrown in the fluid at the same place separate but can meet later, i.e. where (a) and (b) are both not satisfied. These flows can always be coupled with a coalescent flow.

Let us explain in more detail the contents of the paper. We give in the first section construction results from [16], which generalize a theorem by De Finetti on exchangeable variables. A stochastic flow of kernels $K$ is associated with a general compatible family $(\mathsf{P}_t^{(n)},\ n \geq 1)$ of Feller semigroups. The flow $K$ is induced by a flow of measurable mappings when

$$\mathsf{P}_t^{(2)} f^{\otimes 2}(x, x) = \mathsf{P}_t f^2(x),$$

for all $f \in C(M)$, $x \in M$ and $t \geq 0$. The Markov process associated with $\mathsf{P}_t^{(n)}$ represents the motion of $n$ indivisible points thrown in the fluid. The key point is that the two notions are shown to be equivalent: the law of a stochastic flow of kernels is uniquely determined by the compatible system of $n$-point motions.

In Section 2 we define the noise associated with a flow and recall the notion of "black noise" introduced by Tsirelson.

Coalescing flows are defined in Section 3. A coalescing flow can be obtained from any flow of kernels the two-point motion of which hits the diagonal. Then the original flow is recovered by filtering the coalescing flow with respect to a sub-noise.

We give the example of Arratia's flow and consider briefly sticky flows.

In Section 4, we present the result of [18] in which the classification of solutions of Tanaka's equation is given.

Finally, in Section 5, we consider stochastic flows on the circle defined by SDE's driven by the white noise $W$, which exhibit most of the features of more general isotropic flows considered in [15] and [16].

## 1. Flows and their construction

This first section is rather formal since we chose to give a precise result. Its intuitive content is rather simple: flows of maps, and more generally flows of transition kernels, are described by their moments which are Markovian semigroups describing the motion of any finite number of points transported by the flow. We refer to [24] for an alternative approach to this construction.

### 1.1. Flows of maps.

Let $M$ be a compact separable metric space.

**Definition 1.1.1.** Let $(\mathsf{P}_t^{(n)},\ n \geq 1)$ be a family of Feller semigroups[1], defined on $M^n$ and acting on $C(M^n)$, respectively. We say that this family is *consistent* as soon as for all $k \leq n$,

$$\mathsf{P}_t^{(k)} f(x_1, \ldots, x_k) = \mathsf{P}_t^{(n)} g(y_1, \ldots, y_n), \tag{1.1}$$

where $f$ and $g$ are any continuous functions such that

$$g(y_1, \ldots, y_n) = f(y_{i_1}, \ldots, y_{i_k}) \tag{1.2}$$

with $\{i_1, \ldots, i_k\} \subset \{1, \ldots, n\}$ and $(x_1, \ldots, x_k) = (y_{i_1}, \ldots, y_{i_k})$. We will denote by $\mathsf{P}^{(n)}_{(x_1,\ldots,x_n)}$ the law of the Markov process associated with $\mathsf{P}_t^{(n)}$ starting from $(x_1, \ldots, x_n)$.

This Markov process will be called the $n$-point motion (see also [21]).

We equip $M$ with its Borel $\sigma$-field $\mathcal{B}(M)$. Let $(F, \mathcal{F})$ be the space of measurable mappings on $M$ equipped with the $\sigma$-field generated by the evaluations at $x$ for all $x$ in $M$.

**Definition 1.1.2.** A probability measure $\mathsf{Q}$ on $(F, \mathcal{F})$ is called *regular* if there exists a measurable mapping $\mathcal{J}\colon (F, \mathcal{F}) \to (F, \mathcal{F})$ such that

$$(M \times F, \mathcal{B}(M) \otimes \mathcal{F}) \to (M, \mathcal{B}(M)),$$
$$(x, \varphi) \mapsto \mathcal{J}(\varphi)(x)$$

[1] $\mathsf{P}_t^{(n)}$ is a Feller semigroup on $M^n$ if and only if $\mathsf{P}_t^{(n)}$ is positive (i.e. $\mathsf{P}_t^{(n)} f \geq 0$ for every $f \geq 0$), $\mathsf{P}_t^{(n)} 1 = 1$ and for every continuous function $f$, $\mathsf{P}_t^{(n)} f$ is continuous and $\lim_{t\to 0} \mathsf{P}_t^{(n)} f(x) = f(x)$, which implies the uniform convergence of $\mathsf{P}_t^{(n)} f$ towards $f$ .

is measurable and for every $x \in M$,

$$\mathsf{Q}(d\varphi)\text{-a.s.}, \quad \mathcal{J}(\varphi)(x) = \varphi(x), \tag{1.3}$$

i.e. $\mathcal{J}$ is a measurable modification of the identity mapping on $(F, \mathcal{F}, \mathsf{Q})$. We call it a measurable presentation of $\mathsf{Q}$.

Let $\mathsf{Q}_1$ and $\mathsf{Q}_2$ be two probability measures on $(F, \mathcal{F})$. Assume that $\mathsf{Q}_1$ is regular. Let $\mathcal{J}$ be a measurable presentation of $\mathsf{Q}_1$. Then the mapping

$$\begin{aligned}(F^2, \mathcal{F}^{\otimes 2}) &\to (F, \mathcal{F}),\\ (\varphi_1, \varphi_2) &\mapsto \mathcal{J}(\varphi_1) \circ \varphi_2\end{aligned}$$

is measurable. Moreover, if $\mathcal{J}'$ is another measurable presentation of $\mathsf{Q}_1$, then for every $x \in M$,

$$\mathsf{Q}_1(d\varphi_1) \otimes \mathsf{Q}_2(d\varphi_2)\text{-a.s.}, \quad \mathcal{J}(\varphi_1) \circ \varphi_2(x) = \mathcal{J}'(\varphi_1) \circ \varphi_2(x). \tag{1.4}$$

Note that $(\varphi_1, \varphi_2) \mapsto \mathcal{J}(\varphi_1) \circ \varphi_2$ is measurable, but $(\varphi_1, \varphi_2) \mapsto \varphi_1 \circ \varphi_2$ is not measurable.

**Definition 1.1.3.** The *convolution product* of $\mathsf{Q}_1$ and $\mathsf{Q}_2$, denoted by $\mathsf{Q}_1 * \mathsf{Q}_2$, is the law of the random variable $(\varphi_1, \varphi_2) \mapsto \mathcal{J}(\varphi_1) \circ \varphi_2$ defined on the probability space $(F^2, \mathcal{F}^{\otimes 2}, \mathsf{Q}_1 \otimes \mathsf{Q}_2)$. A *convolution semigroup* on $(F, \mathcal{F})$ is a family $(\mathsf{Q}_t)_{t \geq 0}$ of regular probability measures on $(F, \mathcal{F})$ such that for all nonnegative $s$ and $t$, $\mathsf{Q}_{s+t} = \mathsf{Q}_s * \mathsf{Q}_t$.

A convolution semigroup $(\mathsf{Q}_t)_{t \geq 0}$ on $(F, \mathcal{F})$ is called Feller if

(i) for all $f \in C(M)$, $\lim_{t \to 0} \sup_{x \in M} \int (f \circ \varphi(x) - f(x))^2 \mathsf{Q}_t(d\varphi) = 0$;

(ii) for all $f \in C(M)$ and $t \geq 0$, $\lim_{d(x,y) \to 0} \int (f \circ \varphi(x) - f \circ \varphi(y))^2 \mathsf{Q}_t(d\varphi) = 0$.

Let $(\mathsf{Q}_t)_{t \geq 0}$ be a Feller convolution semigroup on $(F, \mathcal{F})$. For all $n \geq 1$, $f \in C(M^n)$ and $x \in M^n$ set

$$\mathsf{P}_t^{(n)} f(x) = \int f \circ \varphi^{\otimes n}(x)\, \mathsf{Q}_t(d\varphi). \tag{1.5}$$

Then $(\mathsf{P}_t^{(n)},\ n \geq 1)$ is a compatible family of Feller semigroups on $M$ satisfying

$$\mathsf{P}_t^{(2)} f^{\otimes 2}(x, x) = \mathsf{P}_t f^2(x) \tag{1.6}$$

for all $f \in C(M)$, $x \in M$ and $t \geq 0$. *The semigroup* $(\mathsf{Q}_t)_{t \geq 0}$ *is uniquely determined by* $(\mathsf{P}_t^{(n)},\ n \geq 1)$.

In the following we will consider only probability spaces $(\Omega, \mathcal{A}, \mathsf{P})$ which are separable, i.e., the corresponding Hilbert space $L^2(\Omega, \mathcal{A}, \mathsf{P})$ is separable.

**Definition 1.1.4.** Let $(\Omega, \mathcal{A}, \mathsf{P})$ be a probability space and $(T_h)_{h\in\mathbb{R}}$ a one parameter group of $\mathsf{P}$-preserving $L^2$-continuous transformations of $\Omega$. A family of $(F, \mathcal{F})$-valued random variables $(\varphi_{s,t},\ s \le t)$ is called a *measurable stochastic flow of mappings* if for all $s \le t$ the mapping

$$(M \times \Omega, \mathcal{B}(M) \otimes \mathcal{A}) \to (M, \mathcal{B}(M)),$$
$$(x, \omega) \mapsto \varphi_{s,t}(x, \omega)$$

is measurable and if it satisfies the following properties.

(a) (Cocycle property) For all $s < u < t$ and $x \in M$, $\mathsf{P}$-almost surely, $\varphi_{s,t}(x) = \varphi_{u,t} \circ \varphi_{s,u}(x)$.

(b) (Stationarity) For all $s \le t$, $\varphi_{s+h,t+h} = \varphi_{s,t} \circ T_h$.

(c) The flow has independent increments, i.e. for all $t_1 < t_2 < \cdots < t_n$, the family $\{\varphi_{t_i,t_{i+1}},\ 1 \le i \le n-1\}$ is independent.

(d) For every $f \in C(M)$, $\lim_{(u,v)\to(s,t)} \sup_{x\in M} \mathsf{E}[(f\circ\varphi_{s,t}(x) - f\circ\varphi_{u,v}(x))^2] = 0$.

(e) For all $f \in C(M)$ and $s \le t$, $\lim_{d(x,y)\to 0} \mathsf{E}[(f \circ \varphi_{s,t}(x) - f \circ \varphi_{s,t}(y))^2] = 0$.

Let $\varphi = (\varphi_{s,t},\ s \le t)$ be a stochastic flow of mappings. For all $n \ge 1$, $f \in C(M^n)$ and $x \in M^n$ set

$$\mathsf{P}_t^{(n)} f(x) = \mathsf{E}[f \circ \varphi_{0,t}^{\otimes n}(x)]. \tag{1.7}$$

Then $(\mathsf{P}_t^{(n)},\ n \ge 1)$ is a compatible family of Feller semigroups on $M$ satisfying (1.6). *The law of $\varphi$ is uniquely determined by* $(\mathsf{P}_t^{(n)},\ n \ge 1)$.

**Theorem 1.1.5.** 1) *Let* $(\mathsf{P}_t^{(n)},\ n \ge 1)$ *be a compatible family of Feller semigroups on $M$ satisfying*

$$\mathsf{P}_t^{(2)} f^{\otimes 2}(x, x) = \mathsf{P}_t f^2(x) \tag{1.8}$$

*for all $f \in C(M)$, $x \in M$ and $t \ge 0$. Then there exists a unique Feller convolution semigroup $(\mathsf{Q}_t)_{t\ge 0}$ on $(F, \mathcal{F})$ such that for all $n \ge 1$, $t \ge 0$, $f \in C(M^n)$ and $x \in M^n$,*

$$\mathsf{P}_t^{(n)} f(x) = \int f \circ \varphi^{\otimes n}(x)\ \mathsf{Q}_t(d\varphi). \tag{1.9}$$

2) *For every Feller convolution semigroup $\mathsf{Q} = (\mathsf{Q}_t)_{t\ge 0}$ on $(F, \mathcal{F})$ there exists a stochastic flow of mappings associated with $\mathsf{Q}$ (or equivalently with* $(\mathsf{P}_t^{(n)},\ n \ge 1)$*).*

Let $V, V_1, \ldots, V_k$ be bounded Lipschitz vector fields on a smooth locally compact manifold $M$. We also assume that $V_1, \ldots, V_k$ are $C^1$. Let $W^1, \ldots, W^k$ be $k$ independent real white noises. We consider the following SDE on $M$:

$$dX_t = \sum_{i=1}^{k} V_i(X_t) \circ dW_t^i + V(X_t)\, dt, \quad t \in \mathbb{R}. \tag{1.10}$$

From the usual theory of strong solutions of SDEs (see for example [12]) it is possible to construct a stochastic flow of diffeomorphisms $(\varphi_{s,t},\ s \le t)$ such that for every $x \in M$, $\varphi_{s,t}(x)$ is a strong solution of the SDE (1.10) with $\varphi_{s,s}(x) = x$.

Using this stochastic flow, it is possible to construct a compatible family of Markovian semigroups $(\mathsf{P}_t^{(n)},\ n \ge 1)$ with

$$\mathsf{P}_t^{(n)} h(x_1, \dots, x_n) = \mathsf{E}[h(\varphi_{0,t}(x_1), \dots, \varphi_{0,t}(x_n))] \tag{1.11}$$

for $h \in C(M^n)$ and $x_1, \dots, x_n$ in $M$. It is easy to check that these semigroups are Feller and that the canonical stochastic flow of maps associated with this family of semigroups is equal in law to $(\varphi_{s,t},\ s \le t)$.

**1.2. Flows of transition kernels.** We denote by $\mathcal{P}(M)$ the space of probability measures on $M$, equipped with the weak convergence topology. $\mathcal{P}(M)$ is a compact metric space. Let us recall that a kernel $K$ on $M$ is a measurable mapping from $M$ into $\mathcal{P}(M)$, $M$ and $\mathcal{P}(M)$ being equipped with their Borel $\sigma$-fields. For all $f \in C(M)$ and $x \in M$, $Kf(x)$ denotes $\int f(y)\, K(x, dy)$. For every $\mu \in \mathcal{P}(M)$, $\mu K$ denotes the probability measure defined by $\int f(y)\, \mu K(dy) = \int Kf(x)\, \mu(dx)$. We denote by $E$ the space of all kernels on $M$, and we equip $E$ with the $\sigma$-field $\mathcal{E}$ generated by the mappings $K \mapsto \mu K$ for every $\mu \in \mathcal{P}(M)$. Convolution semigroups on the space of kernels can be defined in a similar way as on the space of measurable maps (cf. [16]).

**Definition 1.2.1.** Let $(\Omega, \mathcal{A}, \mathsf{P})$ be a probability space and $(T_h)_{h\in\mathbb{R}}$ a one parameter group of $\mathsf{P}$-preserving $L^2$-continuous transformations of $\Omega$. Then a family of $(E, \mathcal{E})$-valued random variables $(K_{s,t},\ s \le t)$ is called a (*measurable*) *stochastic flow of kernels* if for all $s \le t$,

$$(x, \omega) \mapsto K_{s,t}(x, \omega) \tag{1.12}$$

is a measurable mapping from $(M \times \Omega, \mathcal{B}(M) \otimes \mathcal{A})$ onto $(\mathcal{P}(M), \mathcal{B}(\mathcal{P}(M)))$ and if it satisfies the following properties.

(a) (Cocycle property) For all $s < u < t$ and $x \in M$, $\mathsf{P}$-almost surely, for every $f \in C(M)$, $K_{s,t} f(x) = K_{s,u}(K_{u,t} f)(x)$.

(b) (Stationarity) For all $s \le t$, $K_{s+h,t+h} = K_{s,t} \circ T_h$.

(c) The flow has independent increments, i.e. for all $t_1 < t_2 < \cdots < t_n$, the family $\{K_{t_i,t_{i+1}},\ 1 \le i \le n-1\}$ is independent.

(d) For every $f \in C(M)$,

$$\lim_{(u,v)\to(s,t)} \sup_{x\in M} \mathsf{E}[(K_{s,t} f(x) - K_{u,v} f(x))^2] = 0. \tag{1.13}$$

(e) For all $f \in C(M)$ and $s < t$,

$$\lim_{d(x,y)\to 0} \mathsf{E}[(K_{s,t} f(x) - K_{s,t} f(y))^2] = 0. \tag{1.14}$$

Let $(K_{s,t},\ s \le t)$ be a stochastic flow of kernels. For all $n \ge 1$, $f \in C(M^n)$ and $x \in M^n$ set

$$\mathsf{P}_t^{(n)} f(x) = \mathsf{E}[K^{\otimes n} f(x)]. \tag{1.15}$$

Then $(\mathsf{P}_t^{(n)},\ n \ge 1)$ is a compatible family of Feller semigroups on $M$.

**Theorem 1.2.2.** 1) *For every compatible family* $(\mathsf{P}_t^{(n)},\ n \ge 1)$ *of Feller semigroups on* $M$ *there exists a unique Feller convolution semigroup* $(\nu_t)_{t\ge 0}$ *on* $(E, \mathcal{E})$ *such that for all* $n \ge 1$, $t \ge 0$, $f \in C(M^n)$ *and* $x \in M^n$,

$$\mathsf{P}_t^{(n)} f(x) = \int K^{\otimes n} f(x)\ \nu_t(dK). \tag{1.16}$$

2) *For every Feller convolution semigroup* $\nu = (\nu_t)_{t\ge 0}$ *on* $(E, \mathcal{E})$ *there exists a stochastic flow of kernels associated with* $\nu$ (*or equivalently with* $(\mathsf{P}_t^{(n)},\ n \ge 1)$).

**Remark 1.2.3.** If (1.6) is satisfied the stochastic flow of kernels $K$ is induced by a stochastic flow of mappings $\varphi$.

## 2. Noise and stochastic flows

The definition of a noise we give here is very close to the one given by Tsirelson in [25].

**Definition 2.1.1.** A *noise* consists of a separable probability space $(\Omega, \mathcal{A}, \mathsf{P})$, a one parameter group $(T_h)_{h\in\mathbb{R}}$ of $\mathsf{P}$-preserving $L^2$-continuous transformations of $\Omega$ and a family $\{\mathcal{F}_{s,t},\ -\infty \le s \le t \le \infty\}$ of sub-$\sigma$-fields of $\mathcal{A}$ such that

(a) $T_h$ maps $\mathcal{F}_{s,t}$ onto $\mathcal{F}_{s+h,t+h}$ for all $h \in \mathbb{R}$ and $s \le t$,

(b) $\mathcal{F}_{s,t}$ and $\mathcal{F}_{t,u}$ are independent for all $s \le t \le u$,

(c) $\mathcal{F}_{s,t} \vee \mathcal{F}_{t,u} = \mathcal{F}_{s,u}$ for all $s \le t \le u$.

A classical white noise or a stationary Poisson measure clearly define a noise in this sense.

A square integrable random variable with zero mean is said to belong to the first chaos if the sum of its conditional expectations with respect to the fields associated with disjoint intervals is the conditional expectation with respect to the field associated with the union of these intervals. The noise is called black when the first chaos reduces to zero. Clearly, the white noise or the Poisson noise are not black.

Let $(\Omega, \mathcal{A}, \mathsf{P}_\nu)$ denote the probability space of a stochastic flow of kernels $K = (K_{s,t},\ s \le t)$ associated with a Feller convolution semigroup $\nu$.

For all $-\infty \le s \le t \le \infty$ let $\mathcal{F}_{s,t}$ be the sub-$\sigma$-field of $\mathcal{A}$ generated by the random variables $K_{u,v}$ for all $s \le u \le v \le t$. Then the cocycle property of $K$ implies that $N_\nu := (\Omega, \mathcal{A}, (\mathcal{F}_{s,t})_{s\le t}, \mathsf{P}_\nu, (T_h)_{h\in\mathbb{R}})$ is a noise ($T_h$ is $L^2$-continuous by the Feller property). We call it the noise generated by the flow $K$.

## 3. Stochastic coalescing flows

Starting from a compatible family of Feller semigroups, under the hypothesis that the two-point motion hits the diagonal almost surely, we construct another compatible family of Feller semigroups to which is associated a stochastic coalescing flow. It appears that the stochastic flow of kernels associated with the first family of semigroups can be recovered by filtering the stochastic coalescing flow with respect to a sub-noise of an extension of its noise.

Finally, we give the example of Arratia's flow ([2]), which describes a space-time continuum of independent Brownian motions sticking together when they meet. The construction of a stochastic coalescing flow solution of SDE's will be presented in the next sections (see also [11], [5]).

### 3.1. Definition and construction

**Definition 3.1.1.** A stochastic flow of mappings on $M$, $(\varphi_{s,t},\ s \leq t)$, is called a *stochastic coalescing flow* if for all $(x, y) \in M^2$, $T_{x,y} = \inf\{t \geq 0,\ \varphi_{0,t}(x) = \varphi_{0,t}(y)\}$ is finite and for every $t \geq T_{x,y}$, $\varphi_{0,t}(x) = \varphi_{0,t}(y)$ almost surely.

This definition depends only on the two-point motion.

Let $(\mathsf{P}_t^{(n)},\ n \geq 1)$ be a compatible family of Feller semigroups on a compact separable metric space $M$, $\nu = (\nu_t)_{t\in\mathbb{R}}$ the associated Feller convolution semigroup on $(E, \mathcal{E})$ and $K_t$ the associated flow of kernels. Let $\Delta_n = \{x \in M^n,$ there exists $i \neq j$ such that $x_i = x_j\}$ and $T_{\Delta_n} = \inf\{t \geq 0,\ X_t^{(n)} \in \Delta_n\}$, where $X_t^{(n)}$ denotes the $n$-point motion, i.e. the Markov process on $M^n$ associated with the semigroup $\mathsf{P}_t^{(n)}$. Denoting by $\mathsf{P}_{(x,y)}^{(2)}$ the law of the Markov process associated with $\mathsf{P}_t^{(2)}$ starting from $(x, y)$ and $\Delta_2$ by $\Delta$, assume that for all $t > 0$ and $x \in M$,

$$\lim_{y\to x} \mathsf{P}_{(x,y)}^{(2)}[\{T_\Delta > t\}] = 0,$$

and that for all $x$ and $y$ in $M$, $\mathsf{P}_{(x,y)}^{(2)}[T_\Delta < \infty] = 1$.

