**Abstract.** Epitaxy is the growth of a thin film on a substrate in which the crystal properties of the film are inherited from those of the substrate. Because of the wide range of relevant length and time scales, multiscale mathematical models have been developed to describe epitaxial growth. This presentation describes atomistic, island dynamics and continuum models. Island dynamics models are multiscale models that use continuum coarse-graining in the lateral direction, but retain atomistic discreteness in the growth direction. Establishing connections between the various length and time scales in these models is a principal goal of mathematical materials science. Progress towards this goal is described here, including the derivation of surface diffusion, line tension and continuum equations from atomistic, kinetic models.

## 1. Introduction

Epitaxy is the growth of a thin film on a substrate in which the crystal properties of the film are inherited from those of the substrate. Since an epitaxial film can (at least in principle) grow as a single crystal without grain boundaries or other defects, this method produces crystals of the highest quality. In spite of its ideal properties, epitaxial growth is still challenging to mathematically model and numerically simulate because of the wide range of length and time scales that it encompasses, from the atomistic scale of Ångstroms and picoseconds to the continuum scale of microns and seconds.

The geometry of an epitaxial surface consists of step edges and island boundaries, across which the height of the surface increases by one crystal layer, and adatoms which are weakly bound to the surface. Epitaxial growth involves deposition, diffusion and attachment of adatoms on the surface. Deposition is from an external source, such as a molecular beam. Figure 1 provides a schematic illustration of the processes involved in epitaxial growth.

The models that are most often used to describe epitaxial growth include the following: A typical *Kinetic Monte Carlo* (KMC) method simulates the dynamics of

of Mathematicians, Madrid, Spain, 2006

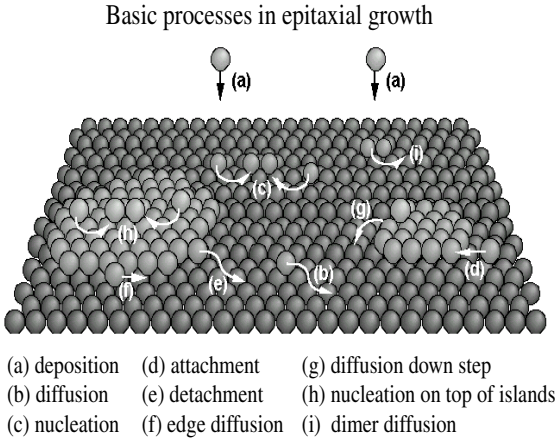

Figure 1. Schematic view of the processes involved in epitaxial growth.

the epitaxial surface through the hopping of adatoms along the surface. The hopping rate has the Arrhenius form $e^{-E/kT}$ in which $E$ is the energy barrier for going from the initial to the final position of the hopping atom. *Island dynamics* describe the surface through continuum scaling in the lateral directions but atomistic discreteness in the growth direction. *Continuum equations* approximate the surface using a smooth height function $z = h(x, y, t)$, obtained by coarse graining in all directions. Two other models are used to describe epitaxial growth on a limited time range. *Molecular dynamics* (MD) consists of Newton's equations for the motion of atoms on an energy landscape. Because the time scale for MD is femtoseconds ($10^{-15}$ seconds), this can only be applied to very short time periods. *Rate equations* describe the surface through a set of bulk variables without spatial dependence. With some exceptions [5], [16], these have been used only for submonolayer growth.

The initial theories for epitaxial growth, such as [3], relied on an assumption that the system is close to equilibrium. In many epitaxial systems, however, the system is far from equilibrium so that a kinetic description is required. The emphasis in this article will be on KMC, island dynamics and continuum models for epitaxial systems that are far from equilibrium. A principal goal of mathematical materials science is to analyze the connections between these models. The results presented below, from the work of Margetis [18], Caflisch & Li [7], Margetis & Caflisch [19], Chua et al. [10], and Haselwandter & Vvedensky [14], [15] are for surface diffusion and step stiffness derived from atomistic kinetic models of epitaxy, and general continuum equations from a simplified model. These results are among the first of their kind; e.g., the formula for step stiffness comes from the first derivation of the Gibbs–Thomson formula from an atomistic, kinetic model rather than from a thermodynamic driving force. The results are far from complete. Other effects, such as the nonlinear terms in the continuum equations, have not been derived for a full model of epitaxy. In

addition, the derivations presented here are based on formal asymptotics, rather than rigorous mathematical analysis. Nevertheless, these results are a significant step toward a more complete theory and can serve as a starting point for more rigorous analysis.

For simplicity in the presentation, the lattice constant $a$ will be taken to be $a = 1$, except in a few places where it is useful as a placeholder. Also, all transition rates (with units 1/time) are expressed in terms of equivalent diffusion constants (with units length$^2$/time); i.e., a rate $r$ is replaced by a diffusion coefficient $D = a^2 r$.

## 2. Mathematical models for epitaxial growth

In this section, various models for epitaxial growth are described, including atomistic KMC, island dynamics and continuum models, as well as a kinetic model for the structure of a step edge (or island boundary) that is used with island dynamics.

**2.1. Atomistic Models.** The simplest KMC model is a simple cubic pair-bond solid-on-solid (SOS) model [28], [29]. In this model, there is a stack of atoms, without vacancies, above each site on a two-dimensional lattice. New atoms are randomly deposited at a deposition rate $F$. Any surface atom (i.e., the top atom in the stack of atoms at a lattice point) is allowed to move to its nearest neighbor site at a rate $r = D/a^2$ in which $a$ is the lattice constant and $D$ is a diffusion coefficient. In the simplest case, $D$ is determined by

$$D = D_0 \exp\{-(E_S + nE_N)/k_B T\}. \tag{1}$$

In this equation, $D_0$ is a constant prefactor of size $10^{13} a^2 s^{-1}$, $k_B$ is the Boltzmann constant, $T$ is the surface temperature, $E_S$ and $E_N$ represent the surface and nearest neighbor bond energies, and $n$ is the number of in-plane nearest neighbors. The terrace diffusion coefficient $D_T$ for adatoms on a flat terrace and the edge diffusion coefficient $D_E$ for adatoms along a step edge (with a single in-plane neighbor) are

$$D_T = D_0 \exp\{-E_S/k_B T\}, \tag{2}$$

$$D_E = D_0 \exp\{-(E_S + E_N)/k_B T\}. \tag{3}$$

Validity of this KMC model for epitaxial growth has been demonstrated by comparison to RHEED measurements from molecular beam epitaxy (MBE) experiments [11]. More complicated models for the diffusion coefficient, subject to the condition of detailed balance, are also used.

**2.2. Island dynamics models.** Burton, Cabrera and Frank [3] developed the first detailed theoretical description for epitaxial growth. This BCF model is an "island dynamics" model, since it describes an epitaxial surface by the location and evolution of the island boundaries and step edges. It employs a mixture of coarse graining and

atomistic discreteness, since island boundaries are represented as smooth curves that signify an atomistic change in crystal height.

Adatom diffusion on the epitaxial surface is described by a diffusion equation of the form

$$\partial_t \rho - D_T \nabla^2 \rho = F - 2(dN_{\text{nuc}}/dt) \tag{4}$$

in which $F$ is the deposition flux rate and the last term represents loss of adatoms due to nucleation. Desorption from the epitaxial surface has been neglected.

The net flux to the step edge from upper and lower terraces is denoted as $f_+ = f_+(y,t)$ and $f_- = f_-(y,t)$, respectively, in which

$$v\rho_+ + D_T \boldsymbol{n} \cdot \nabla \rho_+ = -f_+, \tag{5}$$

$$v\rho_- + D_T \boldsymbol{n} \cdot \nabla \rho_- = f_-. \tag{6}$$

The total flux is

$$f = f_+ + f_-. \tag{7}$$

Different island dynamics models are distinguished by having different formulas for the diffusive boundary conditions and normal velocity.

1. *The island dynamics model with irreversible aggregation:*

$$\begin{aligned} \rho &= 0, \\ v &= f. \end{aligned} \tag{8}$$

2. *The BCF boundary conditions:*

$$\begin{aligned} \rho &= \rho_*, \\ v &= f, \end{aligned} \tag{9}$$

   in which $\rho_*$ is the equilibrium adatom density at a step.

3. *The island dynamics model with step-edge kinetics:*

$$\begin{aligned} f_+ &= (D_T \rho_+ - D_E \phi)\cos\theta, \\ f_- &= (D_T \rho_- - D_E \phi)\cos\theta, \\ v &= k\, w \cos\theta, \end{aligned} \tag{10}$$

   in which $\phi$ and $k$ are the densities of edge-atoms and kinks, and $w$ is the kink velocity, defined in Section 2.3.

4. *The island dynamics model with line tension and surface diffusion:*

$$\begin{aligned} f_+ &= D_{d+}(\rho_+ - \rho_*) - \mu_+ \kappa, \\ f_- &= D_{d-}(\rho_- - \rho_*) - \mu_- \kappa, \\ v &= D_T \boldsymbol{n} \cdot [\nabla \rho] + \beta \rho_{*yy} + (\mu/D_E)\kappa_{ss}, \end{aligned} \tag{11}$$

in which $\kappa$ is curvature and $\kappa_{ss}$ is its second derivative along the length of a step edge, $\rho_*$ is a reference adatom density, $D_{d\pm}$ are the attachment/detachment rates, and $\mu_\pm = (D_{d\pm}\rho_*/k_BT)\tilde{\gamma}$ in which $\tilde{\gamma}$ is the step stiffness. This is further discussed in Section 4.

For the case of irreversible aggregation, a dimer (consisting of two atoms) is the smallest stable island, and the nucleation rate is

$$\frac{dN_{\text{nuc}}}{dt} = D\sigma_1\langle\rho^2\rangle, \tag{12}$$

where $\langle\cdot\rangle$ denotes the spatial average of $\rho(\boldsymbol{x}, t)^2$ and

$$\sigma_1 = \frac{4\pi}{\ln[(1/\alpha)\langle\rho\rangle D/F]} \tag{13}$$

is the adatom capture number. The parameter $\alpha$ reflects the island shape, and $\alpha \simeq 1$ for compact islands. Expression (12) for the nucleation rate implies that the time of a nucleation event is chosen deterministically. The choice of the location of the new island is determined by probabilistic choice with spatial density proportional to the nucleation rate $\rho^2$. This probabilistic choice constitutes an atomistic fluctuation that is retained in the island dynamics model [24].

Snapshots of the results from a typical island dynamics simulation are shown in Figure 2. Shown is the island geometry after coverage of 0.25 layers (left) and

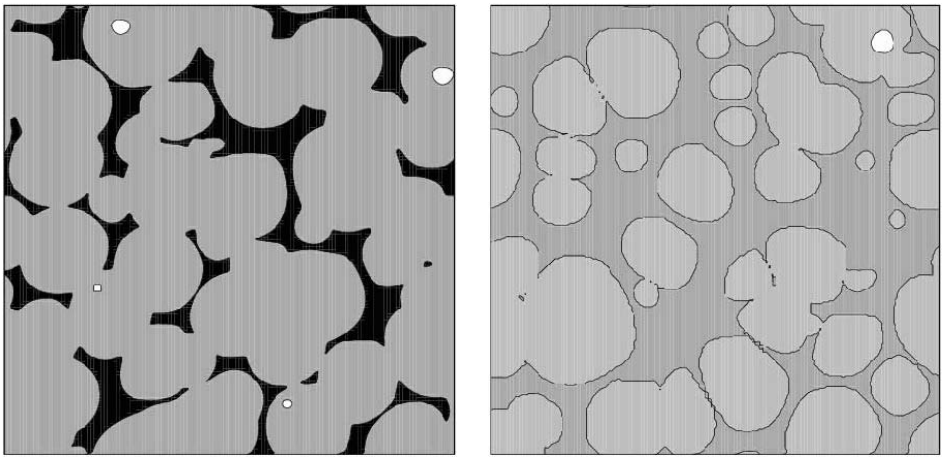

Figure 2. Island geometry for island dynamics with irreversible aggregation after deposition of 0.25 layers (left) and 10.25 layers (right).

coverage of 10.25 layers (right). These simulations are for irreversible aggregation with boundary conditions from Eq. (8). Numerical simulation of the island dynamics is performed using a level set method for thin film growth, as described in [4], [8].

Validation of the island dynamics/level set method has been performed by careful comparison to the results of the atomistic KMC models. Various generalizations and additional physics results are described in [22], [23]. Related work on level set methods for epitaxial growth are found in [9], [25], [26].

The principal dimensionless parameters for epitaxial growth are the ratios of flux and diffusive coefficients, which we refer to as "Péclet numbers" by analogy with fluid mechanics. Let $\bar{f}$ be a characteristic size for the flux to an edge. Let $P_T$ be the terrace Péclet number and $P_E$ be the edge Péclet number, defined as

$$P_T = F/D_T, \tag{14}$$

$$P_E = f/D_E, \tag{15}$$

in which $D_E$ is the edge diffusion constant. Typical values for $P_T^{-1} = D_T/F$ are in the range of $10^4$ to $10^8$.

**2.3. The kinetic edge model.** The kinetic edge model of island dynamics was developed in [6]. It involves a statistical description of the crystalline structure of a step edge, including the edge-atom density $\phi$ and the kink density $k$. Edge-atoms are atoms with a single in-plane neighbor along the step; kinks are atoms with two in-plane neighbors. Kinks are of two types – right-facing kinks and left-facing kinks – the densities of which are denoted by $k_r$ and $k_\ell$. Figure 3 provides a schematic picture

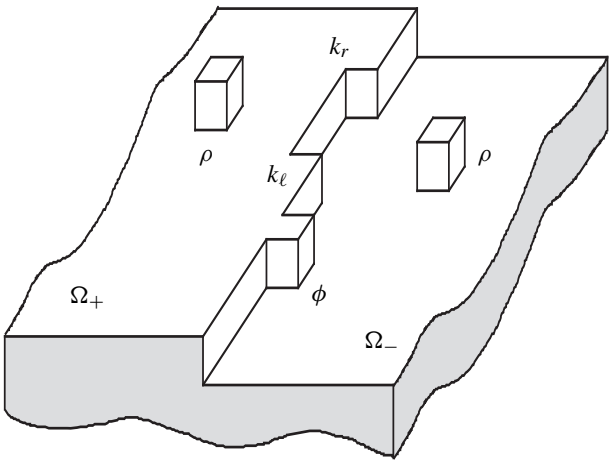

Figure 3. The geometry of step edge, showing adatoms with density $\rho$ on the upper and lower terraces $\Omega_+$ and $\Omega_-$, edge-atoms with density $\phi$, and right and left facing kinks with density $k_r$ and $k_\ell$.

of the kink density model for a step edge. Related models have been derived by Balykov et al. [1], Balykov & Voigt [2] and Filimonov & Hervieu [13].

The kinetic edge model consists of a diffusion equation for the edge-atom density $\phi$ and a convection equation for the kink density $k$

$$\partial_t \phi - D_E \partial_s^2 \phi = f_+ + f_- - f_0, \tag{16}$$

$$\partial_t k + \partial_s (w(k_r - k_\ell)) = 2(g - h). \tag{17}$$

In Eq. (16), $f_\pm$ are the net fluxes to the edge from terraces as defined in Eq. (5) and Eq. (6), and $f_0$ is the net loss term due to the attachment of edge-atoms to kinks. In Eq. (17), $w$ is the kink velocity, and $g$ and $h$ represent, respectively, the creation and annihilation of left-right kink pairs. Note that left-facing kinks and right-facing kinks move in opposite directions with velocity $w$ and $-w$, respectively. The total kink density and the relation between the kink density and the normal angle [3] are

$$k_r + k_\ell = k, \tag{18}$$

$$k_r - k_\ell = \tan\theta. \tag{19}$$

The quantities $f_+$, $f_-$, $f_0$, $w$, $g$, $h$, and $v$ are determined by the following constitutive relations (in simplified form):

$$f_+ = (D_T \rho_+ - D_E \phi)\cos\theta, \tag{20}$$

$$f_- = (D_T \rho_- - D_E \phi)\cos\theta, \tag{21}$$

$$f_0 = v\,(\phi\kappa + 1)\,, \tag{22}$$

$$w = l_1 D_E \phi + D_T(l_2\rho_+ + l_3\rho_-) = l_{123} D_E \phi + (l_2 f_+ + l_3 f_-)/\cos\theta, \tag{23}$$

$$\begin{aligned} g &= \phi\,(m_1 D_E \phi + D_T(m_2\rho_+ + m_3\rho_-)) \\ &= \phi(m_{123} D_E \phi + (m_2 f_+ + m_3 f_-)/\cos\theta), \end{aligned} \tag{24}$$

$$\begin{aligned} h &= k_r k_\ell\,(n_1 D_E \phi + D_T(n_2\rho_+ + n_3\rho_-)) \\ &= k_r k_\ell (n_{123} D_E \phi + (n_2 f_+ + n_3 f_-)/\cos\theta), \end{aligned} \tag{25}$$

$$X_t = v = wk\cos\theta, \tag{26}$$

where $D_T$ is the (diffusion) hopping rate of an adatom on a terrace, $D_E$ is the (diffusion) hopping rate of an edge-atom along or off an edge, and all $l_i, m_i, n_i$ $(i = 1, 2, 3)$ are nonnegative numbers. The geometric parameters $l_i, m_i, n_i$ count the number of paths from one state to another, cf. [6] for details. Here, these parameters are generalized to allow a factor relating the macroscopic density $\rho$ or $\phi$ to the local density of adatoms or edge atoms at a specific site. For convenience, we have used the notation

$$q_{ij} = q_i + q_j \quad \text{and} \quad q_{ijk} = q_i + q_j + q_k$$

for $q = l, m$, or $n$. For simplicity in this presentation, the constitutive laws (20)–(25) have been simplified by omission of terms that are insignificant for the kinetic steady state solutions of relevance to step-flow growth and by specialization to the case of $\theta$ near 0. The terms omitted from (20)–(25) include terms that are important for detailed

balance, so that they are required for determination of the equilibrium solution for this model. In the more complete analysis of [6], [7], [19], all of the neglected terms are included.

There are several significant solutions for the kinetic step edge model Eq. (16)–Eq. (26). First, there is an equilibrium solution that was originally determined in [3] (note that some terms that have been omitted from the presentation here are significant for the equilibrium). Second there is a kinetic (i.e., nonequilibrium) steady state solution, for which the presentation includes all of the significant terms. Suppose that the kink density and edge Peclet number are small (i.e., $ak \ll 1$ and $P_E \ll 1$) and that the step is symmetric (i.e., $\rho_+ = \rho_-$), then the adatom, edge-adatom and kink densities of the kinetic steady state are approximately

$$\rho = (D_E/D_T)a^{-1}\varphi, \tag{27}$$

$$\varphi = (16a/3)k^2, \tag{28}$$

$$k = \left(\frac{16}{15}P_E\right)^{\frac{1}{3}} a^{-1}. \tag{29}$$

The exponent $1/3$ in (29) is related to the critical size for formation of a left-right kink pair. If the critical size were $j$ (i.e., if $j+1$ edge-adatoms were required to form a stable kink pair) then the exponent would be $j/(j+2)$.

Figure 4 shows a comparison of this steady state solution (solid line) and computational results from KMC (squares, circles and triangles) for kink density $k$. The

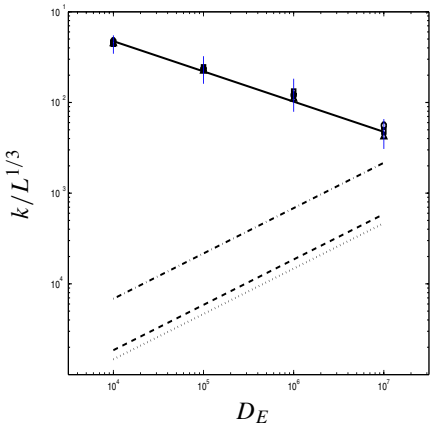

Figure 4. Kink density $k$, normalized by $L^{1/3}$, vs. edge diffusion coefficient $D_E$ for kinetic steady state, for various values of terrace width $L$. Parameter values are flux $F = 1$ and adatom diffusion $D_T = 10^{12}$. Results are shown from the kinetic theory (solid line) and KMC computations with $L = 25$ (squares), $L = 50$ ($\circ$), and $L = 100$ ($\triangle$). These are compared to the corresponding equilibrium values for $L = 25$ (dash-dotted line), $L = 50$ (dashed line), and $L = 100$ (dotted line), showing that the steady state and equilibrium differ both qualitatively and quantitatively.

BCF equilibrium values for $k$ are also plotted (lower three lines) for comparison. In this figure, $F = 1$ and $D_T = 10^{12}$, while $D_E$ varies between $10^4$ and $10^7$. The computations are for a periodic step train with straight steps at angle $\theta = 0$ and with distance $L = 25$, 50, and 100 between the steps. The figure shows excellent agreement between the predictions of the present theory and the results of the KMC simulation, with differences that are less than one standard deviation of the KMC results. The results are significantly different from equilibrium both in size and in dependence on $D_E$.

**2.4. Continuum models.** Continuum models of epitaxial growth employ coarse graining in all directions. In most cases, they describe the epitaxial surface through a smooth height function $z = h(x, y, t)$. The general equation of this type, as discussed by Haselwandter and Vvedensky [14], [15], is

$$h_t = \nu_2 \nabla^2 h - \nu_4 \nabla^4 h + \lambda_{13} \nabla (\nabla h)^3 + \lambda_{22} \nabla^2 (\nabla h)^2 + \xi \tag{30}$$

in which the $\nu_2$ term comes from a height-dependence in the energy, the $\nu_4$ term is surface diffusion, the $\lambda$ terms are nonlinearities, and $\xi$ is a stochastic noise term. This equation generalizes previous models, including the Edwards–Wilkinson (EW) equation with $\nu_4 = \lambda_{13} = \lambda_{22} = 0$, the Mullins–Herring (MH) equation with $\nu_2 = \lambda_{13} = \lambda_{22} = 0$, and the Villain–Lai–Das Sarma (VLDS) equation with $\nu_2 = \lambda_{13} = 0$. The relations between these models are further discussed in Section 5, through a renormalization group analysis applied to the Edwards–Wilkinson and Wolf–Villain models for epitaxial growth.

Derivation of these continuum equations has been mostly through symmetry arguments, thermodynamic driving force or by heuristics. The results reported in Sections 3 and 5 are among the first derivation of these equations from kinetic, atomistic models. Alternative modeling approaches have included additional dependent variables, not just the interface height. For example, Lo & Kohn [17] included adatom density in addition to height. Margetis et al. [20] derive similar results starting from an island dynamics model with a kinetic step edge description, as in Section 2.2 and 2.3.

## 3. Surface diffusion

As first derived by Mullins [21], the surface diffusion equation

$$h_t = -\nu_4 \nabla^4 h \tag{31}$$

describes the evolution of a surface through diffusion of the material that comprises the surface. Margetis [18] has given an atomistic, kinetic derivation of surface diffusion for epitaxial growth, and he found the surprising result that surface diffusion is not isotropic. While his derivation is based on detailed asymptotics starting from an island

dynamics model, the presentation here will be phenomenological but faithful to the spirit of Margetis's derivation.

Consider an epitaxial surface that consists of a series of steps that are nearly parallel. The terrace width $\ell$ between steps is approximately $\ell = a/|\nabla h|$ in which $a$ is the lattice constant. Assume that the steps are slowly varying but widely spaced, so that $a \ll \ell \ll \lambda$ in which $\lambda$ is the length scale for the variation in the steps away from straight. Also, assume that edge diffusion coefficient $D_E$ and the edge attachment/detachment rate $D_d$ are much smaller than the terrace diffusion coefficient $D_T$.

The analysis is based on the following fundamental property of diffusion: Consider a composite consisting of strips of two material with diffusion coefficients $D_1$ and $D_2$ and with strip widths $a_1$ and $a_2$. The effective diffusion coefficient $D_*$ for the composite is the arithmetic average if the diffusion is in the direction along the strips (i.e., a parallel configuration) and it is the harmonic average if the diffusion is in the direction perpendicular to the strips (i.e., a series configuration); i.e.,

$$D_* = \begin{cases} (a_1 D_1 + a_2 D_2)/(a_1 + a_2) & \text{parallel configuration,} \\ ((a_1 D_1^{-1} + a_2 D_2^{-1})/(a_1 + a_2))^{-1} & \text{series configuration.} \end{cases} \tag{32}$$

Define a tangential variable $s$ along the steps and a normal variable $n$ perpendicular to the steps. In the tangential direction, adatoms diffuse at the terrace diffusion rate of $D_T$ on the terraces between steps and at the edge diffusion rate $D_E$ along the steps. Since the terraces and steps are in parallel in the tangential direction, the corresponding diffusion coefficient

$$D_{ss} = (aD_E + \ell D_T)/(a + \ell) \approx D_T. \tag{33}$$

Diffusion of adatoms normal the steps is also at rate $D_T$, but it is interrupted by attachment and detachment from the steps at rate $D_d$. Since the terraces and steps are in a series configuration in the normal direction $n$, the diffusion coefficient in this direction is

$$D_{nn} = ((2aD_d^{-1} + \ell D_T^{-1})/(a + \ell))^{-}1 \approx D_T(1 + m|\nabla h|)^{-1} \tag{34}$$

in which

$$m = 2D_T/D_d. \tag{35}$$

The factor of 2 in the last two formulas is due to the details of the attachment/detachment model used in [18].

Now follow the derivation of diffusion from the thermodynamic driving force (but note that Margetis used a perturbation expansion based on the kinetic equations rather than this near-equilibrium argument). The evolution of the height $h$ is given in terms of the mobility tensor $M$, current $j$ and chemical potential $\mu$ as

$$\begin{aligned} h_t &= -\nabla \cdot j \\ &= \nabla \cdot (M \nabla \mu) \end{aligned} \tag{36}$$

since $j = -M\nabla\mu$ and $\mu = \delta E/\delta h = -g_1\nabla\cdot(\nabla h/|\nabla h|) - g_3\nabla h\cdot(|\nabla h|\nabla h)$. By the argument above, $M$ is the matrix

$$M = \frac{D_T\rho_*}{K_BT}\begin{pmatrix}1 & 0\\ 0 & (1+m|\nabla h|)^{-1}\end{pmatrix} \tag{37}$$

in the $n$, $s$ coordinates.

## 4. Step stiffness

In [7], Caflisch and Li considered the zero limit of the edge Peclet $P_E$ number for the kinetic edge model from Section 2.3 for a step that is a slight perturbation of a straight step with $\theta = 0$, i.e., parallel to a crystallographic direction. They used a very specific form for the wavelength and amplitude of the perturbation and their scaling with $P_E$, and they assumed that the solution was close to the kinetic steady state Eq. (29) for $\theta = 0$. They derived the boundary conditions Eq. (11) for the evolution of a step, including the Gibbs–Thomson form of the step stiffness and a term due to edge diffusion of the adatoms that attach to the step.

More recently, Margetis and Caflisch [19] performed a more general analysis for a step with variable $\theta$. Under the assumption that $P_E \ll 1$ and that the solution is close to the kinetic steady state, they identified several regimes for the behavior of the solution and the step stiffness coefficient. Since the complete results are complicated, we present the results in an abbreviated form and refer to [19] for a detailed expression.

First, suppose that the curvature $\kappa$ of the step satisfies

$$|\kappa| < O(P_E) \ll 1. \tag{38}$$

Then the step edge kinetics allow for two regimes for the step stiffness $\tilde\gamma$:

$$\tilde\gamma = \begin{cases}(k_BT/D_T\rho_*)\theta^{-1} & \text{for } P_E^{1/3} \ll \theta \ll 1,\\ (k_BT/D_T\rho_*)\tilde\gamma_0 & \text{for } 0 < \theta \ll P_E^{1/3}.\end{cases} \tag{39}$$

The results for step stiffness imply results for the line tension $\gamma$, since $\tilde\gamma = \gamma + \gamma_{\theta\theta}$ then to leading order

$$\gamma \approx \begin{cases}(kT_B/D_T\rho_*)\theta\log\theta & \text{for } P_E^{1/3} \ll \theta \ll 1,\\ c_0 & \text{for } 0 < \theta \ll P_E^{1/3}.\end{cases} \tag{40}$$

in which $c_0$ is an undetermined constant. In the outer solution, $\gamma_\theta$ is nearly infinite for $\theta$ small, which predicts a flat facet corresponding to $\theta = 0$. The inner solution provides some curvature to this facet, however. These results are consistent with the recent results of Stasevich et al. [27] for the step stiffness in an Ising model.

## 5. Coarse graining

In a remarkable series of papers [10], [14], [15], Chua et al. and Haselwandter & Vvedensky performed coarse-graining, followed by a renormalization group analysis, for the Edwards–Wilkinson [12] and Wolf–Villain [30] models of epitaxial growth. In the Wolf–Villain model, particles are randomly deposited on the surface at rate $F$. Instead of diffusing along the surface, however, each deposited particle makes a single hop to the nearest neighbor site that has the largest number of neighbors (i.e., the highest coordination), or stays where it landed if that hop does not increase the number of neighbors. In two-dimensions (i.e., a one dimensional surface), a particle hops to a position that is no higher than its original position, while in three-dimensions, some particles may increase their coordination by hopping to a higher position.

For a general lattice model, Haselwandter and Vvedensky first write the stochastic evolution in terms of a Chapman–Kolmogorov transition probability $T_t(H_2|H_1)$ for transition between height configuration $H_1$ to $H_2$ in time $t$

$$T_{t+t'}(H_3|H_1) = \sum_{H_2} T_{t'}(H_3|H_2)T_t(H_2|H_1). \tag{41}$$

This can be converted to a Master equation

$$P(H,t) = \sum_r [W((H-r;r)P(H-r,t) - W(H;r)P(H,t)] \tag{42}$$

in which $P(H,t)$ is the probability for height configuration $H$ at time $t$, $W(H;r)$ is the transition rate between $H$ and $H+r$, and $r$ is the array of jump lengths between configurations. They then apply a Kramers–Moyal–van Kampen expansion with "largeness" parameter $\Omega$, with the lattice size and time between depositions being proportional to $\Omega^{-1}$. In the limit $\Omega \to \infty$, this expansion yields a lattice Langevin equation

$$\partial h_{ij}/\partial t = K_{ij}^{(1)} + \eta_{ij} \tag{43}$$

in which $K_{ij}^{(1)}$ are the first moment of the transition rates and $\eta_{ij}$ are Gaussian noises with mean zero and covariances given by the second moment of the transition rates. After performing a smoothing and a cutoff Taylor expansion and specializing to the Wolf–Villain (or Edwards–Wilkinson) model, the Langevin equation becomes Eq. (30).

Finally they perform a renormalization group (RG) analysis of equation Eq. (30). In the RG "flow", length and time are scaled at an exponential rate in the flow variable $\ell$. This analysis shows that the RG fixed points consist of the EW, MH and VLDS equations, as well as three previously unrecognized fixed points. The significance of this result is that as the solution of Eq. (30) evolves, it will linger near the fixed points, so that the solution will approximate a solution of each of these equations. The most important of the equations corresponding to these new fixed points, is their "FP1".

Although it is complicated in general, in the two dimensional case it has the form

$$h_t = -|\nu_2|\nabla^2 h - |\nu_4|\nabla^4 h - |\lambda_{13}|\nabla(\nabla h)^3 + \lambda_{22}\nabla^2(\nabla h)^2 + \xi \qquad (44)$$

which should be compared to Eq. (30). In two-dimensions this equation corresponds to a stable fixed point, but the corresponding equation in three dimensions corresponds to an unstable fixed point for the RG flow. This coarse graining and RG analysis provides both a derivation of these equations, starting from the EW or WV model, as well as an indication of the regimes of their validity.

**Acknowledgments.** The presentation here benefitted from discussions with Ted Einstein, Christoph Haselwandter, Dionisios Margetis, Tim Stasevich, Axel Voigt, and Dimitri Vvedensky. In particular, Margetis, Haselwandter and Vvedensky provided the author with advance copies of their unpublished work.

# Compressive sampling

Emmanuel J. Candès*

**Abstract.** Conventional wisdom and common practice in acquisition and reconstruction of images from frequency data follow the basic principle of the Nyquist density sampling theory. This principle states that to reconstruct an image, the number of Fourier samples we need to acquire must match the desired resolution of the image, i.e. the number of pixels in the image. This paper surveys an emerging theory which goes by the name of "compressive sampling" or "compressed sensing," and which says that this conventional wisdom is inaccurate. Perhaps surprisingly, it is possible to reconstruct images or signals of scientific interest accurately and sometimes even exactly from a number of samples which is far smaller than the desired resolution of the image/signal, e.g. the number of pixels in the image.

It is believed that compressive sampling has far reaching implications. For example, it suggests the possibility of new data acquisition protocols that translate analog information into digital form with fewer sensors than what was considered necessary. This new sampling theory may come to underlie procedures for sampling and compressing data simultaneously.

In this short survey, we provide some of the key mathematical insights underlying this new theory, and explain some of the interactions between compressive sampling and other fields such as statistics, information theory, coding theory, and theoretical computer science.

## 1. Introduction

One of the central tenets of signal processing is the Nyquist/Shannon sampling theory: the number of samples needed to reconstruct a signal without error is dictated by its bandwidth – the length of the shortest interval which contains the support of the spectrum of the signal under study. In the last two years or so, an alternative theory of "compressive sampling" has emerged which shows that super-resolved signals and images can be reconstructed from far fewer data/measurements than what is usually considered necessary. The purpose of this paper is to survey and provide some of the key mathematical insights underlying this new theory. An enchanting aspect of compressive sampling it that it has significant interactions and bearings on some fields in the applied sciences and engineering such as statistics, information theory, coding

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

theory, theoretical computer science, and others as well. We will try to explain these connections via a few selected examples.

From a general viewpoint, sparsity and, more generally, compressibility has played and continues to play a fundamental role in many fields of science. Sparsity leads to efficient estimations; for example, the quality of estimation by thresholding or shrinkage algorithms depends on the sparsity of the signal we wish to estimate. Sparsity leads to efficient compression; for example, the precision of a transform coder depends on the sparsity of the signal we wish to encode [24]. Sparsity leads to dimensionality reduction and efficient modeling. The novelty here is that *sparsity has bearings on the data acquisition process itself, and leads to efficient data acquisition protocols.*

In fact, compressive sampling suggests ways to economically translate analog data into already compressed digital form [20], [7]. The key word here is "economically." Everybody knows that because typical signals have some structure, they can be compressed efficiently without much perceptual loss. For instance, modern transform coders such as JPEG2000 exploit the fact that many signals have a sparse representation in a fixed basis, meaning that one can store or transmit only a small number of adaptively chosen transform coefficients rather than all the signal samples. The way this typically works is that one acquires the full signal, computes the complete set of transform coefficients, encode the largest coefficients and discard *all* the others. This process of massive data acquisition followed by compression is extremely wasteful (one can think about a digital camera which has millions of imaging sensors, the pixels, but eventually encodes the picture on a few hundred kilobytes). This raises a fundamental question: because most signals are compressible, why spend so much effort acquiring all the data when we know that most of it will be discarded? Wouldn't it be possible to acquire the data in already compressed form so that one does not need to throw away anything? "Compressive sampling" also known as "compressed sensing" [20] shows that this is indeed possible.

This paper is by no means an exhaustive survey of the literature on compressive sampling. Rather this is merely an account of the author's own work and thinking in this area which also includes a fairly large number of references to other people's work and occasionally discusses connections with these works. We have done our best to organize the ideas into a logical progression starting with the early papers which launched this subject. Before we begin, we would like to invite the interested reader to also check the article [17] by Ronald DeVore – also in these proceedings – for a complementary survey of the field (Section 5).

## 2. Undersampled measurements

Consider the general problem of reconstructing a vector $x \in \mathbb{R}^N$ from linear measurements $y$ about $x$ of the form

$$y_k = \langle x, \varphi_k \rangle, \ k = 1, \dots, K, \quad \text{or} \quad y = \Phi x. \tag{2.1}$$

That is, we acquire information about the unknown signal by sensing $x$ against $K$ vectors $\varphi_k \in \mathbb{R}^N$. We are interested in the "underdetermined" case $K \ll N$, where we have many fewer measurements than unknown signal values. Problems of this type arise in a countless number of applications. In radiology and biomedical imaging for instance, one is typically able to collect far fewer measurements about an image of interest than the number of unknown pixels. In wideband radio frequency signal analysis, one may only be able to acquire a signal at a rate which is far lower than the Nyquist rate because of current limitations in Analog-to-Digital Converter technology. Finally, gene expression studies also provide examples of this kind. Here, one would like to infer the gene expression level of thousands of genes – that is, the dimension $N$ of the vector $x$ is in the thousands – from a low number of observations, typically in the tens.

At first glance, solving the underdertermined system of equations appears hopeless, as it is easy to make up examples for which it clearly cannot be done. But suppose now that the signal $x$ is *compressible*, meaning that it essentially depends on a number of degrees of freedom which is smaller than $N$. For instance, suppose our signal is sparse in the sense that it can be written either exactly or accurately as a superposition of a small number of vectors in some fixed basis. Then this premise radically changes the problem, making the search for solutions feasible. In fact, accurate and sometimes exact recovery is possible by solving a simple convex optimization problem.

**2.1. A nonlinear sampling theorem.** It might be best to consider a concrete example first. Suppose here that one collects an incomplete set of frequency samples of a discrete signal $x$ of length $N$. (To ease the exposition, we consider a model problem in one dimension. The theory extends easily to higher dimensions. For instance, we could be equally interested in the reconstruction of 2- or 3-dimensional objects from undersampled Fourier data.) The goal is to reconstruct the full signal $f$ given only $K$ samples in the Fourier domain

$$y_k = \frac{1}{\sqrt{N}} \sum_{t=0}^{N-1} x_t \, e^{-i2\pi\omega_k t/N}, \tag{2.2}$$

where the 'visible' frequencies $\omega_k$ are a subset $\Omega$ (of size $K$) of the set of all frequencies $\{0, \ldots, N-1\}$. Sensing an object by measuring selected frequency coefficients is the principle underlying Magnetic Resonance Imaging, and is common in many fields of science, including Astrophysics. In the language of the general problem (2.1), the sensing matrix $\Phi$ is obtained by sampling $K$ rows of the $N$ by $N$ discrete Fourier transform matrix.

We will say that a vector $x$ is *S-sparse* if its support $\{i : x_i \neq 0\}$ is of cardinality less or equal to $S$. Then Candès, Romberg and Tao [6] showed that one could almost always recover the signal $x$ exactly by solving the convex program[1] ($\|\tilde{x}\|_{\ell_1} := \sum_{i=1}^N |\tilde{x}_i|$)

$$(\mathrm{P}_1) \qquad \min_{\tilde{x}\in\mathbb{R}^N} \|\tilde{x}\|_{\ell_1} \quad \text{subject to} \quad \Phi\tilde{x} = y. \tag{2.3}$$

[1] ($\mathrm{P}_1$) can even be recast as a linear program [3], [15].

**Theorem 2.1** ([6]). *Assume that $x$ is $S$-sparse and that we are given $K$ Fourier coefficients with frequencies selected uniformly at random. Suppose that the number of observations obeys*

$$K \geq C \cdot S \cdot \log N. \tag{2.4}$$

*Then minimizing $\ell_1$ reconstructs $x$ exactly with overwhelming probability. In details, if the constant $C$ is of the form $22(\delta + 1)$ in* (2.4)*, then the probability of success exceeds $1 - O(N^{-\delta})$.*

The first conclusion is that one suffers no information loss by measuring just about any set of $K$ frequency coefficients. The second is that the signal $x$ can be exactly recovered by minimizing a convex functional which does not assume any knowledge about the number of nonzero coordinates of $x$, their locations, and their amplitudes which we assume are all completely unknown a priori.

While this seems to be a great feat, one could still ask whether this is optimal, or whether one could do with even fewer samples. The answer is that in general, we cannot reconstruct $S$-sparse signals with fewer samples. There are examples for which the minimum number of samples needed for exact reconstruction by any method, no matter how intractable, must be about $S \log N$. Hence, the theorem is tight and $\ell_1$-minimization succeeds nearly as soon as there is any hope to succeed by any algorithm.

The reader is certainly familiar with the Nyquist/Shannon sampling theory and one can reformulate our result to establish simple connections. By reversing the roles of time and frequency in the above example, we can recast Theorem 1 as a new nonlinear sampling theorem. Suppose that a signal $x$ has support $\Omega$ in the frequency domain with $B = |\Omega|$. If $\Omega$ is a connected set, we can think of $B$ as the bandwidth of $x$. If in addition the set $\Omega$ is known, then the classical Nyquist/Shannon sampling theorem states that $x$ can be reconstructed perfectly from $B$ equally spaced samples in the time domain[2]. The reconstruction is simply a linear interpolation with a "sinc" kernel.

Now suppose that the set $\Omega$, still of size $B$, is unknown and not necessarily connected. In this situation, the Nyquist/Shannon theory is unhelpful – we can only assume that the connected frequency support is the entire domain suggesting that *all* $N$ time-domain samples are needed for exact reconstruction. However, Theorem 2.1 asserts that far fewer samples are necessary. Solving $(P_1)$ will recover $x$ perfectly from about $B \log N$ time samples. What is more, these samples do not have to be carefully chosen; almost any sample set of this size will work. Thus we have a nonlinear analog (described as such since the reconstruction procedure $(P_1)$ is nonlinear) to Nyquist/Shannon: we can reconstruct a signal with *arbitrary and unknown* frequency support of size $B$ from about $B \log N$ *arbitrarily chosen* samples in the time domain.

Finally, we would like to emphasize that our Fourier sampling theorem is only a special instance of much more general statements. As a matter of fact, the results

[2]For the sake of convenience, we make the assumption that the bandwidth $B$ divides the signal length $N$ evenly.

extend to a variety of other setups and higher dimensions. For instance, [6] shows how one can reconstruct a piecewise constant (one or two-dimensional) object from incomplete frequency samples provided that the number of jumps (discontinuities) obeys the condition above by minimizing other convex functionals such as the total variation.

**2.2. Background.** Now for some background. In the mid-eighties, Santosa and Symes [44] had suggested the minimization of $\ell_1$-norms to recover sparse spike trains, see also [25], [22] for early results. In the last four years or so, a series of papers [26], [27], [28], [29], [33], [30] explained why $\ell_1$ could recover sparse signals in some special setups. We note though that the results in this body of work are very different than the sampling theorem we just introduced. Finally, we would like to point out important connections with the literature of theoretical computer science. Inspired by [37], Gilbert and her colleagues have shown that one could recover an $S$-sparse signal with probability exceeding $1-\delta$ from $S \cdot \mathrm{poly}(\log N, \log \delta)$ frequency samples placed on special equispaced grids [32]. The algorithms they use are not based on optimization but rather on ideas from the theory of computer science such as isolation, and group testing. Other points of connection include situations in which the set of spikes are spread out in a somewhat even manner in the time domain [22], [51].

**2.3. Undersampling structured signals.** The previous example showed that the structural content of the signal allows a drastic "undersampling" of the Fourier transform while still retaining enough information for exact recovery. In other words, if one wanted to sense a sparse object by taking as few measurements as possible, then one would be well-advised to measure randomly selected frequency coefficients. In truth, this observation triggered a massive literature. To what extent can we recover a compressible signal from just a few measurements. What are good sensing mechanisms? Does all this extend to object that are perhaps not sparse but well-approximated by sparse signals? In the remainder of this paper, we will provide some answers to these fundamental questions.

## 3. The Mathematics of compressive sampling

**3.1. Sparsity and incoherence.** In all what follows, we will adopt an abstract and general point of view when discussing the recovery of a vector $x \in \mathbb{R}^N$. In practical instances, the vector $x$ may be the coefficients of a signal $f \in \mathbb{R}^N$ in an orthonormal basis $\Psi$

$$f(t) = \sum_{i=1}^{N} x_i \psi_i(t), \quad t = 1, \ldots, N. \tag{3.1}$$

For example, we might choose to expand the signal as a superposition of spikes (the canonical basis of $\mathbb{R}^N$), sinusoids, $B$-splines, wavelets [36], and so on. As a side

note, it is not important to restrict attention to orthogonal expansions as the theory and practice of compressive sampling accommodates other types of expansions. For example, $x$ might be the coefficients of a digital image in a tight-frame of curvelets [5]. To keep on using convenient matrix notations, one can write the decomposition (3.1) as $x = \Psi f$ where $\Psi$ is the $N$ by $N$ matrix with the waveforms $\psi_i$ as rows or equivalently, $f = \Psi^* x$.

We will say that a signal $f$ is sparse in the $\Psi$-domain if the coefficient sequence is supported on a small set and compressible if the sequence is concentrated near a small set. Suppose we have available undersampled data about $f$ of the same form as before

$$y = \Phi f.$$

Expressed in a different way, we collect partial information about $x$ via $y = \Phi' x$ where $\Phi' = \Phi\Psi^*$. In this setup, one would recover $f$ by finding – among all coefficient sequences consistent with the data – the decomposition with minimum $\ell_1$-norm

$$\min \|\tilde{x}\|_{\ell_1} \quad \text{such that} \quad \Phi'\tilde{x} = y.$$

Of course, this is the same problem as (2.3), which justifies our abstract and general treatment.

With this in mind, the key concept underlying the theory of compressive sampling is a kind of uncertainty relation, which we explain next.

**3.2. Recovery of sparse signals.** In [7], Candès and Tao introduced the notion of uniform uncertainty principle (UUP) which they refined in [8]. The UUP essentially states that the $K \times N$ sensing matrix $\Phi$ obeys a "restricted isometry hypothesis." Let $\Phi_T,\ T \subset \{1, \ldots, N\}$ be the $K \times |T|$ submatrix obtained by extracting the columns of $\Phi$ corresponding to the indices in $T$; then [8] defines the $S$-restricted isometry constant $\delta_S$ of $\Phi$ which is the smallest quantity such that

$$(1 - \delta_S)\,\|c\|_{\ell_2}^2 \le \|\Phi_T c\|_{\ell_2}^2 \le (1 + \delta_S)\,\|c\|_{\ell_2}^2 \tag{3.2}$$

for all subsets $T$ with $|T| \le S$ and coefficient sequences $(c_j)_{j\in T}$. This property essentially requires that every set of columns with cardinality less than $S$ approximately behaves like an orthonormal system.

An important result is that if the columns of the sensing matrix $\Phi$ are approximately orthogonal, then the exact recovery phenomenon occurs.

**Theorem 3.1** ([8]). *Assume that $x$ is $S$-sparse and suppose that $\delta_{2S} + \delta_{3S} < 1$ or, better, $\delta_{2S} + \theta_{S,2S} < 1$. Then the solution $x^\star$ to* (2.3) *is exact, i.e., $x^\star = x$.*

In short, if the UUP holds at about the level $S$, the minimum $\ell_1$-norm reconstruction is provably exact. The first thing one should notice when comparing this result with the Fourier sampling theorem is that it is deterministic in the sense that it does not involve any probabilities. It is also universal in that *all* sufficiently sparse vectors

are exactly reconstructed from $\Phi x$. In Section 3.4, we shall give concrete examples of sensing matrices obeying the exact reconstruction property for large values of the sparsity level, e.g. for $S = O(K/\log(N/K))$.

Before we do so, however, we would like to comment on the slightly better version $\delta_{2S} + \theta_{S,2S} < 1$, which is established in [10]. The number $\theta_{S,S'}$ for $S + S' \leq N$ is called the $S, S'$-*restricted orthogonality constants* and is the smallest quantity such that

$$|\langle \Phi_T c, \Phi_{T'} c' \rangle| \leq \theta_{S,S'} \cdot \|c\|_{\ell_2} \|c'\|_{\ell_2} \tag{3.3}$$

holds for all *disjoint* sets $T, T' \subseteq \{1, \ldots, N\}$ of cardinality $|T| \leq S$ and $|T'| \leq S'$. Thus $\theta_{S,S'}$ is the cosine of the smallest angle between the two subspaces spanned by the columns in $T$ and $T'$. Small values of restricted orthogonality constants indicate that disjoint subsets of covariates span nearly orthogonal subspaces. The condition $\delta_{2S} + \theta_{S,2S} < 1$ is better than $\delta_{2S} + \delta_{3S} < 1$ since it is not hard to see that $\delta_{S+S'} - \delta_{S'} \leq \theta_{S,S'} \leq \delta_{S+S'}$ for $S' \geq S$ [8, Lemma 1.1].

Finally, now that we have introduced all the quantities needed to state our recovery theorem, we would like to elaborate on the condition $\delta_{2S} + \theta_{S,2S} < 1$. Suppose that $\delta_{2S} = 1$ which may indicate that there is a matrix $\Phi_{T_1 \cup T_2}$ with $2S$ columns ($|T_1| = S, |T_2| = S$) that is rank-deficient. If this is the case, then there is a pair $(x_1, x_2)$ of nonvanishing vectors with $x_1$ supported on $T_1$ and $x_2$ supported on $T_2$ obeying

$$\Phi(x_1 - x_2) = 0 \iff \Phi x_1 = \Phi x_2.$$

In other words, we have two very distinct $S$-sparse vectors which are indistinguishable. This is why any method whatsoever needs $\delta_{2S} < 1$. For, otherwise, the model is not identifiable to use a terminology borrowed from the statistics literature. With this in mind, one can see that the condition $\delta_{2S} + \theta_{S,2S} < 1$ is only slightly stronger than this identifiability condition.

**3.3. Recovery of compressible signals.** In general, signals of practical interest may not be supported in space or in a transform domain on a set of relatively small size. Instead, they may only be concentrated near a sparse set. For example, a commonly discussed model in mathematical image or signal processing assumes that the coefficients of elements taken from a signal class decay rapidly, typically like a power law. Smooth signals, piecewise signals, images with bounded variations or bounded Besov norms are all of this type [24].

A natural question is how well one can recover a signal that is just nearly sparse. For an arbitrary vector $x$ in $\mathbb{R}^N$, denote by $x_S$ its best $S$-sparse approximation; that is, $x_S$ is the approximation obtained by keeping the $S$ largest entries of $x$ and setting the others to zero. It turns out that if the sensing matrix obeys the uniform uncertainty principle at level $S$, then the recovery error is not much worse than $\|x - x_S\|_{\ell_2}$.

**Theorem 3.2** ([9]). *Assume that $x$ is $S$-sparse and suppose that $\delta_{3S} + \delta_{4S} < 2$. Then the solution $x^\star$ to* (2.3) *obeys*

$$\|x^* - x\|_{\ell_2} \le C \cdot \frac{\|x - x_S\|_{\ell_1}}{\sqrt{S}}. \tag{3.4}$$

*For reasonable values of $\delta_{4S}$, the constant in* (3.4) *is well behaved; e.g. $C \le 8.77$ for $\delta_{4S} = 1/5$. Suppose further that $\delta_S + 2\theta_{S,S} + \theta_{2S,S} < 1$, we also have*

$$\|x^* - x\|_{\ell_1} \le C \, \|x - x_S\|_{\ell_1}, \tag{3.5}$$

*for some positive constant $C$. Again, the constant in* (3.5) *is well behaved.*

Roughly speaking, the theorem says that minimizing $\ell_1$ recovers the $S$-largest entries of an $N$-dimensional unknown vector $x$ from $K$ measurements only. As a side remark, the $\ell_2$-stability result (3.4) appears explicitly in [9] while the '$\ell_1$ instance optimality' (3.5) is implicit in [7] although it is not stated explicitely. For example, it follows from Lemma 2.1 – whose hypothesis holds because of Lemma 2.2. in [8] – in that paper. Indeed, let $T$ be the set where $x$ takes on its $S$-largest values. Then Lemma 2.1 in [7] gives $\|x^* \cdot 1_{T^c}\|_{\ell_1} \le 4\|x - x_S\|_{\ell_1}$ and, therefore, $\|(x^* - x) \cdot 1_{T^c}\|_{\ell_1} \le 5\|x - x_S\|_{\ell_1}$. We conclude by observing that on $T$ we have

$$\|(x^* - x) \cdot 1_T\|_{\ell_1} \le \sqrt{S} \, \|(x^* - x) \cdot 1_T\|_{\ell_2} \le C \, \|x - x_S\|_{\ell_1},$$

where the last inequality follows from (3.4). For information, a more direct argument yields better constants.

To appreciate the content of Theorem 3.2, suppose that $x$ belongs to a weak-$\ell_p$ ball of radius $R$. This says that if we rearrange the entries of $x$ in decreasing order of magnitude $|x|_{(1)} \ge |x|_{(2)} \ge \cdots \ge |x|_{(N)}$, the $i$th largest entry obeys

$$|x|_{(i)} \le R \cdot i^{-1/p}, \quad 1 \le i \le N. \tag{3.6}$$

More prosaically, the coefficient sequence decays like a power-law and the parameter $p$ controls the speed of the decay: the smaller $p$, the faster the decay. Classical calculations then show that the best $S$-term approximation of an object $x \in w\ell_p(R)$ obeys

$$\|x - x_S\|_{\ell_2} \le C_2 \cdot R \cdot S^{1/2 - 1/p} \tag{3.7}$$

in the $\ell_2$ norm (for some positive constant $C_2$), and

$$\|x - x_S\|_{\ell_1} \le C_1 \cdot R \cdot S^{1 - 1/p}$$

in the $\ell_1$-norm. For generic elements obeying (3.6), there are no fundamentally better estimates available. Hence, Theorem 3.2 shows that with $K$ measurements only, we can achieve an approximation error which is as good as that one would obtain by knowing everything about the signal and selecting its $S$-largest entries.

**3.4. Random matrices.** Presumably all of this would be interesting if one could design a sensing matrix which would allow us to recover as many entries of $x$ as possible with as few as $K$ measurements. In the language of Theorem 3.1, we would like the condition $\delta_{2S} + \theta_{S,2S} < 1$ to hold for large values of $S$, ideally of the order of $K$. This poses a design problem. How should one design a matrix $\Phi$ – that is to say, a collection of $N$ vectors in $K$ dimensions – so that any subset of columns of size about $S$ be about orthogonal? And for what values of $S$ is this possible?

While it might be difficult to exhibit a matrix which provably obeys the UUP for very large values of $S$, we know that trivial randomized constructions will do so with overwhelming probability. We give an example. Sample $N$ vectors on the unit sphere of $\mathbb{R}^K$ independently and uniformly at random. Then the condition of Theorems 3.1 and 3.2 hold for $S = O(K/\log(N/K))$ with probability $1 - \pi_N$ where $\pi_N = O(e^{-\gamma N})$ for some $\gamma > 0$. The reason why this holds may be explained by some sort of "blessing of high-dimensionality." Because the high-dimensional sphere is mostly empty, it is possible to pack many vectors while maintaining approximate orthogonality.

- *Gaussian measurements.* Here we assume that the entries of the $K$ by $N$ sensing matrix $\Phi$ are independently sampled from the normal distribution with mean zero and variance $1/K$. Then if

$$S \leq C \cdot K/\log(N/K), \tag{3.8}$$

  $S$ obeys the condition of Theorems 3.1 and 3.2 with probability $1 - O(e^{-\gamma N})$ for some $\gamma > 0$. The proof uses known concentration results about the singular values of Gaussian matrices [16], [45].

- *Binary measurements.* Suppose that the entries of the $K$ by $N$ sensing matrix $\Phi$ are independently sampled from the symmetric Bernoulli distribution $P(\Phi_{ki} = \pm 1/\sqrt{K}) = 1/2$. Then it is conjectured that the conditions of Theorems 3.1 and 3.2 are satisfied with probability $1 - O(e^{-\gamma N})$ for some $\gamma > 0$ provided that $S$ obeys (3.8). The proof of this fact would probably follow from new concentration results about the smallest singular value of a subgaussian matrix [38]. Note that the exact reconstruction property for $S$-sparse signals and (3.7) with $S$ obeying (3.8) are known to hold for binary measurements [7].

- *Fourier measurements.* Suppose now that $\Phi$ is a partial Fourier matrix obtained by selecting $K$ rows uniformly at random as before, and renormalizing the columns so that they are unit-normed. Then Candès and Tao [7] showed that Theorem 3.1 holds with overwhelming probability if $S \leq C \cdot K/(\log N)^6$. Recently, Rudelson and Vershynin [43] improved this result and established $S \leq C \cdot K/(\log N)^4$. This result is nontrivial and use sophisticated techniques from geometric functional analysis and probability in Banach spaces. It is conjectured that $S \leq C \cdot K/\log N$ holds.

- *Incoherent measurements.* Suppose now that $\Phi$ is obtained by selecting $K$ rows uniformly at random from an $N$ by $N$ orthonormal matrix $U$ and renormalizing the columns so that they are unit-normed. As before, we could think of $U$ as the matrix $\Phi\Psi^*$ which maps the object from the $\Psi$ to the $\Phi$-domain. Then the arguments used in [7], [43] to prove that the UUP holds for incomplete Fourier matrices extend to this more general situation. In particular, Theorem 3.1 holds with overwhelming probability provided that

$$S \le C \cdot \frac{1}{\mu^2} \cdot \frac{K}{(\log N)^4}, \tag{3.9}$$

  where $\mu := \sqrt{N}\,\max_{i,j}|U_{i,j}|$ (observe that for the Fourier matrix, $\mu = 1$ which gives the result in the special case of the Fourier ensemble above). With $U = \Phi\Psi^*$,

$$\mu := \sqrt{N}\,\max_{i,j}|\langle\varphi_i, \psi_j\rangle| \tag{3.10}$$

  which is referred to as the mutual coherence between the measurement basis $\Phi$ and the sparsity basis $\Psi$ [27], [28]. The greater the incoherence of the measurement/sparsity pair $(\Phi, \Psi)$, the smaller the number of measurements needed.

In short, one can establish the UUP for a few interesting random ensembles and we expect that in the future, many more results of this type will become available.

**3.5. Optimality.** Before concluding this section, it is interesting to specialize our recovery theorems to selected measurement ensembles now that we have established the UUP for concrete values of $S$. Consider the Gaussian measurement ensemble in which the entries of $\Phi$ are i.i.d. $N(0, 1/K)$. Our results say that one can recover any $S$-sparse vector from a random projection of dimension about $O(S \cdot \log(N/S))$, see also [18]. Next, suppose that $x$ is taken from a weak-$\ell_p$ ball of radius $R$ for some $0 < p < 1$, or from the $\ell_1$-ball of radius $R$ for $p = 1$. Then we have shown that for all $x \in w\ell_p(R)$

$$\|x^\star - x\|_{\ell_2} \le C \cdot R \cdot (K/\log(N/K))^{-r}, \quad r = 1/p - 1/2, \tag{3.11}$$

which has also been proven in [20]. An important question is whether this is optimal. In other words, can we find a possibly adaptive set of measurements and a reconstruction algorithm that would yield a better bound than (3.11)? By adaptive, we mean that one could use a sequential measurement procedure where at each stage, one would have the option to decide which linear functional to use next based on the data collected up to that stage.

It proves to be the case that one cannot improve on (3.11), and we have thus identified the optimal performance. Fix a class of object $\mathcal{F}$ and let $E_K(\mathcal{F})$ be the best reconstruction error from $K$ linear measurements

$$E_K(\mathcal{F}) = \inf \sup_{f\in\mathcal{F}} \|f - D(y)\|_{\ell_2}, \quad y = \Phi f, \tag{3.12}$$

where the infimum is taken over all set of $K$ linear functionals and all reconstruction algorithms $D$. Then it turns out $E_K(\mathcal{F})$ nearly equals the *Gelfand* numbers of a class $\mathcal{F}$ defined as

$$d_K(\mathcal{F}) = \inf_V \{\sup_{f\in\mathcal{F}} \|P_V f\| : \operatorname{codim}(V) < K\}, \tag{3.13}$$

where $P_V$ is the orthonormal projection on the subspace $V$. Gelfand numbers play an important role in approximation theory, see [40] for more information. If $\mathcal{F} = -\mathcal{F}$ and $\mathcal{F} = \mathcal{F}+\mathcal{F} \le c_{\mathcal{F}}\mathcal{F}$, then $d_K(\mathcal{F}) \le E_K(\mathcal{F}) \le c_{\mathcal{F}} d_K(\mathcal{F})$. Note that $c_{\mathcal{F}} = 2^{1/p}$ in the case where $\mathcal{F}$ is a weak-$\ell_p$ ball. The thing is that we know the approximate values of the Gelfand numbers for many classes of interest. Suppose for example that $\mathcal{F}$ is the $\ell_1$-ball of radius $R$. A seminal result of Kashin [35] and improved by Garnaev and Gluskin [31] shows that for this ball, the Gelfand numbers obey

$$C_1 \cdot R \cdot \sqrt{\frac{\log(N/K)+1}{K}} \le d_k(\mathcal{F}) \le C_2 \cdot R \cdot \sqrt{\frac{\log(N/K)+1}{K}}, \tag{3.14}$$

where $C_1, C_2$ are universal constants. Gelfand numbers are also approximately known for weak-$\ell_p$ balls as well; the only difference is that $((\log(N/K)+1)/K)^r$ substitutes $((\log(N/K)+1)/K)^{1/2}$. Hence, Kashin, Garnaev and Gluskin assert that with $K$ measurements, the minimal reconstruction error (3.12) one can hope for is bounded below by a constant times $(K/\log(N/K))^{-r}$. Kashin's arguments [35] also used probabilistic functionals which establish the existence of recovery procedures for which the reconstruction error is bounded above by the right-hand side of (3.14). Similar types of recovery have also been known to be possible in the literature of theoretical computer science, at least in principle, for certain types of random measurements [1].

In this sense, our results – specialized to Gaussian measurements – are optimal for weak-$\ell_p$ norms. The novelty is that the information about the object can be retrieved from random coefficients by minimizing a simple linear program (2.3), and that the decoding algorithm adapts automatically to the weak-$\ell_p$ signal class, without knowledge thereof. Minimizing the $\ell_1$-norm is adaptive and nearly gives the best possible reconstruction error simultaneously over a wide range of sparse classes of signals; no information about $p$ and the radius $R$ are required.

## 4. Robust compressive sampling

In any realistic application, we cannot expect to measure $\Phi x$ without any error, and we now turn our attention to the robustness of compressive sampling vis a vis measurement errors. This is a very important issue because any real-world sensor is subject to at least a small amount of noise. And one thus immediately understands that to be widely applicable, the methodology needs to be stable. Small perturbations in the

observed data should induce small perturbations in the reconstruction. Fortunately, the recovery procedures may be adapted to be surprisingly stable and robust vis a vis arbitrary perturbations.

Suppose our observations are inaccurate and consider the model

$$y = \Phi x + e, \tag{4.1}$$

where $e$ is a stochastic or deterministic error term with bounded energy $\|e\|_{\ell_2} \le \varepsilon$. Because we have inaccurate measurements, we now use a noise-aware variant of (2.3) which relaxes the data fidelity term. We propose a reconstruction program of the form

$$(\mathrm{P}_2) \qquad \min \ \|\tilde{x}\|_{\ell_1} \quad \text{such that} \quad \|\Phi\tilde{x} - y\|_{\ell_2} \le \varepsilon. \tag{4.2}$$

The difference with $(\mathrm{P}_1)$ is that we only ask the reconstruction be consistent with the data in the sense that $y - \Phi x^\star$ be within the noise level. The program $(\mathrm{P}_2)$ has a unique solution, is again convex, and is a special instance of a second order cone program (SOCP) [4].

**Theorem 4.1** ([9]). *Suppose that $x$ is an arbitrary vector in $\mathbb{R}^N$. Under the hypothesis of Theorem* 3.2*, the solution $x^\star$ to* $(\mathrm{P}_2)$ *obeys*

$$\|x^\star - x\|_{\ell_2} \le C_{1,S} \cdot \varepsilon + C_{2,S} \cdot \frac{\|x_0 - x_{0,S}\|_{\ell_1}}{\sqrt{S}}. \tag{4.3}$$

*For reasonable values of $\delta_{4S}$ the constants in* (4.3) *are well behaved, see* [9].

We would like to offer two comments. The first is that the reconstruction error is finite. This quiet observation is noteworthy because we recall that the matrix $\Phi$ is rectangular with many more columns than rows – thus having a fraction of vanishing singular values. Having said that, the mere fact that the severely ill-posed matrix inversion keeps the perturbation from "blowing up" may seem a little unexpected. Next and upon closer inspection, one sees that the reconstruction error is the sum of two terms: the first is simply proportional to the size of the measurement error while the second is the approximation error one would obtain in the noiseless case. In other words, the performance of the reconstruction degrades gracefully as the measurement noise increases. This brings us to our second point. In fact, it is not difficult to see that no recovery method can perform fundamentally better for arbitrary perturbations of size $\varepsilon$ [9]. For related results for Gaussian sensing matrices, see [19].

## 5. Connections with statistical estimation

In the remainder of this paper, we shall briefly explore some connections with other fields, and we begin with statistics. Suppose now that the measurement errors in (4.1) are stochastic. More explicitly, suppose that the model is of the form

$$y = \Phi x + z, \tag{5.1}$$

where $z_1, \ldots, z_k$ are i.i.d. with mean zero and variance $\sigma^2$. In this section, we will assume that the $z_k$'s are Gaussian although nothing in our arguments heavily relies upon this assumption. The problem is again to recover $x$ from $y$ which is a central problem in statistics since this is just the classical multivariate linear regression problem. Because the practical environment has changed dramatically over the last two decades or so, applications have emerged in which the number of observations is small compared to the dimension of the object we wish to estimate – here, $K \leq N$. This new paradigm sometimes referred to as "high-dimensional data" is currently receiving much attention and, clearly, the emerging theory of compressive sampling might prove very relevant.

The results from the previous sections are directly applicable. Suppose that $x$ is $S$-sparse to simplify our exposition. Because $\|z\|_{\ell_2}^2$ is distributed as a chi-squared with $K$ degrees of freedom, the reconstruction (4.2) would obey

$$\|x^* - x\|_{\ell_2}^2 \leq C \cdot K\sigma^2 \tag{5.2}$$

with high probability. While this may seem acceptable to the nonspecialist, modern results in the literature suggest that one might be able to get a better accuracy. In particular, one would like an adaptive error bound which depends upon the complexity of the true unknown parameter vector $x \in \mathbb{R}^N$. For example, if $x$ only has $S$ significant coefficients, we would desire an error bound of size about $S\sigma^2$; the less complex the estimand, the smaller the squared-error loss. This poses an important question: can we design an estimator whose accuracy depends upon the information content of the object we wish to recover?

**5.1. Ideal model selection.** To get a sense of what is possible, consider regressing the data $y$ onto an arbitrary subset $T$ by the method of least squares. Define $\hat{x}[T]$ to be the least squares estimate whose restriction to the set $T$ is given by

$$\hat{x}_T[T] = (\Phi_T^T \Phi_T)^{-1} \Phi_T^T y, \tag{5.3}$$

and which vanishes outside $T$. Above, $\hat{x}_T[T]$ is the restriction of $\hat{x}[T]$ to $T$ and similarly for $x_T$. Since $\hat{x}[T]$ vanishes outside $T$, we have

$$\mathbf{E}\|x - \hat{x}[T]\|^2 = \|x_T - \hat{x}_T[T]\|^2 + \sum_{i \notin T} |x_i|^2,$$

Consider the first term. We have

$$x_T - \hat{x}_T[T] = (\Phi_T^T \Phi_T)^{-1} \Phi_T^T (s + z),$$

where $s = \Phi_{T^c} x_{T^c}$. It follows that

$$\mathbf{E}\|x_T - \hat{x}_T[T]\|^2 = \|(\Phi_T^T \Phi_T)^{-1} \Phi_T^T s\|^2 + \sigma^2 \operatorname{Tr}((\Phi_T^T \Phi_T)^{-1}).$$

However, since all the eigenvalues of $\Phi_T^T \Phi_T$ belong to the interval $[1-\delta_{|T|}, 1+\delta_{|T|}]$, we have

$$\mathbf{E}\|x_T - \hat{x}_T[T]\|^2 \geq \frac{1}{1+\delta_{|T|}} \cdot |T| \cdot \sigma^2.$$

For each set $T$ with $|T| \leq S$ and $\delta_S < 1$, we then have

$$\mathbf{E}\|x - \hat{x}[T]\|^2 \geq \sum_{i \in T^c c} x_i^2 + \frac{1}{2}\,|T| \cdot \sigma^2.$$

We now search for an *ideal estimator* which selects that estimator $\hat{x}[T^*]$ from the family $(\hat{x}[T])_{T \subset \{1,\ldots,N\}}$ with minimal Mean-Squared Error (MSE):

$$\hat{x}[T^*] = \mathrm{argmin}_{T \subset \{1,\ldots,N\}}\ \mathbf{E}\|x - \hat{x}[T]\|^2.$$

This estimator is ideal because we would of course not know which estimator $\hat{x}_T$ is best; that is, to achieve the ideal MSE, one would need an oracle that would tell us which model $T$ to choose.

We will consider this ideal estimator nevertheless and take its MSE as a benchmark. The ideal MSE is bounded below by

$$\begin{aligned}\mathbf{E}\|x - \hat{x}[T^*]\|^2 &\geq \frac{1}{2}\ \min_T \left(\|x - \hat{x}[T]\|^2 + |T| \cdot \sigma^2\right) \\ &= \frac{1}{2} \sum_i \min(x_i^2, \sigma^2). \end{aligned} \tag{5.4}$$

Letting $x_S$ be the best $S$-sparse approximation to $x$, another way to express the right-hand side (5.4) is in term of the classical trade-off between the approximation error and the number of terms being estimated times the noise level

$$\mathbf{E}\|x - \hat{x}_{T^*}\|^2 \geq \frac{1}{2} \inf_{S \geq 0} \left(\|x - x_S\|^2 + S\sigma^2\right).$$

Our question is of course whether there is a computationally efficient estimator which can mimic the ideal MSE.

**5.2. The Dantzig selector.** Assume for simplicity that the columns of $\Phi$ are normalized (there are straightforward variations to handle the general case). Then the Dantzig selector estimates $x$ by solving the convex program

$$\text{(DS)} \qquad \min_{\tilde{x} \in \mathbb{R}^N} \|\tilde{x}\|_{\ell_1} \quad \text{subject to} \quad \sup_{1 \leq i \leq N} |(\Phi^T r)_i| \leq \lambda \cdot \sigma \tag{5.5}$$

for some $\lambda > 0$, and where $r$ is the vector of residuals

$$r = y - \Phi\tilde{x}. \tag{5.6}$$

The solution to this optimization problem is the minimum $\ell_1$-vector which is consistent with the observations. The constraints impose that the residual vector is within the noise level and does not correlate too well with the columns of $\Phi$. For information, there exist related, yet different proposals in the literature, and most notably the lasso introduced by [47], see also [15]. Again, the program (DS) is convex and can be recast as a linear program (LP).

The main result in this line of research is that the Dantzig selector is not only computationally tractable, it is also accurate.

**Theorem 5.1** ([10]). *Set* $\lambda := (1 + t^{-1})\sqrt{2\log p}$ *in* (5.5) *and suppose that* $x$ *is* $S$*-sparse with* $\delta_{2S} + \theta_{S,2S} < 1 - t$. *Then with very large probability, the Dantzig selector* $\hat{x}$ *solution to* (5.5) *obeys*

$$\|\hat{x} - x\|^2 \leq O(\log p) \cdot \Big(\sigma^2 + \sum_i \min(x_i^2, \sigma^2)\Big). \tag{5.7}$$

Our result says that the Dantzig selector achieves a loss within a logarithmic factor of the ideal mean squared error one would achieve with an *oracle* which would supply perfect information about which coordinates are nonzero, and which were above the noise level. To be complete, it is possible to obtain similar bounds on the MSE.

There are extensions of this result to signals which are not sparse but compressible, e.g. for signals which belong to weak-$\ell_p$ balls. What is interesting here is that in some instances, even though the number of measurements is much smaller than the dimension of the parameter vector $x$, the Dantzig selector recovers the minimax rate that one would get if we were able to measure all the coordinates of $x$ *directly* via $\tilde{y} = x + \sigma z$ where $z$ is i.i.d. $N(0, 1)$.

## 6. Connections with error correction

Compressive sampling also interacts with the agenda of coding theory. Imagine we wish to transmit a vector $x$ of length $M$ to a remote receiver reliably. A frequently discussed approach consists in encoding the information $x$ with an $N$ by $M$ coding matrix $C$ with $N > M$. Assume that gross errors occur upon transmission and that a fraction of the entries of $Cx$ are corrupted in a completely arbitrary fashion. We do not know which entries are affected nor do we know how they are affected. Is it possible to recover the information $x$ exactly from the corrupted $N$-dimensional vector $y$?

To decode, [8] proposes solving the minimum $\ell_1$-approximation problem

$$(\mathrm{D}_1) \qquad \min_{\tilde{x} \in \mathbb{R}^M} \|y - C\tilde{x}\|_{\ell_1}, \tag{6.1}$$

which can also be obviously recast as an LP. The result is that if $C$ is carefully chosen, then (6.1) will correctly retrieve the information $x$ with no error provided that the

fraction $\rho$ of errors is not too large, $\rho \leq \rho^*$. This phenomenon holds for all $x$'s and all corruption patterns.

To see why this phenomenon occurs, consider a matrix $B$ which annihilates the $N \times M$ coding matrix $C$ on the left, i.e. such that $BC = 0$; $B$ is called a parity-check matrix and is any $(N - M) \times N$ matrix whose kernel is the range of $C$ in $\mathbb{R}^N$. The transmitted information is of the form $y = Cx + e$, where $e$ is a sparse vector of possibly gross errors, and apply $B$ on both sides of this equation. This gives

$$\tilde{y} = B(Cx + e) = Be \tag{6.2}$$

since $BC = 0$. Therefore, the decoding problem is reduced to that of recovering the error vector $e$ from the observations $Be$. Once $e$ is known, $Cx$ is known and, therefore, $x$ is also known since we may just assume that $C$ has full rank.

Now the reader knows that we could solve the underdetermined system (6.2) by $\ell_1$-minimization. He also knows that if the UUP holds, the recovery is exact. Now $(\mathrm{D}_1)$ and $(\mathrm{P}_1)$ are equivalent programs. Indeed, it follows from the decomposition $\tilde{x} = x + h$ that

$$(\mathrm{D}_1) \iff \min_{h \in \mathbb{R}^M} \|e - Ch\|_{\ell_1}.$$

Now the constraint $Bd = Be$ means that $d = e - Ah$ for some $h \in \mathbb{R}^M$ and, therefore,

$$\begin{aligned} \min \|d\|_{\ell_1}, \quad Bd = Be &\iff \min_{h \in \mathbb{R}^n} \|d\|_{\ell_1}, \quad d = e - Ah \\ &\iff \min_{h \in \mathbb{R}^n} \|e - Ah\|_{\ell_1}, \end{aligned}$$

which proves the claim.

Hence, if one uses a random coding matrix which is a popular choice, we have the following result, see also [42]:

**Theorem 6.1** ([8]). *Suppose the coding matrix $C$ has i.i.d. $N(0, 1)$ entries. Then with probability exceeding $1 - O(e^{-\gamma M})$ for some $\gamma > 0$, $(\mathrm{D}_1)$ exactly decodes all $x \in \mathbb{R}^M$ provided that the fraction $\rho$ of arbitrary errors obeys $\rho \leq \rho^*(M, N)$.*

In conclusion, one can correct a constant fraction of errors with arbitrary magnitudes by solving a convenient LP. In [8], the authors reported on numerical results showing that in practice $(\mathrm{D}_1)$ works extremely well and recovers the vector $x$ exactly provided that the fraction of the corrupted entries be less than about 17% in the case where $N = 2M$ and less than about 34% in the case where $N = 4M$.

## 7. Further topics

Our intention in this short survey was merely to introduce the new compressive sampling concepts. We presented an approach based on the notion of uncertainty principle

which gives a powerful and unified treatment of some of the main results underlying this theory. As we have seen, the UUP gives conditions for exact, approximate, and stable recoveries which are almost necessary. Another advantage that one can hardly neglect is that this makes the exposition fairly simple. Having said that, the early papers on compressive sampling – e.g. [6], [7], [20] – have spurred a large and fascinating literature in which other approaches and ideas have been proposed. Rudelson and Vershynin have used tools from modern Banach space theory to derive powerful results for Gaussian ensembles [42], [14], [43]. In this area, Pajor and his colleagues have established the existence of abstract reconstruction procedures from subgaussian measurements (including random binary sensing matrices) with powerful reconstruction properties. In a different direction, Donoho and Tanner have leveraged results from polytope geometry to obtain very precise estimates about the minimal number of Gaussian measurements needed to reconstruct $S$-sparse signals [21], [23], see also [43]. Tropp and Gilbert reported results about the performance of greedy methods for compressive sampling [49]. Haupt and Nowak have quantified the performance of combinatorial optimization procedures for estimating a signal from undersampled random projections in noisy environments [34]. Finally, Rauhut has worked out variations on the Fourier sampling theorem in which a sparse continuous-time trigonometric polynomials is randomly sampled in time [41]. Because of space limitations, we are unfortunately unable to do complete justice to this rapidly growing literature.