**Theorem 3.1.2.** *There exists a unique compatible family* $(\mathsf{P}_t^{(n),c},\ n \geq 1)$ *of Feller semigroups on* $M$ *such that if* $X^{(n),c}$ *is the associated* $n$*-point motion and* $T_{\Delta_n}^c = \inf\{t \geq 0,\ X_t^{(n),c} \in \Delta_n\}$, *then*

- $(X_t^{(n),c},\ t \leq T_{\Delta_n}^c)$ *is equal in law to* $(X_t^{(n)},\ t \leq T_{\Delta_n})$,
- *for* $t \geq T_{\Delta_n}^c$, $X_t^{(n),c} \in \Delta_n$.

*Moreover,* $(\mathsf{P}_t^{(n),c},\ n \geq 1)$ *satisfies* (1.6) *and is associated with a coalescing flow* $\varphi_{s,t}^c$.

We denote by $\nu^c$ the associated Feller convolution semigroup. An important result is the following:

**Theorem 3.1.3.** *There is a joint realisation of $K$ and $\varphi^c$ such that $K_{s,t}g(y) = \mathsf{E}[\varphi^c_{s,t}(y)|\sigma(K)]$*

We say that the convolution semigroup $\nu^c$ weakly dominates $\nu$.

**3.2. Arratia's coalescing flow of independent Brownian motions.** The first example of coalescing flows was given by Arratia [2]. On $\mathbb{R}$, or on the unit circle, let $\mathsf{P}_t$ be the semigroup of a Brownian motion. With this semigroup we define the compatible family $(\mathsf{P}_t^{\otimes n},\ n \geq 1)$ of Feller semigroups. Note that the $n$-point motion of this family of semigroups is given by $n$ independent Brownian motions. Let us also remark that the canonical stochastic flow of kernels associated with this family of semigroups is not random and is given by $(\mathsf{P}_{t-s},\ s \leq t)$.

Let $(\mathsf{P}_t^{(n)},\ n \geq 1)$ be the compatible family of Markovian coalescent semigroups associated with $(\mathsf{P}_t^{\otimes n},\ n \geq 1)$. Note that the $n$-point motion of this family of semigroups is given by $n$ independent Brownian motions which stick together when they meet.

**Theorem 3.2.1.** *The family $(\mathsf{P}_t^{(n)},\ n \geq 1)$ is constituted of Feller semigroups and is associated with a coalescing flow. The noise defined by this flow is black*

Blackness of the noise was first proved in [25] and then in a different way in [17]. It may seem a paradox but note that the increments of a one point motion between two times depend on the position of that point at the first time and not only on the increment of the flow of maps. In the latter paper a related family of flows of kernels, called sticky flows, was also constructed. The associated $n$ point motions are given by Brownian paths which are independent except they stick together (during a Cantor type set of times of positive Lebesgue measure) when they meet. These flows interpolate between the heat flow and Arratia's flow. They also define a black noise. Any flow of kernels induces naturally a Markov process on measures which has often an invariant probability distribution. For sticky flows it is explicitly given in terms of the Poisson Dirichlet distribution. Finally, let us mention that a discrete model converging to these flows was presented in [13].

## 4. Tanaka's equation

Tanaka's stochastic differential equation (SDE) is one of the simplest examples of an SDE that does not have a strong solution in the usual sense. The objective is to apply to this example the theory of flows of transition kernels and to classify all the solutions of Tanaka's SDE, extended to transition kernels. It is shown that they can be characterized by a probability measure on $[0, 1]$. The domination and the weak domination relations (defined in [15]) between different solutions are then fully understood in terms of barycenter and balayage of the associated measures.

On a probability space $(\Omega, \mathcal{F}, \mathsf{P})$ let $W = (W_{s,t},\ s \le t)$ be a real white noise and $K = (K_{s,t},\ s \le t)$ (resp. $\varphi = (\varphi_{s,t},\ s \le t)$) be a stochastic flow of kernels (resp. flow of measurable maps) on the real line. Recall that for all $s \le t$, $K_{s,t} : \mathbb{R} \to \mathcal{P}(\mathbb{R})$ is measurable, with $\mathcal{P}(\mathbb{R})$ denoting the set of probability measures on $\mathbb{R}$ equipped with the topology of weak convergence. We say that $(K, W)$ solves Tanaka's SDE if for all $s \le t$, $f \in C_K^2(\mathbb{R})$ and $x \in \mathbb{R}$,

$$K_{s,t} f(x) = f(x) + \int_s^t K_{s,u}(f' \mathrm{sgn})(x) W(du) + \frac{1}{2} \int_s^t K_{s,u}(f'') du, \tag{4.1}$$

with $\mathrm{sgn}(x) = 1_{x \ge 0} - 1_{x<0}$. Note that (4.1) is a generalization of the SDE

$$dX_t = \mathrm{sgn}(X_t) dW_t,$$

where $W_t = W_{0,t} 1_{t \ge 0} - W_{t,0} 1_{t<0}$.

It can be shown that this implies that $\sigma(W) \subset \sigma(K)$. Let $N^K$ be the noise of $K$. The noise $N^W$ of $W$ is a subnoise of $N^K$. So we can simply say that $K$ solves Tanaka's SDE (since $W$ is a function of $K$). We say that a flow of maps $\varphi$ solves Tanaka's SDE if $\delta_\varphi$ solves Tanaka's SDE. The law of a solution $K$ is given by a Feller convolution semigroup $\nu = (\nu_t,\ t \ge 0)$, where $\nu_t$ is the law of $K_{0,t}$.

Two particular solutions of Tanaka's SDE are given in [15]: the coalescing solution $\varphi^c$ and the Wiener solution $K^W$. The solution $K^W$ is the only solution of Tanaka's SDE such that $N^K = N^W$, and $\varphi^c$ is the only flow of maps solution of Tanaka's SDE. The Wiener solution can be obtained by filtering the coalescing solution: $K^W = \mathsf{E}[\delta_\varphi | W]$. An explicit expression of $K^W$ can be given. For $x \in \mathbb{R}$ set $\tau_x = \inf\{t > 0,\ W_{0,t} = -|x|\}$. Let $W^+ = (W_t^+,\ t \ge 0)$ be defined by

$$W_t^+ = W_{0,t} - \inf_{s \le t} W_{0,s}.$$

It is well known that the law of $(W_t^+)_{t \ge 0}$ and the law of $(|W_t|)_{t \ge 0}$ coincide. Note that $W_{0,\cdot}$ can be recovered out of $W^+$ by Doob–Meyer decomposition. Then for $t \ge 0$,

$$K_{0,t}^W(x) = \delta_{x + \mathrm{sgn}(x) W_{0,t}} 1_{\{t \le \tau_x\}} + \frac{1}{2}(\delta_{W_t^+} + \delta_{-W_t^+}) 1_{\{t > \tau_x\}}. \tag{4.2}$$

Let $\theta_h^W$ be the shift operator such that $W_{s,t} \circ \theta_h^W = W_{s+h,t+h}$. Then for all $s < t$, $K_{s,t}^W = K_{0,t-s}^W \circ \theta_s^W$. The coalescing solution $\varphi^c$ can be defined by the consistent family of its $n$-point motions obtained by transforming the $n$-point motion associated with $K^W$ into a coalescing motion. A more explicit definition can be given in this special case, as is shown in [18], where we also prove the following result:

**Theorem 4.1.1.** a) *Each solution $K$ of Tanaka's SDE verifies $K^W = \mathsf{E}[K|W]$ (this means in particular that the support of $K$ has at most two points). It defines a probability measure $m$ on $[0, 1]$ with mean $1/2$, which is the law of $\int_0^\infty K_{0,t}(0, dy)$ for all $t > 0$.*

b) *The mapping defined in* a) *is a bijection between solutions of* (4.1) *and probability measures on* $[0, 1]$ *with mean* $1/2$. *The Feller convolution semigroup associated with a measure* $m$ *is denoted* $\{\nu_t^m,\ t \geq 0\}$ *or* $\nu^m$.

c) $K^W$ *is associated with* $\delta_{1/2}$ *and* $\varphi^c$ *with* $\frac{1}{2}(\delta_0 + \delta_1)$.

Let us now describe the domination relations.

**Definition 4.1.2.** Let $m_1$ and $m_2$ be probability measures on $[0, 1]$.

a) $m_1$ is swept by $m_2$ if and only if for all positive convex function $f$, $\int f dm_2 \leq \int f dm_1$.

b) $m_2$ is a barycenter of $m_1$ if and only if there exists a measurable map $\psi : [0, 1] \to [0, 1]$ such that $\psi^* m_1 = m_2$ and $\psi^*(I \cdot m_1) = I \cdot m_2$ (where $I$ denotes the identity function).

It can easily be seen that a) and b) define partial order relations. The order defined in a) is the balayage order. The fact that $m_2$ is a barycenter of $m_1$ is equivalent to saying that if $U_1$ is a random variable of law $m_1$, then there exists a $\sigma(U_1)$-measurable random variable $U_2$ of law $m_2$ such that $\mathsf{E}[U_1|U_2] = U_2$.

In [16], a domination and a weak domination relation between (laws of) stochastic flow of kernels is defined: Let $\nu^1$ and $\nu^2$ be two Feller convolution semigroups. We recall that Definition 3.3 in [16] essentially says that $\nu^1$ dominates $\nu^2$ if and only if there is a joint realisation $(K^1, K^2)$ such that $K^1$ (resp. $K^2$) is a stochastic flow of kernels associated to $\nu^1$ (resp. to $\nu^2$) satisfying $\mathsf{E}[K^1|K^2] = K^2$ and $\sigma(K^2) \subset \sigma(K^1)$. One says that $\nu^1$ weakly dominates $\nu^2$ when only the conditional expectation assumption is verified ($\sigma(K^2)$ needs not be a sub-$\sigma$-field of $\sigma(K^1)$). A full understanding of the solutions of a general SDE should involve a classification of the solutions according to these domination relations. As we will see in the following section, this is not achieved yet even in relatively simple cases.

**Theorem 4.1.3.** *Let* $m_1$ *and* $m_2$ *be two probability measures on* $[0, 1]$ *with mean* $1/2$.

a) $\nu^{m_1}$ *dominates* $\nu^{m_2}$ *if and only if* $m_2$ *is a barycenter of* $m_1$.

b) $\nu^{m_1}$ *weakly dominates* $\nu^{m_2}$ *if and only if* $m_1$ *is swept by* $m_2$.

## 5. Stochastic flows of kernels and SDEs: an example on the circle

**Notation.** In all the following we will denote by $\mathbb{S}$ the unit circle $\mathbb{R}/2\pi\mathbb{Z}$, by $m$ the Lebesgue measure on $\mathbb{S}$ and by $\mathcal{P}(\mathbb{S})$ the set of Borel probability measures on $\mathbb{S}$.

Let $(\mathcal{W}, \mathcal{F}^W, \mathsf{P}_W)$ be the canonical probability space of a sequence of independent Wiener processes $(W_t^k,\ k \geq 0,\ t \geq 0)$. For all $s < t$ let $\mathcal{F}_{s,t}^W$ denote the $\sigma$-field generated by the random variables $W_v^k - W_u^k$, $s \leq u < v \leq t$ and $k \geq 0$. Being

given $(a_k)_{k\geq 0}$ a sequence of nonnegative numbers such that $\sum_{k\geq 0} a_k^2 < \infty$, we set $C(z) = \sum_{k\geq 0} a_k^2 \cos(kz)$. Note that all real positive definite functions on $\mathbb{S}$ can be written in this form and that $C(0) = \sum_{k\geq 0} a_k^2$.

**5.1. Flows of diffeomorphisms.** Assume that $\sum_{k\geq 1} k^2 a_k^2 < \infty$. Then by a stochastic version of Gronwall's lemma it can be shown that for each $x_0 \in \mathbb{S}$ the stochastic differential equation (SDE)

$$x_t = x_0 + a_0 W_t^0 + \sum_{k\geq 1} a_k \left( \int_0^t \sin(kx_s) dW_s^{2k-1} + \int_0^t \cos(kx_s) dW_s^{2k} \right) \tag{5.1}$$

has a unique strong solution. These solutions can be considered jointly to form a stochastic flow of diffeomorphisms $(\varphi_{s,t})_{s<t}$. Set $\varphi_t = \varphi_{0,t}$.

Note that the one point motion $x_t := \varphi_t(x)$ is a Brownian motion on $\mathbb{S}$ starting at $x$. Denote the associated heat semigroup $\mathsf{P}_t$. For $h \in C^2(\mathbb{S}^2)$ set $A^{(2)}h(x, y) = \frac{C(0)}{2}(\partial_{xx}^2 h(x, y) + \partial_{yy}^2 h(x, y)) + C(x-y)\partial_{xy}^2 h(x, y)$. The two point motion $(x_t, y_t) := (\varphi_t(x), \varphi_t(y))$ is a diffusion on $\mathbb{S}^2$ satisfying

- for all $h \in C^2(\mathbb{S}^2)$, $h(x_t, y_t) - \int_0^t A^{(2)}h(x_s, y_s)ds$ is an $L^2$-martingale.

This in particular implies the following:

- For all $x, y \in \mathbb{S}$, $f \in C(\mathbb{S})$, if $Z_t = \varphi_t(x) - \varphi_t(y)$, $Z_t$ is a diffusion on $\mathbb{S}$ and $f(Z_t) - \int_0^t (C(0) - C(Z_s)) f''(Z_s) ds$ is an $L^2$-martingale.

For all $x, y \in \mathbb{S}$, $\lim_{t\to\infty}(\varphi_t(x) - \varphi_t(y)) = 0$. Using the isotropy one can compute the Lyapounov exponent of the flow: for all $x \in \mathbb{S}$,

$$\lim_{t\to\infty} \frac{1}{t} \log |\varphi_t'(x)| = -\frac{1}{2} \sum_{k\geq 1} k^2 a_k^2.$$

The Lyapounov exponent of the flow being negative, the flow is stable. In the particular case $a_k^2 = k^{-(1+\alpha)}$, for $\alpha > 2$ the condition $\sum_{k\geq 1} k^2 a_k^2 < \infty$ is satisfied. When $\alpha$ is close to the boundary case, $\alpha = 2$, the Lyapounov exponent gets close to $-\infty$. In the following we will define stochastic flows corresponding to the case $\alpha \leq 2$ which are not flows of diffeomorphisms.

**5.2. Wiener chaos expansion: Lipschitz case.** Suppose that $\sum_k k^2 a_k^2 < \infty$ and let $\varphi_{s,t}$ be the flow defined in the previous section. For any function $f \in C(\mathbb{S})$, $x \in \mathbb{S}$ and $s \leq t$, $f \circ \varphi_{s,t}(x)$ belongs to the Wiener space $L^2(\mathsf{P}_W)$. Following the original idea of [26], its Wiener chaos expansion can be explicitly computed as follows.

**Proposition 5.2.1.** *For all $s \le t$ and $f \in C(\mathbb{S})$,*

$$f \circ \varphi_{s,t}(x) = \mathsf{P}_{t-s} f(x) + \sum_{n \ge 1} J^n_{s,t} f(x) \quad \text{in } L^2(\mathsf{P}_W), \tag{5.2}$$

*where $J^n$ is defined recursively as follows (denoting $c_k$ the function $x \mapsto \cos(kx)$ and $s_k$ the function $x \mapsto \sin(kx)$):*

$$\begin{aligned} J^{n+1}_{s,t} f(x) = a_0 \int_s^t J^n_{s,u}((\mathsf{P}_{t-u} f)')(x) dW^0_u \\ + \sum_{k \ge 1} a_k \Big( \int_s^t J^n_{s,u}(s_k(\mathsf{P}_{t-u} f)')(x) dW^{2k-1}_u \\ + \int_s^t J^n_{s,u}(c_k(\mathsf{P}_{t-u} f)')(x) dW^{2k}_u \Big) \end{aligned}$$

*for $n \ge 0$ with $J^0_{s,t} = \mathsf{P}_{t-s}$.*

**Remark 5.2.2.** The chaos expansion (5.2) can be extended to all $f \in L^2(m)$, the two terms being equal in $L^2(m \otimes \mathsf{P}_W)$.

**5.3. Non-Lipschitz case.** From now on we assume $\sum_{k \in \mathbb{N}} k^2 a_k^2 = \infty$. In this case, using Gronwall's inequality, the existence of a strong solution to the SDE (5.1) cannot be proven. But the series giving the Wiener chaos expansion of $f \circ \varphi_{s,t}$ in the Lipschitz case for $f \in L^2(m)$ also converges in $L^2(m \otimes \mathsf{P}_W)$ in the non-Lipschitz case.

We can construct a family $S^n_{s,t}$ of random operators acting of $L^2(m)$ recursively: let $S^0_{s,t} = \mathsf{P}_{t-s}$ and for $f \in L^2(m)$ and $n \ge 0$ set

$$\begin{aligned} S^{n+1}_{s,t} f = \mathsf{P}_{t-s} f + a_0 \int_0^t S^n_{s,u}((\mathsf{P}_{t-u} f)') dW^0_u \\ + \sum_{k \ge 1} a_k \left( \int_s^t S^n_{s,u}(s_k(\mathsf{P}_{t-u} f)') dW^{2k-1}_u + \int_s^t S^n_{s,u}(c_k(\mathsf{P}_{t-u} f)') dW^{2k}_u \right). \end{aligned}$$

It can be seen that for all $n$, $\mathsf{E}[(S^n_{s,t} f)^2] \le \mathsf{P}_{t-s} f^2$ and

$$S^n_{s,t} f = \sum_{k=0}^n J^k_{s,t} f, \tag{5.3}$$

where $J^k_{s,t} f$ belongs to the $k$-th Wiener chaos. Thus all these terms are orthogonal and $S^n_{s,t} f$ converges in $L^2(m \otimes \mathsf{P}_W)$ towards a limit we denote by $S_{s,t} f$. The family $S = (S_{s,t})$ of random operators acting on $L^2(m)$ satisfies the following.

(i) Cocycle property: $S_{s,u} = S_{s,t} S_{t,u}$ for all $s < t < u$.

(ii) Stationary increments: for all $s \le t$, $S_{s,t}$ and $S_{0,t-s}$ have the same law.

(iii) Independent increments: for $t_0 \le \cdots \le t_n$, $S_{t_0,t_1}, \ldots, S_{t_{n-1},t_n}$ are independent.

(iv) Solution of the SDE

$$\begin{aligned} S_{s,t}f = f &+ a_0 \int_s^t S_{s,u}(f')dW_u^0 \\ &+ \sum_{k\ge 1} a_k \left( \int_s^t S_{s,u}(s_k f')dW_u^{2k-1} + \int_s^t S_{s,u}(c_k f')dW_u^{2k} \right) \\ &+ \frac{C(0)}{2} \int_s^t S_{s,u} f'' du, \end{aligned} \tag{5.4}$$

for all $f \in H^2(\mathbb{S})$ and all $s < t$.

Moreover, $S$ is the unique family of random operators acting on $L^2(m)$ verifying $\mathsf{E}[(S_{s,t}f)^2] \le \mathsf{P}_{t-s}f^2$, satisfying (i), (ii), (iii), (iv) and such that $S_{s,t}$ is $\mathcal{F}_{s,t}^W$-measurable.

Obviously $S_{s,t}1 = 1$, and it can be proved that $S_{s,t}$ is nonnegative as follows. Consider an independent stationary Brownian motion $B_t$ with diffusion coefficient $C(0)$ on $\mathbb{S}$. Set, for $k \ge 1$,

$$\begin{aligned} \widetilde{W}_t^{2k-1} = W_t^{2k-1} &+ a_k \int_0^t s_k(B_s)dB_s - a_k a_0 \int_0^t s_k(B_s)dW_s^0 \\ &- a_k \sum_{l\ge 1} a_l \left( \int_0^t s_k s_l(B_s)dW_s^{2l-1} + \int_0^t s_k c_l(B_s)dW_s^{2l} \right) \end{aligned}$$

and, for $k \ge 0$,

$$\begin{aligned} \widetilde{W}_t^{2k} = W_t^{2k} &+ a_k \int_0^t c_k(B_s)dB_s - a_k a_0 \int_0^t c_k(B_s)dW_s^0 \\ &- a_k \sum_{l\ge 1} a_l \left( \int_0^t c_k s_l(B_s)dW_s^{2l-1} + \int_0^t c_k c_l(B_s)dW_s^{2l} \right). \end{aligned}$$

These formulas are obtained by conditioning the "velocity differential" at time $t$ and site $B_t$ to be $dB_t$. Then $\widetilde{W}$ forms a family of independent Wiener processes. Set

$$\tilde{S}_{s,t}f(x) = \mathsf{E}[f(B_t)|\widetilde{W}, B_s = x].$$

It is clear that $\tilde{S}$ is nonnegative and that $\tilde{S}$ verifies the properties listed above ((i), (ii), (iii) and (iv)) with respect to $\widetilde{W}$. This implies $\tilde{S} = S$ and proves that $S$ is nonnegative.

Two cases may occur:

(a) $S_{s,t}f^2 = (S_{s,t}f)^2$ for all $f \in L^\infty(m)$.

(b) $S_{s,t}f^2 > (S_{s,t}f)^2$ for some $f \in L^\infty(m)$, and in fact for all non constant $f \in L^\infty(m)$.

**5.4. *n*-point motions.** Let $\mathsf{P}_t^{(n)}$ be the family of random operators acting on $L^\infty(m^{\otimes n})$ defined by

$$\mathsf{P}_t^{(n)} f_1 \otimes \cdots \otimes f_n = \mathsf{E}[S_{0,t} f_1 \otimes \cdots \otimes S_{0,t} f_n].$$

Properties (i), (ii) and (iii) imply that $\mathsf{P}_t^{(n)}$ is a Markovian semigroup. As in the case of $\mathbb{R}^d$ or $\mathbb{S}^d$ studied in [16], one can show that the isotropy implies that $\mathsf{P}_t^{(n)}$ is a Feller semigroup acting on $C(\mathbb{S}^n)$.

The *n-point motion* of $(S_{s,t})$ is the diffusion on $\mathbb{S}^n$ associated with $\mathsf{P}_t^{(n)}$. The generator $A^{(n)}$ of this diffusion is given by

$$A^{(n)} = \frac{1}{2} \sum_{1 \le i,j \le n} C(x_i - x_j) \partial_{x_i} \partial_{x_j}. \tag{5.5}$$

The case (a) appears when the diagonal is absorbing for the two-point motion. If this is not the case we are in case (b).

**5.5. Diffusive or coalescing?** In case (a) it can be shown (using the Feller property) that there exists a flow of random mappings $\varphi = (\varphi_{s,t})$ such that for all $s \le t$ and all $f \in L^2(m)$, we have $S_{s,t} f = f \circ \varphi_{s,t}$ in $L^2(m \otimes \mathsf{P}_W)$. Furthermore, $\varphi_{s,t} \colon (\mathbb{S} \times \mathcal{W}, \mathcal{B}(\mathbb{S}) \otimes \mathcal{F}^W) \to (\mathbb{S}, \mathcal{B}(\mathbb{S}))$ is measurable and solves the SDE (5.1).

In case (b) it can be shown that there exists a flow of random kernels $K = (K^W_{s,t})$ such that $S_{s,t} f = K^W_{s,t} f$ in $L^2(m \otimes \mathsf{P}_W)$ for all $s \le t$ and all $f \in L^2(m)$. The stochastic flow of kernels will be called *diffusive* when the kernels are not induced by maps, which clearly happens in case (b). This flow solves the SDE in the sense that for all $f \in C^2(\mathbb{S})$, $s \le t$ and $x \in \mathbb{S}$,

$$\begin{aligned} K^W_{s,t} f = f + \sum_{k \ge 1} a_k \left( \int_s^t K^W_{s,u}(s_k f') dW_u^{2k-1} + \int_s^t K^W_{s,u}(c_k f') dW_u^{2k} \right) \\ + a_0 \int_s^t K^W_{s,u}(f') dW_u^0 \quad + \quad \frac{C(0)}{2} \int_s^t K^W_{s,u} f'' du. \end{aligned} \tag{5.6}$$

In the following the flow $\varphi$ (in case (a)) or the flow $K^W$ (in case (b)) will be called the *Wiener solution* of the SDE (5.1). Since $(S_{s,t})$ is the unique solution of (5.4) which is $\mathcal{F}^W_{s,t}$-measurable, the Wiener solution $\varphi$ (or $K^W$) is the unique solution of SDE (5.1) (or of (5.6)) which is $\mathcal{F}^W_{s,t}$-measurable.

A diffusive flow is called *diffusive with hitting* if the two-point motion hits the diagonal $\Delta = \{(x, x),\ x \in \mathbb{S}\}$.

The diffusion $z_t \in [0, 2\pi)$ such that $z_t = X_t - Y_t$ modulo $2\pi$, where $(X_t, Y_t)$ is the two point motion, has a natural scale. The speed measure $m$ of this diffusion is given by $m(dz) = (C(0) - C(z))^{-1} dz$. Let $\kappa$ be defined by $\kappa(z) = \int_\pi^z \frac{z-x}{C(0)-C(x)} dx$. Note that $\kappa(0+) = \infty$ implies that $m((0, 2\pi)) = \infty$.

**Theorem 5.5.1.** 1) *If $\kappa(0^+) = \infty$ then the Wiener solution is a stochastic flow of maps, which is not a coalescing flow.*

2) *If $m((0, 2\pi)) = \infty$ and $\kappa(0^+) < \infty$ then the Wiener solution is a coalescing flow.*

3) *If $m((0, 2\pi)) < \infty$ then the Wiener solution is a diffusive flow with hitting.*

**Corollary 5.5.2.** *Let $a_k^2 = k^{-(1+\alpha)}$ with $\alpha > 0$.*

1) *If $\alpha > 2$, then the Wiener solution is a stochastic flow of $C^1$-diffeomorphisms.*

2) *If $\alpha = 2$ then the Wiener solution is a stochastic flow of maps, which is not a coalescing flow.*

3) *If $\alpha \in [1, 2)$ then the Wiener solution is a coalescing flow.*

4) *If $\alpha \in (0, 1)$ then the Wiener solution is a diffusive flow with hitting.*

**Remark 5.5.3.** The case $\alpha = 2$ has been studied in [1], [8], [22]. It is shown in particular that the maps of the flow are homeomorphisms.

**5.6. Extension of the noise and weak solution.** Let $(\Omega, \mathcal{A}, \mathsf{P})$ be an extension of the probability space $(\mathcal{W}, \mathcal{F}^W, \mathsf{P}_W)$. We say that a measurable flow of maps $\varphi = (\varphi_{s,t})$ is a *weak solution* of (5.1) if it satisfies (5.1) without being $\mathcal{F}_{s,t}^W$-measurable. Similarly, a measurable flow of kernels $K = (K_{s,t})$ will be called *weak* (*generalized*) *solution* of the SDE (5.1) if it satisfies (5.6) without being $\mathcal{F}_{s,t}^W$-measurable.

We have seen that uniqueness is verified if one assumes in addition Wiener measurability: $K_{s,t}$ is $\mathcal{F}_{s,t}^W$-measurable for all $s \le t$.

In case (b) a different consistent system of Feller semigroups $\mathsf{P}_t^{(n),c}$ can be constructed by considering the coalescing $n$-point motion $X_t^{(n),c}$ associated with $X_t^{(n)}$, the $n$-point motion of the Wiener solution. A measurable flow of coalescing maps $\varphi_{s,t}^c$ whose $n$-point motion is $X_t^{(n),c}$ can be defined on an extension $(\Omega, \mathcal{A}, \mathsf{P})$ of the probability space $(\mathcal{W}, \mathcal{F}^W, \mathsf{P}_W)$. This coalescing flow also solves the SDE (5.1). It is a weak solution.

For $s \le t$ set $\mathcal{F}_{s,t}^c = \sigma(\varphi_{u,v}^c,\ s \le u \le v \le t)$. Then $(\mathcal{F}_{s,t}^c)_{s \le t}$ defines a noise. It can be seen (for details see [16]) that $\mathcal{F}_{s,t}^W \subset \mathcal{F}_{s,t}^c$ (this property also holds for any flow solution of SDE). This solution being different from the Wiener solution implies $\mathcal{F}_{s,t}^W \ne \mathcal{F}_{s,t}^c$. The noise $(\mathcal{F}_{s,t}^c)$ cannot be generated by Brownian motions. It is a non-classical noise (see also [27], [28]). The Wiener solution $K^W$ can be recovered by filtering:

$$K_{s,t}^W f = \mathsf{E}[f \circ \varphi_{s,t}^c | \mathcal{F}_{s,t}^W], \quad \text{for all } f \in C(\mathbb{S}).$$

It can be shown that in case (a) there is no weak solution different in law from the Wiener solution. In case (b), $\varphi_{s,t}^c$ is the only solution which is a flow of maps. There are certainly other "intermediate" kernel solutions similar to the sticky flows, but they have not been constructed yet.

**Final remarks.** Similar results hold in a more general context, especially in the case of $\mathbb{S}^d$ and $\mathbb{R}^d$ (including $d = 1$). In fact, for isotropic flows in dimension $d \geq 2$, a different phase appears, in which the Wiener solution is a diffusive flow without hitting. This solution cannot be represented by filtering a coalescing solution defined on an extended probability space and there are no weak (generalized) solutions. In dimension 2 and 3 the coalescing phase (where the Wiener solution is a coalescing flow) and the phase of non uniqueness (where the Wiener solution is diffusive with hitting) still occurs.

Many important questions remain open: for example, the nature of the noises when they are not classical, the possible relations with rough paths ([20]), and the classifications of all solutions, starting with the isotropic case.

# Stochastic classification models

Peter McCullagh and Jie Yang*

**Abstract.** Two families of stochastic processes are constructed that are intended for use in classification problems where the aim is to classify units or specimens or species on the basis of measured features. The first model is an exchangeable cluster process generated by a standard Dirichlet allocation scheme. The set of classes is not pre-specified, so a new unit may be assigned to a previously unobserved class. The second model, which is more flexible, uses a marked point process as the mechanism generating the units or events, each with its associated class and feature. The conditional distribution given the superposition process is obtained in closed form for one particular marked point process. This distribution determines the conditional class probabilities, and thus the prediction rule for subsequent units.

**Mathematics Subject Classification (2000).** Primary 62H30; Secondary 68T10.

**Keywords.** Cluster process, Cox process, Dirichlet process, Gauss–Ewens process, lack of interference, marked point process, permanent polynomial, Random subset, supervised learning.

## 1. Introduction

**1.1. Classification.** The problem of numerical taxonomy is to classify individual specimens or units $u$ on the basis of measured variables or features $x(u) \in \mathcal{X}$. The units may be anything from tropical insects to bitmap images of handwritten digits or vocalizations of English words. The feature variables may be length or width or weight measurements in the case of insects, or the Fourier transformation at certain frequencies in the case of spoken words. The choice of feature variables is an important problem in its own right, but this matter is of little concern in the present paper.

A deterministic classification model is a rule or algorithm that associates with each feature value $x \in \mathcal{X}$ a class $y(x) \in \mathcal{C}$. Ordinarily the model must be primed or trained on a sample of units with measured features and known classes. In the dialect of artificial intelligence and computer science, the classifier learns the characteristics peculiar to each class and classifies subsequent units accordingly. When the training is over, each subsequent input is a feature value $x(u')$ for a new unit, and the output is the assigned class. The error rate is the fraction of wrong calls.

A stochastic classification model is a process determining a rule that associates with each feature value $x$ a probability distribution $p(\cdot\,; x)$ on the set of classes.

*We are grateful to Jim Pitman for helpful comments. Support for this research was provided by NSF Grant DMS-0305009.

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

Once again, the classification model must be primed or trained on a sample of units with measured features and known classes. In statistical language, the classifier is a statistical model with unknown parameters to be estimated from the training data. Subsequent units are classified in the usual stochastic sense by computing the conditional distribution given the training data and the feature value for the new unit.

Three stochastic models are described in the sections that follow. The first of these is a regression model with independent components in which the feature values are treated as covariates. The second is an exchangeable cluster process closely related to Fisher's discriminant model, but different in several fundamental ways. The third model is also an exchangeable cluster process, called a permanent cluster process because the conditional distributions are expressed in terms of permanent polynomials.

The distinction between a closed classification model with a pre-determined set of labelled classes, and an open model with unlabelled classes is emphasized. A model of the latter type has a mathematical framework that permits a new unit to be assigned to a class that has not previously been observed and therefore does not have a name. The goal is to construct a classification model with no more than 4–5 parameters to be estimated regardless of the number of classes or the dimension of the feature space. In this way, the technically difficult problems associated with consistency and parameter estimation in high dimensional models are evaded. Ideally, the model should be capable of adapting to classification problems in which one or more classes occupies a non-convex region, or even several disconnected regions, in the feature space.

**1.2. Remarks on the literature.** The literature on stochastic classification is very extensive, the modern theory beginning with Fisher's discriminant model ([12]). Logistic regression models emerged in the 1960s, and with the advent of faster computing, smoothed versions using penalized likelihood became more popular. Stochastic models used in the statistical literature are sometimes complicated, but they are frequently of the most elementary form with independent components such that

$$\log(\mathrm{pr}(Y(u) = r \mid X)) = f_r(X(u)).$$

The goal is to estimate the functions $f_r$ under certain smoothness conditions, which are enforced through penalty functions added to the log likelihood. For a good overview see [29], [15], [27] or [16].

At the more mathematical end of the statistical spectrum, the same model with independent components is frequently used, with $f$ belonging to a suitable space of functions, usually a Besov space. The stated mathematical goal is to obtain the best estimate of $f$ under the most adverse conditions in very large samples ([9]). Smoothing is usually achieved by shrinkage or thresholding of coefficients in a wavelet expansion.

The past decade has seen an upsurge of work in the computer science community under the headings of artificial intelligence, data mining and supervised learning.

Methods used include neural nets, support vector machines and tree classifiers. The emphasis is primarily on algorithms, regularization, efficiency of computation, how best to combine weak classifiers ([13]), and so on. Few algorithms and methods of this type have an overt connection with a generative stochastic process beyond the simple additive form with independent components.

In the Bayesian literature, more complicated processes are constructed using mixture models with Dirichlet priors for the class frequencies ([11], [2], [24], [14]). The cluster process in Section 3 is in fact a simple special case of a more general classification model ([4], [8]). It is used here mainly for illustrative purposes because the distributions can be studied analytically, which is rare for processes generated by Dirichlet allocation schemes.

The semi-parametric models described in Section 4 are of a different type. They are based on Cox processes ([5]) with a baseline intensity measure $\mu$ treated as an unknown parameter. One major attraction for practical work is that the conditional distribution of the class labels given the observed features does not depend on the baseline measure. The unknown nuisance parameter is eliminated by conditioning rather than by integration, and this conditional distribution is the basis for inference and classification.

## 2. Logistic discrimination

**2.1. Non-interference and regression models.** Let $\mathcal{U}$ be the set of units, the infinite set of objects such as plots or subjects or specimens, on which the process $Y$ is defined. A covariate $x\colon \mathcal{U} \to \mathcal{X}$ is a function on the units, the values of which are thought to have an effect on the distribution. In a logistic regression model it is the class $Y(u) \in \mathcal{C}$ that is regarded as the response, and the measured feature $x(u)$ is the covariate.

In practical work, it is often helpful to distinguish between covariates such as sex, age and geographical position that are intrinsic to the unit, and treatment variables such as medication or variety that can in principle be controlled by the experimenter. For mathematical purposes it is more useful to distinguish between a covariate as a function on the units, and a relationship as a function on pairs of units. Examples of the latter include distance if the units are arrayed in space, temporal ordering for time points, genetic or familial relationships if the units are individual organisms, or a block factor as an equivalence relation on units. The statistical distinction, roughly speaking, is that a covariate affects one-dimensional marginal distributions, while a relationship affects bivariate distributions. For present purposes, however, distinctions of this sort are unnecessary.

A regression model is a process in which the joint distribution of the response $(Y(u_1), \ldots, Y(u_n))$ on $n$ units is determined by the covariate values $x = (x(u_1), \ldots, x(u_n))$ on those units. We write $P_n(\cdot\,; x)$ for the joint distribution on an ordered set of $n$ distinct units, implying that two sets of units having the

same ordered list of covariate values, also have the same distribution. In other words, if $(x(u_1), \ldots, x(u_n)) = (x(u'_1), \ldots, x(u'_n))$ then $(Y(u_1), \ldots, Y(u_n))$ and $(Y(u'_1), \ldots, Y(u'_n))$ are both distributed as $P_n(\,\cdot\,; x)$.

In general, the probability assigned to an event $A \subset \mathcal{C}^n$ depends on the covariate vector $(x_1, \ldots, x_n)$. However, the lack of interference condition

$$P_n(A; (x_1, \ldots, x_n)) = P_{n+1}(A \times \mathcal{C}; (x_1, \ldots, x_n, x_{n+1})) \tag{2.1}$$

implies that the probability assigned by $P_{n+1}$ to the event $A \times \mathcal{C}$ does not depend on the final component $x_{n+1}$ of $x$. The failure of this condition means that the probability assigned by $P_2$ to an event of the form $Y(u_1) = 0$ depends on the value of $x(u_2)$. Since the value assigned by $P_1$ to the same event depends only on $x(u_1)$, the two probability distributions are mutually inconsistent. At the very least, interference of this sort may lead to ambiguities in the calculation of probabilities.

Consider two disjoint sets of units with associated vectors $X^{(1)}$, $Y^{(1)}$, $X^{(2)}$, $Y^{(2)}$, all regarded as random variables. Lack of interference is equivalent to the condition that the response $Y^{(1)}$ be conditionally independent of $X^{(2)}$ given $X^{(1)}$. The condition is asymmetric in $X$ and $Y$. As a consequence, the covariate value on unit $u'$ has no effect on the joint distribution for other units. The same term is used in the applied statistical literature ([6], section 2.4; [26]) with a similar meaning, though usually interpreted as a physical or biological property of the system rather than a mathematical property of the model. Without this property, it is difficult to give the model a causal interpretation, so lack of interference is often taken for granted as a logical necessity in applications involving deliberate intervention or assignment of treatment to units.

For applications in which the $x$-values are generated by a process, the preceding argument is not compelling, and the non-interference condition is in fact unduly restrictive. The classification model in Section 3 is derived from an exchangeable bivariate process $(Y(u), X(u))_{u \in \mathcal{U}}$ with finite-dimensional distributions $Q_n$. The conditional distributions $Q_n(\,\cdot \mid X = x)$ determine the joint classification probabilities for $n$ units having the given covariate values as generated by the process. This is not a regression model because the non-interference condition (2.1) is not satisfied by the conditional distributions. As a result, the response distribution for a set of units selected on the basis of their covariate values is not easily determined and is not equal to $Q_n(\,\cdot \mid X = x)$.

We argue that condition (2.1) is unnecessarily strong for certain applications, and that a weaker condition is sufficient for applications in which intervention does not arise. Consider a family of distributions $P_n(\,\cdot\,; x)$, one such distribution for each covariate configuration. It may happen that there exists a bivariate process with distributions $Q_n$ such that, for each covariate configuration $x$ and each event $A \subset \mathcal{C}^n$, the conditional distributions satisfy $P_n(A; x) = Q_n(A \mid X = x)$. The distributions $\{P_n(\,\cdot\,; x)\}$ are then said to be weakly compatible with one another. If such a bivariate process exists, it is not unique because the marginal distribution of the $X$-process is arbitrary. Since the units in the bivariate process have no covariates to distinguish one

from another, the bivariate process is ordinarily exchangeable. Lack of interference implies weak compatibility, but the converse is false.

**2.2. Logistic regression.** In a logistic regression model, the components $Y(u_1), \ldots$ are independent, so the joint distributions are determined by the one-dimensional marginal distributions. The dependence on $x$ is determined by a suitable collection of discriminant functions, $f_j : \mathcal{X} \to \mathcal{R}$, which could be the coordinate projections if $\mathcal{X} = \mathcal{R}^q$, but might include quadratic or other non-linear functions. For a unit $u$ whose feature value is $x = x(u)$ the class probabilities are

$$\log \operatorname{pr}(Y(u) = r) = \sum_j \beta_{rj} f_j(x),$$

where the coefficients $\beta_{rj}$ are parameters to be estimated from the training data. In particular, if there are only two classes, the log odds for class 0 are

$$\log(\operatorname{pr}(Y(u) = 0)/\operatorname{pr}(Y(u) = 1)) = \sum_j (\beta_{0j} - \beta_{1j}) f_j(x). \tag{2.2}$$

For a model with $k$ classes and $q$ linearly independent discriminant functions, the number of parameters is $q(k-1)$, which can be large.

The lack of interference condition is automatically satisfied by the logistic regression model, and in fact by any similar model with independent components.

## 3. An exchangeable cluster process

**3.1. Random permutations and random partitions.** A partition $B$ of the set $[n] = \{1, \ldots, n\}$ is a set of disjoint non-empty subsets called blocks whose union is the whole set. The symbol $\#B$ denotes the number of blocks, and for each block $b \in B$, $\#b$ is the number of elements. The partition is also an equivalence relation on $[n]$, i.e. a function $B : [n] \times [n] \to \{0, 1\}$ that is reflexive, symmetric and transitive. Finally, $B$ is also a symmetric binary matrix with components $B(i, j)$. No distinction is made in the notation between $B$ as a set of subsets, $B$ as a matrix, and $B$ as an equivalence relation. If the partition is regarded as a matrix, $\#B$ is its rank.

Denote by $\mathcal{B}_n$ the set of partitions of $[n]$. Thus, $\mathcal{B}_2 = \{12,\ 1|2\}$ has two elements, and $\mathcal{B}_3$ has five elements

$$123, \quad 12|3, \quad 13|2, \quad 23|1, \quad 1|2|3,$$

where $13|2$ is an abbreviation for $\{\{1, 3\}, \{2\}\}$, containing two blocks. The 15 elements of $\mathcal{B}_4$ can be grouped by block sizes as follows

$$1234, \quad 123|4\ [4], \quad 12|34\ [3], \quad 12|3|4\ [6], \quad 1|2|3|4$$

where 12|34 [3] is an abbreviation for the three distinct partitions 12|34, 13|24, 14|23, each having two blocks of size two. The number of elements in $\mathcal{B}_n$ is the $n$th Bell number, the coefficient of $t^n/n!$ in the generating function $\exp(e^t - 1)$. The first few values are 1, 2, 5, 15, 52, 203, 877,…, increasing rapidly with $n$.