We would like to emphasize that there are many aspects of compressive sampling that we have not touched. For example, we have not discussed the practical performance of this new theory. In fact, numerical experiments have shown that compressive sampling behaves extremely well in practice. For example, it has been shown that from $3S-4S$ nonadaptive measurements, one can reconstruct an approximation of an image in a fixed basis which is more precise than that one would get by measuring all the coefficients of the object in that basis and selecting the $S$ largest [13], [50]. Further, numerical simulations with noisy data show that compressive sampling is very stable and performs well in noisy environments. In practice, the constants appearing in Theorems 4.1 and 5.1 are very small, see [9] and [10] for empirical results.

We would like to close this article by returning to the main theme of this paper, which is that compressive sampling invites to rethink sensing mechanisms. Because if one were to collect a comparably small number of general linear measurements rather than the usual pixels, one could in principle reconstruct an image with essentially the same resolution as that one would obtain by measuring all the pixels. Therefore, if one could design incoherent sensors (i.e. measuring incoherent linear functionals), the payoff could be extremely large. Several teams have already reported progress in this direction. For example, a team led by Baraniuk and Kelly have proposed a new camera architecture that employs a digital micromirror array to perform optical calculations of linear projections of an image onto pseudorandom binary patterns [46], [52]. Compressive sampling may also address challenges in the processing of wideband radio frequency signals since high-speed analog-to-digital convertor

technology indicates that current capabilities fall well short of needs, and that hardware implementations of high precision Shannon-based conversion seem out of sight for decades to come. Finally, compressive sampling has already found applications in wireless sensor networks [2]. Here, compressive sampling allows of *energy efficient* estimation of sensor data with comparably few sensor nodes. The power of these estimation schemes is that they require no prior information about the sensed data. All these applications are novel and exciting. Others might just be around the corner.

# Total variation based image denoising and restoration

Vicent Caselles*

**Abstract.** This paper is devoted to the total variation (TV) based approach to image denoising and restoration. The restored image minimizes total variation in the class of images which satisfy the contraints given by the image acquisition model. We compute some explicit solutions of the denoising model which explain some of the features observed in numerical experiments. We also comment on some alternatives recently proposed by Y. Meyer which lead to $u + v$ image decompositions. Finally we propose a total variation approach to image restoration, i.e., deconvolution and denoising, in which the image acquisition model is incorporated as a set of local constraints.

**Mathematics Subject Classification (2000).** Primary 68U10; Secondary 65K10, 65J20, 94A08.

**Keywords.** Image restoration, total variation, variational methods.

## 1. Introduction

We assume that the image acquisition system may be modelled by the following image formation model

$$z = h * u + n, \tag{1}$$

where $u\colon \mathbb{R}^2 \to \mathbb{R}$ denotes the ideal undistorted image, $h\colon \mathbb{R}^2 \to \mathbb{R}$ is a blurring kernel, $z$ is the observed image which is represented as a function $z\colon \mathbb{R}^2 \to \mathbb{R}$, and $n$ is an additive Gaussian white noise with zero mean and standard deviation $\sigma$.

Let us denote by $\Omega$ the interval $(0, N]^2$. As in most of works, in order to simplify this problem, we shall assume that the functions $h$ and $u$ are periodic of period $N$ in each direction. That amounts to neglecting some boundary effects. Therefore, we shall assume that $h, u$ are functions defined in $\Omega$ and, to fix ideas, we assume that $h, u \in L^2(\Omega)$. Our problem is to recover as much as possible of $u$, from our knowledge of the blurring kernel $h$, the statistics of the noise $n$, and the observed image $z$.

The problem of recovering $u$ from $z$ is ill-posed due to the ill-conditioning of the operator $Hu = h * u$. Several methods have been proposed to recover $u$. Most of them can be classified as regularization methods which may take into account statistical properties (Wiener filters), information theoretic properties ([19]), a priori

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

geometric models ([30]) or the functional analytic behavior of the image given in terms of its wavelet coefficients ([20]).

The typical strategy to solve this ill-conditioning is regularization. Probably one of the first examples of regularization method [31] consists in choosing between all possible solutions of (1) the one which minimized the Sobolev (semi) norm of $u$

$$\int_\Omega |Du|^2\,dx. \tag{2}$$

Usually, the only information we know about the noise is statistical and limited to an estimate of its mean and its variance. In that case, the model equation (1) is incorporated as a set of constraints for (2): a first constraint corresponding to the assumption that the noise has zero mean, and a second one translating the fact that $\sigma$ is an upper bound of the standard deviation of $n$.

This formulation was an important step, but the results were not satisfactory, mainly due to the unability of the previous functional to resolve discontinuities (edges) and oscillatory textured patterns. The smoothness required by the Dirichlet integral (2) is too restrictive and information corresponding to high frequencies of $z$ is attenuated by it. Indeed, functions in $W^{1,2}(\Omega)$ (i.e., functions $u \in L^2(\Omega)$ such that $Du \in L^2(\Omega)$) cannot have discontinuities along rectifiable curves. These observations motivated the introduction of total variation in image restoration problems by L. Rudin, S. Osher and E. Fatemi in their work [30]. The a priori hypothesis is that functions of bounded variation (the BV model) ([5]) are a reasonable functional model for many problems in image processing, in particular, for restoration problems ([30]). Typically, functions of bounded variation have discontinuities along rectifiable curves, being continuous in some sense (in the measure theoretic sense) away from discontinuities. The discontinuities could be identified with edges. The ability of total variation regularization to recover edges is one of the main features which advocates for the use of this model but its ability to describe textures is less clear, even if some textures can be recovered, up to a certain scale of oscillation.

On the basis of the BV model, Rudin–Osher–Fatemi [30] proposed to solve the following constrained minimization problem

$$\begin{aligned} &\text{Minimize} \quad \int_\Omega |Du| \\ &\text{subject to} \quad \int_\Omega |h*u(x) - z(x)|^2\,dx \le \sigma^2|\Omega|. \end{aligned} \tag{3}$$

Notice that the image acquisition model (1) is only incorporated through a global constraint. Notice also that, assuming that $h*1 = 1$ (energy preservation), the constraint that $\int_\Omega h*u\,dx = \int_\Omega z(x)$ is automatically satisfied by its minima [17]. In practice, the above problem is solved via the following unconstrained minimization problem

$$\text{Minimize} \quad \int_\Omega |Du| + \frac{\lambda}{2}\int_\Omega |h*u - z|^2\,dx \tag{4}$$

where the parameter $\lambda$ is positive. Recall that we may interpret $\lambda^{-1}$ as a penalization parameter which controls the trade-off between the goodness of fit of the constraint and the smoothness term given by the total variation. In this formulation, a methodology is required for a correct choice of $\lambda$. The connections between (3) and (4) were studied by A. Chambolle and P. L. Lions in [17] where they proved that both problems are equivalent for some positive value of the Lagrange multiplier $\lambda$.

A particular and important case contained in the above formulation is the denoising problem which corresponds to the case where $h = \delta$, so that equation (1) is written as $z = u + n$ where $n$ is an additive Gaussian white noise of zero mean and variance $\sigma^2$. In this case, the unconstrained variational formulation (5) with $h = \delta$ is

$$\text{Minimize} \quad \int_\Omega |Du| + \frac{\lambda}{2} \int_\Omega |u - z|^2 \, dx, \tag{5}$$

and it has been the object of much theoretical and numerical research (see [7] for a survey). Even if this model represented a theoretical and practical progress in the denoising problem due to the introduction of BV functions as image models, the experimental analysis readily showed its main drawbacks. Between them, let us mention the staircasing effect (when denoising a smooth ramp plus noise, the staircase is an admissible result), the pixelization of the image at smooth regions and the loose of fine textured regions, to mention some of them. This can be summarized with the simple observation that the residuals $z - u$, where $u$ represents the solution of (5), do not look like noise. The theoretical analysis of the behavior of solutions of (5) has been the objects of several works [3], [12], [13], [27], [26] and will be developed in Section 2 by exhibiting explicit solutions for specially constructed functions $z$.

In spite of this, a second life in the interest of total variation based regularization was initiated after the proposal of $u + v$ models by Y. Meyer in [26]. The solution $u$ of (5) permits to obtain a decomposition of the data $z$ as a sum of two components $u + v$ where $v$ is supposed to contain the noise and textured parts of the image $z$, while $u$ contains the geometric sketch of the image $z$. As Meyer observed, the $L^2$ norm of the residual $v := z - u$ in (5) is not the right one to obtain a decomposition of $z$ in terms of geometry plus texture and he proposed to measure the size of the textured part $v$ in terms of a dual BV norm showing that some models of texture have a small dual BV norm: this will be the object of Section 3.

The restoration problem (which corresponds to the case of nontrivial kernel $h$) has also been the object of much interest due to its applications in many contexts, like satellite, astronomical or video images, to mention a few of them. In Section 4 we shall discuss a total variation based approach to the restoration model in which the image acquisition model is incorporated as a set of local constraints. Indeed, when incorporating (1) as a constraint in (3) we loose the local character of (1) and the restored image does not look satisfactory in textured and smooth regions at the same time. Thus, we propose to incorporate (1) by ensuring that the residuals $z - h * u$ have a variance bounded by $\sigma^2$ in a sufficiently large region around each pixel (the sampling process is incorporated in the model), the size of the region has to be sufficient in

order to estimate the variance of the noise. This gives a constrained formulation of the problem with as many Lagrange multipliers as pixels, and a solution is computed using Uzawa's method. Finally, in Section 5 we display some experiments on restoration of satellite images which illustrate the results that can be obtained with this method.

## 2. Explicit solutions of TV based denoising

The constrained formulation of the total variation denoising is given by (3) with $h = \delta$. Its unconstrained formulation is given by (5) where $\lambda > 0$ is a penalization parameter. Both problems are equivalent for a certain value of $\lambda$ [17]. Our purpose in this section is to exhibit some qualitative features of total variation denoising by constructing explicit solutions of (5). Those features are well known at the experimental level, and the results give a theoretical justification of these observations. Our solutions will exhibit the possibility to resolve discontinuities, but also the loss of contrast, and the regularization of corners (thus, the image is loosing structure). The staircasing effect was explained in [27].

The construction of explicit solutions of (5) is related to the computation of solutions of the eigenvalue problem for the 1-Laplacian operator.

$$-\operatorname{div}\left(\frac{Du}{|Du|}\right) = u. \tag{6}$$

We denote by $\mathrm{BV}(\mathbb{R}^N)$ the space of functions of bounded variation in $\mathbb{R}^N$. For definitions concerning bounded variation functions we refer to [5]. The solution of (6) is understood in the following sense ([6], [7], [13]).

**Definition 2.1.** We say that a function $u \in L^2(\mathbb{R}^N) \cap \mathrm{BV}(\mathbb{R}^N)$ is a solution of (6) in $\mathbb{R}^N$ if there exits a vector field $\xi \in L^\infty(\mathbb{R}^N; \mathbb{R}^N)$ with $\|\xi\|_\infty \leq 1$, such that $(\xi, Du) = |Du|$ and

$$-\operatorname{div}\xi = u \quad \text{in } \mathcal{D}'(\mathbb{R}^N).$$

If the vector field $\xi \in L^\infty(\mathbb{R}^N; \mathbb{R}^N)$ is such that $\operatorname{div}\xi \in L^2(\mathbb{R}^N)$ and $u \in \mathrm{BV}(\mathbb{R}^N)$, the expression $(\xi, Du)$ is a distribution defined by the formula

$$\langle(\xi, Dw), \varphi\rangle := -\int_{R^N} w\,\varphi \operatorname{div}\xi\,dx - \int_{R^N} w\,\xi\cdot\nabla\varphi\,dx \quad \text{for all } \varphi \in C_0^\infty(\mathbb{R}^N).$$

Then $(\xi, Du)$ is a Radon measure in $\mathbb{R}^N$ which coincides with $\xi\cdot\nabla u$ when $u \in L^2(\mathbb{R}^N) \cap W^{1,1}(\mathbb{R}^N)$ [11].

The following result is taken from [13] and it explains how can we derive from solutions of (6) data $z$ for which the solution of (5) is explicit.

**Proposition 2.2.** *Let $u_i \in \mathrm{BV}(\mathbb{R}^N)$ be such that $\inf(|u_i|, |u_j|) = 0$, $i, j \in \{1, \ldots, m\}$, $i \neq j$. Assume that $u_i$ and $\sum_{i=1}^m u_i$ are solutions of the eigenvalue problem* (6),

*$i \in \{1, \dots, m\}$. Let $b_i \in R$, $i = 1, \dots, m$, $z := \sum_{i=1}^m b_i u_i$, and $\lambda > 0$. Then the solution $u$ of the variational problem* (5) *is* $u := \sum_{i=1}^m \operatorname{sign}(b_i)(|b_i| - \lambda^{-1})^+ u_i$.

Assume that $m = 1$ and $\bar{u}$ is a solution of (6). If $0 < \lambda^{-1} \le b$, then $u := a\bar{u}$ with $a = b - \lambda^{-1}$ is a solution of (5) for the datum $z = b\bar{u}$. Indeed, $u$ satisfies the Euler–Lagrange equation of (5) which characterizes its unique solution:

$$z = b\bar{u} = a\bar{u} + \lambda^{-1}\bar{u} = a\bar{u} - \lambda^{-1}\operatorname{div}\left(\frac{D\bar{u}}{|D\bar{u}|}\right) = u - \lambda^{-1}\operatorname{div}\left(\frac{Du}{|Du|}\right).$$

If $\lambda^{-1} > b$, then $u = 0$ is the solution of (5). Indeed, in this case $\|\lambda z\|_{\mathrm{BV}^*} \le 1$ (the dual norm in $\mathrm{BV}(\mathbb{R}^N)^*$) and there is a vector field $\xi \in L^\infty(\mathbb{R}^N; \mathbb{R}^N)$ with $\|\xi\|_\infty \le 1$, such that $-\operatorname{div}\xi = \lambda z$. Thus, $u = 0$ satisfies the Euler–Lagrange equation of (5). The proof when $b \le 0$ is similar and we skip the details. This solution exhibits a loss of contrast of size $\min(\lambda^{-1}, |b|)$ when the datum is $z = b\bar{u}$.

Our next theorem gives a family of solutions of (6) and is taken from [12] (see also [4]).

**Theorem 2.3.** *Let $C_1, \dots, C_m$ be bounded convex subsets of $\mathbb{R}^2$ which are disjoint. Let $b_i > 0$, $i = 1, \dots, m$, $k \in \{1, \dots, m\}$. Then $v := -\sum_{i=1}^k b_i \chi_{C_i} + \sum_{i=k+1}^m b_i \chi_{C_i}$ is a solution of* (6) *if and only if the following conditions holds.*

(i) *The sets $C_i$, $i = 1, \dots, m$, are of class $C^{1,1}$.*

(ii) *$b_i = \frac{P(C_i)}{|C_i|}$ for any $i \in \{1, \dots, m\}$.*

(iii) *The following inequalities hold:*

$$\operatorname*{ess\,sup}_{p \in \partial C_i} \kappa_{C_i}(p) \le \frac{P(C_i)}{|C_i|} \quad \text{for all } i = 1, \dots, m.$$

(iv) *If $E_1$ is a solution of the variational problem*

$$\min\left\{P(E) : \bigcup_{j=k+1}^m C_j \subseteq E \subseteq \mathbb{R}^2 \setminus \bigcup_{i=1}^k C_i\right\},$$

*then we have*

$$P(E_1) = \sum_{j=k+1}^m P(C_j).$$

*If $E_2$ is a solution of the variational problem*

$$\min\left\{P(E) : \bigcup_{i=1}^k C_i \subseteq E \subseteq \mathbb{R}^2 \setminus \bigcup_{j=k+1}^m C_j\right\},$$

*then we have*

$$P(E_2) = \sum_{i=1}^k P(C_i).$$

*Moreover, if $k = m$, then we do not need to assume that the $C_i$ are convex and we can replace condition* (i) *by the following one:*

(i′) *The sets $C_i$, $i = 1, \dots, m$, are convex and of class $C^{1,1}$.*

This result was essentially proved in [12] (though we only stated the result in its second assertion). Its extension to $\mathbb{R}^N$ was proved in [4] (replacing the curvature of the boundaries by the sum of principal curvatures) under the assumption that the sets $C_i$ are convex and of class $C^{1,1}$. Let us point out the following corollary for connected sets.

**Corollary 2.4.** *Let $C \subset \mathbb{R}^2$ be a bounded set of finite perimeter, and assume that $C$ is connected. The function $v := \lambda \chi_C$ is a solution of* (6) *if and only if the following three conditions hold.*

(i) $\lambda = \lambda_C := \frac{P(C)}{|C|}$.

(ii) *$C$ is convex and $\partial C$ is of class $C^{1,1}$.*

(iii) *The following inequality holds:*

$$\operatorname*{ess\,sup}_{p \in \partial C} \kappa_{\partial C}(p) \leq \frac{P(C)}{|C|}.$$

A convex set $C \subseteq \mathbb{R}^2$ such that $u := \lambda_C \chi_C$ is a solution of (6) is called calibrable. The above result gives a characterization of calibrable sets in $\mathbb{R}^2$ and was proved in [24], [12]. For convex sets in $\mathbb{R}^N$ of class $C^{1,1}$ the above result is true if we replace the curvature of the boundary by the sum of the principal curvatures [4].

**Example 1.** Let $C \subset \mathbb{R}^2$ be the set of Figure 1. It is easy to check that $C$ satisfies the

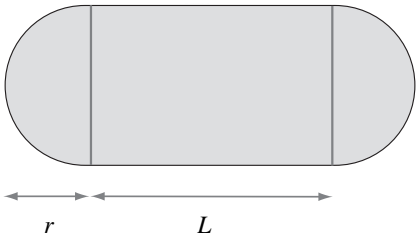

Figure 1. A bean-shaped set is calibrable.

assumptions of Corollary 2.4, since $C$ is a convex set with $C^{1,1}$ boundary and there holds

$$\operatorname*{ess\,sup}_{p \in \partial C} \kappa_{\partial C}(p) = \frac{1}{r} < \frac{2\pi r + 2L}{\pi r^2 + 2rL} = \frac{P(C)}{|C|}. \tag{7}$$

Moreover, since the inequality in (7) is always strict, any convex set $C'$ of class $C^{1,1}$ close enough to $C$ in the $C^{1,1}$-norm is also calibrable.

**Example 2.** Let $\Omega \subset \mathbb{R}^2$ be the union of two disjoint balls $B_1$ and $B_2$ of radius $r$, whose centers are at distance $L$ (see Figure 2). Then $k = 0$ and $m = 2$ in Theorem 2.3 and condition (iv) in it reads as

$$L \geq \pi r.$$

Under this condition the set $\Omega$ is calibrable. The condition $L \geq \pi r$ is nothing else than $P(\mathrm{co}(B_1 \cup B_2)) \geq P(B_1) + P(B_2)$ (co denotes the convex envelope) and in this case the solution of the denoising problem with $z = \chi_{B_1 \cup B_2}$ coincides with the

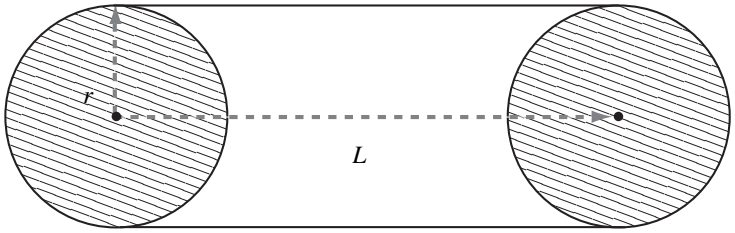

Figure 2. Two balls as initial datum for the denoising problem.

addition of the solutions obtained with $\chi_{B_1}$ and $\chi_{B_2}$. In case that $P(\mathrm{co}(B_1 \cup B_2)) < P(B_1) + P(B_2)$ there is interaction of the two sets and the solution is not the addition of solutions corresponding to the data $\chi_{B_1}$ and $\chi_{B_2}$.

These solutions exhibit two features of (5): that discontinuities may be preserved and the loss of contrast.

We could expand the above family of solutions by classifying all possible solutions of (6). Along this line, we extended the above results in two directions: in [13] we looked for solutions of (6) which are built up as sums of linear combinations of characteristic functions of convex sets of class $C^{1,1}$ (not disjoint, in general), and we considered in [3], [4] the case of general convex sets.

Let us illustrate the results in [13] with a simple case.

**Proposition 2.5.** *Let $K_0$, $K_1$ be two bounded open convex sets of $\mathbb{R}^2$ with boundary of class $C^{1,1}$ such that $\overline{K_1} \subseteq K_0$. Let $F := K_0 \setminus \overline{K_1}$. Let*

$$J := \frac{P(K_0) - P(K_1)}{|F|} > 0.$$

*If*

$$\operatorname*{ess\,sup}_{\partial K_0} \kappa_{\partial K_0} \leq J, \quad \operatorname*{ess\,inf}_{x \in \partial K_1} \kappa_{\partial K_1}(x) \geq J, \quad \operatorname*{ess\,sup}_{x \in \partial K_1} \kappa_{\partial K_1}(x) \leq \lambda_{K_1}$$

*then $v = \lambda_{K_1} \chi_{K_1} + J \chi_{K_0 \setminus K_1}$ is a solution of* (6).

The works [3], [4] describe the denoising of the characteristic function of any convex set of $\mathbb{R}^2$ and $\mathbb{R}^N$, respectively, and the results in them illustrate the regularization of corners. Even if the more general case of linear combinations of convex sets in $\mathbb{R}^2$ and $\mathbb{R}^N$ is considered, we illustrate the results in [3], [4] with a simple case.

**Theorem 2.6.** *Assume that $C$ is a bounded convex set in $\mathbb{R}^2$. Then there is a calibrable set $C_R \subseteq C$ such that $\partial C \setminus \partial C_R$ is formed by arcs of circle of radius $R$ such that $\frac{1}{R} = \frac{P(C_R)}{|C_R|}$ and for each $x \in C \setminus C_R$ it passes a unique arc of circle of radius $r(x)$ and those circles fiber $C \setminus C_R$. Let $r(x) = R$ for $x \in C_R$. Then $u(x) = \left(1 - \frac{\lambda^{-1}}{r(x)}\right)^+ \chi_C$ is the solution of* (6) *for the data $z = \chi_C$.*

## 3. Image decomposition models

In his work [26], Y. Meyer interpreted the denoising model as a $u + v$ decomposition. Assume that $\Omega$ is a bounded connected domain in $\mathbb{R}^2$ with Lipschitz boundary. If $z \in L^2(\Omega)$ and $u$ is the solution of (5), then its Euler–Lagrange equation can be written as

$$u + v = z \quad \text{where } v = -\frac{1}{\lambda}\operatorname{div}\left(\frac{Du}{|Du|}\right).$$

This type of decompositions is called a $u + v$ decomposition and $u$ is supposed to be a geometric sketch of the image [26]. As we have shown in the previous section, model (5) does not attain its objective of separating an image into its $u + v$ decomposition. This conclusion was also derived in [26] through complementary arguments. For instance, if $z = \chi_\omega$ where $\omega$ is a bounded domain with a $C^\infty$ boundary, then $z$ is not preserved by the Rudin–Osher–Fatemi (ROF) model (contrary to what it should be expected). The $v$ component contains the noise but also part of the image structure and, in particular, part of the texture (depending on the value of $\lambda$). On the other hand if $z(x) = \chi_A(x) + p(mx)\chi_B(x)$ where $A$ and $B$ are two bounded domains with smooth boundary, $m \geq 1$, and $p(x)$, $x = (x_1, x_2)$, is a smooth $2\pi$-periodic function of the two variables $x_1$, $x_2$, then the ROF model does not give $u(x) = \chi_A(x)$, $v(x) = p(mx)\chi_B(x)$ [26] (this will be explained after Theorem 3.1). Then to improve the ROF model Meyer proposed a different decomposition [26], which is based in the following variational model

$$\inf_{u \in \mathrm{BV}(\Omega), v \in G(\Omega), z = u+v} \int_\Omega |Du|\,dx + \lambda \|v\|_G,$$

where $\lambda > 0$ and $G(\Omega)$ denotes the Banach space of distributions $f$ in $\Omega$ that may be written

$$f = \operatorname{div} \xi$$

where $\xi \in L^\infty(\Omega; \mathbb{R}^2)$. The norm in $G$ is defined by

$$\|f\|_G := \inf\{\|\xi\|_\infty : \xi \in L^\infty(\Omega; \mathbb{R}^2),\ f = \operatorname{div}\xi\}$$

where $\|\xi\|_\infty := \operatorname{ess\,sup}_{x\in\Omega} |\xi(x)|$. $G(\Omega)$ is exactly $W^{-1,\infty}(\Omega)$, the dual space of $W_0^{1,1}(\Omega)$. The justification for the introduction of the space $G$ comes from the next result [26].

**Theorem 3.1.** *Let $f_n$ be a sequence of functions in $L^2(\Omega)$ with the following properties*

(i) *There exists a compact set $K \subset \Omega$ such that the support of $f_n$ is contained in $K$ for each $n$,*

(ii) *There exists $q > 2$ and $C > 0$ such that $\|f_n\|_q \leq C$,*

(iii) *The sequence $f_n$ converges to 0 in a distributional sense.*

*Then $\|f_n\|_G$ converges to 0 as $n \to \infty$.*

In other words, oscillating textures have a small norm in $G(\Omega)$. Now, if $z(x) = \chi_A(x) + p(mx)\chi_B(x)$ is as in the first paragraph of this section, then $v$ cannot be $p(mx)\chi_B(x)$ for large $m$ [26]. Otherwise we would have $p(mx)\chi_B(x) = -\frac{1}{\lambda}\operatorname{div}\left(\frac{Du}{|Du|}\right)$ and therefore $\|p(mx)\chi_B(x)\|_G = \frac{1}{\lambda}$. But we know from Theorem 3.1 that the $G$-norm of $p(mx)\chi_B(x)$ is small for large values $m$ (indeed the $G$-norm of $p(mx)\chi_B(x)$ is an $O(m^{-1})$ [26]).

Theorem 3.1 and other results [26], [25] were the starting point of extensive numerical work on $u + v$ decompositions [32], [28], [10], [9] to explore and compare the relative ability of the $G$ based model versus the ROF model. Meyer's model was first implemented by Vese–Osher in [32]. A different approach was proposed in [10], [9] where the decomposition is computed by minimizing a convex functional which depends on the two variable $u$ and $v$, alternatively in each variable. Each minimization is based on the projection algorithm introduced in [16]. The problem to solve is:

$$\inf_{(u,v)\in \mathrm{BV}(\Omega)\times\mu B_G} \int_\Omega |Du| + \frac{\lambda}{2}\int_\Omega |z-u-v|^2\,dx, \tag{8}$$

where $B_G := \{v \in G : \|v\|_G \leq 1\}$. We refer to [10] for its precise connection with Meyer's model. Let us mention that other dual Sobolev norms, indeed $H^{-1}$, have been explored in [28].

Figure 3 displays the comparison between ROF and model (8) for a simple figure. These images are courtesy of J. F. Aujol and A. Chambolle and have been obtained with the numerical methods developed by the authors in [9], [10]. Figures 3.a and 3.b display the original reference image and the noisy image with an additive Gaussian white noise with $\sigma = 35$. Figures 3.c and 3.d display the $u$ and $v$ components obtained with the ROF model with $\lambda$ chosen so that $\|v\| = \sigma$. For better visualization, the $v$ component will be always displayed as $v + 128$. Figures 3.e and 3.f display the $u$ and $v$ components obtained with model (8) with $\lambda = 10$ and $\mu = 55$ (for more details on the choice of parameters, see [9], [10]). In this case, for well chosen values of the parameter, the results are quite comparable. But let us point out that model (8) is able

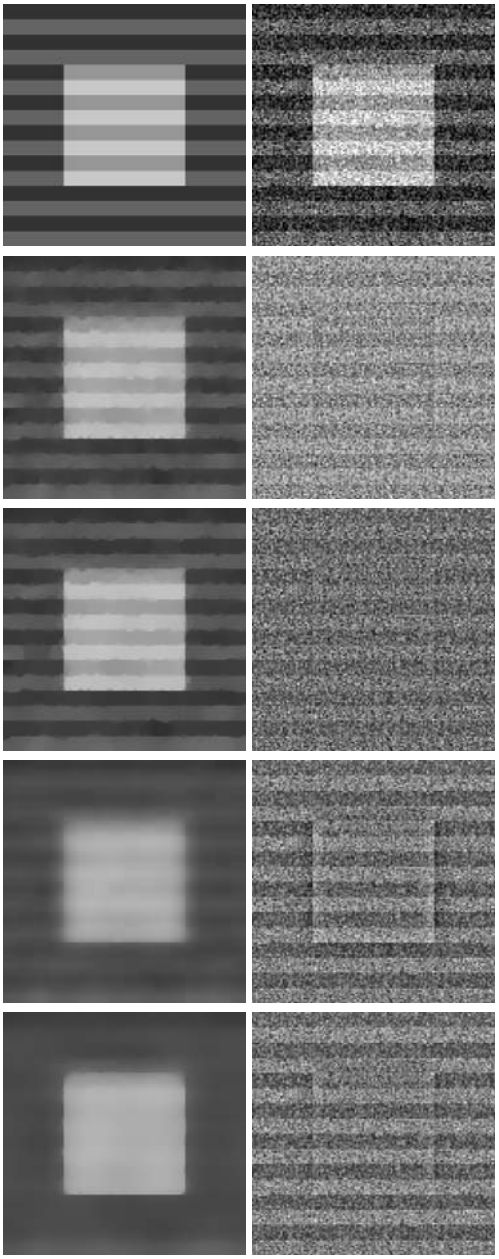

Figure 3. *Comparison of ROF and model* (8). From left to right and top to bottom: a) Original reference image. b) Noisy image with $\sigma = 35$. c) and d) Result of the ROF model: $u$ and $v$ component (with $\lambda$ chosen so that $\|v\| = \sigma$). For a better visualization, the $v$ component will be displayed as $v + 128$. e) and f) Result of model (8): $u$ and $v$ component ($\lambda = 10$, $\mu = 55$). g) and h) Result of the ROF model: $u$ and $v$ component (in this case $\sigma = 40.8$). i) and j) Result of model (8): $u$ and $v$ component (in this case $\sigma = 40.8$ and $\mu = 200$). These images are courtesy of J. F. Aujol and A. Chambolle. See the text for more details.

to separate the horizontal bands from the square for large values of the parameter $\mu$ while this does not seem to be possible with the ROF model. This is displayed in the next figures. Figures 3.g and 3.h display the $u$ and $v$ components obtained with the ROF model (the noise corresponds to a value of $\sigma = 40.8$) with $\lambda$ chosen so that $\|v\| = \sigma$. Figures 3.i and 3.j display the $u$ and $v$ components obtained with model (8) with $\mu = 200$. In any case, the choice of the parameters is open to further analysis and it the separation of the image in two components is related to the different scales present in the image.

## 4. Image restoration

To approach the problem of image restoration from a numerical point of view we shall assume that the image formation model incorporates the sampling process in a regular grid

$$z(i, j) = h * u(i, j) + n(i, j), \quad (i, j) \in \{1, \dots, N\}^2 \tag{9}$$

where $u\colon \mathbb{R}^2 \to \mathbb{R}$ denotes the ideal undistorted image, $h\colon \mathbb{R}^2 \to \mathbb{R}$ is a blurring kernel, $z$ is the observed sampled image which is represented as a function $z\colon \{1, \dots, N\}^2 \to \mathbb{R}$, and $n(i, j)$ is, as usual, a white Gaussian noise with zero mean and standard deviation $\sigma$.

Let us denote by $\Omega_N$ the interval $(0, N]^2$. As we said in the introduction, in order to simplify this problem, we assume that the functions $h$ and $u$ are periodic of period $N$ in each direction. That amounts to neglecting some boundary effects. Therefore, we assume that $h, u$ are functions defined in $\Omega_N$. To fix ideas, we assume that $h, u \in L^2(\Omega_N)$, so that $h * u$ is a continuous function in $\Omega_N$ (which may be extended to a continuous periodic function in $\mathbb{R}^2$) and the samples $h * u(i, j)$, $(i, j) \in \{1, \dots, N\}^2$, have sense.

Our next purpose is to introduce a restoration model with local constraints and to explain the numerical approach to solve it. For that, let us introduce some notation. We denote by $X$ the Euclidean space $\mathbb{R}^{N\times N}$. Then the image $u \in X$ is the vector $u = (u(i, j))_{i,j=1}^N$, and the vector field $\xi$ is the map $\xi\colon \{1, \dots, N\} \times \{1, \dots, N\} \to \mathbb{R}^2$. If $u \in X$, the discrete gradient is a vector in $Y = X \times X$ given by

$$\nabla^{+,+}u := (\nabla_x^+ u, \nabla_y^+ u),$$

where

$$\nabla_x^+ u(i, j) = \begin{cases} u(i+1, j) - u(i, j) & \text{if } i < N, \\ 0 & \text{if } i = N, \end{cases}$$

$$\nabla_y^+ u(i, j) = \begin{cases} u(i, j+1) - u(i, j) & \text{if } j < N, \\ 0 & \text{if } j = N, \end{cases}$$

for $i, j \in \{1, \dots, N\}$. We denote $\nabla^{+,+}u = (\nabla_x^+ u, \nabla_y^+ u)$. Other choices of the gradient are possible, this one will be convenient for the developments below.

Let us define the discrete functional

$$J_d^\beta(u) = \sum_{1 \le i,j \le N} \sqrt{\beta^2 + |\nabla^{+,+}u(i,j)|^2}, \quad \beta \ge 0.$$

For any function $w \in L^2(\Omega_N)$, its Fourier coefficients are

$$\hat{w}_{\frac{l}{N},\frac{j}{N}} = \int_{\Omega_N} w(x,y) e^{-2\pi i \frac{(lx+jy)}{N}} \quad \text{for } (l,j) \in \mathbb{Z}^2.$$

Our plan is to compute a band limited approximation to the solution of the restoration problem for (9). For that we define

$$\mathcal{B} := \left\{ u \in L^2(\Omega_N) : \hat{u} \text{ is supported in } \{-\tfrac{1}{2} + \tfrac{1}{N}, \dots, \tfrac{1}{2}\} \right\}.$$

We notice that $\mathcal{B}$ is a finite dimensional vector space of dimension $N^2$ which can be identified with $X$. Both $J(u) = \int_{\Omega_N} |Du|$ and $J_d^0(u)$ are norms on the quotient space $\mathcal{B}/\mathbb{R}$, hence they are equivalent. With a slight abuse of notation we shall indistinctly write $u \in \mathcal{B}$ or $u \in X$.

We shall assume that the convolution kernel $h \in L^2(\Omega_N)$ is such that $\hat{u}$ is supported in $\left\{ -\frac{1}{2} + \frac{1}{N}, \dots, \frac{1}{2} \right\}$ and $\hat{h}(0,0) = 1$.

In the discrete framework, the ROF model for restoration is

$$\text{Minimize}_{u \in X} \quad J_d^\beta(u) \tag{10}$$

$$\text{subject to} \quad \sum_{i,j=1}^{N} |h * u(i,j) - z(i,j)|^2 \le \sigma^2 N^2. \tag{11}$$

Notice again that the image acquisition model (1) is only incorporated through a global constraint. In practice, the above problem is solved via the following unconstrained formulation

$$\min_{u \in X} \max_{\lambda \ge 0} J_d^\beta(u) + \frac{\lambda}{2}\Big[ \frac{1}{N^2} \sum_{i,j=1}^{N} |h * u(i,j) - z(i,j)|^2 - \sigma^2 \Big] \tag{12}$$

where $\lambda \ge 0$ is a Lagrange multiplier. The appropriate value of $\lambda$ can be computed using Uzawa's algorithm [15], [2] so that the constraint (11) is satisfied. Recall that if we interpret $\lambda^{-1}$ as a penalization parameter which controls the importance of the regularization term, and we set this parameter to be small, then homogeneous zones are well denoised while highly textured regions will loose a great part of its structure. On the contrary, if $\lambda^{-1}$ is set to be small, texture will be kept but noise will remain in homogeneous regions. On the other hand, as the authors of [15], [2] observed, if we use the constrained formulation (10)-(11) or, equivalently (12), then

the Lagrange multiplier does not produce satisfactory results since we do not keep textures and denoise flat regions simultaneously, and they proposed to incorporate the image acquisition model as a set of local constraints.

Following [2], we propose to replace the constraint (11) by

$$G*(h*u-z)(i,j) \le \sigma^2, \quad \text{for all } (i,j) \in \{1,\dots,N\}, \tag{13}$$

where $G$ is a discrete convolution kernel such that $G(i,j) > 0$ for all $(i,j) \in \{1,\dots,N\}$. The effective support of $G$ must permit the statistical estimation of the variance of the noise with (13) (see [2]). Then we shall minimize the functional $J_d^\beta(u)$ on $X$ submitted to the family of constraints (13) (plus eventually the constraint $\sum_{i,j=1}^N h*u(i,j) = \sum_{i,j=1}^N z(i,j)$). Thus, we propose to solve the optimization problem:

$$\begin{aligned} &\min_{u\in\mathcal{B}} J_d^\beta(u) \\ &\text{subject to} \quad G*(h*u-z)^2(i,j) \le \sigma^2 \quad \text{for all } (i,j). \end{aligned} \tag{14}$$

This problem is well-posed, i.e., there exists a solution and is unique if $\beta > 0$ and $\inf_{c\in\mathbb{R}} G*(z-c)^2 > \sigma^2$. In case that $\beta = 0$ and $\inf_{c\in\mathbb{R}} G*(z-c)^2 > \sigma^2$, then $h*u$ is unique. Moreover, it can be solved with a gradient descent approach and Uzawa's method [2].

To guarantee that the assumptions of Uzawa's method hold we shall use a gradient descent strategy. For that, let $v \in X$ and $\gamma > 0$. At each step we have to solve a problem like

$$\begin{aligned} &\min_{u\in\mathcal{B}} \gamma|u-v|_X^2 + J_d^\beta(u) \\ &\text{subject to} \quad G*(h*u-z)^2(i,j) \le \sigma^2 \quad \text{for all } (i,j). \end{aligned} \tag{15}$$

We solve (15) using the unconstrained formulation

$$\min_{u\in X} \max_{\lambda\ge 0} \mathcal{L}^\gamma(u,\{\lambda\};v),$$

where $\lambda = (\lambda(i,j))_{i,j=1}^N$ and

$$\mathcal{L}^\gamma(u,\{\lambda\};v) = \gamma|u-v|_X^2 + J_d^\beta(u) + \sum_{i,j=1}^N \lambda(i,j)(G*(h*u-z)^2(i,j)-\sigma^2).$$

**Algorithm: TV based restoration algorithm with local constraints**

1. Set $u^0 = 0$ or, better, $u^0 = z$. Set $n = 0$.
2. Use Uzawa's algorithm to solve the problem

$$\min_{u\in X} \max_{\lambda\ge 0} \mathcal{L}^\gamma(u,\{\lambda\};u^n), \tag{16}$$

that is:

(a) Choose any set of values $\lambda^0(i,\, j) \geq 0$, $(i,\, j) \in \{1, \ldots, N\}^2$, and $u_0^n = u^n$. Iterate from $p = 0$ until convergence of $\lambda^p$ the following steps:

(b) With the values of $\lambda^p$ solve the problem

$$\min_u \mathcal{L}^\gamma(u, \{\lambda^p\}; u^n)$$

starting with the initial condition $u_p^n$. Let $u_{p+1}^n$ be the solution obtained.

(c) Update $\lambda$ in the following way:

$$\lambda^{p+1}(i,\, j) = \max(\lambda^p(i,\, j) + \rho(G * (h * u_p^n - z)^2(i,\, j) - \sigma^2), 0)$$

for all $(i,\, j)$.

Let $u^{n+1}$ be the solution of (16). Stop when convergence of $u^n$.

We notice that, since $\gamma > 0$, Uzawa's algorithm converges if $z \in h * \mathcal{B}$. Moreover, if $u^0$ satisfies the constraints, then $u^n$ tends to a solution $u$ of (14) as $n \to \infty$ [2].

Finally, to solve problem (16) in Step 2.(b) of the algorithm we use either the extension of Chambolle's algorithm [16] to the restoration case given in [1] if we use $\beta = 0$, or the Bermúdez–Moreno algorithm [14] adapted to solve (16) when $\beta > 0$ as given in [2]. Being differentiable at when $\nabla^{+,+}u = 0$, this second possibility produces slightly smoother solutions in smooth non textured areas. We shall not enter on the comparison of both possibilities here and we shall use $\beta = 0$. For more details, we refer to [1], [2].

Let us mention the work [23] where the authors introduce a spatially varying fidelity term which controls the amount of denoising in any region of the image in order to preserve textures and small details. The philosophy is the same as ours but the value of $\lambda(i,\, j)$ is chosen in a different way.

## 5. Some restoration experiments

To simulate our data we use the modulation transfer function corresponding to SPOT 5 HRG satellite with Hipermode sampling (see [29] for more details):

$$\hat{h}(\eta_1, \eta_2) = e^{-4\pi\beta_1|\eta_1|} e^{-4\pi\alpha\sqrt{\eta_1^2+\eta_2^2}} \operatorname{sinc}(2\eta_1) \operatorname{sinc}(2\eta_2) \operatorname{sinc}(\eta_1), \qquad (17)$$

where $\eta_1, \eta_2 \in [-1/2, 1/2]$, $\operatorname{sinc}(\eta_1) = \sin(\pi\eta_1)/(\pi\eta_2)$, $\alpha = 0.58$, and $\beta_1 = 0.14$. Then we filter the reference image given in Figure 4.a with the filter (17) and we add some Gaussian white noise of zero mean and standard deviation $\sigma$ (in our case $\sigma = 1$, which is a realistic assumption for the case of satellite images [29]) to obtain the image displayed in Figure 4.b.

Figure 5.a displays the restoration of the image in Figure 4.b obtained using the algorithm of last section with $\beta = 0$. We have used a Gaussian function $G$ of standard deviation $\sigma = 6$. The mean value of the constraint is $\text{mean}((G*(Ku-z))^2) = 1.0933$ and RMSE $= 7.9862$. Figure 5.b displays the function $\lambda(i,\, j)$ obtained.

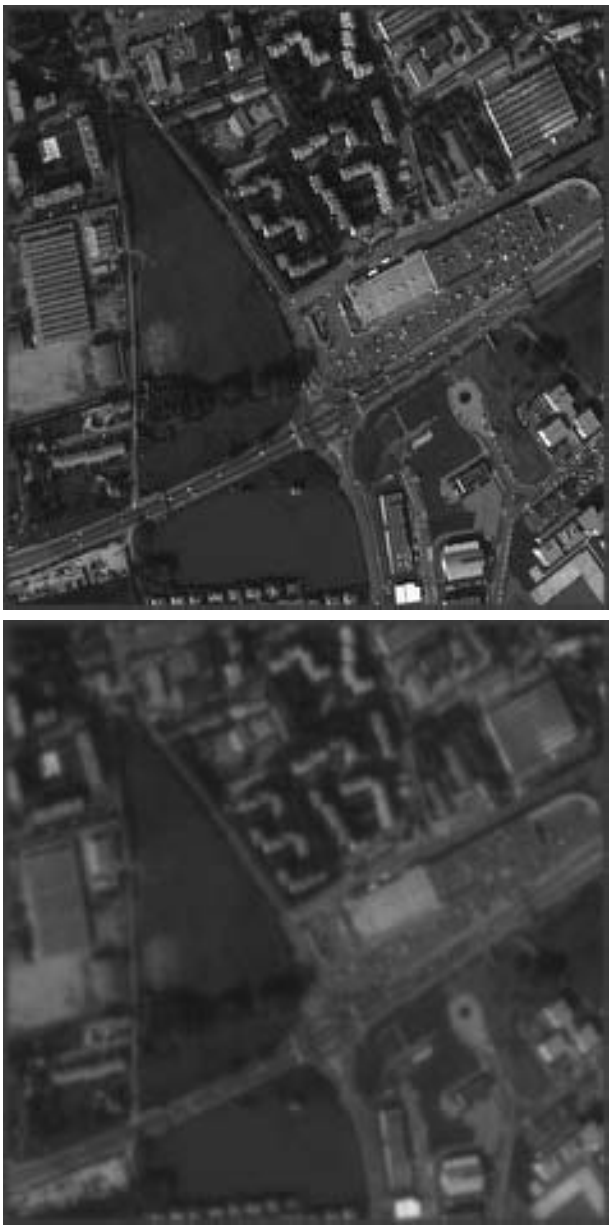

Figure 4. *Reference image and a filtered and noised image.* a) Top: reference image. b) Bottom: the data. This image has been generated applying the MTF given in (17) to the top image and adding a Gaussian white noise of zero mean and standard deviation $\sigma = 1$.

Figure 6 displays some details of the results that are obtained using a single global constraint (11) and show its main drawbacks. Figure 6.a corresponds to the result obtained with the Lagrange multiplier $\lambda = 10$ (thus, the constraint (11) is satisfied). The result is not satisfactory because it is difficult to denoise smooth regions and keep the textures at the same time. Figure 6.b shows that most textures are lost when using a small value of $\lambda$ ($\lambda = 2$) and Figure 6.c shows that some noise is present if we use a larger value of $\lambda$ ($\lambda = 1000$). This result is to be compared with the same detail of Figure 5.a which is displayed in Figure 6.d.

**The modulation transfer function for satellite images.** We describe here a simple model for the Modulation Transfer Function of a general satellite. More details can be found in [29] where specific examples of MTF for different acquisition systems are shown. The MTF used in our experiments (17) corresponds to a particular case of the general model described below [29].

Recall that the MTF, that we denote by $\hat{h}$, is the Fourier transform of the impulse response of the system. Let $(\eta_1, \eta_2) \in [-1/2, 1/2]$ denote the coordinates in the frequency domain. There are different parts in the acquisition system that contribute to the global transfer function:

**Sensors.** Every sensor has a sensitive region where all the photons that arrive are integrated. This region can be approximated by a unit square $[-c/2, c/2]^2$ where $c$ is the distance between consecutive sensors. Its impulse response is then the convolution of two pulses, one in each spatial direction. The corresponding transfer function also includes the effect of the conductivity (diffusion of information) between neighbouring sensors, which is modeled by an exponential decay factor, thus:

$$\hat{h}_S(\eta_1, \eta_2) = \operatorname{sinc}(\eta_1 c)\operatorname{sinc}(\eta_2 c) e^{-2\pi\beta_1 c|\eta_1|} e^{-2\pi\beta_2 c|\eta_2|},$$

where $\operatorname{sinc}(\eta_1) = \sin(\pi\eta_1)/(\pi\eta_1)$ and $\beta_1, \beta_2 > 0$.

**Optical system.** It is considered as an isotropic low-pass filter

$$\hat{h}_O(\eta_1, \eta_2) = e^{-2\pi\alpha c\sqrt{\eta_1^2+\eta_2^2}}, \quad \alpha > 0.$$

**Motion.** Each sensor counts the number of photons that arrive to its sensitive region during a certain time of acquisition. During the sampling time the system moves a distance $\tau$ and so does the sensor; this produces a motion blur effect in the motion direction $(d_1, d_2)$:

$$\hat{h}_M(\eta_1, \eta_2) = \operatorname{sinc}(\langle(\eta_1, \eta_2), (d_1, d_2)\rangle\tau).$$

Finally, the global MTF is the product of each of these intermediate transfer functions modeling the different aspects of the satellite:

$$\hat{h}(\eta_1, \eta_2) = \hat{h}_S\hat{h}_O\hat{h}_M.$$

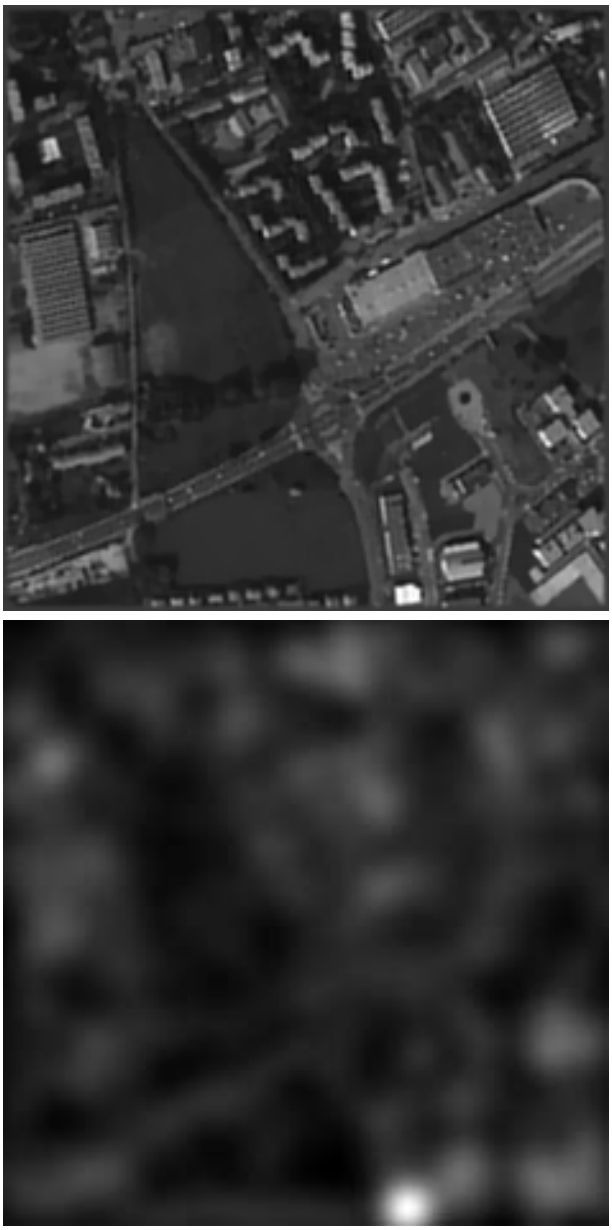

Figure 5. *Restored image with local Lagrange multipliers.* a) Top: the restored image corresponding to the data given in Figure 4.b. The restoration has been obtained using the algorithm of last section We have used a Gaussian function $G$ of standard deviation $\sigma = 6$. b) Bottom: the function $\lambda(i, j)$ obtained.

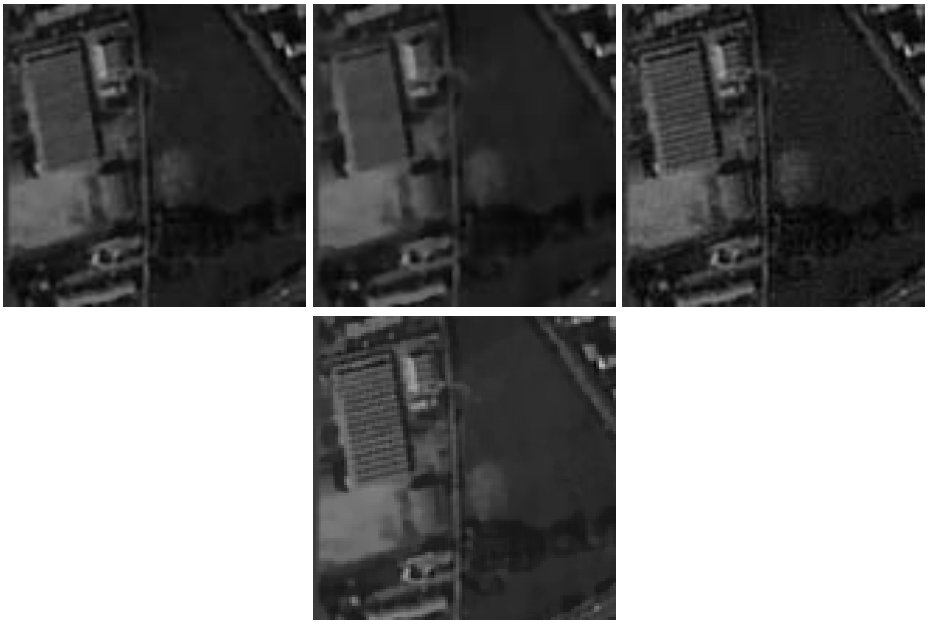

Figure 6. *A detail of the restored images with global and local constraints.* Top: a), b) and c) display a detail of the results that are obtained using a single global constraint (11) and show its main drawbacks. Figure a) corresponds to the result obtained with the value of $\lambda$ such that the constraint (11) is satisfied, in our case $\lambda = 10$. Figure b) shows that most textures are lost when using a small value of $\lambda$ ($\lambda = 2$)and Figure c) shows that some noise is present if we use a larger value of $\lambda$ ($\lambda = 1000$). Bottom: d) displays the same detail of Figure 5.a which has been obtained using restoration with local constraints.

# A wavelet based sparse grid method for the electronic Schrödinger equation

Michael Griebel and Jan Hamaekers*

**Abstract.** We present a direct discretization of the electronic Schrödinger equation. It is based on one-dimensional Meyer wavelets from which we build an anisotropic multiresolution analysis for general particle spaces by a tensor product construction. We restrict these spaces to the case of antisymmetric functions. To obtain finite-dimensional subspaces we first discuss semi-discretization with respect to the scale parameter by means of sparse grids which relies on mixed regularity and decay properties of the electronic wave functions. We then propose different techniques for a discretization with respect to the position parameter. Furthermore we present the results of our numerical experiments using this new generalized sparse grid methods for Schrödinger's equation.

**Mathematics Subject Classification (2000).** 35J10, 65N25, 65N30, 65T40, 65Z05.

**Keywords.** Schrödinger equation, numerical approximation, sparse grid method, antisymmetric sparse grids.

## 1. Introduction

In this article we consider the electronic Schrödinger equation (first without spin for reasons of simplicity)

$$H\Psi(\boldsymbol{x}_1,\ldots,\boldsymbol{x}_N) = E\Psi(\boldsymbol{x}_1,\ldots,\boldsymbol{x}_N) \tag{1}$$

with the Hamilton operator

$$H = T + V \quad \text{where } T = -\frac{1}{2}\sum_{p=1}^{N}\Delta_p$$

and

$$V = -\sum_{p=1}^{N}\sum_{q=1}^{N_{\text{nuc}}}\frac{Z_q}{|\boldsymbol{x}_p - \boldsymbol{R}_q|_2} + \sum_{p=1}^{N}\sum_{q>p}^{N}\frac{1}{|\boldsymbol{x}_p - \boldsymbol{x}_q|_2}. \tag{2}$$

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

Here, with $d = 3$, $\boldsymbol{x}_p := (x_{1,p}, \ldots, x_{d,p}) \in \mathbb{R}^d$ denotes the position of the $p$-th electron, $p = 1 \ldots, N$, and $\boldsymbol{R}_q \in \mathbb{R}^d$ denotes the fixed position of the $q$-th nucleus, $q = 1, \ldots, N_{\text{nuc}}$. The operator $\Delta_p$ is the Laplacian acting on the $\boldsymbol{x}_p$-component of $\Psi$, i.e. $\Delta_p = \sum_{i=1}^{d} \partial^2/\partial(x_{i,p})^2$, $Z_q$ is the charge of the $q$-th nucleus and the norm $|\,.\,|_2$ denotes the usual Euclidean distance in $\mathbb{R}^d$. The solution $\Psi$ describes the wave function associated to the eigenvalue $E$.

This eigenvalue problem results from the Born–Oppenheimer approximation [51] to the general Schrödinger equation for a system of electrons and nuclei which takes the different masses of electrons and nuclei into account. It is one of the core problems of computational chemistry. Its successful treatment would allow to predict the properties of arbitrary atomic systems and molecules [22]. However, except for very simple cases, there is no analytical solution for (1) available. Also a direct numerical approach is impossible since $\Psi$ is a $d \cdot N$-dimensional function. Any discretization on e.g. uniform grids with $O(K)$ points in each direction would involve $O(K^{d \cdot N})$ degrees of freedoms which are impossible to store for $d = 3$, $N > 1$. Here, we encounter the curse of dimensionality [8]. Therefore, most approaches resort to an approximation of (1) only. Examples are the classical Hartree–Fock method and its successive refinements like configuration interaction and coupled clusters. Alternative methods are based on density functional theory which result in the Kohn–Sham equations or the reduced density matrix (RDM) [50] and the r12 approach [23] which lead to improved accuracy and open the way to new applications. A survey of these methods can be found in [3], [10], [46]. A major problem with these techniques is that, albeit quite successful in practice, they nevertheless only provide approximations. A systematical improvement is usually not available such that convergence of the model to Schrödinger's equation is achieved.

Instead, we intend to directly discretize the Schrödinger equation without resorting to any model approximation. To this end, we propose a new variant of the so-called sparse grid approach. The sparse grid method is a discretization technique for higher-dimensional problems which promises to circumvent the above-mentioned curse of dimensionality provided that certain smoothness prerequisites are fulfilled. Various sparse grid discretization methods have already been developed in the context of integration problems [27], [28], integral equations [24], [32] and elliptic partial differential equations, see [12] and the references cited therein for an overview. In Fourier space, such methods are also known under the name hyperbolic cross approximation [5], [21], [61]. A first heuristic approach to apply this methodology to the electronic Schrödinger equation was presented in [26]. The sparse grid idea was also used in the fast evaluation of Slater determinants in [33]. Recently Yserentant showed in [67] that the smoothness prerequisite necessary for sparse grids is indeed valid for the solution of the electronic Schrödinger equation. To be more precise, he showed that an antisymmetric solution of the electronic Schrödinger equation with $d = 3$ possesses $\mathcal{H}^{1,1}_{\text{mix}}$- or $\mathcal{H}^{1/2,1}_{\text{mix}}$-regularity for the fully antisymmetric and the partially symmetric case, respectively. This motivated the application of a generalized sparse grid approach in Fourier space to the electronic Schrödinger equation as presented

in [30]. There, sparse grids for general particle problems as well as antisymmetric sparse grids have been developed and were applied to (1) in the periodic setting. Basically, estimates of the type

$$\|\Psi - \Psi_M\|_{\mathcal{H}^1} \leq C(N,d) \cdot M^{-1/d} \cdot \|\Psi\|_{\mathcal{H}^{1,1}_{\text{mix}}}$$

could be achieved where $M$ denotes the number of Fourier modes used in the discretization. Here, the norm $\|.\|_{\mathcal{H}^{1,1}_{\text{mix}}}$ involves bounded mixed first derivatives. Thus the order of the method with respect to $M$ is asymptotically independent of the dimension of the problem, i.e. the number $N$ of electrons. But, the constants and the $\mathcal{H}^{1,1}_{\text{mix}}$-norm of the solution nevertheless depend on the number of electrons. While the dependency of the order constant might be analysed along the lines of [29], the problem remains that the smoothness term $\|\Psi\|_{\mathcal{H}^{1,1}_{\text{mix}}}$ grows exponentially with the number of electrons. This could be seen from the results of the numerical experiments in [30] and was one reason why in the periodic Fourier setting problems with higher numbers of electrons could not be treated. It was also observed in [69] where a certain scaling was introduced into the definitions of the norms which compensates for this growth factor. In [68], [70] it was suggested to scale the decomposition of the hyperbolic cross into subspaces accordingly and to further approximate each of the subspace contributions by some individually properly truncated Fourier series to cope with this problem.

In this article, we present a modified sparse grid/hyperbolic cross discretization for the electronic Schrödinger equation which implements this approach. It uses one-dimensional Meyer wavelets as basic building blocks in a tensor product construction to obtain a $\mathcal{L}^2$-orthogonal multiscale basis for the many-electron space. Then a truncation of the associated series expansion results in sparse grids. Here, for the level index we truncate according to the idea of hyperbolic crosses whereas we truncate for the position index according to various patterns which take to some extent the decay of the scaling function coefficients for $x \to \infty$ into account. Note that since we work in an infinite domain this resembles a truncation to a compact domain in which we then consider a local wavelet basis. Here, domain truncation error and scale resolution error should be balanced. Antisymmetry of the resulting discrete wavelet basis is achieved by a restriction of the active indices.

The remainder of this article is organized as follows: In Section 2 we present the Meyer wavelet family on $\mathbb{R}$ and discuss its properties. In Section 3 we introduce a multiresolution analysis for many particle spaces build by a tensor product construction from the one-dimensional Meyer wavelets and introduce various Sobolev norms. Then we discuss semi-discretization with respect to the scale parameter by means of generalized sparse grids and present a resulting error estimate in Section 4. Section 5 deals with antisymmetric generalized sparse grids. In Section 6 we invoke results on the mixed regularity of electronic wave functions and we discuss rescaling of norms and sparse grid spaces to obtain error bounds which involve the $\mathcal{L}^2$-norm of the solution instead of the mixed Sobolev norm. Then, in Section 7 we comment on the setup

of the system matrix and on the solution procedure for the discrete eigenvalue problem on general sparse grids and we propose different techniques for the discretization with respect to the position parameter. Furthermore we present the results of our numerical experiments. Finally we give some concluding remarks in Section 8.

## 2. Orthogonal multilevel bases and the Meyer wavelet family on $\mathbb{R}$

We intend to use for the discretization of (1) a $\mathcal{L}^2$-orthogonal basis system.[1] This is an important prerequisite from the practical point of view, since it allows to apply the well-known Slater–Condon rules. They reduce the $\mathbb{R}^{d\cdot N}$- and $\mathbb{R}^{2\cdot d\cdot N}$-dimensional integrals necessary in the Galerkin discretization of the one- and two electron part of the potential function of (1) to short sums of $d$-dimensional and $2d$-dimensional integrals, respectively. Otherwise, due to the structure of the Slater determinants necessary to obtain antisymmetry, these sums would contain exponentially many terms with respect to the number $N$ of electrons present in the system.

Let us recall the definition of a multiresolution analysis on $\mathbb{R}$, see also [52]. We consider an infinite sequence

$$\cdots \subset V_{-2} \subset V_{-1} \subset V_0 \subset V_1 \subset V_2 \subset \cdots$$

of nested spaces $V_l$ with $\bigcap_{l\in\mathbb{Z}} V_l = 0$ and $\overline{\bigcup_{l\in\mathbb{Z}} V_l} = \mathcal{L}^2(\mathbb{R})$. It holds $f(x) \in V_l \Leftrightarrow f(2x) \in V_{l+1}$ and $f(x) \in V_0 \Leftrightarrow f(x-j) \in V_0$, where $j \in \mathbb{Z}$. Furthermore, there is a so-called scaling function (or father wavelet) $\phi \in V_0$, such that $\{\phi(x-j) \,:\, j \in \mathbb{Z}\}$ forms an orthonormal basis for $V_0$. Then

$$\{\phi_{l,j}(x) = 2^{\frac{l}{2}}\phi(2^l x - j) \,:\, j \in \mathbb{Z}\}$$

forms an orthonormal basis of $V_l$ and we can represent any $u(x) \in V_l$ as $u(x) = \sum_{j=-\infty}^{\infty} v_{l,j}\phi_{l,j}(x)$ with coefficients $v_{l,j} := \int_{\mathbb{R}} \phi^*_{l,j}(x)u(x)dx$. With the definition

$$W_l \perp V_l,\ V_l \oplus W_l = V_{l+1} \tag{3}$$

we obtain an associated sequence of detail spaces $W_l$ with associated mother wavelet $\varphi \in W_0$, such that $\{\varphi(x-j) \,:\, j \in \mathbb{Z}\}$ forms an orthonormal basis for $W_0$. Thus

$$\{\varphi_{l,j}(x) = 2^{\frac{l}{2}}\varphi(2^l x - j) \,:\, j \in \mathbb{Z}\}$$

gives an orthonormal basis for $W_l$ and $\{\varphi_{l,j} \,:\, l, j \in \mathbb{Z}\}$ is an orthonormal basis of $\mathcal{L}^2(\mathbb{R})$. Then, we can represent any $u(x)$ in $\mathcal{L}^2(\mathbb{R})$ as

$$u(x) = \sum_{l=-\infty}^{\infty} \sum_{j=-\infty}^{\infty} u_{l,j}\varphi_{l,j}(x) \tag{4}$$

[1] Note that a bi-orthogonal system would also work here.

with the coefficients $u_{l,j} := \int_{\mathbb{R}} \varphi^*_{l,j}(x)u(x)dx$.

In the following we focus on the Meyer wavelet family for the choice of $\phi$ and $\varphi$. There, with the definition of the Fourier transform $\mathcal{F}[f](\omega) = \hat{f}(\omega) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} f(x)e^{-i\omega x}\,dx$ we set as father and mother wavelet in Fourier space

$$\hat{\phi}(\omega) = \frac{1}{\sqrt{2\pi}} \begin{cases} 1 & \text{for } |\omega| \leq \frac{2}{3}\pi, \\ \cos(\frac{\pi}{2}\nu(\frac{3}{2\pi}|\omega| - 1)) & \text{for } \frac{2\pi}{3} < |\omega| \leq \frac{4\pi}{3}, \\ 0 & \text{otherwise,} \end{cases} \tag{5}$$

$$\hat{\varphi}(\omega) = \frac{1}{\sqrt{2\pi}} e^{-i\frac{\omega}{2}} \begin{cases} \sin(\frac{\pi}{2}\nu(\frac{3}{2\pi}|\omega| - 1)) & \text{for } \frac{2}{3}\pi \leq |\omega| \leq \frac{4}{3}\pi, \\ \cos(\frac{\pi}{2}\nu(\frac{3}{4\pi}|\omega| - 1)) & \text{for } \frac{4\pi}{3} < |\omega| \leq \frac{8\pi}{3}, \\ 0 & \text{otherwise,} \end{cases} \tag{6}$$

where $\nu\colon \mathbb{R} \to \mathbb{R} \in C^r$ is a parameter function still do be fixed, which has the properties $\nu(x) = 0$ for $x \leq 0$, $\nu(x) = 1$ for $x > 1$ and $\nu(x) + \nu(1 - x) = 1$. By dilation and translation we obtain

$$\mathcal{F}[\phi_{l,j}](\omega) = \hat{\phi}_{l,j}(\omega) = 2^{-\frac{l}{2}} e^{-i2^{-l}j\omega} \hat{\phi}(2^{-l}\omega),$$
$$\mathcal{F}[\varphi_{l,j}](\omega) = \hat{\varphi}_{l,j}(\omega) = 2^{-\frac{l}{2}} e^{-i2^{-l}j\omega} \hat{\varphi}(2^{-l}\omega)$$

where the $\hat{\phi}_{l,j}$ and $\hat{\varphi}_{l,j}$ denote the dilates and translates of (5) and (6), respectively.

This wavelet family can be derived from a partition of unity $\sum_l \hat{\chi}_l(\omega) = 1$ for all $\omega \in \mathbb{R}$ in Fourier space, where

$$\hat{\chi}_l(\omega) = \begin{cases} 2\pi \hat{\phi}^*_{0,0}(\omega)\hat{\phi}_{0,0}(\omega) & \text{for } l = 0, \\ 2^l \pi \hat{\varphi}^*_{l-1,0}(\omega)\hat{\varphi}_{l-1,0}(\omega) & \text{for } l > 0, \end{cases} \tag{7}$$

see [4] for details. The function $\nu$ basically describes the decay from one to zero of one partition function $\hat{\chi}_l$ in the overlap with its neighbor. The smoothness of the $\hat{\chi}_l$ is thus directly determined by the smoothness of $\nu$. The mother wavelets $\hat{\varphi}_{l,j}$ and the father wavelets $\hat{\phi}_{l,j}$ in Fourier space inherit the smoothness of the $\hat{\chi}_l$'s via the relation (7).

There are various choices for $\nu$ with different smoothness properties in the literature, see [4], [45], [53], [54]. Examples are the Shannon wavelet and the raised cosine wavelet [63], i.e. (6) with

$$\nu(x) = \nu^0(x) := \begin{cases} 0 & \text{for } x \leq \frac{1}{2}, \\ 1 & \text{otherwise} \end{cases} \quad \text{and} \quad \nu(x) = \nu^1(x) \begin{cases} 0 & \text{for } x \leq 0, \\ x & \text{for } 0 \leq x \leq 1, \\ 1 & \text{otherwise} \end{cases} \tag{8}$$

or, on the other hand,

$$\nu(x) = \nu^{\infty}(x) := \begin{cases} 0 & \text{for } x \leq 0 \\ \frac{\tilde{\nu}(x)}{\tilde{\nu}(1-x)+\tilde{\nu}(x)} & \text{for } 0 < x \leq 1 \\ 1 & \text{otherwise} \end{cases} \quad \text{where } \tilde{\nu}(x) = \begin{cases} 0 & \text{for } x \leq 0 \\ e^{-\frac{1}{x^{\alpha}}} & \text{otherwise} \end{cases} \tag{9}$$

with $\alpha = 1, 2$ [62], respectively. Other types of Meyer wavelets with different smoothness properties can be found in [19], [34], [40], [65]. The resulting mother wavelet functions in real space and Fourier space are given in Figure 1. Note the

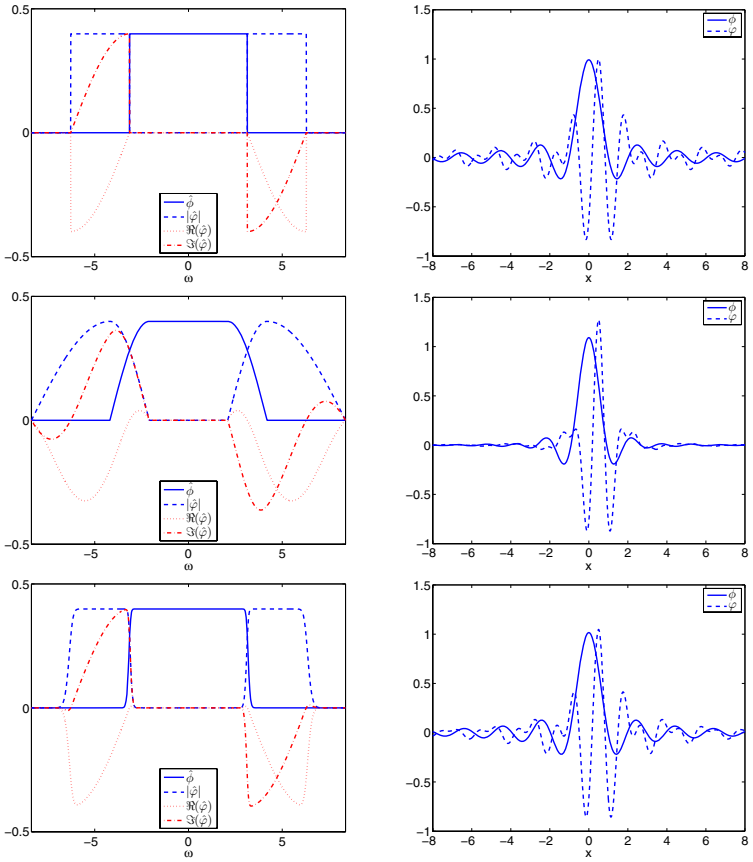

Figure 1. Top: (6) with $\nu^0$ from (8) in Fourier space (left) and real space (right). Middle: (6) with $\nu^1$ from (8) in Fourier space (left) and real space (right). Bottom: (6) with $\nu^{\infty}$ from (9) in Fourier space (left) and real space (right).

two symmetric areas of support and the associated two bands with non-zero values of the wavelets in Fourier space which resemble the line of construction due to Wilson,

Malvar, Coifman and Meyer [17], [20], [39], [49], [64] to circumvent the Balian–Low theorem[2] [7], [48]. In real space, these wavelets are $C^\infty$-functions with global support, in Fourier space, they are piecewise continuous, piecewise continuous differentiable and $C^\infty$, respectively, and have compact support. Furthermore they possess infinitely many vanishing moments. Finally their envelope in real space decays with $|x| \to \infty$ as $|x|^{-1}$ for $\nu^0$, as $|x|^{-2}$ for $\nu^1$ and faster than any polynomial (subexponentially) for $\nu^\infty$, respectively. To our knowledge, only for the Meyer wavelets with (8) there are analytical formulae in both real and Fourier space available. Certain integrals in a Galerkin discretization of (1) can then be given analytically. For the other types of Meyer wavelets analytical formulae only exist in Fourier space and thus numerical integration is necessary in a Galerkin discretization of (1).

For a discretization of (4) with respect to the level-scale $l$ we can restrict the doubly infinite sum to an interval, i.e. $l \in [L_1, L_2]$. However to obtain the space $V_{L_2}$ we have to complement the sum of detail spaces $W_l$, $l \in [L_1, L_2]$ by the space $V_{L_1}$, i.e. we have

$$V_{L_2} = V_{L_1} \oplus \bigoplus_{l=L_1}^{L_2} W_l.$$

with the associated representation

$$u(x) = \sum_{j=-\infty}^{\infty} v_{L_1,j}\phi_{L_1,j}(x) + \sum_{L_1}^{L_2}\sum_{j=-\infty}^{\infty} u_{l,j}\varphi_{l,j}(x).$$

Note that for the case of $\mathbb{R}$, beside the choice of a finest scale $L_2$, we here also have a choice of the coarsest scale $L_1$. This is in contrast to the case of a finite domain where the coarsest scale is usually determined by the size of the domain and is denoted as level zero.

Additionally we can scale our spaces and decompositions by a parameter $c > 0$, $c \in \mathbb{R}$. For example, we can set

$$V_l^c = \operatorname{span}\{\phi_{c,l,j}(x) = c^{\frac{1}{2}} 2^{\frac{l}{2}} \phi(c2^l x - j) \ : \ j \in \mathbb{Z}\}.$$

For $c = 2^k$, $k \in \mathbb{Z}$, the obvious identity $V_l^c = V_{l+k}^1$ holds. Then we obtain the scaled decomposition

$$V_{L_2}^c = V_{L_1}^c \oplus \bigoplus_{l=L_1}^{L_2} W_l^c$$

with the scaled detail spaces $W_l^c = \operatorname{span}\{\varphi_{c,l,j}(x) = c^{\frac{1}{2}} 2^{\frac{l}{2}} \varphi(c2^l x - j) \ : \ j \in \mathbb{Z}\}$. For $c = 2^k$, $k \in \mathbb{Z}$, the identity $W_l^c = W_{l+k}^1$ holds.

[2]The Balian–Low theorem basically states that the family of functions $g_{m,n}(x) = e^{2\pi i m x} g(x-n), m, n \in \mathbb{Z}$, which are related to the windowed Fourier transform, cannot be an orthonormal basis of $\mathcal{L}^2(\mathbb{R})$, if the two integrals $\int_{\mathbb{R}} x^2 |g(x)|^2 dx$ and $\int_{\mathbb{R}} k^2 |\hat{g}(k)|^2 dk$ are both finite. Thus there exists no orthonormal family for a Gaussian window function $g(x) = \pi^{-1/4} e^{-x^2/2}$ which is both sufficiently regular and well localized.

With the choice $c = 2^{-L_1}$ we can get rid of the parameter $L_1$ and may write our wavelet decomposition as

$$V_L^c = V_0^c \oplus \bigoplus_{l=0}^{L} W_l^c, \tag{10}$$

i.e. we can denote the associated coarsest space with level zero and the finest detail space with level $L$ (which now expresses the rescaled parameter $L_2$). To simplify notation we will skip the scaling index $c$ in the following.

We also introduce with

$$\psi_{l,j} := \begin{cases} \phi_{l,j}^c & \text{for } l = 0, \\ \varphi_{l-1,j}^c & \text{for } l \geq 1 \end{cases} \tag{11}$$

for $c = 2^{-L_1}$ a unique notation for both the father wavelets on the coarsest scale and the mother wavelets of the detail spaces. Bear however in mind that in the following the function $\psi_{l,j}$ with $l = 0$ denotes a father wavelet, i.e. a scaling function only, whereas it denotes for $l \geq 1$ a true wavelet on scale $l - 1$.

Let us finally consider the wavelet representation of the function $e^{-\sigma|x-x_0|}$ which is the one-dimensional analogon of the ground state wavefunction of hydrogen centered in $x_0 = 0$. For two types of Meyer wavelets, i.e. with $\nu^0$ from (8) and $\nu^\infty$ from (9) with $\alpha = 2$, Figure 2 gives the isolines to the values $10^{-3}$ and $10^{-4}$ for both the absolute value of the coefficients $v_{l,j}$ of the representation with respect to the scaling functions and the absolute value of the coefficients $u_{l,j}$ of the representation with respect to the wavelet functions.

Here we see the following: For the Meyer wavelet with $\nu^\infty$ from (9) where $\alpha = 2$, the isolines to different values (only $10^{-3}$ and $10^{-4}$ are shown) are nearly parallel for both the wavelet coefficients $u_{l,j}$ and the scaling coefficients $v_{l,j}$. For levels larger than $-2$ the isolines of the wavelet coefficients are even straight lines. Furthermore, on sufficiently coarse levels, the isoline for the wavelet coefficients and the scaling coefficients practically coincide. This is an effect of the $C^\infty$-property of the underlying mother wavelet. For the Meyer wavelet with $\nu^0$ from (8), i.e. for wavelets which are not $C^\infty$ in both real space *and* Fourier space, these two observations do not hold.

If we compare the isolines of the wavelet coefficients $u_{l,j}$ for the Meyer wavelet with $\nu^\infty$ from (9) where $\alpha = 2$ and that of the Meyer wavelet with $\nu^0$ from (8) we observe that the level on which the bottom kink occurs is exactly the same. However the size of the largest diameter (here roughly on level $-2$) is substantially bigger for the Shannon wavelet. Note the different scaling of the x-axis of the diagrams on the left and right side.