Consider a probability distribution on the symmetric group $\mathcal{S}_n$ in which the probability assigned to the permutation $\sigma$ depends on the number of cycles as follows:

$$p_n(\sigma) = \lambda^{\#\sigma}\Gamma(\lambda)/\Gamma(n+\lambda), \tag{3.1}$$

where $\lambda > 0$, and the ratio of gamma functions is the required normalizing constant. This is the exponential family generated from the uniform distribution with weight function $\lambda^{\#\sigma}$, canonical parameter $\log\lambda$ and canonical statistic $\#\sigma$ the number of cycles. It is evident that the distribution is invariant under the action of the group on itself by conjugation, so $p_n$ is finitely exchangeable. Less obvious but easily verified is the fact that $p_n$ is the marginal distribution of $p_{n+1}$ under the natural deletion operation $\sigma' \mapsto \sigma$ from $\mathcal{S}_{n+1}$ into $\mathcal{S}_n$, which operates as follows. Write $\sigma'$ in cycle form, for example $\sigma' = (1,3)(5)(2,6,4)$ for $n = 5$, and delete element $n+1 = 6$ giving $\sigma = (1,3)(5)(2,4)$. This construction, together with the associated Chinese restaurant process, is described by Pitman ([24], section 4). The projection $\mathcal{S}_{n+1} \to \mathcal{S}_n$ is not a group homomorphism, but successive deletions are commutative. For each $\lambda > 0$, these distributions determine an exchangeable permutation process closely related to the Ewens process on partitions.

The cycles of the permutation $\sigma \in \mathcal{S}_n$ determine a partition of the set $[n]$, and thus a map $\mathcal{S}_n \to \mathcal{B}_n$. The inverse image of $B \in \mathcal{B}_n$ contains $\prod_{b\in B}\Gamma(\#b)$ permutations all having the same probability. Thus, the marginal distribution on partitions induced by (3.1) is

$$p_n(B;\lambda) = \frac{\Gamma(\lambda)\lambda^{\#B}}{\Gamma(n+\lambda)}\prod_{b\in B}\Gamma(\#b) \tag{3.2}$$

for $B \in \mathcal{B}_n$ and $\lambda > 0$ ([10], [1]). This distribution is symmetric in the sense that for each permutation $\sigma\colon [n] \to [n]$, the permuted matrix $(B^\sigma)_{ij} = B_{\sigma(i),\sigma(j)}$ has the same distribution as $B$. The partition $B^\sigma$ has the same block sizes as $B$, which are maximal invariant, and the probability $p_n(B;\lambda)$ depends only on the block sizes. In addition if $B' \sim p_{n+1}(\cdot\,;\lambda)$ is a random partition of $[n+1]$, the leading $n \times n$ submatrix $B$ is a random partition of $[n]$ whose distribution is $p_n(\cdot\,;\lambda)$ ([19]). For each $\lambda > 0$, the sequence of distributions $\{p_n\}$ determines an exchangeable process called the Ewens partition process. For further details, see Pitman ([25]).

The Ewens process is by no means the only example of an exchangeable partition process, but it is one of the simplest and most natural, and it is sufficient to illustrate the ideas in the sections that follow. Some simple extensions are described by Pitman ([24]).

**3.2. Gauss–Ewens cluster process.** A cluster process with state space $\mathcal{X}$ is an infinite sequence of $\mathcal{X}$-valued random variables $X(u)$ for $u \in \mathcal{U}$, together with a random

partition $B\colon \mathcal{U} \times \mathcal{U} \to \{0, 1\}$, which determines the clusters. An observation on a finite set of units $\{u_1, \ldots, u_n\}$ consists of the values $X(u_1), \ldots, X(u_n)$ together with the components of the matrix $B_{ij} = B(u_i, u_j)$. The finite-dimensional distributions on $\mathcal{B}_n \times \mathcal{X}^n$ with densities $p_n$ satisfy the obvious Kolmogorov consistency condition:

$$p_n(B, x_1, \ldots, x_n) = \sum_{B' : \phi B' = B} \int_{\mathcal{X}} p_{n+1}(B', x_1, \ldots, x_{n+1})\, dx_{n+1}$$

where $\phi\colon \mathcal{B}_{n+1} \to \mathcal{B}_n$ is the deletion operator that removes the last row and column.

In the Gauss–Ewens process, $\mathcal{X} = \mathcal{R}^q$ is a vector space. The observation $(B, (X_1, \ldots, X_n))$ on a finite set of $n$ units has a joint density in which $B$ is a partition with distribution (3.2). The conditional distribution given $B$ is Gaussian with constant mean vector, here taken to be zero, and covariance matrix $\Sigma_B = I_n \otimes \Sigma + B \otimes \Sigma_1$, where $\Sigma$, $\Sigma_1$ are $q \times q$ covariance matrices. In component form

$$\operatorname{cov}(X_{ir}, X_{js} \mid B) = \delta_{ij}\Sigma_{rs} + B_{ij}\Sigma_{1\,rs}.$$

This construction implies that $X$ is a sum of two independent processes, one i.i.d. on the units, and one with i.i.d. components for each block.

If $\mathcal{X} = \mathcal{R}$, the coefficient matrices are scalars and the joint density is

$$p_n(B, x) = \frac{\Gamma(\lambda)\lambda^{\#B}}{\Gamma(n + \lambda)} \prod_{b \in B} \Gamma(\#b) \times (2\pi)^{-n/2} |\Sigma_B|^{-1/2} \exp(-x' \Sigma_B^{-1} x/2).$$

It is helpful here to re-parameterize by writing $\bar{x}_b$ for the mean in block $b$, $\theta = \sigma_1^2/\sigma^2$ for the ratio of variance components, $w_b = \#b/(1 + \theta\, \#b)$ and $\bar{x} = \sum w_b \bar{x}_b / \sum w_b$, in which case we have

$$|\Sigma_B|^{-1/2} = \sigma^{-n} \prod_{b \in B} (1 + \theta\, \#b)^{-1/2},$$
$$x' \Sigma_B^{-1} x = \sum_{b \in B} (S^2(b) + w_b \bar{x}_b^2)/\sigma^2,$$

where $S^2(b)$ is the sum of squares for block $b$.

A permutation of the units sends $X_1, \ldots, X_n$ to $X_{\sigma(1)}, \ldots, X_{\sigma(n)}$ and also transforms the components of $B$ in such a way that the $i, j$ component of $B^\sigma$ is $B_{\sigma(i)\sigma(j)}$. Evidently, the distribution $p_n$ is unaffected by such permutations, so the Gauss–Ewens process is infinitely exchangeable. As it stands, the Gauss–Ewens process is not a mixture of independent and identically distributed processes because the observation space $\mathcal{B}_n \times \mathcal{X}^n$ for a finite set of $n$ units is not an $n$-fold product space. However, if the blocks are labelled at random, the new process is equivalent in every way to the original, and the new process does follow the de Finetti characterization ([25], p. 44).

**3.3. Conditional distributions.** Given the observed list of feature values $x = (x_1, \ldots, x_n)$, the conditional distribution on partitions induced by the one-dimensional Gauss–Ewens process is

$$p_n(B \mid x) \propto \prod_{b \in B} \lambda\Gamma(\#b)(1 + \theta\,\#b)^{-1/2} \exp((-S^2(b) - w_b\bar{x}_b^2)/(2\sigma^2)).$$

This is a distribution of the product-partition type $p_n(B) \propto \prod_{b\in B} C(b; x)$ ([17]) with cohesion function

$$C(b; x) = \lambda\Gamma(\#b)(1 + \theta\,\#b)^{-1/2} \exp((-S^2(b) - w_b\bar{x}_b^2)/(2\sigma^2))$$

depending on the feature values of the units in block $b$ only. In particular, $C(b; x)$ does not depend on $\#B$ or on $n$. Evidently, two sets of units having the same ordered list of feature values are assigned the same conditional distribution. The marginal distribution on $\mathcal{B}_n$ induced from $p_{n+1}(\cdot \mid (x, x_{n+1}))$ by deleting the last component, depends on the value of $x_{n+1}$, so these conditional distributions do not determine a process. However, there is no contradiction here because these are conditional distributions, and the two conditioning events are different. Since they are derived from a bivariate process, the distributions are weakly compatible with one another in the sense of Section 2.1.

For the multivariate Gauss–Ewens process, the conditional distributions are not of the product-partition type unless the coefficient matrices are proportional, i.e. $\Sigma_1 = \theta\Sigma$. When this condition is satisfied, the cohesion function is an obvious multivariate analogue of the univariate version.

Product partition distributions are certainly convenient for use in applied work, but the great majority of product partition models are incompatible with any process. Consider for example, the product partition model with cohesion function $C(b, x) = \lambda$, independent of the covariate values. For $\lambda = 1$, the distributions are uniform on each $\mathcal{B}_n$. But the distribution on $\mathcal{B}_n$ induced from the uniform distribution on $\mathcal{B}_{n+1}$ is not uniform. The Ewens distributions with cohesion function $\lambda\Gamma(\#b)$ are the only product partition models that are compatible with an exchangeable process.

**3.4. Stochastic classification.** Given the observation $(B, x(u_1), \ldots, x(u_n))$ on $n$ units, plus the feature value $x(u')$ on a subsequent unit, we aim to calculate the conditional distribution $p_{n+1}(\cdot \mid \text{data})$ on $\mathcal{B}_{n+1}$ given the observed values generated by the process. The only missing piece of information is the block to which unit $u'$ is assigned, so the conditional distribution is determined by the probabilities assigned to the events $u' \mapsto b$ for those blocks $b \in B$ or $b = \emptyset$.

A straightforward calculation for a product partition model shows that

$$\text{pr}(u' \mapsto b \mid \text{data}) \propto \begin{cases} C(b \cup \{u'\}, (x, x'))/C(b, x) & b \in B, \\ C(\{u'\}, x') & b = \emptyset, \end{cases}$$

where $(x, x')$ is the complete list of $n+1$ observed feature values. For $b \in B$, the cohesion ratio for the univariate Gauss–Ewens process is

$$\#b\gamma^{1/2} \exp(-\gamma(x' - \theta\#b\bar{x}_b/(1+\theta\#b))^2/(2\sigma^2))$$

where $\gamma = (1+\theta\#b)/(1+\theta(\#b+1))$. If $\theta\#b$ is large, blocks whose sample means are close to $x'$ have relatively high probability, which is to be expected.

The predictive distribution for the general multivariate Gauss–Ewens process involves a ratio of multivariate normal densities. Although preference is given to larger blocks, the predictive distribution also puts more weight on those classes whose block means are close to $x'$. If $x'$ is sufficiently far removed from all observed block means, the empty set (new class) is given relatively greater weight. When the empty set is excluded from consideration the parameter $\lambda$ has no effect, and the predictive distribution is roughly the same as that obtained from the Fisher discriminant model with prior probabilities proportional to class sizes.

## 4. Point process models

**4.1. Permanent polynomial.** To each square matrix $K$ of order $n$ there corresponds a polynomial of degree $n$,

$$\mathrm{per}_t(K) = \sum_\sigma t^{\#\sigma} K_{1\sigma(1)} \cdots K_{n\sigma(n)}$$

where the sum runs over permutations of $\{1, \ldots, n\}$, and $\#\sigma$ is the number of cycles. The conventional permanent is the value at $t = 1$, and the determinant is $\det(K) = \mathrm{per}_{-1}(-K)$. The coefficient of $t$ is the sum of cyclic products

$$\mathrm{cyp}(K) = \lim_{t\to 0} t^{-1} \mathrm{per}_t(K) = \sum_{\sigma:\#\sigma=1} K_{1\sigma(1)} \cdots K_{n\sigma(n)}.$$

For certain types of patterned matrices, the permanent polynomial can be evaluated in closed form or by recursion. Consider, for example, the matrix $J$ of order $n$ such that $J_{ii} = \zeta$ and $J_{ij} = 1$ otherwise. The permanent polynomial is the value $f_n(t)$ obtained by recursion

$$\begin{pmatrix} f_{n+1}(t) \\ h_{n+1}(t) \end{pmatrix} = \begin{pmatrix} \zeta t & n \\ t & n \end{pmatrix} \begin{pmatrix} f_n(t) \\ h_n(t) \end{pmatrix}$$

starting with $f_0(t) = h_0(t) = 1$. In particular, for $\zeta = 1$ and $t = \lambda$ we obtain the value $f_n(\lambda) = \Gamma(n+\lambda)/\Gamma(\lambda)$, which is the normalizing constant in the distribution (3.1).

**4.2. Gaussian moments.** The permanent polynomial arises naturally in statistical work associated with factorial moment measures of Cox processes as follows. Let $Z$ be

a zero-mean real Gaussian process on $\mathcal{X}$ with covariance function $\operatorname{cov}(Z(x), Z(x')) = K(x, x')/2$. The joint cumulant and the joint moment of the squared variables $|Z(x_1)|^2, \ldots, |Z(x_n)|^2$ are

$$\operatorname{cum}_n\big(|Z(x_1)|^2, \ldots, |Z(x_n)|^2\big) = \operatorname{cyp}[K](x_1, \ldots, x_n)/2,$$
$$E\big(|Z(x_1)|^2 \cdots |Z(x_n)|^2\big) = \operatorname{per}_{1/2}[K](x_1, \ldots, x_n),$$

where $[K](x_1, \ldots, x_n)$ is the symmetric matrix of order $n$ whose entries are $K(x_i, x_j)$. More generally, if $\Lambda(x) = |Z_1(x)|^2 + \cdots + |Z_k(x)|^2$ is the sum of squares of $k$ independent and identically distributed Gaussian processes, we have

$$\begin{aligned} \operatorname{cum}_n(\Lambda(x_1), \ldots, \Lambda(x_n)) &= \alpha \ \operatorname{cyp}[K](x_1, \ldots, x_n), \\ E(\Lambda(x_1) \cdots \Lambda(x_n)) &= \operatorname{per}_\alpha[K](x_1, \ldots, x_n) \end{aligned} \tag{4.1}$$

with $\alpha = k/2$ ([22]). Thus, if $\Lambda$ is the intensity function for a doubly stochastic Poisson process, the $n$th order product density at $x = (x_1, \ldots, x_n)$ is $\operatorname{per}_\alpha[K](x)$. In other words, the expected number of ordered $n$-tuples of distinct events occurring in an infinitesimal ball of volume $dx$ centered at $x \in \mathcal{X}^n$ is $\operatorname{per}_\alpha[K](x)\, dx$.

The analogous result for zero-mean complex-valued processes with covariance function $\operatorname{cov}(Z(x), \bar{Z}(x')) = K(x, x')$ and $\Lambda$ as defined above is the same except that $\alpha = k$ rather than $k/2$. A proof for $\alpha = 1$ can be found in Macchi ([21]), and for general $k$ in McCullagh and Møller ([22]). Although $K$ is Hermitian, the polynomial is real because inverse permutations have conjugate coefficients.

**4.3. Convolution semi-group properties.** Permanent polynomials also have a semi-group convolution property that is relevant for probability calculations connected with the superposition of independent processes. In describing this property, it is helpful to regard the points $\boldsymbol{x} = \{x_1, \ldots, x_n\}$ as distinct and unordered, so $\boldsymbol{x}$ is a finite subset of $\mathcal{X}$. Since $\operatorname{per}_\alpha[K](x_1, \ldots, x_n)$ is a symmetric function of $x$, we may write $\operatorname{per}_\alpha[K](\boldsymbol{x})$ without ambiguity for non-empty sets. For the empty subset, $\operatorname{per}_\alpha[K](\emptyset) = 1$. It is shown in McCullagh and Møller ([22]) that

$$\sum_{\boldsymbol{w} \subset \boldsymbol{x}} \operatorname{per}_\alpha[K](\boldsymbol{w}) \operatorname{per}_{\alpha'}[K](\bar{\boldsymbol{w}}) = \operatorname{per}_{\alpha+\alpha'}[K](\boldsymbol{x}) \tag{4.2}$$

where the sum is over all $2^n$ subsets, and $\bar{\boldsymbol{w}}$ is the complement of $\boldsymbol{w}$ in $\boldsymbol{x}$.

Suppose that $\operatorname{per}_\alpha[K](\boldsymbol{x})$ is the density at $\boldsymbol{x}$, with respect to some product measure $\mu(dx_1) \cdots \mu(dx_n)$, of a finite point process in $\mathcal{X}$. The convolution property implies that the superposition of two independent processes having the same covariance function $K$ has a distribution in the same family with parameter $\alpha + \alpha'$. Furthermore, the ratio

$$q(\boldsymbol{w}; \boldsymbol{x}) = \frac{\operatorname{per}_\alpha[K](\boldsymbol{w}) \operatorname{per}_{\alpha'}[K](\bar{\boldsymbol{w}})}{\operatorname{per}_{\alpha+\alpha'}[K](\boldsymbol{x})} \tag{4.3}$$

determines a probability distribution on the subsets of $\boldsymbol{x}$. If in fact some components of $\boldsymbol{x}$ are duplicated, these duplicates must be regarded as distinct units that happen to have the same $x$-value, and $q$ is then regarded as a distribution on subsets of the $n$ units. In the extreme case where all components are identical, all components of the matrix $[K](\boldsymbol{x})$ are equal, and the distribution reduces to

$$q(\boldsymbol{w};\boldsymbol{x}) = \frac{\Gamma(\#\boldsymbol{w}+\alpha)\,\Gamma(\#\overline{\boldsymbol{w}}+\alpha')\,\Gamma(\alpha+\alpha')}{\Gamma(n+\alpha+\alpha')\,\Gamma(\alpha)\,\Gamma(\alpha')}.$$

In other words, $\#\boldsymbol{w}$ has the beta-binomial distribution.

The statistical construction ensures that the polynomial $\mathrm{per}_\alpha(K)$ is positive at all positive half-integer values of $\alpha$ provided only that $K$ is real symmetric and positive semi-definite. In view of the convolution property, it is natural to ask whether the permanent polynomial of a real symmetric positive semi-definite matrix is positive for all $\alpha \geq 1/2$. The numerical evidence on this point is compelling, but so far there is no proof. On the one hand, there exist positive semi-definite symmetric matrices such that $\mathrm{per}_\alpha(K) < 0$ for values in the interval $0 < \alpha < 1/2$. On the other hand, extensive numerical work has failed to produce a positive semi-definite matrix such that the permanent polynomial has a root whose real part exceeds one half. Although no proof is offered, it seems safe to proceed as if $\mathrm{per}_\alpha(K) \geq 0$ for all $\alpha \geq 1/2$ and positive semi-definite symmetric $K$. In applications where the covariance function is non-negative, the permanent polynomial is clearly positive for all $\alpha > 0$.

**4.4. A marked point process.** Consider a Poisson process $\boldsymbol{X}$ in $\mathcal{X}$ with intensity measure $\mu$. In the first instance, $\boldsymbol{X}$ is a counting measure in $\mathcal{X}$ such that the number of events $\boldsymbol{X}(A)$ has the Poisson distribution with mean $\mu(A)$. In addition, for non-overlapping sets $A, A'$, the event counts $\boldsymbol{X}(A)$ and $\boldsymbol{X}(A')$ are independent. The process is said to be regular if it has no multiple events at the same point and is finite on compact sets. In that case $\boldsymbol{X}$ is a random subset of $\mathcal{X}$ such that $\boldsymbol{X} \cap A$ is finite for compact sets $A$. For linguistic convenience, we use the terminology associated with random sets rather than the terminology associated with random measures or multisets. All processes are assumed to be regular.

A Poisson process driven by a random intensity measure $\Lambda(x)\mu(dx)$ is called a doubly stochastic Poisson process, or a Cox process. Details of such processes can be found in the books by Kingman ([20]) and Daley and Vere-Jones ([7]).

Let $\mu$ be a non-random measure in $\mathcal{X}$ serving as a baseline for the construction of subsequent point processes. For probabilistic purposes, $\mu$ is a fixed measure defined on a suitable algebra of subsets of $\mathcal{X}$ that includes all singletons. For statistical purposes, $\mu$ is a parameter to be estimated, if necessary, from the data. Given a random non-negative intensity function $\Lambda(x)$, the associated Cox process is such that the expected number of events occurring in an infinitesimal ball $dx$ centered at $x$ is $E(\Lambda(x))\,\mu(dx)$. Likewise, the expected number of ordered pairs of distinct events in the infinitesimal product set $dx\,dx'$ at $(x, x')$ is $E(\Lambda(x)\Lambda(x'))\,\mu(dx)\,\mu(dx')$, and

so on. In general, for $\boldsymbol{x} = (x_1, \ldots, x_n)$,

$$m^{(n)}(\boldsymbol{x}) = E(\Lambda(x_1) \cdots \Lambda(x_n))$$

is called the $n$th order product density at $\boldsymbol{x} \in \mathcal{X}^n$. These expectations are the densities of the factorial moment measures of the process with respect to the product measure $\mu^n$. The order is implicit from the argument $\boldsymbol{x} \in \mathcal{X}^n$, so we usually write $m(\boldsymbol{x})$ rather than $m^{(n)}(\boldsymbol{x})$.

Ordinarily, in typical ecological applications or studies of the spatial interactions of particles, an observation on a point process consists of a census $\boldsymbol{X} \cap S$ of all events occurring in the bounded set $S$. The observation tells us not only that an event occurred at certain points in $S$, but also that no events occurred elsewhere in $S$. For the sorts of applications with which we are concerned, however, the training sample is not exhaustive, so the observation is regarded as a sample of the events in $\mathcal{X}$. Such an observation tells us only that an event occurred at certain points in $\mathcal{X}$, and says nothing about the occurrence or non-occurrence of events elsewhere.

Suppose now that $\boldsymbol{X}^{(1)}, \ldots, \boldsymbol{X}^{(k)}$ are $k$ independent Cox process on $\mathcal{X}$ driven by independent random intensity functions $\Lambda_1(x), \ldots, \Lambda_k(x)$, all relative to the same measure $\mu$. The marked process can be represented by the pair $(\boldsymbol{X}, y)$ in which $\boldsymbol{X} = \cup \boldsymbol{X}^{(r)}$ is the superposition process, and $y\colon \boldsymbol{X} \to \mathcal{C}$ is the list of labels. Then the $r$th component process $\boldsymbol{X}^{(r)} = y^{-1}(r)$ is the inverse image of label $r$.

Let $\boldsymbol{x} \subset \mathcal{X}$ be a given finite point configuration consisting of $n$ points. Given that $\boldsymbol{x} \subset \boldsymbol{X}$, i.e. that the superposition process contains $\boldsymbol{x}$, each event $x \in \boldsymbol{x}$ has a label $y(x)$ in the marked process so there are $k^n$ possible values for the labels of the events in $\boldsymbol{x}$. Denote by $\boldsymbol{x}^{(r)}$ the subset $\boldsymbol{x} \cap y^{-1}(r)$, possibly empty, consisting of those events in $\boldsymbol{x}$ having label $r$. The conditional distribution of the class labels given $\boldsymbol{x} \subset \boldsymbol{X}$ is proportional to the product of the product densities of the component processes

$$p_n(y \mid \boldsymbol{x}) = \frac{\prod_{r \in \mathcal{C}} m_r(\boldsymbol{x}^{(r)})}{m_\cdot(\boldsymbol{x})}. \tag{4.4}$$

In this expression, $m_r(\boldsymbol{x}^{(r)})$ is the product density of order $\#\boldsymbol{x}^{(r)}$ at $\boldsymbol{x}^{(r)}$ for the process labelled $r$, and $m_\cdot(\boldsymbol{x})$ is the $n$th order product density for the superposition process at $\boldsymbol{x}$. For the empty set, $m_r(\emptyset) = 1$. A key point to note is that the conditional distribution of the class labels depends only on the product densities, and not on the baseline measure $\mu$.

The conditional distribution of the unlabelled partition $B$ is obtained by ignoring labels, in effect by multiplying by the combinatorial coefficient $k!/(k - \#B)!$. Since the combinatorial coefficient depends on the number of blocks, the conditional distribution of the unlabelled partition is not a product partition model, but it is a distribution of Gibbs type ([25], p. 26)

These conditional distributions do not determine a regression model because they fail to satisfy the lack of interference condition (2.1). However, they are derived from a bona fide bivariate process, so they are mutually compatible in the weak sense.

In this context of prediction, it may be helpful to think of each event as a unit or specimen, in such a way that $x(u)$ is the position or feature value of the event, and $y(u)$ is the label. To classify a new unit or event $u'$ such that $x(u') = x'$, it is sufficient to calculate the conditional distribution as determined by $p_{n+1}$ given the extended configuration $\boldsymbol{x}' = \boldsymbol{x} \cup \{x'\}$ plus the labels of those points in $\boldsymbol{x}$. The conditional probabilities are proportional to the ratio of product densities

$$p_{n+1}(y(u') = r \mid \text{data}) \propto m_r(\boldsymbol{x}^{(r)} \cup \{x'\})/m_r(\boldsymbol{x}^{(r)}) \tag{4.5}$$

for $r \in \mathcal{C}$.

**4.5. Specific examples.** We consider two examples, one in which the intensity is the square of a Gaussian process with product density (4.1), and one in which the intensity is log normal.

*Permanent process.* Suppose that each component process is a permanent process and that the product density for process $r$ is $m_r(\boldsymbol{x}) = \text{per}_{\alpha_r}[K](\boldsymbol{x})$. Then the product density for the superposition process is $\text{per}_{\alpha_\cdot}[K](\boldsymbol{x})$ and the conditional distribution of the labels given $\boldsymbol{x}$ is

$$p_n(y \mid \boldsymbol{x}) = \frac{\text{per}_{\alpha_1}[K](\boldsymbol{x}^{(1)}) \cdots \text{per}_{\alpha_k}[K](\boldsymbol{x}^{(k)})}{\text{per}_{\alpha_\cdot}[K](\boldsymbol{x})}. \tag{4.6}$$

This distribution determines a random labelled partition of the given events into $k$ classes, some of which may be empty. It is the 'multinomial' generalization of (4.3), and is closed under aggregation of classes.

For a new unit $u'$ such that $x(u') = x'$, the conditional probability of class $r$ is proportional to the permanent ratio

$$p_{n+1}(y(u') = r \mid \text{data}) \propto \text{per}_{\alpha_r}[K](\boldsymbol{x}^{(r)}, x')/\,\text{per}_{\alpha_r}[K](\boldsymbol{x}^{(r)}).$$

This expression is restricted to the set of $k$ classes in $\mathcal{C}$, but it may include classes for which $\boldsymbol{x}^{(r)}$ is empty, i.e. named classes that do not occur in the training sample. In the extreme case where $\boldsymbol{x}$ is empty, the probability of class $r$ is $\alpha_r/\alpha_\cdot$ regardless of $x'$.

The derivation of the conditional distribution from the marked point process requires each $\alpha$ to be a half-integer, and $K$ to be positive semi-definite. Alternatively, $K$ could be Hermitian and $\alpha_r$ a whole integer. However, if $K$ is non-negative on $\mathcal{X}$, the distribution (4.6) exists for arbitrary $\alpha_r > 0$, even if $K$ is not positive semi-definite. We shall therefore consider the limit in which $\alpha_r = \alpha$ and $k \to \infty$ such that $\alpha_\cdot = k\alpha = \lambda > 0$ is held fixed. The limit distribution for the unlabelled partition is

$$p_n(B \mid \boldsymbol{x}; \lambda) = \frac{\lambda^{\#B} \prod_{b \in B} \text{cyp}[K](\boldsymbol{x}^{(b)})}{\text{per}_\lambda[K](\boldsymbol{x})}, \tag{4.7}$$

which is a product partition model, and reduces to the Ewens distribution if $K$ is constant on $\mathcal{X}$. For a new unit $u'$ such that $x(u') = x'$, the conditional probability of

assignment to block $b$ is

$$p_{n+1}(u' \mapsto b \mid \text{data}) \propto \begin{cases} \text{cyp}[K](\boldsymbol{x}^{(b)}, x')/\,\text{cyp}[K](\boldsymbol{x}^{(b)}) & b \in B, \\ \lambda K(x', x') & b = \emptyset. \end{cases}$$

Our experience with these classification rules is restricted to the simplest versions of the model in which $\mathcal{X}$ is Euclidean space and $K(x, x') = \exp(-|x - x'|^2/\rho^2)$ or similar versions such as $\exp(-|x - x'|/\rho)$. On the whole, the smoother version is better, and the value of $\alpha$ in (4.6) has only minor effects. It is necessary to select a suitable value of the range parameter $\rho$, but the qualitative conclusions are the same for all $\rho$. The region in the $\mathcal{X}$-space for which the predictive probability of class $r$ is high need not be convex or simply connected. In that sense, both of these classification rules are qualitatively different from the one derived from the Gauss–Ewens process.

*Log Gaussian Cox processes.* Suppose that each component process is log Gaussian, i.e. $\log \Lambda_r$ is a Gaussian process with mean and variance

$$E \log \Lambda_r(x) = \theta_r(x), \quad \text{cov}(\log \Lambda_r(x), \log \Lambda_r(x')) = K_r(x, x').$$

Then the $n$th order product density at $x = (x_1, \ldots, x_n)$ is

$$m_r(x) = \exp\Big(\sum_j \theta_r(x_j) + \tfrac{1}{2} \sum_{ij} K_r(x_i, x_j)\Big).$$

Given that $\boldsymbol{x}$ occurs in the superposition process, the conditional distribution of the labels satisfies

$$\log p_n(y \mid \boldsymbol{x}) = \sum_{x \in \boldsymbol{x}} \theta_{y(x)}(x) + \tfrac{1}{2} \sum_{\substack{x, x' \in \boldsymbol{x} \\ y(x) = y(x')}} K_{y(x)}(x, x') + \text{const.}$$

Finally, a new unit with $x(u') = x'$ generated from the process is assigned to class $r$ with probability

$$\log p_{n+1}(y(u') = r \mid \text{data}) = \theta_r(x') + \tfrac{1}{2} K_r(x', x') + \sum_{x \in \boldsymbol{x}^{(r)}} K_r(x', x) + \text{const.}$$

Thus, if $\theta_r(x) = \sum_j \beta_{rj} f_j(x)$ as in Section 2.2, and there are only two classes with $K_0 = K_1 = K$, the conditional log odds that the new unit is assigned to class 0 are

$$\sum_j (\beta_{0j} - \beta_{1j}) f_j(x') + \sum_{x \in \boldsymbol{x}^{(0)}} K(x', x) - \sum_{x \in \boldsymbol{x}^{(1)}} K(x', x), \tag{4.8}$$

coinciding with (2.4) when $K = 0$.

**4.6. Numerical illustration.** A simple artificial example suffices to illustrate the qualitative difference between classification models based on Cox processes, and classification models of the type described in Section 3. We use the two-class permanent model (4.6) with $\alpha_1 = \alpha_2 = 1$. The feature space is a $3 \times 3$ square in the plane, the covariance function is $K(x, x') = \exp(-\|x - x'\|^2/\rho^2)$ with $\rho = 0.5$, and the true class is determined by a $3 \times 3$ chequerboard pattern with white in the center square. The training data consists of 90 units, with 10 feature values uniformly distributed in each small square as shown in the first panel of Figure 1. The second panel is a density plot, and the third panel a contour plot, of the conditional probability that a new unit at that point is assigned to class 'white'. These probabilities were computed by an approximation using a cycle expansion for the permanent ratio.

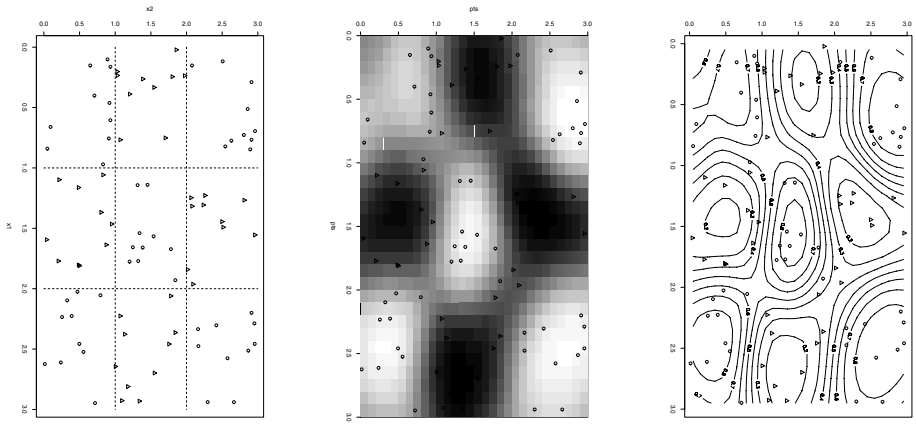

Figure 1. Predictive probability of class I using a permanent model.

For the parameter values chosen, the range of predictive probabilities depends to a moderate extent on the configuration of $x$-values in the training sample, but the extremes are seldom below 0.1 or above 0.9 for a configuration of 90 points with 10 in each small square. The range of predictive probabilities decreases as $\rho$ increases, but the 50% contour is little affected, so the classification is fairly stable. Given that the correct classification is determined by the chequerboard rule, the error rate for the permanent model using this particular training configuration can be computed exactly: it is around 13% for a point chosen uniformly at random from the large square. This error rate is a little misleading because most of those errors occur near an internal boundary where the predictive probability is close to 0.5. Gross errors are rare.

## 5. Parameter estimation

Let $(y, \boldsymbol{x})$ be the training data, and let $x'$ be the feature value for a subsequent unit. In principle, the likelihood function should be computed for the full data including the

value for the subsequent unit. In practice, it is more convenient to base the likelihood on the training data alone, i.e. $p_n(y, \boldsymbol{x}; \theta)$ at the parameter point $\theta$. Ordinarily, the information sacrificed by ignoring the additional factor is negligible for large $n$, and the gain in simplicity may be substantial.

Likelihood computations are straightforward for logistic regression models, and the same is true for the Gauss–Ewens process, but the state of affairs is more complicated for point process models. Consider a marked permanent process model with $\alpha_r = \alpha$, in which $\mathcal{X}$ is a Euclidean space and $K(x, x') = \exp(-\|x - x'\|^2/\rho^2)$. The parameters of the process are the scalars $\alpha$, $\rho$ plus the baseline measure $\mu$. However, the conditional likelihood given the observation $\boldsymbol{x}$ from the training sample depends only on $\alpha$, $\rho$, and the predictive distribution also depends only on $(\alpha, \rho)$. In this setting, the distribution of $\boldsymbol{x}$ is governed largely by the baseline measure $\mu$, so the information for $(\alpha, \rho)$ in the superposition process must be negligible. Accordingly, we use the conditional likelihood instead of the full likelihood, for parameter estimation.

Even though the most troublesome component of the parameter has been eliminated, computation of the likelihood for the remaining parameters does present difficulties. In the case of the log Gaussian model, the normalizing constant is not available in closed form. In the case of the permanent models (4.6) or (4.7), for which the normalizing constants are available, the only remaining obstacle is the calculation of cyclic products and permanent polynomials. The permanent of a large matrix is notoriously difficult to compute exactly ([28]), and the permanent polynomial appears to be even more challenging. For $\alpha = 1$, polynomial-time algorithms are available for fixed-rank matrices ([3]). In addition, the existence of polynomial-time Monte Carlo algorithms for non-negative matrices, has been demonstrated but not implemented ([18]).

Our experience for positive definite matrices is less pessimistic than the preceding remarks suggest. Reasonably accurate polynomial-time continued-fraction approximations for the ratio of permanent polynomials can be developed without resorting to Monte Carlo approximation. We use a cycle expansion whose accuracy improves as $\alpha$ increases. Here, reasonably accurate means within 2–3% for typical covariance matrices of order $n = 100$, and for $\alpha \geq 1/2$. These expansions, which were used in the construction of Figure 1, will be described elsewhere.

# Random partitions and instanton counting

Andrei Okounkov*

**Abstract.** We summarize the connection between random partitions and $\mathcal{N} = 2$ supersymmetric gauge theories in 4 dimensions and indicate how this relation extends to higher dimensions.

**Mathematics Subject Classification (2000).** Primary 81T13; Secondary 14J60.

## 1. Introduction

**1.1. Random partitions.** A partition of $n$ is a monotone sequence

$$\lambda = (\lambda_1 \geq \lambda_2 \geq \cdots \geq 0)$$

of nonnegative integers with sum $n$. The number $n$ is denoted $|\lambda|$ and called the size of $\lambda$. A geometric object associated to a partition is its *diagram*; it contains $\lambda_1$ squares in the first row, $\lambda_2$ squares in the second row and so on. An example, flipped and rotated by $135^\circ$ can be seen in Figure 1. Partitions naturally label many basic objects

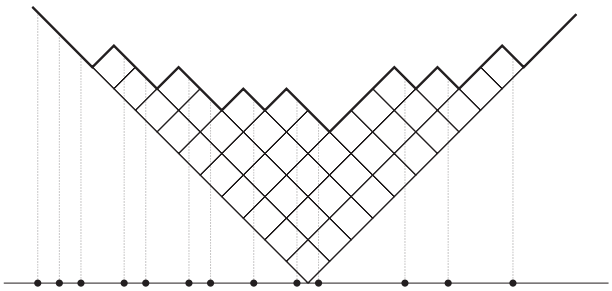

Figure 1. The diagram of $\lambda = (10, 8, 7, 4, 4, 3, 2, 2, 1, 1)$, flipped and rotated by $135^\circ$. Bullets indicate the points of $\mathfrak{S}(\lambda)$. The profile of $\lambda$ is plotted in bold.

in mathematics and physics, such as e.g. conjugacy classes and representations of the symmetric group $S(n)$, and very often appear as modest summation ranges or indices. A simple but fruitful change of perspective, which I wish to stress here, is to treat sums over partitions probabilistically, that is, treat them as expectations of some functions of a random partition.

*The author thanks Packard Foundation for partial financial support.

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

A survey of the theory of random partitions may be found in [33]. Of the several natural measures on partitions, the Plancherel measure

$$\mathfrak{M}_{\mathrm{Planch}}(\lambda) = \frac{(\dim \lambda)^2}{n!}, \quad |\lambda| = n, \tag{1}$$

stands out as the one with deepest properties and widest applications. Here $\dim \lambda$ is the dimension of the corresponding representation of $S(n)$. This is a probability measure on partitions of $n$. It can be viewed as a distinguished discretization of the GUE ensemble of the random matrix theory. Namely, a measure on partitions can be made a point process on a lattice by placing particles in positions

$$\mathfrak{S}(\lambda) = \left\{\lambda_i - i + \tfrac{1}{2}\right\} \subset \mathbb{Z} + \tfrac{1}{2}.$$

Figure 1 illustrates the geometric meaning of this transformation. An important theme of recent research was to understand how and why for a Plancherel random partition of $n \to \infty$ the particles $\mathfrak{S}(\lambda)$ behave like the eigenvalues of a random Hermitian matrix. See [3], [4], [14], [31] and e.g. [15], [32], [33] for a survey.

In these notes, we consider a different problem, namely, the behavior of (1) in a *periodic potential*, that is, additionally weighted by a multiplicative periodic function of the particles' positions. This leads to new phenomena and new applications. As we will see, the partition function of $\mathfrak{M}_{\mathrm{Planch}}$ in a periodic potential is closely related to Nekrasov partition function from supersymmetric gauge theory. This relationship will be reviewed in detail in Section 2 and its consequences may be summarized as follows.

**1.2. Instanton counting.** In 1994, Seiberg and Witten proposed an exact description of the low-energy behavior of certain supersymmetric gauge theories [38], [39]. In spite of the enormous body of research that this insight has generated, only a modest progress was made towards its gauge-theoretic derivation. This changed in 2002, when Nekrasov proposed in [28] a physically meaningful and mathematically rigorous definition of the regularized partition function $Z$ for supersymmetric gauge theories in question.

Supersymmetry makes the gauge theory partition function the partition function of a *gas of instantons*. Nekrasov's idea was to use *equivariant integration* with respect to the natural symmetry group in lieu of a long-distance cut-off for the instanton gas. He conjectured that as the regularization parameter $\varepsilon \to 0$

$$\ln Z \sim -\frac{1}{\varepsilon^2}\mathcal{F}$$

where the free energy $\mathcal{F}$ expressed by the Seiberg–Witten formula in terms of periods of a certain differential $dS$ on a certain algebraic curve $C$.

This conjecture was proven in 2003 by Nekrasov and the author for a list of gauge theories with gauge group $U(r)$, namely, pure gauge theory, theories with matter

fields in fundamental and adjoint representations of the gauge group, as well as 5-dimensional theory compactified on a circle [29]. Simultaneously, independently, and using completely different ideas, the formal power series version of Nekrasov's conjecture was proven for the pure $U(r)$-theory by Nakajima and Yoshioka [25]. The methods of [29] were applied to classical gauge groups in [30] and to the 6-dimensional gauge theory compactified on a torus in [11]. Another algebraic approach, which works for pure gauge theory with any gauge group, was developed by Braverman [5] and Braverman and Etingof [6].

In these notes, we outline the results of [29] in the simplest, yet fundamental, case of pure gauge theory. As should be obvious from the title, the main idea is to treat the gauge theory partition function $Z$ as the partition function of an ensemble of random partitions. The $\varepsilon \to 0$ limit turns out to be the *thermodynamic limit* in this ensemble. What emerges in this limit is a nonrandom *limit shape*, an example of which may be seen in Figure 6. This is a form of the law of large numbers, analogous, for example, to Wigner's semicircle law for the spectrum of a large random matrix. The limit shape is characterized as the unique minimizer $\psi_\star$ of a certain convex functional $\mathcal{S}(\psi)$, leading to

$$\mathcal{F} = \min \mathcal{S}.$$

We solve the variational problem explicitly and the limit shape turns out to be an algebraic curve $C$ is disguise. Namely, the limit shape is essentially the graph of the function

$$\Re \int_{x_0}^{x} dS,$$

where $dS$ is the Seiberg–Witten differential. Thus all ingredients of the answer appear very naturally in the proof.

Random matrix theory and philosophy had many successes in mathematics and physics. Here we have an example when random partitions, while structurally resembling random matrices, offer several advantages. First, the transformation into a random partition problem is geometrically natural and exact. Second, the discretization inherent in partitions regularizes several analytic issues. For further examples along these lines the reader may consult [33].

**1.3. Higher dimensions.** The translation of the gauge theory problem into a random partition problem is explained in Section 2. In Section 3, we analyze the latter problem, in particular, derive and solve the variational problem for the limit shape. Section 4 summarizes parallel results for 3-dimensional partitions, where similar algebraic properties of limit shapes are now proven in great generality.

The surprising fact that free energy $\mathcal{F}$ is given in terms of periods of a hidden algebraic curve $C$ is an example of *mirror symmetry*. A general program of interpreting mirror partners as limit shapes was initiated in [34]. Known results about the limit shapes of periodically weighted 3-dimensional partitions, together with the

conjectural equality of Gromov–Witten and Donaldson–Thomas theories of projective algebraic 3-folds [22] can be interpreted as a verification of this program for toric Calabi–Yau 3-folds. See [35] for an introduction to these ideas.

Note that something completely different is expected to happen in dimensions $> 3$, where the behavior of both random interfaces and Gromov–Witten invariants changes qualitatively.

## 2. The gauge theory problem

**2.1. Instantons.** We begin by recalling some basic facts, see [9] for an excellent mathematical treatment and [8], [10], [44] for a physical one. This will serve as motivation for the introduction of Nekrasov's partitions function in (8) below.

In gauge theories, interactions are transmitted by gauge fields, that is, unitary connections on appropriate vector bundles. In coordinates, these are matrix-valued functions $A_i(x)$ that define covariant derivatives

$$\nabla_i = \frac{\partial}{\partial x_i} + A_i(x), \quad A_i^* = -A_i.$$

We consider the most basic case of the trivial bundle $\mathbb{R}^4 \times \mathbb{C}^r$ over the flat Euclidean space-time $\mathbb{R}^4$, where such coordinate description is global.