We furthermore observe for the isolines of the scaling coefficients an exponential behavior, i.e. from level $l$ to level $l + 1$ the associated value for $j$ nearly doubles in a sufficient distance away from point $x = 0$. With respect to the wavelet coefficients, however, we see that the support shrinks super-exponentially towards the bottom kink with raising level.

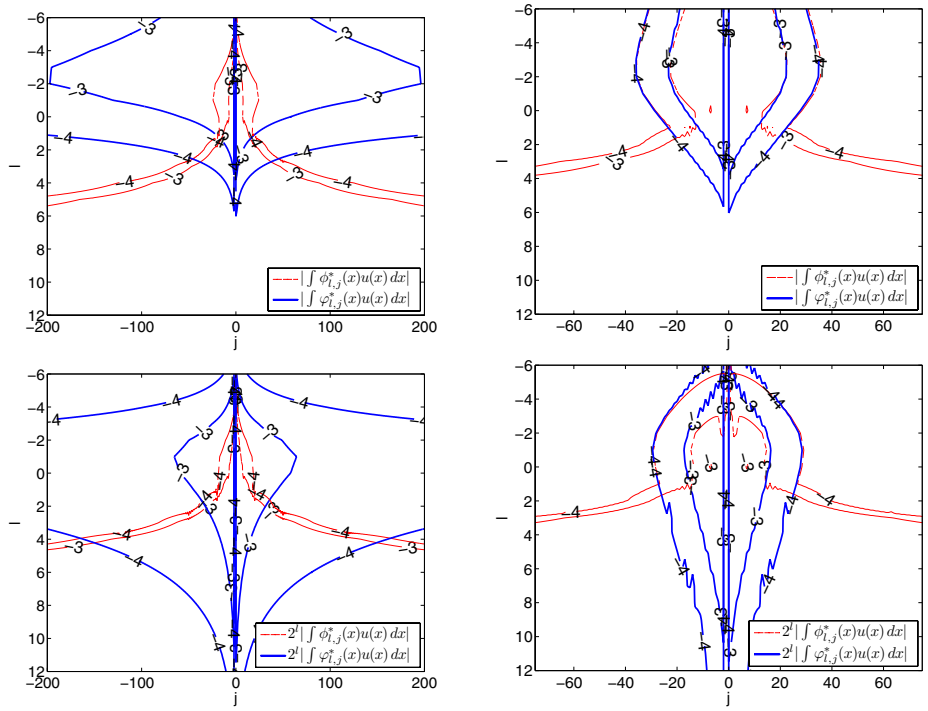

Figure 2. Isolines to the values $10^{-3}$ and $10^{-4}$ of the absolute value of the coefficients $v_{l,j}$ and $u_{l,j}$ for the Meyer wavelets with $\nu^0$ from (8) (left) and $\nu^\infty$ from (9) with $\alpha = 2$ (right), no scaling (top) and scaling with $2^l$ (bottom).

The relation (3) relates the spaces $V_l$, $W_l$ and $V_{l+1}$ and allows to switch between the scaling coefficients and the wavelet coefficients on level $l$ to the scaling coefficients on level $l+1$ and vice versa. This enables us to choose an optimal coarsest level for a prescribed accuracy and we also can read off the pattern of indices $(l, j)$ which result in a best $M$-term approximation with respect to the $\mathcal{L}^2$- and $\mathcal{H}^1$-norm for that prescribed accuracy, respectively. For the Meyer wavelet with $\nu^\infty$ from (9) where $\alpha = 2$, the optimal choice of the coarsest level $L_1$ on which we use scaling functions is just the level where, for a prescribed accuracy, the two absolute values of the wavelet coefficients on one level possess their largest distance, i.e. the associated isoline of the wavelet coefficients shows the largest diameter (here roughly on level $-2$). The selection of a crossing isoline then corresponds to the fixation of a boundary error by truncation of the further decaying scaling function coefficients on that level which resembles a restriction of $\mathbb{R}$ to just a finite domain. From this base a downward pointing triangle then gives the area of indices to be taken into account into the finite sum of best approximation with respect to that error. We observe that the use of the wavelets with $\nu^0$ from (8) would result in a substantially larger area of indices and

thus number of coefficients to be taken into account to obtain the same error level. There, the form of the area is no longer a simple triangle but shows a "butterfly"-like shape where the base of the pattern is substantially larger.

## 3. MRA and Sobolev spaces for particle spaces

In the following we introduce a multiresolution analysis based on Meyer wavelets for particle spaces on $(\mathbb{R}^d)^N$ and discuss various Sobolev spaces on it.

First, let us set up a basis for the one-particle space $\mathcal{H}^s(\mathbb{R}^d) \subset \mathcal{L}^2(\mathbb{R}^d)$. Here, we use the $d$-dimensional product of the one-dimensional system $\{\psi_{l,j}(x), l \in \mathbb{N}_0, j \in \mathbb{Z}\}$. We then define the $d$-dimensional multi-indices $\boldsymbol{l} = (l_1, l_2, \ldots, l_d) \in \mathbb{N}_0^d$ and $\boldsymbol{j} = (j_1, j_2, \ldots, j_d) \in \mathbb{Z}^d$, the coordinate vector $\boldsymbol{x} = (x_1, \ldots, x_d) \in \mathbb{R}^d$ and the associated $d$-dimensional basis functions

$$\psi_{\boldsymbol{l},\boldsymbol{j}}(\boldsymbol{x}) := \prod_{i=1}^{d} \psi_{l_i,j_i}(x_i). \tag{12}$$

Note that due to (11) this product may involve both father and mother wavelets depending on the values of the components of the level index $\boldsymbol{l}$. We furthermore denote $|\boldsymbol{l}|_2 = \left(\sum_{i=1}^d l_i^2\right)^{1/2}$ and $|\boldsymbol{l}|_\infty = \max_{1\le i\le d} |l_i|$. Let us now define isotropic Sobolev spaces in $d$ dimensions with help of the wavelet series expansion, i.e. we classify functions via the decay of their wavelet coefficients. To this end, we set

$$\lambda(\boldsymbol{l}) := |2^{\boldsymbol{l}}|_2 = |(2^{l_1}, \ldots, 2^{l_d})|_2 \tag{13}$$

and define

$$\begin{aligned}\mathcal{H}^s(\mathbb{R}^d) = \Big\{u(\boldsymbol{x}) = \sum\nolimits_{\substack{l\in\mathbb{N}_0^d,\\ \boldsymbol{j}\in\mathbb{Z}^d}} u_{\boldsymbol{l},\boldsymbol{j}}\psi_{\boldsymbol{l},\boldsymbol{i}}(\boldsymbol{x}) :\\ \|u\|^2_{\mathcal{H}^s(\mathbb{R}^d)} = \sum\nolimits_{\substack{l\in\mathbb{N}_0^d,\\ \boldsymbol{j}\in\mathbb{Z}^d}} \lambda(\boldsymbol{l})^{2s}\cdot|u_{\boldsymbol{l},\boldsymbol{j}}|^2 \le c^2 < \infty\Big\},\end{aligned} \tag{14}$$

where $u_{\boldsymbol{l},\boldsymbol{j}} = \int_{\mathbb{R}^d} \psi^*_{\boldsymbol{l},\boldsymbol{j}}(\boldsymbol{x})u(\boldsymbol{x})d\vec{\boldsymbol{x}}$ and $c$ is a constant which depends on $d$.

Based on the given one-particle basis (12) we now define a basis for many-particle spaces on $\mathbb{R}^{d\cdot N}$. We then have the $d \cdot N$-dimensional coordinates $\vec{\boldsymbol{x}} := (\boldsymbol{x}_1, \ldots, \boldsymbol{x}_N)$ where $\boldsymbol{x}_i \in \mathbb{R}^d$. To this end, we first employ a tensor product construction and define the multi-indices $\vec{\boldsymbol{l}} = (\boldsymbol{l}_1, ..., \boldsymbol{l}_N) \in \mathbb{N}_0^{d\cdot N}$ and the associated multivariate wavelets

$$\psi_{\vec{\boldsymbol{l}},\vec{\boldsymbol{j}}}(\vec{\boldsymbol{x}}) := \prod_{p=1}^{N} \psi_{\boldsymbol{l}_p,\boldsymbol{j}_p}(\boldsymbol{x}_p) = \Big(\bigotimes_{p=1}^{N} \psi_{\boldsymbol{l}_p,\boldsymbol{j}_p}\Big)(\boldsymbol{x}_1, \ldots, \boldsymbol{x}_N). \tag{15}$$

Note again that this product may involve both father and mother wavelets depending on the values of the components of the level index $\vec{\boldsymbol{l}}$. The wavelets $\psi_{\vec{\boldsymbol{l}},\vec{\boldsymbol{j}}}$ span the

subspaces $W_{\vec{l},\vec{j}} := \operatorname{span}\{\psi_{\vec{l},\vec{j}}\}$ whose union forms[3] the space

$$V = \bigoplus_{\substack{\vec{l}\in\mathbb{N}_0^{dN} \\ \vec{j}\in\mathbb{Z}^{dN}}} W_{\vec{l},\vec{j}}. \tag{16}$$

We then can uniquely represent any function $u$ from $V$ as

$$u(\vec{x}) = \sum_{\substack{\vec{l}\in\mathbb{N}_0^{dN} \\ \vec{j}\in\mathbb{Z}^{dN}}} u_{\vec{l},\vec{j}}\ \psi_{\vec{l},\vec{j}}(\vec{x}) \tag{17}$$

with coefficients $u_{\vec{l},\vec{j}} = \int_{\mathbb{R}^{dN}} \psi^*_{\vec{l},\vec{j}}(\vec{x})u(\vec{x})d\vec{x}$.

Now, starting from the one-particle space $\mathcal{H}^s(\mathbb{R}^d)$ we build Sobolev spaces for many particles. Obviously there are many possibilities to generalize the concept of Sobolev spaces [1] from the one-particle case to higher dimensions. Two simple possibilities are the additive or multiplicative combination i.e. an arithmetic or geometric averaging of the scales for the different particles. We use the following definition that combines both possibilities. We denote

$$\lambda_{\text{mix}}(\vec{l}) := \prod_{p=1}^{N} \lambda(\boldsymbol{l}_p) \quad \text{and} \quad \lambda_{\text{iso}}(\vec{l}) := \sum_{p=1}^{N} \lambda(\boldsymbol{l}_p). \tag{18}$$

Now, for $-\infty < t, r < \infty$, set

$$\begin{aligned} &\mathcal{H}^{t,r}_{\text{mix}}((\mathbb{R}^d)^N) \\ &\quad = \Big\{u(\vec{x}) = \textstyle\sum_{\substack{\vec{l}\in\mathbb{N}_0^{dN} \\ \vec{j}\in\mathbb{Z}^{dN}}} u_{\vec{l},\vec{j}}\psi_{\vec{l},\vec{j}}(\vec{x}) : \\ &\qquad \|u\|^2_{\mathcal{H}^{t,r}_{\text{mix}}((\mathbb{R}^d)^N)} = \textstyle\sum_{\vec{l}\in\mathbb{N}_0^{dN}} \lambda_{\text{mix}}(\vec{l})^{2t} \cdot \lambda_{\text{iso}}(\vec{l})^{2r} \cdot \sum_{\vec{j}\in\mathbb{Z}^{dN}} |u_{\vec{l},\vec{j}}|^2 \le c^2 < \infty\Big\} \end{aligned} \tag{19}$$

with a constant $c$ which depends on $d$ and $N$.

The standard isotropic Sobolev spaces [1] as well as the Sobolev spaces of dominating mixed smoothness [58], both generalized to the $N$-particle case, are included here. They can be written as the special cases

$$\mathcal{H}^s((\mathbb{R}^d)^N) = \mathcal{H}^{0,s}_{\text{mix}}((\mathbb{R}^d)^N) \quad \text{and} \quad \mathcal{H}^t_{\text{mix}}((\mathbb{R}^d)^N) = \mathcal{H}^{t,0}_{\text{mix}}((\mathbb{R}^d)^N),$$

respectively. Hence, the parameter $r$ from (19) governs the isotropic smoothness, whereas $t$ governs the mixed smoothness. Thus, the spaces $\mathcal{H}^{t,r}_{\text{mix}}$ give us a quite flexible framework for the study of problems in Sobolev spaces. Note that the relations $\mathcal{H}^t_{\text{mix}} \subset \mathcal{H}^t \subset \mathcal{H}^{t/N}_{\text{mix}}$ for $t \ge 0$ and $\mathcal{H}^{t/N}_{\text{mix}} \subset \mathcal{H}^t \subset \mathcal{H}^t_{\text{mix}}$ for $t \le 0$ hold. See [58] and [36] for more information on the spaces $\mathcal{H}^t_{\text{mix}}$.

[3] Except for the completion with respect to a chosen Sobolev norm, $V$ is just the associated Sobolev space.

## 4. Semidiscrete general sparse grid spaces

We now consider truncation of the series expansion (17) with respect to the level parameter $\vec{l}$ but keep the part of the full series expansion with respect to the position parameter $\vec{j}$. To this end, we introduce, besides the parameter $L$ (after proper scaling with $c$) which indicates the truncation of the scale with respect to the one-particle space, an additional parameter $T \in (-\infty, 1]$ which regulates the truncation pattern for the interaction between particles. We define the generalized sparse grid space

$$V_{L,T} := \bigoplus_{\vec{l} \in \Omega_{L,T}} W_{\vec{l}} \quad \text{where } W_{\vec{l}} = \text{span}\{\psi_{\vec{l},\vec{j}}, \vec{j} \in \mathbb{Z}^{dN}\} \tag{20}$$

with associated generalized hyperbolic cross with respect to the scale-parameter $\vec{l}$

$$\Omega_{L,T} := \{\vec{l} \in \mathbb{N}_0^{d \cdot N} : \lambda_{\text{mix}}(\vec{l}) \cdot \lambda_{\text{iso}}(\vec{l})^{-T} \leq (2^L)^{1-T}\}. \tag{21}$$

The parameter $T$ allows us to switch from the full grid case $T = -\infty$ to the conventional sparse grid case $T = 0$, compare [12], [31], [42], and also allows to create with $T \in (0, 1]$ subspaces of the hyperbolic cross/conventional sparse grid space. Obviously, the inclusions $V_{L,T_1} \subset V_{L,T_2}$ for $T_1 \leq T_2$ hold. Figure 3 displays the index sets for various choices of $T$ for the case $d = 1$, $N = 2$ and $L = 128$.

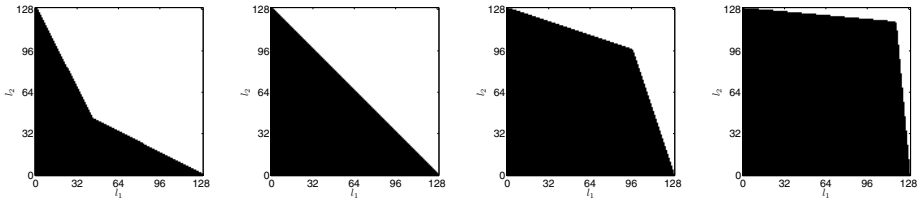

Figure 3. $\Omega_{128,T}$ for $T = 0.5, 0, -2, -10$ (from left to right), $d = 1$, $N = 2$; the conventional sparse grid/hyperbolic cross corresponds to $T = 0$. For $T = -\infty$ we get a completely black square.

We then can uniquely represent any function $u$ from $V_{K,T}$ as

$$u(\vec{x}) = \sum_{\vec{l} \in \Omega_{L,T}, \vec{j} \in \mathbb{Z}^{d \cdot N}} u_{\vec{l},\vec{j}} \; \psi_{\vec{l},\vec{j}}(\vec{x}).$$

Such a projection into $V_{K,T}$ introduces an error. Here we have the following error estimate:

**Lemma 1.** *Let $s < r + t, t \geq 0$, $u \in \mathcal{H}^{t,r}_{\text{mix}}((\mathbb{R}^d)^N)$. Let $\tilde{u}_{L,T}$ be the best approximation in $V_{L,T}$ with respect to the $\mathcal{H}^s$-norm and let $u_{L,T}$ be the interpolant of $u$ in*

$V_{L,T}$, *i.e.* $u_{L,T} = \sum_{\vec{l} \in \Omega_{L,T}} \sum_{\vec{j} \in \mathbb{Z}^{dN}} u_{\vec{l},\vec{j}} \psi_{\vec{l},\vec{j}}(\vec{x})$. *Then, there holds*

$$\inf_{V_{L,T}} \|u - v\|_{\mathcal{H}^s} = \|u - \tilde{u}_{L,T}\|_{\mathcal{H}^s} \leq \|u - u_{L,T}\|_{\mathcal{H}^s} \leq \begin{cases} O((2^L)^{s-r-t+(Tt-s+r)\frac{N-1}{N-T}}) \cdot \|u\|_{\mathcal{H}^{t,r}_{\mathrm{mix}}} & \text{for } T \geq \frac{s-r}{t}, \\ O((2^L)^{s-r-t}) \cdot \|u\|_{\mathcal{H}^{t,r}_{\mathrm{mix}}} & \text{for } T \leq \frac{s-r}{t}. \end{cases} \quad (22)$$

For a proof, compare the arguments in [31], [42], [43], [30]. This type of estimate was already given for the case of a dyadically refined wavelet basis with $d = 1$ for the periodic case on a finite domain in [31], [42], [43]. It is a generalization of the energy-norm based sparse grid approach of [11], [12], [29] where the case $s = 1$, $t = 2$, $r = 0$ was considered using a hierarchical piecewise linear basis.

Let us discuss some cases. For the standard Sobolev space $\mathcal{H}^{0,r}_{\mathrm{mix}}$ (i.e. $t = 0$, $r = 2$) and the spaces $V_{L,T}$ with $T \geq -\infty$ the resulting order is dependent of $T$ and dependent on the number of particles $N$. In particular the order even deteriorates with larger $T$. For the standard Sobolev spaces of bounded mixed derivatives $\mathcal{H}^{t,0}_{\mathrm{mix}}$ (i.e. $t = 2$, $r = 0$) and the spaces $V_{L,T}$ with $T > \frac{s}{2}$ the resulting order is dependent of $T$ and dependent on the number of particles $N$ whereas for $T \leq \frac{s}{2}$ the resulting order is independent of $T$ and $N$. If we restrict the class of functions for example to $\mathcal{H}^{1,1}_{\mathrm{mix}}$ (i.e. $t = 1$, $r = 1$) and measure the error in the $\mathcal{H}^1$-norm (i.e. $s = 1$) the approximation order is dependent on $N$ for all $T > 0$ and independent on $N$ and $T$ for all $T \leq 0$. Note that in all cases the constants in the $O$-notation depend on $N$ and $d$.

## 5. Antisymmetric semidiscrete general sparse grid spaces

Let us now come back to the Schrödinger equation (1). Note that in general an electronic wave function depends in addition to the positions $\boldsymbol{x}_i$ of the electrons also on their associated spin coordinates $\sigma_i \in \{-\frac{1}{2}, \frac{1}{2}\}$. Thus electronic wave functions are defined as $\Psi\colon (\mathbb{R}^d)^N \times \{-\frac{1}{2}, \frac{1}{2}\}^N \to \mathbb{R}\colon (\vec{x}, \vec{\sigma}) \to \Psi(\vec{x}, \vec{\sigma})$ with spin coordinates $\vec{\sigma} = (\sigma_1, \ldots, \sigma_N)$. Furthermore, physically relevant eigenfunctions $\Psi$ obey the following two assumptions: First, elementary particles are indistinguishable from each other (fundamental principle of quantum mechanics). Second, no two electrons may occupy the same quantum state simultaneously (Pauli exclusion principle). Thus, we consider only wave functions which are antisymmetric with respect to an arbitrary simultaneous permutation $P \in \mathcal{S}_N$, of the electron positions and spin variables, i.e. which fulfil

$$\Psi(P\vec{x}, P\vec{\sigma}) = (-1)^{|P|} \Psi(P\vec{x}, P\vec{\sigma}).$$

Here $\mathcal{S}_N$ is the symmetric group. The permutation $P$ is a mapping $P\colon \{1, \ldots, N\} \to \{1, \ldots, N\}$ which translates to a permutation of the corresponding numbering of

electrons and thus to a permutation of indices, i.e. we have $P(\boldsymbol{x}_1, \ldots, \boldsymbol{x}_N)^T := (\boldsymbol{x}_{P(1)}, \ldots, \boldsymbol{x}_{P(N)})^T$ and $P(\sigma_1, \ldots, \sigma_N)^T := (\sigma_{P(1)}, \ldots, \sigma_{P(N)})^T$. In particular, the symmetric group is of size $|\mathcal{S}_N| = N!$ and the expression $(-1)^{|P|}$ is equal to the determinant $\det P$ of the associated permutation matrix.

Now, to a given spin vector $\vec{\sigma} \in \left\{-\frac{1}{2}, \frac{1}{2}\right\}^N$ we define the associated spatial component of the full wave function $\Psi$ by $\Psi_{\vec{\sigma}}\colon (\mathbb{R}^d)^N \to \mathbb{R}\colon \vec{\boldsymbol{x}} \to \Psi(\vec{\boldsymbol{x}}, \vec{\sigma})$. Then, since there are $2^N$ possible different spin distributions $\vec{\sigma}$, the full Schrödinger equation, i.e. the eigenvalue problem $H\Psi = E\Psi$, decouples into $2^N$ eigenvalue problems for the $2^N$ associated spatial components $\Psi_{\vec{\sigma}}$. Here, the spatial part $\Psi_{\vec{\sigma}}$ to a given $\vec{\sigma}$ obeys the condition

$$\Psi_{\vec{\sigma}}(P\vec{\boldsymbol{x}}) = (-1)^{|P|}\Psi_{\vec{\sigma}}(P\vec{\boldsymbol{x}}) \quad \text{for all } P \in \mathcal{S}_{\vec{\sigma}} := \{P \in \mathcal{S}_N \,:\, P\vec{\sigma} = \vec{\sigma}\}. \tag{23}$$

In particular, the minimal eigenvalue of all eigenvalue problems for the spatial components is equal to the minimal eigenvalue of the full eigenvalue problem. Moreover, the eigenfunctions of the full system can be composed by the eigenfunctions of the eigenvalue problems for the spatial parts.

Although there are $2^N$ possible different spin distributions $\vec{\sigma}$, the bilinear form $\langle \Psi(P\cdot)|H|\Psi(P\cdot)\rangle$ is invariant under all permutations $P \in \mathcal{S}_N$ of the position coordinates $\vec{\boldsymbol{x}}$. Thus it is sufficient to consider the eigenvalue problems which are associated to the spin vectors $\vec{\sigma}^{(N,S)} = (\sigma_1^{(N,S)}, \ldots, \sigma_N^{(N,S)})$ where the first $S$ electrons possess spin $-\frac{1}{2}$ and the remaining $N - S$ electrons possess spin $\frac{1}{2}$, i.e.

$$\sigma_j^{(N,S)} = \begin{cases} -\frac{1}{2} & \text{for } j \le S, \\ \frac{1}{2} & \text{for } j > S. \end{cases}$$

In particular, it is enough to solve only the $\lfloor N/2 \rfloor$ eigenvalue problems which correspond to the spin vectors $\vec{\sigma}^{(N,S)}$ with $S \le N/2$. For further details see [66]. Therefore, we consider in the following without loss of generality only spin distributions $\vec{\sigma}^{(N,S)} = (\sigma_1^{(N,S)}, \ldots, \sigma_N^{(N,S)})$. We set $\mathcal{S}_{(N,S)} := \mathcal{S}_{\vec{\sigma}^{(N,S)}}$. Note that there holds $|\mathcal{S}_{(N,S)}| = S!(N-S)!$.

Now we define spaces of antisymmetric functions and their semi-discrete sparse grid counterparts. The functions of the $N$-particle space $V$ from (16) which obey the anti-symmetry condition (23) for a given $\vec{\sigma}^{(N,S)}$ form a linear subspace $V^{\mathcal{A}^{(N,S)}}$ of $V$. We define the projection into this subspace, i.e. the antisymmetrization operator $\mathcal{A}^{(N,S)}\colon V \to V^{\mathcal{A}^{(N,S)}}$ by

$$\mathcal{A}^{(N,S)}u(\vec{\boldsymbol{x}}) := \frac{1}{S!(N-S)!} \sum_{P \in \mathcal{S}_{N,S}} (-1)^{|P|} u(P\vec{\boldsymbol{x}}). \tag{24}$$

For any basis function $\psi_{\vec{l},\vec{j}}$ of our general $N$-particle space $V$ we then have

$$\begin{aligned}
\mathcal{A}^{(N,S)}\psi_{\vec{l},\vec{j}}(\vec{x}) &= \mathcal{A}^{(N,S)}\Big(\Big(\bigotimes_{p=1}^{S}\psi_{l_p,j_p}\Big)(x_1,\ldots,x_S)\Big(\bigotimes_{p=S+1}^{N}\psi_{l_p,j_p}\Big)(x_{S+1},\ldots x_N)\Big)\\
&= \Big(\mathcal{A}^{(S,S)}\bigotimes_{p=1}^{S}\psi_{l_p,j_p}(x_1,\ldots,x_S)\Big)\Big(\mathcal{A}^{(N-S,N-S)}\bigotimes_{p=S+1}^{N}\psi_{l_p,j_p}(\vec{x}_{S+1},\ldots,x_N)\Big)\\
&= \Big(\frac{1}{S!}\bigwedge_{p=1}^{S}\psi_{l_p,j_p}\Big(x_1,\ldots,x_S\Big)\Big)\Big(\frac{1}{(N-S)!}\bigwedge_{p=S+1}^{N}\psi_{l_p,j_p}\Big(x_{S+1},\ldots,x_N\Big)\Big)\\
&= \frac{1}{S!(N-S)!}\sum_{P\in\mathcal{S}_{N,S}}(-1)^{|P|}\psi_{\vec{l},\vec{j}}(P\vec{x}) = \frac{1}{S!(N-S)!}\sum_{P\in\mathcal{S}_{N,S}}(-1)^{|P|}\psi_{P\vec{l},P\vec{j}}(\vec{x}).
\end{aligned}$$

In other words, the classical product

$$\psi_{\vec{l},\vec{j}}(\vec{x}) := \prod_{p=1}^{N}\psi_{l_p,j_p}(x_p) = \Big(\bigotimes_{p=1}^{N}\psi_{l_p,j_p}\Big)(x_1,\ldots,x_N)$$

gets replaced by the product of two outer products

$$\frac{1}{S!}\bigwedge_{p=1}^{S}\psi_{l_p,j_p}(x_1,\ldots,x_S) \quad\text{and}\quad \frac{1}{(N-S)!}\bigwedge_{p=S+1}^{N}\psi_{l_p,j_p}(x_{S+1},\ldots,x_N)$$

that correspond to the two sets of coordinates and one-particle bases which are associated to the two spin values $-\frac{1}{2}$ and $\frac{1}{2}$. The outer product involves just the so-called slater determinant [55], i.e.

$$\bigwedge_{p=1}^{N}\psi_{l_p,j_p}(x_1,\ldots,x_N) = \begin{vmatrix}\psi_{l_1,j_1}(x_1) & \ldots & \psi_{l_1,j_1}(x_N)\\ \vdots & \ddots & \vdots\\ \psi_{l_N,j_N}(x_1) & \ldots & \psi_{l_N,j_N}(x_N)\end{vmatrix}.$$

Note here again that due to (11) both father wavelet functions and mother wavelet functions may be involved in the respective products.

The sequence $\{\mathcal{A}^{(N,S)}\psi_{\vec{l},\vec{j}}\}_{\vec{l}\in\mathbb{N}_0^{dN},\vec{j}\in\mathbb{Z}^{dN}}$ only forms a generating system of the antisymmetric subspace $V^{\mathcal{A}^{(N,S)}}$ and no basis since many functions $\mathcal{A}^{(N,S)}\psi_{\vec{l},\vec{j}}$ are identical (up to the sign). But we can gain a basis for the antisymmetric subspace $V^{\mathcal{A}^{(N,S)}}$ if we restrict the sequence $\{\mathcal{A}^{(N,S)}\psi_{\vec{l},\vec{j}}\}_{\vec{l}\in\mathbb{N}_0^{dN},\vec{j}\in\mathbb{Z}^{dN}}$ properly. This can be done in many different ways. A possible orthonormal basis $\mathcal{B}^{(N,S)}$ for $V^{\mathcal{A}^{(N,S)}}$ is given with help of

$$\Phi^{(N,S)}_{\vec{l},\vec{j}}(\vec{x}) := \frac{1}{\sqrt{S!(N-S)!}}\cdot\bigwedge_{p=1}^{S}\psi_{l_p,j_p}(x_1,\ldots,x_S)\cdot\bigwedge_{p=S+1}^{N}\psi_{l_p,j_p}(x_{S+1},\ldots,x_N) \tag{25}$$

as follows:

$$\mathcal{B}^{(N,S)} := \big\{\Phi^{(N,S)}_{\vec{l},\vec{j}} : \vec{l} \in \mathbb{N}_0^{d\cdot N},\ \vec{j} \in \mathbb{Z}^{d\cdot N},\ (\boldsymbol{l}_1, \boldsymbol{j}_1) < \cdots < (\boldsymbol{l}_S, \boldsymbol{j}_S) \text{ and } (\boldsymbol{l}_{S+1}, \boldsymbol{j}_{S+1}) < \cdots < (\boldsymbol{l}_N, \boldsymbol{j}_N)\big\} \tag{26}$$

where for the index pair

$$\boldsymbol{I}_p := (\boldsymbol{l}_p, \boldsymbol{j}_p) = (\boldsymbol{l}_{p,(1)}, \ldots, \boldsymbol{l}_{p,(d)}, \boldsymbol{j}_{p,(1)}, \ldots, \boldsymbol{j}_{p,(d)})$$

the relation $<$ is defined as

$$\boldsymbol{I}_p < \boldsymbol{I}_q \quad \Longleftrightarrow \quad \begin{array}{l}\text{there exists } \alpha \in \{1, \ldots, 2d\} \text{ such that } \boldsymbol{I}_{p,(\alpha)} < \boldsymbol{I}_{q,(\alpha)} \\ \text{and } \boldsymbol{I}_{p,(\beta)} \le \boldsymbol{I}_{q,(\beta)} \text{ for all } \beta \in \{1, \ldots, \alpha - 1\}.\end{array}$$

With

$$\Omega^{\mathcal{A}^{(N,S)}} = \{(\vec{l}, \vec{j}) : \vec{l} \in \mathbb{N}_0^{d\cdot N},\ \vec{j} \in \mathbb{Z}^{d\cdot N},\ (\boldsymbol{l}_1, \boldsymbol{j}_1) < \cdots < (\boldsymbol{l}_S, \boldsymbol{j}_S) \text{ and } (\boldsymbol{l}_{S+1}, \boldsymbol{j}_{S+1}) < \cdots < (\boldsymbol{l}_N, \boldsymbol{j}_N)\big\}$$

we then can define the antisymmetric subspace $V^{\mathcal{A}^{(N,S)}}$ of $V$ as

$$V^{\mathcal{A}^{(N,S)}} = \bigoplus_{(\vec{l},\vec{j})\in\Omega^{\mathcal{A}^{(N,S)}}} W_{\vec{l},\vec{j}} \tag{27}$$

where we denote from now on $W_{\vec{l},\vec{j}} = \operatorname{span}\{\Phi^{(N,S)}_{\vec{l},\vec{j}}(\vec{x})\}$. Any function $u$ from $V^{\mathcal{A}^{(N,S)}}$ can then uniquely be represented as

$$u(\vec{x}) = \sum_{(\vec{l},\vec{j})\in\Omega^{\mathcal{A}^{(N,S)}}} u_{\vec{l},\vec{j}}\ \Phi^{(N,S)}_{\vec{l},\vec{j}}(\vec{x})$$

with coefficients $u_{\vec{l},\vec{j}} = \int_{I^{dN}} \Phi^{(N,S)*}_{\vec{l}\vec{j}}(\vec{x}) u(\vec{x}) d\vec{x}$.

Now we are in the position to consider semidiscrete subspaces of $V^{\mathcal{A}^{(N,S)}}$. To this end, in analogy to (20) we define the generalized semidiscrete antisymmetric sparse grid spaces

$$V^{\mathcal{A}^{(N,S)}}_{L,T} := \bigoplus_{(\vec{l},\vec{j})\in\Omega^{\mathcal{A}^{(N,S)}}_{K,T}} W_{\vec{l},\vec{j}}$$

with associated antisymmetric generalized sets

$$\Omega^{\mathcal{A}^{(N,S)}}_{L,T} := \{(\vec{l}, \vec{j}) : \vec{l} \in \mathbb{N}_0^{d\cdot N},\ \vec{j} \in \mathbb{Z}^{d\cdot N},\ \lambda_{\text{mix}}(\vec{l}) \cdot \lambda_{\text{iso}}(\vec{l})^{-T} \le (2^L)^{1-T},\ (\boldsymbol{l}_1, \boldsymbol{j}_1) < \cdots < (\boldsymbol{l}_S, \boldsymbol{j}_S) \text{ and } (\boldsymbol{l}_{S+1}, \boldsymbol{j}_{S+1}) < \cdots < (\boldsymbol{l}_N, \boldsymbol{j}_N)\}.$$

Obviously, the inclusions $V^{\mathcal{A}^{(N,S)}}_{K,T_1} \subset V^{\mathcal{A}^{(N,S)}}_{K,T_2}$ for $T_1 \le T_2$ hold. Note that for the associated error the same type of estimate as in Lemma 1 holds. The number of $\vec{l}$-subbands however, i.e. the number of subsets of indices from $\Omega^{\mathcal{A}^{(N,S)}}_{L,T}$ with the same $\vec{l}$, is reduced by the factor $S!(N-S)!$.

## 6. Regularity and decay properties of the solution

So far we introduced various semidiscrete sparse grid spaces for particle problems and carried these techniques over to the case of antisymmetric wave functions. Here, the order of the error estimate depended on the degree $s$ of the Sobolev-norm in which we measure the approximation error and the degrees $t$ and $r$ of anisotropic and isotropic smoothness, respectively, which was assumed to hold for the continuous wave function.

We now return to the electronic Schrödinger problem (1) and invoke our general theory for this special case. To this end, let us recall a major result from [67]. There, Yserentant showed with the help of Fourier transforms that an antisymmetric solution of the electronic Schrödinger equation with $d = 3$ possesses $\mathcal{H}^{1,1}_{\text{mix}}$-regularity in the case $S = 0$ or $S = N$ and at least $\mathcal{H}^{1/2,1}_{\text{mix}}$-regularity otherwise. The main argument to derive this fact is a Hardy type inequality, see [67] for details.

Let us first consider the case of a full antisymmetric solution, i.e. the case $S = 0$ or $S = N$, and the resulting approximation rate in more detail. If we measure the approximation error in the $\mathcal{H}^1$-norm, we obtain from Lemma 1 with $s = 1$ and $t = r = 1$ the approximation order $O((2^L)^{-1+T\cdot\frac{N-1}{N-T}})$ for $T \geq 0$ and $O(2^{-L})$ for $T \leq 0$. In particular, for the choice $T = 0$ we have a rate of $O(2^{-L})$. Also note that the constant in the estimate still depends on $N$ and $d$.

In an analog way we can argue for the partial antisymmetric case where we have for an arbitrary chosen $1 \leq S \leq N$ at least $\mathcal{H}^{1/2,1}_{\text{mix}}$-regularity of the associated wave function. If we measure the approximation error in the $\mathcal{H}^1$-norm, we obtain from Lemma 1 with $s = 1$ and $t = 1/2$, $r = 1$ ($\mathcal{H}^{1/2,1}_{\text{mix}}$-regularity) the approximation order $O((2^{L/2})^{-1+T\cdot\frac{N-1}{N-T}})$ for $T \geq 0$ and $O(2^{-L/2})$ for $T \leq 0$. In particular, for the choice $T = 0$ we have a rate of $O(2^{-L/2})$.

Note however that the order constant depends on $N$ and $d$. Moreover, also the $\mathcal{H}^{1,1}_{\text{mix}}$- and $\mathcal{H}^{1/2,1}_{\text{mix}}$-terms may grow exponentially with the number $N$ of electrons. This is a serious problem for any further discretization in $\vec{j}$-space since to compensate for this exponential growth, the parameter $L$ has to be chosen dependent on $N$. Such a behavior could be seen in the case of a finite domain with periodic boundary conditions with Fourier bases from the results of the numerical experiments in [30] and was one reason why problems with higher numbers of electrons could not be treated.

In [69], a rescaling of the mixed Sobolev norm is suggested. To this end, a scaled analog of the $\mathcal{H}^{1,r}_{\text{mix}}$-norm, $r \in \{0, 1\}$, albeit in Fourier space notation (one $\vec{k}$-scale in Fourier space only instead of the $\vec{l}$- and $\vec{j}$-scales in wavelet space) is introduced, compare also [30], via

$$\|\Psi\|_{\mathcal{H}^{1,r}_{\text{mix}}} = \int_{\mathbb{R}^{dN}} \Big(\prod_{p\in I}\Big(1+\Big|\frac{\boldsymbol{k}_p}{R}\Big|^2\Big)\Big)\Big(\sum_{p=1}^{N}\Big|\frac{\boldsymbol{k}_p}{R}\Big|^2\Big)^r |\hat{\Psi}(\vec{\boldsymbol{k}})|^2 d\vec{\boldsymbol{k}} \tag{28}$$

where $I$ denotes the subset of indices of electrons with the same spin, $\hat{\Psi}(\vec{\boldsymbol{k}})$ is the

Fourier transform of $\Psi$ and $\vec{\boldsymbol{k}} \in \mathbb{Z}^{dN}$ are the coordinates in Fourier space with single-particle-components $\boldsymbol{k}_p \in \mathbb{R}^d$. Here the scaling parameter $R$ relates to the intrinsic length scale of the atom or molecule under consideration. It must hold $R \leq C\sqrt{N}\max(N, Z)$ with $Z = \sum_q Z_q$ the totals charge of the nuclei, see also [56], [69]. For an electronically neutral system $Z = N$ and thus $R \leq CN^{3/2}$. Compared to our definitions $\lambda_{\text{mix}}$ and $\lambda_{\text{iso}}$ of (18) we see the following difference: Besides that (28) involves integration instead of summation, (28) deals with the non-octavized case whereas we used the octavized version which involves powers of two. This is one reason why in the product $\prod_{p\in I}(1 + |\boldsymbol{k}_p/R|^2)$ the factor one must be present. Otherwise the case $\boldsymbol{k}_p = \boldsymbol{0}$ is not dealt properly with. But this also opens the possibility to treat the coordinates with values zero differently in the scaling, since the scaling with $1/R$ in the product acts only on the coordinates with non-zero values.

Furthermore, with $I_+$ and $I_-$ the sets of indices $p$ of electrons for which the spin attains the values $-1/2$ and $1/2$, respectively, and a parameter $K$ (non-octavized case), the subdomain

$$H^Y_{R,K} := \left\{(\boldsymbol{k}_1, \ldots \boldsymbol{k}_N) \in (\mathbb{R}^3)^N : \prod_{p\in I_+}\left(1 + \left|\frac{\boldsymbol{k}_p}{R}\right|_2^2\right) + \prod_{p\in I_-}\left(1 + \left|\frac{\boldsymbol{k}_p}{R}\right|_2^2\right) \leq K^2\right\} \tag{29}$$

in Fourier space describes a cartesian product of two scaled hyperbolic crosses. In the extreme cases $S = 0$ or $S = N$ it degenerates to just one hyperbolic cross. Then, with the projection

$$(P_{R,K}\Psi)(x) = \left(\frac{1}{\sqrt{2\pi}}\right)^{3N} \int \hat{\chi}_{R,K}(\vec{\boldsymbol{k}})\hat{\Psi}(\vec{\boldsymbol{k}})e^{i\vec{\boldsymbol{k}}\cdot\vec{\boldsymbol{x}}}d\vec{\boldsymbol{k}},$$

where $\hat{\chi}_{R,K}$ is the characteristic function of the domain $H^Y_{R,K}$, the following error estimate is shown in [69]: For all eigenfunctions with negative eigenvalues and $s = 0, 1$ there holds

$$\|\Psi - P_{R,K}\Psi\|_s \leq \frac{2\sqrt{e}}{K} R^s \|\Psi\|_0. \tag{30}$$

The restriction to eigenfunctions of the Schrödinger–Hamiltonian whose associated eigenvalues are strictly smaller than zero is not a severe issue since such an assumption holds for bounded states, i.e. any system with localized electrons, compare also [25], [38], [59].

This surprising result shows that, with proper scaling in the norms and the associated choice of a scaled hyperbolic cross, it is possible to get rid of the $\|\Psi\|_{\mathcal{H}^{1,r}_{\text{mix}}}$-terms on the right hand side of sparse grid estimates of the type (22). Note that these terms may grow exponentially with $N$ whereas $\|\Psi\|_0 = 1$. To derive semidiscrete approximation spaces which, e.g. after scaling, overcome this problem is an important step towards any efficient discretization for problems with higher numbers of electrons $N$. Note however that e.g. already for the most simple case $S = 0$ or $S = N$ where in (29) only one cross is involved due to $I_- = \{\,\}$ or $I_+ = \{\,\}$, the subdomain $H^Y_{R,K}$ is no longer a conventional hyperbolic cross in Fourier space. Now, depending of

the different dimensions, the "rays" of the cross are chopped off due to the rescaling with $R$. This gets more transparent if we use the relation

$$\prod_{p=1}^{N}(1+|\boldsymbol{k}_p|_2^2) = \sum_{p=0}^{N}\sum_{\substack{a\subset\{1,\ldots,N\}\\|a|=p}}\prod_{j\in\alpha}|\boldsymbol{k}_j|_2^2$$

and rewrite (29) e.g. in the case $S=0$ or $S=N$ as

$$H_{R,K}^{Y} = \big\{\vec{\boldsymbol{k}} \,:\, K^{-2}\big(\textstyle\sum_{p=0}^{N}\sum_{\substack{a\subset\{1,\ldots,N\}\\|a|=p}} R^{-2p}\prod_{j\in\alpha}|\boldsymbol{k}_j|_2^2\big) \le 1\big\}. \tag{31}$$

If we now define for $K_0, K_1, \ldots, K_N \in \mathbb{N}$

$$H_{K_0,K_1,\ldots,K_N} := \big\{\vec{\boldsymbol{k}} \,:\, \big(\textstyle\sum_{p=0}^{N}\sum_{\substack{a\subset\{1,\ldots,N\}\\|a|=p}} K_p^{-2}\prod_{j\in\alpha}|\boldsymbol{k}_j|_2^2\big) \le 1\big\} \tag{32}$$

we have

$$H_{R^0K,R^1K,\ldots,R^NK} = H_{R,K}^{Y}$$

and see more clearly how the scaling with $R$ acts individually on the different dimensional subsets of the Fourier coordinates. In Figure 4 we give in logarithmic and absolute representation the boundaries of the domains $H_{1,K}^{Y}$, $H_{R,K}^{Y}$ and $H_{1,R^NK}^{Y}$ for $R=8$, $K=2^8$. Here we can observe how the scaled variant $H_{R,K}^{Y}$ is just embedded between the two non-scaled domains $H_{1,K}^{Y}$ and $H_{1,R^NK}^{Y}$. While the boundary of $H_{R,K}^{Y}$ matches in "diagonal" direction that of the huge regular sparse grid $H_{1,R^NK}^{Y}$ this is no longer the case for the other directions.

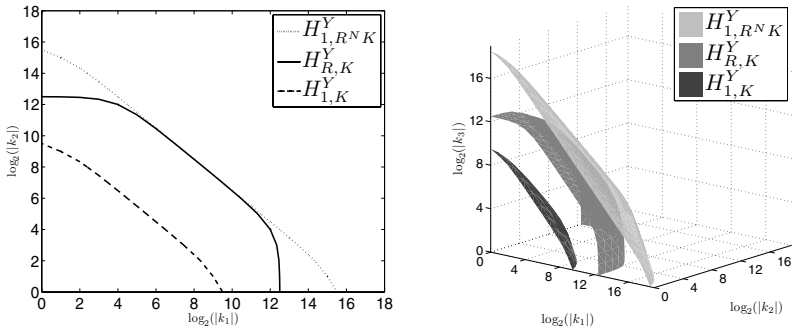

Figure 4. Sets of level indices for $H_{1,K}^{Y}$, $H_{R,K}^{Y}$, $H_{1,R^NK}^{Y}$ in the case $d=1$, $R=8$, $K=2^8$ for $N=2$ and $N=3$.

This dimensional scaling is closely related to well-known decay properties of the solution of Schrödinger's equation which we now recall from the literature. In the seminal work of Agmon [2] the $\mathcal{L}^2$-decay of the eigenfunctions of the electronic

Schrödinger–Hamiltonian of an atom with one nucleus fixed in the origin of the coordinate system is studied in detail and a characterization of the type

$$\int_{\mathbb{R}^{N\cdot d}} |\Psi(\vec{\boldsymbol{x}})|^2 e^{2(1-\varepsilon)\rho(\vec{\boldsymbol{x}})} d\vec{\boldsymbol{x}} \leq c < \infty$$

for any $\varepsilon > 0$ is given for eigenfunctions $\Psi$ with associated eigenvalue $\mu$ below the so-called essential spectrum of $H$. In other words, $\Psi$ decays in the $\mathcal{L}^2$-sense roughly like $e^{-\rho(\vec{\boldsymbol{x}})}$. Here, $\rho(\vec{\boldsymbol{x}})$ is the geodesic distance from $\vec{\boldsymbol{x}}$ to the origin in the Riemannian metric

$$d\vec{\boldsymbol{s}}^2 = (\Lambda_{I(\vec{\boldsymbol{x}})} - \mu) \sum_{i=1}^{N} 2|d\boldsymbol{x}_i|_2^2.$$

To this end, if $I$ denotes any proper subset of $\{1, \ldots N\}$, let $H_I$ denote the restriction of the full Hamiltonian $H$ to the subsystem involving only the electrons associated to $I$ and $\Lambda_I = \inf \sigma(H_I)$, $\Lambda_I = 0$ if $I$ is empty. For any $\vec{\boldsymbol{x}} \in \mathbb{R}^{N\cdot d}/\{0\}$, $I(\vec{\boldsymbol{x}})$ denotes the subset of integers $i \in \{1, \ldots, N\}$ for which $\boldsymbol{x}_i = \boldsymbol{0}$. Note that $\rho$ is *not* isotropic but takes at each point $\vec{\boldsymbol{x}}$ the amount of electrons with position $\boldsymbol{0}$, i.e. the number of electron-nucleus cusps into account.

The result (30) gives some hope that it might indeed be possible to find after additional discretization (in $\vec{\boldsymbol{j}}$-space) an overall discretization which is cost effective and results in an error which does not grow exponentially with the amount of electrons.

The idea is now to decompose the scaled hyperbolic cross $H^Y_{R,K}$ in Fourier space and to approximate the corresponding parts of the associated projection $P_{R,K}\hat{\Psi}(\vec{\boldsymbol{k}})$ properly. To this end, let us assume that we consider a non-periodic, isolated system. It then can be shown that any eigenfunction $\Psi$ with negative eigenvalue below the essential spectrum of the Schrödinger operator $H$ decays exponentially in the $\mathcal{L}^2$-sense with $|\vec{\boldsymbol{x}}| \to \infty$. The same holds for its first derivative [37]. A consequence is that the Fourier transform $\hat{\Psi}$ is infinitely often differentiable as a function in $\vec{\boldsymbol{k}}$. Let us now decompose $H^Y_{R,K}$ into finitely many subdomains $H^Y_{R,K,\vec{\boldsymbol{l}}}$ and let us split $\hat{\Psi}_{R,K}(\vec{\boldsymbol{k}}) := \hat{\chi}_{R,K}(\vec{\boldsymbol{k}})\hat{\Psi}(\vec{\boldsymbol{k}})$ accordingly into $\hat{\Psi}_{R,K,\vec{\boldsymbol{l}}}(\vec{\boldsymbol{k}})$, i.e.

$$\hat{\Psi}_{R,K}(\vec{\boldsymbol{k}}) = \sum_{\vec{\boldsymbol{l}}} \hat{\chi}_{\vec{\boldsymbol{l}}} \hat{\Psi}_{R,K}(\vec{\boldsymbol{k}}) = \sum_{\vec{\boldsymbol{l}}} \hat{\Psi}_{R,K,\vec{\boldsymbol{l}}}(\vec{\boldsymbol{k}})$$

by means of a $C^\infty$-partition of unity $\sum_{\vec{\boldsymbol{l}}} \hat{\chi}_{\vec{\boldsymbol{l}}} = 1$ on $H^Y_{R,K}$, i.e. each $\hat{\chi}_{\vec{\boldsymbol{l}}}(\vec{\boldsymbol{k}}) \in C^\infty$ as a function in $\vec{\boldsymbol{k}}$. Then the functions $\hat{\Psi}_{R,K,\vec{\boldsymbol{l}}}(\vec{\boldsymbol{k}})$ inherit the $C^\infty$-smoothness property and thus can each be well and efficiently approximated by e.g. a properly truncated Fourier series expansion. Note that the detailed choice of partition of unity is not yet specified and there are many possibilities. In the following we will use, e.g. after proper scaling, cf. (10) and (11), the partition

$$\hat{\chi}_{\vec{\boldsymbol{l}}}(\vec{\boldsymbol{k}}) = \prod_{p=1}^{N} \prod_{i=1}^{d} \hat{\chi}_{I_{p,(i)}}(\boldsymbol{k}_{p,(i)})$$

where

$$\hat{\chi}_l(k) := \begin{cases} \hat{\chi}(\frac{k}{c}) & \text{for } l = 0, \\ \hat{\chi}(\frac{k}{c2^l}) - \hat{\chi}(\frac{k}{c2^{l-1}}) & \text{for } l > 0, \end{cases}$$

with

$$\hat{\chi}(k) = \begin{cases} 1 & \text{for } |k| \le \frac{2\pi}{3}, \\ \cos\left( \frac{\pi}{2} \frac{e^{-\frac{4\pi^2}{(3k+2\pi)^2}}}{e^{-\frac{4\pi^2}{(4\pi+3k)^2}} + e^{-\frac{4\pi^2}{(3x+2\pi)^2}}} \right)^2 & \text{for } \frac{2\pi}{3} \le |k| \le \frac{4\pi}{3}, \\ 0 & \text{for } |k| \ge \frac{4\pi}{3}. \end{cases}$$

This choice results in just a representation with respect to the Meyer wavelet series with $\nu^\infty$, i.e. (9) with $\alpha = 2$, compare also (7). The Fourier series expansion of each $\hat{\Psi}_{R,K,\vec{l}}(\vec{k})$ then introduces just the $\vec{j}$-scale, while the $\vec{k}$-scale of the Fourier space relates to the $\vec{l}$-scale of the Meyer wavelets. All we now need is a good decomposition of $H^Y_{R,K}$ into subdomains, a choice of smooth $\hat{\chi}_{\vec{l}}$'s and a proper truncation of the Fourier series expansion of each of the $\hat{\Psi}_{R,K,\vec{l}}$'s. This corresponds to a *truncation* of the Meyer wavelet expansion of $\Psi$ in $\mathbb{R}^{d\cdot N}$ with respect to both the $\vec{l}$- and the $\vec{j}$-scale. Presently, however, it is not completely clear what choice of decomposition and what kind of truncation of the expansion within each subband $\vec{l}$ is most favourable with respect to both the resulting number $M$ of degrees of freedom and the corresponding accuracy of approximation for varying number $N$ of electrons. Anyway, with the choice $K = 2^L$ the set of indices in $\vec{l}, \vec{j}$-wavelet space which is associated to (29) reads

$$\Omega^{\mathcal{A}^{(N,S)}}_{H^Y_{R,2^L}} := \Big\{ (\vec{l}, \vec{j}) \in \Omega^{\mathcal{A}^{(N,S)}} \ : \ \prod_{i=1}^{S} \left(1 + \left|\frac{\tilde{\lambda}(\boldsymbol{l}_i)}{R}\right|_2^2\right) + \prod_{i=S+1}^{N} \left(1 + \left|\frac{\tilde{\lambda}(\boldsymbol{l}_i)}{R}\right|_2^2\right) \le 2^{2L} \Big\},$$

where for $\boldsymbol{l} \in \mathbb{N}_0^d$ we define

$$\tilde{\lambda}(\boldsymbol{l}) := \min_{\boldsymbol{k} \in \mathrm{supp}(\hat{\chi}_{\boldsymbol{l}})} \{|\boldsymbol{k}|_2\}.$$

Note that this involves a kind of octavization due to the size of the support of the $\hat{\chi}_{\boldsymbol{l}}$. For example, we obtain for the Shannon wavelet $\tilde{\lambda}(\boldsymbol{l}) = |(\tilde{\lambda}_{\nu^0}(l_1), \ldots, \tilde{\lambda}_{\nu^0}(l_d))|_2$ with

$$\tilde{\lambda}_{\nu^0}(l) = \begin{cases} 0 & \text{for } l = 0, \\ c\pi 2^{l-1} & \text{otherwise.} \end{cases}$$

## 7. Numerical experiments

We now consider the assembly of the discrete system matrix which is associated to a generalized antisymmetric sparse grid space $V_\Lambda^{\mathcal{A}^{(N,S)}}$ with corresponding finite-dimensional set $\Omega_\Lambda^{\mathcal{A}^{(N,S)}} \subset \Omega^{\mathcal{A}^{(N,S)}}$ and basis functions $\{\Phi_{\vec{l},\vec{j}}^{(N,S)} : (\vec{l},\vec{j}) \in \Omega_\Lambda^{\mathcal{A}^{(N,S)}}\}$ with $\{\Phi_{\vec{l},\vec{j}}^{(N,S)}\}$ from (25) in a Galerkin discretization of (1). To this end, we fix $N > 0$ and $0 \le S \le N$ and omit for reasons of simplicity the indices $S$ and $N$ in the following.

To each pair of indices $(\vec{l},\vec{j})$, $(\vec{l}',\vec{j}')$, each from $\Omega_\Lambda^{\mathcal{A}^{(N,S)}}$, and associated functions $\Phi_{\vec{l},\vec{j}}^{(N,S)}$, $\Phi_{\vec{l}',\vec{j}'}^{(N,S)}$ we obtain one entry in the stiffness matrix, i.e.

$$A_{(\vec{l},\vec{j}),(\vec{l}',\vec{j}')} := \langle \Phi_{\vec{l},\vec{j}}^{(N,S)} | H | \Phi_{\vec{l}',\vec{j}'}^{(N,S)} \rangle = \int \Phi_{\vec{l},\vec{j}}^{(N,S)*}(\vec{x}) H \Phi_{\vec{l}',\vec{j}'}^{(N,S)}(\vec{x})\, \mathrm{d}\vec{x}. \tag{33}$$

Since we use $\mathcal{L}^2$-orthogonal one-dimensional Meyer wavelets as basic building blocks in our construction, also the one-particle basis functions are $\mathcal{L}^2$-orthogonal and we furthermore have $\mathcal{L}^2$-orthogonality of the antisymmetric many-particle basis functions $\Phi_{\vec{l},\vec{j}}^{(N,S)}(\boldsymbol{x})$. We then can take advantage of the well-known Slater–Condon rules [18], [55], [60]. Consequently, quite a few entries of the system matrix are zero and the remaining non-zero entries can be put together from the values of certain $d$- and $2d$-dimensional integrals. These integrals can be written in terms of the Fourier transformation of the Meyer wavelets. In case of the kinetic energy operator we obtain for $\boldsymbol{l}_\alpha, \boldsymbol{l}_\beta \in \mathbb{N}_0^d$ and $\boldsymbol{j}_\alpha, \boldsymbol{j}_\beta \in \mathbb{Z}^d$

$$\begin{aligned}\langle \psi_{\boldsymbol{l}_\alpha,\boldsymbol{j}_\alpha} | -\frac{1}{2}\Delta | \psi_{\boldsymbol{l}_\beta,\boldsymbol{j}_\beta} \rangle &= \frac{1}{2}\int_{\mathbb{R}^d} \nabla \psi^*_{\boldsymbol{l}_\alpha,\boldsymbol{j}_\alpha}(\boldsymbol{x}) \cdot \nabla \psi_{\boldsymbol{l}_\beta,\boldsymbol{j}_\beta}(\boldsymbol{x}) d\boldsymbol{x} \\ &= \frac{1}{2}\sum_{\mu=1}^{d} \int_{\mathbb{R}} k_\mu^2 \hat{\psi}^*_{\boldsymbol{l}_{\alpha,(\mu)},\boldsymbol{j}_{\alpha,(\mu)}}(k_\mu) \hat{\psi}_{\boldsymbol{l}_{\beta,(\mu)},\boldsymbol{j}_{\beta,(\mu)}}(k_\mu)\, dk_\mu \prod_{\nu\neq\mu}^{d} \delta_{\boldsymbol{l}_{\alpha,(\nu)},\boldsymbol{l}_{\beta,(\nu)}} \delta_{\boldsymbol{j}_{\alpha,(\nu)},\boldsymbol{j}_{\beta,(\nu)}}\end{aligned}$$

and for the integrals related to the $d$-dimensional Coulomb operator $v(\boldsymbol{x}) = 1/|\boldsymbol{x}|_2$ we can write

$$\begin{aligned}\langle \psi_{\boldsymbol{l}_\alpha,\boldsymbol{j}_\alpha} | v | \psi_{\boldsymbol{l}_\beta,\boldsymbol{j}_\beta} \rangle &= \int_{\mathbb{R}^d} \psi^*_{\boldsymbol{l}_\alpha,\boldsymbol{j}_\alpha}(\boldsymbol{x}) v(\boldsymbol{x}) \psi_{\boldsymbol{l}_\beta,\boldsymbol{j}_\beta}(\boldsymbol{x}) d\boldsymbol{x} \\ &= \int_{\mathbb{R}^d} \hat{v}(\boldsymbol{k}) (\hat{\psi}_{\boldsymbol{l}_\alpha,\boldsymbol{j}_\alpha} * \hat{\psi}_{\boldsymbol{l}_\beta,\boldsymbol{j}_\beta})(\boldsymbol{k})\, d\boldsymbol{k}.\end{aligned}$$

For $\boldsymbol{l}_\alpha, \boldsymbol{l}_\beta, \boldsymbol{l}_{\alpha'}, \boldsymbol{l}_{\beta'} \in \mathbb{N}_0^d$ and $\boldsymbol{j}_\alpha, \boldsymbol{j}_\beta, \boldsymbol{j}_{\alpha'}, \boldsymbol{j}_{\beta'} \in \mathbb{Z}^d$ we obtain the integrals related to the electron-electron operator $v(\boldsymbol{x}-\boldsymbol{y}) = 1/|\boldsymbol{x}-\boldsymbol{y}|_2$ in the form

$$\begin{aligned}&\int_{\mathbb{R}^d}\int_{\mathbb{R}^d} \psi^*_{\boldsymbol{l}_\alpha,\boldsymbol{j}_\alpha}(\boldsymbol{x}) \psi^*_{\boldsymbol{l}'_\alpha,\boldsymbol{j}_{\alpha'}}(\boldsymbol{y}) v(\boldsymbol{x}-\boldsymbol{y}) \psi_{\boldsymbol{l}_\beta,\boldsymbol{j}_\beta}(\boldsymbol{x}) \psi_{\boldsymbol{l}_{\beta'},\boldsymbol{j}_{\beta'}}(\boldsymbol{y}) d\boldsymbol{x}\, d\boldsymbol{y} \\ &\qquad = (2\pi)^{\frac{d}{2}} \int_{\mathbb{R}^d} \hat{v}(\boldsymbol{k}) (\hat{\psi}_{\boldsymbol{l}_\alpha,\boldsymbol{j}_\alpha} * \hat{\psi}_{\boldsymbol{l}_\beta,\boldsymbol{j}_\beta})(\boldsymbol{k}) (\hat{\psi}_{\boldsymbol{l}_{\alpha'},\boldsymbol{j}_{\alpha'}} * \hat{\psi}_{\boldsymbol{l}_{\beta'},\boldsymbol{j}_{\beta'}})(\boldsymbol{k})\, d\boldsymbol{k}.\end{aligned}$$

Here, $f * g$ denotes the Fourier convolution, namely $(2\pi)^{-\frac{d}{2}} \int_{\mathbb{R}^d} f(\boldsymbol{x} - \boldsymbol{y}) g(\boldsymbol{y})\, d\boldsymbol{y}$. Note that, in the case of the Meyer wavelet tensor-product basis, the $d$-dimensional Fourier convolution can be written in terms of the one-dimensional Fourier convolution

$$(\hat{\psi}_{\boldsymbol{l}_\alpha, \boldsymbol{j}_\alpha} * \hat{\psi}_{\boldsymbol{l}_\beta, \boldsymbol{j}_\beta})(\boldsymbol{k}) = \prod_{\mu=1}^{d} (\hat{\psi}_{l_{\alpha,(\mu)}, j_{\alpha,(\mu)}} * \hat{\psi}_{l_{\beta,(\mu)}, j_{\beta,(\mu)}})(k_\mu).$$

Thus the $d$-dimensional and $2d$-dimensional integrals in real space which are associated to the Coulomb operator and the electron-electron operator can be written in form of $d$-dimensional integrals of terms involving one-dimensional convolution integrals.

For the solution of the resulting discrete eigenvalue problem we invoke a parallelized conventional Lanczos method taken from the software package SLEPc [35] which is based on the parallel software package PETSc [6]. Note that here also other solution approaches are possible with improved complexities, like multigrid-type methods [13], [15], [44], [47] which however still need to be carried over to the setting of our generalized antisymmetric sparse grids.

Note that an estimate for the accuracy of an eigenfunction relates to an analogous estimate for the eigenvalue by means of the relation $|E - E^{\text{app}}| \leq 4 \cdot \|\Psi - \Psi^{\text{app}}\|^2_{\mathcal{L}^2}$ where $E$ and $\Psi$ denote the exact minimal eigenvalue and associated eigenfunction of $H$, respectively, and $E^{\text{app}}$ and $\Psi^{\text{app}}$ denote finite-dimensional Galerkin approximations in arbitrary subspaces, see also [66].

Then, with Lemma 1, we would obtain for the case $d = 3$ with $s = 0$ and, for example, $r = 1$, $t = 1$ and $S = 0$ the estimate

$$\left|E - E^{\mathcal{A}^{(N,0)}}_{L,T}\right| \leq 4 \cdot \left\|\Psi - \Psi^{\mathcal{A}^{(N,0)}}_{L,T}\right\|^2_{\mathcal{L}^2} \leq O((2^L)^{2\cdot(-2+(T+1)\frac{N-1}{N-T})}) \cdot \left\|\Psi^{\mathcal{A}^{(N,0)}}\right\|^2_{\mathcal{H}^{1,1}_{\text{mix}}}$$

and we see that the eigenvalues are in general much better approximated than the eigenfunctions. For example, for $T = 0$, this would result in a (squared) rate of the order $-4 + 2(N-1)/N$ which is about $-4$ for small numbers of $N$ but gets $-2$ for $N \to \infty$.

Let us now describe our heuristic approach for a finite-dimensional subspace choice in wavelet space which hopefully gives us efficient a-priori patterns $\Omega^{\mathcal{A}^{(N,S)}}_{\Lambda}$ and associated subspaces $V^{\mathcal{A}^{(N,S)}}_{\Lambda}$. We use a model function of the Hylleraas-type [16], [41], [57][4]

$$h(\vec{\boldsymbol{x}}) = \prod_{p=1}^{N} \left( e^{-\alpha_p |\boldsymbol{x}_p|_2} \prod_{q>p}^{N} e^{-\beta_{p,q} |\boldsymbol{x}_p - \boldsymbol{x}_q|_2} \right) \tag{34}$$

which reflects the decay properties, the nucleus cusp and the electron-electron cusps of an atom in real space with nucleus fixed in the origin as guidance to a-priori derive a pattern of active wavelet indices in space and scale similar to the simple

[4]Note that we omitted here any prefactors for reasons of simplicity.

one-dimensional example of Figure 2. The localization peak of a Meyer wavelet $\psi_{l,j}$ in real space (e.g. after proper scaling with some $c$ analogously to (10)) is given by

$$\theta(l, j) = \iota(l, j)2^{-l} \quad \text{where } \iota(l, j) = \begin{cases} j & \text{for } l = 0, \\ 1 + 2j & \text{otherwise,} \end{cases}$$

which leads in the multidimensional case to

$$\theta_{\vec{l},\vec{j}} = (\theta(l_1, j_1), \ldots, \theta(l_d, j_d)) \in \mathbb{R}^d$$
$$\theta_{\vec{l},\vec{j}} = (\theta(\boldsymbol{l}_1, \boldsymbol{j}_1), \ldots, \theta(\boldsymbol{l}_N, \boldsymbol{j}_N)) \in (\mathbb{R}^d)^N$$

We now are in the position to describe different discretizations with respect to both the $\vec{\boldsymbol{l}}$-scale and the $\vec{\boldsymbol{j}}$-scale. We focus with respect to the $\vec{\boldsymbol{j}}$-scale on three cases: First, we restrict the whole real space to a finite domain and take the associated wavelets on all incorporated levels into account. Note that in this case the number of wavelets grows from level to level by a factor of 2. Second, we use on each level the same prescribed fixed number of wavelets. And third we let the number of wavelets decay from level to level by a certain factor which results in a multivariate analog to the triangular subspace of Figure 2 (right). With respect to the $\vec{\boldsymbol{l}}$-scale we rely in all cases on the regular sparse grid with $T = 0$. These three different discretization approaches are illustrated in the Figures 5–8 for $d = 1$, $N = 1$ and $d = 1$, $N = 2$, respectively.

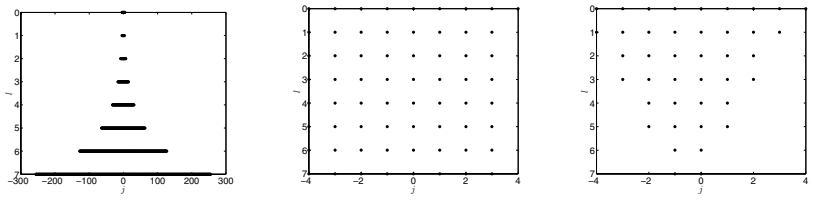

Figure 5. From left to right: Index sets $\Omega^{\mathcal{A}^{(N,S)}}_{\Lambda^{\text{full}}(L,J,R)}$, $\Omega^{\mathcal{A}^{(N,S)}}_{\Lambda^{\Theta_{\text{rec}}}(L,J,R)}$ and $\Omega^{\mathcal{A}^{(N,S)}}_{\Lambda^{\Theta_{\text{tri}}}(L,J,R)}$ with $d = 1$, $N = 1$, $L = 8$, $J = 4$, $R = 1$ and $\alpha_1 = 1$.

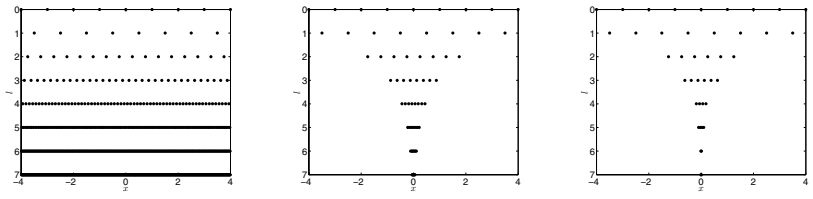

Figure 6. From left to right: Localization peaks of basis functions in real space corresponding to index sets $\Omega^{\mathcal{A}^{(N,S)}}_{\Lambda^{\text{full}}(L,J,R)}$, $\Omega^{\mathcal{A}^{(N,S)}}_{\Lambda^{\Theta_{\text{rec}}}(L,J,R)}$ and $\Omega^{\mathcal{A}^{(N,S)}}_{\Lambda^{\Theta_{\text{tri}}}(L,J,R)}$ with $d = 1$, $N = 1$, $L = 8$, $J = 4$, $R = 1$ and $\alpha_1 = 1$.

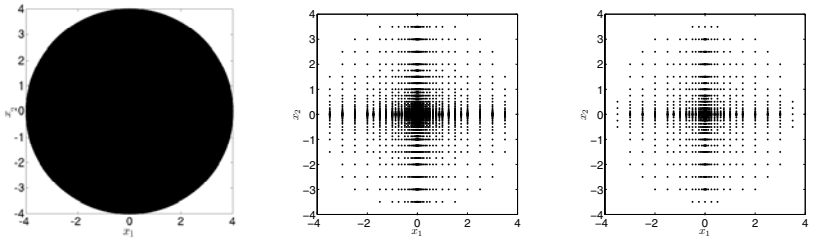

Figure 7. From left to right: Localization peaks of basis functions in real space corresponding to the index sets $\Omega^{\mathcal{A}^{(N,S)}}_{\Lambda^{\text{full}}(L,J,R)}$, $\Omega^{\mathcal{A}^{(N,S)}}_{\Lambda^{\Theta_{\text{rec}}}(L,J,R)}$ and $\Omega^{\mathcal{A}^{(N,S)}}_{\Lambda^{\Theta_{\text{tri}}}(L,J,R)}$ with $d = 2$, $N = 1$, $L = 8$, $J = 4$, $R = 1$ and $\alpha_1 = 1$.

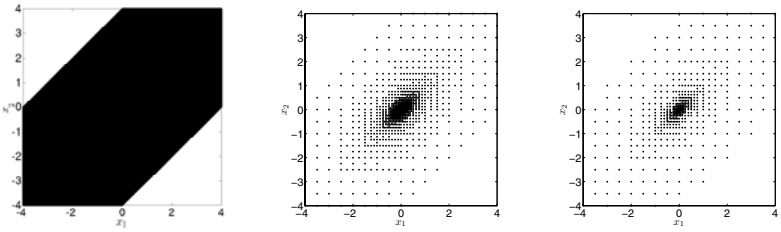

Figure 8. From left to right: Localization peaks of basis functions in real space corresponding to the index sets $\Omega^{\mathcal{A}^{(N,S)}}_{\Lambda^{\text{full}}(L,J,R)}$, $\Omega^{\mathcal{A}^{(N,S)}}_{\Lambda^{\Theta_{\text{rec}}}(L,J,R)}$ and $\Omega^{\mathcal{A}^{(N,S)}}_{\Lambda^{\Theta_{\text{tri}}}(L,J,R)}$ with $d = 1$, $N = 2$, $L = 8$, $J = 4$, $R = 1$, $S = 1$ and $\alpha_1 = \alpha_2 = \beta_{1,2} = \frac{1}{2}$.

To this end, we define with the parameter $J \in \mathbb{N}_+$ the pattern for the finite domain with full wavelet resolution, i.e. the *full* space (with respect to $\vec{\boldsymbol{j}}$-scale after a finite domain is fixed), as

$$\begin{aligned}\Omega^{\mathcal{A}^{(N,S)}}_{\Lambda^{\text{full}}(L,J,R)} &:= \left\{(\vec{\boldsymbol{l}}, \vec{\boldsymbol{j}}) \in \Omega^{\mathcal{A}^{(N,S)}}_{H^Y_{R,2^L}} : h(\theta(\vec{\boldsymbol{l}}, \vec{\boldsymbol{j}})) > e^{-J}\right\} \\ &= \left\{(\vec{\boldsymbol{l}}, \vec{\boldsymbol{j}}) \in \Omega^{\mathcal{A}^{(N,S)}}_{H^Y_{R,2^L}} : \sum_{p=1}^{N} \left(\alpha_p |\theta(\boldsymbol{l}_p, \boldsymbol{j}_p)|_2 \right.\right. \\ &\qquad \left.\left. + \sum_{q>p}^{N} \beta_{p,q} |\theta(\boldsymbol{l}_p, \boldsymbol{j}_p) - \theta(\boldsymbol{l}_q, \boldsymbol{j}_q)|_2\right) < J\right\}\end{aligned}$$

with prescribed $\alpha_p$, $\beta_{p,q}$. Note here the equivalence of the sum to $\ln(h(\theta(\vec{\boldsymbol{l}}, \vec{\boldsymbol{j}})))$.

To describe the other two cases we set with a general function $\Theta$ which still has to be fixed

$$\begin{aligned}&\Omega^{\mathcal{A}^{(N,S)}}_{\Lambda^{\Theta}(L,J,R)} := \left\{(\vec{\boldsymbol{l}}, \vec{\boldsymbol{j}}) \in \Omega^{\mathcal{A}^{(N,S)}}_{\Lambda^{\text{full}}(L,J,R)} :\right. \\ &\left.\sum_{p=1}^{N} \left(\alpha_p \left|\Theta\left(\boldsymbol{l}_p, \boldsymbol{j}_p\right)\right|_2 + \sum_{q>p}^{N} \beta_{p,q} \left|\Theta\left(\theta^{-1}\left(\theta\left(\boldsymbol{l}_p, \boldsymbol{j}_p\right) - \theta\left(\boldsymbol{l}_q, \boldsymbol{j}_q\right)\right)\right)\right|_2\right) < J\right\}.\end{aligned}$$

Note that $\theta^{-1}$ denotes the inverse mapping to $\theta$. It holds

$$\theta^{-1}\left(\theta\,(l,\,j)-\theta\left(l',\,j'\right)\right)=\begin{cases}\tilde{\iota}^{-1}(l,\,\iota(l,\,j)-\iota(l',\,j')2^{l-l'}) & \text{for } l\geq l',\\ \tilde{\iota}^{-1}(l',\,\iota(l,\,j)2^{l'-l}-\iota(l',\,j')) & \text{for } l'\geq l\end{cases}$$

where $\tilde{\iota}(l,\,j)=(l,\,\iota(l,\,j))$. We now define the *rectangular* index set $\Omega^{\mathcal{A}^{(N,S)}}_{\Lambda^{\mathrm{rec}}(L,J,R)}$ via the following choice of $\Theta$: For $\boldsymbol{l}\in\mathbb{N}_0^d$ and $\boldsymbol{j}\in\mathbb{Z}^d$ we set

$$\Theta_{\mathrm{rec}}(\boldsymbol{l},\,\boldsymbol{j}):=(\Theta_{\mathrm{rec}}(l_1,\,j_1),\ldots,\Theta_{\mathrm{rec}}(l_d,\,j_d))$$

and for $l\in\mathbb{N}_0$ and $j\in\mathbb{Z}$ we set

$$\Theta_{\mathrm{rec}}(l,\,j):=\begin{cases}|j|, & \text{for } l=0,\\ |\frac{1}{2}+j| & \text{otherwise.}\end{cases}$$

Finally we define the *triangle* space $\Omega^{\mathcal{A}^{(N,S)}}_{\Lambda^{\mathrm{tri}}(L,J,R)}$ with help of

$$\Theta_{\mathrm{tri}}(\boldsymbol{l},\,\boldsymbol{j}):=(\Theta_{\mathrm{tri}}(l_1,\,j_1),\ldots,\Theta_{\mathrm{tri}}(l_d,\,j_d))$$

where for $l\in\mathbb{N}_0$ and $j\in\mathbb{Z}$ we set

$$\Theta_{\mathrm{tri}}(l,\,j):=\begin{cases}\frac{|j|}{1-\frac{l}{L_{\max}+1}} & \text{for } l=0,\\ \frac{|\frac{1}{2}+j|}{1-\frac{l}{L_{\max}+1}} & \text{for } 0<l\leq L_{\max},\\ \infty & \text{otherwise}\end{cases}$$

with $L_{\max}$ as the maximum level for the respective triangle.

Let us now discuss the results of our first, very preliminary numerical experiments with these new sparse grid methods for Schrödinger's equation. To this end, we restrict ourselves for complexity reasons to the case of one-dimensional particles only. The general three-dimensional case will be the subject of a forthcoming paper. We use in the following in (1) the potential

$$V=-\sum_{p=1}^{N}\sum_{q=1}^{N_{\mathrm{nuc}}}Z_q\,v(\boldsymbol{x}_p-\boldsymbol{R}_q)+\sum_{p=1}^{N}\sum_{q>p}^{N}v(\boldsymbol{x}_p-\boldsymbol{x}_q)\tag{35}$$

with

$$v(\boldsymbol{r})=\begin{cases}D-|\boldsymbol{r}|_2 & \text{for } |\boldsymbol{r}|_2\leq D,\\ 0 & \text{otherwise}\end{cases}$$

which is truncated at radius $D$ and shifted by $D$. Note that $\lim_{|\boldsymbol{r}|_2\to\infty}v(\boldsymbol{r})=0$. Up to truncation and the shift with $D$, $|\boldsymbol{r}|_2$ is just the one-dimensional analogue to the

Coulomb potential. The Fourier transform reads

$$\hat{v}(\boldsymbol{k}) = \begin{cases} \frac{\sqrt{2}}{\sqrt{\pi}} \frac{1}{|\boldsymbol{k}|_2^2}(1 - \cos(D|\boldsymbol{k}|_2)) & \text{for } |\boldsymbol{k}|_2 \neq 0, \\ \frac{D^2}{\sqrt{2\pi}} & \text{otherwise.} \end{cases}$$

Note that $\hat{v}$ is continuous.