The natural (Yang–Mills) energy functional for gauge fields is $L^2$-norm squared $\|F\|^2$ of the curvature

$$F = \sum \left[\nabla_i, \nabla_j\right] dx_i \wedge dx_j.$$

The path integral in quantum gauge theory then takes the form

$$\int_{\text{connections}/\mathcal{G}} \mathcal{D}A \ \exp\left(-\beta \|F\|^2\right) \times \cdots, \tag{2}$$

where dots stand for terms involving other fields of the theory and $\mathcal{G}$ is the group of gauge transformations $g : \mathbb{R}^4 \to U(r)$ acting by

$$\nabla \mapsto g \nabla g^{-1}.$$

In these notes, we will restrict ourselves to pure gauge theory, which is already quite challenging due to the complicated form of the energy. A parallel treatment of certain matter fields can be found in [29].

Our goal is to study (2) as function of the parameter $\beta$ (and boundary conditions at infinity, see below). A head-on probabilistic approach to this problem would be to make it a theory of many interacting random matrices through a discretization of space-time. This is a fascinating topic about which I have nothing to say. In a different direction, when $\beta \gg 0$, the minima of $\|F\|^2$ should dominate the integral.

In *supersymmetric* gauge theory, there is a way to make such approximation exact, thereby reducing the path integral to the following finite-dimensional integrals.

Local minima of $\|F\|^2$ are classified by a topological invariant $c_2 \in \mathbb{Z}$,

$$c_2 = \frac{1}{8\pi^2}\int_{\mathbb{R}^4} \operatorname{tr} F^2,$$

called *charge*, and satisfy a system of first order PDEs

$$F \pm \star F = 0, \tag{3}$$

where $\star$ is the Hodge star operator on 2-forms on $\mathbb{R}^4$. With the plus sign, (3) corresponds to $c_2 > 0$ and is called the anti-self-duality equation. Its solutions are called *instantons*. Minima with $c_2 < 0$ are obtained by reversing the orientation of $\mathbb{R}^4$.

The ASD equations (3) are conformally invariant and can be transported to a punctured 4-sphere $S^4 = \mathbb{R}^4 \cup \{\infty\}$ via stereographic projection. From the removable singularities theorem of Uhlenbeck it follows that any instanton on $\mathbb{R}^4$ extends, after a gauge transformation, to an instanton on $S^4$. Thus we can talk about the value of an instanton at infinity.

Let $\mathcal{G}_0$ be the group of maps $g : S^4 \to U(r)$ such that $g(\infty) = 1$. Modulo $\mathcal{G}_0$, instantons on $S^4$ with $c_2 = n$ are parametrized by a smooth manifold $\mathcal{M}(r, n)$ of real dimension $4rn$. Naively, one would like the contribution from charge $n$ instantons to (2) to be the volume of $\mathcal{M}(r, n)$ in a natural symplectic structure. However, $\mathcal{M}(r, n)$ is noncompact (and its volume is infinite) for two following reasons.

Approximately, an element of $\mathcal{M}(r, n)$ can be imagined as a nonlinear superposition of $n$ instantons of charge 1. Some of those may become point-like, i.e. their curvature may concentrate in a $\delta$-function spike, while others may wander off to infinity. A partial compactification of $\mathcal{M}(r, n)$, constructed by Uhlenbeck, which replaces point-like instanton by just points of $\mathbb{R}^4$, takes care of the first problem but not the second. Nekrasov's idea was to use *equivariant integration* to regularize the instanton contributions.

**2.2. Equivariant regularization.** The group

$$K = \mathrm{SU}(2) \times \mathrm{SU}(r)$$

acts on $\mathcal{M}(r, n)$ by rotations of $\mathbb{R}^4 = \mathbb{C}^2$ and constant gauge transformation, respectively. Our plan is to use this action for regularization. Let us start with the following simplest example: suppose we want to regularize the volume of $\mathbb{R}^2$. A gentle way to do it is to introduce a Gaussian well

$$\int_{\mathbb{R}^2} e^{-t\pi(x^2+y^2)} dx\, dy = \frac{1}{t}, \quad \Re t \geq 0 \tag{4}$$

and thus an effective cut-off at the $|t|^{-1/2}$ scale. Note that the Hamiltonian flow on $\mathbb{R}^2$ generated by $H = \frac{1}{2}(x^2 + y^2)$ with respect to the standard symplectic form

$\omega = dx \wedge dy$ is rotation about the origin with angular velocity one. This makes (4) a simplest instance of the Atiyah–Bott–Duistermaat–Heckman *equivariant localization* formula [2]. We will use localization in the following complex form.

Let $T = \mathbb{C}^*$ act on a complex manifold $X$ with isolated fixed points $X^T$. Suppose that the action of $U(1) \subset T$ is generated by a Hamiltonian $H$ with respect to a symplectic form $\omega$. Then

$$\int_X e^{\omega - 2\pi t H} = \sum_{x \in X^T} \frac{e^{-2\pi t H(x)}}{\det t|_{T_x X}}, \tag{5}$$

where $t$ should be viewed as an element of $\mathrm{Lie}(T) \cong \mathbb{C}$, an so it acts in the complex tangent space $T_x X$ to a fixed point $x \in X$. While (5) is normally stated for compact manifolds $X$, example (4) shows that with care it can work for noncompact ones, too. Scaling both $\omega$ and $H$ to zero, we get from (5) a formal expression

$$\int_X 1 \stackrel{\text{def}}{=} \sum_{x \in X^T} \frac{1}{\det t|_{T_x X}}, \tag{6}$$

which does not depends on the symplectic form and vanishes if $X$ is compact.

A theorem of Donaldson identifies instantons with *holomorphic bundles* on $\mathbb{C}^2 = \mathbb{R}^4$ and thus gives a complex description of $\mathcal{M}(r, n)$. Concretely, $\mathcal{M}(r, n)$ is the moduli space of rank $r$ holomorphic bundles $\mathcal{E} \to \mathbb{CP}^2$ with given 2nd Chern class $c_2(\mathcal{E}) = n$ and a given trivialization along the line

$$L_\infty = \mathbb{CP}^2 \setminus \mathbb{C}^2$$

at infinity. Note that existence of such trivialization implies that $c_1(\mathcal{E}) = 0$. A similar but larger moduli space $\overline{\mathcal{M}}(r, n)$ of *torsion-free sheaves*, see e.g. [12], [24], is a smooth partial compactification of $\mathcal{M}(r, n)$.

The complexification of $K$

$$K_{\mathbb{C}} = \mathrm{SL}(2) \times \mathrm{SL}(r)$$

acts on $\overline{\mathcal{M}}(r, n)$ by operating on $\mathbb{C}^2$ and changing the trivialization at infinity. Equivariant localization with respect to a general $t \in \mathrm{Lie}(K)$

$$t = (\mathrm{diag}(-i\varepsilon, i\varepsilon), \mathrm{diag}(ia_1, \ldots, ia_r)) \tag{7}$$

combines the two following effects. First, it introduces a spatial cut-off parameter $\varepsilon$ as in (4). Second, it introduces dependence on the instanton's behavior at infinity through the parameters $a_i$. While the first factor in $K$ works to shepherd run-away instantons back to the origin, the second works to break the gauge invariance at infinity. In supersymmetric gauge theories, the parameters $a_i$ correspond to the vacuum expectation of the Higgs field and thus are responsible for masses of gauge bosons. In short, they are live physical parameters.

**2.3. Nekrasov partition function.** We are now ready to introduce our main object of study, the partition function of the pure ($\mathcal{N} = 2$ supersymmetric) $U(r)$ gauge theory:

$$Z(\varepsilon; a_1, \dots, a_r; \Lambda) = Z_{\text{pert}} \sum_{n \geq 0} \Lambda^{2rn} \int_{\bar{\mathcal{M}}(r,n)} 1, \tag{8}$$

where the integral is defined by (6) applied to (7),

$$\Lambda = \exp(-4\pi^2 \beta / r),$$

and $Z_{\text{pert}}$ is a certain perturbative factor to be discussed below. The series in (8) is denoted $Z_{\text{inst}}$. Because of factorials in denominators, see (24), $Z_{\text{inst}}$ converges whenever we avoid zero denominators, that is, on the complement of

$$a_i - a_j \equiv 0 \mod \varepsilon. \tag{9}$$

In essence, these factorials are there because the instantons are unordered. Also note that $Z$ is an even function of $\varepsilon$ and a symmetric function of the $a_i$'s.

Since by our regularization rule

$$\operatorname{vol} \mathbb{R}^4 = \int_{\mathbb{R}^4} 1 = \frac{1}{\varepsilon^2},$$

we may expect that as $\varepsilon \to 0$

$$\ln Z(\varepsilon; a; \Lambda) \sim -\frac{1}{\varepsilon^2} \mathcal{F}(a; \Lambda),$$

where $\mathcal{F}$ is the *free energy*. At first, the poles (9) of $Z_{\text{inst}}$, which are getting denser and denser, may look like a problem. Indeed, poles of multiplicity $O(\varepsilon^{-1})$ may affect the free energy, but it is a question of competition with the other terms in $Z_{\text{inst}}$, which the pole-free terms win if $|a_i - a_j| \gg 0$. As a result, either by passing to a subsequence of $\varepsilon$, or by restricting summation in $Z_{\text{inst}}$ to the relevant pole-free terms, we obtain a limit

$$\mathcal{F}_{\text{inst}} = -\lim \varepsilon^2 Z_{\text{inst}},$$

which is analytic and monotone far enough from the walls of the Weyl chambers. Recall that Weyl chambers for $\mathrm{SU}(r)$ are the $r!$ cones obtained from

$$\mathsf{C}_+ = \{a_1 > a_2 > \cdots > a_r,\ \textstyle\sum a_i = 0\}$$

by permuting the coordinates. As $|a_i - a_j|$ get small, poles do complicate the asymptotics. This is the origin of cuts in the analytic function $\mathcal{F}(a)$, $a_i \in \mathbb{C}$.

Nekrasov conjectured in [28] that the free energy $\mathcal{F}$ is the *Seiberg–Witten prepotential*, first obtained in [38], [39] through entirely different considerations. It is defined in terms of a certain family of algebraic curves.

**2.4. Seiberg–Witten geometry.** In the affine space of complex polynomials of the form $P(z) = z^r + O(z^{r-2})$ consider the open set $\boldsymbol{U}$ of polynomials such that

$$P(z) = \pm 2\Lambda^r \tag{10}$$

has $2r$ distinct roots. Over $\boldsymbol{U}$, we have a $g$-dimensional family of complex algebraic curves $C$ of genus $g = r - 1$ defined by

$$\Lambda^r \left( w + \frac{1}{w} \right) = P(z), \quad P \in \boldsymbol{U}. \tag{11}$$

The curve (11) is compactified by adding two points $\partial C = \{w = 0, \infty\}$.

Let $\mathsf{M} \subset \boldsymbol{U}$ be the set of $P(z)$ for which all roots of (10) are real. The corresponding curves $C$ are called *maximal* and play a special role, see e.g. [40]. They arise, for example, as spectral curves of a periodic Toda chain [41]. A maximal curve $C$ has $r$ real ovals, as illustrated in Figure 2. Note that for $z \in \mathbb{R}$, $w$ is either real or lies on the unit circle $|w| = 1$.

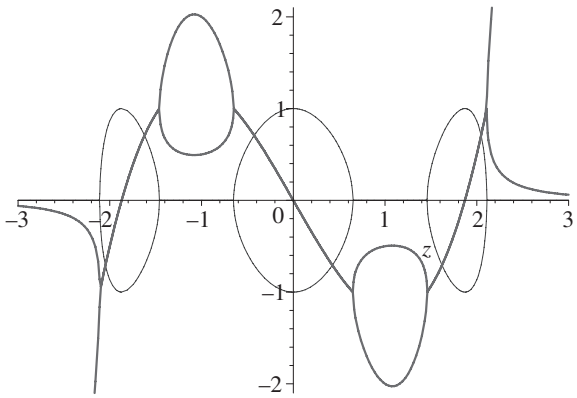

Figure 2. $\Re w$ (bold) and $\Im w$ for $w + 1/w = z^3 - 3.5\,z$ and $z \in \mathbb{R}$.

The intervals $P^{-1}([-2\Lambda^r, 2\Lambda^r]) \subset \mathbb{R}$ on which $|w| = 1$ are called *bands*. The intervals between the bands are called *gaps*. The smaller (in absolute value) root $w$ of the equation (11) can be unambiguously defined for $z \in \mathbb{C} \setminus \{\text{bands}\}$. On the corresponding sheet of the Riemann surface of $w$, we define cycles

$$\alpha_i \in H_1(C - \partial C), \quad \beta_i \in H_1(C, \partial C), \quad i = 1, \dots, r \tag{12}$$

as illustrated in Figure 3, where dotted line means that $\beta_i$ continues on the other sheet. Note that $\alpha_i \cap \beta_j = \delta_{ij}$ and that

$$\overline{\alpha}_i = -\alpha_i, \quad \overline{\beta}_i = \beta_i, \tag{13}$$

where bar stands for complex conjugation. The ovals in Figure 2 represent the cycles $\alpha_i$ and $\beta_i - \beta_{i+1}$.

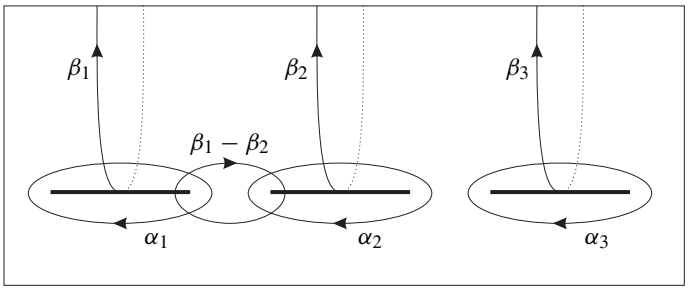

Figure 3. Cycles $\beta_i$ go from $w = \infty$ to $w = 0$. Bold segments indicate bands.

The Seiberg–Witten differential

$$dS = \frac{1}{2\pi i}\, z\, \frac{dw}{w} = \pm\frac{r}{2\pi i}\left(1 + O\left(z^{-2}\right)\right) dz$$

is holomorphic except for a second order pole (without residue) at $\partial C$. Its derivatives with respect to $P \in \boldsymbol{U}$ are, therefore, holomorphic differentials on $C$. In fact, this gives

$$T_P\boldsymbol{U} \cong \text{holomorphic diff. on } C.$$

Nondegeneracy of periods implies the functions

$$a_i \stackrel{\text{def}}{=} \int_{\alpha_i} dS, \quad \sum a_i = 0, \tag{14}$$

which are real on $\mathsf{M}$ by (13), are local coordinates on $\boldsymbol{U}$, as are

$$a_i^\vee - a_{i+1}^\vee \stackrel{\text{def}}{=} 2\pi i \int_{\beta_i - \beta_{i+1}} dS, \quad \sum a_i^\vee = 0. \tag{15}$$

Further, there exists a function $\mathcal{F}(a;\, \Lambda)$, which is real and convex on $\mathsf{M}$, such that

$$\left(\frac{\partial}{\partial a_i} - \frac{\partial}{\partial a_{i+1}}\right)\mathcal{F} = -\left(a_i^\vee - a_{i+1}^\vee\right). \tag{16}$$

Indeed, the Hessian of $\mathcal{F}$ equals $(-2\pi i)$ times the period matrix of $C$, hence symmetric (and positive definite on $\mathsf{M}$). The function $\mathcal{F}$ is called the *Seiberg–Witten prepotential*. Note that $\mathcal{F}$ is multivalued on $\boldsymbol{U}$ and, in fact, its monodromy played a key role in the argument of Seiberg and Witten. By contrast, $\mathsf{M}$ is simply-connected, indeed

$$a^\vee : \mathsf{M} \to \mathsf{C}_+$$

is a diffeomorphism, see e.g. [18] for a more general result. Note that the periods (15) are the areas enclosed by the images of real ovals of $C$ under $(z, w) \mapsto (z, \ln|w|)$. A similar geometric interpretation of the $a_i$'s will be given in (40) below. In particular, the range

$$\mathsf{A} = a(\mathsf{M})$$

of the coordinates (14) is a proper subset of $\mathsf{C}_- = -\mathsf{C}_+$. At infinity of $\mathsf{M}$, we have

$$a_i \sim \{\text{roots of } P\}, \quad a_1 \ll a_2 \ll \cdots \ll a_r.$$

**2.5. Main result.** We have now defined all necessary ingredients to confirm Nekrasov's conjecture in the following strong form:

**Theorem 1** ([29]). *For $a \in \mathsf{A}$,*

$$-\lim_{\varepsilon\to 0} \varepsilon^2 \ln Z(\varepsilon; a; \Lambda) = \mathcal{F}(a; \Lambda), \tag{17}$$

*where $\mathcal{F}$ is the Seiberg–Witten prepotential* (16).

At the boundary of $\mathsf{A}$, free energy has a singularity of the form

$$\mathcal{F} = -\left(a_i^\vee - a_j^\vee\right)^2 \ln\left(a_i^\vee - a_j^\vee\right) + \cdots$$

where dots denote analytic terms. This singularity is one of the main physical features of the Seiberg–Witten theory.

In broad strokes, the logic of the proof was explained in the Introduction. We now proceed with the details.

## 3. The random partition problem

**3.1. Fixed points contributions.** A rank 1 torsion-free sheaf on $\mathbb{C}^2$ is a fancy name to call an ideal $I$ of $\mathbb{C}[x, y]$. Any partition $\lambda$ defines one by

$$I_\lambda = (x^{\lambda_1}, x^{\lambda_2} y, x^{\lambda_3} y^2, \dots) \subset \mathbb{C}[x, y].$$

It is easy to see that all torus-fixed points of $\overline{\mathcal{M}}(r, n)$ have the form

$$\mathfrak{F} = \bigoplus_{k=1}^{r} I_{\lambda^{(k)}}, \quad \sum \left|\lambda^{(k)}\right| = n, \tag{18}$$

where $\lambda^{(k)}$ is an $r$-tuple of partitions. Our goal now is to compute the character of the torus action in the tangent space to the fixed point (18) and thus the contribution of $\mathfrak{F}$ to the sum in (6).

By construction of $\overline{\mathcal{M}}(r, n)$, its tangent space at $\mathfrak{F}$ equals $\operatorname{Ext}^1_{\mathbb{P}^2}(\mathfrak{F}, \mathfrak{F}(-L_\infty))$. From the vanishing of the other Ext-groups we conclude

$$\operatorname{tr} e^t|_{\operatorname{Ext}^1_{\mathbb{P}^2}(\mathfrak{F},\mathfrak{F}(-L_\infty))} = \mathcal{X}_{\mathcal{O}^{\oplus r}}(t) - \mathcal{X}_{\mathfrak{F}}(t), \tag{19}$$

where $\mathcal{X}_{\mathfrak{F}}(t)$ is the character

$$\mathcal{X}_{\mathfrak{F}}(t) = \operatorname{tr} e^t|_{\chi_{\mathbb{C}^2}(\mathfrak{F},\mathfrak{F})}$$

of the infinite-dimensional virtual representation

$$\chi_{\mathbb{C}^2}(\mathfrak{F},\mathfrak{F}) = \operatorname{Ext}^0_{\mathbb{C}^2}(\mathfrak{F},\mathfrak{F}) - \operatorname{Ext}^1_{\mathbb{C}^2}(\mathfrak{F},\mathfrak{F}) + \operatorname{Ext}^2_{\mathbb{C}^2}(\mathfrak{F},\mathfrak{F}).$$

Any graded free resolution of $\mathfrak{F}$ gives

$$\mathcal{X}_{\mathfrak{F}}(t) = |\mathsf{G}_{\mathfrak{F}}(t)|^2, \quad t \in \operatorname{Lie}(K),$$

where $\mathsf{G}_{\mathfrak{F}}(t)$ is, up to a factor, the character of $\mathfrak{F}$ itself

$$\begin{aligned}\mathsf{G}_{\lambda^{(1)},\dots,\lambda^{(r)}}(t) &= (e^{-i\varepsilon/2} - e^{i\varepsilon/2}) \operatorname{tr} e^t|_{\mathfrak{F}} \\ &= \sum_{k=1}^{r} e^{ia_k} \sum_{j=1}^{\infty} \exp\bigl(i\varepsilon\bigl(\lambda_j^{(k)} - j + \tfrac{1}{2}\bigr)\bigr). \end{aligned} \tag{20}$$

It is also a natural generating function of the $r$-tuple $\lambda^{(k)}$.

Note that the weight of any $\mathfrak{F}$ is real and positive, being a product of purely imaginary numbers in conjugate pairs.

**3.2. Perturbative factor.** In the spirit of the original uncompactified gauge theory problem on $\mathbb{R}^4$, we would like to drop the first term in (19) and declare its contribution canceled by $Z_{\text{pert}}$. In view of (20), this requires a regularization of the following product

$$Z_{\text{pert}} \text{“=”} \prod_{k,k'=1}^{r} \prod_{j,j'=1}^{\infty} i(a_k - a_{k'} + \varepsilon(j - j')).$$

A natural regularization is provided by Barnes' double $\Gamma$-function (21), see e.g. [37]. For $c_1, c_2 \in \mathbb{R}$ and $\Re w \gg 0$, define

$$\zeta_2(s; w \mid c_1, c_2) = \frac{1}{\Gamma(s)} \int_0^\infty \frac{dt}{t}\, t^s \, \frac{e^{-wt}}{\prod(1 - e^{-c_i t})}.$$

This has a meromorphic continuation in $s$ with poles at $s = 1, 2$. Define

$$\Gamma_2(w \mid c_1, c_2) = \exp \frac{d}{ds}\, \zeta(s; w \mid c_1, c_2)\big|_{s=0}. \tag{21}$$

Through the difference equation

$$w\, \Gamma_2(w)\, \Gamma_2(w + c_1 + c_2) = \Gamma_2(w + c_1)\, \Gamma_2(w + c_2) \tag{22}$$

it extends to a meromorphic function of $w$. We define

$$Z_{\text{pert}} = \prod_{k,k'} \Gamma_2\left(\frac{i(a_k - a_{k'})}{\Lambda} \,\middle|\, \frac{i\varepsilon}{\Lambda}, \frac{-i\varepsilon}{\Lambda}\right)^{-1}. \tag{23}$$

where $\Gamma_2$ is analytically continued to imaginary arguments using

$$\Gamma_2\,(Mw \mid Mc, -Mc) = M^{\frac{w^2}{2c^2}-\frac{1}{12}}\ \Gamma_2(w \mid c, -c), \quad M \notin (-\infty, 0].$$

The scaling by $\Lambda$ is introduced in (23) to make (8) homogeneous of degree 0 in $a$, $\varepsilon$, and $\Lambda$. Note also

$$\Gamma_2(0 \mid 1, -1) = e^{-\zeta'(-1)}.$$

Our renormalization rule (23) fits nicely with the following transformation of the partition function $Z$.

**3.3. Dual partition function.** For $r = 1$, the weight of $I_\lambda$ in (8) equals

$$\Lambda^{2n}\ \det{}^{-1} t\big|_{T_{I_\lambda}\bar{\mathcal{M}}(1,n)} = \frac{1}{n!}\left(\frac{\Lambda^2}{\varepsilon^2}\right)^n \mathfrak{M}_{\text{Planch}}(\lambda), \tag{24}$$

where $\mathfrak{M}_{\text{Planch}}$ is the Plancherel measure (1) and the prefactor is the Poisson weight with parameter $\Lambda^2/\varepsilon^2$. For $r > 1$, we will transform $Z$ into the partition function (29) of the Plancherel measure in a *periodic potential* with period $r$.

Let a function $\xi : \mathbb{Z} + \frac{1}{2} \to \mathbb{R}$ be periodic with period $r$ and mean 0. The energy $\Xi(\lambda)$ of the configuration $\mathfrak{S}(\lambda)$ in the potential $\xi$ is defined by Abel's rule

$$\Xi(\lambda) = \sum_{x\in\mathfrak{S}(\lambda)} \xi(x) \stackrel{\text{def}}{=} \lim_{z\to+0} \sum_{x\in\mathfrak{S}(\lambda)} \xi(x)\, e^{zx}.$$

Grouping the points of $\mathfrak{S}(\lambda)$ modulo $r$ uniquely determines an $r$-tuple of partitions $\lambda^{(k)}$, known as $r$-quotients of $\lambda$, and shifts $s_k \in \mathbb{Q}$ such that

$$\mathfrak{S}(\lambda) = \bigsqcup_{k=1}^{r} r\big(\mathfrak{S}\big(\lambda^{(k)}\big) + s_k\big) \tag{25}$$

and

$$rs \equiv \rho \mod r\,\mathbb{Z}_0^r, \quad \rho = \left(\tfrac{r-1}{2}, \dots, \tfrac{1-r}{2}\right),$$

where $\mathbb{Z}_0^r$ denotes vectors with zero sum. It follows from (25) that

$$\mathsf{G}_\lambda\,(\varepsilon/r) = \mathsf{G}_{\lambda^{(1)},\dots,\lambda^{(r)}}(\varepsilon;\, \varepsilon s). \tag{26}$$

Letting $\varepsilon \to 2\pi i k$, $k = 1, \dots, r-1$, in (26) gives

$$\Xi(\lambda) = (s, \xi) = \sum s_i\, \xi_i, \quad \xi_i = \xi\left(\tfrac{1}{2} - i\right), \tag{27}$$

while the $\varepsilon \to 0$ limit in (26) yields

$$|\lambda| = r\left(\sum |\lambda^{(k)}| + \sum \frac{s_k^2}{2}\right) + \frac{1-r^2}{24}.$$

Using these formulas and the difference equation (22), we compute

$$Z^\vee(\varepsilon;\xi_1,\dots,\xi_r;\Lambda) \stackrel{\text{def}}{=} \sum_{a\in\varepsilon(\rho+r\mathbb{Z}_0^r)} \exp\left(\frac{(\xi,a)}{r\varepsilon^2}\right) Z(r\varepsilon;a;\Lambda) \tag{28}$$

$$= e^{\zeta'(-1)+\frac{\pi i}{24}} \sum_\lambda \left|\frac{\Lambda}{\varepsilon}\right|^{2|\lambda|-\frac{1}{12}} \left(\frac{\dim\lambda}{|\lambda|!}\right)^2 \exp\left(\frac{\Xi(\lambda)}{\varepsilon}\right). \tag{29}$$

We call (28) the *dual partition function*. By (29), it equals the partition function of a periodically weighted Plancherel measure on partitions.

While it will play no role in what follows, it may be mentioned here that $Z^\vee$ is a very interesting object to study not asymptotically but exactly. For example, Toda equation for $\ln \mathbb{Z}^\vee$ may be found in Section 5 of [29].

**3.4. Dual free energy.** Define the dual free energy by

$$\mathcal{F}^\vee(\xi;\Lambda) = -\lim_{\varepsilon\to 0} \varepsilon^2 \ln Z^\vee. \tag{30}$$

Since (28) is a Riemann sum for Laplace transform, we may expect that

$$\mathcal{F}^\vee(\xi;\Lambda) = \min_{a\in\mathbb{R}_0^r} \frac{1}{r^2}\mathcal{F}(a;\Lambda) - \frac{1}{r}(\xi,a) \tag{31}$$

that is, up to normalization, $\mathcal{F}^\vee$ is the Legendre transform of $\mathcal{F}$. This is because the asymptotics of Laplace transform is determined by one point – the maximum. Our plan is apply to same logic to the infinite-dimensional sum (29), namely, to show that its $\varepsilon \to 0$ asymptotics is determined by a single term, the *limit shape*.

The law of large numbers, a basic principle of probability, implies that on a large scale most random system are deterministic: solids have definite shape, fluids obey the laws of hydrodynamics, etc. Only magnification reveals the full randomness of nature.

In the case at hand, the weight of a partition $\lambda$ in (29), normalized by the whole sum, defines a probability measure on the set of partitions. This measure depends on a parameter $\varepsilon$ and as $\varepsilon \to 0$ it clearly favors partitions of larger and larger size. In fact, the expected size of $\lambda$ grows as $\varepsilon^{-2}$. We thus expect the diagram of $\lambda$, scaled by $\varepsilon$ in both directions, to satisfy a law of large numbers, namely, to have a nonrandom limit shape. By definition, this limit shape will dominate the leading $\varepsilon \to 0$ asymptotics of $Z^\vee$. In absence of the periodic potential $\Xi$, such analysis is a classical result of Logan–Shepp and Vershik–Kerov [21], [42], [43].

Note that the maximum in (31) is over all of $a$, including the problematic region where $|a_i - a_j|$ get small. However, this region does not contribute to $\mathcal{F}^\vee$ as the convexity of free energy is lost there. We will see this reflected in the following properties of $\mathcal{F}^\vee$: it is strictly concave, analytic in the interior of the Weyl chambers, and singular along the chambers' walls.

**3.5. Variational problem for the limit shape.** The *profile* of a partition $\lambda$ is, by definition, the piecewise linear function plotted in bold in Figure 1. Let $\psi_\lambda$ be the profile of $\lambda$ scaled by $\varepsilon$ in both directions. The map $\lambda \mapsto \psi_\lambda$ embeds partitions into the convex set $\Psi$ of functions $\psi$ on $\mathbb{R}$ with Lipschitz constant 1 and

$$|\psi| = \int |\psi(x) - |x||\, dx < \infty.$$

The Lipschitz condition implies

$$\|\psi_1 - \psi_2\|_C \le \|\psi_1 - \psi_2\|_{L^1}^{1/2}, \quad \psi_1, \psi_2 \in \Psi,$$

and so $\Psi$ is complete and separable in the $L^1$-metric. Some function of a partition have a natural continuous extension to $\Psi$, for example

$$\mathsf{G}_\lambda(\varepsilon) = \frac{1}{e^{i\varepsilon/2} - e^{-i\varepsilon/2}} \left(1 - \frac{1}{2}\int e^{ix}\,(\psi_\lambda(x) - |x|)\, dx\right),$$

while others, specifically the ones appearing in (29), do not. An adequate language for dealing with this is the following.

Let $f(\lambda) \ge 0$ be a function on partitions depending on the parameter $\varepsilon$. We say that it satisfies a *large deviation* principle with action (rate) functional $\mathcal{S}_f(\psi)$ if for any set $A \subset \Psi$

$$-\lim \varepsilon^2 \ln \sum_{\psi_\lambda \in A} f(\lambda) \subset \left[\inf_{\bar{A}} \mathcal{S}_f, \inf_{A^\circ} \mathcal{S}_f\right] \subset \mathbb{R} \cup \{+\infty\}, \tag{32}$$

where lim denotes all limit points, $A^\circ$ and $\bar{A}$ stand for the interior and closure of $A$, respectively.

For the Plancherel weight (24), Logan–Shepp and Vershik–Kerov proved a large deviation principle with action

$$\mathcal{S}_{\mathrm{pl}}(\psi) = \frac{1}{2}\int_{x<y} (1 + \psi'(x))(1 - \psi'(y)) \ln \frac{|x-y|}{\Lambda}\, dx\, dy. \tag{33}$$

Note that in this case the sum in (32) may be replaced by maximum because the number of partitions of $n$ grows subexponentially in $n$. In other words, there is no entropic contribution in (33).

The periodic potential $\Xi(\lambda)$ produces a *surface tension* addition to the total action $\mathcal{S}$

$$\mathcal{S} = \mathcal{S}_{\mathrm{pl}} + \mathcal{S}_{\mathrm{surf}}, \quad \mathcal{S}_{\mathrm{surf}}(\psi) = \frac{1}{2}\int \sigma(\psi')\, dt,$$

where $\sigma$ is a convex piecewise-linear function of the kind plotted in Figure 4. It is linear on segments of length $2/r$ with slopes $\{\xi_i\}$, in increasing order. The form of $\mathcal{S}_{\mathrm{surf}}$ is easy to deduce directly; it can also be seen as e.g. the most degenerate case of

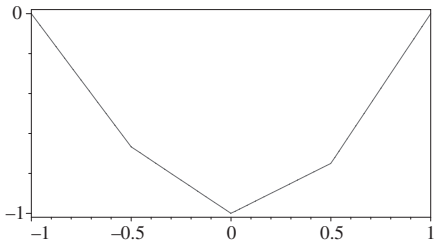

Figure 4. The surface tension $\sigma$ for $r = 4$ and $\xi = \{-\frac{4}{3}, -\frac{2}{3}, \frac{1}{2}, \frac{3}{2}\}$.

the surface tension formula from Section 4.2. The singularities in the surface tension $\sigma$ are responsible for *facets*, that is, linear pieces, in the minimizer, see Figure 6. The slopes of these facets are precisely the points where $\sigma'$ is discontinuous[1]. Note that $\sigma$ and hence $\mathcal{I}$ is a symmetric function of the $\xi_i$'s.

The functional $\mathcal{I}$ is strictly convex and its sublevel sets $\mathcal{I}^{-1}((-\infty, c])$ are compact, which can be seen by rewriting $\mathcal{I}_{\mathrm{pl}}$ in terms of the Sobolev $H^{1/2}$ norm, see [21], [43]. Therefore it has a unique minimum $\psi_\star$ – the limit shape. The large deviation principle and the definition of the dual free energy and (30) together imply

$$\mathcal{F}^{\vee}(\xi; \Lambda) = \mathcal{I}(\psi_\star). \tag{34}$$

Our business, therefore, is to find this minimizer $\psi_\star$.

**3.6. The minimizer.** By convexity, a local minimum of $\mathcal{I}$ is automatically a global one. Since $\sigma$ has one-sided derivatives, a local minimum can be characterized by nonnegativity of all directional derivatives. This leads to the following *complementary slackness* conditions for the convolution of $\psi_\star''(x)$ with the kernel

$$\mathsf{L}(x) = x \ln \frac{|x|}{\Lambda} - x = \int_0^x \ln \left| \frac{y}{\Lambda} \right| dy.$$

There exists a constant $c_0$, which is the Lagrange multiplier from the constraint $\int \delta\psi' = 0$, such that

$$\begin{aligned} &\mathsf{L} * \psi_\star''(x) + c_0 = \xi_i, && \psi_\star'(x) \in \left(-1 + \tfrac{2i-2}{r}, -1 + \tfrac{2i}{r}\right), \\ &\mathsf{L} * \psi_\star''(x) + c_0 \in [\xi_i, \xi_{i+1}], && \psi_\star'(x) = -1 + \tfrac{2i}{r}, \end{aligned} \tag{35}$$

where to simplify notation we assumed that

$$\xi \in \mathsf{C}_-, \quad \xi_0 = -\infty, \quad \xi_{r+1} = +\infty.$$

[1]There are many advantages in viewing random partitions as 2-dimensional slices of random 3-dimensional objects discussed in Section 4. From the probability viewpoint, this links random partitions with rather realistic models of crystalline surfaces with local interaction, enriching both techniques and intuition. In particular, coexistence of facets and curved regions in our limit shapes is the same phenomenon as observed in natural crystals. From the gauge theory viewpoint, it is also very natural, especially in the context of 5-dimensional theory on $\mathbb{R}^4 \times S^1$, which corresponds to the $K$-theory of the instanton moduli spaces.

Recall that $\mathsf{C}_-$ denotes the negative Weyl chamber.

The function $\psi_\star''$ will turn out to be nonnegative and supported on a union of $r$ intervals, which are precisely the *bands* of Section 2.4. The gaps will produce the facets in the limit shape.

It is elementary to see that for a maximal curve (11) the map

$$\Phi(z) = 1 + \frac{2}{\pi i r} \ln w = 1 + \frac{2}{\pi i} \ln \frac{\Lambda}{z} + O(z^{-1}), \quad z \to \infty \tag{36}$$

where $w$ is the smaller root of (11), defines a conformal map of the upper half-plane to a slit half-strip

$$\Delta \subset \{z \,|\Im z > 0, |\Re z| < 1\}$$

as in Figure 5. The slits in $\Delta$ go along

$$\Re z = -1 + 2i/r, \quad i = 1, \dots, r-1,$$

and their lengths are, essentially, the critical values of the polynomial $P(z)$. The bands and gaps are preimages of the horizontal and vertical segments of $\partial\Delta$, respectively.

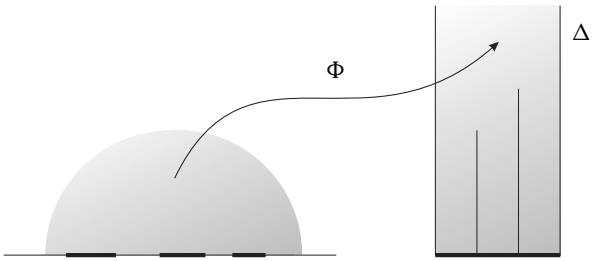

Figure 5. Conformal map defined by a maximal curve.

We claim that

$$\psi_\star' = \Re\Phi\big|_{\mathbb{R}}, \tag{37}$$

where the polynomial $P(z)$ is determined by the relation (39) below. The equations (35) are verified for (37) as follows. Since $\Phi'(z) = O(z^{-1})$, $z \to \infty$, we have the Hilbert transform relation

$$\text{P.V.}\,\frac{1}{x} * \Re\Phi'\big|_{\mathbb{R}} = \pi\Im\Phi'\big|_{\mathbb{R}}.$$

Integrating it once and using (36) to fix the integration constant, we get

$$(\mathsf{L} * \Re\Phi')' = \pi\Im\Phi.$$

Therefore, the function $\mathsf{L} * \Re\Phi'$ is constant on the bands and strictly increasing on the gaps, hence (37) satisfies (35) with

$$\xi_{i+1} - \xi_i = \pi \int_{i\text{th gap}} \Im\Phi(x)\,dx \tag{38}$$

Integrating (38) by parts and using definitions from Section 2.4 gives

$$\xi = -\frac{a^{\vee}}{r}, \tag{39}$$

thus every limit shape $\psi_\star$ comes from a maximal curve. For example, the limit shape corresponding to the curve from Figure 2 is plotted in Figure 6. Note also that for $C \in \mathsf{M}$, we have

$$a_i = \frac{r}{2}\left(I_{i-1} - I_i\right), \tag{40}$$

where $I_i$ is the intercept of the $i$th facet of the limit shape. In particular, $\mathsf{A} \subset \mathsf{C}_-$.

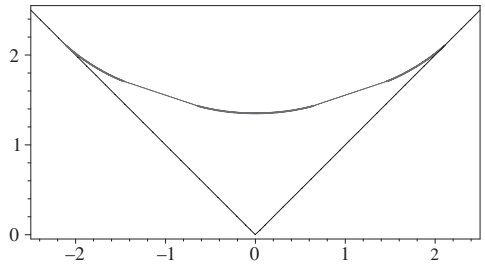

Figure 6. Limit shape corresponding to the curve from Figure 2. Thin segments are facets.

For given $\xi \in \mathsf{C}_-$, consider the distribution of the $r$-quotients $\lambda^{(i)}$ of the partition $\lambda$, as defined in Section 3.3. For the shifts $s_k$ in (25) we have using (27)

$$\varepsilon s \to -\frac{\partial \mathcal{F}^{\vee}}{\partial \xi}, \quad \varepsilon \to 0,$$

in probability. Observe that

$$\frac{\partial}{\partial \xi}\mathcal{F}^{\vee}(\xi) = \left[\frac{\partial}{\partial \xi}\mathcal{S}\right](\psi_\star)$$

since the other term, containing $\frac{\partial}{\partial \xi}\psi_\star$, vanishes by the definition of a maximum. Definitions and integration by parts yield

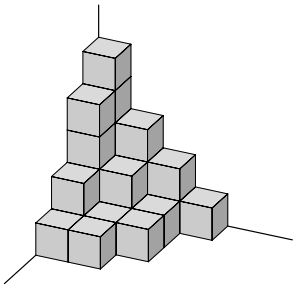
$$-\left(\frac{\partial}{\partial \xi_i} - \frac{\partial}{\partial \xi_{i+1}}\right)\mathcal{F}^{\vee} = \frac{a_i - a_{i+1}}{r}.$$

By (26), this means that the resulting sum over the $r$-quotients $\lambda^{(i)}$ is the original partition function $Z$ with parameters $a \in \mathsf{A}$. This concludes the proof.

## 4. The next dimension

### 4.1. Stepped surfaces

An obvious 3-dimensional generalization of a partition, also known as a plane partition can be seen on the right. More generally, we consider *stepped surfaces*, that is, continuous surfaces glued out of sides of a unit cube, spanning a given polygonal contour in $\mathbb{R}^3$, and projecting 1-to-1 in the (1, 1, 1) direction, see Figure 7. Note that stepped surfaces minimize the surface area for given boundary conditions, hence can be viewed as zero temperature limit of the interface in the 3D Ising model.



The most natural measure on stepped surfaces is the uniform one with given boundary conditions, possibly conditioned on the volume enclosed. It induces Plancherel-like measures on 2-dimensional slices. Stepped surfaces are in a natural bijection with fully packed dimers on the hexagonal lattice and Kasteleyn theory of planar dimers [16] forms the basis of most subsequent developments.

The following law of large numbers for stepped surfaces was proven in [7]. Let $C_n$ be a sequence of boundary contours such that each $C_n$ can be spanned by at least one stepped surface. Suppose that $n^{-1}C_n$ converge to a given curve $C \subset \mathbb{R}^3$. Then, scaled by $n^{-1}$, uniform measures on stepped surfaces spanning $C_n$ converge to the $\delta$-measure on a single Lipschitz surface spanning $C$ – the limit shape. This limit shape formation is clearly visible in Figure 7.

Figure 7. A limit shape simulation. The frozen boundary is the inscribed cardioid.

The limit shape is the unique minimizer of the following functional. Let the surface be parameterized by $x_3 = h(x_3 - x_1, x_3 - x_2)$, where $h$ is a Lipschitz function

with gradient in the triangle $\triangle$ with vertices $(0, 0)$, $(0, 1)$, $(1, 0)$. Let $\Omega$ be the planar region enclosed by the projection of $C$ in the $(1, 1, 1)$ direction. We will use $(x, y) = (x_3 - x_1, x_2 - x_1)$ as coordinates on $\Omega$. The limit shape is the unique minimizer of

$$\mathcal{S}_{\text{step}}(h) = \int_\Omega \sigma_{\text{step}}(\nabla h)\, dx\, dy, \tag{41}$$

where, in the language of [20], the surface tension $\sigma_{\text{step}}$ is the Legendre dual of the Ronkin function of the straight line

$$z + w = 1. \tag{42}$$

We recall that for a plane curve $P(z, w) = 0$, its Ronkin function [23] is defined by

$$R(x, y) = \frac{1}{(2\pi i)^2} \iint_{\substack{|z|=e^x \\ |w|=e^y}} \log|P(z, w)|\, \frac{dz}{z}\, \frac{dw}{w}. \tag{43}$$

The gradient $\nabla R$ always takes values in the Newton polygon $\Delta(P)$ of the polynomial $P$, so $\Delta(P)$ is naturally the domain of the Legendre transform $R^\vee$. For the straight line as above, the Newton polygon is evidently the triangle $\triangle$.

The surface tension $\sigma_{\text{step}}$ is singular and not strictly convex at the boundary of $\triangle$, which leads to formation of *facets* and *edges* in the limit shape (which can be clearly seen in Figure 7). This models facet formation in natural interfaces, e.g. crystalline surfaces, and is the most interesting aspect of the model. Note that facets are completely ordered (or *frozen*). The boundary between the ordered and disordered (or *liquid*) regions is known as the *frozen boundary*.