We study for varying numbers $N$ of particles the behavior of the discrete energy $E$, i.e. the smallest eigenvalue of the associated system matrix $A$, as $L$ and $J$ increase. Here, we use the generalized antisymmetric sparse grids $\Omega^{\mathcal{A}^{(N,S)}}_{\Lambda^{\text{full}}(L,J,R)}$, $\Omega^{\mathcal{A}^{(N,S)}}_{\Lambda^{\Theta_{\text{rec}}}(L,J,R)}$ and $\Omega^{\mathcal{A}^{(N,S)}}_{\Lambda^{\Theta_{\text{tri}}}(L,J,R)}$ and focus on the two cases $S = 0$ or $S = \lfloor N/2 \rfloor$. We employ the Meyer wavelets with (9) where $\nu^\infty$, $\alpha = 2$, and the Shannon wavelet with $\nu^0$ from (8). Tables 1 and 2 give the obtained results. Here, $M$ denotes the number of degrees of freedom and $\#A$ denotes the number of the non-zero matrix entries. Furthermore, $\Delta E$ denotes the difference of the obtained values of $E$ and $\varepsilon$ denotes the quotient of the values of $\Delta E$ for two successive rows in the table. Thus, $\varepsilon$ indicates the convergence rate of the discretization error.

In Table 1, with just one particle, i.e. $N = 1$, we see that the minimal eigenvalues for the Shannon wavelet are slightly, i.e. by $10^{-3} - 10^{-2}$, worse than the minimal eigenvalues for the Meyer wavelet with $\nu^\infty$. Furthermore, from the first part of the table where we fix $L = 1$ and vary $J$ and alternatively fix $J = 16$ and vary $L$ it gets clear that it necessary to increase both $J$ *and* $L$ to obtain convergence. While just an increase of $J$ with fixed $L = 1$ does not improve the result at all (with $D$ fixed), the increase of $L$ for a fixed $J$ at least gives a convergence to the solution on a bounded domain whose size is associated to the respective value of $D$ and $J$. In the second part of the table we compare the behavior for $\Omega^{\mathcal{A}^{(N,S)}}_{\Lambda^{\text{full}}(L,J,R)}$ and $\Omega^{\mathcal{A}^{(N,S)}}_{\Lambda^{\Theta_{\text{rec}}}(L,J,R)}$ for the wavelets with $\nu^\infty$ and $\nu^0$. While we see relatively stable monotone rates of around 33 and better in case of $\Omega^{\mathcal{A}^{(N,S)}}_{\Lambda^{\text{full}}(L,J,R)}$, the convergence behavior for $\Omega^{\mathcal{A}^{(N,S)}}_{\Lambda^{\Theta_{\text{rec}}}(L,J,R)}$ is more erratic. Nevertheless, when we compare the achieved results for the same amount of matrix entries $\#A$ we see not much difference. For example, with $\nu^\infty$, we get for $J = 16, L = 6$ with 125 degrees of freedom and 15625 matrix entries a value of $-7.191371$ for $\Omega^{\mathcal{A}^{(N,S)}}_{\Lambda^{\Theta_{\text{rec}}}(L,J,R)}$ whereas we get for $\Omega^{\mathcal{A}^{(N,S)}}_{\Lambda^{\text{full}}(L,J,R)}$ with $J = 16, L = 4$ with about the same degrees of freedom and matrix entries nearly the same value $-7.191377$.

Let us now consider the results for $N > 1$ given in Table 2. Here we restricted ourself to the sparse grid $\Omega^{\mathcal{A}^{(N,S)}}_{\Lambda^{\Theta_{\text{tri}}}(L,J,R)}$ due to complexity reasons. We see that the computed minimal eigenvalues in the case $S = \frac{N}{2}$ are higher than that in the case $S = 0$, as to be expected. Furthermore, our results suggest convergence for rising $L$. If we compare the cases $R = 1$ and $R = 2^{\frac{3}{2}}$ for $N = 2$, we see that both the number of degrees of freedom and the minimal eigenvalues are for $R = 1$ approximately the same as for $R = 2^{\frac{3}{2}}$ on the next coarser level. An analogous observation holds in the case $N = 4$.

Note furthermore that the sparse grid effect acts only on the fully antisymmetric subspaces of the total space. This is the reason for the quite large number of degrees of freedom for the case $N = 4$, $S = 2$.

Note finally that our present simple numerical quadrature procedure is relatively expensive. To achieve results for higher numbers of particles with sufficiently large $L$ and $J$, the numerical integration scheme has to be improved. Moreover, to deal in the future with the case of three-dimensional particles using the classical potential (2) and the Meyer wavelets with $\nu^\infty$, an efficient and accurate numerical quadrature still has to be derived.[5]

[5]Such a numerical quadrature scheme must be able to cope with oscillatory functions and also must resolve the singularity in the Coulomb operator.

## 8. Concluding remarks

In this article we proposed to use Meyer's wavelets in a sparse grid approach for a direct discretization of the electronic Schrödinger equation. The sparse grid constructions promises to break the curse of dimensionality to some extent and may allow a numerical treatment of the Schrödinger equation without resorting to any model approximation. We discussed the Meyer wavelet family and their properties and built on them an anisotropic multiresolution analysis for general particle spaces. Furthermore

we studied a semidiscretization with respect to the level and introduced generalized semidiscrete sparse grid spaces. We then restricted these spaces to the case of anti-symmetric functions with additional spin. Using regularity and decay properties of the eigenfunctions of the Schrödinger operator we discussed rescaled semidiscrete sparse grid spaces due to Yserentant. They allow to get rid of the terms that involve the $\mathcal{H}^{1,1}_{\text{mix}}$- and $\mathcal{H}^{1/2,1}_{\text{mix}}$-norm of the eigenfunction which may grow exponentially with the number of electrons present in the system. Thus a direct estimation of the approximation error can be achieved that only involves the $\mathcal{L}^2$-norm of the eigenfunction. We also showed that a Fourier series approximation of a splitting of the eigenfunctions living on a scaled hyperbolic cross in Fourier space essentially just results in Meyer wavelets. Therefore, we directly tried to discretize Schrödinger's equation in properly chosen wavelet subspaces.

We only presented preliminary numerical results with one-dimensional particles and a shifted and truncated potential. For the Meyer wavelets with $\nu^\infty$ and for the classical, not truncated Coulomb potential, substantially improved quadrature routines have to be developed in the future to achieved reasonable run times for the set up of the stiffness matrix. Furthermore, the interplay and the optimal choice of the coarsest scale, i.e. of $c$, the scaling parameter $R$, the domain truncation parameter $J$, the scale truncation parameter $L$ and the parameters $L_{\max}$, $\alpha_p$, $\beta_{p,q}$ is not clear at all and needs further investigation. Finally more experiments are necessary with other types of sparse grid subspaces beyond the ones derived from the Hylleraas-type function (34) to complete our search for an accurate and cost effective approximation scheme for higher numbers $N$ of electrons. Probably not the best strategy for subspace selection was yet used and substantially improved schemes can be found in the future. This may be done along the lines of best $M$-term approximation which, from a theoretical point of view, would however involve a new, not yet existing Besov regularity theory for high-dimensional spaces in an anisotropic setting. Or, from a practical point of view, this would involve new adaptive sparse grid schemes using tensor product Meyer wavelets which need proper error estimators and refinement strategies for both the boundary truncation error and, balanced with it, the scale truncation error.

The sparse grid approach is based on a tensor product construction which allows to treat the nucleus–electron cusps properly which are aligned to the particle-coordinate axes of the system but which does not fit to the "diagonal" directions of the electron–electron cusps. Here, proper a-priori refinement or general adaptivity must be used which however involves for $d = 3$ at least the quite costly resolution of three-dimensional manifolds in six-dimensional space which limits the approach. To this end, new features have to brought into the approximation like for example wavelets which allow additionally for multivariate rotations in the spirit of curvelets [14]. Also an approach in the spirit of wave-ray multigrid methods [9] may be envisioned. Alternatively an embedding in still higher-dimensional formulations which allows to express the electron-electron pairs as new coordinate directions might be explored. This, however, is future work.

# Mathematical and numerical analysis for molecular simulation: accomplishments and challenges

Claude Le Bris

**Abstract.** Molecular simulation is explored from the mathematical viewpoint. The field comprises computational chemistry and molecular dynamics. A variety of mathematical and numerical questions raised is reviewed. Placing the models and the techniques employed for simulation on a firm mathematical ground is a difficult task, which has begun decades ago. The time is right for assessing the field, and the issues and challenges ahead.

**Mathematics Subject Classification (2000).** 35Bxx, 35Jxx, 35Pxx, 49Kxx, 81Q05, 81Q10, 82Bxx.

**Keywords.** Computational chemistry, molecular simulation, molecular dynamics, Schrödinger equations, Hartree–Fock theory, Thomas–Fermi theory, Density Functional Theory, nonlinear eigenvalue problems, spectral theory, spectral methods, elliptic partial differential equations, optimization, reduced basis methods, sparse grids, Hamiltonian dynamics, symplectic methods, geometric integration, stochastic differential equations, Markov chains, Monte-Carlo techniques.

## 1. Introduction

*Molecular simulation* is an increasingly important field of scientific computing. It comprises *computational chemistry*, focused on the calculations of electronic structures and the related properties, and *molecular dynamics*, devoted to the simulation of molecular evolutions, evaluations of ensemble averages and thermodynamic quantities. Examples of reference treatises are [68], [70] and [1], [39], respectively. We also refer to [14, Chapter 1] for a mathematically-oriented introductory text.

**1.1. Ubiquity of molecular simulation.** The field has several intimate connections with many other fields. Indeed, *molecular simulation* is above all important because many macroscopic properties of matter originate from phenomena at the microscopic scale. Instances are: electrical conductivities, colors, chemical reactivities, mechanical behaviour, aging. Accurate calculations on representative microscopic systems allow for the evaluation of such properties. Additionally, even the macroscopic phenomena that proceed from bulk effects, and which thus necessitate the consideration of large size microscopic systems, may now be studied by advanced techniques in molecular simulation. Recent record calculations simulate the dynamics of billions

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

of atoms over a microsecond. Molecular biology, chemistry and physics are thus inseparable today from molecular simulation. An easy observation sheds some light on this. Roughly one publication out of ten in chemistry journals presents some numerical simulations performed on theoretical models. This is an impressive ratio for a field so much experimentally oriented.

Computations are first seen as complements to experiments. For instance, all the information about the electronic properties is contained in the wave function; the latter cannot be measured but it can be computed. Computations are also seen as an alternative to experiment. It is possible to simulate molecular systems that have not been synthesized yet, or phenomena inaccessible to experiments (huge temperature or pressure, time scales smaller than the femtosecond, evolutions on decades or more). Additionally, computations can serve for the laser control of molecular systems ([6]), and other emerging fields of high energy physics.

Other, apparently distant, fields also make an extensive use of molecular simulation. Rheology of complex fluids and more generally materials science were once focused at the macroscopic scale and based on purely macroscopic descriptions. They used to be far from molecular concerns. However, the accuracy needed in the quantitative evaluation of many properties (think e.g. of constitutive laws or slip boundary conditions) requires models to be more and more precise, involving the finest possible scales in the simulation. This eventually includes the molecular scale.

The last application field that we shall mention, besides the fields using the macroscopic impact of molecular simulation, regards the emerging field of nanotechnology. Nanosystems are indeed accessible today to a direct molecular simulation.

Overall, major technological challenges for the years to come may, or more properly stated must, be addressed by molecular simulation techniques. Examples are the detailed simulation of protein folding, and the description of the long time radiation damage of materials in nuclear power plants. To appreciate this ubiquity of molecular simulation, it is sufficient to consider the enormous proportion of computational time devoted to molecular simulation in the largest centers of computational resources worldwide.

**1.2. Relation to mathematics.** On the other hand, the interface of molecular simulation with mathematics is not yet comparable to the practical importance of the field.

Molecular simulation, and more precisely computational quantum chemistry, were born in the 1950s for molecular systems consisting of a few electrons. Contemporary methods and techniques now allow for the simulation of molecules of hundreds of electrons, modelled by very precise quantum models, up to samples of billions of particles modelled by molecular dynamics. This is an enormous success. The calculations are often surprisingly accurate, but also sometimes desperately inaccurate. Experts in chemistry have constantly improved the models and the methods. They have turned the field into an almighty tool. However, in many respects, molecular simulation is still an art. It relies upon a delicate mix of physical intuition, prag-

matic cleverness, and practical know-how. Mathematics has already provided with significant contributions to the theoretical understanding. Also, its companion fields, numerical analysis and scientific computing, have definitely improved the efficiency of the techniques. Yet, they all need to irrigate more molecular simulation. To state it otherwise, *there is an enormous gap between the sophistication of the models and the success of the numerical approaches used in practice and, on the other hand, the state of the art of their rigorous understanding.*

We are witnessing an evolution that is due to two different reasons.

First, the mathematical knowledge on the models is rather satisfactory. Efforts were initiated as early as the 1970s by pioneers such as E. H. Lieb, B. Simon, W. Thirring, Ch. Feffermann, focusing on fundamental theoretical issues. Questions were addressed about the well-posedness of the models, and the relation between the various models, in various asymptotic regimes. Researchers such as R. Benguria, J. P. Solovej, V. Bach, G. Friesecke, to only name a few, continued the effort over the years. Those were later joined by contributors following the impulsion given by P-L. Lions: M. J. Esteban, I. Catto, E. Séré, X. Blanc, M. Lewin, and the author. A number of researchers, experts in analysis, spectral theory, partial differential equations, evolution equations, now become involved in the field. The enclosed bibliography cites several of them.

Second, and as a natural follow-up to mathematical analysis, numerical analysis has indeed come into the picture. The numerical analysis of computational chemistry methods was a completely unexplored subject until the mid 1990s. Boosted by the state of the mathematical analysis, it is now a quickly developing topic. The work in this field was pioneered by E. Cancès. Researchers such as Y. Maday, M. Griebel, W. Hackbush, Ch. Lubich, W. E, well known for their contributions in various other fields of the engineering sciences, now get involved, along with their collaborators (G. Turinici, …) in electronic structure calculations or in molecular dynamics.

It is therefore a good time for assessing the field, and the issues and challenges ahead. Doing so might help to boost the research in the area.

The present contribution rapidly reviews some commonly used models and their mathematical nature, indicating the progress achieved over the last decades in their mathematical understanding. Questions of numerical analysis are also addressed. Important unsolved issues are emphasized. Owing to the evident space limitation, this review is not meant to be exhaustive: see [54], [55] for more comprehensive reviews, and [56] for a recent collection of various contributions. This is rather an invitation for mathematicians to get involved in the endeavour of placing the field on a firm mathematical ground.

## 2. Mathematical overview of the models of computational chemistry

**2.1. The Schrödinger equation.** For most applications of molecular simulation, the matter is described by an assembly of nuclei, which are point particles treated classically, equipped with electrons, which are light particles modelled by quantum mechanics. For systems of limited size, called *molecular systems*, there are $M$ nuclei, of charge $z_k$, located at $\bar{x}_k$, and $N$ electrons of unit charge. The finest models are called *ab initio* models since they only involve universal constants and no experimentally determined parameters. Assuming the molecular system nonrelativistic, placing it at zero temperature, and, for clarity of exposition, omitting the spin variable, the state of the electrons is modelled by the $N$-body Hamiltonian

$$H_e^{\bar{x}_1,\ldots,\bar{x}_M} = -\sum_{i=1}^{N} \frac{1}{2}\Delta_{x_i} - \sum_{i=1}^{N}\sum_{k=1}^{M} \frac{z_k}{|x_i - \bar{x}_k|} + \sum_{1\le i<j\le N} \frac{1}{|x_i - x_j|}, \tag{1}$$

where the terms respectively model the kinetic energy, the attraction between nuclei and electrons, the repulsion between electrons. Notice that the positions $\bar{x}_k$ of the nuclei are *parameters* of this operator. The *electronic ground-state* is by definition the minimizer of the energy:

$$W(\bar{x}_1, \bar{x}_2, \ldots, \bar{x}_M) = \inf\left\{\langle\psi, H_e^{\bar{x}_1,\ldots,\bar{x}_M}\psi\rangle,\ \psi \in \mathcal{W}_N\right\} + \sum_{1\le k<l\le M} \frac{z_k\, z_l}{|\bar{x}_k - \bar{x}_l|}. \tag{2}$$

The variational space reads

$$\mathcal{W}_N = \left\{\psi \in \bigwedge_{i=1}^{N} L^2(\mathbb{R}^3) : \int_{\mathbb{R}^{3N}} |\psi|^2 = 1,\ \int_{\mathbb{R}^{3N}} |\nabla\psi|^2 < +\infty\right\} \tag{3}$$

where the wedge product denotes the antisymmetrized tensor product (owing to the Pauli exclusion principle). The Euler–Lagrange equation of (2) is the (time-independent) Schrödinger equation

$$H_e^{\bar{x}_1,\ldots,\bar{x}_M}\psi = E\,\psi \tag{4}$$

where the energy $E$, lowest possible eigenvalue of $H_e^{\bar{x}_1,\ldots,\bar{x}_M}$ on $\mathcal{W}_N$ is called the ground-state energy. The resolution of (2) (or one approximation of it, which we will detail below) is at the core of any computational chemistry calculation, prior to any calculation related to excited states, energies, linear response, etc. We therefore focus on this problem here.

Analogously, a time-dependent version of the problem exists: then the *time-dependent* Schrödinger equation

$$i\frac{\partial}{\partial t}\psi = H_e^{\bar{x}_1,\ldots,\bar{x}_M}\psi \tag{5}$$

is to be solved. The treatment of the electronic problem is usually the *inner* loop of the simulation, the *outer* loop consisting of the treatment of the nuclei. In the static setting, this consists in solving the *molecular mechanics* problem (also termed *geometry optimization*): finding the configuration of nuclei that minimizes the overall energy, i.e. the minimizer of

$$\inf_{(\bar{x}_1,\bar{x}_2,\ldots,\bar{x}_M)\in\mathbb{R}^{3M}} W(\bar{x}_1,\bar{x}_2,\ldots,\bar{x}_M). \tag{6}$$

The time-dependent setting requires solving the equations of *molecular dynamics*, i.e. the Newton equations of motion for the nuclei:

$$m_k \frac{d^2}{dt^2}\bar{x}_k = -\nabla_{\bar{x}_k} W(\bar{x}_1,\bar{x}_2,\ldots,\bar{x}_M). \tag{7}$$

**2.2. Standard approximations.** Problem (2) is well explored mathematically: [37], [49]. In addition to their own interest, theoretical studies of (2) provide with useful practical information on the quantities (wavefunction and energy) to be evaluated in practice (see [48] and other works by the same authors). The practical bottleneck of quantum chemistry calculations is however that state-of-the-art numerical techniques only allow for (2) to be solved for ridiculously small numbers of electrons. Indeed, the dimension of the tensor product $\bigwedge_{i=1}^{N} L^2(\mathbb{R}^3)$ makes the problem untractable by usual techniques of scientific computing for the practically relevant numbers of electrons, say a few tens to thousands. The practice of computational chemistry is thus to *approximate* (2). The purpose of such approximations is to reduce the computational complexity of the problem, whilst providing the accuracy required by chemistry. The energy of molecular systems must indeed be determined within an incredibly demanding degree of accuracy (often termed the *chemical accuracy*). Energies such as (2) are typically $10^3$ to $10^6$ as large as the energy of an hydrogen bond. As the interest lies in the *difference* of energy between two systems, in order to determine which is the more stable one, the difficulty is challenging. Surprisingly, clever approximations do succeed in this task. We now review them. For more details on the analysis, implementation and efficiency of all the numerical techniques mentioned below, see [53].

In chemistry, approximations of (2) are schematically sorted into two categories.

*Wavefunctions methods* are used preferably by chemists, on small systems, when accuracy is the primary goal, and computational time is a secondary issue. The focus is on the *interaction* between electrons. The prototypical example is the Hartree–Fock model. The latter is the best known model in the mathematical community. The bottom line for deriving the Hartree–Fock model is a variational approximation of the set (3) by the subspace of wavefunctions $\psi$ that read as *determinants* (antisymmetrized products) of wavefunctions of *one* electron. More precisely, the Hartree–Fock problem reads

$$\inf\left\{E^{\mathrm{HF}}(\{\phi_i\}) : \phi_i \in H^1(\mathbb{R}^3),\ \int_{\mathbb{R}^3} \phi_i\phi_j^* = \delta_{ij},\ 1\le i,j\le N\right\} \tag{8}$$

with

$$E^{\mathrm{HF}}(\{\phi_i\}) = \frac{1}{2}\sum_{i=1}^{N}\int_{\mathbb{R}^3}|\nabla\phi_i(x)|^2\,dx + \int_{\mathbb{R}^3}\rho(x)\,V(x)\,dx + \frac{1}{2}\iint_{(\mathbb{R}^3)^2}\frac{\rho(x)\,\rho(y)}{|x-y|}\,dx\,dy - \frac{1}{2}\iint_{(\mathbb{R}^3)^2}\frac{|\tau(x,y)|^2}{|x-y|}\,dx\,dy, \tag{9}$$

with $V = -\sum_{k=1}^{M}\frac{z_k}{|\cdot-\bar{x}_k|}$, $\tau(x,y) = \sum_{i=1}^{N}\phi_i(x)\,\phi_i(y)^*$ and $\rho(x) = \tau(x,x) = \sum_{i=1}^{N}|\phi_i(x)|^2$, where the star denotes the complex conjugate. *Post–Hartree–Fock methods* consist in enlarging the variational space by considering *linear combinations* of determinants: *Configuration Interaction* (CI) methods, *Multiconfiguration Self Consistent Field* (MCSCF) methods. Nonvariational correction methods, mostly based on linear perturbation theory, are also employed: *Möller–Plesset*, *Coupled Cluster*.

On the other hand, *Density Functional Theory based methods* are used preferably for larger systems (and beyond for materials science), when computational time matters and wavefunctions methods are too expensive. They consist in rephrasing the problem (2) in terms of the electronic density

$$\rho(x) = N\int_{\mathbb{R}^{3(N-1)}}|\psi(x,x_2,x_3,\ldots,x_N)|^2\,dx_2\,dx_3\ldots dx_N.$$

Formally, a minimization problem of the type

$$\inf\left\{\mathcal{E}(\rho);\ \int_{\mathbb{R}^3}\rho(x)\,dx = N\right\} \tag{10}$$

is obtained. The idea has a rigorous theoretical grounding, but making it tractable in practice requires some approximation procedure. The energy $\mathcal{E}(\rho)$, which is a reformulation of $\langle\psi, H_e^{\bar{x}_1,\ldots,\bar{x}_M}\psi\rangle$, is not explicit. Adequately adjusting the parameters (and even the terms) of the approximate energy functional $\mathcal{E}(\rho)$ is an issue, sometimes controversial. Ancestors of DFT-based methods are Thomas–Fermi type theories, very well investigated mathematically (see [60], [63], [74] for reviews). The latter currently see a revival through *orbital-free* methods, which precisely consist in discretizing $\rho$ itself as the primary unknown. They therefore allow for the treatment of larger systems, notably for materials science applications.

The general trend is that DFT-based models are increasingly popular. A commonly used setting is the *Kohn–Sham Local Density Approximation* (KS-LDA) setting that explicitly reads as the minimization problem

$$\inf\left\{E^{\text{KS-LDA}}(\{\phi_i\}) : \phi_i \in H^1(\mathbb{R}^3),\ \int_{\mathbb{R}^3}\phi_i(x)\phi_j^*(x)\,dx = \delta_{ij},\ 1\le i,j\le N\right\} \tag{11}$$

with

$$E^{\text{KS-LDA}}(\{\phi_i\}) = \frac{1}{2}\sum_{i=1}^{N}\int_{\mathbb{R}^3}|\nabla\phi_i(x)|^2\,dx + \int_{\mathbb{R}^3}\rho(x)\,V(x)\,dx + \frac{1}{2}\iint_{\mathbb{R}^3\times\mathbb{R}^3}\frac{\rho(x)\,\rho(y)}{|x-y|}\,dx\,dy - \int_{\mathbb{R}^3}F(\rho(x))\,dx, \tag{12}$$

where $F$ is a nonlinear function determined on chemical basis.

Reducing the complexity of (2) comes at a price: *nonlinearity*. Whereas the optimality equation (4) is a linear eigenvalue problem (in a high dimensional space), the equation to be solved for most of the approximations of (2) is a *nonlinear eigenvalue problem* (in a space of lower dimension, though). This is easily seen on the expressions (9) and (12). However they are derived and irrespective of their chemical meaning, the wavefunctions methods and DFT-based methods both lead to a *nonlinear eigenvalue problem*:

$$-\Delta\phi_j + \mathcal{W}(\phi_1,\ldots,\phi_N)\phi_j = \lambda_j\phi_j, \quad j = 1,\ldots,N, \tag{13}$$

where the $\lambda_j$ are the Lagrange multipliers of the constraints. Equations (13) are often called *Self-Consistent Field* (SCF) equations to emphasize the nonlinear feature, encoded in the operator $\mathcal{W}$.

There are many questions of mathematical interest. The existence of a minimizer (under appropriate physically relevant conditions) for several models related to HF and DFT-type approximations is now established. Very important contributions in this direction are [62], [61], [8], [65], [66], [73], [40], [59]. For most models of practical interest, the existence of a minimizer is known. In contrast, nothing is known on the uniqueness. A major reason for this is that almost all models of practical interest are *nonconvex*. The relation of these approximated models with the original model (2) has also been investigated, e.g. in [4], [38] for some physically relevant asymptotic regimes.

Mathematically, all problems arising in electronic structure theory are *nonlinear minimization problems* with possible lacks of compactness at infinity (most of them are posed on the whole space $\mathbb{R}^N$, and are subject to a constraint, see (8) and (11)). The Euler–Lagrange equation is a system of *nonlinear elliptic partial differential equations* such as (13). The ellipticity basically comes from the Laplacian operator, modelling the kinetic energy in (1). At one stage or another, *spectral theory* comes into the picture. More precisely, the spectral theory of *Schrödinger operators* $-\Delta + V$ often plays a key role. All this concerns the search for the ground state in the nonrelativistic setting, at zero temperature. When relativistic effects have to be accounted for, the Laplacian operator is replaced by the Dirac operator (unbounded from below), and the theoretical setting drastically changes. Important mathematical contributions on the relativistic setting are [36], [34], [35]. They have given birth to more efficient computational techniques. On the other hand, temperature effects may

also be accounted for, through the introduction of a statistics, see [64] for one of the rare mathematical studies. Like for temperature effects, the theory of excited states is not in a satisfactory state. Attempts to place the latter notion on a sound ground are [59], [23].

In the numerical practice, the problem is discretized using *Galerkin techniques*, and more precisely *spectral methods*. The basis functions used for discretization are typically gaussian approximations of the eigenfunctions of a hydrogen-like operator ($M = N = 1$ in (1)), or plane waves. The latter is very well adapted to solid state calculations. The former is incredibly efficient for calculations of molecular systems. A remarkable accuracy is reached with a limited number of basis functions. One reason why hydrogen-like basis functions outperform all other basis sets is that they are problem-dependent basis functions, which very well reproduce the exponential decrease at infinity and the cusp of wavefunctions at the point nuclei. More general purpose basis sets, such as finite elements, have difficulties in doing so, unless expensive mesh refinement techniques are employed. Finite-difference methods also exist, termed in this context *real-space* methods, but they are used for very specific applications, related to solid-state calculations.

After discretization, the equations are solved using *nonlinear optimization* techniques. Surprisingly, the problem is not addressed as a minimization problem, but in the form of the optimality equations (13). The latter is the only possible approach, considering the number of local minima, and despite the fact there is no theoretical basis for this. It reveals as an efficient approach, mostly because computations often benefit from prior calculations for adequately preconditioning the solution procedure. The algorithms in use for solving (13) are known as *SCF-algorithms*. Formally, they are elaborate variants of fixed-point iterations such as

$$-\Delta\phi_j^{n+1} + \mathcal{W}(\phi_1^n, \ldots, \phi_N^n)\phi_j^{n+1} = \lambda_j^{n+1}\phi_j^{n+1}, \quad j = 1, \ldots, N. \tag{14}$$

Their numerical analysis, initiated in [3], was performed only recently, see [18], [19] and [54] for a review. A rigorous mathematical insight into SCF-algorithms has led to definite improvements of their efficiency [52]. Alternative techniques may also be used. An original approach, based on *a posteriori error estimators* and related to Newton-type algorithms, is introduced in [69].

Notice that each inner loop of the nonlinear procedure involves a *linear* eigenvalue problem. This restricts the range of tractable systems (say typically that systems with a few hundreds of electrons can be standardly treated on a workstation). Ad hoc techniques may however be employed to broaden the spectrum of tractable systems. The latter are known as *linear scaling techniques*, for they significantly reduce the complexity of the diagonalization step, which in principle scales cubically with respect to the size of the system, see [12], [41], [42]. The bottom line for such a reduction is that the eigenelements are not explicitly needed: only the projector on the space spanned by the first $N$ eigenvectors is needed for the computation of all quantities of practical interest. The problem is thus rephrased so that an explicit diagonalization is avoided. Correspondingly, advanced techniques such as *Fast Multipole techniques* [51], are

used for assembling the huge matrices to be manipulated. Using a combination of such techniques, larger systems, consisting of thousands of electrons, may be treated on a workstation. The approach however still waits for a rigorous mathematical analysis.

The above description of the numerical approach concerns isolated molecular systems. Specific models are employed for the simulation of the liquid phase, and of the solid (crystalline) phase, respectively. In the former case, a commonly used setting is the *continuum model*: the molecule is placed in a cavity, surrounded by a dielectric medium modelling the solvent. Consequently, the Coulomb interaction potential appearing in $V$ (see (9) and (12)) is replaced by the Green function of electrostatics set on the cavity. *Integral equation methods* are utilized for the numerical resolution: [20], [21]. On the other hand, the modelling of the crystal phase corresponds to a periodic setting [2]: loosely speaking, the functions $\psi_j$ are indexed by a vector, i.e. for each $k$, $\psi_j^k(x)$ is the $j$-th eigenvector periodic in $x$ up to a phase factor $e^{-ik.x}$. In practice, the set of vectors $k$ is discretized, and the corresponding equations (13), now indexed by $k$, are solved. For the practical discretization and resolution of the equations, dedicated techniques are employed: see [53], [30]. Several theoretical issues regarding the rigorous derivation of the models for the crystalline phase have already been considered: see [62], [24], and other works by the same authors. Seminal contributions by L. Van Hove, F. Dyson, A. Lenard, D. Ruelle, E. Lieb, J. Lebowitz, B. Simon, Ch. Fefferman predated those. The bottom line is to justify the models of the solid phase proving they are the limits of models for molecular systems, as the system size grows. More generally, this is part of an enormous body of literature in mathematical physics addressing questions related to *thermodynamic limits*.

**2.3. Emerging approaches.** Wavefunctions methods and DFT-based methods are dominant computational methods. Apart from the main stream, there are three promising tracks followed either by chemists or mathematicians, that need to be advertised. They consist in addressing the problem (2) in its original form, without any approximation, in principle.

The first approach ([28]), actually almost as old as theoretical chemistry itself, is based on a rephrasing of the minimization problem in terms of the marginals

$$\gamma(x_1, x_2, x_1', x_2') = \int_{\mathbb{R}^{3(N-2)}} \psi(x_1, x_2, x_3, \ldots, x_N)\, \psi^*(x_1', x_2', x_3, \ldots, x_N)\, dx_3 \ldots dx_N,$$

called *second-order reduced density matrices*. This is possible because the operator (1) only involves the positions $x_i$ and $x_j$ of two electrons simultaneously.

The second approach (called *diffusion Monte-Carlo* in the specific context of chemistry) consists in determining the minimizer to problem (2) by solving the fictitious evolution equation

$$\frac{\partial \psi}{\partial t} + H_e \psi = 0,$$

using the Feynmann–Kac representation formula. Considering the long time limit provides with a strategy to evaluate (2), see [67], [22].

The third approach, advocated by some mathematicians ([44], [43]), consists in recognizing (4) as a high-dimensional partial differential equation and applying the techniques of *sparse tensor products*. The technique relies upon a theoretical framework set in this context in [78] (see also other works by the same author).

For all these three approaches, enormous theoretical and practical difficulties are still unsolved. For the first approach, the theoretical challenge is to determine the variational space for $\gamma$ corresponding to the variational space (3) for $\psi$. This is where *approximations* are again introduced. The story is not closed. Current techniques rely upon *semi-definite programming* or *Augmented Lagrangian methods* to solve the associated discretized problem. Somehow related to this, the difficulty for the last two approaches lies in the fermionic nature of the electrons: the wavefunction is constrained to be antisymmetric. In addition, the problem also requires appropriate techniques such as high-dimensional integration techniques, mainly based upon Monte-Carlo, or Quasi Monte-Carlo, techniques.

These three approaches are not in position today to compete with the other more classical ones, which have benefited over the past years from constant efforts shared by a huge community. They are however instances of approaches that may be turning points and may change the landscape of computational chemistry in the years to come.

All the above describes approaches to determine the electronic structure. As mentioned in the Introduction, this is most often the inner part of a calculation. The outer part concerns the nuclei, parameters of the inner calculation so far. In the static setting, the problem is usually to determine their optimal position, i.e. the most stable conformation. This is the molecular mechanics problem (6). In biology, such a problem is crucial. It is the well-known question of determining the 3-dimensional structure of the molecule (protein,…) under study. Techniques of *discrete optimization*, *combinatorial optimization*, in particular using *stochastics-based algorithms*, are employed. Notice that the mathematical question of the existence of such a most stable configuration is mostly open for all models of interest, in spite of outstanding contributions on academic models [25].

## 3. Dynamical problems and problems at larger scales

Regarding time-dependent problems, the evolution of the nuclei is again often considered classical. The Newton equations of motion (7) are solved. This is the extremely popular field of molecular dynamics. It is called *ab initio* when $W$ in the right-hand side of (7) is calculated *on-the-fly* from quantum mechanical models for the electronic structure (see [76] for a review), and *classical* when $W$ has a parameterized analytic form, fitted on previous calculations or experiments. Parameterized potentials reportedly work well in biological applications, but experience some difficulties for materials science applications.

For the explicit evaluation of $W$, a very common assumption in chemistry is *adiabaticity* (see [45], [46], [75] and other works by the same authors for mathematical discussions). When adiabaticity is assumed, $W$ ideally takes the form (2) and is computed using the static models and the techniques of Section 2.

In some cases such as collisions that involve electronic excited states with intersecting energy surfaces, the adiabatic approximation is not valid. Then equations (7) are coupled with the explicit time evolution of the electronic structure, simulated by (5), or one of its approximation (analogous to those of Section 2, adapted to the dynamics setting): see [17], [26], [50] for related mathematical studies.

A peculiarity to be borne in mind, which has a huge impact on the mathematical analysis, is that (7) is not only solved in order to determine the precise evolution of the system. Often, based on the *ergodicity* assumption, (7) serves as a tool for sampling the configuration space of the system in the microcanonical ensemble. Averages on this space are indeed related to quantities of macroscopic interest. Examples include the determination of the temperature, or the pressure, of a liquid system, or the determination of some mechanical properties such as the Young modulus of a crystalline solid.

Numerous challenging issues in numerical analysis arise from molecular dynamics. First, system (7) contains several, disproportionate, timescales. Think e.g. of bond lengths or angles oscillating either rapidly (i.e. at the femtosecond ($10^{-15}$ s) scale) or slowly (hundreds of femtoseconds). Adequate techniques must be employed: multi-timestep techniques, homogenization, damping of rapid degrees of freedom, integration of differential algebraic equations. Second, the integration of (7) over long times raises specific questions: geometric integration, backward error analysis, integration of Hamiltonian, symplectic, reversible systems, etc. For related questions, reference treatises or reviews in the numerical analysis literature are e.g. [11], [58], [47], [71, 13]. See also [72], [31] in the molecular dynamics community. Third, the longest timescales that may be reached using an explicit Hamiltonian dynamics are not sufficient to cover the practical needs. Say the limit is, in good cases, the microsecond and, more generally, the nanosecond. A major reason for this is that the evolution of the system basically consists of long period of oscillations around metastable sets (basins of energy), separated by rapid hoppings between these states (*simulation of infrequent events*). Techniques for reaching extremely long simulation times or for efficiently sampling the phase space are mandatory to complement standard molecular dynamics: *stochastic differential equations*, *Markov chains*, *path integrals*, etc. In addition, other ensembles than the microcanonical ensemble may be sampled by adequate deterministic modifications of Hamiltonian dynamics (*thermostated* equations of motion) or by stochastic equations (*Langevin dynamics*). See [27], [29], [33], [32], [77] and many other references by these authors and others, for examples of techniques. The above shows that molecular dynamics problems have a twofold *multiscale nature*: even on small time frames, they involve degrees of freedom with drastically different characteristic times, and in addition to this, the integration must be carried over extremely long times. This is a significant difficulty.

In spite of this, molecular dynamics simulation, along with acceleration techniques, is an extremely successful field and provides with impressively good quantitative results on some macroscopic quantities. Standard calculations on workstations simulate $10^8$ atoms over the nanosecond, record calculations largely outperform this. Here again, some practical and theoretical pitfalls remain and the mathematical understanding of the methods is to be improved. In a nutshell, one could say that it is not thoroughly understood *why molecular dynamics techniques perform so well, i.e. why averages calculated from erroneous or approximate trajectories are so close to the actual values of macroscopic quantities.*

The connection between the microscopic scale and the macroscopic scale is a broad subject. Calculations of ensemble averages using molecular dynamics and related techniques is one instance of it. Other questions concern the relation of molecular simulation with continuum mechanics. An example of a theoretical work in this direction is [9]. See also [10] for a review and references on the numerous practical applications, in particular applications related to computational materials science where strategies coupling molecular simulation techniques and continuum mechanics techniques are rapidly developping.

## 4. Trends

As briefly overviewed above, molecular simulation is an extremely rich application field of mathematics. Only a tiny part of the models and methods used in practice have been explored mathematically to date. There is much room for improvement in the mathematical understanding, the numerical analysis, the design of advanced techniques, to further enhance the field.

Some theoretical challenges concern the uniqueness of the ground state, the definition of excited states, the foundations of models at finite temperature, etc.

On the numerical side, current efforts in the mathematical community are directed towards the development of novel methods: sparse grids techniques, domain decomposition methods [7], stochastic methods for electronic structure calculations [22], methods for the determination of excited states [23], reduced basis methods [15], [16], parallel-in-time methods [5], stochastic methods for the computation of free energies [57], etc.

# Evolutionary dynamics of cooperation

Martin A. Nowak

**Abstract.** Cooperation means a donor pays a cost, $c$, for a recipient to get a benefit $b$. In evolutionary biology, cost and benefit are measured in terms of fitness. While mutation and selection represent the main 'forces' of evolutionary dynamics, cooperation is a fundamental principle that is required for every level of biological organization. Individual cells rely on cooperation among their components. Multi-cellular organisms exist because of cooperation among their cells. Social insects are masters of cooperation. Most aspects of human society are based on mechanisms that promote cooperation. Whenever evolution constructs something entirely new (such as multi-cellularity or human language), cooperation is needed. Evolutionary construction is based on cooperation. I will present five basic principles for the evolution of cooperation, which arise in the theories of kin selection, direct reciprocity, indirect reciprocity, graph selection and group selection.

**Mathematics Subject Classification (2000).** 92B05.

**Keywords.** Mathematical biology, evolutionary dynamics, kin selection, evolutionary graph theory, indirect reciprocity, Prisoner's Dilemma.

## 1. Kin selection

In a pub conversation, J. B. S. Haldane, one of the founding fathers of a mathematical approach to biology, once remarked: 'I will jump into the river to save two brothers or eight cousins.' This insight was precisely formulated by William Hamilton many years later. He wrote a PhD thesis on this topic, submitted a long paper to the Journal of Theoretical Biology, disappeared into the Brazilian jungle and was world famous when he returned a few years later (Hamilton 1964a, b). The theory was termed 'kin selection' by John Maynard Smith (1964). The crucial equation is the following. Cooperation among relatives can be favored by natural selection if the coefficient of genetic relatedness, $r$, between the donor and the recipient exceeds the cost to benefit ratio of the altruistic act

$$r > c/b. \tag{1}$$

Kin selection theory has been tested in numerous experimental studies. Many cooperative acts among animals occur between close kin (Frank 1998, Hamilton 1998). The exact relationship between kin selection and other mechanisms such as group selection and spatial reciprocity, however, remains unclear. A recent study even suggests that much of cooperation in social insects is due to group selection rather than kin selection (Wilson & Hölldobler 2005).

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

## 2. Direct reciprocity

In 1971, Robert Trivers published a landmark paper entitled 'The evolution of reciprocal altruism' (Trivers 1971). Trivers analyzed the question of how natural selection could lead to cooperation between unrelated individuals. He discusses three biological examples: cleaning symbiosis in fish, warning calls in birds and human interactions. Trivers cites Luce & Raiffa (1957) and Rapoport & Chammah (1965) for the Prisoner's Dilemma, which is a game where two players have the option to cooperate or to defect. If both cooperate they receive the 'reward', $R$. If both defect they receive the 'punishment', $P$. If one cooperates and the other defects, then the cooperator receives the 'sucker's payoff', $S$, while the defector receives the 'temptation', $T$. The PD is defined by the ranking $T > R > P > S$.

Would you cooperate or defect? Assuming the other person will cooperate it is better to defect, because $T > R$. Assuming the other person will defect it is also better to defect, because $P > S$. Hence, no matter what the other person will do it is best to defect. If both players analyze the game in this 'rational' way then they will end up defecting. The dilemma is that they both could have received a higher payoff if they had chosen to cooperate. But cooperation is 'irrational'.

We can also imagine a population of cooperators and defectors and assume that the payoff for each player is determined by many random interactions with others. Let $x$ denote the frequency of cooperators and $1-x$ the frequency of defectors. The expected payoff for a cooperator is $f_C = Rx + S(1-x)$. The expected payoff for a defector is $f_D = Tx + P(1-x)$. Therefore, for any $x$, defectors have a higher payoff than cooperators. In evolutionary game theory, payoff is interpreted as fitness. Successful strategies reproduce faster and outcompete less successful ones. Reproduction can be cultural or genetic. In the non- repeated PD, in a well mixed population, defectors will outcompete cooperators. Natural selection favors defectors.

Cooperation becomes an option if the game is repeated. Suppose there are $m$ rounds. Let us compare two strategies, 'always defect' (ALLD), and GRIM, which cooperates on the first move, then cooperates as long as the opponent cooperates, but permanently switches to defection if the opponent defects once. The expected payoff for GRIM versus GRIM is $nR$. The expected payoff for ALLD versus GRIM is $T + (m-1)P$. If $nR > T + (m-1)P$ then ALLD cannot spread in a GRIM population when rare. This is an argument of evolutionary stability. Interestingly, Trivers (1971) quotes 'Hamilton (pers. commun.)' for this idea.

A small problem of the above analysis is that given a known number of rounds it is best to defect in the last round and by backwards induction it is also best to defect in the penultimate round and so on. Therefore, it is more natural to consider a repeated game with a probability $w$ of having another round. In this case, the expected number of rounds is $1/(1-w)$, and GRIM is stable against invasion by ALLD provided $w > (T-R)/(T-P)$.

We can also formulate the PD as follows. The cooperator helps at a cost, $c$, and the other individual receives a benefit $b$. Defectors do not help. Therefore we have

$T = b$, $R = b - c$, $P = 0$ and $S = -c$. The family of games that is described by the parameters $b$ and $c$ is a subset of all possible Prisoner's Dilemma games as long as $b > c$. For the repeated PD, we find that ALLD cannot invade GRIM if

$$w > c/b. \tag{2}$$

The probability of having another round must exceed the cost to benefit ratio of the altruistic act (Axelrod & Hamilton 1981, Axelrod 1984).

Thus, the repeated PD allows cooperation, but the question arises – what is a good strategy for playing this game? This question was posed by the political scientist, Robert Axelrod. In 1979, he decided to conduct a tournament of computer programs playing the repeated PD. He received 14 entries, from which the surprise winner was tit-for-tat (TFT), the simplest of all strategies that were submitted. TFT cooperates in the first move, and then does whatever the opponent did in the previous round. TFT cooperates if you cooperate, TFT defects if you defect. It was submitted by the game theorist Anatol Rapoport (who is also the co-author of the book Rapoport & Chammah,1965). Axelrod analyzed the events of the tournament, published a detailed account and invited people to submit strategies for a second championship. This time he received 63 entries. John Maynard Smith submitted 'tit-for-two-tats', a variant of TFT which defects only after the opponent has defected twice in a row. Only one person, Rapoport, submitted TFT, and it won again. At this time, TFT was considered to be the undisputed world champion in the heroic world of the repeated PD.

But one weakness became apparent very soon (Molander 1985, May 1987). TFT cannot correct mistakes. The tournaments were conducted without strategic noise. In the real world, 'trembling hands' and 'fuzzy minds' cause erroneous moves. If two TFT players interact with each other, a single mistake leads to a long sequence of alternating defection and cooperation. In the long run two TFT players get the same low payoff as two players who flip coins for every move in order to decide whether to cooperate or to defect. Errors destroy TFT.

In 1989, we began to conduct 'evolutionary tournaments' (Nowak & Sigmund 1992). Instead of inviting experts to submit programs, we asked mutation and selection to explore (some portion of) the strategy space of the repeated PD in the presence of noise. The initial random ensemble of strategies was quickly dominated by ALLD. If the opposition is nonsensical, it is best to defect. A large portion of the population began to adopt the ALLD strategy and everything seemed lost. But after some time, a small cluster of players adopted a strategy very close to TFT. If this cluster is sufficiently large, then it can increase in abundance, and the entire population swings from ALLD to TFT. Reciprocity (and therefore cooperation) has emerged. We can show that TFT is the best catalyst for the emergence of cooperation. But TFT's moment of glory was brief and fleeting. In all cases, TFT was rapidly replaced by another strategy. On close inspection, this strategy turned out to be 'generous-tit-for-tat' (GTFT) which always cooperates if the opponent has cooperated on the previous move, but sometimes (probabilistically) even cooperates when the opponent has defected. Natural selection had discovered 'forgiveness'.

After many generations, however, GTFT is undermined by unconditional cooperators, ALLC. In a society, where everybody is nice (using GTFT), there is almost no need to remember how to retaliate against a defection. A biological trait which is not used is likely to be lost by random drift. Birds that escape to islands without predators lose the ability to fly. Similarly, a GTFT population is softened and turns into an ALLC population.

Once most people play ALLC, there is an open invitation for ALLD to seize power. This is precisely what happens. The evolutionary dynamics run in cycles: from ALLD to TFT to GTFT to ALLC and back to ALLD. These oscillations of cooperative and defecting societies are a fundamental part of all our observations regarding the evolution of cooperation. Most models of cooperation show such oscillations. Cooperation is never a final state of evolutionary dynamics. Instead it is always lost to defection after some time and has to be re-established. These oscillations are also reminiscent of alternating episodes of war and peace in human history (Figure 1).

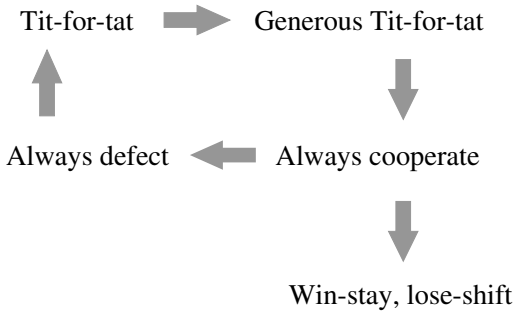

Figure 1. Evolutionary cycles of cooperation and defection. A small cluster of tit-for-tat (TFT) players or even a lineage starting from a single TFT player in a finite population can invade 'always defect' (ALLD). In fact, TFT is the most efficient catalyst for the first emergence of cooperation in an ALLD population. But in a world of 'fuzzy minds' and 'trembling hands', TFT is soon replaced by generous-tit-for-tat (GTFT), which can re-establish cooperation after occasional mistakes. If everybody uses GTFT, then 'always cooperate' (ALLC) is a neutral variant. Random drift leads to ALLC. An ALLC population invites invasion by ALLD. But ALLC is also dominated by 'win-stay, lose-shift' (WSLS), which leads to more stable cooperation than tit-for-tat-like strategies.

A subsequent set of simulations, exploring a larger strategy space, led to a surprise (Nowak & Sigmund 1993). The fundamental oscillations were interrupted by another strategy which seems to be able to hold its ground for a very long period of time. Most surprisingly, this strategy is based on the extremely simple principle of win-stay, lose-shift (WSLS). If my payoff is $R$ or $T$ then I will continue with the same move next round. If I have cooperated then I will cooperate again, if I have defected then I will defect again. If my payoff is only $S$ or $P$ then I will switch to the other move next round. If I have cooperated then I will defect, if I have defected then I will cooperate (Figure 2). If two WSLS strategists play each other, they cooperate

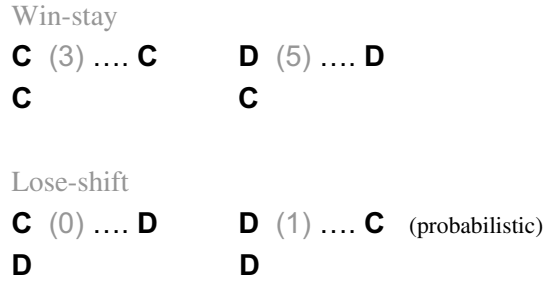

Figure 2. 'Win-stay, lose-shift' (WSLS) embodies a very simple principle. If you do well then continue with what you are doing. If you are not doing well, then try something else. Here we consider the Prisoner's Dilemma (PD) payoff values $R = 3$, $T = 5$, $P = 1$ and $S = 0$. If both players cooperate, you receive 3 points, and you continue to cooperate. If you defect against a cooperator, you receive 5 points, and you continue to defect. But if you cooperate with a defector, you receive 0 points, and therefore you will switch from cooperation to defection. If, on the other hand, you defect against a defector, you receive 1 point, and you will switch to cooperation. Your aspiration level is 3 points. If you get at least 3 points then you consider it a 'win' and you will 'stay' with your current choice. If you get less than 3 points, you consider it a 'loss' and you will 'shift' to another move. If $R > (T + P)/2$ (or $b/c > 2$) then WSLS is stable against invasion by ALLD. If this inequality does not hold, then our evolutionary simulations lead to a stochastic variant of WSLS, which cooperates after a DD move only with a certain probability. This stochastic variant of WSLS is then stable against invasion by ALLD.

most of the time. If a defection occurs accidentally, then in the next move both will defect. Hereafter both will cooperate again. WSLS is a simple deterministic machine to correct stochastic noise. While TFT cannot correct mistakes, both GTFT and WSLS can correct mistakes. But WSLS has an additional ace in its hand. When WSLS plays ALLC it will discover after some time that ALLC does not retaliate. After an accidental defection, WSLS will switch to permanent defection. Therefore, a population of WSLS players does not drift to ALLC. Cooperation based on WSLS is more stable than cooperation based on tit-for-tat-like strategies. The repeated PD is mostly known as a story of tit-for-tat, but win-stay, lose-shift is a superior strategy in an evolutionary scenario with errors, mutation and many generations (Fudenberg & Maskin 1990, Nowak & Sigmund 1993).

Incidentally, WSLS is stable against invasion by ALLD if $b/c > 2$. If instead $1 < b/c < 2$ then a stochastic variant of WSLS dominates the scene; this strategy cooperates after a mutual defection only with a certain probability. Of course, all strategies of direct reciprocity, such as TFT, GTFT or WSLS can only lead to the evolution of cooperation if the fundamental inequality (2) is fulfilled.

## 3. Indirect reciprocity

While direct reciprocity embodies the idea 'You scratch my back and I scratch yours', indirect reciprocity suggests 'You scratch my back and I scratch someone else's'. Why should this work? Presumably I will not get scratched if it becomes known that I scratch nobody. Indirect reciprocity, in this view, is based on reputation (Nowak & Sigmund 1998a, b, 2005). But why should you care about what I do to a third person?

The main reason why economists and social scientists are interested in indirect reciprocity is because one-shot interactions between anonymous partners in a global market become increasingly common and tend to replace the traditional long-lasting associations and long-term interactions between relatives, neighbors, or members of the same village. A substantial part of our life is spent in the 'company of strangers', and many transactions are no longer face-to-face. The growth of e-auctions and other forms of e-commerce is based, to a considerable degree, on reputation and trust. The potential to exploit such trust raises what economists call moral hazards. How effective is reputation, especially if information is only partial?

Evolutionary biologists, on the other hand, are interested in the emergence of human societies, which constitutes the last (up to now) of the major transitions in evolution. In contrast to other eusocial species, such as bees, ants or termites, humans display a high degree of cooperation between non-relatives (Fehr & Fischbacher 2003). A considerable part of human cooperation is based on moralistic emotions, such as anger directed towards cheaters or the 'warm inner glow' felt after performing an altruistic action. Intriguingly, humans not only feel strongly about interactions which involve them directly, they also judge actions between third parties as evidenced by the contents of gossip. There are numerous experimental studies of indirect reciprocity based on reputation (Wedekind & Milinski 2000, Milinski et al. 2002, Wedekind & Braithwaite 2002, Seinen & Schramm 2006).

A simple model of indirect reciprocity (Nowak & Sigmund 1998a, b) assumes that, within a well-mixed population, individuals meet randomly, one in the role of the potential donor, the other as the potential recipient. Each individual experiences several rounds of this interaction in each role, but never with the same partner twice. A player can follow either an unconditional strategy, such as always cooperate or always defect, or a conditional strategy, which discriminates among the potential recipients according to their past interactions. In a simple example, a discriminating donor helps a recipient if her score exceeds a certain threshold. A player's score is 0 at birth, increases whenever that player helps and decreases whenever the player withholds help. Individual-based simulations and direct calculations show that cooperation based on indirect reciprocity can evolve provided the probability, $p$, of knowing the social score of another person exceeds the cost-to-benefit ratio of the altruistic act,

$$p > c/b. \tag{3}$$

The role of genetic relatedness that is crucial for kin selection is replaced by social acquaintanceship. In a fluid population, where most interactions are anonymous and

people have no possibility of monitoring the social score of others, indirect reciprocity has no chance. But in a socially viscous population, where people know one another's reputation, cooperation by indirect reciprocity can thrive (Nowak & Sigmund 1998a).

In a world of binary moral judgments (Nowak & Sigmund 1998b, Leimar & Hammerstein 2001, Panchanathan & Boyd 2003, Fishman 2003, Brandt & Sigmund 2004, 2005), there are four ways of assessing donors in terms of 'first-order assessment': always consider them as good, always consider them as bad, consider them as good if they refuse to give, or consider them as good if they give. Only this last option makes sense. Second-order assessment also depends on the score of the receiver; for example, it can be deemed good to refuse help to a bad person. There are 16 second-order rules. Third-order assessment also depends on the score of the donor; for example, a good person refusing to help a bad person may remain good, but a bad person refusing to help a bad person remains bad. There are 256 third-order assessment rules. We display three of them in Figure 3. Using the Scoring assessment rule,

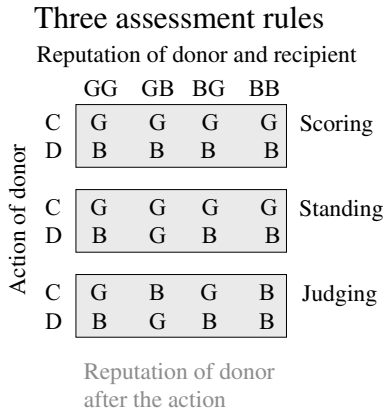

Figure 3. Assessment rules specify how an observer judges an interaction between a potential donor and a recipient. Here we show three examples of assessment rules in a world of binary reputation, good (G) and bad (B). For 'Scoring', cooperation (C) earns a good reputation and defection (D) earns a bad reputation. 'Standing' is very similar to Scoring, the only difference is that a 'good' donor can defect against a 'bad' recipient without losing his 'good' reputation. Note that Scoring is associated with costly punishment (Fehr & Gaechter 2002, Sigmund et al. 2001), whereas for Standing punishment of 'bad' recipients is cost-free. For 'Judging' it is 'bad' to help a 'bad' recipient.

cooperation, C, always leads to a good reputation, G, whereas defection, D, always leads to a bad reputation, B. Standing (Sugden 1986) is like Scoring, but it is not bad if a good donor defects against a bad recipient . With Judging, in addition, it is bad to cooperate with a bad recipient.

An action rule for indirect reciprocity prescribes giving or not giving, depending on the scores of both donor and recipient. For example, you may decide to help if the recipient's score is good or your own score is bad. Such an action might increase your

own score and therefore increase the chance of receiving help in the future. There are 16 action rules.

If we view a strategy as the combination of an action rule and an assessment rule, we obtain 4096 strategies. In a remarkable calculation, Ohtsuki & Iwasa (2004, 2005) analyzed all 4096 strategies and proved that only eight of them are evolutionarily stable under certain conditions and lead to cooperation (Figure 4). Both Standing

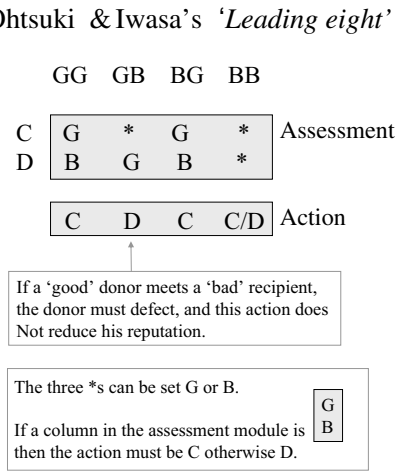

Figure 4. Ohtsuki & Iwasa (2004, 2005) analyzed the combination of $2^8 = 256$ assessment modules with $2^4 = 16$ action modules. This is a total of 4096 strategies. They found that 8 of these strategies can be evolutionarily stable and lead to cooperation, provided that everybody agrees on each other's reputation. (In general, uncertainty and incomplete information might lead to private lists of the reputation of others.) The three asterisks in the assessment module indicate a free choice between G and B. There are therefore $2^3 = 8$ different assessment rules which make up the 'leading eight'. The action module is built as follows: if the column in the assessment module is G and B, then the corresponding action is C, otherwise the action is D. Note that Standing and Judging are members of the leading eight, but neither Scoring nor Shunning is included.

and Judging belong to the leading eight, but not Scoring. We expect, however, that Scoring has a similar role in indirect reciprocity to that of tit-for-tat in direct reciprocity. Neither strategy is evolutionarily stable, but their ability to catalyze cooperation in adverse situations and their simplicity constitute their strength. In extended versions of indirect reciprocity in which donors can sometimes deceive others about the reputation of the recipient, Scoring is the 'foolproof' concept of 'I believe what I see'. Scoring judges the action and ignores the stories. There is also experimental evidence that in certain situations humans follow scoring rather than standing (Milinski et al. 2001).

In human evolution, there must have been a tendency to move from the simple cooperation promoted by kin or group selection to the strategic subtleties of direct and indirect reciprocity. Direct reciprocity requires precise recognition of individual

people, a memory of the various interactions one had with them in the past, and enough brain power to conduct multiple repeated games simultaneously. Indirect reciprocity, in addition, requires the individual to monitor interactions among other people, possibly judge the intentions that occur in such interactions, and keep up with the ever changing social network of the group. Reputation of players may not only be determined by their own actions, but also by their associations with others.

We expect that indirect reciprocity has coevolved with human language. On one hand, it is helpful to have names for other people and to receive information about how a person is perceived by others. On the other hand, a complex language is especially necessary if there are intricate social interactions. The possibilities for games of manipulation, deceit, cooperation and defection are limitless. It is likely that indirect reciprocity has provided the very selective scenario that led to cerebral expansion in human evolution.

## 4. Graph selection (or network reciprocity)

Game theory was invented by von Neumann and Morgenstern (1944) as a mathematical approach to understanding the strategic and economic decisions of humans. Hamilton (1967), Trivers (1971) and Maynard Smith & Price (1973) brought game theory to biology. Instead of analyzing the interaction between two rational players, evolutionary game theory explores the dynamics of a population of players under the influence of natural selection (Maynard Smith 1982). In the classical setting of the replicator equation, the population size is infinite and interactions are equally likely between any two individuals (Taylor & Jonker 1978, Hofbauer et al. 1979, Zeeman 1980). Each individual obtains an average payoff which is interpreted as biological fitness: strategies reproduce according to their payoff. Successful strategies spread and eliminate less successful ones. The payoff depends on the frequency of strategies in the population. Hence, natural selection is frequency dependent. The replicator equation is deeply connected to the concept of an evolutionarily stable strategy (ESS) or Nash equilibrium. In the framework of the replicator equation, an ESS cannot be invaded by any mutant strategy (Hofbauer & Sigmund 1998). For recent books on game theory and evolutionary game theory we refer to Fudenberg & Tirole 1991, Binmore 1994, Weibull 1995, Samuelson 1997, Fudenberg & Levine 1998, Hofbauer & Sigmund 1998, Gintis 2000, Cressman 2003. Recent reviews of evolutionary game dynamics are Hofbauer & Sigmund (2003) and Nowak & Sigmund (2004).

The traditional model of evolutionary game dynamics assumes that populations are well-mixed, which means that interactions between any two players are equally likely. More realistically, however, the interactions between individuals are governed by spatial effects or social networks. Let us therefore assume that the individuals of a population occupy the vertices of a graph (Nakamaru et al. 1997, 1998, Skyrms & Pemantle 2000, Abramson & Kuperman 2001, Ebel & Bornholdt 2002, Lieberman et al. 2005, Nakamaru & Iwasa 2005, Santos et al. 2005, Santos & Pacheco 2005).

The edges of the graph determine who interacts with whom (Figure 5). Consider a population of $N$ individuals consisting of cooperators and defectors. A cooperator

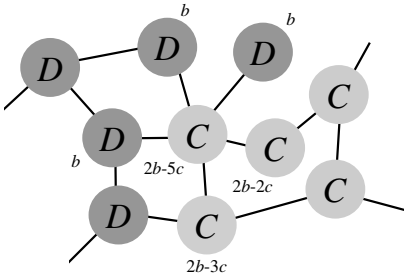

Figure 5. Games on graphs. The members of a population occupy the vertices of a graph (or social network). The edges denote who interacts with whom. Here we consider the specific example of cooperators, $C$, competing with defectors, $D$. A cooperator pays a cost, $c$, for every link. Each neighbor of a cooperator receives a benefit, $b$. The payoffs of some individuals are indicated in the figure. The fitness of each individual is a constant, denoting the 'baseline fitness', plus the payoff of the game. For evolutionary dynamics, we assume that in each round a random player is chosen to die, and the neighbors compete for the empty site in a mode proportional to their fitness. A simple rule emerges: if $b/c > k$ then selection favors cooperators over defectors. Here $k$ is the average number of neighbors per individual.

helps all individuals to whom it is connected. If a cooperator is connected to $k$ other individuals and $i$ of those are cooperators, then its payoff is $bi - ck$. A defector does not provide any help, and therefore has no costs, but it can receive the benefit from neighboring cooperators. If a defector is connected to $k$ other individuals and $j$ of those are cooperators, then its payoff is $bj$. Evolutionary dynamics are described by an extremely simple stochastic process: at each time step, a random individual adopts the strategy of one of its neighbors proportional to their fitness.

We note that stochastic evolutionary game dynamics in finite populations is sensitive to the intensity of selection. In general, the reproductive success (fitness) of an individual is given by a constant, denoting the baseline fitness, plus the payoff that arises from the game under consideration. Strong selection means that the payoff is large compared to the baseline fitness; weak selection means the payoff is small compared to the baseline fitness. It turns out that many interesting results can be proven for weak selection, which is an observation also well known in population genetics.

The traditional, well-mixed population of evolutionary game theory is represented by the complete graph, where all vertices are connected, which means that all individuals interact equally often. In this special situation, cooperators are always opposed by natural selection. This is the fundamental intuition of classical evolutionary game theory. But what happens on other graphs?

We need to calculate the probability, $\rho_C$, that a single cooperator, starting in a random position, turns the whole population from defectors into cooperators. If selection neither favors nor opposes cooperation, then this probability is $1/N$, which

is the fixation probability of a neutral mutant. If the fixation probability $\rho_C$ is greater than $1/N$, then selection favors the emergence of cooperation. Similarly, we can calculate the fixation probability of defectors, $\rho_D$.

A surprisingly simple rule determines whether selection on graphs favors cooperation. If

$$b/c > k, \tag{4}$$

then cooperators have a fixation probability greater than $1/N$ and defectors have a fixation probability less than $1/N$. Thus, for graph selection to favor cooperation, the benefit-to-cost ratio of the altruistic act must exceed the average degree, $k$, which is given by the average number of links per individual . This relationship can be shown with the method of pair-approximation for regular graphs, where all individuals have exactly the same number of neighbors (Ohtsuki et al. 2006). Regular graphs include cycles, all kinds of spatial lattices and random regular graphs. Moreover, computer simulations suggest that the rule $b/c > k$ also holds for non-regular graphs such as random graphs and scale free networks. The rule holds in the limit of weak selection and $k \ll N$. For the complete graph, $k = N$, we always have $\rho_D > 1/N > \rho_C$.

The basic idea is that natural selection on graphs (in structured populations) can favor unconditional cooperation without any need of strategic complexity, reputation or kin selection.

Games on graphs grew out of the earlier tradition of spatial evolutionary game theory (Nowak & May 1992, Herz 1994, Killingback & Doebeli 1996, Mitteldorf & Wilson 2000, Hauert et al. 2002, Le Galliard et al 2003, Hauert & Doebeli 2004, Szabo & Vukov 2004) and investigations of spatial models in ecology (Durrett & Levin 1994a, b, Hassell et al. 1994, Tilman & Kareiva 1997, Neuhauser 2001) and spatial models in population genetics (Wright 1931, Fisher & Ford 1950, Maruyama 1970, Slatkin 1981, Barton 1993, Pulliam 1988, Whitlock 2003).

## 5. Group selection

The enthusiastic approach of early group selectionists to explain the evolution of cooperation entirely from this one perspective (Wynne-Edwards 1962) has met with vigorous criticism (Williams 1966) and has led to a denial of group selection for decades. Only an embattled minority of scientists defended the approach (Eshel 1972, Wilson 1975, Matessi & Jayakar 1976, Wade 1976, Uyenoyama & Feldman 1980, Slatkin 1981, Leigh 1983, Szathmary & Demeter 1987). Nowadays, however, it seems clear that group selection acts as a powerful mechanism for the promotion of cooperation (Sober & Wilson 1998, Keller 1999, Michod 1999, Swenson et al. 2000, Kerr & Godfrey-Smith 2002, Paulsson 2002, Boyd & Richerson 2002, Bowles & Gintis 2004, Traulsen et al. 2005). We only have to make sure that its basic requirements are fulfilled in a particular situation (Maynard Smith 1976). We would like to illustrate exactly what these requirements are through the use of a simple model (Traulsen & Nowak 2006).

Imagine a population of individuals subdivided into groups. For simplicity, we assume the number of groups is constant and given by $m$. Each group contains between one and $n$ individuals. The total population size can fluctuate between the bounds $m$ and $nm$. Again, there are two types of individuals, cooperators and defectors. Individuals interact with others in their group and thereby receive a payoff. At each time step a random individual from the entire population is chosen proportional to payoff in order to reproduce. The offspring is added to the same group. If the group size is less than or equal to $n$ nothing else happens. If the group size, however, exceeds $n$ then with probability $q$ the group splits into two. In this case, a random group is eliminated (in order to maintain a constant number of groups). With probability $1-q$, the group does not divide, but instead a random individual from that group is eliminated (Figure 6). This minimalist model of multi-level selection has some interesting fea-

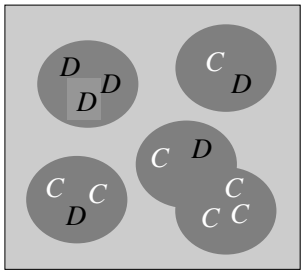

Figure 6. A simple model of group selection. A population consists of $m$ groups of maximum size $n$. Individuals interact with others in their group in the context of an evolutionary game. Here we consider the game between cooperators, $C$, and defectors, $D$. For reproduction, individuals are chosen from the entire population with a probability proportional to their payoff. The offspring is added to the same group. If a group reaches the maximum size, $n$, then it either splits in two or a random individual from that group is eliminated. If a group splits, then a random group dies, in order to keep the total population size constant. This meta-population structure leads to the emergence of two levels of selection, although only individuals reproduce.

tures. Note that the evolutionary dynamics are entirely driven by individual fitness. Only individuals are assigned payoff values. Only individuals reproduce. Groups can stay together or split (divide) when reaching a certain size. Groups that contain fitter individuals reach the critical size faster and therefore split more often. This concept leads to selection among groups, even though only individuals reproduce. The higher level selection emerges from lower level reproduction. Remarkably, the two levels of selection can oppose each other.

As before, we can compute the fixation probabilities, $\rho_C$ and $\rho_D$, of cooperators and defectors in order to check whether selection favors one or the other. If we add a single cooperator to a population of defectors, then this cooperator must first take over a group. Subsequently the group of cooperators must take over the entire population. The first step is opposed by selection, the second step is favored by selection. Hence,

we need to find out if the overall fixation probability is greater to or less than what we would obtain for a neutral mutant. An analytic calculation is possible in the limit $q \ll 1$ where individuals reproduce much more rapidly than groups divide. In this case, most of the groups are at their maximum size and hence the total population size is almost constant and given by $N = nm$. We find that selection favors cooperators and opposes defectors, $\rho_C > 1/N > \rho_D$, if

$$\frac{b}{c} > 1 + \frac{n}{m-2}. \tag{5a}$$

This result holds for weak selection. Smaller group sizes and larger numbers of competing groups favor cooperation. We also notice that the number of groups, $m$, must exceed two. There is an intuitive reason for this threshold. Consider the case of $m = 2$ groups with $n = 2$ individuals. In a mixed group, the cooperator has payoff $-c$ and the defector has payoff $b$. In a homogeneous group, two cooperators have payoff $b - c$, while two defectors have payoff 0. Thus the disadvantage for cooperators in mixed groups cannot be compensated for by the advantage they have in homogeneous groups. Interestingly, however, for larger splitting probabilities, $q$, we find that cooperators can be favored even for $m = 2$ groups. The reason is the following: for very small $q$, the initial cooperator must reach fixation in a mixed group; but for larger $q$, a homogeneous cooperator group can also emerge if a mixed group splits giving rise to a daughter group that has only cooperators. Thus, larger splitting probabilities make it easier for cooperation to emerge.

Let us also consider the effect of migration between groups. The average number of migrants accepted by a group during its life-time is denoted by $z$. We find that selection favors cooperation provided

$$\frac{b}{c} > 1 + z + \frac{n}{m}. \tag{5b}$$

In order, to derive this condition we have assumed weak selection and $q \ll 1$, as before, but also that both the numbers of groups, $m$, and the maximum group size, $n$, are much large than one.

Group selection (or multi-level selection) is a powerful mechanism for the evolution of cooperation if there are a large number of relatively small groups and migration between groups is not too frequent.

## 6. Conclusion

I have presented five simple (Equations 1–5) rules that determine whether particular mechanisms can promote the evolution of cooperation. In all five theories, $b$ is the benefit for the recipient and $c$ the cost for the donor of an altruistic act. The comparison of the five rules enables us to understand the crucial quantities that are responsible

for the natural selection of cooperation by the various mechanisms that have been proposed.

1. Kin selection leads to cooperation if $b/c > 1/r$, where $r$ is the coefficient of genetic relatedness between donor and recipient (Hamilton 1964a).

2. Direct reciprocity leads to cooperation if $b/c > 1/w$, where $w$ is the probability of playing another round in the repeated Prisoner's Dilemma (Axelrod & Hamilton 1981).

3. Indirect reciprocity leads to cooperation if $b/c > 1/q$, where $q$ is the probability to know the reputation of a recipient (Nowak & Sigmund 1998a).

4. Graph selection (or 'network reciprocity') leads to cooperation if $b/c > k$, where $k$ is the degree of the graph, that is the average number of neighbors (Ohtsuki et al. 2006).

5. Group selection leads to cooperation if $b/c > 1 + z + n/m$, where $z$ is the number of migrants accepted by a group during its life-time, $n$ is the group size and $m$ is the number of groups (Traulsen & Nowak 2006).

# Fractional Brownian motion: stochastic calculus and applications

David Nualart

**Abstract.** Fractional Brownian motion (fBm) is a centered self-similar Gaussian process with stationary increments, which depends on a parameter $H \in (0, 1)$ called the Hurst index. In this note we will survey some facts about the stochastic calculus with respect to fBm using a pathwise approach and the techniques of the Malliavin calculus. Some applications in turbulence and finance will be discussed.

**Mathematics Subject Classification (2000).** Primary 60H30; Secondary 60G18.

**Keywords.** Fractional Brownian motion, stochastic integrals, Malliavin calculus, Black–Scholes formula, stochastic volatility models.

## 1. Introduction

A real-valued stochastic process $X = \{X_t, t \geq 0\}$ is a family of random variables

$$X_t : \Omega \to \mathbb{R}$$

defined on a probability space $(\Omega, \mathcal{F}, P)$. The process $X$ is called *Gaussian* if for all $0 \leq t_1 < t_2 < \cdots < t_n$ the probability distribution of the random vector $(X_{t_1}, \ldots, X_{t_n})$ on $\mathbb{R}^n$ is normal or Gaussian. From the properties of the normal distribution it follows that the probability distribution of a Gaussian process is entirely determined by the mean function $\mathbb{E}(X_t)$ and the covariance function

$$\mathrm{Cov}(X_t, X_s) = \mathbb{E}((X_t - \mathbb{E}(X_t))(X_s - \mathbb{E}(X_s))),$$

where $\mathbb{E}$ denotes the mathematical expectation or integral with respect to the probability measure $P$.

One of the most important stochastic processes used in a variety of applications is the *Brownian motion* or *Wiener process* $W = \{W_t, t \geq 0\}$, which is a Gaussian process with zero mean and covariance function $\min(s, t)$. The process $W$ has independent increments and its formal derivative $\frac{dW_t}{dt}$ is used as input noise in dynamical systems, giving rise to stochastic differential equations. The stochastic calculus with respect to the Brownian motion, developed from the works of Itô in the forties, permits to formulate and solve stochastic differential equations.

Proceedings of the International Congress of Mathematicians, Madrid, Spain, 2006

Motivated from some applications in hydrology, telecommunications, queueing theory and mathematical finance, there has been a recent interest in input noises without independent increments and possessing long-range dependence and self-similarity properties. Long-range dependence in a stationary time series occurs when the covariances tend to zero like a power function and so slowly that their sums diverge. The self-similarity property means invariance in distribution under a suitable change of scale. One of the simplest stochastic processes which is Gaussian, self-similar and it has stationary increments is fractional Brownian motion, which is a generalization of the classical Brownian motion. As we shall see later, the fractional Brownian motion possesses long-range dependence when its Hurst parameter is larger than 1/2.

In this note we survey some properties of the fractional Brownian motion, and describe different methods to construct a stochastic calculus with respect to this process. We will also discuss some applications in mathematical finance and in turbulence.

## 2. Fractional Brownian motion

A Gaussian process $B^H = \{B_t^H, t \geq 0\}$ is called *fractional Brownian motion* (fBm) of Hurst parameter $H \in (0, 1)$ if it has mean zero and the covariance function

$$\mathbb{E}(B_t^H B_s^H) = R_H(t, s) = \frac{1}{2}\big(s^{2H} + t^{2H} - |t - s|^{2H}\big). \tag{2.1}$$

This process was introduced by Kolmogorov [25] and studied by Mandelbrot and Van Ness in [30], where a stochastic integral representation in terms of a standard Brownian motion was established. The parameter $H$ is called Hurst index from the statistical analysis, developed by the climatologist Hurst [24], of the yearly water run-offs of Nile river.

The fractional Brownian motion has the following properties.

1. *Self-similarity:* For any constant $a > 0$, the processes $\{a^{-H} B_{at}^H, t \geq 0\}$ and $\{B_t^H, t \geq 0\}$ have the same probability distribution. This property is an immediate consequence of the fact that the covariance function (2.1) is homogeneous of order $2H$, and it can be considered as a "fractal property" in probability.

2. *Stationary increments:* From (2.1) it follows that the increment of the process in an interval $[s, t]$ has a normal distribution with zero mean and variance

$$\mathbb{E}\big((B_t^H - B_s^H)^2\big) = |t - s|^{2H}. \tag{2.2}$$

Hence, for any integer $k \geq 1$ we have

$$\mathbb{E}\big((B_t^H - B_s^H)^{2k}\big) = \frac{(2k)!}{k!2^k}|t - s|^{2Hk}. \tag{2.3}$$

Choosing $k$ such that $2Hk > 1$, Kolmogorov's continuity criterion and (2.3) imply that there exists a version of the fBm with continuous trajectories. Moreover, using Garsia–Rodemich–Rumsey lemma [19], we can deduce the following modulus of continuity for the trajectories of fBm: For all $\varepsilon > 0$ and $T > 0$, there exists a nonnegative random variable $G_{\varepsilon,T}$ such that $\mathbb{E}(|G_{\varepsilon,T}|^p) < \infty$ for all $p \geq 1$, and, almost surely,

$$\left|B_t^H - B_s^H\right| \leq G_{\varepsilon,T}|t-s|^{H-\varepsilon},$$

for all $s, t \in [0, T]$. In other words, the parameter $H$ controls the regularity of the trajectories, which are Hölder continuous of order $H - \varepsilon$, for any $\varepsilon > 0$.

For $H = 1/2$, the covariance can be written as $R_{1/2}(t, s) = \min(s, t)$, and the process $B^{1/2}$ is an ordinary Brownian motion. In this case the increments of the process in disjoint intervals are independent. However, for $H \neq 1/2$, the increments are not independent.

Set $X_n = B_n^H - B_{n-1}^H, n \geq 1$. Then $\{X_n, n \geq 1\}$ is a Gaussian stationary sequence with unit variance and covariance function

$$\begin{aligned}\rho_H(n) &= \frac{1}{2}\left((n+1)^{2H} + (n-1)^{2H} - 2n^{2H}\right)\\ &\approx H(2H-1)n^{2H-2} \to 0,\end{aligned}$$

as $n$ tends to infinity. Therefore, if $H > \frac{1}{2}$, $\rho_H(n) > 0$ for $n$ large enough and $\sum_{n=1}^{\infty} \rho_H(n) = \infty$. We say that the sequence $\{X_n, n \geq 1\}$ has *long-range dependence*. Moreover, this sequence presents an aggregation behavior which can be used to describe cluster phenomena. For $H < \frac{1}{2}$, $\rho_H(n) < 0$ for $n$ large enough and $\sum_{n=1}^{\infty} |\rho_H(n)| < \infty$. In this case, $\{X_n, n \geq 1\}$ can be used to model sequences with intermittency.

**2.1. Construction of the fBm.** In order to show the existence of the fBm we should check that the symmetric function $R_H(t, s)$ defined in (2.1) is nonnegative definite, that is,

$$\sum_{i,j=1}^{n} a_i a_j R_H(t_i, t_j) \geq 0 \tag{2.4}$$

for any sequence of real numbers $a_i$, $i = 1, \ldots, n$ and for any sequence $t_i \geq 0$. Property (2.4) follows from the integral representation

$$B_t^H = \frac{1}{C_1(H)} \int_{\mathbb{R}} \left[((t-s)^+)^{H-\frac{1}{2}} - ((-s)^+)^{H-\frac{1}{2}}\right] dW_s, \tag{2.5}$$

where $\{W(A), A \text{ Borel subset of } \mathbb{R}\}$ is a Brownian measure on $\mathbb{R}$ and

$$C_1(H) = \left(\int_0^{\infty} \left((1+s)^{H-\frac{1}{2}} - s^{H-\frac{1}{2}}\right)^2 ds + \frac{1}{2H}\right)^{\frac{1}{2}},$$

obtained by Mandelbrot and Van Ness in [30]. The stochastic integral (2.5) is well defined, because the function $f_t(s) = ((t-s)^+)^{H-\frac{1}{2}} - ((-s)^+)^{H-\frac{1}{2}}$, $s \in \mathbb{R}$, $t \geq 0$ satisfies $\int_{\mathbb{R}} f_t(s)^2 ds < \infty$. On the other hand, the right-hand side of (2.5) defines a zero mean Gaussian process such that

$$\mathbb{E}\big((B_t^H)^2\big) = t^{2H}$$

and

$$\mathbb{E}\big((B_t^H - B_s^H)^2\big) = (t-s)^{2H},$$

which implies that $B^H$ is an fBm with Hurst parameter $H$.

**2.2. *p*-variation of the fBm.** Suppose that $X = \{X_t, t \geq 0\}$ is a stochastic process with continuous trajectories. Fix $p > 0$. We define the $p$-variation of $X$ on an interval $[0, T]$ as the following limit in probability:

$$\lim_{n\to\infty} \sum_{j=1}^{n} \big| X_{\frac{jT}{n}} - X_{\frac{(j-1)T}{n}} \big|^p.$$

If the $p$-variation exists and it is nonzero a.s., then for any $q > p$ the $q$-variation is zero and for any $q < p$ the $q$-variation is infinite. For example, the 2-variation (or quadratic variation) of the Brownian motion is equal to the length of the interval $T$.

Rogers has proved in [40] that the fBm $B^H$ has finite $1/H$-variation equals to $c_p T$, where $c_p = \mathbb{E}(|B_1^H|^p)$. In fact, the self-similarity property implies that the sequence

$$\sum_{j=1}^{n} \big| B^H_{\frac{jT}{n}} - B^H_{\frac{(j-1)T}{n}} \big|^{1/H}$$

has the same distribution as

$$\frac{T}{n} \sum_{j=1}^{n} \big| B_j^H - B_{j-1}^H \big|^{1/H},$$

and by the Ergodic Theorem this converges in $L^1(\Omega)$ and almost surely to $\mathbb{E}(|B_1^H|^p)T$.

As a consequence, the fBm with Hurst parameter $H \neq 1/2$ is not a semimartingale. Semimartingales are the natural class of processes for which a stochastic calculus can be developed, and they can be expressed as the sum of a bounded variation process and a local martingale which has finite quadratic variation. The fBm cannot be a semimartingale except in the case $H = 1/2$ because if $H < 1/2$, the quadratic variation is infinite, and if $H > 1/2$ the quadratic variation is zero and the 1-variation is infinite.

Let us mention the following surprising result proved by Cheridito in [8]. Suppose that $\{B_t^H, t \geq 0\}$ is an fBm with Hurst parameter $H \in (0, 1)$, and $\{W_t, t \geq 0\}$ is an ordinary Brownian motion. Assume they are independent and set

$$M_t = B_t^H + W_t.$$

Then $\{M_t, t \geq 0\}$ is not a semimartingale if $H \in \left(0, \frac{1}{2}\right) \cup \left(\frac{1}{2}, \frac{3}{4}\right]$, and it is a semimartingale, equivalent in law to a Brownian motion on any finite time interval $[0, T]$, if $H \in \left(\frac{3}{4}, 1\right)$.

The $1/H$-variation of Wick stochastic integrals with respect to the fractional Brownian motion with parameter $H > 1/2$ has been computed by Guerra and Nualart in [20].

## 3. Stochastic calculus with respect to the fBm

The aim of the stochastic calculus is to define stochastic integrals of the form

$$\int_0^T u_t \, dB_t^H, \tag{3.1}$$

where $u = \{u_t, t \in [0, T]\}$ is some stochastic process. If $u$ is a deterministic function there is a general procedure to define the stochastic integral of $u$ with respect to a Gaussian process using the convergence in $L^2(\Omega)$. We will first review this general approach in the particular case of the fBm.

**3.1. Integration of deterministic processes.** Consider an fBm $B^H = \{B_t^H, t \geq 0\}$ with Hurst parameter $H \in (0, 1)$. Fix a time interval $[0, T]$ and denote by $\mathcal{E}$ the set of step functions on $[0, T]$. The integral of a step function of the form

$$\varphi_t = \sum_{j=1}^m a_j \mathbf{1}_{(t_{j-1}, t_j]}(t)$$

is defined in a natural way by

$$\int_0^T \varphi_t \, dB_t^H = \sum_{j=1}^m a_j (B_{t_j}^H - B_{t_{j-1}}^H).$$

We would like to extend this integral to a more general class of functions, using the convergence in $L^2(\Omega)$. To do this we introduce the Hilbert space $\mathcal{H}$ defined as the closure of $\mathcal{E}$ with respect to the scalar product

$$\langle \mathbf{1}_{[0,t]}, \mathbf{1}_{[0,s]} \rangle_{\mathcal{H}} = R_H(t, s).$$

Then the mapping $\varphi \longrightarrow \int_0^T \varphi_t \, dB_t^H$ can be extended to a linear isometry between $\mathcal{H}$ and the Gaussian subspace $H_T(B^H)$ of $L^2(\Omega, \mathcal{F}, P)$ spanned by the random variables $\{B_t^H, t \in [0, T]\}$. We will denote this isometry by $\varphi \longrightarrow B^H(\varphi)$.

We would like to interpret $B^H(\varphi)$ as the stochastic integral of $\varphi \in H_T(B^H)$ with respect to $B^H$ and to write $B^H(\varphi) = \int_0^T \varphi_t dB_t^H$. However, we do not know whether the elements of $\mathcal{H}$ can be considered as real-valued functions. This turns out to be true for $H < \frac{1}{2}$, but is false when $H > \frac{1}{2}$ (see Pipiras and Taqqu [38], [39]). We state without proof the following results about the space $\mathcal{H}$.

**3.1.1. Case $H > \frac{1}{2}$.** In this case the second partial derivative of the covariance function

$$\frac{\partial^2 R_H}{\partial t \partial s} = \alpha_H |t - s|^{2H-2},$$

where $\alpha_H = H(2H - 1)$, is integrable, and we can write

$$R_H(t, s) = \alpha_H \int_0^t \int_0^s |r - u|^{2H-2} \, du dr. \tag{3.2}$$

Formula (3.2) implies that the scalar product in the Hilbert space $\mathcal{H}$ can be written as

$$\langle \varphi, \psi \rangle_{\mathcal{H}} = \alpha_H \int_0^T \int_0^T |r - u|^{2H-2} \varphi_r \psi_u \, du dr \tag{3.3}$$

for any pair of step functions $\varphi$ and $\psi$ in $\mathcal{E}$.

As a consequence, we can exhibit a linear space of functions contained in $\mathcal{H}$ in the following way. Let $|\mathcal{H}|$ be the Banach space of measurable functions $\varphi \colon [0, T] \to \mathbb{R}$ such that

$$\|\varphi\|^2_{|\mathcal{H}|} = \alpha_H \int_0^T \int_0^T |r - u|^{2H-2} |\varphi_r| |\varphi_u| \, du dr < \infty.$$

It has been shown in [39] that the space $|\mathcal{H}|$ equipped with the inner product $\langle \cdot, \cdot \rangle_{\mathcal{H}}$ is not complete and it is isometric to a subspace of $\mathcal{H}$. The following estimate has been proved in [31] using Hölder and Hardy–Littlewood inequalities.

**Lemma 3.1.** *Let $H > \frac{1}{2}$ and $\varphi \in L^{\frac{1}{H}}([0, T])$. Then*

$$\|\varphi\|_{|\mathcal{H}|} \leq b_H \|\varphi\|_{L^{\frac{1}{H}}([0,T])}, \tag{3.4}$$

*for some constant $b_H$.*

Thus we have the embeddings

$$L^2([0, T]) \subset L^{\frac{1}{H}}([0, T]) \subset |\mathcal{H}| \subset \mathcal{H},$$

and Wiener-type integral $\int_0^T \varphi_t dB_t$ can be defined for functions $\varphi$ in the Banach space $|\mathcal{H}|$. Notice that we can integrate more functions that in the case of the Brownian motion, and the isometry property of the Itô stochastic integral is replaced here by the formula

$$\mathbb{E}\left(\left(\int_0^T \varphi_t \, dB_t^H\right)^2\right) = \alpha_H \int_0^T \int_0^T |r-u|^{2H-2} \varphi_r \varphi_u \, du dr = \|\varphi\|_{\mathcal{H}}^2.$$

**3.1.2. Case $H < \frac{1}{2}$.** In this case, one can show that $\mathcal{H} = I_{T-}^{\frac{1}{2}-H}(L^2([0,T]))$ (see [14] and Proposition 6 of [2]), where $I_{T-}^{\frac{1}{2}-H}$ is the right-sided fractional integral operator defined by

$$I_{T-}^{H-\frac{1}{2}}\varphi(t) = \frac{1}{\Gamma\left(H-\frac{1}{2}\right)} \int_t^T (s-t)^{H-\frac{3}{2}} \varphi_s \, ds.$$

This means that $\mathcal{H}$ is a space of functions. Moreover the norm of the Hilbert space $\mathcal{H}$ can be computed as follows:

$$\|\varphi\|_{\mathcal{H}}^2 = c_H^2 \int_0^T s^{1-2H} \left(D_{T-}^{\frac{1}{2}-H}(u^{H-\frac{1}{2}}\varphi_u)\right)^2(s) \, ds, \tag{3.5}$$

where $c_H$ is a constant depending on $H$ and $D_{T-}^{\frac{1}{2}-H}$ is the right-sided fractional derivative operator. The operator $D_{T-}^{\frac{1}{2}-H}$ is the inverse of $I_{T-}^{H-\frac{1}{2}}$, and it has the following integral expression:

$$D_{T-}^{\frac{1}{2}-H}\varphi(t) = \frac{1}{\Gamma\left(H+\frac{1}{2}\right)} \left( \frac{\varphi_t}{(T-t)^{\frac{1}{2}-H}} + \left(\frac{1}{2}-H\right) \int_t^T \frac{\varphi_t - \varphi_s}{(s-t)^{\frac{3}{2}-H}} \, ds \right). \tag{3.6}$$

The following embeddings hold:

$$C^\gamma([0,T]) \subset \mathcal{H} \subset L^{1/H}([0,T])$$

for any $\gamma > H - \frac{1}{2}$. The first inclusion is a direct consequence of formula (3.6), and the second one follows from Hardy–Littlewood inequality. Roughly speaking, in this case the fractional Brownian motion is more irregular than the classical Brownian motion, and some Hölder continuity is required for a function to be integrable. Moreover the computation of the variance of an integral using formula (3.5) is more involved.

**3.2. Integration of random processes.** Different approaches have been used in the literature in order to define stochastic integrals with respect to the fBm. Lin [26] and Dai and Heyde [13] have defined a stochastic integral $\int_0^T u_t dB_t^H$ as limit in $L^2$ of Riemann sums in the case $H > \frac{1}{2}$. The techniques of Malliavin calculus have been used to develop the stochastic calculus for the fBm starting from the pioneering

work of Decreusefond and Üstünel [14]. We refer to the works of Carmona and Coutin in [7], Alòs, Mazet and Nualart [1], [2], Alòs and Nualart [3], and the recent monograph by Hu [21], among others. We will first describe a path-wise approach based on Young integrals.

**3.2.1. Path-wise approach.** We can define $\int_0^T u_t\, dB_t^H$ using path-wise Riemann–Stieltjes integrals taking into account the results of Young in [43]. In fact, Young proved that the Riemann–Stieltjes integral $\int_0^T f_t\, dg_t$ exists, provided that $f, g\colon [0,T] \to \mathbb{R}$ are Hölder continuous functions of orders $\alpha$ and $\beta$ with $\alpha + \beta > 1$. Therefore, if $u = \{u_t, t \in [0,T]\}$ is a stochastic process with $\gamma$-Hölder continuous trajectories, where $\gamma > 1 - H$, then the Riemann–Stieltjes integral $\int_0^T u_t\, dB_t^H$ exists path-wise. That is for any element $\omega \in \Omega$, the integral $\int_0^T u_t(\omega)\, dB_t^H(\omega)$ exists as the point-wise limit of Riemann sums. In particular, if $H > 1/2$, the path-wise Riemann–Stieltjes integral $\int_0^T F(B_t^H)\, dB_t^H$ exists if $F$ is a continuously differentiable function. Moreover the following change of variables formula holds:

$$\Phi(B_t^H) = \Phi(0) + \int_0^t F(B_s^H)\, dB_s^H \tag{3.7}$$

if $\Phi' = F$.

In the case $\frac{1}{4} < H < \frac{1}{2}$, there is a path-wise approach to the stochastic integrals of the form

$$\int_0^T F(B_t^H)\, dB_t^H$$

using the theory of *rough paths analysis* introduced by Lyons in [27] (see also [28]). This theory has allowed Coutin and Qian [12] to show the existence of a solution and to prove the convergence of the Wong–Zakai approximations for stochastic differential equations driven by an fBm with Hurst parameter $H \in \left(\frac{1}{4}, \frac{1}{2}\right)$.

Nevertheless, unlike the case of the Itô stochastic integral with respect to the Brownian motion, the path-wise integral $\int_0^T F(B_t^H)\, dB_t^H$ does not have zero mean and there is no easy formula for its variance. We are going to explain how the techniques of Malliavin calculus allow us to compute the mean and the variance of this integral.

**3.3. Malliavin calculus for the fBm.** Let $B^H = \{B_t^H, t \geq 0\}$ be an fBm with Hurst parameter $H \in (0,1)$. The process $B^H$ is Gaussian and we can develop the corresponding stochastic calculus of variations or Malliavin calculus. The Malliavin calculus is an infinite dimensional differential calculus introduced by Malliavin in [29] to provide a probabilistic proof of Hörmander hypoellipticity theorem. The basic operators of Malliavin calculus are the derivative operator $D$ and its adjoint the divergence operator $\delta$. We refer to Nualart [32] and [33] for a detailed account of the Malliavin calculus and its application in the framework of the fBm.

Fix a time interval $[0, T]$. Let $\mathcal{S}$ be the set of elementary random variables of the form

$$F = f(B^H(\varphi_1), \dots, B^H(\varphi_n)), \tag{3.8}$$

where $n \geq 1$, $f \in C_p^\infty(\mathbb{R}^n)$ ($f$ and all its partial derivatives have polynomial growth order), and $\varphi_i \in \mathcal{H}$.

The *derivative operator* $D$ of an elementary random variable $F$ of the form (3.8) is defined as the $\mathcal{H}$-valued random variable

$$DF = \sum_{i=1}^{n} \frac{\partial f}{\partial x_i}(B^H(\varphi_1), \dots, B^H(\varphi_n))\varphi_i.$$

The following integration-by-parts formula holds.

**Lemma 3.2.** *Let $F$ be an elementary random variable of the form* (3.8). *Then, for any $\varphi \in \mathcal{H}$ we have*

$$\mathbb{E}(\langle DF, \varphi\rangle_{\mathcal{H}}) = \mathbb{E}(FB^H(\varphi)). \tag{3.9}$$

*Proof.* First notice that we can normalize Eq. (3.9) and assume that the norm of $\varphi$ is one. There exist orthonormal elements of $\mathcal{H}$, $e_1, \dots, e_n$, such that $\varphi = e_1$ and $F$ is an elementary random variable of the form

$$F = f(B^H(e_1), \dots, B^H(e_n)),$$

where $f$ is in $C_p^\infty(\mathbb{R}^n)$. Let $\phi(x)$ denote the density of the standard normal distribution on $\mathbb{R}^n$, that is,

$$\phi(x) = (2\pi)^{-\frac{n}{2}} \exp\Big(-\frac{1}{2}\sum_{i=1}^{n} x_i^2\Big).$$

Then we have

$$\begin{aligned}\mathbb{E}(\langle DF, \varphi\rangle_{\mathcal{H}}) &= \int_{\mathbb{R}^n} \frac{\partial f}{\partial x_1}(x)\phi(x)\,dx \\ &= \int_{\mathbb{R}^n} f(x)\phi(x)x_1\,dx \\ &= \mathbb{E}(FB^H(e_1)) = \mathbb{E}(FB^H(\varphi)),\end{aligned}$$

which completes the proof of the lemma. □

As a consequence, if $F$ and $G$ are elementary random variables and $h \in \mathcal{H}$, then we have

$$\mathbb{E}(G\langle DF, h\rangle_{\mathcal{H}}) = \mathbb{E}(-F\langle DG, h\rangle_{\mathcal{H}} + FGB^H(h)). \tag{3.10}$$

Formula (3.10) implies that the derivative operator $D$ is a closable operator from $L^p(\Omega)$ into $L^p(\Omega; \mathcal{H})$, for any $p \geq 1$. We denote by he Sobolev space $\mathbb{D}^{1,p}$ is the closure of $\mathcal{S}$ with respect to the norm

$$\|F\|_{1,p} = [\mathbb{E}(|F|^p) + \mathbb{E}(\|DF\|^p_{\mathcal{H}})]^{1/p}.$$

One can interpret $\mathbb{D}^{1,p}$ as an infinite-dimensional weighted Sobolev space.

The *divergence operator* $\delta$ is the adjoint of the derivative operator. That is, we say that a random variable $u$ in $L^2(\Omega; \mathcal{H})$ belongs to the domain of the divergence operator, denoted by Dom $\delta$, if

$$|\mathbb{E}(\langle DF, u\rangle_{\mathcal{H}})| \leq c_u \|F\|_{L^2(\Omega)}$$

for any $F \in \mathcal{S}$. In this case $\delta(u)$ is defined by the duality relationship

$$\mathbb{E}(F\delta(u)) = \mathbb{E}(\langle DF, u\rangle_{\mathcal{H}}), \tag{3.11}$$

for any $F \in \mathbb{D}^{1,2}$.

For example, consider an elementary $\mathcal{H}$-valued random variable of the form $u = \sum_{k=1}^m F_k \varphi_k$, where $F_k \in \mathbb{D}^{1,2}$ and $\varphi_k \in \mathcal{H}$. Then, $u$ belongs to the domain of the divergence and from (3.10) we deduce

$$\delta(u) = \sum_{k=1}^m [F_k B^H(\varphi_k) - \langle DF_k, \varphi_k\rangle_{\mathcal{H}}]. \tag{3.12}$$

The expression $F_k B^H(\varphi_k) - \langle DF_k, \varphi_k\rangle_{\mathcal{H}}$ is called the *Wick product* of the random variables $F_k$ and $B^H(\varphi_k)$ and it is denoted by

$$F_k \diamond B^H(\varphi_k) = F_k B^H(\varphi_k) - \langle DF_k, \varphi_k\rangle_{\mathcal{H}}. \tag{3.13}$$

With this notation (3.12) can be written as

$$\delta(u) = \sum_{k=1}^m F_k \diamond B^H(\varphi_k).$$

We will make use of the notation

$$\delta(u) = \int_0^T u_t \diamond dB^H_t,$$

when $u$ is a stochastic process in the domain of the divergence operator.

Here are some basic formulas of the Malliavin calculus which hold for any elementary random variables $F$ and $u$.

$$\mathbb{E}(\delta(u)^2) = \mathbb{E}(\|u\|^2_{\mathcal{H}}) + \mathbb{E}(\langle Du, (Du)^*\rangle_{\mathcal{H}\otimes\mathcal{H}}), \tag{3.14}$$

$$\delta(Fu) = F\delta(u) - \langle DF, u\rangle_{\mathcal{H}}, \tag{3.15}$$

$$\langle D(\delta(u)), h\rangle_{\mathcal{H}} = \langle u, h\rangle_{\mathcal{H}} + \delta(\langle Du, h\rangle_{\mathcal{H}}), \tag{3.16}$$

where $(Du)^*$ is the adjoint of $Du$ in the Hilbert space $\mathcal{H} \otimes \mathcal{H}$. Equation (3.14) holds for any $u$ in the Sobolev space $\mathbb{D}^{1,2}(\mathcal{H})$ of $\mathcal{H}$-valued random variables and it implies that $\mathbb{D}^{1,2}(\mathcal{H}) \subset \operatorname{Dom} \delta$ . Equation (3.15) holds if $F \in \mathbb{D}^{1,2}$, $u$ belongs to the domain of $\delta$ and $Fu$ and $F\delta(u) + \langle DF, u\rangle_{\mathcal{H}}$ are square integrable. Finally, the commutation relation (3.16) holds for any $h \in \mathcal{H}$ and $u \in \mathbb{D}^{1,2}(\mathcal{H})$ such that $\delta(u) \in \mathbb{D}^{1,2}$:

In case of an ordinary Brownian motion, the adapted processes in $L^2([0, T] \times \Omega)$ belong to the domain of the divergence operator, and on this class of processes the divergence operator coincides with the Itô stochastic integral (see Nualart and Pardoux [34]). Actually, the divergence operator coincides with an extension of Itô's stochastic integral introduced by Skorohod in [42]. This is a consequence of formula (3.13), because if $\varphi_k = \mathbf{1}_{[a_k,b_k]}$ and $F_k$ is a random variable measurable with respect to the $\sigma$-field generated by $\{B_t^{1/2}, t \le a_k\}$, then $\langle DF_k, \mathbf{1}_{[a_k,b_k]}\rangle_{L^2([0,T])} = 0$, and the Wick product of $F_k$ and $B_{b_k}^{1/2} - B_{a_k}^{1/2}$ is equal to the ordinary product. Notice here that the random variables $F_k$ and $B_{b_k}^{1/2} - B_{a_k}^{1/2}$ are independent.

**3.4. Wick integrals with respect to the fBm.** A natural question in this framework is to ask in which sense the divergence operator with respect to a fractional Brownian motion $B$ can be interpreted as a stochastic integral. The following proposition provides an answer to this question.

**Proposition 3.3.** *Fix a time interval* $[0, T]$. *Let* $F$ *be a function of class* $C^1$ *such which satisfies, together with* $F'$, *the growth condition*

$$|F(x)| \le ce^{\lambda x^2}, \tag{3.17}$$

*where* $c$ *and* $\lambda$ *are positive constants such that* $\lambda < \frac{1}{4T^{2H}}$. *Suppose that* $H > \frac{1}{2}$. *Then,* $F(B_t^H)$ *belongs to the domain of the divergence operator and*

$$\int_0^T F(B_t^H) \diamond dB_t^H = \int_0^T F(B_t^H)\, dB_t^H - H \int_0^T F'(B_t^H) t^{2H-1}\, dt, \tag{3.18}$$

*where* $\int_0^T F(B_t^H)\, dB_t^H$ *is the path-wise Riemann–Stieltjes integral.*

**Remarks.** 1. Formula (3.18) leads to the following equation for the expectation of a path-wise integral:

$$\mathbb{E}\left( \int_0^T F(B_t^H)\, dB_t^H \right) = H \int_0^T \mathbb{E}(F'(B_t^H)) t^{2H-1}\, dt.$$

2. Suppose that $F$ is a function of class $C^2$ such that $F$, $F'$ and $F''$ satisfy the growth condition (3.17). Then, (3.18) and (3.7) yield

$$F(B_T^H) = F(0) + \int_0^T F'(B_t^H) \diamond dB_t^H + H \int_0^T F''(B_t^H) t^{2H-1}\, dt, \tag{3.19}$$

which can be considered as an Itô formula for the Wick integral.

*Proof of Proposition* 3.3. Set $t_i = \frac{iT}{n}$. Then formula (3.13) yields

$$\sum_{i=1}^{n} F(B^H_{t_{i-1}}) \diamond (B^H_{t_i} - B^H_{t_{i-1}}) = \sum_{i=1}^{n} F(B^H_{t_{i-1}})(B^H_{t_i} - B^H_{t_{i-1}}) - \sum_{i=1}^{n} \langle D(F(B^H_{t_{i-1}})), \mathbf{1}_{[t_{i-1},t_i]} \rangle_{\mathcal{H}}.$$

We have, using the chain rule and $DB^H_{t_{i-1}} = \mathbf{1}_{[0,t_{i-1}]}$,

$$\begin{aligned} \langle D(F(B^H_{t_{i-1}})), \mathbf{1}_{[t_{i-1},t_i]} \rangle_{\mathcal{H}} &= F'(B^H_{t_{i-1}}) \langle \mathbf{1}_{[0,t_{i-1}]}, \mathbf{1}_{[t_{i-1},t_i]} \rangle_{\mathcal{H}} \\ &= F'(B^H_{t_{i-1}})(R_H(t_{i-1}, t_i) - R_H(t_{i-1}, t_{i-1})) \\ &= \frac{1}{2} F'(B^H_{t_{i-1}})((t_i)^{2H} - (t_{i-1})^{2H} - (t_i - t_{i-1})^{2H}). \end{aligned}$$

Then it suffices to take the limit as $n$ tends to infinity. The convergences are almost surely and in $L^2(\Omega)$. □

As an application of Proposition 3.3 we will derive the following estimate for the variance of the path-wise stochastic integral of a trigonometric function.

**Proposition 3.4.** *Let $B^H$ be a $d$-dimensional fractional Brownian motion with Hurst parameter $H > 1/2$. Then for any $\xi \in \mathbb{R}^d$ we have*

$$\mathbb{E}\left( \left\| \int_0^T e^{i\langle \xi, B^H_t \rangle} \, dB^H_t \right\|^2_{\mathbb{C}} \right) \leq C(1 \wedge |\xi|^{\frac{1}{H}-2}), \tag{3.20}$$

*where $\|z\|_{\mathbb{C}} = \sum_{i=1}^d z^i \bar{z}^i$ and $C$ is a constant depending on $T$, $d$ and $H$.*

*Proof.* From (3.18) we get

$$\int_0^T e^{i\langle \xi, B^H_t \rangle} \, dB^H_t = \int_0^T e^{i\langle \xi, B^H_t \rangle} \diamond dB^H_t + H \int_0^T i\xi e^{i\langle \xi, B^H_t \rangle} t^{2H-1} \, dt. \tag{3.21}$$

We denote by $\pi_\xi(x) = x - \frac{\xi}{|\xi|^2}\langle \xi, x \rangle$ the projection operator on the orthogonal subspace of $\xi$. Clearly

$$\int_0^T e^{i\langle \xi, B^H_t \rangle} \, dB^H_t = \pi_\xi\left( \int_0^T e^{i\langle \xi, B^H_t \rangle} \, dB^H_t \right) + \frac{i\xi}{|\xi|^2}(e^{i\langle \xi, B^H_T \rangle} - 1), \tag{3.22}$$

and, as a consequence, it suffices to show the estimate (3.20) for the first summand in the right-hand side of (3.22). From (3.21) it follows that

$$Z := \pi_\xi\left( \int_0^T e^{i\langle \xi, B^H_t \rangle} \, dB^H_t \right) = \pi_\xi\left( \int_0^T e^{i\langle \xi, B^H_t \rangle} \diamond dB^H_t \right).$$

Then we need to compute the expectation of the square norm of the $\mathbb{C}^3$-valued random variable $Z$. This is done using the duality relationship (3.11) and the commutation formula (3.16). The composition of the projection operator $\pi_\xi$ and the derivative operator $D$ vanishes on a random variable of the form $e^{i\langle \xi, B_t^H\rangle}$. Hence, only the first term in the commutation formula (3.16) applied to $u_t = e^{i\langle \xi, B_t^H\rangle}$ will contribute to $\mathbb{E}(\|Z\|_{\mathbb{C}}^2)$ and we obtain

$$\begin{aligned}
\mathbb{E}(\|Z\|_{\mathbb{C}}^2) &= \sum_{j=1}^{d} \mathbb{E}(Z^j \overline{Z^j}) \\
&= \sum_{j=1}^{d} \left(1 - \frac{(\xi^j)^2}{|\xi|^2}\right) \mathbb{E}\big(\big\langle e^{-i\langle \xi, B_\cdot^H\rangle}, e^{-i\langle \xi, B_\cdot^H\rangle}\big\rangle_{\mathcal{H}}\big) \\
&= (d-1)\alpha_H \int_0^T \int_0^T \mathbb{E}\big(e^{i\langle \xi, B_s^H - B_r^H\rangle}\big)|s-r|^{2H-2}\, ds dr \\
&= (d-1)\alpha_H \int_0^T \int_0^T e^{-\frac{|s-r|^{2H}}{2}|\xi|^2}|s-r|^{2H-2}\, ds dr,
\end{aligned}$$

which leads to the desired estimate. □

Proposition 3.3 also holds for $H \in \left(\frac{1}{4}, \frac{1}{2}\right]$ if we replace the path-wise integral in the right-hand side of (3.18) by the *Stratonovich integral* defined as the limit in probability of symmetric sums

$$\int_0^T F(B_t^H)\, dB_t^H = \lim_{n\to\infty} \sum_{i=1}^{n} \frac{1}{2}\big[F\big(B^H_{\frac{(i-1)T}{n}}\big) + F\big(B^H_{\frac{iT}{n}}\big)\big]\big(B^H_{\frac{iT}{n}} - B^H_{\frac{(i-1)T}{n}}\big).$$

For $H = 1/2$ the Wick integral appearing in Equation (3.18) is the classical Itô integral and it is the limit of forward Wick or ordinary Riemann sums:

$$\begin{aligned}
\int_0^T F\big(B_t^{1/2}\big) \diamond dB_t^{1/2} &= \lim_{n\to\infty} \sum_{i=1}^{n} F\big(B^{1/2}_{\frac{(i-1)T}{n}}\big) \diamond \big(B^{1/2}_{\frac{iT}{n}} - B^{1/2}_{\frac{(i-1)T}{n}}\big) \\
&= \lim_{n\to\infty} \sum_{i=1}^{n} F\big(B^{1/2}_{\frac{(i-1)T}{n}}\big)\big(B^{1/2}_{\frac{iT}{n}} - B^{1/2}_{\frac{(i-1)T}{n}}\big).
\end{aligned}$$

Nevertheless, for $H < 1/2$ the forward Riemann sums do not converge in general. For example, in the simplest case $F(x) = x$, we have, with the notation $t_i = \frac{iT}{n}$

$$\begin{aligned}
\mathbb{E}\Big(\sum_{i=1}^{n} (B^H_{t_{i-1}}(B^H_{t_i} - B^H_{t_{i-1}}))\Big) &= \frac{1}{2}\sum_{i=1}^{n}\big[t_i^{2H} - t_{i-1}^{2H} - (t_i - t_{i-1})^{2H}\big] \\
&= \frac{1}{2}T^{2H}(1 - n^{1-2H}) \to -\infty,
\end{aligned}$$

as $n$ tends to infinity.

The convergence of the forward Wick Riemann sums to the forward Wick integral in the case $H \in \left(\frac{1}{4}, \frac{1}{2}\right)$ has been recently established in [36] and [5]. More precisely, the following theorem has been proved in [36].

**Theorem 3.5.** *Suppose $H \in \left(\frac{1}{4}, \frac{1}{2}\right)$ and let $F$ be a function of class $C^7$ such that $F$ together with its derivatives satisfy the growth condition* (3.17). *Then, the forward Wick integral*

$$\int_0^T F(B_t^H) \diamond dB_t^H = \lim_{n\to\infty} \sum_{i=1}^n F\left(B^H_{\frac{(i-1)T}{n}}\right) \diamond \left(B^H_{\frac{iT}{n}} - B^H_{\frac{(i-1)T}{n}}\right)$$

*exists and the Wick–Itô formula* (3.19) *holds.*

More generally, we can replace the fractional Brownian motion $B^H$ by an arbitrary Gaussian process $\{X_t, t \geq 0\}$ with zero mean and continuous covariance function $R(s,t) = \mathbb{E}(X_s X_t)$. Suppose that the variance function $V_t = \mathbb{E}(X_t^2)$ has bounded variation on any finite interval and the following conditions hold for any $T > 0$:

$$\lim_{n\to\infty} \sum_{i,j=1}^n \left(\mathbb{E}\left(\left(X_{\frac{iT}{n}} - X_{\frac{(i-1)T}{n}}\right)\left(X_{\frac{jT}{n}} - X_{\frac{(j-1)T}{n}}\right)\right)\right)^2 \to 0, \tag{3.23}$$

$$\lim_{n\to\infty} \sum_{i=1}^n \sup_{0\leq t\leq T} \left(\mathbb{E}\left(\left(X_{\frac{iT}{n}} - X_{\frac{(i-1)T}{n}}\right)X_t\right)\right)^2 \to 0. \tag{3.24}$$

Then it is proved in [36] that the forward Wick integral $\int_0^T F(X_t) \diamond dX_t$ exists and the following version of the Wick–Itô formula holds:

$$F(X_T) = F(X_0) + \int_0^T F'(X_t) \diamond dX_t + \frac{1}{2}\int_0^T F''(X_t)\, dV_t.$$

## 4. Application of fBm in turbulence

The observations of three-dimensional turbulent fluids indicate that the vorticity field of the fluid is concentrated along thin structures called vortex filaments. In his book Chorin [10] suggests probabilistic descriptions of vortex filaments by trajectories of self-avoiding walks on a lattice. Flandoli [17] introduced a model of vortex filaments based on a three-dimensional Brownian motion. A basic problem in these models is the computation of the kynetic energy of a given configuration.

Denote by $u(x)$ the velocity field of the fluid at point $x \in \mathbb{R}^3$, and let $\xi = \mathrm{curl} u$ be the associated vorticity field. The kynetic energy of the field will be

$$\mathbb{H} = \frac{1}{2}\int_{\mathbb{R}^3} |u(x)|^2 dx = \frac{1}{8\pi}\int_{\mathbb{R}^3}\int_{\mathbb{R}^3} \frac{\xi(x)\cdot\xi(y)}{|x-y|}\, dxdy. \tag{4.1}$$

We will assume that the vorticity field is concentrated along a thin tube centered in a curve $\gamma = \{\gamma_t, 0 \le t \le T\}$. Moreover, we will choose a random model and consider this curve as the trajectory of a three-dimensional fractional Brownian motion $B^H = \{B_t^H, 0 \le t \le T\}$ with Hurst parameter $H$. That is, the components of the process $B^H$ are independent fractional Brownian motions. This modelization is justified by the fact that the trajectories of the fractional Brownian motion are Hölder continuous of any order $H \in (0, 1)$. For technical reasons we are going to consider only the case $H > \frac{1}{2}$.

Then the vorticity field can be formally expressed as

$$\xi(x) = \Gamma \int_{\mathbb{R}^3} \left( \int_0^T \delta(x - y - B_s^H) \dot{B}_s^H \, ds \right) \rho\,(dy), \tag{4.2}$$

where $\Gamma$ is a parameter called the circuitation, and $\rho$ is a probability measure on $\mathbb{R}^3$ with compact support.

Substituting (4.2) into (4.1) we derive the following formal expression for the kinetic energy:

$$\mathbb{H} = \int_{\mathbb{R}^3} \int_{\mathbb{R}^3} \mathbb{H}_{xy} \rho(dx) \rho(dy), \tag{4.3}$$

where the so-called interaction energy $\mathbb{H}_{xy}$ is given by the double integral

$$\mathbb{H}_{xy} = \frac{\Gamma^2}{8\pi} \sum_{i=1}^3 \int_0^T \int_0^T \frac{1}{|x + B_t^H - y - B_s^H|} \, dB_s^{H,i} dB_t^{H,i}. \tag{4.4}$$

We are interested in the following problems: Is $\mathbb{H}$ a well defined random variable? Does it have moments of all orders and even exponential moments?

In order to give a rigorous meaning to the double integral (4.4) we introduce the regularization of the function $|\cdot|^{-1}$:

$$\sigma_n = |\cdot|^{-1} * p_{1/n}, \tag{4.5}$$

where $p_{1/n}$ is the Gaussian kernel with variance $\frac{1}{n}$. Then the smoothed interaction energy

$$\mathbb{H}_{xy}^n = \frac{\Gamma^2}{8\pi} \sum_{i=1}^3 \int_0^T \left( \int_0^T \sigma_n(x + B_t^H - y - B_s^H) \, dB_s^{H,i} \right) dB_t^{H,i} \tag{4.6}$$

is well defined, where the integrals are path-wise Riemann–Stieltjes integrals. Set

$$\mathbb{H}^n = \int_{\mathbb{R}^3} \int_{\mathbb{R}^3} \mathbb{H}_{xy}^n \rho(dx) \rho(dy). \tag{4.7}$$

The following result has been proved in [35].

**Theorem 4.1.** *Suppose that the measure $\rho$ satisfies*

$$\int_{\mathbb{R}^3}\int_{\mathbb{R}^3} |x-y|^{1-\frac{1}{H}}\rho(dx)\rho(dy) < \infty. \tag{4.8}$$

*Let $\mathbb{H}^n_{xy}$ be the smoothed interaction energy defined by* (4.5). *Then $\mathbb{H}^n$ defined in* (4.7) *converges, for all $k \geq 1$, in $L^k(\Omega)$ to a random variable $\mathbb{H} \geq 0$ that we call the energy associated with the vorticity field* (4.2).

If $H = \frac{1}{2}$, the fBm $B^H$ is a classical three-dimensional Brownian motion. In this case condition (4.8) would be $\int_{\mathbb{R}^3}\int_{\mathbb{R}^3} |x-y|^{-1}\rho(dx)\rho(dy) < \infty$, which is the assumption made by Flandoli [17] and Flandoli and Gubinelli [18]. In this last paper, using Fourier approach and Itô's stochastic calculus, the authors show that $\mathbb{E}(e^{-\beta\mathbb{H}}) < \infty$ for sufficiently small negative $\beta$.

The proof of Theorem 4.1 is based on the stochastic calculus with respect to fBm and the application of Fourier transform. Using Fourier transform we can write

$$\frac{1}{|z|} = \int_{\mathbb{R}^3} (2\pi)^3 \frac{e^{-i\langle\xi,z\rangle}}{|\xi|^2}\, d\xi$$

and

$$\sigma_n(x) = \int_{\mathbb{R}^3} |\xi|^{-2} e^{i\langle\xi,x\rangle - |\xi|^2/2n}\, d\xi. \tag{4.9}$$

Substituting (4.9) into in (4.6), we obtain the following formula for the smoothed interaction energy:

$$\begin{aligned}\mathbb{H}^n_{xy} &= \frac{\Gamma^2}{8\pi}\sum_{j=1}^3 \int_0^T\int_0^T \left(\int_{\mathbb{R}^3} e^{i\langle\xi,x+B_t-y-B_s\rangle}\frac{e^{-|\xi|^2/2n}}{|\xi|^2}\right) dB_s^{H,j}\, dB_t^{H,j} \\ &= \frac{\Gamma^2}{8\pi}\int_{\mathbb{R}^3} |\xi|^{-2} e^{i\langle\xi,x-y\rangle - |\xi|^2/2n}\|Y_\xi\|^2_{\mathbb{C}}\, d\xi, \end{aligned} \tag{4.10}$$

where

$$Y_\xi = \int_0^T e^{i\langle\xi, B_t^H\rangle}\, dB_t^H.$$

Integrating with respect to $\rho$ yields

$$\mathbb{H}^n = \frac{\Gamma^2}{8\pi}\int_{\mathbb{R}^3} \|Y_\xi\|^2_{\mathbb{C}} |\xi|^{-2} |\widehat{\rho}(\xi)|^2 e^{-|\xi|^2/2n} d\xi \geq 0. \tag{4.11}$$

From Fourier analysis and condition (4.8) we know that

$$\int_{\mathbb{R}^3}\int_{\mathbb{R}^3} |x-y|^{1-\frac{1}{H}}\rho(dx)\rho(dy) = C_H \int_{\mathbb{R}^3} |\widehat{\rho}(\xi)|^2 |\xi|^{\frac{1}{H}-4} d\xi < \infty. \tag{4.12}$$

Then, taking into account (4.12) and (4.11), in order to show the convergence in $L^k(\Omega)$ of $\mathbb{H}^n$ to a random variable $\mathbb{H} \geq 0$ it suffices to check that

$$\mathbb{E}(\|Y_\xi\|_{\mathbb{C}}^{2k}) \leq C_k\big(1 \wedge |\xi|^{k(\frac{1}{H}-2)}\big). \tag{4.13}$$

For $k = 2$ this has been proved in Proposition 3.4. The general case $k \geq 2$ follows by similar arguments making use of the *local nondeterminism property* of fBm (see Berman [4]):

$$\mathrm{Var}\Big(\sum_i (B_{t_i}^H - B_{s_i}^H)\Big) \geq k_H \sum_i (t_i - s_i)^{2H}.$$

## 5. Application to financial mathematics

Fractional Brownian motion has been used to describe the behavior to prices of assets and volatilities in stock markets. The long-range dependence self-similarity properties make this process a suitable model to describe these quantities. We refer to Shiryaev [41] for a general description of the applications of fractional Brownian motion to model financial quantities. We will briefly present in this section two different uses of fBm in mathematical finance.

**5.1. Fractional Black and Scholes model.** It has been proposed by several authors to replace the classical Black and Scholes model which has no memory and is based on the geometric Brownian motion by the so-called *fractional Black and Scholes model*. In this model the market stock price of the risky asset is given by

$$S_t = S_0 \exp\left(\mu t + \sigma B_t^H - \frac{\sigma^2}{2} t^{2H}\right), \tag{5.1}$$

where $B^H$ is an fBm with Hurst parameter $H$, $\mu$ is the mean rate of return and $\sigma > 0$ is the volatility. The price of the non-risky assets at time $t$ is $e^{rt}$, where $r$ is the interest rate.

Consider an investor who starts with some initial endowment $V_0 \geq 0$ and invests in the assets described above. Let $\alpha_t$ be the number of non-risky assets and let $\beta_t$ the number of stocks owned by the investor at time $t$. The couple $(\alpha_t, \beta_t)$, $t \in [0, T]$ is called a *portfolio* and we assume that $\alpha_t$ and $\beta_t$ are stochastic processes. Then the investor's wealth or value of the portfolio at time $t$ is

$$V_t = \alpha_t e^{rt} + \beta_t S_t.$$

We say that the portfolio is *self-financing* if

$$V_t = V_0 + r \int_0^t \alpha_s e^{rs} ds + \int_0^t \beta_s dS_s. \tag{5.2}$$

This means that there is no fresh investment and there is no consumption. We see here that the self-financing condition requires the definition of a stochastic integral with respect to the fBm, and there are two possibilities: path-wise integrals and Wick-type integrals.

The use of path-wise integrals leads to the existence of arbitrage opportunities, which is one of the main drawbacks of the model (5.1). Different authors have proved the existence of arbitrages for the fractional Black and Scholes model (see Rogers [40], Shiryaev [41], and Cheridito [9]). By definition, an arbitrage is a self-financing portfolio which satisfies $V_0 = 0$, $V_T \geq 0$ and $P(V_T > 0) > 0$.

In the case $H > \frac{1}{2}$, one can construct an arbitrage in the following simple way. Suppose, to simplify, that $\mu = r = 0$. Consider the self-financing portfolio defined by

$$\begin{aligned} \beta_t &= S_t - S_0, \\ \alpha_t &= \int_0^t \beta_s dS_s - \beta_t S_t. \end{aligned}$$

This portfolio satisfies $V_0 = 0$ and $V_t = (S_t - S_0)^2 > 0$ for all $t > 0$, and hence it is an arbitrage.

In the classical Black and Scholes model (case $H = \frac{1}{2}$), there exists an equivalent probability measure $Q$ under which $\mu = r$ and the discounted price process $\widetilde{S}_t = e^{-rt} S_t$ is a martingale. Then, the discounted value of a self-financing adapted portfolio satisfying $\mathbb{E}_Q\big(\int_0^T \beta_s^2 \widetilde{S}_s^2 ds\big) < \infty$ is a martingale on the time interval $[0, T]$ given by the Itô stochastic integral

$$\widetilde{V}_t = V_0 + \int_0^t \beta_s d\widetilde{S}_s.$$

As a consequence, $V_t = e^{-r(T-t)} \mathbb{E}_Q(V_T | \mathcal{F}_t)$, and the price of an European option with payoff $G$ at the maturity time $T$ is given by $e^{-r(T-t)} \mathbb{E}_Q(G|\mathcal{F}_t)$. The probability $Q$ is called the martingale measure. In the case $H \neq \frac{1}{2}$, there exist an equivalent probability $Q$ under which $\mu = r$ and $S_t = S_0 \exp(\sigma B_t^H - \frac{\sigma^2}{2} t^{2H})$ has constant expectation. However, $e^{-rt} S_t$ is not a martingale under $Q$.

The existence of arbitrages can be avoided using forward Wick integrals to define the self-financing property (5.2). In fact, using the Wick–Itô formula in (5.1) yields

$$dS_t = \mu S_t dt + \sigma S_t \diamond dB_t^H,$$

and then the self-financing condition (5.2) could be written as

$$V_t = V_0 + \int_0^t (r\alpha_s e^{rs} + \mu \beta_s S_s) ds + \sigma \int_0^t \beta_s S_s \diamond dB_s^H.$$

Applying the stochastic calculus with respect to the Wick integral, Hu and Øksendal in [22], and Elliott and Hoek in [16] have derived the following formula for the value

of the call option with payoff $(S_T - K)^+$ at time $t \in [0, T]$:

$$C(t, S_t) = S_t \Phi(y_+) - K e^{-r(T-t)} \Phi(y_-), \tag{5.3}$$

where

$$y_\pm = \left( \ln \frac{S_t}{K} + r(T-t) \pm \frac{\sigma^2 (T^{2H} - t^{2H})}{2} \right) \Big/ \sigma \sqrt{T^{2H} - t^{2H}}. \tag{5.4}$$

In [6] Björk and Hult argue that the definition of a self-financing portfolio using the Wick product is quite restrictive and in [37] Nualart and Taqqu explain the fact that in formula (5.4) only the increment of the variance of the process in the interval $[t, T]$ appears, and extend this formula to price models driven by a general Gaussian process.

**5.2. Stochastic volatility models.** It has been observed that in the classical Black and Scholes model the implied volatility $\sigma^{\text{imp}}_{t,T}$ obtained from formula (5.3) for different options written on the same asset is not constant and heavily depends on the time $t$, the time to maturity $T - t$ and the strike price $S_t$. The $U$-shaped pattern of implied volatilites across different strike prices is called "smile", and it is believed that this and other features as the volatility clustering can be explained by stochastic volatility models. Hull and White have proposed in [23] an option pricing model in which the volatility of the asset price is of the form $\exp(Y_t)$, where $Y_t$ is an Ornstein–Uhlenbeck process.

Consider the following stochastic volatility model based on the fractional Ornstein–Uhlenbeck process. The price of the asset $S_t$ is given by

$$dS_t = \mu S_t dt + \sigma_t S_t dW_t,$$

where $\sigma_t = f(Y_t)$ and $Y_t$ is a fractional Ornstein–Uhlenbeck process:

$$dY_t = \alpha(m - Y_t)dt + \beta_t dB_t^H.$$

The process $W_t$ is an ordinary Brownian motion and $B_t^H$ is a fractional Brownian motion with Hurst parameter $H > \frac{1}{2}$, independent of $W$. Examples of functions $f$ are $f(x) = e^x$ and $f(x) = |x|$.

Comte and Renault studied in [11] this type of stochastic volatility model which introduces long memory and mean reverting in the Hull and White setting. The long-memory property allows this model to capture the well-documented evidence of persistence of the stochastic feature of Black and Scholes implied volatilities, when time to maturity increases.

Hu has proved in [21] the following properties of this model.

1) The market is incomplete and martingale measures are not unique.

2) Set $\gamma_t = (r - \mu)/\sigma_t$ and

$$\frac{dQ}{dP} = \exp\left( \int_0^T \gamma_t \, dW_t - \frac{1}{2} \int_0^T |\gamma_t|^2 \, dt \right).$$

Then $Q$ is the *minimal martingale measure* associated with $P$.

3) The risk minimizing-hedging price at time $t = 0$ of an European call option with payoff $(S_T - K)^+$ is given by

$$C_0 = e^{-rT}\mathbb{E}_Q[(S_T - K)^+]. \tag{5.5}$$

As a consequence of (5.5), if $\mathcal{G}_t$ denotes the filtration generated by fBm, we obtain

$$\begin{aligned} C_0 &= e^{-rT}\mathbb{E}_Q[\mathbb{E}_Q((S_T - K)^+|\mathcal{G}_T)] \\ &= e^{-rT}\mathbb{E}_Q[C_{BS}(\sigma)]. \end{aligned}$$

Here $\sigma = \sqrt{\int_0^T \sigma_s^2 ds}$ and $C_{BS}(\sigma)$ is the Black and Scholes price function given by

$$C_{BS} = S_0\Phi(y_+) - Ke^{-rT}\Phi(y_-),$$

where

$$y_\pm = \frac{\ln\frac{S_0}{K} + (r \pm \frac{\sigma^2}{2})T}{\sigma\sqrt{T}}.$$

# Atomistic and continuum models for phase change dynamics

Anders Szepessy

**Abstract.** The dynamics of dendritic growth of a crystal in an undercooled melt is determined by macroscopic diffusion-convection of heat and capillary forces acting on length scales compared to the nanometer width of the solid-liquid interface. Its modeling is useful for instance in processing techniques based on casting. The phase field method is widely used to study evolution of such microstructures of phase transformations on a continuum level; it couples the energy equation to a phenomenological Allen–Cahn/Ginzburg–Landau equation modeling the dynamics of an order parameter determining the solid and liquid phases, including also stochastic fluctuations to obtain the qualitative correct result of dendritic side branching. This lecture presents some ideas to derive stochastic phase field models from atomistic formulations by coarse-graining molecular dynamics and kinetic Monte Carlo methods.

**Mathematics Subject Classification (2000).** 82C31, 65C30.

**Keywords.** Phase transformation, phase-field, coarse-grained, molecular dynamics, Brownian dynamics, Langevin equation, Smoluchowski equation, kinetic Monte Carlo.

## 1. Introduction to phase-field models

The phase field model for modeling a liquid solid phase transformation is an Allen–Cahn/Ginzburg–Landau equation coupled to the energy equation

$$\begin{aligned} \partial_t \phi &= \operatorname{div}(k_1 \nabla \phi) - k_0 (f'(\phi) + g'(\phi) k_4 T) + \text{noise}, \\ \partial_t (c_v T + k_2 g(\phi)) &= \operatorname{div}(k_3 \nabla T) \end{aligned} \tag{1.1}$$

with a double-well potential $f$ having local minima at $\pm 1$, smoothed step function $g$, temperature $T$ and specific heat $c_v$, cf. [3]. The phase field variable $\phi \colon \mathbb{R}^d \times [0, \infty) \to [-1, 1]$ interprets the solid and liquid phases as the domains $\{x \in \mathbb{R}^d : \phi(x) > 0\}$ and $\{x \in \mathbb{R}^d : \phi(x) < 0\}$ respectively. To have such an implicit definition of the phases, as in the level set method, is a computational advantage compared to a sharp interface model, where the necessary direct tracking of the interface introduce computational drawbacks. This phenomenological phase-field model, with free energy potentials motived by thermodynamics, has therefore become a popular and effective computational method to solve problems with complicated microstructures of dendrite and eutectic growth, cf. [1], [3]. The phase-field model has mathematical wellposedness and convergence to sharp interface results [34].

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

Assuming that the reaction term in the Allen–Cahn equation takes a given form, e.g. a standard choice is

$$f(\phi) := (1-\phi^2)^2,$$
$$g(\phi) := \tfrac{15}{16}\left(\tfrac{1}{5}\phi^5 - \tfrac{2}{3}\phi^3 + \phi\right) + \tfrac{1}{2},$$

then the parameters $k_0$, $k_1$, $k_2$, $k_3$, $k_4$ in the phase-field model can be determined from atomistic molecular simulations [19]; an alternative in [1] uses a steeper step function $g$ to easy derive consistency with sharp interface models. The evolution of the phase interface depends on the orientation of the solid crystal; this is modeled by an anisotropic matrix $k_1$. Added noise to system (1.1) is also important, e.g. to obtain sidebranching dendrites [22] explained in Section 5.4.

Phase changes can be modeled on an atomistic level by molecular dynamics or kinetic Monte Carlo methods. This lecture first presents some ideas and questions to derive a stochastic phase field model by coarse-graining molecular dynamics, to determine the reaction term (i.e. $f$ and $g$) and the noise. This is made in three steps in Sections 2 to 4: to give a precise quantitative atomistic definition of the phase-field variable, to introduce an atomistic molecular dynamics model based on Brownian dynamics, and to derive the dynamics for the coarse-grained phase-field. Section 5 derives stochastic hydrodynamical limits of solutions to an Ising model with long range interaction, i.e. coarse-graining a kinetic Monte Carlo method following [24]. Section 5.4 presents a simple kinetic Monte Carlo method for dendrite dynamics.

## 2. Quantitative atomistic definition of the phase-field variable

The aim is to give a unique definition of the phase-field variable, so that it can be determined precisely from atomistic simulations. The usual interpretation is to measure interatomic distances and use structure functions (or similar methods) to measure where the phase is solid and where it is liquid, which then implicitly defines the phase-field variable [3]. Here we instead use the energy equation for a quantitative and explicit definition of the phase-field variable. The macroscopic energy equation with a phase transformation and heat conduction is

$$\partial_t(c_v T + m) = \operatorname{div}(k\nabla T) \tag{2.1}$$

where $m$ corresponds to the latent heat release. In (1.1) the latent heat determines the parameter $k_2$, since $\phi$ is defined to jump from 1 to $-1$ in the phase transformation. We will instead use this latent heat to directly define the phase field function, and not only the parameter $k_2$. The total energy, $c_v T + m$, can be defined from molecular dynamics of $N$ particles with position $X_i$, velocity $v_i$ and mass $\mu$ in a potential $V$, see [20], [18],

$$c_v T + m = \sum_{i=1}^{N} \mu \frac{|v_i|^2}{2} + V(X_1, \ldots, X_N). \tag{2.2}$$

Assume that the potential can be defined from pair interactions

$$V(X) = \frac{1}{2}\sum_{i=1}^{N}\sum_{j\neq i}\Phi(X_i - X_j), \tag{2.3}$$

where $\Phi\colon \mathbb{R}^3 \to \mathbb{R}$ is a molecular dynamics pair potential, e.g. a Lennard–Jones potential

$$\Phi(x) = z_1\Big(\frac{\sigma}{|x|}\Big)^{12} - z_2\Big(\frac{\sigma}{|x|}\Big)^{6}.$$

In the macroscopic setting the jump of $m$ in a phase change is called the latent heat, which depends on the thermodynamic variables kept constant: with constant $N, T$ and volume it is called the internal energy and with constant pressure instead of volume it is called enthalpy. The kinetic energy $\sum_i \mu|v_i|^2/2$ is related to the temperature. It is therefore natural to let the phase field variable be determined by the potential energy $V(X)$. In a pointwise setting the potential energy can be represented by the distribution

$$\frac{1}{2}\sum_{i=1}^{N}\sum_{j\neq i}\Phi(X_i - X_j)\delta(x - X_i)$$

where $\delta$ is the point mass at the origin [20]. We seek an averaged variant and we will study a microscopic phase change model where the interface is almost planar in the microscopic scale with normal in the $x_1$ direction. Therefore we take a smooth average and define the phase-field variable by

$$m(X, x) := \frac{1}{2}\sum_{i=1}^{N}\underbrace{\sum_{j\neq i}\Phi(X_i - X_j)}_{m_i(X)}\eta(x - X_i) \tag{2.4}$$

where $\eta\colon \mathbb{R}^3 \to (0,\infty)$ is a smooth approximation of the point (delta) mass, with scale $\varepsilon_i > 0$ in the $x_i$ direction,

$$\eta(x) := \prod_{i=1}^{3}\frac{e^{-|x_i|^2/(2\varepsilon_i^2)}}{(2\pi\varepsilon_i^2)^{1/2}}. \tag{2.5}$$

Smooth averages have been used in molecular dynamics for fluid dynamics, cf. [18] and for the vortex blob method and the smoothed particle hydrodynamics approximation of moving particles in fluid dynamics, cf. [29], [2]. Sections 3–4 present a molecular dynamics model for the potential energy (2.4) and Section 5.4 formulates a kinetic Monte Carlo model.

**Question 2.1.** How accurate is it to say that the (macroscopic) latent heat is equal to a jump in $V$?

## 3. An atomistic Brownian dynamics model

The standard method to simulate molecular dynamics is to write Newton's laws for the particles, cf. [10], [32]. We will instead use Brownian dynamics with the Ito differential equations

$$dX_i^t = -\partial_{X_i} V(X^t)dt + \sqrt{2\gamma}\, dW_i^t \tag{3.1}$$

where $W_i$ are independent Brownian motions and the notation $X_i^t := X_i(t)$ is the position of the $i$'th particle at time $t$. This equation, called the Smoluchowski equation, is the zero relaxation time limit (i.e. $\tau \to 0+$) of Langevin's equation ( cf. [25], [30], [32], [21])

$$\begin{aligned} d\hat{X}_i^s &= p_i/\mu ds \\ dp_i^s &= -\partial_{X_i} V(\hat{X}^s)ds - \frac{p_i^s}{\tau}ds + \sqrt{\frac{2\gamma\mu}{\tau}}\, d\hat{W}_i^s, \end{aligned} \tag{3.2}$$

in the faster time scale $s = \mu t/\tau$, where $\mu$ is the mass and $\hat{W}_i$ are independent Brownian motions. The zero relaxation time limit is explained more in Remark 3.2. The simplified Brownian dynamics has the same invariant measure with density proportional to $e^{-V(X)/\gamma}$ as in Monte-Carlo molecular dynamics simulations of equilibrium problems with $\gamma = k_B T$, where $T$ is the absolute temperature and $k_B$ is the Boltzmann constant. In this sense, the parameter $\gamma/k_B$ in the Brownian dynamics is the local temperature $T$. In contrast to the standard Monte-Carlo method, the model (3.1) includes the time variable. Our microscopic model of a phase change is then the Brownian dynamics model (3.1) for the phase-field (latent heat) variable $m$ in (2.4) coupled to the macroscopic energy equation (2.1). The Brownian dynamics uses $\gamma := k_B T$, where the temperature varies on the macroscopic scale, due to the energy equation, so that $T$ is almost constant on the microscopic scale of a molecular dynamics simulation and makes its Gibbs equilibrium density proportional to $e^{-V(X)/(k_B T(x))}$ reasonable.

We have two reasons to use Brownian dynamics instead of standard deterministic Newton dynamics ($\tau = \infty$ in (3.2)): the most important reason is to have a formulation that separates the noise and the mean drift, which is a much harder issue in deterministic many particle dynamics, in fact so far the only derivation of the Euler equations of conservation laws from particle dynamics use a weak noise perturbation of a Hamiltonian system in [31]; and the second reason is to try to simulate molecular dynamics longer time.

**Question 3.1.** Is Brownian dynamics a reasonable alternative to standard molecular dynamics here?

**Remark 3.2** (Smoluchowski limit of the Langevin equation). The Smoluchowski high friction limit of the Langevin equation has been computed with different methods using strong [30] and weak convergence [25]. Strong convergence has the drawback to

yield error estimates of order $e^{Kt}\tau$, due to a Gronwall estimate and Lipschitz bound $K$ of the forces; in contrast, error estimates of probabilities using weak convergence can show good accuracy for long time. The proof that the Langevin solution $\hat{X}_{\mu t/\tau}$ converges weakly (i.e. in law) to the Smoluchowski solution $X_t$ as $\tau \to 0+$ in [25], [28] uses a Chapman–Enskog expansion of the Kolmogorov backward equation, for the Langevin dynamics in the diffusion time scale $t$, combined with a general convergence result for such diffusion processes in [26]. Dissipative particle dynamics [15] has dissipation-fluctuation perturbations of a Hamiltonian system where the momentum is conserved, in contrast to the analogous Langevin dynamics. The work [25] also shows that a Smoluchowski type limit seems more subtly for dissipative particle dynamics.

## 4. Coarse-grained phase-field dynamics

We want to determine a mean drift function $a(\bar{m})$ and a diffusion function $b(\bar{m})$ so that the coarse-grained approximation $\bar{m}^t$, solving the coarse-grained equation

$$d\bar{m}^t = a(\bar{m}^t)dt + \sum_{k=1}^{M} b_k(\bar{m}^t)d\tilde{W}_k^t,$$

is an optimal approximation to the phase field $m(X^t, \cdot)$ defined in (2.4), where $X^t$ solves the Brownian dynamics (3.1). Here $\tilde{W}_k$, $k = 1, \ldots, M$ are all independent Brownian motions, also independent of all $W_i$. For this purpose we seek to minimize the error of the expected value at any time $\mathcal{T}$

$$E[g(m(X^{\mathcal{T}}, \cdot))] - E[g(\bar{m}^{\mathcal{T}})]$$

for any given function $g$ with the same initial value $\bar{m}^0 = m(X^0, \cdot)$. Here the expected value of a stochastic variable $w$, with set of outcomes $\Omega$ and probability measure $P$, is defined by

$$E[w] := \int_{\Omega} w \, dP.$$

The first idea, in Section 4.1, is that Ito's formula and the Brownian dynamics (3.1) determine functions $\alpha$ and $\beta$, depending on the microscopic state $X$, so that

$$dm(X^t, \cdot) = \alpha(X^t)dt + \sum_{j=1}^{N} \beta_j(X^t)dW_j^t. \tag{4.1}$$

The next step, in Section 4.2, is to estimate the error, using the Kolmogorov equations for $\bar{m}$ and (4.1) similar to [35], [24], which leads to

$$E[g(m(X^{\mathcal{T}}, \cdot)) - g(\bar{m}^{\mathcal{T}})] = E\left[\int_0^{\mathcal{T}} \langle \bar{u}', \alpha - a\rangle + \langle \bar{u}'', \sum_{j=1}^{N} \beta_j \otimes \beta_j - \sum_{k=1}^{M} b_k \otimes b_k\rangle \, dt\right],$$

where $\langle \bar{u}', \cdot \rangle$ is the $L^2(\mathbb{R})$ scalar product corresponding to the variable $x$ with $\bar{u}'$, which is the Gateaux derivative (i.e. functional derivative) of the functional $E[g(\bar{m}^{\mathcal{T}}) \,|\, \bar{m}^t = n]$ with respect to $n$; and similarly $\langle \bar{u}'', \cdot \rangle$ is the $L^2(\mathbb{R} \times \mathbb{R})$ scalar product with the second Gateaux derivative $\bar{u}''$ of the functional $E[g(\bar{m}^{\mathcal{T}}) \,|\, \bar{m}^t = n]$ with respect to $n$. The notation $b_k \otimes b_k(x, x') := b_k(x) b_k(x')$ is the tensor product.

The final step, in Section 4.3, is to use molecular dynamics simulations for a planar two phase problem and take averages in cross sections parallel to the interface, where $\bar{u}', \bar{u}'', a, \sum_k b_k \otimes b_k$ are constant, to evaluate approximations to the functions $a$ and $\sum_k b_k \otimes b_k$ by

$$a = \frac{1}{\mathcal{T}} E\left[ \int_0^{\mathcal{T}} \alpha \, dt \right],$$

$$\sum_k b_k \otimes b_k = \frac{1}{\mathcal{T}} E\left[ \int_0^{\mathcal{T}} \sum_{j=1}^N \beta_j \otimes \beta_j \, dt \right].$$

**4.1. The Ito formula for the phase-field.** The Ito formula (cf. [13]) implies

$$dm(X^t, x) = \underbrace{\sum_{j=1}^N (-\partial_{X_j} m \, \partial_{X_j} V + \gamma \partial_{X_j X_j} m)}_{\alpha(X^t)} \, dt + \sum_{j=1}^N \underbrace{\sqrt{2\gamma} \partial_{X_j} m}_{\beta_j(X^t)} \, dW_j. \tag{4.2}$$

The definition in (2.4),

$$m(X^t, x) = \sum_i m_i(X) \eta(x - X_i^t),$$

yields

$$\partial_{X_j} m = \sum_i \partial_{X_j} m_i \eta(x - X_i) + m_j \partial_{X_j} \eta(x - X_j).$$

In (4.2) we will use (2.5) to evaluate the last derivative as

$$\partial_{X_j} \eta(x - X_j) = -\partial_x \eta(x - X_j) \quad \text{in } dt \text{ terms},$$

$$\partial_{X_j} \eta(x - X_j) = -\eta(x - X_j) \left( \frac{(x - X_j)_1}{\varepsilon_1^2}, \frac{(x - X_j)_2}{\varepsilon_2^2}, \frac{(x - X_j)_3}{\varepsilon_3^2} \right) \quad \text{in } dW_j \text{ terms},$$

in order to avoid spatial derivatives on the diffusion coefficient, while including them in the drift. Since

$$m_i = \frac{1}{2} \sum_{k \neq i} \Phi(X_i - X_k)$$

and

$$V(X) = \frac{1}{2} \sum_i \sum_{j \neq i} \Phi(X_i - X_j)$$

there holds

$$\partial_{X_j} m_i = \frac{1}{2}\sum_{k\neq i} \Phi'(X_i - X_k)\delta_{ij} - \frac{1}{2}\Phi'(X_i - X_j)(1-\delta_{ij}),$$
$$\partial_{X_j} V(X) = \sum_{k\neq j} \Phi'(X_j - X_k),$$

where

$$\delta_{ij} := \begin{cases} 1 & i = j, \\ 0 & i \neq j \end{cases}$$

is the Kronecker symbol. The second derivatives are

$$\partial_{X_j X_j} m = \sum_i \partial_{X_j X_j} m_i \eta(x - X_i) - 2\partial_{X_j} m_j \partial_x \eta(x - X_j) + m_j \partial_{xx}\eta(x - X_j),$$

with

$$\partial_{X_j X_j} m_i = \frac{1}{2}\sum_{k\neq i} \Phi''(X_i - X_k)\delta_{ij} + \frac{1}{2}\Phi''(X_i - X_j)(1-\delta_{ij})$$

and all terms in (4.2) are now expressed in terms of $\Phi$, its gradient $\Phi'$ and Hessian $\Phi''$. We note that the drift, $\alpha$, has the form

$$\partial_x\Big(\sum_{i=1}^N n_{2i}(X^t)\eta(x - X_i^t)\Big) + \sum_{i=1}^N n_{1i}(X^t)\eta(x - X_i^t)$$

of conservative and non conservative reaction terms. Similarly the diffusion, $\beta_j$, takes the form

$$\sum_{i=1}^N n_{3i}(X^t)\eta(x - X_i^t)(x - X_i^t).$$

**4.2. The error representation.** The conditioned expected value

$$\bar{u}(n,t) := E[g(\bar{m}^{\mathcal{T}}) \,|\, \bar{m}^t = n] \tag{4.3}$$

satisfies the Kolmogorov equation (cf. [35], [24])

$$\begin{aligned} &\partial_t u + \langle \bar{u}', a\rangle + \Big\langle \bar{u}'', \sum_{k=1}^M b_k \otimes b_k \Big\rangle = 0 \\ &\bar{u}(\cdot, \mathcal{T}) = g \end{aligned} \tag{4.4}$$

Let $m^t := m(X^t, \cdot)$. The final condition in (4.4) and the definition (4.3) show that

$$E[g(m(X^{\mathcal{T}}, \cdot)) - g(\bar{m}^{\mathcal{T}})] = E[\bar{u}(m^{\mathcal{T}}, \mathcal{T})] - \bar{u}(m^0, 0) = E\Big[\int_0^{\mathcal{T}} d\bar{u}(m^t, t)\Big].$$

Use the Ito formula and (4.2) to evaluate $d\bar{u}(m^t, t)$ and Kolmogorov's equation (4.4) to replace $\partial_t \bar{u}$ in this right hand side to obtain the error representation

$$
\begin{aligned}
&E[g(m(X^{\mathcal{T}}, \cdot)) - g(\bar{m}^{\mathcal{T}})] \\
&\quad = E\Big[\int_0^{\mathcal{T}} \langle \bar{u}', \alpha \rangle + \langle \bar{u}'', \sum_{j=1}^{N} \beta_j \otimes \beta_j \rangle + \partial_t \bar{u}\, dt\Big] \\
&\quad = E\Big[\int_0^{\mathcal{T}} \langle \bar{u}', \alpha - a \rangle + \langle \bar{u}'', \sum_{j=1}^{N} \beta_j \otimes \beta_j - \sum_{k=1}^{M} b_k \otimes b_k \rangle\, dt\Big].
\end{aligned}
$$

**4.3. Computation of averages in cross sections.** The optimal choice of the function $a$ is to minimize $E\big[\int_0^{\mathcal{T}} \langle \bar{u}', \alpha - a\rangle\, dt\big]$, which seems hard to determine exactly since $\bar{u}'(m(X^t, \cdot), t)$ depends on $X^t$. However, the function $\bar{u}'(m(X^t, \cdot), t)$ depends only mildly on the coarse-grained $m(X^t, \cdot)$ and not directly on $X^t$. Therefore a reasonable approximation of this optimum is to think of an expansion of $\bar{u}'$ in $\alpha - a$ and determine $a$ by the leading order condition $E\big[\int_0^{\mathcal{T}} \alpha - a\, dt\big] = 0$, which means that the drift $\bar{a}(x) := a(\bar{m}(\cdot, x))$ is

$$
\bar{a}(x) = \frac{1}{\mathcal{T}} E\Big[\int_0^{\mathcal{T}} \alpha(x)\, dt\Big],
$$

and similarly for the diffusion matrix

$$
\bar{d}(x, x') = \frac{1}{\mathcal{T}} E\Big[\int_0^{\mathcal{T}} \sum_{j=1}^{N} \beta_j(x) \otimes \beta_j(x')\, dt\Big].
$$

We expect the spatial averages of the microscopic variables to vary on a much smaller scale in the $x_1$ direction normal to the phase front than in its orthogonal directions. Consequently we use an average function $\eta$ in (2.4) with higher resolution in the $x_1$ direction, so that $0 < \varepsilon_1 \ll \varepsilon_2 = \varepsilon_3$. In a microscopic simulation the molecular dynamics (3.1) has a small spatial volume, so that $\varepsilon_2$ is much larger than the size of the simulation box. Consequently we may first think of $\alpha$ and $\beta$ depending only on the $x_1$ coordinate.

In practice, the drift $\bar{a}$ and diffusion $\bar{d}$ can only be determined for a discrete set of points

$$
\{(x_1(1), x_2(1), x_3(1)), \ldots, (x_1(M/3), x_2(M/3)), x_3(M/3))\} =: \mathcal{X}_M
$$

and $\mathcal{X}_M \times \mathcal{X}_M$, respectively, related to the scales $\varepsilon_i$. The diffusion coefficient $\bar{b}$, as a function of $x$, can then be obtained from Choleski factorization of the $M \times M$ matrix $\bar{d}$

$$
\sum_{k=1}^{M} \bar{b}_k(x) \bar{b}_k(x') = \bar{d}(x, x').
$$

We expect that $x_1 \mapsto \mathcal{T}^{-1} E\big[\int_0^{\mathcal{T}} m^t\, dt\big]$ is monotone, for fixed $(x_2, x_3)$, so that its inverse function, denoted by $m^{-1}$, is well defined. Then the coarse-grained drift and the diffusion can be obtained as function of $\bar{m}$ by

$$a(\bar{m}) := \bar{a}(m^{-1}(\bar{m})),$$

and similarly for $b_j$.

**Question 4.1.** Will the computed $a$ and $b$ be reasonable?

**Question 4.2.** Can the phase-field method be coupled to the molecular dynamics method for improved localized resolution?

**Question 4.3.** Note that the approximation error $E[g(m(X^{\mathcal{T}}, \cdot)) - g(\bar{m}^{\mathcal{T}})]$ becomes proportional to the variances

$$E\bigg[\int_0^{\mathcal{T}} \langle \alpha - a, \alpha - a\rangle\, dt\bigg],$$

$$E\bigg[\int_0^{\mathcal{T}} \Big\langle \sum_{j=1}^{N} \beta_j \otimes \beta_j - \sum_{k=1}^{M} b_k \otimes b_k, \sum_{j=1}^{N} \beta_j \otimes \beta_j - \sum_{k=1}^{M} b_k \otimes b_k \Big\rangle dt\bigg].$$

The first variations $\partial \bar{u}'(m(X^t, \cdot), t)/\partial\alpha$ and $\partial \bar{u}''(m(X^t, \cdot), t)/\partial\beta_j$ determine the factors of proportionality. Can this be used to adaptively determine the resolution scale $\varepsilon$?

**Remark 4.4.** If we integrate the noise term over all $x_1$, i.e. take $\varepsilon_1$ very large, and let $g(m) = m^2$, then the error $E[g(m(X^{\mathcal{T}}, \cdot)) - g(\bar{m}^{\mathcal{T}})]$ we are studying is the usual fluctuation of energy $E[V^2 - E[V]^2]$ (proportional to the specific heat [21]), provided we set $\bar{m} = E[V]$.

## 5. An atomistic kinetic Monte Carlo method

Kinetic Monte Carlo methods can also be used to simulate solid-liquid phase changes on an atomistic level, cf. [14]. Here the reaction states and rates are given a priori, which makes it possible to simulate crystal growth on larger time scales than in molecular dynamics. The reaction rates and states can in principle be determined from a molecular dynamics simulations on smaller systems, cf. [37]; however often several reactions are involved making this a demanding modeling task. This section is a short version of [24] and derives stochastic hydrodynamical limits of the Ising model with long range interaction, which is the simplest model of this kind of an stochastic interacting particle system on a square lattice with two possible states in each lattice point, cf. [21].

Define a periodic lattice $\mathcal{L} := \gamma Z^d \cap [0, 1]^d$, with neighboring sites on distance $\gamma$, and consider spin configurations $\sigma : \mathcal{L} \times [0, \mathcal{T}] \to \{-1, 1\}$ defined on this lattice.

Introduce a stochastic spin system where the spin $\sigma_t(x)$, at site $x \in \mathcal{L}$ and time $t$, will flip to $-\sigma_t(x)$ with the rate $c(x, \sigma_t(\cdot))dt$, in the time interval $(t, t+dt)$, independent of possible flips at other sites, cf. [27]. Let $\sigma^x$ denote the configuration of spins after a flip at $x$ of state $\sigma$, i.e.

$$\sigma^x(y) = \begin{cases} \sigma(y) & y \neq x, \\ -\sigma(x) & y = x, \end{cases}$$

the probability density $P(\sigma, t)$ of finding the spin system in configuration $\sigma \in \{-1, 1\}^{\mathcal{L}}$ at time $t$ then solves the master equation

$$\frac{dP(\sigma, t)}{dt} = \sum_{x \in \mathcal{L}} (c(x, \sigma^x)P(\sigma^x, t) - c(x, \sigma)P(\sigma, t)), \tag{5.1}$$

where the gain term $\sum_x c(x, \sigma^x)P(\sigma^x, t)$ is the probability of jumping to state $\sigma$ at time $t$ and the loss term $\sum_x c(x, \sigma)P(\sigma, t)$ is the probability to leave state $\sigma$. Similar master equations are used for microscopic models of chemical reactions and phase transformations, cf. [36], [14], where lattice sites are occupied by different species of particles. For instance with two species the state space could be $\{0, 1\} \times \{0, 1\}$ instead of $\{-1, 1\}$ for the classical spin model above.