The following transformation of the Euler-Lagrange equation for (41) found in [19] greatly facilitates the study of the facet formation. Namely, in the liquid region we have

$$\nabla h = \frac{1}{\pi}(\arg w, -\arg z), \tag{44}$$

where the functions $z$ and $w$ solve the differential equation

$$\frac{z_x}{z} + \frac{w_y}{w} = c \tag{45}$$

and the algebraic equation (42). Here $c$ is the Lagrange multiplier for the volume constraint $\int_\Omega h = \text{const}$, the unconstrained case is $c = 0$. At the boundary of the liquid region, $z$ and $w$ become real and the $\nabla h$ starts to point in one of the coordinate directions.

The first-order quasilinear equation (45) is, essentially, the complex Burgers equation $z_x = z z_y$ and, in particular, it can be solved by complex characteristics as follows. There exists an analytic function $Q(z, w)$ such that

$$Q(e^{-cx} z, e^{-cy} w) = 0. \tag{46}$$

In other words, $z(x, y)$ can be found by solving (42) and (46). In spirit, this is very close to Weierstraß parametrization of minimal surfaces in terms of analytic data.

Frozen boundary can only develop if $Q$ is real, in which case the roots $(z, w)$ and $(\bar{z}, \bar{w})$ of (46) coincide at the frozen boundary. At a smooth point of the frozen boundary, the multiplicity of this root will be exactly two, hence $\nabla h$ has a square-root singularity there. As a result, the limit shape has an $x^{3/2}$ singularity at the generic point of the frozen boundary, thus recovering the well-known Pokrovsky–Talapov law [36] in this situation. At special points of the frozen boundary, triple solutions of (46) occur, leading to a cusp singularity. One such point can be seen in Figure 7.

Remarkably, for a dense set of boundary condition the function $Q$ is, in fact, a polynomial. Consequently, the frozen boundary takes the form $R(e^{cx}, e^{cy}) = 0$, where $R$ is the polynomial defining the planar dual of the curve $Q = 0$. This allows to use powerful tools of algebraic geometry to study the singularities of the solutions, see [19]. The precise result proven there is

**Theorem 2** ([19]). *Suppose the boundary contour $C$ is a connected polygon with $3k$ sides in coordinate directions* (*cyclically repeated*) *which can be spanned by a Lipschitz function with gradient in $\triangle$. Then $Q = 0$ is an algebraic curve of degree $k$ and genus zero.*

For example, for the boundary contour in Figure 7 we have $k = 3$ (one of the boundary edges there has zero length) and hence $R$ is the dual of a degree 3 genus 0 curve – a cardioid. The procedure of determining $Q$ from the boundary conditions is effective and can be turned into a practical numeric homotopy procedure, see [19]. Higher genus frozen boundaries occur for multiply-connected domains, in fact, the genus of $Q$ equals the genus of the liquid region.

Of course, for a probabilist, the law of large numbers is only the beginning and the questions about CLT corrections to the limit shape and local statistics of the surface in various regions of the limit shape follow immediately. Conjecturally, the limit shape controls the answers to all these questions. For example, the function $e^{-cx}z$ defines a *complex structure* on the liquid region and, conjecturally, the Gaussian correction to the limit shape is given by the *massless free field* in the corresponding conformal structure. In the absence of frozen boundaries and without the volume constraint, this is proven in [17]. See e.g. [15], [17], [20], [32] for an introduction to the local statistics questions.

**4.2. Periodic weights.** Having discussed periodically weighted Plancherel measure and a 3-dimensional analog of the Plancherel measure, we now turn to periodically weighted stepped surfaces. This is very natural if stepped surfaces are interpreted as crystalline interfaces. Periodic weights are introduced as follows: we weight each square by a periodic function of $x_3 - x_1$ and $x_2 - x_1$ (with some integer period $M$).

The role previously played by the straight line (42) is now played by a certain higher degree curve $P(z, w) = 0$, the spectral curve of the corresponding periodic

Kasteleyn operator. In particular, the surface tension $\sigma_{\text{step}}$ is now replaced by the Legendre dual of the Ronkin function of $P$, see [20]. We have

$$\deg P = M$$

and the coefficients of $P$ depend polynomially on the weights.

The main result of [20], known as *maximality*, says that for real and positive weights the curve $P$ is always a real algebraic curve of a very special kind, namely, a *Harnack curve*, see [23]. Conversely, as shown in [18], all Harnack curves arise in this way.

Harnack curves are, in some sense, the best possible real curves; their many remarkable properties are discussed in [23]. One of several equivalent definitions of a Harnack curve is that the map

$$(z, w) \mapsto (\log|z|, \log|w|) \tag{47}$$

from $P(z, w) = 0$ to $\mathbb{R}^2$ is 1-to-1 on the real locus of $P$ and 2-to-1 over the rest. The image of $P = 0$ under (47) is known as the *amoeba* of $P$. Note from (43) that the gradient $\nabla R$ of the Ronkin function of $P$ is nonconstant precisely for $(x, y)$ in the amoeba of $P$. In other words, the Ronkin function has a facet (that is, a linear piece) over every component of the amoeba complement. The 2-to-1 property implies that the number of compact facets of Ronkin function equals the (geometric) genus of the curve $P$. Each of these facets translates into the singularity of the surface tension and, hence, into facets with the same slope in limit shapes.

By Wulff's theorem, the Ronkin function itself is a minimizer, corresponding to its own ("crystal corner") boundary conditions. An example of the Ronkin function of a genus 1 Harnack curve can be seen in Figure 8.

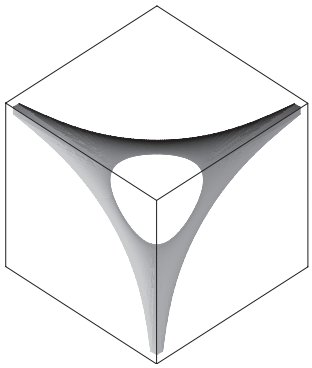


Figure 8. The (curved part of the) Ronkin function of a genus 1 curve. Its projection to the plane is the amoeba.

Maximality implies *persistence of facets*, namely, for fixed period $M$, there will be $\binom{M-1}{2}$ compact facets of the Ronkin function and $\binom{M-1}{2}$ corresponding singularities

of the surface tension, except on a codimension 2 subvariety of the space of weights. It also implies e.g. the following *universality of height fluctuations* in the liquid region

$$\operatorname{Var}(h(a) - h(b)) \sim \frac{1}{\pi} \ln \|a - b\|, \quad \|a - b\| \to \infty.$$

Remarkably, formulas (44), (45), and (46) need no modifications for periodic weights. Replacing (42) by $P(z, w) = 0$ is the only change required, see [19].

From our experience with periodically weighted Plancherel measure, it is natural to expect that, for some special boundary conditions, the partition function of periodically weighted stepped surfaces will encode valuable physical information. A natural choice of "special boundary conditions" are the those of a *crystal corner*, when we require the surface to be asymptotic to given planes at infinity, as in Figure 8. For convergence of the partition function, one introduces a fugacity factor $q^{\mathrm{vol}}$, where the missing volume is measured with respect to the "full corner".

I hope that further study will reveal many special properties of such crystal corner partition functions. Their extremely degenerate limits have been identified with all-genera, all-degree generating functions for Donaldson–Thomas invariants of toric Calabi–Yau threefolds. Namely, as the periodic weights become extreme, all limit shapes, and the Ronkin function in particular, degenerate to piecewise linear functions. This is known as the *tropical limit*. The only remaining features of limit shapes are the edges and the triple points, where 2 and 3 facets meet, respectively. In this tropical limit, the partition function becomes the partition function of ordinary, unweighted, 3D partitions located at triple points. These 3D partitions may have infinite legs along the edges, as in Figure 9 and through these legs they interact with their neighbors. This description precisely matches the localization formula for Donaldson–Thomas invariants of the toric threefold whose toric polyhedron is given by the piecewise linear limit shape, see [22].

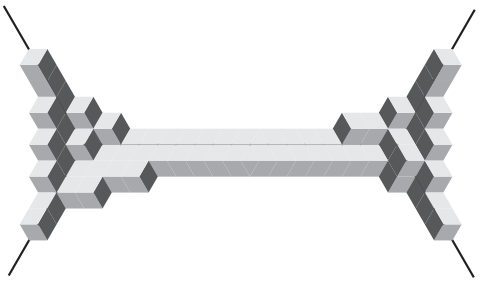

Figure 9. Two 3D partitions connected at an angle through an infinite leg.

Donaldson–Thomas theory of any 3-fold has been conjectured to be equivalent, in a nontrivial way, to the Gromov–Witten theory of the same 3-fold in [22]. For the toric Calabi–Yau 3-folds, this specializes to the earlier *topological vertex* conjecture of [1]. It is impossible to adequately review this subject here, see [35] for an introduction.

This is also related to the supersymmetric gauge theories considered in Section 2, or rather their 5-dimensional generalizations, via a procedure called *geometric engineering* of gauge theories. See for example [13] and references therein.

I find such close and unexpected interaction between rather basic statistical models and instantons in supersymmetric gauge and string theories very exciting and promising. The field is still full of wide open questions and, in my opinion, it is also full of new phenomena waiting to be discovered.

# Estimation in inverse problems and second-generation wavelets

Dominique Picard and Gérard Kerkyacharian

**Abstract.** We consider the problem of recovering a function $f$ when we receive a blurred (by a linear operator) and noisy version: $Y_\varepsilon = Kf + \varepsilon \dot{W}$. We will have as guides 2 famous examples of such inverse problems: the deconvolution and the Wicksell problem. The direct problem ($K$ is the identity) isolates the denoising operation. It cannot be solved unless accepting to estimate a smoothed version of $f$: for instance, if $f$ has an expansion on a basis, this smoothing might correspond to stopping the expansion at some stage $m$. Then a crucial problem lies in finding an equilibrium for $m$, considering the fact that for $m$ large, the difference between $f$ and its smoothed version is small, whereas the random effect introduces an error which is increasing with $m$. In the true inverse problem, in addition to denoising, we have to 'inverse the operator' $K$, an operation which not only creates the usual difficulties, but also introduces the necessity to control the additional instability due to the inversion of the random noise. Our purpose here is to emphasize the fact that in such a problem there generally exists a basis which is fully adapted to the problem, where for instance the inversion remains very stable: this is the singular value decomposition basis. On the other hand, the SVD basis might be difficult to determine and to numerically manipulate. It also might not be appropriate for the accurate description of the solution with a small number of parameters. Moreover, in many practical situations the signal provides inhomogeneous regularity, and its local features are especially interesting to recover. In such cases, other bases (in particular, localised bases such as wavelet bases) may be much more appropriate to give a good representation of the object at hand. Our approach here will be to produce estimation procedures keeping the advantages of a localisation properly without loosing the stability and computability of SVD decompositions. We will especially consider two cases. In the first one (which is the case of the deconvolution example) we show that a fairly simple algorithm (WAVE-VD), using an appropriate thresholding technique performed on a standard wavelet system, enables us to estimate the object with rates which are almost optimal up to logarithmic factors for any $\mathbb{L}_p$ loss function and on the whole range of Besov spaces. In the second case (which is the case of the Wicksell example where the SVD basis lies in the range of Jacobi polynomials) we prove that a similar algorithm (NEED-VD) can be performed provided one replaces the standard wavelet system by a second generation wavelet-type basis: the needlets. We use here the construction (essentially following the work of Petrushev and co-authors) of a localised frame linked with a prescribed basis (here Jacobi polynomials) using a Littlewood–Paley decomposition combined with a cubature formula. Section 5 describes the direct case ($K = I$). It has its own interest and will act as a guide for understanding the 'true' inverse models for a reader who is not familiar with nonparametric statistical estimation. It can be read first. Section 1 introduces the general inverse problem and describes the examples of deconvolution and Wicksell's problem. A review of standard methods is given with a special focus on SVD methods. Section 2 describes the WAVE-VD procedure. Section 3 and 4 give a description of the needlets constructions and the performances of the NEED-VD procedure.

## 1. Inverse models

Let $\mathbb{H}$ and $\mathbb{K}$ be two Hilbert spaces. $K$ is a linear operator: $f \in \mathbb{H} \mapsto Kf \in \mathbb{K}$. The standard linear ill-posed inverse problem consists of recovering a good approximation $f_\varepsilon$ of $f$, solution of

$$g = Kf, \tag{1}$$

when only a perturbation $g_\varepsilon$ of $g$ is observed. In this paper we will consider the case where this perturbation is an additive stochastic white noise. Namely, we observe $Y_\varepsilon$ defined by the following equation:

$$Y_\varepsilon = Kf + \varepsilon \dot{W}, \ \mathbb{H}, \ \mathbb{K}, \tag{2}$$

where $\varepsilon$ is the amplitude of the noise. It is supposed to be a small parameter which will tend to 0. Our error will be measured in terms of this small parameter.

$\dot{W}$ is a $\mathbb{K}$-white noise: i.e. for any $g, h$ in $\mathbb{K}$, $\xi(g) := (\dot{W}, g)_{\mathbb{K}}$, $\xi(h) := (\dot{W}, h)_{\mathbb{K}}$ form a random gaussian vector, centered, with marginal variance $\|g\|^2_{\mathbb{K}}$, $\|h\|^2_{\mathbb{K}}$, and covariance $(g, h)_{\mathbb{K}}$ (with the obvious extension when one considers $k$ functions instead of 2).

Equation (2) means that for any $g$ in $\mathbb{K}$, we observe $Y_\varepsilon(g) := (Y_\varepsilon, g)_{\mathbb{K}} = (Kf, g)_{\mathbb{K}} + \varepsilon\xi(g)$ where $\xi(g) \sim N(0, \|g\|^2)$, and $Y_\varepsilon(g)$, $Y_\varepsilon(h)$ are independent random variables for orthogonal functions $g$ and $h$.

The case where $K$ is the identity is called the 'direct model' and is summarized as a memento in Section 5. The reader who is unfamiliar with nonparametric statistical estimation is invited to consult this section, which will act as a guide for understanding the more general inverse models. In particular it is recalled therein that the model (2) is in fact an approximation of models appearing in real practical situations, for instance the case where (2) is replaced by a discretisation.

### 1.1. Two examples: the problem of deconvolution and Wicksell's problem

**1.1.1. Deconvolution.** The following problem is probably one of the most famous among inverse problems in signal processing. In the deconvolution problem we consider the following operator. In this case let $\mathbb{H} = \mathbb{K}$ be the set of square integrable periodic functions with the standard $\mathbb{L}_2([0, 1])$ norm and consider

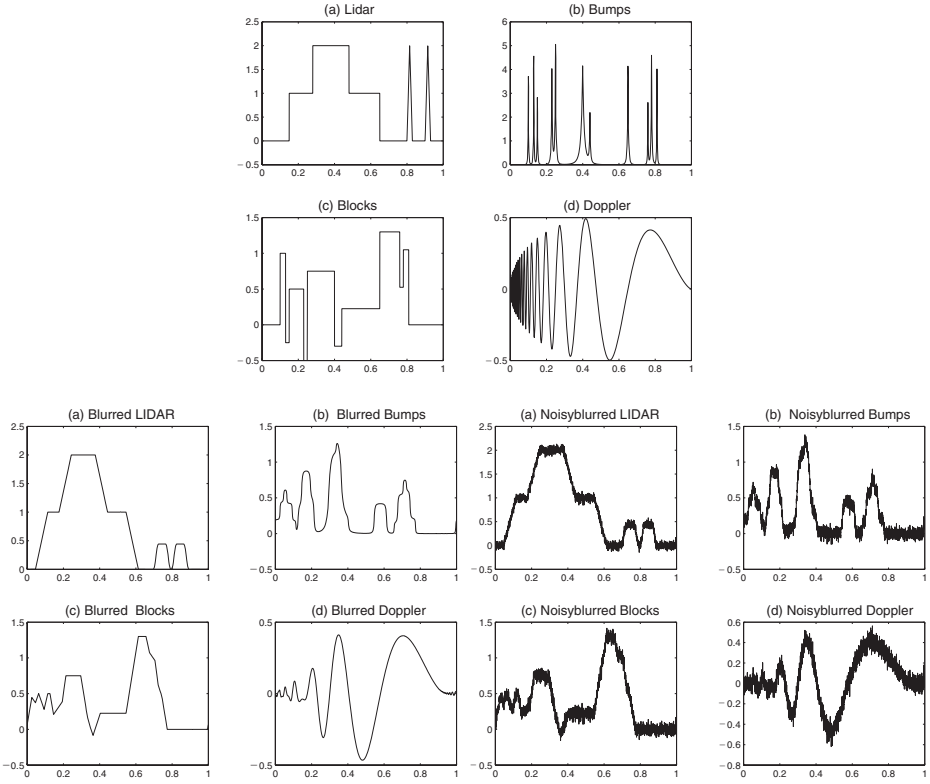
$$f \in \mathbb{H} \mapsto Kf = \int_0^1 \gamma(u - t) f(t)\, dt \in \mathbb{H}, \tag{3}$$

where $\gamma$ is a known function of $\mathbb{H}$, which is generally assumed to be a regular function (often in the sense that its Fourier coefficients $\hat{\gamma}_k$ behave like $k^{-\nu}$). A very common example is also the box-car function: $\gamma(t) = \frac{1}{2a}\mathbb{I}\{[-a, a]\}(k)$.

The following figures show first four original signals to recover, which are well-known test-signals of the statistical literature. They provide typical features which are difficult to restore: bumps, blocks and Doppler effects. The second and third series of

pictures show their deformation after blurring (i.e. convolution with a regular function) and addition of a noise. These figures show how the convolution regularizes the signal, making it very difficult to recover, especially the high frequency features. A statistical investigation of these signals can be found in [22].

A variant of this problem consists in observing $Y_1, \ldots, Y_n$, $n$ independent and identically distributed random variables where each $Y_i$ may be written as $Y_i = X_i + U_i$, where $X_i$ and $U_i$ again are independent, the distribution of $U_i$ is known and of density $\gamma$ and we want to recover the common density of the $X_i$'s. The direct problem is the case where $U_i = 0$, for all $i$, and is corresponding to a standard density estimation problem (see Section 5.1) . Hence the variables $U_i$ are acting as perturbations of the $X_i$'s, whose density is to be recovered.



**1.1.2. Wicksell's problem.** Another typical example is the following classical Wicksell problem [42]. Suppose a population of spheres is embedded in a medium. The spheres have radii that may be assumed to be drawn independently from a density $f$. A random plane slice is taken through the medium and those spheres that are intersected by the plane furnish circles the radii of which are the points of observation $Y_1, \ldots, Y_n$. The unfolding problem is then to infer the density of the sphere radii from the observed circle radii. This unfolding problem also arises in medicine, where

the spheres might be tumors in an animal's liver [36], as well as in numerous other contexts (biological, engineering,…), see for instance [9].

Following [42] and [23], Wicksell's problem corresponds to the following operator:

$$\mathbb{H} = \mathbb{L}_2([0,1], d\mu)\ d\mu(x) = (4x)^{-1}dx,$$
$$\mathbb{K} = \mathbb{L}_2([0,1], d\lambda)\ d\lambda(x) = 4\pi^{-1}(1-y^2)^{1/2}dy$$
$$Kf(y) = \frac{\pi}{4}y(1-y^2)^{-1/2}\int_y^1 (x^2-y^2)^{-1/2}f(x)d\mu.$$

Notice, however, that in this presentation, again in order to avoid additional technicalities, we handle this problem in the white noise framework, which is simpler than the original problem expressed above in density terms.

**1.2. Singular value decomposition and projection methods.** Let us begin with a quick description of well-known methods in inverse problems with random noise.

Under the assumption that $K$ is compact, there exist 2 orthonormal bases (SVD bases) $(e_k)$ of $\mathbb{H}$ and $(g_k)$ of $\mathbb{K}$, respectively, and a sequence $(b_k)$, tending to 0 when $k$ goes to infinity, such that

$$Ke_k = b_k g_k, \quad K^* g_k = b_k e_k$$

if $K^*$ is the adjoint operator.

For the sake of simplicity we suppose in the sequel that $K$ and $K^*$ are into. Otherwise we have to take care of the kernels of these operators. The bases $(e_k)$ and $(g_k)$ are called singular value bases, whereas the $b_k$'s are simply called singular values.

**Deconvolution.** In this standard case simple calculations prove that the SVD bases $(e_k)$ and $(g_k)$ both coincide with the Fourier basis. The singular values are corresponding to the Fourier coefficients of the function $\gamma$:

$$b_k = \hat{\gamma}_k. \tag{4}$$

**Wicksell.** In this case, following [23], we have the following SVD:

$$e_k(x) = 4(k+1)^{1/2}x^2 P_k^{0,1}(2x^2-1),$$
$$g_k(y) = U_{2k+1}(y).$$

$P_k^{0,1}$ is the Jacobi polynomial of type (0, 1) with degree $k$, and $U_k$ is the second type Chebyshev polynomial with degree $k$. The singular values are

$$b_k = \frac{\pi}{16}(1+k)^{-1/2}. \tag{5}$$

**1.2.1. SVD method.** The singular value decomposition (SVD) of $K$,

$$Kf = \sum_k b_k \langle f, e_k \rangle g_k,$$

gives rise to approximations of the type

$$f_\varepsilon = \sum_{k=0}^{N} b_k^{-1} \langle y_\varepsilon, g_k \rangle e_k,$$

where $N = N(\varepsilon)$ has to be chosen properly. This SVD method is very attractive theoretically and can be shown to be asymptotically optimal in many situations (see Mathé and Pereverzev [31], Cavalier and Tsybakov [6], Mair and Ruymgaart [29]). It also has the big advantage of performing a quick and stable inversion of the operator. However, it suffers from different types of limitations. The SVD bases might be difficult to determine as well as to numerically manipulate. Secondly, while these bases are fully adapted to describe the operator $K$, they might not be appropriate for the accurate description of the solution with a small number of parameters.

Also in many practical situations the signal provides inhomogeneous regularity, and its local features are especially interesting to recover. In such cases other bases (in particular localised bases such as wavelet bases) may be much more appropriate to give a good representation of the object at hand.