We want a spin system that has statistical mechanics relevance, which can achieved e.g. by choosing the rate function $c$ as follows. Consider the Hamiltonian

$$H(\sigma) = -\frac{1}{2} \sum_{x \in \mathcal{L}} \sum_{y \neq x} J(x - y)\sigma(x)\sigma(y) - \sum_{x \in \mathcal{L}} h(x)\sigma(x)$$

$$J = \gamma^d J_0, \qquad J_0(x) = 0 \quad \text{for } |x| \geq 1,$$

where the long range interaction potential, $J_0 \in \mathcal{C}^2(\mathbb{R}^d)$, is compactly supported and the function $h \in \mathcal{C}^2(\mathbb{R}^d)$ is a given external field. Define the Glauber Markov process on $\{-1, 1\}^{\mathcal{L}}$ with generator

$$\frac{d}{dt} E[f(\sigma_t)|\sigma] = Lf(\sigma) = \sum_{x \in \mathcal{L}} c(x, \sigma)(f(\sigma^x) - f(\sigma)) \tag{5.2}$$

for $f : \{-1, 1\}^{\mathcal{L}} \to \mathbb{R}$ and the flip rate

$$\begin{aligned} c(x, \sigma) &= \frac{e^{-\beta U(x)\sigma(x)}}{e^{-\beta U(x)} + e^{\beta U(x)}} = \frac{1}{2}\big(1 - \sigma(x)\tanh(\beta U(x))\big), \\ U(x) &= h(x) + \sum_{y \neq x} J(x - y)\sigma(y) =: h(x) + J * \sigma(x) - J(0)\sigma(x), \end{aligned} \tag{5.3}$$

where $\beta > 0$ is the inverse temperature. This flip rate has built in invariance of the Gibbs density, $e^{-\beta H(\sigma)} / \sum_\sigma e^{-\beta H(\sigma)}$, since it satisfies the detailed balance

$$c(x, \sigma)e^{-\beta H(\sigma)} = c(x, \sigma^x)e^{-\beta H(\sigma^x)},$$

which implies that this Gibbs density is a time independent (invariant) solution to (5.1). Having this invariant Gibbs measure implies that the model has statistical mechanics relevance, see [12], [4], [5], [6], [11]. For example in a neighborhood of $x \in \mathcal{L}$, where $h$ and $J * (1, \ldots, 1)$ are positive, the construction of the flip rate $c$ makes the system favor phases with spins mostly equal to 1 as compared to phases with spins mostly equal to $-1$.

We will study localized projection averages of $\sigma$ on scale $\varepsilon$. In particular we will find approximations to expected values of such averages. The error analysis uses consistency with the backward equation

$$\partial_t \tilde{u} + L\tilde{u} = 0 \quad \text{for } t < \mathcal{T}, \quad \tilde{u}(\cdot, \mathcal{T}) = g$$

corresponding to the master equation (5.1) for expected values

$$\tilde{u}(\xi, t) := E[g(\sigma_{\mathcal{T}})|\, \sigma_t = \xi].$$

**5.1. A coarse-grained kinetic Monte Carlo method.** Define the coarse periodic lattice $\bar{\mathcal{L}} := q\gamma Z^d \cap [0, 1]^d$ with neighboring sites on distance $q\gamma =: \varepsilon$, where $q$ is an even positive integer and $q^d$ is the number of fine sites projected to a coarse site: the lattice points $y \in \bar{\mathcal{L}}$ define the coarse cells

$$C_y = \{x \in \mathcal{L} : -q\gamma/2 \le x_i - y_i < q\gamma/2\},$$

of $q^d$ neighboring points in the fine lattice and the averaging operator

$$A_\varepsilon(z, x) = \begin{cases} 1/q^d & \text{if } x \text{ and } z \text{ are in the same coarse cell } C_y, \\ 0 & \text{if } x \text{ and } z \text{ are in different coarse cells.} \end{cases}$$

We will study the behavior of the localized projection averages

$$\overline{X}(z) := \sum_{x \in \mathcal{L}} A_\varepsilon(z, x)\sigma(x), \tag{5.4}$$

for $z \in \mathcal{L}$. The coarse-grained average $\overline{X}$ can be interpreted as a function on the coarse lattice since the restriction of $\overline{X}$ to each coarse cell $C_z$ is constant, i.e. $\overline{X} = \sum_{x \in C_\cdot} \sigma(x)/q^d$.

The work [23] derives a coarse-grained kinetic Monte Carlo equation approximating the average $\overline{X}$. The next section shows as in [24] that the average spin, $\overline{X}$, can be approximated by the solution, $X \colon \bar{\mathcal{L}} \times [0, \mathcal{T}] \times \Omega \to \mathbb{R}$, to the Ito stochastic differential equation

$$dX_t(x) = a(X_t)(x)dt + b(X_t)(x)dW^x, \quad X_0 = \overline{X}_0, \tag{5.5}$$

with the drift, $a\colon \mathbb{R}^{\bar{\mathcal{L}}} \to \mathbb{R}^{\bar{\mathcal{L}}}$, and diffusion, $b\colon \mathbb{R}^{\bar{\mathcal{L}}} \to \mathbb{R}^{\bar{\mathcal{L}}}$, coefficients given by

$$\begin{aligned} a(X) &= -X + \tanh(\beta(J * X + h - J(0)X)),\\ b(X)(x) &= \left(\frac{\gamma}{\varepsilon}\right)^{d/2} \sqrt{|1 - X\tanh(\beta(J * X + h - J(0)X))(x)|}\ \eta(X(x)),\\ \eta(r) &= \begin{cases} 1 & \text{for } x \in [-1, 1],\\ 0 & \text{for } x \in (-\infty, -\hat{r}) \cup (\hat{r}, \infty),\end{cases}\\ \hat{r} &:= \min(1 + e^{-2\beta(2|J|_{\ell^1} + \|h\|_{L^\infty})}, 3/2) \end{aligned} \tag{5.6}$$

and a Wiener process $W\colon \bar{\mathcal{L}} \times [0, \mathcal{T}] \times \Omega \to \mathbb{R}$ on a probability space $(\Omega, P, \{\mathcal{F}_t\}_{t=0}^{\mathcal{T}})$, with the set of outcomes $\Omega$, probability measure $P$ and sigma algebra $\mathcal{F}_t$ of events up to time $t$. Here $W^x$ are independent one dimensional standard Brownian motions for $x \in \bar{\mathcal{L}}$, so that formally

$$\begin{aligned} E[dW_t^x] &= 0,\\ E[dW_s^x dW_t^y] &= 0 \quad \text{for } s \neq t,\\ E[dW_t^x dW_t^y] &= 0 \quad \text{for } x \neq y, \text{ and}\\ E[dW_t^x dW_t^x] &= dt. \end{aligned}$$

The $\mathcal{C}^\infty$ cut-off function $\eta\colon \mathbb{R} \to [0, 1]$, with compact support, is introduced to handle the complication that $|X(x)|$ may be larger than 1, although $|\overline{X}(x)|$ is not, so that $1 - X\tanh(\beta(J * X + h - J(0)X))(x)$ may be close to zero causing large values on derivatives of

$$\sqrt{|1 - X\tanh(\beta(J * X + h - J(0)X))(x)|}\,,$$

note that we have $|\overline{X}(x)| \leq 1$ and consequently the cut-off $\eta$ improves the approximation by switching off the noise before $1 - X\tanh(\beta(J * X + h - J(0)X))(x)$ becomes zero making $b$ a $\mathcal{C}^\infty$ function.

The approximation uses that the high dimensional value function $u\colon \mathbb{R}^{\bar{\mathcal{L}}} \times [0, \mathcal{T}] \to \mathbb{R}$ defined by

$$u(\xi, t) = E[g(X_{\mathcal{T}})|X_t = \xi]$$

solves a corresponding Kolmogorov backward equation, where the drift and diffusion coefficients in (5.6) are chosen to minimize the error $E[g(\overline{X}_{\mathcal{T}})] - E[g(X_{\mathcal{T}})]$. To define the Kolmogorov backward equation introduce the weighted scalar products

$$\begin{aligned} w \cdot v &:= \sum_{y \in \bar{\mathcal{L}}} w_y v_y \varepsilon^d && \text{for } w, v \in \ell^2(\bar{\mathcal{L}}),\\ w \cdot v &:= \sum_{x,y \in \bar{\mathcal{L}}} w_{xy} v_{xy} \varepsilon^{2d} && \text{for } w, v \in \ell^2(\bar{\mathcal{L}}^2),\\ w \cdot v &:= \sum_{x,y,z \in \bar{\mathcal{L}}} w_{xyz} v_{xyz} \varepsilon^{3d} && \text{for } w, v \in \ell^2(\bar{\mathcal{L}}^3). \end{aligned}$$

Then $u$ satisfies the Kolmogorov backward equation

$$\partial_t u + a \cdot u' + D \cdot u'' = 0 \quad \text{for } t < \mathcal{T},$$
$$u(\cdot, \mathcal{T}) = g,$$

where

$$D_{xy} = \begin{cases} (1 - X \tanh(\beta(J * X + h))(x))\eta^2(X(x)) & y = x, \\ 0 & y \neq x, \end{cases}$$

and $u'(\xi, t) = \partial_\xi u(\xi, t)$ and $u''(\xi, t)$ are the first and second order Gateaux derivatives of $u$ in $\ell^2(\bar{\mathcal{L}})$ and $\ell^2(\bar{\mathcal{L}}^2)$, respectively.

**5.2. Stochastic hydrodynamical limit of the particle system.** The main result in [24] is

**Theorem 5.1.** *The average spin, $\overline{X}$, can be approximated by the solution, $X$, to the Ito stochastic differential equation* (5.5) *with error*

$$E[g(\overline{X}_{\mathcal{T}})] - E[g(X_{\mathcal{T}})] = \mathcal{O}\big(\mathcal{T}\varepsilon + \mathcal{T}(\gamma/\varepsilon)^{2d}\big) \tag{5.7}$$

*provided that the Gateaux derivatives $u'(\overline{X}_t, t)$, $u''(\overline{X}_t, t)$ and $u'''(\overline{X}_t, t)$ on the path $\overline{X}$ are bounded in the weighted norms $\ell^1(\bar{\mathcal{L}}^i)$ up to time $\mathcal{T}$.*

Note that $a = 0$ gives $\mathcal{O}(1)$ error, while $b = 0$ gives $\mathcal{O}((\gamma/\varepsilon)^d)$ error so that $b$ defined by (5.6) is justified for $\gamma \ll \varepsilon \ll \gamma^{2d/(2d+1)}$, with $\mathcal{T}$ fixed.

The stochastic differential equation (5.5) has $\mathcal{C}^\infty$ coefficients, where perturbations of solutions may grove exponentially in time. The work [24] verifies that mean square estimates of $X$ and its variations up to order three give bounds on the weighted $\ell^1$-norm of the derivatives of $u$ that depend exponentially on time, i.e. $e^{C\mathcal{T}}$.

*Proof of the theorem.* The definitions of $u$, the generator (5.2) and the average (5.4) imply

$$\begin{aligned}
&E[g(\overline{X}_{\mathcal{T}})] - E[g(X_{\mathcal{T}})] = E[u(\overline{X}_{\mathcal{T}}, \mathcal{T})] - E[u(X_0, 0)] \\
&= E\bigg[\int_0^{\mathcal{T}} du(\overline{X}_t, t)\bigg] \\
&= \int_0^{\mathcal{T}} E[Lu + \partial_t u]\, dt = \int_0^{\mathcal{T}} E\big[E[Lu - a \cdot u' - D \cdot u''|\overline{X}_t]\big]\, dt \\
&= \int_0^{\mathcal{T}} E\Big[E\Big[\sum_{x \in \mathcal{L}} c(x, \sigma)\big(u(\overline{X}(\sigma^x)) - u(\overline{X}(\sigma))\big) - a \cdot u' - D \cdot u''|\overline{X}_t\Big]\Big]\, dt \\
&= \int_0^{\mathcal{T}} E\Big[E\Big[\sum_{x \in \mathcal{L}} c(x, \sigma)\big(u(\overline{X}(\sigma) - 2A_\varepsilon(x, \cdot)\sigma(x)) - u(\overline{X}(\sigma))\big) \\
&\qquad\qquad - a \cdot u' - D \cdot u''|\overline{X}_t\Big]\Big]\, dt.
\end{aligned} \tag{5.8}$$

The first step to estimate this error is to write the differences in $u$ in terms of its Gateaux derivatives by Taylor expansion, for some $s \in [0,1]$,

$$\begin{aligned} &u(\overline{X}(\sigma) - 2A_\varepsilon(x,\cdot)\sigma(x)) - u(\overline{X}(\sigma)) \\ &\quad = -2u'(\overline{X}) \cdot A_\varepsilon(x,\cdot)\sigma(x) \\ &\qquad + 2u''(\overline{X}) \cdot A_\varepsilon(x,\cdot)A_\varepsilon(x,\cdot)\sigma^2(x) \\ &\qquad - \frac{4}{3}u'''(\overline{X} - 2sA_\varepsilon(x,\cdot)\sigma(x)) \cdot A_\varepsilon(x,\cdot)A_\varepsilon(x,\cdot)A_\varepsilon(x,\cdot)\sigma^3(x), \end{aligned} \tag{5.9}$$

so that the error representation (5.8) becomes

$$\begin{aligned} &E[g(\overline{X}_{\mathcal{T}})] - E[g(X_{\mathcal{T}})] \\ &= \int_0^{\mathcal{T}} E\Big[E\Big[\sum_{x\in\mathcal{L}} \big(u'(\overline{X}) \cdot (-2c(x,\sigma)A_\varepsilon(x,\cdot)\sigma(x) - a) \\ &\quad + u''(\overline{X}) \cdot (2c(x,\sigma)A_\varepsilon(x,\cdot)A_\varepsilon(x,\cdot)\sigma^2(x) - D) \\ &\quad - \frac{4}{3}u'''(\overline{X} - 2sA_\varepsilon(x,\cdot)\sigma(x)) \cdot c(x,\sigma)A_\varepsilon(x,\cdot)A_\varepsilon(x,\cdot)A_\varepsilon(x,\cdot)\sigma^3(x)\big) \mid \overline{X}_t\Big]\Big]\, dt. \end{aligned} \tag{5.10}$$

The next step is to determine the optimal $a$ and $b$ which minimize the error (5.10). For this purpose we shall in the flipping rate approximate the coupling $J * \sigma$ and $J(0)\sigma = \mathcal{O}(\gamma^d)$ with $J * \overline{X}$ and $J(0)\overline{X}$, using the long range $\mathcal{O}(1)$ interaction distance of $J$. The definition of the average (5.4) implies

$$J * \overline{X} = \sum_{z,y\in\mathcal{L}} J(\cdot - y)A_\varepsilon(y,z)\sigma(z)$$

and consequently the coupling has the uniform error estimate

$$\|J*\sigma - J*\overline{X}\|_{\ell^\infty} \le \Big\|J(\cdot - z) - \sum_{y\in\mathcal{L}} J(\cdot - y)A_\varepsilon(y,z)\Big\|_{\ell^1} \|\sigma\|_{\ell^\infty} = \mathcal{O}(\varepsilon). \tag{5.11}$$

This error estimate, the flip rate (5.3) and $J(0) = \mathcal{O}(\gamma^d)$ imply

$$\begin{aligned} &-\sum_{x\in\mathcal{L}} 2c(x,\sigma)A_\varepsilon(x,\cdot)\sigma(x) \\ &\qquad = -\overline{X} + A_\varepsilon \cdot \tanh(\beta(J*\sigma + h - J(0)\sigma)) \\ &\qquad = -\overline{X} + \tanh(\beta(J*\overline{X} + h - J(0)\overline{X})) + \mathcal{O}(\varepsilon + \gamma^d), \end{aligned} \tag{5.12}$$

and

$$\begin{aligned} &\sum_{x\in\mathcal{L}} 2c(x,\sigma)A_\varepsilon(x,\cdot)A_\varepsilon(x,\cdot)\sigma^2(x) \\ &\qquad = \Big(\frac{\gamma}{\varepsilon}\Big)^d \big[1 - \overline{X}\tanh(\beta(J*\overline{X} + h - J(0)\overline{X}))\big] \\ &\qquad\quad + \mathcal{O}\big((\gamma/\varepsilon)^{2d} + \varepsilon + \gamma^{2d}\big). \end{aligned} \tag{5.13}$$

We have

$$\begin{aligned} \Big\| \sum_x A_\varepsilon(x,\cdot)A_\varepsilon(x,\cdot) \Big\|_{\ell^\infty} &= (\gamma/\varepsilon)^d, \\ \Big\| \sum_x A_\varepsilon(x-\cdot)A_\varepsilon(x-\cdot)A_\varepsilon(x-\cdot) \Big\|_{\ell^\infty} &= (\gamma/\varepsilon)^{2d}, \end{aligned} \tag{5.14}$$

which together with the expansions (5.10), (5.12) and (5.13) proves the theorem. □

We also have

**Lemma 5.2.** *Suppose that the Gateaux derivatives $u'(\overline{X}_t, t)$ and $u''(\overline{X}_t, t)$ on the path $\overline{X}$ are bounded in the weighted norms $\ell^1(\bar{\mathcal{L}}^i)$ up to time $\mathcal{T}$ and that the initial spin $\sigma_0$ has expected value $m$, where $\sigma_0(x) - m_x$ are i.i.d. with bounded variance and second order difference quotients $|d^2m/dx^2| = \mathcal{O}(1)$. Then the deterministic mean field solution, $\hat{X}\colon \mathbb{R}^{\bar{\mathcal{L}}} \times [0, \mathcal{T}] \to \mathbb{R}$,*

$$d\hat{X}/dt = -\hat{X} + \tanh(\beta(J * \hat{X} + h - J(0)\hat{X})), \quad \hat{X}_0 = E[\overline{X}_0],$$

*depends on $\varepsilon$ only through the initial data and satisfies*

$$E[g(\overline{X}_{\mathcal{T}})] - E[g(\hat{X}_{\mathcal{T}})] = \mathcal{O}(\varepsilon + (\gamma/\varepsilon)^d)$$

*provided the drift $a$ is defined by* (5.6).

*Proof.* Think of $\hat{X}$ as an $X$ with $b = 0$ and apply the corresponding expansion (5.8), (5.9) and (5.14). Then it remains to verify that the initial data satisfy

$$E[u(\overline{X}_0, 0) - u(\hat{X}_0, 0)] = \mathcal{O}\big((\gamma/\varepsilon)^d\big),$$

but this is a direct consequence of the central limit theorem and the initial $\sigma_0 - E[\sigma_0]$ being i.i.d. with bounded variance. □

**5.3. Alternative invariant measure diffusion for mean exit times.** Not all expected values $E[g(\overline{X}_{\mathcal{T}})]$ can be approximated using the stochastic differential equation (5.5) with Einstein diffusion, due to the required bounds on the derivatives of $u$; such an example is to determine the expected first exit time $\tau(Y) = \inf\{t : Y_t \notin A\}$ from a neighborhood $A$ of an equilibrium point $y' \in A$, where $a(y') = 0$ and $Y_0 \in A$. Then the expected exit time is exponentially large, i.e.

$$\begin{aligned} &\lim_{\gamma/\varepsilon \to 0+} \left(\tfrac{\gamma}{\varepsilon}\right)^d \log E[\tau(\overline{X})] \text{ and } \lim_{\gamma/\varepsilon \to 0+} \left(\tfrac{\gamma}{\varepsilon}\right)^d \log E[\tau(X)] \\ &\text{are both strictly positive.} \end{aligned} \tag{5.15}$$

These expected values are related to transition rates $k$ and $E[\tau] = 1/k$ in simple cases, see [17], [9]. Hanggi et al. [16] have proposed a remedy by approximating the master equation by a different stochastic differential equation with the same asymptotic drift

but a modified diffusion, to leading order, chosen so that the SDE invariant density $Z^{-1}e^{-U/(\gamma/\varepsilon)^d}$ is asymptotically the same as for the master equation. One perspective on the two different SDEs with Einstein diffusion or invariant measure diffusion is that the two limits, coarse-graining and time tending to infinity, do not commute. Because of (5.15) the theory of large deviations for rare events is relevant for exit times, cf. [9].

Let $\gamma_1 := \gamma/\varepsilon$. Consider an SDE

$$dX_t(x) = (a(X_t) + \gamma_1^d c(X_t))(x)dt + \gamma_1^{d/2}\tilde{b}(X_t)(x)dW_t^x,$$

with the generator

$$Lf = (a + \gamma_1^d c)\cdot f' + \gamma_1^d \tilde{D}\cdot f'', \quad D_{ij} = \tilde{b}_i\tilde{b}_j\delta_{ij};$$

the idea in [16] is to find $c$ and $D$ so that the corresponding SDE asymptotically has the same invariant density $e^{-U/\gamma_1^d}/Z$ as the master equation. Hanggi et al. [16] determine the diagonal diffusion matrix $\tilde{D}$ and the small contribution to the drift $\gamma_1^d c$ by

$$\begin{aligned} \tilde{D}_{ii} &= -a_i/U_i', \\ c_i &= -\partial_{x_i}\tilde{D}_{ii}; \end{aligned} \tag{5.16}$$

note that since $a$ and $U$ have the same zeros, the constructed function $\tilde{D}_{ii}$ is positive in general. The equation (5.16) can be obtained by the WKB expansion

$$\begin{aligned} 0 \simeq L^* e^{-U/\gamma_1^d} = \big(&\gamma_1^{-d}(a_i U_i' + \tilde{D}_{ii}U_i'U_i') \\ &+ \gamma_1^0(\partial_i a_i + 2U_i'\partial_i\tilde{D}_{ii} + U_{ii}''\tilde{D}_{ii} + c_i U_i') \\ &+ \gamma_1^d(\partial_i c - \partial_{ii}\tilde{D}_{ii})\big)e^{-U/\gamma_1^d} \end{aligned}$$

together with the two leading order conditions that the terms of order $\gamma_1^{-d}$ and $\gamma_1^0$ vanish; here $L^*$ is the Chapman–Enskog operator adjoint to $L$. Consequently the choice (5.16) will in general generate an SDE with an invariant density $e^{-\tilde{U}/\gamma_1^d}/Z$, where $|\tilde{U} - U| = \mathcal{O}(\gamma_1^{2d})$.

Let us indicate why good approximation of the invariant measure implies that also the expected values, $E[\tau]$, for exit problems related to rare events with large deviations, are accurately computed: the work [9] shows that

$$\lim_{\gamma_1\to 0+} \gamma_1^d \log E[\tau(X)] = \inf_{y\in\partial A} U(y) - U(y'), \tag{5.17}$$

for one stable attracting equilibrium point $y' \in A$. The work [24] shows that the exit time (5.17) with SDE's and invariant measure diffusion is asymptotically the same as for the master equation for the 1D Curie–Weiss model:

$$\lim_{\gamma_1\to 0+} \gamma_1^d\big(\log E[\tau(X)] - \log E[\bar{\tau}(\overline{X})]\big) = 0\,, \tag{5.18}$$

where $E[\tau(X)]$ and $E[\bar{\tau}(\overline{X})]$ denote the mean exit time for the Hanggi SDE and the Curie–Weiss master equation, respectively. The Curie–Weiss model is a simple adsorption/desorption Ising model with constant interaction potential, cf. Section 5.4. The technique to establish this asymptotic agreement is to use logarithmic (Hopf–Cole) transformations of the two mean exit times, as functions of the initial location, which transforms the corresponding two linear Kolmogorov backward equations to two nonlinear Hamilton–Jacobi equations, cf. [8]. The two processes give rise to two different asymptotic Hamilton–Jacobi equations, however the key observation is that they have the same viscosity solution since they are both convex and have the same set of zeros.

**5.4. Dendrites with Einstein diffusion.** We see by Theorem 5.1 and Lemma 5.2 that the mean field differential equation solution is also an accurate approximation to the spin dynamics, provided the derivatives of the value function are bounded; this indicates that the stochastic differential equation (5.5) then only offers a small quantitative improvement. However, if the derivatives of the value function are large the mean field solution may give a qualitatively wrong answer, with $\mathcal{O}(1)$ error as $\gamma/\varepsilon \to 0+$, while the stochastic differential equation still yields an asymptotically correct limit; such an example is dendrite formation in phase transformations, cf. [22], [19], [3], [14].

Let us try to motivate why the noise in Theorem 5.1 seems applicable to dendrite formation. Dendrite dynamics can be formulated by the phase field method with an Allen–Cahn/Ginzburg–Landau equation coupled to a diffusion equation for the energy, as in (1.1), and by master equations coupled to the energy equation, cf. [14]. Mean field equations related to such a phase field system have been derived from a spin system coupled to a diffusion equation, see [7].

A master equation variant of the molecular dynamics model in Sections 2–4 is to let the coarse-grained potential energy be defined by

$$m(\sigma, z) := \sum_x \Big( \sum_{y \neq x} \frac{1}{2} J(x-y)\sigma(y) - h \Big) \sigma(x) A_\varepsilon(x, z),$$

where $A$ is the average in (5.4), and replace the Glauber dynamics with Arrhenius dynamics. That is, the microscopic dynamics is given by independent spins $\sigma(x) \in \{0, 1\}$, for each lattice point $x \in \mathcal{L}$, flipping with adsorption rate

$$c_a(x) = d_0\big(1 - \sigma(x)\big)$$

from states 0 to 1, and with desorption rate

$$c_d(x) = d_0\sigma(x) \exp\Big( -\frac{1}{k_B T} \Big( \sum_{y \neq x} J(x-y)\sigma(y) - h \Big) \Big)$$

from states 1 to 0, where $h$ is a surface binding energy or an external field and $d_0$ is a given rate, cf. [23]. Arrhenius dynamics also satisfies detailed balance with the same

Gibbs density

$$e^{(\sum_x \sum_{y\neq x} J(x-y)\sigma(x)\sigma(y)/2 - \sum_x h\sigma(x))/(k_B T)}$$

as for Glauber dynamics. The dynamics for the potential energy variable can then be coupled to the energy equation (2.1)

$$\partial_t(c_v T + m) = \operatorname{div}(k\nabla T)$$

by letting the temperature $T$ vary on the coarse-grained scale.

The dendrite grows with a positive non vanishing speed. Without noise in the model there is no side branching, while the side branching is present with added noise to the phase field model, cf. [3], or to the mean field model derived in [14]. This noise induced side branching is explained by the high sensitivity with respect to small perturbations at the dendrite tip, cf. [22]. Therefore the derivatives of an appropriate value function are large. Here the value function, $u$, could for instance measure the total dendrite surface at a fixed time. The inconsistent approximation of the mean field solution could by Lemma 5.2 be explained by having

$$(\gamma/\varepsilon)^d \|u''\|_{\ell^1} = \mathcal{O}(1). \tag{5.19}$$

The smallest scale in the problem is the dendrite tip radius $\rho$; with a bounded value function its derivatives could then be

$$\begin{aligned} \|u'\|_{\ell^1} &= \mathcal{O}(1/\rho), \\ \|u''\|_{\ell^1} &= \mathcal{O}(1/\rho^2), \\ \|u'''\|_{\ell^1} &= \mathcal{O}(1/\rho^3). \end{aligned}$$

Consequently (5.19) yields $(\gamma/\varepsilon)^{d/2} = \rho$, so that the noise error for the stochastic differential equation with the Einstein diffusion of Theorem 5.1 would be bounded by $(\gamma/\varepsilon)^{2d}\|u'''\|_{\ell^1} = \mathcal{O}((\gamma/\varepsilon)^{d/2})$, which tends to zero as $\gamma/\varepsilon \to 0+$. Therefore, this adsorption/desorption kinetic Monte Carlo model with long range interaction generates an approximating stochastic differential equation, which could be applicable also to coupling with the energy equation if the derivation remains valid with slowly varying temperature. An essential and maybe more difficult question is to find accurate kinetic Monte Carlo methods for real systems with dendrite dynamics, e.g. using ideas from the molecular dynamics coarse-graining in Sections 2–4.

# Competitions and mathematics education

Petar S. Kenderov*

**Abstract.** Mathematics competitions, together with the people and organizations engaged with them, form an immense and vibrant global network today. This network has many roles. Competitions help identify students with higher abilities in mathematics. They motivate these students to develop their talents and to seek professional realization in science. Competitions have positive impact on education and on educational institutions. Last but not least, a significant part of the classical mathematical heritage known as "Elementary Mathematics" is preserved, kept alive and developed through the network of competitions and competition-related activities. Nevertheless, competitions need to evolve in order to meet the demands of the new century.

These and many other items are outlined and discussed in the paper.

**Mathematics Subject Classification (2000).** Primary 97U40; Secondary 97C60.

**Keywords.** Mathematics competitions, olympiads, higher ability students.

## 1. Introduction

Competition is essential and intrinsic to life. Every day, living things in nature and economic subjects in society compete for resources, for better living conditions, and for higher efficiency. The desire to compete in overcoming a challenge is deeply rooted in human nature and has been employed for centuries to help people sharpen their skills and improve their performance in various activities.

Competitions, however hotly debated, praised, or condemned, remain central and inherent in education. Both the traditional marking (grading) of students in school and the more innovative measuring of their basic scholastic abilities (implemented by methods such as PISA, TIMSS, or SAT) inevitably create, directly or indirectly, competition among students, among teachers, among schools, and even among whole countries. Heated debates aside, few would deny the positive influence such competitions bring to the process of teaching and learning, and to the overall performance of the educational system.

The interaction between competition and education is more complex, however. It is not only that competitions enhance education. Education itself can be viewed as

*The author is grateful to the Institute of Mathematics and Informatics, Bulgarian Academy of Sciences, and to his colleagues for their support of (and the involvement with) the Bulgarian system of competitions in mathematics, informatics, and mathematical linguistics. Special thanks to E. Belogay, participant in IMO 1979, for carefully reading and editing the early drafts of this paper.

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

preparation of individuals (or groups of individuals, even whole nations) for future competitions.

In what follows, we give a brief history of contemporary math competitions and present the state of the art in this area. Then we outline how competitions help identify, motivate, and develop higher-ability and talented students. Next we focus on the impact of competitions on education, on educational institutions and on mathematics as a science. Finally, we pose challenges and identify venues for improvement.

## 2. Brief history of mathematics competitions

It is difficult to trace precisely the origins of mathematics competitions for school students; after all, in-class testing (which often resembles small-scale competitions) has accompanied the school system from its very beginning. In fact, the archetype of some competitions can be found outside school, in the society. Newspapers and recreational journals frequently offer prizes for solving crosswords, puzzles, and problems of a deeper mathematical nature. This practice is widely used today by many mathematical journals that publish problems and give awards to school students who provide good solutions.

V. Berinde [2] reports that a primary school math competition with 70 participants was held in Bucharest, Romania, as early as 1885. There were eleven prizes awarded to 2 girls and 9 boys. It cannot be excluded that other competitions were held elsewhere before or after that date too. Nevertheless, the 1894 Eötvös competition in Hungary is widely credited as the forerunner of contemporary mathematics (and physics) competitions for secondary school students. The competitors were given four hours to solve three problems individually (no interaction with other students or teachers was allowed). The problems in the Eötvös competition were specially designed to challenge and check creativity and mathematical thinking, not just acquired technical skills; the students were often asked to prove a statement.

As an illustration, here are the three problems given in the very first Eötvös competition in 1894 (the entire collection of problems and their solutions is maintained by John Scholes at www.kalva.demon.co.uk/eotvos.html):

**P1.** Show that $\{(m, n) : 17 \text{ divides } 2m + 3n\} = \{(m, n) : 17 \text{ divides } 9m + 5n\}$.

**P2.** Given a circle $C$, and two points $A$, $B$ inside it, construct a right-angled triangle $PQR$ with vertices on $C$ and hypotenuse $QR$ such that $A$ lies on the side $PQ$ and $B$ lies on the side $PR$. For which $A$, $B$ is this not possible?

**P3.** A triangle has sides length $a$, $a + d$, $a + 2d$ and area $S$. Find its sides and angles in terms of $d$ and $S$. Give numerical answers for $d = 1$, $S = 6$.

The Eötvös competition model still dominates the competition scene.

The year 1894 is notable also for the birth of the famous mathematics journal *KöMaL* (an acronym of the Hungarian name of the journal, which translates to *High School Mathematics and Physics Journal*). Founded by Dániel Arany, a high school teacher in Györ, Hungary, the journal was essential to the preparation of students and teachers for competitions (about one third of each issue was devoted to problems and problem solving and readers were asked to send solutions). As noted by G. Berzsenyi in the preface of [3], about 120–150 problems were published in *KöMaL* each year; about 2500–3000 solutions were received. The best solutions and the names of their authors were published in following issues. This type of year-round competition helped many young people discover and develop their mathematical abilities; many of them later became world-famous scientists. (For more information, see the journal web site, komal.elte.hu.)

About the same time, similar development occurred in Hungary's neighbor, Romania. The first issue of the monthly *Gazeta Matematică*, an important journal for Romanian mathematics, was published in September 1895. The journal organized a competition for school students, which improved in format over the years and eventually gave birth to The National Mathematical Olympiad in Romania. For legal reasons, the journal was transformed to *Society Gazeta Matematică* in August 1909. The following year, the Romanian Parliament approved the legal status of the new society and this is considered to be the birthday of the Romanian Mathematical Society [2].

What happened in Hungary and Romania in the late 1800's was not something isolated and special to these two countries only; most likely, it reflected a much broader trend. Indeed, international collaboration and solidarity were rising steadily and many national math societies were founded around the same time. The Olympic Games were revived in 1896. The First International Congress of Mathematicians took place in Zürich in 1897. Within several decades, other countries started to organize mathematics competitions. In 1934, a Mathematical Olympiad was organized in Leningrad, USSR (now St. Petersburg, Russia).

## 3. Mathematics competitions today

Today the world of mathematics competitions encompasses millions of students, teachers, research mathematicians, educational authorities, and parents, who organize and take part in hundreds of competitions and competition-like events with national, regional, and international importance every year. Even greater is the number of books, journals, and other printed and electronic resources that help students and their mentors prepare for the various types of competitions.

**3.1. International Mathematical Olympiad (IMO).** Of course, the most important and most prestigious math competition is the *International Mathematical Olympiad* (IMO) – an annual competition for high school students. Directly or indirectly, all other competition activities in mathematics and sciences are related to the IMO.

The idea to organize an international mathematics competition crystallized during the Fourth Congress of Romanian Mathematicians in 1956. Paul Jainta [4] points out that "IMO, the pinnacle of competitions among individuals, was the brainchild of Romania's Tiberiu Roman, an educator of monumental vision." The first IMO took place in Romania (1959) with participants from seven countries: Bulgaria, Czechoslovakia, German Democratic Republic, Hungary, Poland, Romania, and the Soviet Union (USSR). The second IMO (1960) was organized by Romania as well, but since then it is hosted by a different country every year (except 1980, when no IMO was held). Over the years, the participation grew dramatically: the 2005 IMO in Mexico gathered 513 competitors from 93 countries!

Strict formalized rules govern every aspect of the IMO, such as participation, problem selection, assessment of solutions, and distribution of medals (for a description of the IMO, browse erdos.fciencias.unam.mx).

Each country sends a team of up to eight (four in 1982; since 1983, six) high-school students, chaperoned by a team leader and a deputy team leader. The competition itself is held on two consecutive days; each day, the students have four and a half hours to solve three problems. Each year, just before the competition, the six problems are selected by an international jury formed by the national team leaders and representatives of the host country. Even though confined to secondary school mathematics, the problems are rather difficult and solving them requires a significant degree of inventive ingenuity and creativity. Each problem is worth seven points, so the perfect score is 42 points.

Formally, like the Olympic Games, the IMO is a competition for *individuals*; participants are ranked according to their score and (multiple) individual medals are awarded. Nevertheless, again as in the Olympic Games, the medals and points obtained by the participants from each country are totaled and the countries are unofficially ranked, providing grounds for comparison between countries.

The two days of heavy problem-solving are followed by a social program for all the participants. Students get to know each other, discuss alternative solutions to the competition problems, and make plans for their future, while the team leaders share their experiences and best practices in creating new problems and preparing their students for the competition.

With its high standards, the IMO prompts the participating countries to constantly improve their educational systems and their methods for selecting and preparing the students. This yielded a great variety of competitions and mathematical enrichment activities around the world which resists any classification. There are "Inclusive" (open for all) competitions which are intended for students of average abilities, while "exclusive" (by invitation only) events target talented students (a prime example of the second type is the IMO and the national olympiad rounds beyond the first). There are "Multiple-choice" competitions where each problem is supplied with several answers, from which the competitor has to find (or guess, as no justification is required) the correct one. In contrast, "classical style" competitions (like the IMO) require the students to present arguments (proofs) in written form. In "correspondence" com-

petitions, such as those organized by *KöMaL* and *Gazeta Matematică*, the students do not necessarily meet each other, while in "presence" competitions (which form the majority of math competitions) the participants are gathered together, which is believed to provide "equal rights" to all students. There are even mixed-style competitions, with a presence-style first stage and correspondence-style subsequent stages. (We will present some newer styles in more detail later.)

Another indication of the importance of the IMO is the fact that other sciences, such as physics, chemistry, and biology, soon followed suit and started international olympiads of their own. Bulgaria organized the first international olympiads in informatics/computer science (1989) and in mathematical linguistics (2003).

**3.2. Mathematics competition networks.** Like any event with positive social impact, each math competition creates and maintains its network of dedicated people. Numerous math competition journals complement these networks, connecting editorial staff, authors, and readers. Good examples in this direction are Kvant (Russia), Crux Mathematicorum (Canada), Mathematics Magazine and Mathematical Spectrum (UK). The math competition networks range in size from regional to international networks that are associated with large and famous competitions, such as the IMO, Le Kangourou Sans Frontiéres [www.mathkang.org], the Australian Mathematics Competition [www.amt.canberra.edu.au], the International Mathematics Tournament of Towns [www.amt.canberra.edu.au/imtot.html], the Ibero-American Mathematics Olympiad [www.campus-oei.org/oim/], and the Asian-Pacific Mathematics Olympiad [www.cms.math.ca/Competitions/APMO/] – the list is far too short to enumerate all networks that deserve to be mentioned.

The different competition networks are not isolated, as many people naturally belong to more than one network. A different and more formal tie is provided by the *World Federation of National Mathematics Competitions* (WFNMC). The WFNMC was founded in 1984, during the Fifth International Congress of Mathematical Education (ICME5) in Adelaide, Australia. Since then it has a "reserved slot" in the programs of every ICME. Every second year after ICME the WFNMC organizes its own Conference. It has an award, named after Paul Erdös, which is given to people with outstanding contributions to mathematics competitions. The Federation publishes also its journal *Mathematics Competitions* [www.amt.canberra.edu.au/wfnmc.html] which is another powerful tool for networking people engaged with competitions. In 1994 the WFNMC became an Affiliated Study Group of the International Commission on Mathematical Instruction (ICMI), which, in turn, is a commission of the International Mathematical Union [1]. In this way the competitions networks are incorporated into the global mathematical community.

Taken together, these networks form a large global network in the field of mathematics competitions and, more generally, in the classical area known under the (somewhat misleading) name *Elementary Mathematics*. Like in any other area of science, this network operates and lives through its journals, conferences, and workshops, but the periodical regularity of its math competitions adds to its strength and

vitality since the people meet more often. In addition, this global network facilitates the dissemination of best practices in curriculum development and in the work with talented youngsters. New problem solving techniques, new classes of problems, and new ideas about organizing competitions spread quickly around the world. We should not forget also that, through this global network, the Elementary Mathematics (which constitutes an important part of our mathematical heritage) is preserved, kept alive and further developed.

## 4. Why are the competitions needed?

Here is a short and incomplete list of reasons on which we expand later on:

1. higher abilities and talent are identified, motivated and developed;
2. what happens before and after the competition is good for education;
3. talented students are steered to careers in science;
4. competitions raise the reputation of an educational institution.

**4.1. Finding higher abilities and talent.** The educational systems in most countries target mainly students of average mathematical abilities (who form the majority in schools). Additional care is often provided for lower-ability students, so that they could cover the educational standards. The standard curriculum and syllabus requirements pose no significant challenge however to students with higher abilities. They do not feel the need to work hard and, as a result, their mathematical abilities and talent remain undiscovered and undeveloped.

This is a pity, of course, since these higher-ability youngsters are a very important resource for the development of society, provided they are properly educated, motivated, and supported. Unlike other natural resources, such as mineral deposits, which remain preserved for the future generations, if undiscovered and unused, the talent of a young person is lost forever, if it is not identified, cultivated, and employed properly. Competitions and other enrichment activities are obvious remedies for this shortcoming, as they allow students to exhibit their abilities and talent. Moreover, competitions motivate the participants to work hard while preparing for them and, as a result, further develop their abilities and talent.

**4.2. Before and after competitions.** Some opponents to competitions complain that there is no apparent direct connection between the competitions and the mathematics as taught in the classroom. This, in our mind, is a rather narrow approach to the issue. Classroom is only one of the many homes of the educational process. One should take into account the integral impact of competitions and competition-related activities on education. What frequently escapes public attention, which often focuses on a rather small group of happy winners, is the fact that the other, "non-winner" participants,

also gain a lot. While preparing for the competition, and trying to solve the problems during the competition itself, all participants increase their knowledge significantly. Taking into account that in some competitions hundreds of thousands of students are taking part, the integral impact on the learning of mathematics becomes significant for the overall development of the contemporary society. From this point of view the contribution of the International Competition “European Kangaroo" with more than 3 millions of participants is difficult to overestimate.

We should not neglect also what happens in the corridors of the school (or outside the school) after the competition is over. The students are sharing their experiences (successes, failures, new ideas generated, etc.). This has a tremendous educational effect which however is not always given proper attention. The competitions and mathematics enrichment activities can be viewed as events that provide impetus for subsequent discussions among the students (as well as among their friends, parents, etc.). From the viewpoint of acquiring new mathematical knowledge (facts and techniques) these after competition discussions might be as important as the preparation for and the competition itself. Many of us owe a significant part of our knowledge to just such “corridor mathematics". From this point of view the social program after IMO gains additional importance. All this could (and should) have some practical implications for the ways the competitions and other enrichment activities are planned and organized. One should deliberately incorporate possibilities (the more the better) for “after event" discussions, reflections and interactions. There is an unexhausted potential for introduction and sharing new practices in this area.

Finally, while preparing their students for competitions the teachers gain experience how to teach mathematical topics that are currently not in the curriculum. This may become important at later stages, if some of these topics become a part of the school program.

**4.3. Steering talented students to careers in science.** The health and longevity of any social sector depends on how many talented young people are attracted to it. The role of math competitions in identifying talented young people and in attracting them to science should be obvious. Indeed, the fact that a significant number of successful participants in math competitions later become famous scientists was recognized rather early. On 17 July 1929, John von Neumann, who was born in Hungary and was influenced by math competitions, wrote in his letter from Berlin to Professor Lipót Fejér in Budapest ([5]):

> Dear highly honored Professor,
>
> I had the opportunity several times to speak to Leo Szilard about the student competitions of the Eötvös Mathematical and Physical Society, also about the fact that the winners of these competitions, so to say, overlap with the set of mathematicians and physicists who later became well-respected world-figures. Taking the general bad reputations of examinations world-wide into account it is to be considered as a great achievement if the selection works with a 50

> percent probability of hitting the talent. Szilard is very interested in whether this procedure can be applied in the German context and this has been the subject of much discussion between us. However, since we would like above all to learn what the reliable statistical details are, we are approaching you with the following request. We would like:
>
> 1. to have a list of names of the winners and runners-ups of the student competitions,
>
> 2. to see marked on the list those who were adopted on a scientific basis and those adopted for other work,
>
> 3. to know your opinion about the extent to which the prizewinner and the talented are the same people and, for example, what proportion of the former would be worthy of financial support from the State in order to make their studies possible.

Very often the future professional realization of a young person is often predetermined by the "first success." The first area where positive results are achieved often becomes the preferred area in which a person invests time and efforts, which in turn brings more success, stronger motivation, and higher professionalism. Math competitions provide such opportunity for early success and thus help attract good young minds to mathematical and scientific careers. In this way competitions contribute to the development and progress of mathematics and other sciences.

**4.4. Raising the reputation of an educational institution.** The academic reputation of a university depends primarily on the merit of the intellectual achievements of its academic staff. "The higher the reputation of the professors, the higher the reputation of the university" is the essence of this widely accepted belief. What is often overlooked, though, is that the level of the students also has a significant impact on the outcome of the educational process and, in the long run, on the reputation of the institution. While higher-ability students still have the chance of becoming good professionals if trained by ordinary professors, even outstanding professors can fail to produce high-level specialists from mediocre and unmotivated students.

Teachers know well that a few good students in class not only motivate the other students and make them work harder, but also place higher demands on the preparation of the teachers themselves. This two-way challenge influences positively the educational process and improves, directly or indirectly, the reputation of the entire educational institution.

It is no wonder that many universities try hard to attract good students. One of the best ways to achieve this is to organize competitions for secondary school students and to offer incentives, such as stipends or entrance exam waivers, to the winners. Such policies usually yield the expected results, as a special type of relationship develops between organizers and the winners during the preparation for the competition, the competition itself, and the post-competition period, which encourages the winners to

consider seriously (sometimes as the first option) enrolling in the university where the competition (and/or the preparation for it) takes place.

In addition to the obvious advantages, enrolling competition winners has a delayed "value-added" effect to the reputation of a university. After graduation, math competition winners, as people with good problem-solving skills, are more likely to get rapid professional recognition, because they are likely to find solutions to difficult and complex real-life problems easier and faster than others. Once their success is noticed and registered by the working environment, the recognition of the problem-solvers' alma mater increases immediately and almost automatically.

As a success story, consider the University of Waterloo, Canada, and the breathtaking rise of its reputation during the seventies and eighties of the last century. Alongside other plausible explanations, such as good management and excellent academic staff, its success can also be attributed to the fact that the University of Waterloo was the host of the Canadian Mathematics Competition [www.cemc.uwaterloo.ca], which attracted a good portion of the best young minds in Canada.

The William Lowell Putnam Competition, widely known as the "Putnam Exam" and administered by the Mathematical Association of America, is the flagship of annual competitions for university students in North America. While enrolled at the University of Waterloo, the former winners in school competitions performed consistently well in the Putnam Exam, securing a prominent presence of Waterloo in the top five teams in North America. This also was contributing to the reputation of the institution. It is no wonder that, within less than 20 years, the University of Waterloo became one of the leading centers for mathematics and computer sciences in the world.

There is another success story related to the University of Waterloo and the Canadian Mathematics Competition, which shows how a new implementation of an inspiring idea at a new place can yield fantastic results.

The Australian mathematician Peter O'Halloran (1931–1994) spent a part of his 1972–73 sabbatical leave from the Canberra College of Advanced Education (now University of Canberra) at the University of Waterloo. There he gained, as Peter Taylor (Executive Director of the Australian Mathematics Trust) recalls ([6]),

> ... the idea of a broadly based mathematics competition for high school students. On his return he often enthused to his colleagues about the potential value of such a competition in Australia. In 1976, while President of the Canberra Mathematical Association, he established a committee to run a mathematics competition in Canberra. This was so successful that the competition became national by 1978 as the Australian Mathematics Competition, sponsored by the Bank of New South Wales (now Westpac Banking Corporation). It is now well known that this competition has grown to over 500,000 entries annually, and is probably the biggest mass-participation event in the country.

The success of Peter O'Halloran was encouraging for others. André Deledicq started in 1991 the Kangaroo Competition in France (the name reveals the Australian

influence). The Kangaroo Competition is now truly international (albeit with focus on Europe), enjoying more than 3 million participants each year.

It is an appropriate place here to pay tribute to Peter O'Halloran, who had the vision for the future of mathematics competitions and knew the strategies how to achieve the goals. He understood the role of international collaboration in this field and was the major force behind the inception of WFNMC and its association with ICMI as an Affiliated Study Group.

## 5. Competitions and science

Before we go any further, we need to consider a natural question:

> Why are math competitions so good in revealing higher mathematical abilities and inclination to doing research?

The simplest and obvious answer seems to be:

> Because both higher abilities and inclination to doing research are *necessary* to be successful in a math competition.

Necessary, but not sufficient. To be successful in a competition, a student often needs not only a good mind, but a very quick one. Most competitions are limited in time to just 3–4 hours, imposing a significant stress on the nervous system of their participants. Not only do students have to solve the problems correctly, they have to do so quickly and in the presence of their direct competitors. Yet, there are many highly creative students, who do not perform well under pressure. Such "slow thinkers" often come up with new and valuable ideas a mere day (or even just five minutes) after the end of the competition, yet receive no reward or incentive.

Traditional competitions disadvantage such students, even though some of them are highly creative and could become good inventors or scientists. Indeed, what matters in science is rarely the speed of solving difficult problems posed by other people. More often, what matters is the ability to formulate questions and pose problems, to generate, evaluate, and reject conjectures, to come up with new and non-standard ideas. All these activities require ample thinking time, access to information resources in libraries or the Internet, communication with peers and experts working on similar problems, none of which are allowed in traditional competitions.

Obviously, other types of competitions are needed to identify, encourage, and develop such special "slower" minds. The competitions should reflect the true nature of research, containing a research-like phase, along with an opportunity to present results to peers – precisely as it is in real science.

As a matter of fact, such competitions, designed to identify students with an inclination to scientific (not only mathematical) research, already exist. Below we present three of them.

**5.1. Germany/Switzerland.** *Jugend Forscht* (*Youth Quests*) celebrated its 40-th anniversary in 2005. It is a German annual competition for students under the age of 21, who work, alone or in teams, on projects of their own. The projects are presented at special sessions, where the winners are awarded [www.jugend-forscht.de].

Switzerland has a similar competition, which is organized by the *Schweizer Jugend Forscht* (*Swiss Youth Quests*) foundation, established in 1970. The competition, which covers all scientific directions, including social sciences and humanities, has existed since 1967 [www.sjf.ch].

A Google search for the phrase "Jugend Forscht" produced 25 000 hits in 2002; the same search produced half a million hits in 2005! This 20-fold increase speaks for itself, especially since only German language area is included.

**5.2. USA.** Many such programs exist in the USA. As a matter of fact, Jugend Forscht was originally shaped after the many "Science Fairs" in USA. We mention only one such program here, because it emphasizes mathematics and because it was used as a model for similar programs in other countries. The Virginia-based *Center for Excellence in Education* (CEE) was founded by Admiral H. G. Rickover in 1983. It has the following goals [www.cee.org]:

> The Center for Excellence in Education nurtures careers of excellence and leadership in science and technology for academically talented high school and college students. CEE is as well dedicated to encouraging international understanding among future leaders of the world. CEE's programs challenge students and assist them on a long-term basis to become creators, inventors, scientists and leaders of the 21st century.

The major CEE event, sponsored jointly with the Massachusetts Institute of Technology, is the *Research Science Institute* (RSI) [www.cee.org/rsi/]:

> Each summer approximately 75 high school students gather for six of the most stimulating weeks of their young lives. Selected from the United States and other nations, these students participate in a rigorous academic program which emphasizes advanced theory and research in mathematics, the sciences, and engineering.
>
> Students attend college-level classes taught by distinguished professors. Nationally recognized teachers conduct classes designed to sharpen research skills. In addition, students complete hands-on research with top mentors at corporations, universities, and research organizations.

Only outstanding, carefully selected students are admitted to the program. RSI starts with a series of professional lectures in mathematics, biology, physics, and chemistry. The students are paired with experienced scientists and mentors, who introduce them to interesting research topics and share with them the joy and excitement of exploring new territories. The RSI days are filled with research, evening lectures,

ultimate Frisbee, sport events, etc. At the end of the program, the students present their own research, both in written and oral form, and awards are given to the best performers.

The RSI is an international program: almost a third of its students come from other countries. It provides a unique environment for talented students from different parts of the world to meet, live and work together for a relatively long period of time (six weeks seems to be optimal – it is neither too long to become boring nor too short to put unbearable stress). Again, one should not neglect the importance of the networking and friendships fostered by the RSI program for the future development of the participants. The fact that they know each other will make their future collaboration more fruitful. Year after year, the Bulgarian participants in RSI emphasize the social character of the event and the unique atmosphere created during the RSI.

**5.3. Bulgaria.** Before the 1989 political changes, Bulgaria had a venue for talented young people, very similar to the above-mentioned Jugend Forscht and RSI. It was called *Movement for Technical and Scientific Creativity of the Youth* (abbreviated in Bulgarian to TNTM). Students worked on individual scientific projects and presented their work on special sessions, where winners were awarded. Like almost everything else related with the youth, the TNTM movement was under the umbrella of the Young Communists' League (Komsomol). After the democratization of the Bulgarian society, the Communist League disappeared, along with everything related to it, including TNTM.

A decade later it became absolutely clear that actions were needed to revive those activities at the level of contemporary challenges and requirements. The RSI model was adapted to the conditions in Bulgaria and, as one of the "Year of Mathematics" initiatives, the new *High School Students' Institute of Mathematics and Informatics* (*HSSIMI*) was founded in 2000.

Throughout one academic year, the involved high school students (grade 8–12) work on freely chosen topics (projects) in mathematics and/or informatics (computer science). They work individually or in teams and are supervised by a teacher, a university student, a relative, or just any specialist in the field, willing to help. In fact, some recent HSSIMI projects were successfully supervised by former HSSMI participants, who are now university students.

Warmly accepted by the mathematical community in Bulgaria, the HSSIMI organizes three major events: two competition-like sessions and a *Research Summer School*. The sessions are held at the stand-alone *Students Conference* for High School students in January and at the *School Section* of the Annual Spring Conference of the Union of Bulgarian Mathematicians(UBM) in April. The latter section is actually the most visited section at the Spring Conference of UBM, attended by university professors, researchers, teachers, parents, and school peers.

To participate in the HSSIMI sessions, students submit a written paper with the results of their work. Specialists referee the papers, assess the projects, and suggest improvements. Students present their research at the sessions and winners are

awarded. As special award, two of the winners are sent to USA in order to participate in RSI.

The authors of the best projects are invited to a three-week *Research Summer School*. During the first two weeks, eminent specialists from universities, research institutes, and software companies give lectures and practical courses in mathematics and informatics. As in similar programs, the main goal of this preliminary training is to expand the students' knowledge in topics of their interest and to offer new problems for possible projects. During the third week, students hold a High School Students Workshop, where they briefly present their ideas for new projects.

For the short period of its existence, the HSSIMI became a valuable addition to the established (and rather densely populated) system of traditional competitions in Bulgaria. As was planned and expected, the HSSIMI attracted students who were not regulars in the traditional competitions.

Similar initiatives can be found in other countries. There are positive signs of networking between them as well. Good examples in this direction are the Tournament of Towns Summer Conference and the annual International Mathematics Projects Competition (IMPC) in Kazakhstan. Reflecting more closely the nature and spirit of research process, these kinds of activities also attract excellent minds to mathematics and definitely deserve better recognition and support by the professional mathematical communities around the world.

## 6. What to do next?

In addition to enhancing the traditional math competitions and developing the non-traditional initiatives discussed above, there are other venues for future improvements, such as implementing the current science trends into competitions, targeting other audiences, and supporting and developing the human resources standing behind competitions and other related activities.

**6.1. Algorithms in mathematics.** The nature of mathematical research has changed significantly since considerable computing power came to the desk of almost every researcher and student. Mathematicians today can conduct complicated numerical experiments, use software for complex algebraic and analytic transformations, find patterns in huge data sets. Like the experiments in other sciences, this could help reject some conjecture or formulate a new one. Thus, research in mathematics became similar to research in the other sciences.

All this is based on mathematical algorithms. Algorithmic thinking is getting higher importance and successfully complements the "axiomatic" approach and thinking in mathematics.

This change should be duly reflected in the creation and selection of competition problems. Perhaps more problems should be offered at various competitions where algorithms and their properties are focused in order to cultivate algorithmic thinking.

Otherwise, we will become witnesses of a "brain-drain" and the best young minds will be driven to competitions in informatics.

**6.2. Teamwork.** Working in teams is a well-established trend in modern science. For centuries, research in mathematics has been a solitary endeavor. Today, we see more and more teamwork in mathematics and, especially, in its applications. This reveals yet another similarity between modern mathematics and the other sciences (where teamwork has traditionally deeper roots). The ability to work in a team is valuable skill that could and should be cultivated early on.

Mathematics team competitions could contribute a lot in this direction. There are many such competitions around the world; it only makes sense to make them more popular.

**6.3. Competitions for university students.** Even though they are not the focus of this paper, mathematics competitions for university students, among other virtues, help attract talented young people to academic careers in mathematics.

Some of these university-level competitions are highly respected and have existed for many years. The above-mentioned Putnam Exam is more than 65 years old. The International Mathematics Competition for University Students began in 1994 [www.imc-math.org]. Of course, there are many other such competitions, but their number is still much smaller than the number of competitions for secondary school students, providing plenty of opportunities for new initiatives and international collaboration in this area.

**6.4. Teachers and the competitions.** In many countries, year after year, some schools consistently "produce" more competition winners than other schools. What is the reason behind this phenomenon? Why are some schools more successful than others?

The reasons may be numerous and fairly different in nature. Very often, however, the prominent success of a particular school can be attributed to the dedicated efforts of a single teacher or a small group of teachers. For these excellent teachers, teaching is a vocation, a mission, and not just means to make both ends meet. Such special teachers are real assets for the school and for the whole country. They possess both the necessary scientific ability and the extraordinary personality needed to identify and motivate for hard work the future winners in competitions.

Such teachers need special care, though. Their higher scientific ability is acquired very slowly, at the expense of great personal efforts. It is no secret that the success of these teachers depends very strongly on their working environment and on the appreciation by their colleagues and administration. Very often however the actual working conditions in the schools do not support the work and the development of these dedicated teachers.

There is a lot that can (and have to) be done in order to improve the situation. For instance, the materials available to the teachers should not include problems and

solutions only, but also provide didactic instructions for the teachers how to use these materials in their work with higher ability students and what type of reactions and difficulties to expect on the side of students. For this to happen a special research is needed, conducted with the help of professional math educators.

Many organizations which are involved with competitions are also organizing seminars and workshops for teachers. There is a valuable experience in many countries in the work with such teachers. The positive results and the problems could be discussed and evaluated with the aim of disseminating the good practices. Teachers are the major human resource for the development of competitions and related activities.

Another problem is that often competition-like activities are not "at home" (and therefore not appreciated) both in Mathematics Departments (because "they concern Elementary Mathematics") and in Mathematics Education Departments (because they are "too mathematical and refer to the relatively small group of talented students"). It is time for both communities (research mathematicians and mathematics educators) to understand their joint interest in supporting competitions and competitions – related activities.

## 7. Summary

Competitions have influenced positively mathematics education and its institutions in different ways for more than a century.

Engaging millions of students and educators, math competitions have a distinguished way to identify, motivate, and develop young talent, steering it to careers in science.

Mathematics competitions have matured and formed an immense and vibrant global network which contributes significantly to the preservation and the maintenance of mathematical heritage.

The flagship IMO not only serves as the "golden standard" for numerous other competitions in mathematics and the sciences (especially with its often-overlooked social program), but it also provides a constant stimulus for improvement of school systems around the world.

Traditional competitions are complemented by more inclusive and less known events that emulate more closely real research and engage even broader student audience.

Nevertheless, stronger consolidation and collaboration of teachers, schools, universities, and educational authorities is needed in order to meet the challenges of the new century.

# Understanding and misunderstanding the Third International Mathematics and Science Study: what is at stake and why K-12 education studies matter

Alan Siegel*

**Abstract.** The technical portion of this paper concerns a videotape classroom study of eighth grade mathematics lessons in Japan, and how methodological design errors led to conclusions that are refuted by the actual video data. We document these errors, and trace their distillation into one- and two-sentence education policy recommendations articulated in U.S. government position papers, implemented in classrooms across the U.S. and imported by countries around the world. We also present the historical context needed to understand the misrepresentations cited in support of questionable education policy.

**Mathematics Subject Classification (2000).** Primary 97D40; Secondary 97-02.

**Keywords.** Third International Mathematics and Science Study, TIMSS.

## 1. Introduction

The outstanding results for the top-performing countries in the Third International Mathematics and Science Study (TIMSS) have generated widespread interest in best teaching practices around the world. In the TIMSS Videotape Classroom Study by James Stigler et al. [31], the teaching styles in Germany, Japan, and the U.S. were compared in an effort to discover what makes some programs so successful. The conclusions from this comparison are striking and have been widely cited, but often in a highly trivialized and even inaccurate manner. Moreover, this particular study, as we will show, is marred by design errors that raise serious doubt about some of its most influential conclusions. Indeed, it is these very findings that have been cited and accidentally distorted in support of the latest reform programs and education policies – both in the U.S. and elsewhere.

For example, it is widely acknowledged (cf. [31, p. 134]) that Japanese lessons often use very challenging problems as motivational focal points for the content being taught. According to the Glenn Commission[1] Report [10, p. 16],

*The author is grateful to the ICM, NSF and AMS for their support of this presentation. Disclaimer: although the assessments and statements in this paper have been made in good faith by the author, they should not necessarily be viewed as representative of or endorsed by the ICM, NSF or AMS.

[1]The commission's proper name is the National Commission on Mathematics and Science Teaching for the 21st Century. It was chaired by former U.S. Senator and astronaut John Glenn. The year-long Commission was

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

> "In Japan, . . . closely supervised, collaborative work among students is the norm. Teachers begin by presenting students with a mathematics problem employing principles they have not yet learned. They then work alone or in small groups to devise a solution. After a few minutes, students are called on to present their answers; the whole class works through the problems and solutions, uncovering the related mathematical concepts and reasoning."

We revisit the TIMSS Videotape Classroom Study to resolve the one crucial classroom question that both the Glenn Commission and the TIMSS Classroom Study group failed to address:

> How can Japanese eighth graders, with just a few minutes of thought, solve difficult problems employing principles they have not yet learned?

We will see that the technique required to solve the challenge problem of the day will have already been taught, and that the lesson begins with a review of the fundamental method needed to solve the problem. Students begin working on these problems individually – not in groups. Sometimes group-work is allowed for second efforts on a given assignment, but only after individual seat-work. These lessons include student-presented solutions, but the presentations are closely supervised by the teacher, and the time allocated for this activity is limited so that students will be able to work on a second challenge exercise of the same type, and the teacher will have enough time to show how to apply a fundamental technique as many as ten times – all in a single lesson. Stigler's videotapes reveal master teaching of substantial content hidden within a warm and inviting teaching style. Students do indeed participate, but in moderation, and subject to the vigilant oversight of instructors who ensure that no one wanders off course.

It is also worth noting that the Videotape Classroom Study identified some of the significant differences between the current reform positions and Japanese teaching practices. For example, it pointed out that students did not use calculators in the Japanese classes, and that Japanese teaching has a far higher concentration of proofs and derivations than both reform and traditional programs in the U.S. The Videotape Study also found that Japanese teachers spend more time lecturing than even traditional U.S. teachers.

These distinctions not withstanding, the notion that Japanese teaching might be implementing U.S. reforms is given far greater emphasis in a major Government report, which flatly declares:

> "Japanese teachers widely practice what the U.S. mathematics reform recommends, while U.S. teachers do so infrequently [25, p. 9]."

---

mandated to develop a strategy to raise the quality of mathematics and science teaching in all of the nation's classrooms. Unfortunately, the cited quote was, quite possibly, the most substantive paragraph in their report to the nation. The preliminary Glenn Commission report cited Stigler and his TIMSS Videotape Classroom Study as the source of this finding, although the final version omitted the specific citation.

This report on best teaching practices worldwide makes no mention of any differences between the U.S. reforms and Japanese teaching styles. Evidently, its perspective (see also [25, pp. 40–43]) differs from that of its source of primary information, which is the more cautiously worded TIMSS Videotape Study [31]. Moreover, the differences identified in the Videotape Study – which concern direct instruction, calculators, and teacher-managed demonstrations – are all matters of contention in the U.S. debate over classroom reform.

Finally, we note that studies of individual classroom lessons – no matter how comprehensive – are necessarily incomplete. They cannot detect how coherent a curriculum might be day-by-day, much less over the course of years, and are ill-equipped to assess the completeness of a given math curriculum.

## 2. Background

The need for sound – and indeed first-rate – K-12 mathematics programs is well understood. In the U.S., many reform programs have been implemented over the last fifty years, but the evidence shows that on balance, we have made very modest progress toward this goal of world-class math education.

The majority of our past reform efforts can be characterized as a tug of war between traditional and student-centric education movements. Just one of these programs was sufficiently different to deserve special mention: the so-called New Math that originated in the 1950s, and which was widely implemented in the '60s. This reform was pioneered by mathematicians, and was the only program ever to attempt to teach elementary mathematics from an informal set-theoretic perspective. It failed, in part, because its implementations did not provide safeguards to ensure that mainstream American students – and teachers – could handle the material, which is an error that the current reformers have been very careful to avoid. Finally, the program has historical importance because its failure led to a fairly sharp separation between those concerned with K-12 math education and those interested in mathematics research and college teaching.

In the mid-1980s, a new version of student-centric learning and teaching began taking hold in the mathematics education community, and it is fair to say that these ideas have swept the American schools of education, and are likewise well represented by advocates in many other parts of the world.

In 1989, these ideas were codified into teaching policy when "educators ... carefully articulated a new vision of mathematics learning and curriculum in the National Council of Teachers of Mathematics' (NCTM's) *Curriculum and Evaluation Standards for School Mathematics* [6]." The 1989 Curriculum Standards [20], together with the follow-up 1991 Teaching Standards [21] and the 1995 Assessment Standards [22] called for a redirection of focus from what to teach grade by grade to new ideas about how to teach and how to assess student progress. And with the publication of these documents, the NCTM completed its transformation from an organization that

began in the 1920s with ties to the Mathematical Association of America, and that had been led by content-oriented math teachers who endorsed the revolutionary New Math of the '60s, to an organization led by professors of mathematics education who endorsed a new type of revolutionary math program[2] in the '90s.

Loosely put, the theoretical core of this new vision of education is called constructivism. Like most complex social theories, constructivism is founded on a few main principles, has many interpretations and derived consequences, and a bewildering variety of implementations. A thumbnail (and necessarily incomplete) sketch of the main principles of constructivism is as follows.

The philosophical basis of constructivism is that everyone learns differently, and that we learn best by integrating new knowledge into our own core understandings and thought processes. Therefore, education is most effective when it engages the learner to become the main agent in the learning process. That is, learning should be engaging in every sense of the word. Since we learn by discovering and by doing, learning is a quintessentially social process wherein through mutual interaction, we organize, communicate, share, and thereby develop deepened understanding. Moreover, content should be based on real-world problems to reach each learner's core knowledge base, and to maximize the purposefulness of each lesson.

As stated, these objectives have merit – especially for teaching younger learners. Indeed, the author believes that the debate over abstract constructivism misses the point. However, the teaching reforms advocated by the NCTM include, in addition to abstract principles, very applied recommendations that have significant impact on curricula, pedagogy and the opportunity for students to learn mathematics.

Thus, the real questions concern the content and training provided by the reform program implementations, as well as the consequences of the derivative theories of learning and testing that are put forward as logical consequences of constructivist principles. And it is this debate about what kinds of education programs work that defines the context for the TIMSS Videotape Classroom Study and the classification of Japanese pedagogy.

**The impact of reform principles on classroom structure and course content.** The applied education theories advanced by contemporary reformers must be sketched out if the various assertions about Japanese teaching and the latest reform recommendations are to make sense.

The principle of discovery-based learning aims to have the students themselves discover mathematical principles and techniques. According to Cobb et al. [5, p. 28],

[2] The NCTM reform program was also endorsed by the federal department of Education and Human Resources, which provided funds to create reform-compliant textbooks, to support their use, and to support studies designed to prove that the new programs were effective. To date, more than $75 million has been allocated to produce these new mathematics textbooks, and about $1 billion has been spent on programs to foster their use. The Educational Systemic Reform programs, for example, ran for nine years with an annual budget of about $100 million, and related programs for K-12 math and science education received comparable funding. More about the history of these programs can be found in [32].

> "It is possible for students to construct for themselves the mathematical practices that, historically, took several thousand years to evolve."

In the 1999 Yearbook of the National Council of Teachers of Mathematics, the article "Teaching Fractions: Fostering Children's Own Reasoning" by Kamii and Warrington [15] advises:

> "1. Do not tell children how to compute by using numerical algorithms. . . .
>
> 2. Do not tell children that an answer is right or wrong. . . .
>
> 3. Encourage children to use their own reasoning instead of providing them with ready-made representations or 'embodiments.'
>
> 4. Ask children to estimate solutions to problems first because estimation is an effective way to build strong number sense."

To be fair to the authors, it should be pointed out that they provide alternatives to prohibitions 1, and 2. For example, they recommend that the issue of correctness be resolved by the entire class through cooperative discussion.

These discovery-based policies are often implemented via the *workshop model* of teaching where students are seated in clusters of four desks facing each other with no central lecture place in the classroom. This organization is designed to foster collaborative learning and to reinforce the teacher's role as a "guide on the side" as opposed to the "sage on the stage." In some programs, the purpose of the teacher is to introduce the exercise of the day. The students then work in groups of four to discover what they can about the problem. In the next phase, the students present their findings to the class, and an active discussion typically ensues. The teacher might have a role that is confined to being a moderator to maintain order in the discussions. Likewise, some of the programs feature unsupervised group-work with the teacher serving mainly as a passive observer.

In the higher grades, the U.S. discovery-based programs feature markedly diminished content depth, and the project-based texts exhibit poor coherence in their management of topics and offering of reinforcement exercises. To date, some reform programs simply omit material that does not fit within this model. Moreover, this style of teaching, absent sufficient guidance from the teacher, is typically very time consuming, and the slow pace cannot help but limit the curriculum.

For example, on page 315 of a tenth grade reform geometry textbook [37], exercise 24 asks the student to draw an equilateral, an isosceles, and a scalene triangle, and to draw the medians and observe the outcome in each case. The assignment also asks the students to measure the lengths of the medians and the distance from the vertices of each triangle to its centroid. The problem finishes by asking, "What do you conclude?" No proofs are offered or requested, and for good reason. The study of similar triangles begins in Chapter 13 on page 737, where the final two chapters of the book present content that is less observation-based.

In 2001, I was invited to observe some of these workshop model classes at a magnet high school in lower Manhattan. In one of the ninth grade classes, the lesson

problem of the day was (in mathematical terms) to determine the equation of a line through the origin that does not intersect any additional points on the integer Cartesian lattice in $\mathbb{R}^2$. The students began the exercise working unsupervised in groups of four. Then the class convened as a whole to discuss their findings with the teacher serving as moderator. The tenth (or so) student to speak observed that if the line were to intersect another lattice point, then it would have a rational slope. The teacher then called on another student, and this key observation was soon lost. The discussion devolved into an unsuccessful effort to understand the difference between rational numbers with finite decimal representations and those with repeating decimal expansions, and the math period ended with no solution to either question.

In a televised eleventh grade lesson [24] from a reform textbook series [7], students seated in groups of four were given the following problem. The teacher displayed boards of different lengths, widths, and thicknesses suspended between pairs of bricks. A karate expert, he explained, can deliver the tremendous energy necessary to break a strong board. For the first part of the lesson, the students were asked to determine a formula for the energy necessary to break a board as a function of its length and thickness. The students discussed the question with great enthusiasm. There was no evidence of any physical modeling, and it was not clear if the class knew Hooke's law or not. In the second portion of the lesson, a representative from each group presented the group's thoughts to the class. The first to speak was able to intuit that a longer thinner board would be easier to break, but nevertheless went on to opine that the formula for the energy $E$, as a function of the length $L$ and thickness $T$, should be $E = L + T$. Another group thought that the formula should be $E = kLT$, where $k$ is a constant that depends on the physical properties of the wood. In the next portion of the lesson, students were given strands of dried spaghetti to form a bridge between two tables, pennies to use as weights, and a paper cup plus paper clip to suspend on the strand(s) of spaghetti. They then conducted tests with different lengths and strand counts to see how many pennies were necessary to break the spaghetti – thus measuring the breaking force, which was misrepresented as energy. The use of multiple strands served to emulate different thicknesses (albeit incorrectly). Data was gathered for 1 to 5 strands, and distances of 2 to 5 inches. Then the students used their graphing calculators under the supervision of the teacher to determine the best fit for the data, which was $E = 10\frac{T}{L}$, where $E$ is measured in pennies, $T$ in spaghetti strands, and $L$ in inches.

The TV program closed by noting that with the introduction of this new curriculum, grades were higher, and more students were electing to take three and four years of math classes. Of course, the stacking of spaghetti strands to model thicker pasta constitutes a fundamental conceptual error. It is no accident that plywood is manufactured with bonded layers, and as straightforward mathematical modeling shows, strength, in a simple model of deformation, is proportional to the square of a beam's thickness. Likewise, the confusion between force and energy ill serves the students, as does the lesson's implication that mathematics might be an experimental science.

The reforms seeking to maximize engagement include mandates to avoid drill and – by extension – the kind of practice necessary to instill knowledge transfer to long-term memory.

In concrete terms, the reform programs do not teach the multiplication table in elementary school. Ocken reviewed all of the printed materials produced by one of the elementary school reform programs [33] for grades K-5, and found fewer than 30 problems asking students to multiply two whole numbers, both of which contain a digit greater than five[23]. This program implements the reduced emphasis on pencil and paper calculations as recommended in the 1989 NCTM Standards, and, as recommended, supports student work with calculators even in the earliest grades.

Likewise, the standard place-based rules for multiplication of multidigit integers are no longer taught as essential material. Opponents of these reforms see the structure of place-based multiplication as precursor knowledge that helps the learner internalize the more abstract operations of polynomial arithmetic.

In one textbook series [16], the division of fractions was simply omitted from the curriculum. And long division is long gone from these programs.

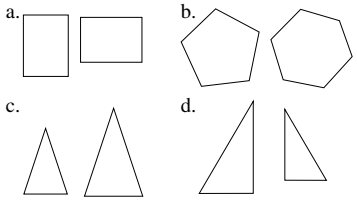
To maximize engagement, reformers recommend that problems and content be *situated*, which means that exercises, derivations and even theorems should be presented in an applied context whenever possible. More generally, abstraction and symbolic methods are eschewed. Of course, the foregoing comments about abstraction and symbolic methods are just words. In order to understand them, we again take a few quick peeks into the reform textbooks to see how these theories and recommendations are turned into practice. For example, one ninth grade reform book [8] has, scattered among its 515 pages, only 25 pages that even contain an equal sign. Of these, only pages 435 and 436 actually concern algebra. The totality of the information about algebra is on page 436, and is as follows.

> "Some such equations are easier to solve than others. Sometimes the particular numbers involved suggest tricks or shortcuts that make them easy to solve. In each of the equations below, the letter x stands for an unknown number. Use any method you like to find the number x stands for, but write down exactly how you do it. Be sure to check your answers and write down in detail how you find them.
>
> $$\frac{x}{5}=7 \qquad \frac{x}{6}=\frac{72}{24} \qquad \frac{x}{8}=\frac{11}{4} \qquad \frac{x}{7}=\frac{5}{3}$$
> $$\frac{x+1}{3}=\frac{4}{6} \qquad \frac{5}{13}=\frac{19}{x} \qquad \frac{2}{x}=6 \qquad \frac{9}{x}=\frac{x}{16}$$"

The preference for encouraging ad hoc "tricks" and "shortcuts" instead of teaching systematic methods is evident. Indeed, the text does not present any methods for solving these problems. The passage also illustrates how the these new programs encourage students to write expository explanations and avoid teaching students to

develop and record logical solution strategies based on correct operations, problem decomposition, and the layered application of systematic methods.

On page 416 of this ninth grade text, problem 3 reads as follows.



3. Consider the following pairs of figures. In each case, state whether you consider the shape to be the same or not, and why.

The chapter goes on to explore some of the most elementary properties of similarity, but the development is probably closer to the level of sixth grade than ninth, and the overall content of the textbook is far weaker than, say, the standard sixth grade books used in Singapore [13].

The comparison with the Singapore books is worthy of elaboration. In an American Educator article [1], the mathematician Ron Aharoni writes about what he learned using the Singapore math program to teach first grade in Israel. He points out that these lessons encourage students to describe problems in words, and feature more discussion than is common in traditional programs. These characteristics are consistent with some of the constructivist principles. There are, however, fundamental differences between this teaching style and the applied recommendations and prohibitions that characterize – and indeed define – the latest reform practices. Aharoni describes how he actively teaches insights based on his mathematical knowledge – even in first grade. And he also points out that significant reinforcement is necessary to help first graders integrate this first grade content into their own thinking. Interestingly, the fifth and sixth grade Singapore texts [13] exhibit a transition from this verbal/expository approach of reasoned problem representation to an informal but precise prealgebra. The books present – with many detailed examples – a kind of pictorial algebra, where a physical segment might be used to represent an unknown length. The modeling allows graphical unknowns to be added, subtracted, and multiplied and divided by integers in physical representations of equations. Students solve many carefully constructed word problems with this modeling process and its physical representation of variables. This representation is used to strengthen intuition and understanding as preparation for variables and algebra. By the sixth grade, the students are using the method to solve sophisticated word problems that would challenge U.S. high schoolers. No U.S. reform text presents such a coherent curriculum, and none provides a systematic increase of content and problem depth chapter-by-chapter and over the course of years to build deepening layers of understanding on behalf of the learner.

In terms of pedagogy, Aharoni emphasizes the importance of deep content knowledge and a deep understanding of *what* is being taught as prerequisites for deciding *how* to teach a particular topic [1, p. 13]. He says that the understanding of fundamental mathematical principles can be taught, but this instruction requires active teaching by a very knowledgeable teacher.

The current reform programs, by way of contrast, aim to teach less, not more. In a ninth grade reform algebra text, for example, students receive enough training to solve for $x$ in the equation $y = 3x + 2$, but there is just one equation in the book that uses variable coefficients. This one exception, which is on page 748 reads [9]:

> "Show how to derive the quadratic formula by applying completing the square to the general quadratic equation, $ax^2 + bx + c = 0$."

This question requires a tremendous leap in skill given the text's limited use of equations with variable coefficients. Moreover, the presentation on completing the square is so weak that it is inconceivable how any but the most exceptional student could learn enough to solve this problem. The totality of the exposition reads:

> "Here's an example of how to use completing the square to solve the quadratic equation $x^2 + 6x - 2 = 5$.
>
> Since $-2$ doesn't make $x^2 + 6x$ a perfect square, it is in the way. Move it to the other side: $x^2 + 6x = 7$.
>
> Add 9 to both sides to make the left side a perfect square: $x^2 + 6x + 9 = 16$.
>
> Write the left side as a perfect square: $(x + 3)^2 = 16$."

There is no attempt to teach a systematic approach for completing the square, or to explain how the magical 9 was selected for use in this particular case.

The avoidance of abstraction and symbolic coefficients, and the recommendations against teaching systematic methods have undermined the quality of the textbook. This instance of teaching by one explicit example cannot instill wide-spread understanding. And the inclusion of the exercise to derive the quadratic formula (which is just about the last problem in a very long book) would appear to be based less on it being an appropriate exercise than on the need to include the topic in the curriculum.[3]

Ralston recommends the outright abandonment of pencil and paper calculations in favor of mental arithmetic supplemented by calculators [26]. Non-reformers disagree, and suggest that proficiency in arithmetic is not taught for its own sake but rather to strengthen the learner's core knowledge and intuition as a prerequisite for understanding fractions. Arithmetic fluency is even more important for a mastery of and fluency in algebra, where the rules of arithmetic are revisited at an abstract level with the introduction of variables and exponents. Many teachers report that those who lack a grounding in the concrete operations of arithmetic experience great difficulty with algebra and its manipulation of symbols. Other non-reformers argue that the written record of pencil and paper problem solving documents a student's approach to a problem, which can be reviewed by the student and the teacher for conceptual errors as well as computational mistakes. Non-reformers also argue that it is the use of the written record that allows learners to combine fundamental steps into more

[3] It is also fair to say that some of the most project-based reform texts are designed around sequences of typically unrelated projects, which result in a disorganized and incomplete curriculum with very few review and reinforcement exercises (cf. [33], [8], [7], [9]).

complex solutions that are too detailed to retain as mental calculations. In addition, it is argued that the written representations of algebra bring a precision of expression, of computation and of modeling that surpasses the written word in accuracy, clarity, and simplicity.

The purpose of this inside review of American mathematics education was to identify the controversies arising from the latest reforms in concrete (i.e. situated) – as opposed to abstract – terms. It is time to explain why Japanese pedagogy has become a topic of worldwide interest, and to investigate how well it aligns with the latest reform principles.

**The Third International Mathematics and Science Study.** TIMSS is an enormous umbrella project that seeks to measure academic achievement around the world, and which includes many subsidiary studies that analyze a host of related issues in an effort to determine how best to improve math and science education. TIMSS began in 1994–95 with the testing of 400,000 students worldwide at grades four, eight, and twelve. It has grown into a quadrennial program that conducted additional testings and data acquisitions in 1999 and 2003, and has already begun to lay the groundwork for the next round in 2007. The program now includes nearly fifty countries, and the studies cover a large number of independent projects with publications in the many thousands of pages.

Although there have been some fluctuations in the TIMSS rankings over the last decade, and the participating countries have varied to some degree over time, the overall results have been much more consistent than not. This fact is probably a testament to the meticulous effort to maintain balanced student samples from the participating countries, and the care that is exercised in the testing protocols and data analyses. The project also deserves very high marks for adhering to a wonderfully high standard of scholarship. The research projects produce not only reports of findings but also detailed documentation of the data acquisition and analysis procedures and indeed every aspect of project methodology. When feasible, these studies even publish enough raw data for independent researchers to review every step of the research effort for independent assessment.

Despite the wealth of information provided by the TIMSS publications, it is fair to say that two specific TIMSS findings have captured the majority of the headlines, and have had the greatest influence on classroom practice and education policy.

The most eye-opening results come from the achievement scores of students around the world. For example, in the little multicultural, multilingual, top-performing country of Singapore, some 46% of the eighth graders scored in the top 10% of the world. And 75% of their students placed among the top 25% of all eighth graders worldwide. Just 1% of their students placed among the bottom 25% of all eighth graders around the world. This is a stunning achievement. Singapore has indeed shown what it really means to have an education system where no child is left behind.

Moreover, these performance results have held up with remarkable consistency in each of the TIMSS testing rounds. Just a notch down from Singapore, the next group

of top performers have been Korea, Hong Kong, Chinese Taipei (formerly known as Taiwan) and Japan (mostly in this order) with Flemish Belgium trailing somewhat behind, but consistently next in line.

The U.S. scores are also worth mentioning. Roughly put, American fourth graders and eighth graders scored somewhat above the international average. But at the twelfth grade, the U.S. scored at the bottom of the industrialized world, and only significantly out-performed two countries: South Africa and Cyprus. No other country fell so far so fast. There was also a more sophisticated twelfth grade test that was reserved for twelfth graders in advanced math programs in the participating countries. On that test, the U.S. was next-to-last; even Cyprus performed significantly better.

For completeness, it should be noted that the twelfth grade testing has not been repeated since 1995 and the U.S. plummet just described. This is unfortunate because the lack of follow-up testing forces us to infer whether the American mathematics programs have recovered from the results documented in 1995. Moreover, the real purpose of a K-8 program is to prepare students for subsequent study as opposed to an eighth grade TIMSS test. So our understanding of mathematics education around the world would be greatly enhanced by a schedule of testing that includes grade twelve as well as grades four and eight.[4]

In view of the absence of follow-up twelfth grade testing, one could speculate that the American TIMSS scores might show that the newest programs are beginning to make a difference. After all, the latest math reforms are often introduced at the earlier grades first, and then extended by one grade level per year. Could it be that U.S. high school students are performing better now because more of them are participating in reform math programs? The answer seems to be a clear no. A variety of studies[5] have documented very little progress in high school math achievement over the last decade. To date, the NAEP scores, for example, have been most notable for their lack of improvement.

In short, TIMSS testing shows that the US, and indeed most of the world have K-12 mathematics programs that are nowhere near the quality of the best programs worldwide. These results constitute a compelling argument for continued testing on an international scale. Simply stated, TIMSS is one of our best mechanisms for identifying unforeseen weaknesses in national programs, and for discovering exemplary programs that can be investigated in an effort to improve domestic teaching.

The other finding that has generated enormous impact can be traced to "TIMSS Videotape Classroom Study: Methods and Findings from an Exploratory Research Project on Eighth-Grade Mathematics Instruction in Germany, Japan, and the United States" [31]. For convenience, we condense the TIMSS Videotape Classroom Study's name to TVCS.

[4]For countries such as Singapore, which do not have a twelfth grade, the testing might well be given at the completion of the secondary education system.

[5]See, for example, Too Little Too Late: American High Schools in an International Context by William H. Schmidt. In *Brookings Education Policy papers 2003* (ed. by Diane Ravitch), pp. 253–277.

**The Videotape Classroom Study documentation.** During 1994–95, the TVCS team recorded 231 eighth-grade mathematics lessons in Germany, Japan and the U.S. The TVCS project report by Stigler et al. [31] contains an extensive analysis of these tapes and a description of the data acquisition and analysis methodologies. Stigler and James Hiebert subsequently conducted a joint study of Japanese training in pedagogy, which has strong cultural traditions that are surprisingly different from the programs of teacher development in the U.S. [30]. In 1999, Hiebert and Stigler began a second TIMSS videotape classroom study [11] that covered a broader selection of higher performing countries.

These videotape study projects produced a variety of supporting documentation [34], [35], [36], [14], [12], but the follow-up study did not record a new series of Japanese lessons and instead relied on the earlier tapings. We cover the main findings from the second study and the differences in its methodology and conclusions (which may well have resulted from criticisms of the earlier project), but will focus primarily on the 1995 TVCS, which remains the far more influential of the two publications.

The 1995 project produced a publicly available videotape [34] that begins with Stigler presenting an overview of the Japanese lessons that is very similar to the description already quoted from the Glenn Commission Report. It then shows carefully selected representative excerpts of the geometry and algebra lessons recorded in Germany, Japan, and the U.S. The German and American lesson samples were produced in addition to the original 231 recordings, which are not in the public domain due to confidentiality agreements. The Japanese excerpts were selected from the original 50 tapings recorded in Japan, and disclosure permissions were obtained after the fact.

The TIMSS videotape kit includes a guide to the excerpts [36] and a CD ROM [35] is available with the same excerpts, but without Stigler's introduction.

## 3. What the Japanese video excerpts show

**Geometry.** The tape shows the Japanese geometry lesson beginning with the teacher asking what was studied the previous day. After working to extract a somewhat meaningful answer from the class, he himself gives a summary: Any two triangles with a common base (such as $AB$ in Figure 1) and with opposing vertices on a line parallel to the base (such as the line through $D$, $C$ and $P$) have the same area because the lengths of their bases are equal, and their altitudes are equal. The teacher states this principle and uses his computer graphics system to demonstrate its potential application by moving vertex $P$ along the line $CD$. The demonstration

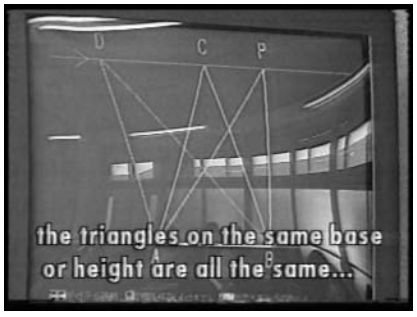


Figure 1

shows how to deform triangle $ABP$ in a way that preserves its area. Next, he explains that this principle or method is to be the "*foundation* [36, p. 136]" for the forthcoming problem, which he then presents. It is the following.

Eda and Azusa each own a piece of land that lies between the same pair of lines. Their common boundary is formed by a bent line segment as shown.

The problem is to change the bent line into a straight line segment that still divides the region into two pieces, each with the same area as before.

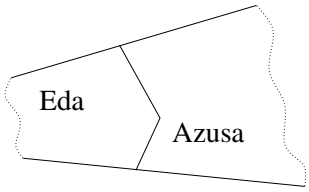

Figure 2

Despite the previous review, the problem is still going to be a challenge for eighth graders, and it is fair to infer that the teacher understands this very well. In geometry, one of the most difficult challenges in a construction or proof is determining where to put the auxiliary lines. These lines are needed to construct the angles, parallel lines, triangle(s), etc. that must be present before a geometry theorem or principle can be applied to solve the problem. For the exercise in Figure 2, the key step is to draw two crucial auxiliary lines. One defines the base of a triangle that must be transformed in a way that preserves its area. The other is parallel to this base, and runs through its opposing vertex.

So what should a master instructor do? The answer is on the tape.

After explaining the problem, the teacher asks the students to estimate where the solution line should go, and playfully places his pointer in various positions that begin in obviously incorrect locations and progress toward more plausible replacements for the bent line. Now here is the point. With the exception of two positions held for about one second (which come shortly after the frame shown in Figure 4), none of his trial placements approximate either of the two answers that are the only solutions any student will find.

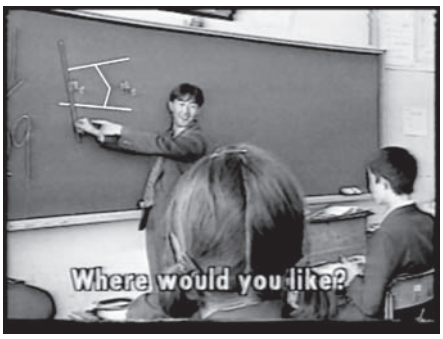

Figure 3

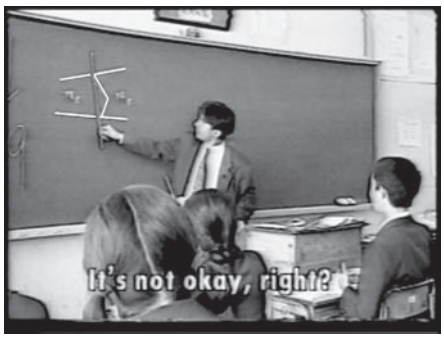

Figure 4

Rather, they are all suggestive of the orientation for the auxiliary lines that must be drawn before the basic method can be applied. He is giving subtle hints, and calling the students' attention to the very geometric features that must be noticed if the problem is to be solved. It is surely no accident that the teacher pauses with his pointer placed in two particular locations far longer than anywhere else. One of the locations is shown in Figure 4. The other is parallel to this placement, but located at the opposing vertex, which forms the bend in the boundary between Eda and Azusa.

Only after this telling warm-up – the heads-up review of the solution technique necessary to get the answer, and the casual discussion loaded with visual cues about what must be done – are the children allowed to tackle the problem.

But this is not the end of the lesson, and the students only get an announced and enforced three minutes to work individually in search of a solution.

As the children work, the teacher circulates among the students and gives hints, typically in the form of leading questions such as: "Would you make this the base? [The question is] that somewhere there are parallel lines, okay [36, p. 140]?"

He then allocates an additional 3 minutes where those who have figured out the solution discuss it with the other teacher. Weaker students are allowed to work in groups or to use previously prepared hint cards. The excerpt does not show what happens next. The TIMSS documentation [36] reports that students prepare explanations on the board (9 minutes).

Then a student presents his solution. The construction is clearly correct, and he starts out with a correct explanation. But when the time comes to demonstrate the solution, he gets lost and cannot see how to apply the area preserving transformation that solves the problem. The teacher then tells him to use "the red triangle" as the target destination.

Figure 5

The advice turns out to be insufficient, and the teacher *steps in* to redraw the triangle that solves the problem, and calls the student's attention to it with the words, "over here, over here." The student seems to understand and begins the explanation afresh. But he soon winds up saying, "Well I don't know what I am saying, but . . . " He then regains his confidence, and the presentation comes to an end without additional explanation.

A number of students say that they do not understand.

Then another student explains her answer, but the presentation is omitted from the tape. According to the Moderator's Guide [36, pp. 139–41], these two student presentations take altogether less than three minutes. Next, the teacher explains how to solve the problem. There are two equivalent answers that correspond to moving the middle vertex in Figure 1 to the left or right. Both directions solve the problem, and he shows this.

For completeness, we also show the two ways that the triangle transformation technique can be used to solve the problem. In order to make the connection between

the review material and the challenge problem absolutely clear, the problem and its two answers have been rotated to present the same perspective as the triangle transformations in Figure 1, which began the day's lesson.

Evidently, no one devised an alternative solution method.

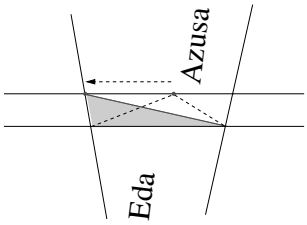

Figure 6

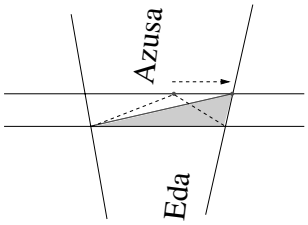

Figure 7

In his discussion of the solution, the teacher points out [36, p. 141] that this line straightening technique eliminates one of the two corners at the base of the triangle in Figures 6 and 7. This observation exposes a subtlety in that the corner that is eliminated is not the apex of the triangle, which is the point being moved to straighten out the line.

The lesson then continues with the teacher posing a new problem that can be solved with the same technique. This time the figure is a quadrilateral, and the exercise is to transform it into a triangle with the same area. At this point, the basic solution method should be within a student's reach, although the problem still requires a sound understanding of the basic method. There is also added difficulty due to the need to recognize that two consecutive sides of the quadrilateral should be viewed as representing the bent line of Figure 2, and that the other two sides should be extended as auxiliary lines to recast this new problem into a version of the Eda–Azusa exercise. The basic line straightening method can be applied so that any one of the four vertices can serve as the point where the line bends, and this designated vertex can be shifted in either of two directions to merge one of its two connecting sides with one of the auxiliary lines. The students again work individually for three minutes, and then are allowed to work in groups, use hint cards or ask the teacher.

Figure 8

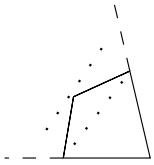

Figure 9

The TIMSS documentation indicates that this joint phase lasts for 20 minutes, and includes student presentations of their answers. There are apparently eight such presentations, which were selected to illustrate all eight ways the basic method can be applied: there are four vertices that can each be moved two ways. Then the teacher analyzes these eight ways in greater depth,

and explains how they all use the same idea. All students remain seated during this portion of the lesson, and he controls the discussion very carefully and does almost all of the speaking. For homework, the teacher asks the students to transform a five-sided polygon[6] into a triangle with the same area.

**An analysis of the teaching and its content.** This lesson is nothing less than a masterpiece of teaching, and the management of classroom time is remarkable. Although many students did not solve the first problem of the day, the assignment certainly succeeded in engaging the attention of everyone. The second problem was no giveaway, but it gave students the chance to walk in the teacher's footsteps by applying the same ideas to turn a quadrilateral into a triangle. The teacher-led study of all possible solutions masked direct instruction and reinforcement practice in an interesting and enlightening problem space.

Evidently, no student ever developed a new mathematical method or principle that differed from the technique introduced at the beginning of the lesson. Altogether, the teacher showed how to apply the method 10 times. Yet the lesson is an excellent example of how to teach problem solving, because each successive problem required a complete understanding of the basic proof technique.

The homework assignment is yet another application of the same method, and gives everyone a chance to revisit the lesson of the day once more. It also hints at the use of induction.

It is also worth pointing out that this geometry lesson, which is a specific application of measure preserving transformations, has additional uses. It appears, for example, in Euclid's proof of the Pythagorean Theorem (cf. Book I Prop 47 of Euclid's Elements).[7] More advanced exercises of this type appear on national middle school mathematics competitions in China and regional high school entrance examinations in Japan. And it is not much of a stretch to suggest that measure preserving transformations lie at the heart of those mysterious changes of variables in the study of integration.

All in all, the lesson is a wonderful example of the importance of a deep understanding of fundamental mathematics.

**Algebra.** The Japanese algebra lesson begins with student-presented answers for each of the previous day's six homework problems [36, p. 114]. These activities, along with the accompanying classroom discussion are omitted from the excerpts.

Then the teacher presents a more challenging problem that uses the same basic calculation method that the students have been studying, but needs one common-sense extension. The problem is this.

[6]The problem probably should be restricted to convex figures; otherwise it includes irregular cases that are difficult to formalize. On the other hand, this concern is just a minor technicality that has no effect on the pedagogical value of the problem.

[7]In fact, the technique is central to Euclid's development of area in general, which is based on transforming any polygon into a square with the same area. And the natural extension of this problem became a question for the ages: how to square the circle.

There are two kinds of cakes for sale. They must be bought in integer multiples; you cannot buy a fraction of a cake. The most delicious cake costs 230 yen, and a less tasty one is available for 200 yen. You wish to purchase 10 cakes but only have 2,100 yen. The problem is to buy 10 cakes and have as many of the expensive cakes as possible while spending no more than 2,100 yen.

The reproduction of the six homework exercises as shown in the TIMSS Moderator's Guide [36, p. 114] confirms that the class was already experienced with the technical mechanics necessary to solve problems with inequalities. Evidently, prior lessons had also covered word problems and the translation of word problems into equations and inequalities. Indeed, the teacher introduces the problem with the remarks, "Today will be the final part of the sentence problems [36, p. 159]." Thus, it is fair to infer that the only difference between the cake problem and the material they had just reviewed is the requirement that the solution use whole numbers of cakes.

After making sure that the students understand the problem, he asks them to devise a way to solve it. They get an announced and enforced three minutes.

Next, the teacher solicits solution approaches from the students. A student volunteers that she tried all possibilities. Her approach was to try 10 cheap cakes, then 9 cheap ones and 1 expensive one, etc., until she had the best answer. However, she was unable to finish in the three minutes that the teacher allocated for the problem. The teacher emphasizes the point, and it will soon become clear that part of the lesson is to show that this unstructured approach is unsound.

He then briefly discusses another way to solve the problem. The approach, which is quite inventive, uses a notion of marginal cost. If we buy 10 of the most expensive cakes, we exceed our budget by 200 yen. Trading in an expensive cake for a cheaper cake gives a net savings of 30 yen. Evidently, seven cakes have to be traded in, which shows that the answer is three expensive cakes and seven cheaper ones. As the teacher expected [36, p. 164], no student solved the problem this way.

Then he calls on another student, who explains how she set up the problem as an inequality, solved it as an equality, and then rounded the number of expensive cakes down to the nearest lesser integer. As she explains the equation, he writes it on the board. Only a few students understand the explanation, and he asks for another explanation of the same process. In subsequent activities that are only summarized on the tape and in the Moderator's Guide, the teacher then passes out a worksheet and works through a detailed analysis of the solution for the class.

After the detailed presentation, another problem of the same type was assigned, but with larger numbers. The teacher's words are telling:

> "If you count one by one, you will be in an incredibly terrible situation. *In the same way that we just did the cake situation, set up an inequality equation by yourself and find out . . . [the answer].* Because finding the answers one by one is hard, I wonder if you see the numerous good points of setting up inequality equations . . . "

The students worked on the problem individually. After 11 minutes, the teacher went over the problem with the class. The class ended with the teacher summarizing the solution technique that constituted the lesson of the day.

The video excerpts contain no group-based problem solving in this algebra lesson, and the Moderator's Guide confirms that none of the class time included problem solving in groups.

**An analysis of the teaching and its content.** Students never developed new solution methods. In the algebra class, the students were given the opportunity to learn first-hand why ad hoc trial-and-error approaches (which are encouraged by some of the latest reform recommendations) do not work. Although the tape does not explicitly show how many students were able to solve the original cake problem in the allotted time, the student responses suggest that no more than five could have possibly succeeded. But the three minutes of struggle might well have served to make the lesson more purposeful.

From a mathematical perspective, the cake problem was designed to require a deep understanding of inequality problems and their solutions. Mathematicians would say that when we solve a problem, we find all of the answers. If the cake problem had allowed fractional purchases, and had simply required that altogether any mix of ten cakes be purchased for at most 2100 yen, then the algebraic formulation would read,

$$230x + 200(10 - x) \leq 2100,$$

where $x$ is the number of expensive cakes purchased, and $10 - x$ is the number of the inexpensive ones. The problem would also require that $x$ be non-negative, since you cannot buy negative quantities of cake. A little manipulation gives:

$$0 \leq x \leq \frac{10}{3}.$$

Now, the point is that every $x$ in this interval is a solution to the simplified problem, and every solution to the problem is in this interval. So if we want a special answer, the interval $\left[0, \frac{10}{3}\right]$ is the place to look. If we want the largest $x$, it is $\frac{10}{3}$. If we want the largest integer $x$, it is 3. And if we wanted the largest even integer, for example, we would look nowhere else but into $\left[0, \frac{10}{3}\right]$ to conclude that this answer is $x = 2$. Incidentally, a complete answer must also observe that the number of inexpensive items must be non-negative.

This problem variant is more than a matter of common sense; it exposes students to a deep understanding of solutions to inequalities and the implications of real world constraints. Moreover, the problem illustrates the idea of decomposing a complex exercise into a more basic problem whose solution can then be adapted to achieve the original objective.

Evidently, the video excerpts feature challenge problems that cover fundamental principles, techniques, and methods of systematic thought that lie at the heart of mathematics and problem solving. As such, they ought to provide experiences that

build a powerful foundation of intuition and understanding for more advanced material yet to come. As a derivative benefit, these problems are so rich they can be readily transformed into follow-up exercises for use as reinforcement problems in class and as homework.

Both lesson excerpts exemplify a multi-round teaching and reinforcement pedagogy that begins with review of the fundamental (and systematic) principle that is the key to solving the challenge problem. The review is followed by two or three rounds (when homework is counted) that feature equivalent problems, often with additional educational content. Between each round, the teacher guides the students through the solution process to open the eyes of each learner to the basic idea, and to give the students yet another chance to apply the technique by themselves and to integrate the material into their own understanding – all in an engaging style without rote or tedium.

## 4. What can be deduced about Japanese teaching?

Many publications claim that the Japanese lessons teach students to invent solutions, develop methods and discover new principles. For example, this view is expressed in the Glenn Commission report [10, p. 4], and is clearly stated in TVCS as well: "[In Japan, the] problem ... comes first [and] ... the student has ... to invent his or her own solutions [31, p. vi]." In fact, TVCS reports that the 50 Japanese lessons averaged 1.7 student-presented alternative solution methods per class [31, Figure 22, p. 55]. Yet the excerpts exhibit no signs of such activity. They contain just one student-devised solution alternative, and it failed to produce an answer.

These differences are fundamental, and they should be reconciled. Part of the problem is that students are unlikely to devise their own solutions when the time is limited, the problems are so difficult that hints are needed, and the exercises are (clearly) designed to teach the value and use of specific techniques. Students would presumably have a better chance of finding alternative solution methods for less challenging exercises. And they would have an even better chance with problems that can be solved by a variety of methods that have already been taught. Examples might include geometry problems where different basic theorems can be used, and studies of auxiliary lines where the exercises are designed so that different auxiliary lines build different structures that have already been studied. TVCS illustrates alternative solution methods with the U.S. assignment to solve $x^2 + 43x - 43 = 0$ by completing the square and by applying the quadratic formula [31, p. 97]. Of course, this problem directed students to use different methods they already knew. The example contains no hint of any discovery.

So the question remains: where are the alternative solution methods, and when do they demonstrate signs of student-discovery?

The answers are in TVCS. It presents the actual examples that were used to train the data analysts who counted the "Student Generated Alternative Solution Methods"

(SGSM1, SGSM2, . . . ) in each lesson. The training lessons, it turns out, were the Japanese excerpts that we have just analyzed. The two student presentations for the Eda–Azusa problem are coded as SGSM1 and SGSM2 [31, p. 26–27]. Similarly, the second problem, where each of four vertices could be moved in two directions, has the codings SGSM1–SGSM8. *Altogether, this lesson is counted as having 10 student-generated alternative solution methods, even though it contains no student-discovered methods whatsoever*. And the failed try-all-possibilities approach in the Japanese algebra excerpt is counted as yet another student-discovered solution method. (See also "Teacher and Students Presenting Alternative Solution Methods [36, pp. 161–163]."")

TVCS also contains a partial explanation for the source of these judgments. It reports that the data coding and interpretation procedures were developed by four doctoral students – none of whom were in mathematics programs [31, p. 24]. Moreover, TVCS states that the project's supporting mathematicians only saw coder-generated lesson tables, and were denied access to the actual tapes [31, p. 31]. It is reasonable to infer, therefore, that they did not participate in the design of these coding practices. As for the question of invention, TVCS explains: "When seat-work is followed by students sharing alternative solution methods, this generally indicates that students were to invent their own solutions to the problem [31, p. 100]." Altogether, there appears to have been a sequence of misinterpretations that counted student presentations as alternative solution methods, which became student-generated, and then invented and which ultimately evolved into invented discoveries that might even depend on new principles the students had not yet learned ([31], [25], [10]).

On the other hand, the contributions by the Japanese teachers received much less generous recognition. Yet in the defining examples of student discovery, the teachers – not the students – manage the ideas and lead the education process.

**Additional statistics from the TIMSS projects.** It is worth reiterating that in the sample Japanese lessons, students began working individually – and not in groups – on each of the four representative exercises. Similarly, the Stigler–Hiebert analysis [30, p. 79] states that "Students rarely work in small groups to solve problems until they have worked first by themselves." TVCS contains no comparable statement, and even implies otherwise: "[After the problem is posed, the Japanese] students are then asked to work on the problem . . . sometimes individually and sometimes in groups [31, p. 134]." However, not one of the 86 figures and bar charts documents instances where problems began with students working in groups. Chart 41 [31, p. 78] indicates that of the seat-work time spent on problem solving, 67.2% of the time comprised individual effort and 32.8% of the time was spent in group-work.

Another TIMSS study addressed this issue in the statistics it gathered for a carefully balanced sampling of 3750 or so eighth graders from each participating country. One of its questionnaires asked teachers about their classroom organization and whether most of their lessons included students working in small groups, individually, as a class, etc. The results, which were weighted by the number of students

in each responding teacher's class, are reproduced below for the U.S. and Japan [3, pp. 154–155].

| Country | Percent of Students Whose Teachers Report Using Each Organizational Approach "Most or Every Lesson" | | | | | |
|---|---|---|---|---|---|---|
| | Work Together as a Class with Students Responding to One Another | Work Together as a Class with Teacher Teaching the Whole Class | Work Individually with Assistance from Teacher | Work Individually without Assistance from Teacher | Work in Pairs or Small Groups with Assistance from Teacher | Work in Pairs or Small Groups without Assistance from Teacher |
| Japan | 22 | 78 | 27 | 15 | 7 | 1 |
| United States | r 22 | r 49 | r 50 | r 19 | r 26 | r 12 |

An "r" indicates teacher response data available for 70–84% of students.

Figure 10

The table shows that Japanese lessons do not have significant numbers of small-group activities. In fact, American classes evidently contain about 4 times as many such lessons. Of course, it should be noted that the data is based on questionnaires and depends, therefore, on the judgment of each respondent. The meaning of "most or every lesson" might have cultural biases, as might the definitions of "small groups" and "teacher assistance." Still, these TIMSS statistics support the notion that the Japanese style of teaching is substantially different from many of the U.S. reform practices.

**Placing Japanese teaching in the context of U.S. reform.** The video excerpts show Japanese lessons with a far richer content than the corresponding offerings from the U.S. and Germany. TVCS reports that the eighth-grade lessons recorded in Japan, Germany, and the U.S. covered material at the respective grade levels 9.1, 8.7, and 7.4 by international standards [31, p. 44]. We suspect that the interactive nature of the teaching style, the coherent, concept-based exercises with disguised reinforcement problems, the motivated direct instruction, and the deep understanding of the teachers all contribute to the quality of the Japanese curriculum.

Additional analysis shows that 53% of the Japanese lessons used proof-based reasoning, whereas the comparable statistic for the US lessons – which included both traditional and reform programs – stood at zero [31, p. vii]. And comparisons evaluating the development of concepts – including their depth and applicability – and the overall coherence of the material likewise judged the Japanese programs to be vastly superior [30, p. 59]. By all evidence, the use of proof-based reasoning as reported in Japan is not at all representative of the reform programs in the U.S., and the use of such remarkably challenging problems is beyond the scope of any American program past or present.

When comparing U.S. reform practices and Japanese teaching methods, TVCS offers somewhat guarded conclusions that are sometimes difficult to interpret:

> "Japanese teachers, in certain respects, come closer to implementing the spirit of current ideas advanced by U.S. reformers than do U.S. teachers. For example, Japanese lessons include high-level mathematics, a clear

> focus on thinking and problem solving, and an emphasis on students deriving alternative solution methods and explaining their thinking. In other respects, though, Japanese lessons do not follow such reform guidelines. They include more lecturing and demonstration than even the more traditional U.S. lessons [a practice frowned upon by reformers], and [contrary to specific recommendations made in the NCTM Professional Standards for Teaching Mathematics] [8] we never observed calculators being used in a Japanese classroom [31, p. vii]."

Subsequent elaboration on the similarities between U.S. reform and Japanese pedagogy recapitulates these ideas in the context of various reform goals, but again offers no statistical evidence to compare with the data accumulated from the analysis of Japanese teaching practices [31, pp. 122–124]. Consequently, it is difficult – absent additional context – to compare these reform notions in terms of mathematical coherence, depth, international grade level, or the preparation of students for more advanced studies and challenging problems. And no matter what "the spirit of current reform ideas" may mean, it is clear that Japanese and U.S. reform pedagogies differ in their management of classroom time, their use of proof-based reasoning, their tradeoffs between student-discovery and the use of direct instruction, as well as their use of individual and small group activities.

For completeness, we note that TVCS makes a distinction between the idealized goals as prescribed in the NCTM Professional Standards for Teaching Mathematics, and as embodied in actual classroom practices of some reform programs. In particular, TVCS discusses two reform-style lessons. One involved students playing a game that was purported by the teacher as being NCTM compliant, but happens to have very little mathematics content: "It is clear to us that the features this teacher uses to define high quality instruction can occur in the absence of deep mathematical engagement on the part of the students [31, p. 129]." The other lesson was deemed compliant with the spirit of NCTM reforms. It began with the teacher whirling an airplane around on a string. The eighth graders then spent the period working in supervised groups to determine the speed of the plane, and came to realize that the key issues were the number of revolutions per second, and the circumference of the plane's circular trajectory. The problem also required a realization that units conversions would be needed to state the speed in miles per hour. The problem engaged the class, and a variant to compute the speed of a bird sitting on the midpoint of the string was evidently a challenge. The homework for this math class was a writing assignment: *the students were asked to describe the problem, to summarize their group's approach, and to write about the role they played in the group's work* [31, p. 127]. TVCS did not evaluate this lesson or the homework in terms of international grade level or its coherence within a curriculum.

[8] The bracketed additions are elaborations from page 123 of TVCS, where the discussion of calculator usage is reworded and thereby avoids the slight grammatical misconstruction we have caused with the unedited in-place insertion.

**Other characterizations of Japanese classroom practices.** Studies that use human interaction as a primary source of data must rely on large numbers of interpretations to transform raw, complex, occasionally ambiguous, and even seemingly inconsistent behavior into meaningful evidence. Given the complexity of the lessons, it is not surprising that different interpretations should arise. TVCS – to its credit – documents an overview of these decision-making procedures, although the actual applications were far too numerous to publish. Moreover, TVCS actually contains widely diverse observations, ideas, and conclusions that sometimes get just occasional mention, and that are necessarily excluded from the Executive Summary. Understandably, this commentary is also missing – along with any supporting context – from the one-sentence to one-paragraph condensations in derivative policy papers (cf. [25], [10]). Perhaps the seventh and eighth words in the opening line of the TVCS Executive Summary explain this issue as succinctly as possible: "preliminary findings [31, p. v]." It is now appropriate to explore these larger-picture observations and to place them within the context of actual lessons.

TVCS even offers some support for our own observations:

> "[Japanese] students are given support and direction through the class discussion of the problem when it is posed (figure 50), through the summary explanations by the teacher (figure 47) after methods have been presented, through comments by the teacher that connect the current task with what students have studied in previous lessons or earlier in the same lesson (figure 80), and through the availability of a variety of mathematical materials and tools (figure 53) [31, p. 134]."

Unfortunately, these insights are located far from the referenced figures and the explanations that accompany them. The words are effectively lost among the suggestions to the contrary that dominate the report. It is also fair to suggest that the wording is too vague to offer any inkling of how powerful the "support and direction through class discussion" really was. Similarly, the value of the connections to previous lessons is left unexplored. This discussion does not even reveal whether these connections were made before students began working on the challenge problems, or after. For these questions, the video excerpts provide resounding answers: the students received masterful instruction.

The Math Content Group analyzed a representative collection of 30 classroom lesson tables. Their assessments, as sampled in TVCS, agree with our overall observations, apart from the use of hints, which were mostly omitted from the tables. These analyses are highly stylized with abstract representations for use in statistical processing and were, presumably, not intended to be a reference for the actual teaching.[9]

[9]For example, the analysis of the excerpted geometry lesson consists of a directed graph with three nodes, two links and nine attributes. The first node represents the basic principle (attribute PPD) illustrated in Figure 1. The node's link has the attributes NR (Necessary Result) and C+ (Increased Complexity). It points to a node representing the first challenge exercise. The representations were used to get a statistical sense of various

Another sentence in TVCS begins with teachers helping students, but ends with students inventing methods.

> "The teacher takes an active role in posing problems and helping students examine the advantages of different solution methods [*however, rather than elaborating on how this takes place, the sentence changes direction with the words*], but the students are expected to struggle with the mathematical problems and invent their own methods. [31, p. 136]."

This interpretation of student work as inventive discovery appears throughout TVCS. In its analysis of the excerpted Japanese geometry lesson, TVCS categorizes the teacher's review of the basic solution method (shown in Figure 1) as "APPLYING CONCEPTS IN NEW SITUATION [31, Figure 63, p. 101]," but inexplicably switches tracks to count the student applications as invented student-generated alternative solution methods. Another such instance reads, "students will struggle because they have not already acquired a procedure to solve the problem [31, p. 135]." Similarly, TVCS never explains how teachers participate in the problem solving by teaching the use of methods and by supplying hints. Its only discussion about hinting is to acknowledge the offer of previously prepared hint cards [31, pp. 26–30]. And by the time the Glenn Commission finished its brief encapsulation of student progress, even the struggle had disappeared along with proper mention of extensive teacher-based assistance.

## 5. The matter of pedagogy

Having sequenced through the Japanese lesson excerpts to determine exactly what took place in the classrooms, we now compare these applied teaching practices with current reform principles.[10] One of the most important differences between these two approaches to teaching concerns discovery-based learning. As with any idealized theory, the real issue is how well it works in practice. Discovery-based lessons can make sense – in moderation – provided suitable safeguards are in place. In particular:

- Judgments must resolve how much time is needed for students to discover the mathematics, and the necessary tradeoffs among time for guided discovery, time for additional (or deeper) lessons, and time for practice.
- There must be detection/correction mechanisms for incomplete "discoveries".
- There must be allowances for the fact that in even the best of circumstances, only a few students will succeed in discovering non-trivial mathematical principles.

The lesson excerpts reveal a teaching style that is surprising and very different from the U.S reforms – in theory and practice. In the Japanese classes, the time allotted for the first round of grappling with problems is remarkably modest. Consequently, the

broad-brush characteristics of the lessons [31, pp. 58–69].

[10] See [2] for an enlightening albeit jargon heavy exposition on the differences between the theories of learning advanced by educators and by cognitive psychologists.

remaining time is sufficient for teacher-assisted student presentations to help identify conceptual weaknesses, and for direct instruction to present new insights, as well as for follow-up problems designed to solidify understanding. Due to the time limitations and the difficulty of the more challenging problems, many students will be learning via a model of "grappling and telling." That is, most students will struggle with a tough problem in class, but not find a solution. They will then learn by being told how to solve it, and will benefit by contrasting their unsuccessful approaches against methods that work [27]. There is no question that preliminarily grappling with a problem is both motivational and educational (cf. [4, p. 11] and [27]). And discussions to understand why some approaches fail, to understand why a solution might be incomplete, and to explore alternative problem solving techniques are all sound investments of class time. However, the use of grappling and telling raises the implementation question:

Who should do the telling?

In some teaching practices, the theory of discovery-based learning is extended to include the notion of *cooperative learning*, which holds that the students should teach one another because they "understand" each other. In contrast, the TIMSS videotape and the data in Figure 10 show that Japanese teaching is by no means purely or principally based on cooperative learning. Although students get to explain their solutions, the video excerpts show that Japanese teachers are by no means passive participants. Student explanations frequently need – and get – supervision, and students can be remarkably incoherent (cf. Figure 5) even when their solutions are absolutely perfect. When all is said and done, the teachers do the teaching – and the most important telling – but in an interactive style that is highly engaging and remarkably skillful.

Stigler and Hiebert report that the lessons do not adhere to a fixed organization. Some lessons feature more direct instruction or extended demonstrations, whereas others demand that the students memorize basic facts [30, pp.48–51]. Students might even be asked to memorize a mandate to think logically [30, p. 49].

Aharoni's article on experimental math programs in Israel deserves mention in this context. In the late 1970s, Israel developed a unique and nearly unrecognizable adaptation of the 1960s New Math, which is still in use to this day. The curriculum has been controversial; Israel had placed first on the original 1964 precursor to the TIMSS exams, and had fallen to 28th place on TIMSS 1999. Of course, this small country has experienced demographic shifts and many other sources of instability, so this drop in rank is by no means proof that the curriculum has failed, but there were other concerns about the program, and the TIMSS results gave little reason to believe that all was well.

Israel was just months away from adopting the latest U.S. reform standards when circumstances led to a reconsideration and the decision to test a program based on translations of the Singapore textbooks (from English). Aharoni is participating in this experiment, and writes about his experiences with these textbooks.

He argues that teachers must have a deep knowledge of fundamental mathematics if they are to instill a sound understanding of elementary arithmetic. His first-grade

teaching uses deep insights to provide a purposeful understanding of the most basic arithmetic operations. For example, he guides first-graders through story problems designed to open their eyes to the many different ways that a single operation – such as subtraction – can be used in the modeling of problems so that all students will enter the higher grades with the intuition and core knowledge necessary to master the translation of word problems into the native language of algebra. Only time will tell if the program is successful, but if so, his observations would have implications about best practices and teacher training.

This perspective places high demands on teachers and – by extension – on schools of education. Currently, most education programs allocate modest resources for courses on mathematics content, and very few programs are prepared to offer the kind of deep applied understanding that Aharoni describes. Instead, schools of education typically emphasize courses on developmental psychology, learning theory, and related topics such as *authentic assessment*, which is a grading practice based on portfolios of student work such as a study of how ancient Greek geometry was used 2000 years ago, or on real-life applications of periodicity – as opposed to exams. Similarly, very few mathematics departments feature course offerings on deep knowledge for K-12 instruction. This problem is further compounded by the certainty that most education majors would not have attended K-12 programs where such deep understanding would have been taught.

A small, but highly respected and widely cited comparative study by Liping Ma gives additional insight into this problem. In her study, American and Chinese elementary school teachers were asked to compute $1\frac{3}{4} \div \frac{1}{2}$, and to give a physically meaningful problem where the answer is determined by this computation. In the U.S., only 43% of those questioned performed the calculation correctly, and just one of the 23 teachers provided a conceptually correct story problem. In China, all 76 teachers performed the calculation correctly, and 80% came up with correct story problems [17].

In contrast, Hiebert and Stigler came to very different conclusions about how best to foster world-class teaching. They began with the TVCS tapes and findings, and conducted new investigations into Japanese teaching traditions. Their findings are published in *The Teaching Gap: Best Ideas from the World's Teachers for Improving Education in the Classroom* [30]. According to the authors, "differences" such as "teaching techniques, ... and [teaching] basic skills [versus teaching for] conceptual understanding ... paled" in comparison to the differences they observed in the culture of teaching. In their view, the Japanese tradition of life-long reflection on how to teach, and the culture of teachers sharing these ideas among each other in a continuing process of professional development was more significant than any of these other issues, which comprise the entirety of the debate over education reform in the U.S. and elsewhere. That is, they opined that the Japanese practices of ongoing collaborative- and self-improvement were even more important than the current state of the Japanese art of teaching as well as the curriculum differences reported in their book.

However, in a follow-up videotape classroom study of teaching in Australia, the

Czech Republic, Hong Kong, Japan, the Netherlands, Switzerland, and the United States, Stigler and Hiebert came to different conclusions [11]. For this study, new data coding schemes were developed to replace those used in the 1995 TVCS. Two of the findings are particularly noteworthy. First, the new study does not mention student-invented or student-discovered solution methods, and instead of reporting an average of 1.7 student-presented solution alternatives per Japanese lesson, the new study reports that 17% of the Japanese problems featured presentations of alternative methods [11, p. 94], and that students had a choice of methods in 31% of the lessons. Second, the study found no unifying theme to explain why the stronger countries perform so well. According to the authors:

> "A broad conclusion that can be drawn from these results is that no single method of teaching eighth-grade mathematics was observed in all the relatively higher achieving countries participating in this study [12, p. 11]."

> "It was tempting for some people who were familiar with the 1995 study to draw the conclusion that the method of teaching mathematics seen in the Japanese videotapes was necessary for high achievement [11, p. 119]."

Evidently, this positional retreat (see also [11, p. 1]) must include Stigler, Hiebert, and the Glenn Commission, among others. And the fact that the follow-up videotape study did not report student-discovered mathematics suggests that the earlier finding of student discoveries was inaccurate.

These changes in understanding notwithstanding, the earlier TVCS and the follow-up *The Teaching Gap: Best Ideas from the World's Teachers for Improving Education in the Classroom* will almost certainly outlive the more recent Hiebert–Stigler classroom study. These earlier publications continue to make must-read lists on education, and continue to inspire calls for reforms based on their findings. For example, on November 21, 2005, a New York Times editorial titled "Why the United States Should Look to Japan for Better Schools" cited the Teaching Gap book, and issued a call to reconsider

> "*how* teachers are trained and *how* they teach what they teach" (emphasis added).

Not one word was spent on the importance of *what content* is taught, and *what* a teacher should know in depth [29].

## 6. Conclusions

Mathematicians often ask what they can do to help preserve the integrity of K-12 math programs. In 1999, a letter protesting the new textbooks was signed by more than 200 leading American mathematicians and scientists and was published in the Washington Post. It had some positive results, but failed to stop the latest reforms. A similar protest in Israel was successful – but just barely. In California, protests

supported by grassroots parents organizations, mathematicians, scientists, concerned journalists, and politicians were able to secure a sound revision of the State K-12 math standards in 1997 – after more than five years of struggle.

In many countries, mathematics societies will probably be most effective by lobbying as a group and by seeking a role in the textbook adoptions and in overseeing the assessment programs. In the U.S., reform curricula have often been introduced in conjunction with new testing programs designed and even managed by the publishers of the newly adopted textbooks. This practice eliminates the opportunity to compare pre- and post-reform student achievement. And publishers seldom provide in-depth testing on the weakest aspects of their own programs.

It is also worth pointing out that program validation tests should cover an entire curriculum. Whereas achievement tests should concentrate on the most important material that can be covered in the allotted time, the testing of education programs should use sampling to achieve comprehensive coverage at a nominal marginal cost in the overall testing process. Needless to say, the oversight required for these assessment programs should be of the highest caliber.

Some tests use closely guarded questions. The secrecy allows the same questions to be used year after year to maintain consistency in the scoring. For example, one of the more widely cited validation studies relied mainly on a test that to the best of my knowledge has had only three of its questions appear in the literature. This achievement test was devised to align with the new math reforms, but is also reported to assess basic computational skills. It is given over a period of three days with the teachers retaining custody of the materials after school. So its questions are not really secret, and the administrative procedures lack safeguards to protect the integrity of the assessment program. Sometimes students were even allowed to rework questions from the previous day. Moreover, the test manufacturer does not require the test to be given with time limits, which are optional even for the testing of basic skills. The validation project reported year-by-year improvement of fourth-grade scores with the new reform program, but this progress was not matched by the scores for the more securely administered state testing of fifth graders.

In the U.S., the government-mandated No Child Left Behind (NCLB) testing (with state-determined tests) shows good progress for the majority of our states year by year, whereas the National Assessment of Educational Progress (NAEP) math testing shows that the net achievement of our twelfth graders has been unchanged nationwide for more than a decade. Something does not quite add up. The NAEP uses a mix of new and secret questions but is designed to be free of the biases that result from test-specific instruction and cramming. It is given to randomly selected schools, and the performance results are reported at the state level with additional results for subcategories based on gender and socio-economic status. Each student is given a randomly selected subset of test questions, and no performance results are released for students, schools, school districts, or education programs. Consequently, there is little incentive to teach to the test. The majority of the California achievement test questions are released and retired each year, and state law forbids the use of these

materials in classroom preparation for forthcoming tests. There are programs in place to detect cheating, but it is not possible to know how effective they are, and students can always use these questions for practice independently of their school assignments. In New York, there are no such prohibitions, and many New York City schools use old tests routinely in required after-school preparation sessions held during the six weeks prior to the State and City testing.

But although the NAEP may be our most uncompromised testing program, it is far from perfect. The test is consensus-based, with an oversight committee that has limited authority and where only about 10% of its members are mathematicians. The web-released sample questions suggest that the twelfth grade test is probably at a sixth grade level, on average. A representative question on fractions might be to compute two-thirds of 12 marbles. Evidently, the NAEP Governing Board (NAGB) has not reached a consensus about the benefits of knowing if an American high school education enables seniors to evaluate, say, $1/6 - 1/9$, much less $2\frac{1}{9} - 4\frac{1}{6}$.

To date, just one of the released algebra problems is categorized as solving a system of equations. This twelfth grade multiple choice question reads:

What number, if placed in each box below, makes both equations true?

$4 \times \square = \square$ and $3 \times \square = \square$: A) 0 B) 1 C) 2 D) 3 E) 4

A "hard" problem reads:

For what value of $x$ is $8^{12} = 16^{x}$? A) 3 B) 4 C) 8 D) 9 E) 12

Only 34% of our high school seniors found the correct answer even though calculators were available for use on this problem. The NAEP testing also asked students if they used a calculator for this question, but this data, unfortunately, does not appear to have been released on the web.

Needless to say, the TIMSS test questions and testing procedures, unlike many U.S. practices, stand out as a beacon of hope. But we must take care to ensure that all of the TIMSS analyses are well documented, are open to external review, and are as accurate as possible. And with so many challenges in the search for sound education reform, we may all be able to contribute somewhere in this complex of vital activities.

We close with the following summary assessments.

1. The undisciplined appeal to constructivist ideas has produced American programs that are more a betrayal of true constructivism than an advance of its principles. The result is an unprecedented reduction in the transmission of mathematical content.

2. The reform books and classroom curricula focus on examples, tricks, and experiments rather than fundamental mathematical principles, systematic methods, and deep understanding.

3. The justification for these "reforms" is based on mostly inaccurate interpretations of the best teaching practices in other countries. In particular, paradigmatic classroom examples from Japan have been misconstrued by researchers to suggest that students discover mathematical principles. In fact, the teacher conveys these

principles quite explicitly, albeit engagingly and through examples.

4. As a consequence of these misinterpretations, "exemplary" math lessons in the U.S. convey little content, take too much time, and can even lead to false "discoveries" of mathematical principles.

5. A proper understanding of best practices suggests that

i. teachers must be trained to understand, at a deep level, the mathematics they are teaching

ii. teachers should encourage individual work, but must ensure that important principles are conveyed in an orderly and cumulative manner.

6. Mathematicians, guided by proven programs such as those in Singapore, should be involved in determining the principles that are taught, the examples that help convey them, and the exercises that reinforce the net learning.

7. Mathematicians must play an active role in overseeing the quality of achievement tests in an effort to determine where our education programs are succeeding and where they are not.

**Acknowledgments.** The author is greatly indebted to Professor Michiko Kosaka for her tutoring on Japanese culture, and her verification of translated and mistranslated passages (cf. Figure 1) in the TIMSS Videotape Study documentation. It is also a pleasure to thank Clilly Castiglia and Kevin Feeley of the NYU Center for Advanced Technology and the Media Research Lab, who graciously provided the VHS frame processing.

# Mathematics, the media, and the public

Ian Stewart

**Abstract.** It is becoming increasingly necessary, and important, for mathematicians to engage with the general public. Our subject is widely misunderstood, and its vital role in today's society goes mostly unobserved. Most people are unaware that any mathematics exists beyond what they did at school. So our prime objective must be to make people aware that new mathematics is constantly being invented, and that the applications of mathematics are essential in a technological world. The mass media can play a significant role in encouraging such understanding, but the world of the media is very different from the academic world. I describe what it is like to engage with the media, concentrating on my own experiences of the past 40 years.

**Mathematics Subject Classification (2000).** Primary 00A06; Secondary 00A08.

**Keywords.** Popularisation of mathematics.

## 1. Introduction

For most of the 20th Century, mathematicians were free to pursue their subject essentially independently of the rest of human society and culture. In his celebrated book *A Mathematician's Apology* (Hardy [3]) the analyst G. H. Hardy wrote: 'It is a melancholy experience for a professional mathematician to find himself writing about mathematics.' In Hardy's view, writing about existing mathematics paled into insignificance when compared to creating new mathematics. In many ways he was, and still is, right. But the two activities are not mutually exclusive. Moreover, as the 20th Century has given way to the 21st, it has become increasingly vital for mathematicians to take steps to increase public awareness of their motives, activities, concerns, and contributions. Such awareness has direct benefits for the mathematical enterprise, even if that is viewed entirely selfishly: ultimately, the public purse funds our private obsessions, and will cease to do so unless the guardians of that purse are assured that the money would not be better spent elsewhere. Public awareness of mathematics (within the broader context of the 'public understanding of science') also benefits the populace at large, because we live in an increasingly technological world that cannot function effectively without substantial input from mathematics and mathematicians.

However, the role of mathematics in maintaining society is seldom appreciated – mostly because it takes place behind the scenes. The computer industry has made sure that it takes the credit (and sometimes the blame) for anything even vaguely related to its machines, but we mathematicians have failed completely to make it known

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

that without our contributions, such as algorithms (and of course much else that has nothing to do with us) those machines would be unable to add 1 and 1 and make 10. So we have a lot of work to do if we want to demonstrate that mathematics is not – as many imagine – a subject that has been rendered obsolete by the computer, but a vital part of what makes computers work. And almost everything else. To quote the preface of my recent book [9]:

> No longer do mathematicians believe that they owe the world an apology. And many are now convinced that writing about mathematics is at least as valuable as writing mathematics – by which Hardy meant new mathematics, new research, new theorems. In fact, many of us feel that it is pointless for mathematicians to invent new theorems unless the public gets to hear of them. Not the details, of course, but the general nature of the enterprise. In particular, that new mathematics is constantly being created, and what it is used for.

At the end of the 19th Century, it was not unusual for the leading mathematicians of the day to engage with the public. Felix Klein and Henri Poincaré both wrote popular books. David Hilbert gave a radio broadcast on the future of mathematics. But within a few decades, the attitude typified by Hardy seems to have taken over. Fortunately, we are now reverting to the attitudes of the late 19th Century. Distaste for mere vulgarisation gave way to grudging acceptance of its occasional necessity, and this in turn has given way to active encouragement and approval. Even today, the role of populariser is not all sweetness and light, but the days when (as happened to a colleague at another institution) a senior member of the administration would castigate a member of his academic staff for daring to write a column in a major daily newspaper are long gone. If anything, we are now more likely to be castigated for *not* not writing a column in a major daily newspaper.

Since my first appointment at the University of Warwick in 1969, indeed even before that, I have been involved in many different forms of mathematical popularisation – mainly books, magazines, newspapers, radio, and television. I generally feel much more comfortable *doing* popularisation than talking about it – in fact the main advice I give to people who are interested in becoming a populariser is to get on with it – so my intention here is to describe what it is like to be engaged in such activities, with specific reference to my own experiences. I hope that this may prove useful for others who may wish to play the role of media mathematician, and informative for those who prefer to watch from the sidelines but would like to understand the nature of the game better.

## 2. What is popularisation?

I have given many talks that popularised mathematics, but I once gave a talk *about* popularising mathematics, which is not the same thing. One example I mentioned

was a description of the Galois group of the quintic equation in comic book form [8]. Here a character in the story juggled five turnips (the 'roots' of the equation) in a blur, showing that they were indistinguishable – in short, the Galois group of the general quintic equation is the symmetric group $\mathbf{S}_5$.

A mathematics teacher in the audience objected that this was not popularisation. Just as Monsieur Jourdain, in Moliere's *The Bourgeois Gentleman*, was astonished to discover that he had been speaking prose all his life, I was astonished to discover that I had *not* been speaking popularisation. The teacher then explained that popularising mathematics meant making it accessible to children and getting them excited about it.

No: that's education. Not, perhaps, education in the sense currently envisaged in the UK (and increasingly everywhere else), which is a sterile process in which boxes are ticked to indicate that the child has temporarily mastered some small item of knowledge or technique, regardless of context, but education in the sense it used to mean, which was teaching things to children. Explaining things in a comprehensible manner, and enthusing children about the topic, are essential features of education at school level – and, indeed, in adult education too.

It was particularly clear that the teacher's view of what constituted 'mathematics' differed from mine. She was referring to the nuts and bolts of the school syllabus; my main concern was, and always will be, the frontiers of past of present mathematical research. The two are about as similar as do-re-mi and Wagner's Ring Cycle.

There is, of course, common ground. It is possible to popularise school mathematics among children without trying to teach it to them. But one of the biggest misconceptions among otherwise intelligent adults is that the 'mathematics' they did at school is *all there is*. One of the most important aspects of popularisation is to make it clear to both children and adults that this presumption is wrong.

By 'popularisation' I mean attempts to convey significant ideas from or about mathematics to intelligent, mostly sympathetic non-specialists, in a manner that avoids scaring them silly and exploits whatever interests them. I say 'attempts' because success can be elusive. The level of exposition can range from humorous short puzzles to books on hot research topics.

## 3. The public

The phrase 'public understanding of science' is widely used but seldom clarified. *Which* public? What are they supposed to understand? Why don't they understand it already?

The schoolteacher mentioned above had a very different idea of what the words 'public' and 'understand' meant, compared to what I meant. Many scientists consider the public to be anyone who is not a scientist, and view their alleged lack of understanding as a deficiency to be remedied by supplying the required information. Thus members of the public who are concerned about possible effects of genetically modified organisms are directed, by such scientists, towards research that demonstrates the

(alleged) safety of GMOs as food; people concerned about the safety of nuclear power are directed to statistical analyses of the probability of accidents, and so on. In this view, the public – whoever they may be – are considered ignorant, and the objective of the 'public understanding of science' is to remedy this deplorable deficiency.

I don't find this view helpful. Even when correct, it is patronising and self-defeating. But mostly it is not correct. Often the public, for all their ignorance of technical details, have a much clearer grasp of overall issues than specialist scientists. A major problem with GMOs, for instance, is not their safety as food, but potential damage done to the ecosystem by introducing alien species. You don't need to know any genetics to observe that numerous confident pronouncements about GMOs made by scientific experts have turned out to be wrong, and badly so. Not long ago people in the UK were assured that genetically modified DNA could not be transferred more than a few metres by pollen. It quickly transpired that such transfer routinely occurred over distances of several kilometres. It is not necessary to prove that such transfer is harmful to notice that the experts did not have a clue what they were talking about, or that their alleged expertise had led them to wildly inaccurate conclusions. On many issues of public concern, reassurance by scientists serves only to educate the public in the limitations of reductionism and the narrow-mindedness of many scientific experts.

Some scientists even seem to think that it is possible to draw up some list of basic scientific 'facts' that members of the public should know, and then teach them. So they should know that the Earth goes round the Sun, that genetic information is encoded in DNA, that the Earth is 4.5 billion years old, and so on. It would certainly help if most people were aware of such things, but this attitude encourages the view that the task of science is to establish 'the facts', and that once these are known, that's all there is to be said. Or, as a friend of mine's Head of Department put it many years ago: 'Our task as educators is to give the students the facts, and their job is to give them back to us in the exams.' Whatever that process might be, it's not education, and it's not public understanding either. Though it does help to train a lot of 'experts' who think that their limited understanding of laboratory genetics qualifies them to pronounce on the effects of GMOs on the ecology.

My view, for what it's worth, goes something like this. Let me phrase it in the context of mathematics, for definiteness: much the same goes for other areas of science.

All over the globe, every day of the week, mathematicians are carrying out research, proving new theorems, inventing new definitions, solving problems, posing new ones. The vast majority of the public have no idea that any of this is happening. They got excited by the TV programme on Andrew Wiles and Fermat's Last Theorem, but that wasn't because they thought it was the most interesting new idea in mathematics. They thought it was the *only* new idea in mathematics. What excited them was not a new breakthrough on an old problem, but the belief that for the first time in several centuries a new piece of mathematics had been brought into existence.

So the primary objective, for the public understanding of mathematics, has to be to make people aware that new mathematics is constantly being created.

This objective is more important than explaining what that new mathematics consists of, and it is more important than explaining what mathematics actually is. Only when people recognise that mathematicians are doing *something* do they start to get interested in *what* they are doing. Only when they've seen examples of what mathematicians are doing do they start to wonder what mathematics is.

If by 'the public' we really do mean the typical, randomly chosen person on the street, then we have succeeded in improving their understanding of our subject as soon as they realise that there is more to it than they met at school.

There is a more restricted subset of the public that requires, and should be given, more. These are the people who are actually interested in mathematics. They are the core audience for popularisation. For them, it is worth trying to convey more than the existence of new mathematics. It is possible to try to give a feeling for what it is.

When you watch a football match on television, it is assumed that you enjoy football and have some general idea of the rules. The commentators do not explain that the round object is a 'ball' and that the aim is to get it into the net; nor do they point out that you have to choose the right net, and that the total number of 'goals' determines who wins. You are expected to know this. On the other hand, you are not expected to know the latest version of the offside rules. The commentators assume you are aware of the issue, but have temporarily forgotten the details. By reminding you of those, they can then engage your attention in a discussion of the issues.

Too often, the media treat science very differently. You want to tell people about Fermat's Last Theorem, but first you are obliged (so the producer or editor insists) to explain what a square and a cube is and who Pythagoras was. If you want to describe the latest work on polynomial-time algorithms for primality testing, you have to explain what a prime number is and what a polynomial is. In that case, the missing information can be sketched quite quickly, but it's all too easy to find yourself in a situation where the main point you are trying to address is Galois theory, but all the programme manages to tackle is the concept of a square root. Better than nothing. . . but not what you intended, and not what is needed to break the mental link 'mathematics = school'.

## 4. Be warned

If you want to promote mathematical awareness among the public by making use of the mass media, you should be aware that it is not quite like standing in front of a blackboard or data projection screen and delivering a lecture to undergraduates. Rather different talents are needed, and in particular you have to be prepared to risk making a fool of yourself. I have dressed up in a white lab coat to talk about the probability theory of Friday 13th, presumably because the TV company concerned thought that was what mathematicians wear – or more likely thought that viewers thought that was what mathematicians wear. I have had my name up in lights on the scoreboard at Wembley football stadium, for a programme about crowd modelling

that should have taken an hour to film and actually took five because the stadium – which was supposed to be empty – was full of schoolkids on their Easter break, and was being dismantled around our ears as well.

I have spent a day lugging a stuffed duck-billed platypus round an ancient castle… a colleague, who often does TV biology, remarked 'I've never done that.' Pause. 'Mine was a stuffed echidna.' (We contemplated forming the Monotreme-Luggers' Society.) I have sat in the hot sun, visibly becoming more and more sunburned as the filming progressed, because the topic was Maxwell's equations and the backdrop of an array of radio telescopes was deemed essential to the atmosphere. I have stood in a huge supermarket at peak period to deliver five seconds of wisdom about the National Lottery to BBC news, live…terrified that the woman who was noisily changing thousands of coins at a nearby machine would still be doing so when we went on air. I have spent 16 hours in a muddy quarry filming the end of the world, and driving a battered VW beetle painted to *resemble* the world. Appropriately, its clutch-cable broke ten minutes into the filming, and I had to drive it all over the quarry, and a local farm, by crashing the gears.

One attempt at a live broadcast for Irish local radio, about alien life forms, failed because they lost the connection. We did it again the next week. In another attempt at a live broadcast – I forget what about – I sat in a cramped studio for an hour, and my slot was then pre-empted by a news flash, so nothing went out at all.

On the other hand, working with the media is occasionally wonderful. My most memorable moment ever was when we started a televised lecture by bringing a live tiger into the lecture room. (Warning: do not attempt this at home.) It's a long story, but here are the bare bones.

In 1826 Michael Faraday inaugurated a series of lectures on science for young people at the Royal Institution in London, where he was resident scientist. They have continued annually ever since, except for four years during World War II, and for almost 40 years they have been televised. Until recently they were recorded 'as live', meaning that most mistakes were left in, in front of an audience consisting mainly of schoolchildren. (Three things you should never do in show business: work with children, work with animals, work without a script. Christmas lecturers have to do all three simultaneously.) There are a few parents too, but they are placed out of sight of the cameras.

Twice in the ensuing 180 years the topic has been mathematics. Christopher Zeeman delivered the first such series in 1978, and I gave the second in 1997. One of my lectures was on symmetry and pattern-formation. We decided to open the lecture with Blake's 'Tyger' poem ('dare frame they fearful symmetry'), which, although being a cliché, seemed unavoidable.

Which meant, by the very direct logic of television, that we had to have a tiger.

A month-long search yielded a baby puma, but no tiger. We had just about decided to go with the puma when my colleague Jack Cohen found us a tiger. More accurately, a six-month old tigress called Nikka. She was wonderful, a real pro – used to the lights and an audience. She had the requisite stripes (pattern-formation, remember?). For

Health and Safety reasons she was separated from the audience by a row of upturned seats, while two burly young men held her on a chain. Apparently Health and Safety did not extend to presenters (me) so I delivered the relevant material squatting next to her. It was one of the most amazing experiences of my life, and I've never really been able to match it as a way of starting a lecture.

## 5. What the media want

When we write research papers on mathematics, the main criteria for publication are that the paper should be competently written, new, true, and interesting.

The criteria for acceptance of a newspaper article, a magazine article, a radio interview, or a TV broadcast are somewhat different. The most important difference is that you have to tell a story. A story has a beginning, an end, and a middle that joins them. Moreover, it should be clear at all times where the story is and where it is heading. This does not mean that you have to give away the punch line before you get to it: it means that the reader or listener must be made aware that a punch line is on its way. One way to describe the process is to say that the reader or listener needs to be given a 'road map', or at least a few signposts.

My feeling is that in principle even a research paper ought to tell a story, but mathematicians are not trained in narrative thinking, and readers are generally able and willing to go over a research paper several times seeking understanding. This is not the case for a newspaper article or a radio broadcast. Readers or listeners are busy people, often on their way to or from work, and they expect to be able to follow the story as it unfolds. A few may read an article twice, or record a radio programme and listen to it again, but on the whole they will do this because they *did* understand it first time, not because they did not.

As an example, suppose you want to write about Andrew Wiles's proof of Fermat's Last Theorem, for the *Ghastliegh Grange Gazette*. It does not work if you start with something like 'Let $E$ be an elliptic curve...' or even something more civilised like 'The key to proving Fermat's Last Theorem is Galois cohomology...' Instead, you need to structure the story around things the reader can readily identify with. The bare bones of the story might be something along the following lines: 'Notorious puzzle that mathematicians have failed to solve for 350 years... Very simple to state but impossible to prove until now... After seven years of solitary research, major breakthrough by Wiles... Unexpectedly linked puzzle to a different area of mathematics, making breakthrough possible... Proof temporarily collapsed after being announced... After desperate last-ditch battle, proof repaired... Triumph!'

Notice that this summary of the narrative line does not include a statement of the theorem (though you would normally work this into the article somewhere) and in fact it does not even include Fermat (though again some historical background would be a good idea). It does not mention elliptic curves or Galois cohomology, and it absolutely does not define them. Your typical reader may well be a lawyer or a greengrocer, and

these terms will be meaningless to them. If some technical idea is absolutely essential to your story, then you will have to find some way to make it comprehensible – but be aware that your readers have no idea what a function is, or a group, or even a rational number. This does not mean they are ignorant or unintelligent – after all, how much do you know about conveyancing or vegetables? It means that you are enticing them to venture into territory that is, for them, very new. They will need a lot of help. 'Infinite intelligence but zero knowledge' is a useful, though perhaps flattering, description.

Another extraordinarily important aspect of a story, for the media, is timeliness. The editor or producer will not only ask 'Why should I publish/broadcast this story?' They will ask 'Why should I publish/broadcast this story *today*?' (Or 'this week' or 'in the next available issue' or whatever.) It is not enough for the material to be important or worthy. There has to be a 'hook' upon which the story can be hung.

Typical hooks include:

- Recent announcement of the relevant research.
- Recent publication of the relevant research.
- A significiant anniversary – 100 years since a major historical figure associated with the work was born, died, or made a key discovery. A genuine professional science writer will keep a diary of such occasions, and be ready for them as they come along.
- A timely application (preferably related to stories currently considered newsworthy – such as cloning, nanotechnology, anything with a gene in it, mobile phones, computer games, the latest blockbuster movie. . .).
- A current controversy – the media always go for a dust-up, and it seldom matters if the source of the dispute is totally obscure. Everyone understands a fight.

There are other kinds of hook. With Christmas coming up, the TV programme *Esther* once decided to feature the science of Christmas, but much of it was deliberately spoof science – for example, my contribution was to point out that the aerodynamics of supersonic flight is very different from subsonic, so that at the hypersonic speeds employed by Santa Claus, reindeer antlers might be much more aerodynamic than they look.

They aren't, of course, but viewers knew it was a joke and subliminally took on board the message about supersonic flight changing the geometry. And they also got to see the back-of-the-envelope calculation that estimated Santa's speed.

One of the more bizarre hooks arose in 2003, when I received a phone call from the *Daily Telegraph*, one of the UK's major newspapers. A reader had written a letter, recalling a puzzle with 12 balls that he had heard about as a boy. All balls have the same weight, except for one. He had been told that it was possible to work out which ball, and whether it was light or heavy, in 3 weighings with a balance but no weights. Could anyone tell him how?

The response was remarkable. The newspaper reported [10] that 'By teatime yesterday [7 February 2003], *The Daily Telegraph* had received its biggest mailbag in living memory and our telephones were still ringing off the hook'. But the editors had a serious problem: it was unclear to them whether any of the proposed solutions was correct. Could I supply a definitive answer?

As it happened, Martin Golubitsky was visiting, and he remembered being inspired by this puzzle as a teenager. In fact, his success in solving it was one of the things that had made him decide to become a mathematician. We put our heads together and reconstructed one method for solving the puzzle. The newspaper duly published it, mainly as a way of ending the flow of letters and phone calls.

There is, by the way, a more elegant solution than the one we devised. The puzzle has been discussed by O'Beirne [4], who gives a solution originating with 'Blanche Descartes' (a pseudonym for Cedric A. B. Smith), see Descartes [2]. Here the hero of the narrative, known as 'F', is inspired to write the letters

F AM NOT LICKED

on the 12 balls: '... And now his mother he'll enjoin:

MA DO LIKE
ME TO FIND
FAKE COIN'

The poetic solution lists a set of weighings (four balls in each pan) whose outcome is different for all 24 possible choices of the odd ball out and its weight. The problem with this answer, clever though it may be, is to motivate it. This is why we settled for the more prosaic 'decision tree' of weighings that you will find in the published article. We felt that readers would be more likely to follow the logic, even if our method was less elegant.

## 6. The media

Let's take quick trip through the main types of media outlet. There are others – webpages, CD-ROMs, DVDs, blogs, podcasting, whatever.

**6.1. Magazines.** Popular science magazines have the advantage that their readership is self-selected for an interest in science. Surveys have shown that mathematics is very popular among such readers. Each magazine has its own level, and its own criteria for what will appeal. *Scientific American* is justly famous for the 'mathematical games' columns originated by the peerless Martin Gardner, which unfortunately no longer run.

In the UK there are *New Scientist* and *Focus*, which regularly feature mathematical items ranging from primality testing to su doku.

If you are thinking of writing an article for such a magazine, it is always better to consult the editors as soon as you have a reasonably well formulated plan. They will be able to advise you on the best approach, and will know whether your topic

has already been covered by the magazine – a problem that can sink an otherwise marvellous idea.

Expect the editors and subeditors to rewrite your material, sometimes heavily. They will generally consult you about the changes, and you can argue your case if you disagree, but you must be prepared to compromise. Despite this editorial input, the article will usually go out under your name alone. There is no way round this: that's how things are in journalism.

**6.2. Newspapers.** Few newspapers run regular features on mathematics, bar the odd puzzle column, but most 'quality' newspapers will run articles on something topical if it appeals to them. Be prepared to write 400 words on the Fields medallists with a four-hour deadline, though, if you aspire to appearing in the national news.

**6.3. Books.** Books, of course, occupy the other end of the deadline spectrum, typically taking a year or so to write and another year to appear in print. They really deserve an article in their own right, and I won't say a lot about them here, except in Section 7 below. Sometimes expediency demands a quicker production schedule. I once wrote a book in 10 weeks. It was short, mind you: 40,000 words. The quality presumably did not suffer because it was short-listed for the science book prize.

If you want to write semi-professionally, you will need an agent to negotiate contracts. At that level, book writing is much like getting a research grant. Instead of ploughing ahead with the book, you write a proposal and go for a contract with a specified advance on royalties.

**6.4. Radio.** Radio is my favourite medium for popularising mathematics. This is paradoxical, because radio seems to have all of the disadvantages (such as no pictures) and none of the advantages (such as being able to write things down and leave them in full view while you discuss them) of other media. However, it has two huge advantages: attention-span and imagination. Radio listeners (to some types of programme) are used to following a discussion for 30 minutes or longer, and they are used to encountering unfamiliar terminology. And radio has the best pictures, because each viewer constructs a mental image that suits *them*.

On radio you can say 'imagine a seven-dimensional analogue of a sphere', and they will. It may not be a good image, but they'll be happy anyway. Say the same on TV and the producer will insist that you build one in the studio for the viewers to see. TV removes choice: what you get is what they choose to show you. On radio, what you see is what you choose to imagine.

**6.5. Television.** Television is far from ideal as a medium for disseminating science, and seems to be becoming worse. As evidence: every year the Association of British Science Writers presents awards for science journalism in seven categories. In 2005 no award was made in the television category, and (Acker [1]) the judges stated:

> To say the quality of entrants was disappointing is an understatement. We were presented with 'science' programmes with virtually no science in them. Some were appalling in their failure to get across any facts or understanding. Whenever there was the possibility of unpicking a little, highly relevant, science, or research methodology, the programmes ran away to non-science territory as fast as possible, missing the whole point of the story as far as we were concerned.

I still vividly recall a TV science programme which informed viewers that Doppler radar uses sound waves to observe the speed of air in a tornado. No, it uses electromagnetic waves – the word 'radar' provides a subtle clue here. Sound waves come into the tale because that's where Doppler noticed them.

The reasons *why* television is far from ideal as a medium for disseminating science are equally disappointing. It is not the medium as such that is responsible – although it does discourage attention-spans longer than microseconds. The responsibility largely rests with the officials who commission television programmes, and the companies who make them.

Television changed dramatically in the 1980s, especially in the UK. Previously, most programmes were made 'in-house' by producers and technicians with established track records and experience. Within a very short period, nearly all programming was subcontracted out to small companies (many of them set up by those same producers and technicians) on a contract-by-contract basis. This saved television companies the expense of pensions schemes for their employees (since they now had none) and protected them against their legal responsibilities as employers (ditto). But as time passed, contracts were increasingly awarded solely on the basis of cost. A new company would get the commission to make a programme, even if they had no experience in the area, merely because they were cheaper.

Very quickly, most of the companies that knew how to make good science programmes were ousted by new kids on the block whose main qualifications were degrees in media studies and, the decisive factor, cheapness. Any lessons previously learned about how to present science on television were lost, and had to be re-learned, over and over again, by a system dedicated to the perpetual reinvention of the wheel. There is still some good TV science, but nowhere near as much as there ought to be given the proliferation of satellite and cable channels.

The good news here is that TV is once again wide open as a medium for popular science, especially now that there are hundreds of channels desperate for content. But we will have to fight all the old battles again.

## 7. Narrative imperative

Sometimes an unexpected opportunity presents itself.

*The Science of Discworld* and its sequels *The Science of Discworld 2: The Globe* and *The Science of Discworld 3: Darwin's Watch* (see [5, 6, 7]) were written jointly with Jack Cohen, a biologist, and Terry Pratchett, one of the UK's bestselling fantasy authors. They are superficially in the tradition established in *The Physics of Star Trek*, *The Science of Jurassic Park*, and *The Science of Harry Potter*, but on closer analysis they are distinctly different, and the difference is important. The latter three books all start from a popular television, film, or book series, and use that as a vehicle for *explaining* the alleged science that could actually make such things as space warps, resurrected dinosaurs, or flying broomsticks work. This approach may be an excellent way to interest non-scientists in Relativity, DNA, or anti-gravity, but it rests on a fundamental untruth: that today's science tells us that such fiction could one day become fact. But typically the true link is rather more tenuous than that between a hang-glider and an interstellar spaceship.

The Science of Discworld series takes the opposite stance. Instead of exploiting an existing body of fantasy as a basis for dubious science, it uses genuine science as a basis for new works of fantasy. In the three Science of Discworld books, we interwove entirely new fantasy stories with voyages through significant areas of modern science. We designed both aspects of the books to complement each other. The three authors worked together to plan the combined structure, choosing scientific topics that would lend themselves to a fantasy setting, tailoring the fiction to fit the facts, and selecting the facts for suitability as components of a work of fiction.

If you've not encountered Discworld before, here's a quick introduction. Pratchett's Discworld series of humorous fantasy novels now comprises 31 novels, three graphic novels, four maps, 12 plays, two television animations, a cookery book, and countless spin-offs ranging from ceramics to computer-games. Its fans are numbered in the millions. Discworld is, as its name suggests, circular in form, and flat (though decorated with forests and oceans and deserts, hills and mountains dominated by the vast heights of the central Ramtops, where the gods live in an analogue of Valhalla). The disc is about 10,000 miles across, supported by four elephants standing on the back of the great turtle A'Tuin, who swims through space.

Discworld is inhabited by people just like us, and by an assortment of wizards, witches, elves, trolls, zombies, ghosts, golems and vampires. Much of the action takes place in the city of Ankh-Morpork, where the wizards reside within the hallowed walls of Unseen University. It is a city of medieval proportions and Elizabethan filth.

Discworld was originally conceived as a vehicle for poking fun at sword-and-sorcery books, such as Robert Howard's tales of Conan the Barbarian and Fritz Leiber's 'Fafhrd and Gray Mouser' series set in the environs of Lankhmar, the model for Ankh-Morpork. But Discworld rapidly transmogrified into a vehicle for poking fun at everything, from Hollywood to the Phantom of the Opera, from religion to engineering, from the press to the police – even mathematics.

Discworld has its own sideways logic, very appealing to mathematicians. It accepts the premises of fantasy (the Tooth Fairy really does come and take away teeth, leaving real cash) but asks hard questions (what's in it for her?). It has no qualms about world-girdling turtles swimming through hard vacuum, but wonders what happens when they mate. It acknowledges the Butterfly Effect of Chaos Theory, but wonders which butterfly has this awesome power, and how to get the blighter.

Discworld is our own planet, reified. Its driving forces are magic and Narrative Imperative. In magic, things happen because people want them to. In Narrative Imperative, things happen because the power of story makes them happen. The eighth son of an eighth son cannot avoid becoming a wizard – even if the midwife made a mistake and she was actually a girl. And so, in *Equal Rites*, the misogynist wizards of Unseen University have to come to terms with a female presence in the hallowed chambers.

Some time in 1998 Cohen and I became convinced that there ought to be a book called *The Science of Discworld*. We broached the possibility to Terry, who pointed out the fatal flaw in the plan. There is *no* science in Discworld.

In vain we argued that there is. When Greebo, the hyper-macho cat belonging to the witch Nanny Ogg is shut in a box, it rapidly emerges that there are three possible states for a cat in a box: alive, dead, and absolutely bloody furious. This is a profound comment on quantum superposition: what is the association between an object's quantum state (wavefunction) and its macroscopic state (what we observe)? If you knew the cat's wavefunction, could you tell whether it was alive or dead? My own view is that you couldn't even tell that it was a cat.

Terry gently explained why this approach would be misleading. On Discworld dragons do not breathe fire because of chemistry and genetics: they breathe fire because that's what dragons do.

What saved the idea was a concept breathtaking in its simplicity. 'Terry: if there's no science in Discworld, then you must put some there.'

Thus was born the Roundworld Project, in which the wizards of Unseen University set out to split the thaum (the fundamental unit of magic) and end up coming within a whisker of destroying the whole of the universe. As the magical reactor is about to go critical and explode, taking the universe with it, the computer Hex bleeds off the excess magic to create a small sphere, a magical containment field within which magic does not work. This is Roundworld, and it is our own universe. It runs not on magic, but on rules. It has helium and magnesium, but no narrativium. Things happen there because the rules say they must, not because someone wants them to.

Oddly, this makes everything in Roundworld harder to understand, not simpler. If a person wants something built – a house, say – then they get some builders and up it goes. But if the *rules* want something built, such as a human being, then the construction process is much more obscure, involving big molecules and bacterial blobs and billions of years of nothing much happening; then blink your eye and the humans have come and gone, leaving only the ruins of the Space Elevator, and you can't even be sure they were human.

The best way to envisage the structure of the Science of Discworld books is to think of a novelette by Pratchett, set on Discworld, with its usual cast of characters and its usual narrative constraints, but with Very Big Footnotes by Cohen and Stewart. The novelette, which comprises the odd-numbered chapters of the book, is fantasy; the footnotes, comprising the even-numbered chapters, are the scientific commentary, and are typically between two and three times as long.

This is a beautiful framework for writing about science, because the differences between magic and science are highly illuminating. Discworld is the perfect framework for a 'What if?' discussion of science – a well-established, self-consistent universe that can be used to 'compare and contrast'. We managed to work quite a lot of mathematics into the books, too: chaos, complexity, Langton's Ant, probability, phase spaces, combinatorics, information theory, infinity, and transfinite numbers. Not to mention scores of applications from astronomy to zoology.

It was fun, too.

# Controversial issues in K-12 mathematical education

Michèle Artigue (*moderator*)
Ehud de Shalit and Anthony Ralston (*panelists*)

**Abstract.** This article sets the background for the panel session at the ICM on controversial issues in K-12 mathematics education. Three specific issues have been selected: Technology, skill building and the role of test and assessment. For each of these, a list of questions has been prepared. After introducing the three themes and the associated questions, this article presents the positions on these of the two panelists: Professor Anthony Ralston, from the State University of New York at Buffalo in the US, and Professor Ehud de Shalit from the Hebrew University of Jerusalem in Israel. The article ends with some personal comments from the coordinator of the panel: Professor Michèle Artigue from the University Paris 7 in France.

**Keywords.** Mathematics education, K-12 curriculum, technology, skill building, concept building, testing, assessment.

## Introduction

by *Michèle Artigue*

K-12 mathematics education is obviously a controversial area, so much so that, in countries like the US, the term Math Wars has been used for describing the kind of conflicts between communities that has been generated in recent years. We all regularly hear colleagues complaining that the students they receive have not been adequately trained and that, every year, the situation becomes worse, or that they are not pleased with the kind of mathematics education their children receive etc. We all know that such feelings are not something new, but we cannot deny that in the last decade they have dramatically increased in intensity in many countries.

Why does such a situation exist? What are the real challenges that K-12 mathematics education has to face at the beginning of the XXI$^{st}$ century? What can mathematicians do in order to enhance or support efficiently the necessary efforts, evolutions and changes of the whole educational community? These are the crucial issues that motivate the existence of a panel session on Controversial Issues in K-12 mathematical education at the ICM2006 in Madrid. It is certainly interesting to keep them in mind even if the panel does not address them all directly.

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

For structuring this panel session, we have selected some particularly controversial issues, and will try to elaborate on these, with the support of the audience. These issues approach the current problems met by K-12 mathematics education through three different, but not independent, topics: technology, the place given to the learning of skills and techniques, and assessment and tests. Everyone will certainly agree that each of these is today a controversial topic, and that frequently in what we read or hear, it is advocated that the ways they have been dealt with in recent years or currently has resulted in some of the difficulties in K-12 mathematics education today.

In what follows, we briefly introduce these three topics and articulate some questions that we would like to discuss for each of them. We then present the positions on these questions of the two panelists, Professor Anthony Ralston from the State University of New York at Buffalo, and Professor Ehud de Shalit from the Hebrew University in Jerusalem. The article ends with some general comments by the moderator of this panel session, Professor Michèle Artigue from the University Paris 7.

## Topics and questions

**Technology.** In 1985, the first study launched by ICMI entitled "The influence of computers and informatics on mathematics and its teaching" was devoted to computers and the ways the learning and the teaching of mathematics as well as this discipline itself was affected by technology. A second edition of the book issued from this study was prepared by B. Cornu and A. Ralston and published in 1992 in the Science and Education Series of UNESCO. As described in its introduction, the UNESCO book addresses the importance of the changes introduced by technology in professional mathematical practices and makes suggestions for new curriculum elements based on these new methods of doing mathematics. It is pointed out that even if these suggestions are judged by the reader to be stimulating and even persuasive as well as reasonably grounded, it is nevertheless the case that "such suggestions are fundamentally speculative at the level of large scale implementation – by which we mean that converting them into a well-developed and tested curriculum for the typical teacher and the typical student is still a major challenge."

Since that time, more and more sophisticated technological tools have continued to be developed for supporting the learning and teaching of mathematics, and their use is today encouraged by the K-12 mathematics curriculum in most countries. Nevertheless, in spite of the existence of an increasing amount of positive small-scale experiments, the real nature of the effect of technology on mathematics education in the large remains under discussion. The problems raised in the first ICMI study have not been solved, and the discourse of those who think that the impact of technology is globally negative and ask for a strict limitation of the use of calculators and software, and even for their banishment from mathematics education in the early grades, is opposed by those who consider that it does not make sense today to think about mathematics learning and teaching without taking into account the existence

of technology and without trying to benefit from the real and increasing potential it offers for mathematics education.

Thus the first set of questions we propose to raise is:

*Up to what point should the changes introduced in social and professional mathematical practices by technology be reflected in mathematics education?*

*What does technology have to offer today to K-12 mathematics education and why does it seem so difficult to have it benefit mathematics education in the large outside experimental settings?*

*What could be done in order to improve the current situation?*

*Is a strict limitation on the use of calculators and software a reasonable solution?*

**Skill building.** Every one of us certainly agrees that mathematical learning, as with any kind of human apprenticeship, requires skill building and also that it requires much more than that. In recent decades all over the world, K-12 mathematics curriculum developers, influenced by constructivist and socio-constructivist epistemologies of learning, by the results of cognitive research on learning processes, and also by the observed limitations of students' achievements in mathematics, have stressed the necessity of moving some distance from teaching practices seen as too focused on drill and practice, and of getting a better balance between the technical and conceptual facets of mathematical learning. K-12 mathematics curricula have given increasing importance to exploration and work on rich and open problems in order to help students understand better the reasons for mathematical conceptualizations, and these conceptualizations themselves. They have also promoted teaching strategies that try to give more importance to the personal and collective elaborations of students in the development of classroom mathematical knowledge. Once more, the global effects of these curricular changes on K-12 mathematics education are a matter of controversy. Voices have arisen asking for a radical change in the role to be given to the learning and mastery of algorithms, with the long division algorithm often appearing as emblematic of the desired changes. In a similar vein, other voices denounce the dangers of what they see as a new "back to basics" program and the inability to understand that mathematics teaching has to take into account social and technological evolution, and the changes in scientific and mathematics culture needed in our societies today.

Thus a second set of questions:

*What is the pertinence of the opposition between skill learning and the exploration of rich problems? Between techniques and concepts?*

*What is the right balance to be achieved in K-12 mathematics education between the different facets of mathematical activity?*

*How can this balance be achieved and what are the respective mathematics responsibilities to be given to the teachers and the students?*

**Test and assessment.** We are all aware of the influence that the form and the content of assessment have on any form of education and, thus, on K-12 mathematics education. We are also aware of the increasing importance given to national and

international testing, as reflected for instance by the coverage in the media of the PISA enterprise of the OECD and TIMSS, and the influence that these results are taking in educational policies. The importance to be given to external assessment versus internal assessment, to international comparisons and standardized testing, to the effect of assessment on the mathematics learning of students, and to the effect of systematic testing on educational systems are all controversial issues, as are the discussions generated by the "No Child Left Behind" legislation in the US. Thus our third set of questions:

*How can we correctly reflect in assessment what we wish to achieve through mathematics education?*

*Is standardized testing ever useful? For what purpose? Under what conditions?*

*What exactly is tested by international assessments such as PISA or TIMSS? Do they represent the mathematical culture that we want K-12 mathematics education to develop? What can we learn from them?*

## A reform perspective

by *Anthony Ralston*

**Preamble.** I believe passionately that the K-12 mathematical curriculum, as it exists in most countries, needs substantial reform. But, because the notion of "reform curriculum" means different things to different people, I think I should begin by delineating the perspective from which I view the reform of mathematics curricula.

First, neither constructivism nor its antithesis plays any role in my beliefs about reform. Thus, arguments about such things as discovery learning or about whether rote memorization is a good or a bad thing will play no role in what follows here.

Next, I believe strongly that mathematics should be a demanding subject in all grades, probably the most demanding that students study in each grade. Thus, any suggestion that mathematics should be "dumbed down" at any level is anathema to me.

Finally, I believe, as surely all attendees of ICM2006 do, that mathematics is a dynamic, growing subject with ever-changing opinions on what is more important or less important mathematical subject matter. But, perhaps in contradistinction to many ICM attendees, I think this perspective must include not just areas of research but also the entire K-12 curriculum. Thus, what is important subject matter in K-12 mathematics today may be – I think, is – different from what it was yesterday and no doubt is different from what it will be tomorrow.

**Technology.** Mathematicians were slower than almost all scientists and engineers to make computing technology a part of their everyday working lives[1]. Nowadays, how-

[1]Mathematicians' attitudes about technology as well as about other matters considered in this paper are discussed in A. Ralston, Research Mathematicians and Mathematics Education: A Critique, *Notices Amer. Math. Soc.* **51** (2004), 403–411.

ever, many research mathematicians use computers routinely for number crunching, for accessing computer algebra systems, and for using a variety of other computer software for both professional and non-professional purposes. Still, it appears that, even as most mathematicians now recognize computer technology as an indispensable tool for doing mathematics research, they resist the notion that computers should be widely used in mathematics education on the grounds that what is important in K-12 mathematics education has hardly changed in – dare one say it? – the past century.

The crucial aspect of whether – and, if so, when – computers or calculators should be used in K-12 mathematics education has resulted in more controversy than any other aspect of mathematics education. I have written elsewhere about my belief that pencil-and-paper arithmetic (p-and-p, hereafter) should be abolished from the primary school curriculum in the sense that no level of proficiency in it should be expected of students although teachers should be free to use p-and-p examples as they wish. Since I published a paper to this effect in 1999[2], I have seen no reason, cogent to me, to back off from this position[3]. Of course, you must understand that, keeping in mind the position stated in the Preamble, I would replace a p-and-p-based curriculum with a rigorous curriculum emphasizing mental arithmetic while allowing free use of calculators in all grades. The goal of such a curriculum, as with any arithmetic curriculum in primary school, would be to achieve the *number sense* in students that would enable them to proceed successfully with secondary school mathematics.

I cannot provide any evidence why a mental arithmetic, calculator based curriculum would work because it has not been tried but neither has anyone adduced a compelling reason why it should not work. Moreover, no one can give good reasons to continue the classical p-and-p curriculum which has never worked very well and must now be working more poorly than ever, given that almost all students will recognize that the classical curriculum tries to teach them a skill without practical value any longer. In addition, since students will almost universally use calculators outside the classroom, forbidding them inside the classroom is self-defeating. Only if it can be argued that a p-and-p-based curriculum is clearly the best way to prepare students for subsequent study of mathematics, can such a curriculum be justified in the 21st century. But I don't believe any compelling argument of this nature can be made; all such attempts I've seen can only be described as feeble.

Learning *arithmetic* – what the operations are, when to use them, place value etc. – is crucial for the study of all subsequent mathematics. But not only is p-and-p calculation not necessary to the goal of learning about arithmetic, it is positively destructive of that goal.

[2]A. Ralston, Let's Abolish Pencil-and-Paper Arithmetic, *Journal of Computers in Mathematics and Science Teaching* **18** (1999), 173–194.

[3]An area of particular controversy is whether the traditional long division algorithm should be taught at all. My opinion on this can be found in A. Ralston, The Case Against Long Division, http://www.doc.ic.ac.uk/∼ar9/LDApaper2.html.

**Skill building.** Skill building is of value in K-12 math education only insofar as the skills learned facilitate the doing of mathematics and the subsequent study of mathematics. It must be recognized that (almost?) none of the skills traditionally taught in K-12 mathematics have value any longer as skills per se. But, following the foregoing argument, if p-and-p skills are not to be taught, it is imperative that learning substantial mental arithmetic skills should be a major goal of primary school mathematics. These skills should include not just the obvious ones of immediate recall of the addition and multiplication tables and the ability to do all one-digit arithmetic mentally but also the ability to do substantial amounts of two-digit arithmetic mentally.

It needs to be emphasized that the development of good mental arithmetic skills requires good coaching from a teacher about the various algorithms that can be used to do mental arithmetic and then hard work by the student. Mental arithmetic, say two-digit by two-digit multiplication, is hard[4]. Learning to do it well involves much practice during which the student will decide which algorithm is most congenial to her/him. Teaching and learning mental arithmetic must be a joint responsibility of teacher and student.

One advantage of learning to do two-digit arithmetic mentally is that such a skill requires a good grasp of place value, an important aspect of primary school mathematics in any case. Another advantage is that automaticity or near automaticity in one- and two-digit mental arithmetic allows students to be given demanding word problems. More generally, sound technique in mathematics must always be the forerunner of good conceptual understanding.

A word about fractions. Primary school is certainly the place where students should learn about fractions, reciprocals and the conversion of fractions to decimals and vice versa. But I doubt it is the right place for them to learn fraction arithmetic except perhaps in some simple cases. When students get to secondary school, they will need to do arithmetic on algebraic fractions. This would be the best time to teach the arithmetic of both numeric and algebraic fractions since, in any case, few students will remember the arithmetic of numeric fractions from when it may have been taught in primary school.

**Test and assessment.** The standardized testing culture that has swept over the United States and is rapidly advancing in the United Kingdom and other countries is perhaps the most serious threat of all to quality mathematics education throughout the world. The standardized testing requirements in the U. S. No Child Left Behind (NCLB) legislation will have the almost certain result that NCLB will be that act most destructive of quality education ever passed by the United States Congress.

The pressure on schools and teachers for students to achieve high grades on stan-

[4]Is there any reason why learning to perform two-digit by two-digit multiplication mentally should not be a realizable goal of school mathematics? I don't think so. Some positive evidence is contained in D. Zhang, Some Characteristics of Mathematics Education in East Asia – An Overview from China, in *Proceedings of the Seventh Southeast Asian Conference on Mathematics Education* (N. D. Tri et al., eds.), Vietnamese Mathematical Society, Hanoi, 1997.

dardized tests always leads to a number of evils that have been widely catalogued. Three of the worst are teaching to the test, emphasis on routine mathematics at the expense of advanced topics and problem solving, and the inordinate amount of time taken to prepare for these tests which not only drives important mathematics from the classroom but also often means decreased attention to science, history and the arts generally. Moreover, the inevitable result of emphasis on standardized tests is that scores increase without any concomitant increase in learning[5].

I am not opposed to testing students. Quite the contrary. It is by far the best way for a teacher to assess the learning of her/his students. But in the not quite antediluvian past, the assessment task was left to individual teachers in their classrooms. Why have things changed so much? The answer in the United States and other countries appears to be that educational administrators, politicians and even parents no longer trust classroom teachers to do the assessment job themselves. This is not altogether wrongheaded. As I and others have argued elsewhere[6], the quality of K-12 mathematics teachers in, at least, American schools has been declining for half a century and, while there are still many excellent mathematics teachers in American schools, too many are not competent to teach the mathematics they are supposed to teach[7]. But, if this is so, standardized testing will only exacerbate this problem by convincing too many who might become teachers that there is no scope for imagination or initiative in school mathematics teaching.

The crucial point is that there is no sign whatever that standardized testing has ever been effective in increasing student learning. If all standardized testing in all subjects were abandoned at all levels short of university entrance, this would be an immediate boon to all education.

I should say a word about TIMSS and PISA. Since both of these are essentially diagnostic tools given to a sampling of students, they do not suffer from most of the strictures above. For example, teachers cannot teach to the test because at most a very few students in each class will take these tests.

## A traditional perspective

by *Ehud de Shalit*

The author of this essay is a mathematician who found himself involved in questions of mathematical education despite lack of formal background in the discipline. I make

[5] See A.Ralston, The Next Disaster in American Education. *The Sacramento Bee*, 1 December 2002 (http://www/doc.ic.ac.uk/∼ar9/NextDisaster.html).

[6] See A. Ralston, The Real Scandal in American School Mathematics, *Education Week*, 27 April 2005 (http://www/doc.ic.ac.uk/∼ar9/TeacherQual.html) and V.Troen and K.C.Boles, *Who's Teaching Your Children? Why The Teacher Crisis is Worse Than You Think and What Can Be Done about It*, 2003, Yale University Press.

[7] Indeed, while mathematicians generally choose to argue about something we may be knowledgeable about – curriculum – a far more serious problem with mathematics education in most countries is the inability to attract enough high quality people to teach school mathematics.

no claim to know the literature of science education, and I am surely ignorant of important studies in the area. I nevertheless dare to participate in the discussion because I believe that educators and scientists alike should bear the burden of shaping our children's education, listening to and learning from each other's point of view. It is deplorable that recently, the two communities of math educators and mathematicians have been poised against each other, mostly, but not always, the first being portrayed as "reformers", the latter as "traditionalists"[8]. Emotions have run high, and the two communities found themselves in conflict, instead of joining forces towards a common cause.

This being said, I also want to apologize for not having equally strong opinions on all issues. In fact, I will address two of the points raised by Prof. Artigue (*the impact of technology* and *skill building*), and make only minor remarks on the third (*tests and assessment*), which I consider to be a political issue more than a mathematical or educational one. I hope to make myself clear in due time. Moreover, depending on the circumstances, these three sample topics, important as they be, need not have a decisive affect on the success or failure of a given system. External factors such as class size, discipline, teacher training and resources, which vary considerably from state to state, are often of greater importance than questions of curriculum and methodology. However, unable to influence the first in a direct way, we, mathematicians, focus on the latter.

My starting point is that mathematics teaching *need not* necessarily follow the rapid changes in the usage of the subject in society or technology. Its prime role is to imbed in our children a basic sense for, and understanding of numbers, symbols[9], shapes and other "mathematical objects", together with skills in manipulating these objects, that are needed to develop what is commonly called "mathematical reasoning". The objects to be chosen, the time devoted, and what is taught about them, should be dictated by their prominence in mathematics, and their epistemic and pedagogical value, and less so by their frequency in daily life. This does not mean, of course, that examples and applications of the material should not be updated and modernized, but I do preach respect for the traditional way of teaching, because more than it was based on old *needs*, it was based on inherent *values* that have not changed with time. A well-trained mathematical mind is a highly flexible system. If brought up correctly, it will find its way to adjust and analyze mathematical scenarios very different from the ones that surrounded it initially, while it was being shaped.

As an example, consider the well trodden issue of long-division. I believe that the standard algorithm should be taught in elementary school, thoroughly explained and practiced *not* because of its practical value. Rather, it is important because it enhances the understanding of the decimal system, of zero as a place-holder, of the Euclidean algorithm, and is a necessary precursor for polynomial arithmetic. It allows

[8] Those unaware of the ongoing controversies, can read David Ross' article *Math Wars* (www.ios.org/articles/dross_math-wars.asp) and the references therein.

[9] A. Arcavi, Symbol sense: informal sense-making in formal mathematics. *For the Learning of Mathematics* **14** (3) (1994), 24–35.

the child to review the multiplication table and develop number sense while doing something else, more advanced, so it makes learning more interesting. Moreover, it is natural. It therefore agrees with *mental arithmetic*, and helps us visualize the process involved in division. For these and for many other reasons, well explained in[10] and not mentioned here for lack of time, long division is a pedagogical gold mine. The abandoned algorithm for extracting the square root, often cited to justify abolishing long division as well, is in comparison a pedagogical swamp, was abandoned for this reason, and not because it became obsolete.

Respect for traditional values in education has another advantage, that new theories are tested gradually, and radical potentially damaging changes are avoided. An ailing educational system need not be ailing because its underlying principles or methods are old-fashioned, and *reform* in itself is not an automatic cure, even where needed. More than often, the reason for failure is that good old principles stopped being implemented correctly, for various sociological reasons on which I do not want to elaborate here.

The second general remark is that I do not believe in teaching in vacuum, or in a content-empty environment. Learning must focus on concrete concepts, methods, algorithms if necessary. Insight and creativity come with variations on a theme, not where there is no theme. Teaching "how to solve it" is not synonymous with dry cookbook mathematics. It can be fun and enlightening. Constructivism[11] has led some educators to minimize teacher's intervention in the learning process. Such an approach may be tried on a single-time basis, through enrichment activities. But it is time consuming, with the average teacher may lead to fixation of mistakes, and for anyone but the brightest students can be very frustrating. We simply cannot expect the children to come up with the great discoveries of arithmetic and geometry, let alone calculus, by pure exploration. A fundamental feature that distinguishes human beings from animals is that we can learn not only from our own experience, but also from that of our ancestors. To be illustrative, I think of the art of teaching as give-and-take. The teacher delivers a package of knowledge, bit by bit, each time taking back from the students their responses, their reflections, their mistakes. On these she or he builds up, shaping and manipulating the dialogue, until a deep understanding and the desired proficiency are achieved. To believe that these can spring up spontaneously, just by setting the stage and giving a slight stimulus, is to assume too much.

Finally, a word about the term *conceptual thinking.* It is often brought up by advocators of certain approaches in education to distinguish their goals from those of others, who – so it is to be understood – lead to lower level thinking. I don't know of any kind of thinking that is not conceptual. Abstraction, in language or in mathematics, making generalizations, or conversely, looking for examples, testing predictions and searching for the right vocabulary to communicate our mental processes, are all instances of conceptual thinking, namely thinking in terms of concepts. The contro-

[10] *The role of long division in the K-12 curriculum,* by D. Klein and J. Milgram, ftp://math.stanford.edu/pub/papers/milgram/long-division/longdivsiondone.htm.

[11] *Constructivism* is the cognitive theory based on the idea that knowledge is constructed by the learner.

versy, in my view, is not about whether conceptual thinking is more or less important than basic skills, but whether acquiring those skills is part of conceptual thinking, as I want to argue, or not[12].

**Skill building.** Drill and practice. Like a swimmer or a pianist the student of mathematics has to absorb great ideas, but also to practice hard to be able to use them efficiently. Contrary to the common belief, the primary reason for skill building is not the need to perform mathematical tasks with great precision and speed, because in our age these human qualities have been surpassed by machines, and we need not regret it.

I see three important reasons to promote skill building. The first is that skill building is essential for forming a sense for numbers, and later on for symbols, functions, or geometry. Subtle instances of insight and analogy, are woven into a web of images and associations in one's mind, and cannot be classified and taught sequentially. They are only the product of long-term practicing and skill building. The distance between knowing something in principle and mastering it is very big in mathematics.

The second reason is that our mind functions on several levels simultaneously, and we are not always aware of the sub-conscious levels that are "running in the background", if I may use a metaphor from computer science. To be able to free the thinking creative part of our mind, to let it form the web of links needed for exploration and discovery, we must defer to the background more routine tasks, that in the past occupied the front, but should now be performed semi-automatically.

The last reason in favor of skill building is rarely mentioned, and might seem to you heretical. Experience has taught me that many children, especially those suffering from math phobia or learning disabilities, are highly rewarded psychologically by success in performing a routine algorithm, such as long division, and by acquiring proficiency in a given task. Such a reward for them is a higher boost than the ability to understand the theory behind it, or the fun in discovering a method by themselves. Once they know the "how" they are lead to ask "why". I would not rule out an approach that harnesses skill building before understanding, if the teacher feels that it suits the child better. Needless to say, both aspects should eventually be covered, and bright children who have mastered the technique and eagerly ask good questions should not be hindered.

Skill building is often confined – by those promoting "conceptual understanding" as a substitute – to algorithmic skills, and algorithmic skills are then downgraded to mere rote. While algorithmic skills are very important, and the algorithmic approach to arithmetic is something to be cherished, as I made clear in the example of long division, mathematical skills are by no means only algorithmic. The ability to translate a word problem into arithmetic, or later on into algebra, is a well-defined skill. Analyzed closely, it consists of many sub-skills, like distinguishing relevant information from irrelevant data, choosing the variables cleverly, translating prose into algebra, and

[12] See *Basic skills versus conceptual understanding, a bogus dichotomy in mathematics education,* by H. Wu (http://www.aft.org/pubs-reports/american_educator/fall99/wu.pdf).

finally the technique of solving, say, a system of linear equations. Geometric skills, drawing to scale, recognizing hidden parts, decomposing and assembling figures, as well as computational skills of area and volume, form another category.

Given my earlier criticism of the constructivist approach, it will not come as a surprise that I believe in *standard algorithms*. It is true, students who come up with their own (correct!) algorithms should never be scolded, but eventually standard algorithms are more efficient, help in the process of automatization of algorithmic tasks discussed above, and also serve an important purpose of establishing a common language.

As an example, after a certain amount of preparatory classes meant to clarify the distributive law, which may include both manipulations of brackets and geometric representation by rectangles, I would simply *teach* the standard algorithm for "vertical multiplication". I do not see the benefit in letting the students make up their own algorithms, where inevitably many will multiply units with units, tens with tens etc. and then add them up. To expect from fourth graders to come up with what was one of the main achievements of the Hindus and the Arab scholars in the Middle Ages is unrealistic. However, once the algorithm has been explained, both the *how* and the *why*, and practiced, there are many subtle questions that can be left for discussion and discovery. Would it always be more economical to apply the algorithm as is, or perhaps switching the position of the two numbers to be multiplied saves some operations? How can we estimate in advance the order of magnitude to save us from potential pitfalls, what double-checks should we make etc. etc.

Anthony Ralston, in his paper "*Let's abolish pencil and paper arithmetic*"[13] advocates to abolish basic algorithmic skills that were the bread-and-butter of elementary school arithmetic for centuries. He summarizes his discussion by saying "*Since no one argues any longer that knowledge of PPA* (*pencil-and-paper arithmetic*) *is a useful skill in life* (*or, for that matter, in mathematics*)*, the question is only whether such 'deprivation' could leave students without the understanding or technique necessary to study further mathematics.*"

Even if we accept the premises, doubtful in my mind, I think he misses the point. First, any attempt to separate understanding from technique is artificial. Second, it is the miracle of the subject that the very same principles underlying higher mathematics, or fashionable topics such as geometry and statistics, often quoted as benefitting from the time freed by the abolishment of PPA, are manifested in their purest and simplest form in these basic skills. A person not knowing how to calculate what $\frac{3}{5}$ of $4\frac{2}{7}$kg of rice are, will not have the technique to analyze the changes in the school budget of England. Nor will he have developed enough intimacy with numbers to estimate those changes in advance, or tell instantly, if his calculator-based computations make sense or not.

As a substitute to PPA, Ralston elevates *mental arithmetic* to a central position in his proposed program. To give examples, he expects elementary school students to

[13] In *Journal of Computers in Mathematics and Science Teaching* **18** (2) (1999), 173–194.

perform two-digit by two-digit multiplication mentally, and high-school students "to be able to factor a variety of three term quadratics mentally". To succeed, he admits, mental arithmetic should be practiced in calculator-free environment. I wholeheartedly agree with the importance of mental mathematics, both for developing number (and symbol) sense, and for practical purposes, estimation and checks. I do not understand though the reluctance to allow one to put things on paper. PPA does not contradict mental arithmetic. It records it, something we shouldn't be ashamed of, and without which we cannot communicate or analyze peacefully what we have done. It also helps in visualizing graphically the steps carried in our mind, and it allows us to organize little mental steps into a larger procedure, without putting too heavy a burden on our memory.

**The impact of technology.** There are two somewhat separate questions here. The first is to what extent should the curriculum be dictated by the way mathematics is used in technology, and to what extent should we conform to requests coming from the changing society, rather than teach basic principles and skills[14]. I have expressed my opinion about this question in the opening statement. Contrary to the quotation just mentioned, I believe that education in the large, ought to enrich the child and teach him or her basic skills, knowledge, values and understanding that are *absolute*. If carried out correctly, they will inevitably produce a knowledgeable, thinking, skilled and creative citizen. If tailored to the needs of a certain industry or society, rather to these absolute values, they will produce poor technocrats.

The second question involved in the issue of technology is to what extent do technological innovations influence the way we teach in class. This concerns mostly calculators in elementary school, but also the use of graphic calculators in calculus, Excel sheets in statistics and computers in general.

It would be wrong to ignore the changes in technology, the challenges that they bring about, and the opportunities which they provide for demonstration and practice. However, we should clearly define our *mathematical goals*, phrase them in mathematical terms and avoid as much as possible slogans, even if we agree with their general mood. We should distinguish mathematical goals from *educational goals*. Only then may we look at issues of technology, and decide whether they help steering math education the right way, or not. To understand the effect this *process* of analyzing the role of technology has, consider the following example.

*The child will be able to derive qualitative and quantitative information form graphs such as a graph displaying the change of temperature with altitude.*

I hope everybody agrees with the statement as a basic goal of K-12 mathematical education. The terms *qualitative and quantitative information* demand further elaboration, but I shall not go into it. Now suppose we have to choose between graphic

[14] Judah Schwartz, in his essay *Intellectually stimulating and socially responsible school curricula – can technology help us get there?* writes: "By far the dominant expectation of education in most societies, at least as articulated by political leaders and by the print and electronic press, is to prepare people for the world of work."

calculators and pencil-and-paper, for a first encounter with graphs as a tool to communicate observations and measurements. Have we phrased our goal as *The child will learn to appreciate the use of graphs in natural sciences such as climatology,* we might be inclined to favor graphic calculators. They are attractive, have the fragrance of modernism, and provide vast opportunities that pencil and paper do not provide. But are they as good in conveying first principles? Can the child learn from them where to choose to draw the axes, what scale to use, and how to plot the data? Even the mere physical act, the hand-eye coordination in handling the ruler, is fundamental in my eyes to the learning process. Feeding the data into a calculator, then pressing a button, produces wonderful results, but has its pedagogical drawbacks. This does not mean I would discard graphic calculators. At a later stage they can be helpful in adding visual affects that are difficult to achieve without them – zooming in and out, changing scale, flipping the axes, to name a few. I would simply be careful in my choices, which tool to apply first in class.

While I can see the benefits of graphic calculators in middle-school in studying functional dependence, I am much less excited by the use of ordinary calculators in elementary school arithmetic. At this early stage building number sense is the teacher's number one task. I still have to hear one good argument in favor of calculators in this regard. I need no proof for how destructive they can be. Even those opposed to PPA value mental arithmetic, as means for estimation and double-check. Unfortunately we have witnessed all around us, at school and at the university, a significant decline in these skills over the last two decades, that I can only attribute to the introduction of calculators. Whoever agrees that skill building is an important component of mathematical understanding, and cannot be separated from conceptual thinking, must also confess that calculators at an early age are impeding normal mathematical development.

Those advocating early use of calculators necessarily advocate early emphasis on decimals at the expense of simple fraction arithmetic. Is it right? From the point of view of technology, simple fractions are probably obsolete. From the point of view of their pedagogical value, in understanding basic principles of arithmetic, such as ratio and proportionality, or unique factorization, and in anticipating similar structures in algebra, they are indispensable. For all these reasons I would happily ban the use of calculators in class until a solid understanding of arithmetic has been achieved, and the associated skills have been built. I am not in a position to judge whether these happen at the end of fifth, sixth or seventh grade, but the general spirit is clear to me.

Two arguments that are often heard in favor of technology at school are (a) that to oppose it is a lost battle and (b) that technological skills are so important in society, that not teaching them early would deprive certain children, especially those coming from poor families, of future opportunities. To the first argument I have nothing to say, except that if we adopt it we shouldn't be here today. As for the second, I must admit I am very sensitive to the social obligations of educators. Fortunately or unfortunately, home computers are not anymore the sign of a privileged family, much as TV is not a sign of progress, and I honestly believe that mastering Excel carries no

more mathematical value than mastering a microwave manual.

Finally, a comment on a growing trend among educators to write computer-assisted material or use sophisticated software, such as Dynamic Geometry Software, in conjunction with the standard curriculum. Some of it is very well made, enriches the learning environment, and I have no objection to computers per se. But from the little I have seen in this medium, in terms of cost-benefit analysis, the added value is not big, so I will never substitute a computer for the informal contact with a talented teacher. When it comes to political decisions, where to invest the money, my preferences are clear, at least in the country I come from.

To this one should add that computers are *not just a tool* to convey the same message more efficiently. Learning in a computerized environment affects our perception of the objects of study. Good or bad, this has to be analyzed before a new computer-dependent program is adopted.

**Tests and assessment.** Testing is a controversial issue among educators. There is a whole separate session at ICM2006 devoted to two competing international comparative tests – PISA and TIMSS. It is well known that certain educators detest testing altogether, while others build their whole curriculum around it. The more I think on it the more I become convinced that testing is a *political issue,* namely an issue that has to be decided by policy makers, based on an ideology, and taking into account factors that are only remotely related to math education. An excellent example is the controversy around US government act "No Child Left Behind" from 2002.

Testing takes various shapes. It can be comprehensive or diagnostic. You may test accumulated knowledge, or you may test the potential of a student. You may test algorithmic skills, or you may test insight and creativity. (Even though, as I said above, the former are indispensable for developing the latter, when it comes to testing, they are quite different.) A math test can be phrased in formal language or in prose. A test can be confined to one school, to one state, or to a nation. Studies show that the framework within which a problem is set affects the rate of success, and this effect changes with gender and origin. I have not mentioned more radical views which claim that western societies test only "western intelligence", and blame the relative failure of certain minorities on the dominant western frame of mind.

Testing can also serve a variety of goals. It may be purely informative, or can serve to rank, for purpose of admissions or stipends. It can test the students, but it can also test teachers success, and inform them of potential problems. Testing can be used for comparing alternative programs, or it may be needed to impose discipline on students, and on educators.

I regard all these goals as legitimate, and every kind of test welcome, *provided* one knows what kind of information to expect form it. A company recruiting civil engineers will probably test different mathematical skills than a software developer, and a matriculation exam summarizing the achievements of a student in high school need not be similar to entrance exams at a university, where a greater emphasis may be put on the student's potential and creativity.

Obviously teaching should center on the subject-matter and not only prepare for tests, but a change in curriculum often requires frequent testing to make sure the message gets across. Where there is a good tradition, and little intervention is needed, testing can be kept at a minimum. Under different circumstances tests may become a central integral part of the program.

Mathematical education will benefit from an open discussion of the issues raised here and others. It is important that mathematicians will express their views, paying respect to educators, and share their convictions with them. It is important to get to the bottom of examples, and refrain from vague statements. It is important to let changes happen, with ample time if needed, but refrain from changes that are made for the sake of reform alone. Changes must be gradual, and objectively followed. Most new ideas succeed when pushed vigorously with a small group of dedicated teachers, and with a fat budget. The problem is what happens when a case-study involving a dozen schools is over, and those ideas are adopted across the board. Do they carry enough weight to keep the momentum? Are the teachers qualified to spread the gospel?

## Concluding remarks

by *Michèle Artigue*

In this panel session, we focus on only a few of many possible controversial issues: technology, skill building, test and assessment. For each theme, as the coordinator of this panel, I articulated a short list of questions and asked the two panelists to express their positions. As could be expected, these positions are quite different, as they probably would be on the following fundamental issues: What do we want to achieve today through elementary and secondary mathematics education? What mathematics should be taught in order to achieve these goals? And how should we teach this mathematics? What are the relationships between mathematics education and the society at large?

K-12 mathematics education does not serve a unique goal. It aims at the transmission from one generation to the next one of a cultural heritage, which is one of the great achievements of humankind, and at the development of the logical reasoning competence which is so strongly attached to it. It aims at providing students with efficient means for understanding the world in which they live, and play their proper role in it. It aims at preparing and making possible the training of future mathematicians and scientists who will be in charge of the development of mathematics and scientific knowledge, and of the teachers who will have the responsibility of the transmission of this knowledge. Such ambitions can be seen as general invariants, but what is certainly not an invariant is the way we understand each of these components, at a given moment, in a given context; the way we understand the adequate balance between these, and last but not least what we consider the most appropriate strategies for achieving these ambitions. Educational systems try to adapt to this variation mainly

through curricular changes. The turbulence and controversies we regularly observe attest to the difficulty of this adaptation, and also the fact that the curricular lever chosen is not necessarily the best one.

As a mathematician who has worked in the area of mathematics education for more than 20 years now, I am struck by the simplistic way in which the complex problems that K-12 mathematics education faces today are often approached; the existing tendency to give the same value to rough affirmations and anecdotes as to well founded analysis and discussions; the persistent belief in the existence of easy and immediate solutions; the brutality of the changes imposed on educational systems, without considering their real cost, and without developing the necessary means for understanding observed success and failure. Education in the large seems a world where opposition and slogans are in front of the stage, hiding shades of meaning and dialectic visions. Slogans used by those favoring or opposing the use of technology, opposing positions on the development of concepts and of techniques are typical examples of these. Even educational research, in its attempts to reach a larger audience, does not always avoid undue simplifications and oppositions[15].

For improving the current situation, we need to overcome such a state, and will try to do so in the ICM panel associated with this contribution. But in order to solve the complex and difficult problems that K-12 mathematics education faces today in many countries, we need to do more than express well-articulated positions on controversial issues and the rationale for these. We need coherent and long-term programs, taking into account the specificities of the different contexts and the existing material and human resources. We need exchanges on our respective situations and experiences for improving these, being aware that solutions in mathematics education are always local ones in terms both of space and time, that it is nearly impossible to determine what is the exact field of validity of a given observed result, the field of extension of a given regularity. We need the collaboration of all those who are involved in mathematics education: mathematicians, mathematics educators, teachers and teachers educators, each of whom can contribute different kinds of expertise. One of the ambitions of ICMI, through its series of ICMI Studies, is to foster such exchanges among all those interested in mathematics education and to make clear what is the state of the international reflection on some selected critical issues, what has been achieved and what is needed[16].

I would like to add to these short comments that curricular choices are certainly important but that the dynamics of complex systems, such as educational systems, is not just a matter of curricular choices. The quality of teachers and of teacher education, both pre-service and also in-service, is certainly as important if not more

[15] See for instance M. Artigue, Learning Mathematics in a CAS environment: The Genesis of a Reflection About Instrumentation and the Dialectics Between Technical and Conceptual Work, *International Journal of Computers for Mathematics Learning* **7** (2002), 245–274.

[16] Themes for the most recent ICMI studies have been: The teaching and learning of mathematics at university level, the future of the teaching and learning of algebra, mathematics education in different cultural traditions – a comparative study of East Asia and the West, applications and modelling in mathematics education, the professional education and development of future teachers of mathematics.

important than curricular choices. From this point of view, the fact that mathematics educational research, which has for a long time focused on students, has in the last decade paid increasing attention to the teacher and to teacher education, is a promising evolution. Research tries today to understand the coherence underlying observed teachers' practices[17] the kind of precise mathematical knowledge the profession requires, how it can be developed, how this mathematical knowledge interacts with other forms of professional knowledge, and how these complex interactions influence teachers' practices and students' learning. Interesting results begin to be obtained, which at the same time help us understand better what can be realistic dynamics for change. The final success of the enterprise requires the collaboration of those with diverse expertise[18].

[18] An example of such a collaboration is given by the Mathematics and Sciences Research Institute in Berkeley which has created an education advisory board and organizes workshops involving mathematicians, mathematics educators, teachers, policy makers etc. on critical issues. The themes of the first two were the assessment of students' mathematical knowledge and the mathematics knowledge for K-8 teachers.

*Panel B*

# What are PISA and TIMSS? What do they tell us?

Lee Peng Yee (*moderator*)

Jan de Lange and William Schmidt (*panelists*)

**Abstract.** This is a panel discussion on PISA and TIMSS, two international comparative studies in educational achievement. The panelists are Jan de Lange of the Freudenthal Institute, the Netherlands, for PISA, and William Schmidt of Michigan State University, the United States, for TIMSS, with Lee Peng Yee of National Institute of Education, Singapore, as a moderator. They are to explain the nature, the aims, and the conclusions of the two studies, and to argue over their relative merits. This document contains three initial statements from the above-mentioned participants respectively.

**Mathematics Subject Classification (2000).** Primary 00A35; Secondary 00A05.

**Keywords.** PISA, TIMSS, comparative studies.

## Introduction

by *Lee Peng Yee*

One area of interest in education is comparative studies in educational achievement, in particular, in mathematics, science and reading. There are two such international studies involving mathematics, namely, PISA and TIMSS. PISA stands for the Programme for International Student Assessment. It is better known in Europe. TIMSS stands for the Trends in International Mathematics and Science Study. TIMSS was previously known as the Third International Mathematics and Science Study. Each study of PISA or TIMSS involves approximately 50 countries and thousands of students in each participating country. The studies generated volumes of publication and numerous related research projects.

The fact that some Asian countries topped the achievement list in TIMSS amazed many people and drew the attention of the industrial countries. Consequently it induced the study on these high-performing Asian countries, namely, China, Korea, Japan, and Singapore. Further a country could do well in TIMSS but not in PISA. This phenomenon is now known as PISA shock. Hence in addition people are also interested in the comparison of these two international studies. The impact of PISA and TIMSS has gone way beyond the mathematics and science community. It even

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

influences the policy makers of a country. It is timely that we have a panel discussion on the topic.

**TIMSS.** The study was commissioned by IEA, the International Association for the Evaluation of Educational Achievement. The first round of TIMSS took place in 1995 and the second round in 1999. It was the third round that made TIMSS famous world wide It collects data on educational achievement from students at the fourth and eighth grades. It also collects extensive information from students, teachers and school principals about the teaching and learning of mathematics. The test items are matched against those in the standards or syllabus. Then the data are analyzed and the reports published. The next round will take place in 2007. For details, see [1].

**PISA.** The study was initiated by the OECD countries. OECD stands for Organisation for Economic Co-operation and Development whose member countries were originally countries from Western Europe but now they are all over the globe. PISA was conducted every three years in 2000, 2003 and the next one in 2006. The tests are administered to 15-years-old students. The tests are supposed to assess how well students are prepared for their full participation in society. Similarly, the data are analyzed and the reports published. As we can see, PISA differs from TIMSS in methodology and aims. For details, see [2].

**Benchmarking.** Both PISA and TIMSS have been used by many countries for benchmarking. Roughly speaking, TIMSS is grade-based, that is, testing students of Grade 4 and Grade 8, whereas PISA is age-based, that is, testing the 15-years-old students. The 15-years-old students are those who are near the end of their compulsory education. Test items in TIMSS are more content or standards orientated, whereas those in PISA are more literacy orientated. TIMSS assesses how much students have achieved in schools. PISA assesses how well students are prepared for the outside world. Of course, this is an over-simplified view of the differences between the two studies. It does give a general idea about the two studies.

**Panelists.** They are Jan de Lange of the Freudenthal Institute, the Netherlands, speaking for PISA, and William Schmidt of Michigan State University, the United States, speaking for TIMSS. Jan de Lange is Director of the Freudenthal Institute and a full professor at University of Utrecht, the Netherlands. He was a member of the National Advisory Board of the Third International Mathematics and Science Study, and is currently Chair of the Mathematical Functional Expert Group of the OECD-PISA. William Schmidt is a professor at the College of Education, Michigan State University, and the national research coordinator and executive director of the United States National Research Center which oversees the United States' participation in the Third International Mathematics and Science Study. At the panel discussion, they are to present what PISA and TIMSS are respectively, and what they are for. Then they will discuss and possibly answer questions from the audience.

**Issues for discussion.** The issues for discussion include at least some or all of the following questions. The questions are divided into three categories. First, what are PISA and TIMSS?

- Does PISA or TIMSS really serve the purpose intended?
- Why do we need PISA when we already had TIMSS?
- What are the good points or bad points of PISA and TIMSS?

Secondly, what do they tell us?

- Is it really meaningful to use PISA or TIMSS for benchmarking?
- Some countries did well in TIMSS but not in PISA. Why?
- Both PISA and TIMSS have collected a vast amount of data. Are they useful for other researchers? What can they do with the data?

The last question above was previously raised at the International Round Table in Tokyo 2000 [3]. Thirdly, what is the future?

- The learning process of a student is a long-term affair. Perhaps the three-year cycle or four-year cycle is simply too short to measure the progressive achievement of a student. Do we need to measure so frequently?
- Will there be PISA or TIMSS 20 years from now?

This short statement serves as an introduction to the panel discussion to be held on 28 August 2006 in Madrid, Spain. Other statements from the panel speakers follow.

## TIMSS as a study of education: why should we care?

by *William H. Schmidt*

Comparative studies of education often seem to evoke a "so what?" or "who cares?" reaction. Studies of students' achievement in different countries may leave one wondering what practical importance such differences hold in the real world or work and commerce. Descriptions that highlight differences in common educational practices may appear intriguing and stimulate curiosity but may leave one wondering what the relevance is to what happens (or should happen) at the school down the street.

The value of such studies is almost assumed to be self-evident given, it seems, by the sort of attention the media frequently affords them. Reports of rankings along with comparisons of scores with countries x, y, and z reduce the entire endeavor to a sort of education Olympics or horserace. The value, obviously, lies in the comparisons! Who is on first? Who is doing it right?

As intriguing and entertaining as some comparisons may be – "Wow! Teachers in country x *never* assign homework!" or "Students in country z have to go to school on *Saturday*!" – these are practices that must be understood within their particular social, cultural, and educational contexts. Attempting to copy or transplant the practices of one country into another will not likely have the desired effect: alien grafts rarely take without extensive preparation and effort.

**Value of international comparative studies.** The real value in international studies lies not in the comparisons themselves, but in the insights we may gain into our own common practices. International comparisons hold up and frame what's familiar against a background of a considerable range of alternatives. This can lead to a thoughtful reconsideration of our rationale for doing things the way we do – or even initiate a thoughtful evaluation of something never before considered.

Many people, for example, are familiar with schools. They know what schools are and what happens in the classrooms inside the schools. Schools are schools; whether they are urban Paris or rural Montana. We began our involvement with international education research in the days leading up to TIMSS with a similar assumption about the nature of schools in various countries. We discovered that school has commonalities everywhere. What is common wherever schools are found are students, teachers, and textbooks. How these commonalities interact and work within a larger education system, however, can vary considerably. We discovered, for example, that in Norway primary teachers typically stay with the same group of students for the first five or six years of students' formal school experience. We also learned that in Switzerland, 'schools' only exist in large cities. The majority of students and teachers meet together in rooms located in buildings that are not necessarily dedicated to housing educational activities. Furthermore, school administrators and other support personnel are only found in such dedicated facilities which generally house the upper secondary grades or are located in the cities.

Clearly there are a number of ways to conduct school. The examples mentioned here were not selected to suggest that all countries change either the nature of their school buildings nor the length of time primary teachers typically work with the same group of students. Some consideration of these issues may be fruitful, but the point to be made here is that these schooling practices represent options – choices that have been made about how school gets done. The more we can see the way we do things as choices, the better position we are in to consider and construct profitable change or reform.

**What we can learn from TIMSS.** In the Third International Mathematics and Science Study (TIMSS) the focus was not on the structural aspects of school such as the previously mentioned examples, although these were a part of the study. The focus, rather, was on the substance of education, the school curriculum, the content that's at the center of what teachers and students do in schools.

Previous international studies led us to suspect that the achieved curriculum, what students demonstrate that they know, varies from one country to another. TIMSS assessed this aspect of curriculum in the context of an extensive investigation of the intended curriculum, what systems intend their students to learn, along with the implemented curriculum, what is taught in the classroom. Measurements of these curriculum aspects led to one unmistakable conclusion: the mathematics taught and studied in the schools of one country can differ substantially from what exists in the schools of another. In short, there are many ways to do mathematics education.

More specifically, this curriculum measurement in TIMSS led to some thought provoking insights into the U.S. mathematics curriculum. For example, the U.S. intends teachers and students to study two to three times the number of topics in the first through eighth grade as is typical in other countries. Consistent with this breadth, U.S. textbooks are truly first in the world in their size, weight, and scope. Not too surprisingly, given these intentions and resources, the U.S. teachers tend to spend some time on every intended topic typically without emphasizing any small number of topics as is common in other countries. All of this contributes to the "mile wide, inch deep" nature of the U.S. curriculum.

These insights were possible because TIMSS was designed from the start to examine the relationship among the various aspects of the curriculum: the intended, the implemented, and the attained. These insights have also led to several efforts to thoughtfully revise the U.S. mathematics curriculum.

So, what is the value of international study? Certainly not to obtain bragging rights for the top spot on some list nor even to identify specific practices that we may want to copy. The real value stems from obtaining a fresh perspective on the array of choices embedded in our own approach to education. Thoughtful and principled insights stimulated by examples from other systems can lead to powerful revision in our quest to provide a challenging and equitable education for all students.

## PISA: promises, problems and possibilities

by *Jan de Lange*

**PISA versus TIMSS.** According to the OECD:

> The OECD's Programme for International Student Assessment (PISA) is a collaborative effort among the member countries of the OECD to measure how well young adults, at age 15 and therefore approaching the end of compulsory schooling, are prepared to meet the challenges of today's knowledge societies. The assessment is forward looking, focusing on young people's ability to use their knowledge and skills to meet real-life challenges, rather than on the extent to which they have mastered a specific school curriculum. This orientation reflects a change in the goals and objectives of curricula themselves, which are increasingly concerned with what students can do with what they learn at school, and not merely whether they have learned it. The term 'literacy' is used to encapsulate this broader conception of knowledge and skills.

The first PISA survey was carried out in 2000 in 32 countries, including 28 OECD member countries. Another 13 countries completed PISA 2000 in 2002, and from PISA 2003 onwards more than 45 countries will participate 'representing more than one third of the world population'. PISA 2000 surveyed reading literacy, mathematical literacy, and scientific literacy, with the primary focus on reading. In 2003 the main focus was on mathematical literacy (published in 2004), and in 2006 scientific literacy will be highlighted.

It will be clear that TIMSS and PISA have a lot of similarities resulting in improper identification of the two series of studies in the media, which is undesirable and confusing. But the descriptions of the organizations that are responsible, show that they both claim similar relevance for the studies. Even for the expert it will be difficult to relate the following either to TIMSS or to PISA: 'Countries participating in this study will have information at regular intervals about how well their students read and what they know and can do in mathematics and science.' Both studies do this and do it, methodologically speaking, in a very similar way (based on Item Response Theory, IRT). Even the reporting tables in the respective reports look very similar.

If there is a problem that both studies share, it is the design of the measuring instrument in relation to the validity of the outcomes. Traditionally, validity concerns associated with tests have centered about test content, meaning how the subject domain has been sampled. Typically evidence is collected through expert appraisal of alignment between the content of the assessment tasks and the curriculum standards (in case of TIMSS) and 'subject matter' assessment framework (PISA). Nowadays, empirical data are often used before an item is included in a test.

Traditionally validation emphasized consistency with other measures, as well as the search for indirect indicators that can show this consistency statistically. More

recently is the recognition that these data should be supplemented with evidence of the cognitive or substantive aspect of validity. Or as *Knowing What Student Knows* (2001) summarized: 'The trustworthiness of the interpretation of test scores should rest in part on empirical evidence that the assessment tasks actually tap the intended cognitive process.'

One method to do this is a protocol analysis in which students are asked to think aloud as they solve problems; another is an analysis of reasons in which students are asked to provide rationales for their responses; and a third method is an analysis of errors in which one draws inferences about processes from incorrect procedures, concepts, or representations of problems. Although some of these methods are applied only after the test is administered, there is a trend that large-scale assessments like TIMSS and PISA use these methods as well. The use of cognitive laboratories to gauge whether students respond to the items in ways the developers intended has become a new instrument in the developmental process. The use of double-digit coding is another sign of interest in the process of problem solving instead of just judging whether an answer is incorrect or correct. A 'correct' or 'partly correct' score given not only to each work of the student, but also to which strategy was used or where in the process the students 'lost track'.

**Validity.** The validity of the test instrument remains a complex issue. It goes without saying that there is an inherent tension between the traditional choice of item formats, usually with very restricted time (1–2 minutes per item), and the rather ambitious definitions of what the instrument is intended to measure. But not only the concern about 'errors' plays an important role in relying so much on multiple-choice, it is also an economic issue: Many countries participating in these large cooperative studies are unwilling or unable to fund much more expensive multiple marker studies, even if such studies have demonstrated their efficacy.

PISA 2003 also had a problem solving component. Many of the items would fit the mathematics Framework, and given the fact that the instrument for problem solving (PS) had much more open 'constructive' items, a study relating the math items and the PS items could be very helpful in advancing the discussion on item instruments and their restrictions in large-scale international studies. According to the PISA report on problem solving: 'The items for problem solving give a first glimpse of what students can do when asked to use their total accumulated knowledge and skills to solve problems in authentic situations that are not associated with a single part of the school curriculum.'

One can easily argue that this is always the case in a curriculum: For mathematical literacy, mathematics as taught at school will not suffice. Students need to read, need to interpret tables and graphs (seen by many as belonging to reading literacy), and, indeed, need problem-solving strategies. But seen from the perspective of promising developments on item formats and item quality, the problem-solving component of PISA is interesting, at least. And if TIMSS implements their intent to 'place more emphasis on questions and tasks that offer better insights into students' analytical,

problem-solving, and inquiry skills and capabilities,' innovation in large-scale assessments could materialize.

**PISA versus TIMSS.** The main differences between TIMSS and PISA seem to be the following:

- curricular emphasis for TIMSS versus functional aspect (literacy) for PISA;
- grade-specific structure of TIMSS versus age-specific structure of PISA.

TIMSS uses the curriculum as the major organizational aspect. The TIMSS curriculum model has three aspects: the intended curriculum, the implemented curriculum, and the achieved curriculum. These represent, respectively, the mathematics and science intended for students to learn, and how the education system should be organized to facilitate this learning: what is actually taught in the classrooms, who teaches it, and how is it taught; and finally, what it is that students have learned, and what they think about those subjects.

International curricular diversity was a serious point of concern to the TIMSS study. The goal was to develop an international test that would be equally fair to all participating countries. Therefore subject-matter specialists from all countries were consulted and asked to contribute to the process of test development. Most countries participating in TIMSS had an intended mathematics curriculum that matched with more than 90% of the items. The outliers were the United States and Hungary with 100% matching, and the Netherlands, with 71% matching.

Insiders have discussed the procedure and its validity of this equally unfair analysis. The question not satisfactorily answered is how the mathematics education communities in the different countries were involved, and how representative they were. But if these numbers are accepted, in this context it is worth looking at the minimal matching result of the Netherlands.

It was expected that students of other countries would outperform Dutch students. However, contrary to expectations, in 1995 Dutch grade 8 students performed well on the TIMSS test. Their score was significantly above the international average, just below the four Asian top-scoring countries. After some additional research it was concluded that somehow the Dutch students were knowledgeable about the 29% of test items that were remote from their intended curriculum. In the end it was concluded that the students had the abilities for transfer of their knowledge and skills to items that did not match with their intended curriculum. It can be very appropriate to test students on material they have not been taught, if the test is used to find out whether the schools are doing their job.

PISA takes this point even further: It is based on a dynamic model of lifelong learning in which new knowledge and skills necessary for successful adaptation to a changing world are continuously acquired throughout life. It focuses on young people's ability to use their knowledge and skills to meet real-life challenges, rather than on the extent to which they have mastered a specific school curriculum.

The two different approaches can both be critiqued: What does it mean that the Netherlands scored so high with the minimal relation with its curriculum? What does

it mean if PISA will not constrain itself to any national curricula? It is clearly not true that international studies of student achievement may be unintentionally measuring little more than the degree of alignment between the test instrument and the curriculum. What it does measure is still a question open to interpretation.

Another indication that shows how difficult it is to make statements that go beyond well-intended opinions can be found in the observation of Westbury in 1992, in relation to SIMS, when he observed that the lower achievement of the United States is the result of curricula that are not as well matched to the SIMS test as are the curricula of Japan. But in TIMSS the match was 100% (see earlier), and still the United States did not perform very well.

**Impact.** The Germans produced a national PISA 2000 report of 550 pages, the international OECD report was 330 pages, and the Dutch report a mere 65 pages. Most countries had something around 150 pages. It is not the statistics that are interesting here, but the message from the report and what has been selected to be included. Even a superficial analysis, which was carried out for this article with the reports mentioned and the one from the United States, makes significant differences visible. There is a common myth that numbers do not lie. It is now widely accepted that data can be gathered, processed, mathematized, and interpreted in a variety of ways. So a key issue is the question of who influences this process, for what reasons, and through what means. The studies just mentioned underscore this concern apart from the fact that even numbers can lie.

Back to the very *gründliches* German report. Not only did the German PISA Konsortium do an excellent and thoughtful job, it also made recommendations for immediate improvement, including ones that directly affect the content. The changes should include:

- more integration of inner- and outer-mathematical 'networks';
- fewer calculations;
- more thinking activities and student mental 'constructions';
- more reflection;
- more flexible use of schoolbooks.

These goals can be reached when the recommendations that were formulated after TIMSS are implemented:

- development of a different math-problems culture: more open-ended, more 'real-world';
- a new teaching-and-learning culture, with a more exiting cognitive school environment;
- more and different professionalization of teachers, emphasizing teamwork.

PISA adds to these recommendations a 'very different conceptualization' of mathematical concepts and emphasis of modeling and mathematization, situated in contexts. And, argued the report, the Germans have definitely not reached the optimum in using different representations as a tool to build better conceptual understanding.

Mathematics education is in a state of transition, in part because of the fact that both TIMSS and PISA were taken seriously. Surprisingly the shock and catastrophe that struck Germany as some kind of natural disaster, if one had only the popular media as a resource, has resulted in a government-supported nationwide action-plan with a very strong content part that will result in a different mathematics education culture at schools. Of course, the success of these changes will be measured by PISA 2003, 2006, 2009, and so on. At least in part.

**The future of PISA.** It is very hard to predict the future of PISA. Of course it is a very successful project if one looks at the number of countries participating: 58 in 2006 and growing. And there are many opportunities to make PISA more successful from the content point of view. If PISA is able to include longer and more complex items, as it did with its Problem Solving study in 2003, if technology gets a proper place (as is intended), if group-work can be included in some way PISA would make itself much more rewarding for policy makers and practitioners alike.

PISA will also start a study for the 9-year olds, in the near future. In short the OECD definitely has the intention to continue PISA for the next decade at least. And if the instrument keeps improving, it seems worth the effort – although OECD has to be more clear about the fact that PISA measures mathematical literacy, and not curricular mathematics – and how to deal with this principle in the future.

PISA will have to address the problem of the Horse-race – a very undesirable aspect that draws a lot of criticism – and rightfully so. Another format of the international report with portraying country by country would not only be more informative, but also would give a more valid picture: one number cannot represent the quality of an educational system.

Validity issues have to be addressed, even if PISA is using state-of-the-art methodology. Not only the methodology should be of the highest quality, but also the content – and improvement should be on the agenda continuously.

And of course: communication between all parties should improve: Math educators and research mathematicians feel as being watchers of a game they hardly feel any ownership for. This is undesirable: PISA should not address just policy makers if it really wants to make a difference: the data of PISA are in the public domain and any country can analyse these data for its own purpose. This opportunity should not be lost. The meaning of PISA can be co-defined by its users.

# The role of mathematicians in K-12 mathematics education

Fr. Ben Nebres (*moderator*)

Shiu-Yuen Cheng, Konrad Osterwalder, and Hung-Hsi Wu (*panelists*)

**Abstract.** The need for mathematics educators, schoolteachers and mathematicians to work together to improve K-12 mathematics education continues to be a great concern throughout the world. The main paper for this panel discussion proposes a paradigm or perspective within which to organize this working together of the different groups. This is to see mathematics education as mathematical engineering. From this perspective, the challenge of the mathematics educator and the schoolteacher is to customize mathematics to students' needs. The role, in turn, of the university mathematician is to customize mathematics courses for teachers so that they in turn may be able to customize the mathematics for the different needs of their students. This paradigm is then discussed in different contexts, in the United States, Hong Kong, Switzerland, and the Philippines. The paradigm is seen to be fruitful in these different contexts.

**Keywords.** Mathematical Engineering, curriculum, assessment, professional development, student creativity, gymnasium mathematics.

## Introduction and overview

by *Ben Nebres, S. J.*

The theme of this panel discussion is "How mathematicians contribute to K-12 mathematics education." Three distinguished mathematicians, coming from different contexts and different mathematics education traditions, provide challenging and helpful insights into this theme. Because the contexts in which they write are quite different (United States, China, Switzerland), it was decided to present the papers separately. This introductory note is meant to highlight the main proposal and perspective coming from Prof. Wu's paper and relate the contributions from the other two panelists to it. I also add a few comments from the context of a developing country, the Philippines.

First, a brief note on the diversity of contexts. In terms of mathematics achievement based on international comparative studies such as TIMSS, the United States ranks in the middle, while Hong Kong and Switzerland rank towards the top. The Philippines ranks towards the bottom. In terms of educational systems, the U.S. is quite decentralized with great diversity in terms of curriculum, textbooks, teacher

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

training, while Hong Kong schools would have greater commonality in terms of curriculum, textbooks, assessment. Some would say that it may be better to compare not the performance of all U.S. schools, but to take account of the diversity of systems and compare blocks of schools (by states or groups of school districts). In terms of resources, the U.S., Switzerland and Hong Kong have first world resources, while Philippine schools operate in the context of great scarcity: classes of 80 students in rooms built for 40, one textbook shared by 5 or 6 pupils and so forth. One can even look at the differences in mathematics education between Hong Kong and the U.S. and Switzerland and the Philippines from the point of view of mathematics education cultures. This is discussed in the recently published "Mathematics Education in Different Cultural Traditions: A Comparative Study of East-Asia and the West", edited by Frederick Leung, Klaus Dieter Graf and Frances Lopez-Real, Volume 9 in the New ICMI Study Series. My own role as a mathematician in helping improve mathematics education in the Philippine context of poverty of resources is described in a chapter entitled "Philippine Perspective on the ICMI Comparative Study" in this volume of the ICMI Study Series.

Despite this diversity of contexts, there is agreement in all the three papers (and in the Philippine experience as well) on the importance of the role of mathematicians in K-12 mathematics education and on a particular paradigm or perspective (mathematics education as mathematical engineering) on how mathematicians can effectively fulfill this role.

In the main paper for this panel presentation and discussion, Prof. Hung-Hsi Wu of the University of California Berkeley, proposes a re-conceptualization of mathematics education as mathematical engineering: "Thus chemical engineering is the science of customizing chemistry to solve human problems… . I will put forth the contention that mathematics education is mathematical engineering, in the sense that it is the application of basic mathematical principles to meet the needs of teachers and students." This is somewhat different from the suggestion of Hyman Bass to look at mathematics education as a branch of applied mathematics. In engineering, what is important is the customization of scientific principles to address human needs. Similarly, in mathematics education as mathematical engineering, what is crucial is the customization of mathematical principles to address the needs of teachers and pupils.

From this viewpoint, the challenge is to work out the role of mathematicians in mathematics education analogous to that of physicists in engineering. Just as the roles of physicists and engineers in engineering are deeply intertwined, so should the roles of mathematicians and mathematics educators be in mathematics education. Right now the two worlds are separate and do not communicate well with each other. Prof. Wu writes: "… if mathematicians want to participate in serious educational work in K-12, … the most important thing is the awareness that K-12 mathematics education is not a subset of mathematics, and that there is quite a bit to learn about the process of customization that distinguishes K-12 mathematics education from mathematics."

In my communication with Prof. Wu, we agreed that it is important that the term "mathematics educator" include both the university mathematics educator as

researcher and the school mathematics teacher as practitioner. While the university mathematics education researcher is an expert on teaching and learning theories, the mathematics master teacher is most knowledgeable about actual teacher, student, and classroom contexts. Success in improving mathematics education will require good communication and working together among mathematicians, university mathematics educators and school mathematics teachers.

To properly customize mathematics in different student contexts, a mathematics teacher needs: solid mathematical knowledge, clear perception of the setting defined by students' knowledge, and flexibility of mind to customize this mathematics knowledge for use in this particular setting. In this model of mathematics education as mathematical engineering, the role of the mathematician is to provide the solid mathematical knowledge. This should be done in such a way that the teacher is provided with different ways of understanding and approaching a mathematics concept so that he can have a repertoire to draw from in customizing the mathematics for different student contexts. Prof. Wu gives examples such as in the teaching of fractions or in providing intervention for students at-risk.

The paper of Prof. Shiu-Yuen Cheng of the Hong Kong University of Science and Technology picks up from the "mathematics education as mathematical engineering" framework of Prof. Wu and sets it in the context of mathematics education in Hong Kong. He notes "the main factors for providing an effective mathematics education as curriculum design, teacher competence and assessment methods." He says that most important is teacher competence and it is to this factor that mathematicians can contribute the most. They can contribute in the university curriculum for mathematics teacher programs and in in-service workshops for mathematics teachers. Together with Prof. Wu (and from my experience as well) he points out that the university curriculum for mathematics teachers, which is usually a combination of courses for mathematics majors and education courses, "do not serve the purpose of providing the necessary understanding to be a competent mathematics teacher." (Reasons for this are very well argued in Liping Ma, "Knowing and Teaching Elementary Mathematics.")

Prof. Cheng points out that the Hong Kong mathematics education context is one which shows great success as shown by the excellent performance of Hong Kong students in international comparative studies. "In Hong Kong, Johnny can add! In fact, Johnny can do fractions and decimals quite well." There is, however, a downside to this achievement. Prof. Cheng is concerned that this is at great cost, particularly in "suffocating students' creativity and motivation for learning." He stresses the important role of mathematicians in communicating effectively to the public and to decision-makers these important concerns for mathematics education. (This balance between effective mastery of fundamentals and the need to foster creativity has been an important recent concern in East Asia and was the theme of the ICMI-East Asian Regional Conference on Mathematics Education in Shanghai in August 2005.)

Prof. K. Osterwalder of the ETH Zurich writes in the context of the upper years of the Swiss gymnasium (years 9–12) and the role of mathematicians in universities

such as ETH Zurich in preparing mathematics teachers for these upper years. He points out that in Switzerland, students do quite well in international comparative studies in mathematics. Teachers are well trained. They are required to get a masters degree at a level where they could equally opt to go into industry as mathematicians. On the role of mathematicians in K-12 mathematics education, he agrees that the main contribution of research mathematicians is in the education of mathematics teachers. He focuses in a special way on the "Specialized Mathematics Courses with an Educational Focus" taken by mathematics teachers in the university. He provides various examples of course material, from linear equations and linear algebra to noting recent research breakthroughs accessible to gymnasium students, where these course materials "narrow the gap between Gymnasium mathematics and University mathematics" in the spirit of Felix Klein's "Elementary Mathematics from a Higher Viewpoint."

The paradigm or perspective of "mathematics education as mathematical engineering" proposed by Prof. Wu is thus seen to be quite fruitful in these different contexts. They all point to the central role of the mathematics teacher, whose challenge is to customize the mathematics to the students' needs. The important role of the university mathematician is then to customize mathematics courses for these teachers in such a way that they may in turn be able to customize the mathematics needed by students in different contexts and with different needs.

## How mathematicians can contribute to K-12 mathematics education

by *Hung-Hsi Wu*

> *"To overcome the isolation of education research, more effective links must be created between educational faculties and the faculties of universities. This could allow scholars of education better acquaintance with new developments in and across the disciplines and other professional fields of the university, while also encouraging discipline-based scholars with interests in education to collaborate in the study of education."*
>
> Lagemann [14], p. 241.

I would like to make a general disclaimer at the outset. I think I should only talk about things I know firsthand, so I will limit my comments to the K-12 mathematics education in the U.S. rather than take a more global view. Such a restriction is not necessarily fatal since a friend of mine observed that what takes place in the U.S. tends also to take place elsewhere a few years later. For example, in France there is now a Math War that resembles the American Math Wars of the nineties (Education Week [7]). We live in a global village after all.

Let me begin with a fairy tale. Two villages are separated by a hill, and it was decided that for ease of contact, they would drill a tunnel. Each village was entrusted

with the drilling of its own half of the tunnel, but after both had done their work, it was discovered that the two halves didn't meet in the middle of the hill. Even though a connecting tunnel between the two lengths already built could be done at relatively small expense, the two villages, each in defense of its honor, prefer to continue the quarrel to this day.

This fairy tale is too close to reality for comfort when the two villages are replaced by the education and mathematics communities, with the former emphasizing the overriding importance of pedagogy and the latter, mathematical content.[1] Mathematics education rests on the twin pillars of mathematics and pedagogy, but the ongoing saga in mathematics education is mostly a series of episodes pitting one against the other. There is probably no better proof of the disunity between these communities than the very title of this article. Indeed, if someone were to write about "How chemists can contribute to chemical engineering", that person would be considered a crank for wasting ink on a non-issue. Chemical engineering is a well-defined discipline, and chemical engineers are perfectly capable of doing what they are entrusted to do. They know the chemistry they need for their work, and if there is any doubt, they would freely consult with their colleagues in chemistry in the spirit of cooperation and collegiality. Therefore, the fact that we are going to discuss "How mathematicians can contribute to K-12 mathematics education" in the setting of the International Congress speaks volumes about both mathematics education and mathematicians.

In matters of education it is of course natural for the power structure to hold the reins, just as in matters of engineering they are held by engineers. But while the chemical engineers are glad to have chemists down the hall, and glad to learn what they can use in their work, the corresponding relationship has not been the case for mathematics educators. Since education research is thriving and research funding is ample, it is not surprising that educators want to protect their intellectual independence in the university environment. Rumblings about how mathematically unqualified teachers or deficient curricula are undercutting mathematics learning do surface from time to time, but we have not witnessed the expected aggressive action agitating for collaboration with mathematicians. Other troubling issues related to mathematics content, such as the presence of incorrect assessment items in standardized tests, likewise fail to arouse genuine concern in the mathematics education community. To an outsider, the protection of the "education" enclave seems to matter more to university educators than collaboration with the research mathematics community that could strengthen K-12 mathematics education. By contrast, if the department of chemical engineering consistently produces engineers with a defective knowledge of chemistry, or if accidents occur in its laboratories with regular frequency, would the chemical engineering faculty not immediately spring to action? This question prompts the thought that maybe we no longer know what mathematics education is

[1] In writing about sociological phenomena, especially education, it is understood that all statements are statistical in nature unless stated to the contrary, and that exceptions are part and parcel to each statement. In fact, there are striking (though isolated) exceptions in the present context. The reader is asked to be aware of this caveat for the rest of this article.

about and it is time for us to take a second look.

One meaning of the word "engineering" is the art or science of customizing scientific theory to meet human needs. Thus chemical engineering is the science of customizing chemistry to solve human problems, or electrical engineering is the science of customizing electromagnetic theory to design all the nice gadgets that we have come to consider indispensable. I will put forth the contention that mathematics education is mathematical engineering, in the sense that it is the customization of basic mathematical principles to meet the needs of teachers and students.[2] I will try to convince you that this is a good model for the understanding of mathematics education before proceeding to a discussion of how mathematicians can contribute to K-12 mathematics education. The far-from-surprising conclusion is that, unless mathematicians and educators can work as equal partners, K-12 mathematics education cannot improve.

Regarding the nature of mathematics education, Bass made a similar suggestion in [5] that it should be considered a branch of applied mathematics.[3] What I would like to emphasize is the aspect of engineering that customizes scientific principles to the needs of humanity in contrast with the scientific-application aspect of applied mathematics. Thus, when H. Hertz demonstrated the possibility of broadcasting and receiving electromagnetic waves, he made a breakthrough in science by making a scientific application of Maxwell's theory. But when G. Marconi makes use of Hertz's discovery to create a radio, Marconi was making a fundamental contribution in electrical engineering, because he had taken the extra step of harnessing an abstract phenomenon to fill a human need.[4] In this sense what separates mathematics education as mathematical engineering from mathematics education as applied mathematics is the crucial step of customizing the mathematics, rather than simply applying it in a straightforward manner to the specific needs of the classroom. There is no better illustration of this idea of customization than the teaching of fractions in upper elementary and middle schools, as I now explain.

Students' failure to learn fractions is well-known. School texts usually present a fraction as parts of a whole, i.e., pieces of a pizza, and this is the most basic conception of a fraction for most elementary students. However, when fractions are applied to

[2]After the completion of this article, Skip Fennell brought to my attention the article "Access and Opportunities to Learn Are Not Accidents: Engineering Mathematical Progress in Your School" by William F. Tate, which is available at: http://www.serve.org/_downloads/publications/AccessAndOpportunities.pdf. Tate is concerned with equity and uses "engineering" as a metaphor to emphasize the potential for designing different educational policies and pedagogical activities to promote learning, but without addressing the mathematics. On the other hand, the present article explains why mathematics education is the engineering of mathematics.

[3]Hy Bass lectured on this idea in December of 1996 at MSRI, but [5] seems to be a convenient reference. After the completion of this article, Zalman Usiskin informed me that in the Proceedings of the U.S.-Japan workshop on the mathematics education of teachers in 2000 that followed ICME-9 in Japan, he had written that " 'Teachers' mathematics' is a field of applied mathematics that deserves its own place in the curriculum." Along this line, let it be mentioned that the paper of Ferrini-Mundy and Findell [8] made the same assertion and, like Bass, it does not touch on the engineering aspect of mathematics education. The need for mathematicians and educators to work on equal footing in mathematics education is likewise not mentioned by these educators.

[4]The invention was actually due to N. Tesla, but like many things in life, popular preception displaces the truth. I am indebted to S. Simic for pointing this out to me.

everyday situations, then it is clear that there is more to fractions than parts-of-a-whole, e.g., if there are 15 boys and 18 girls in a classroom, then the ratio of boys to girls is the fraction, which has nothing to do with cutting up a pizza into 18 equal parts and taking 15. In the primary grades, it is not a serious problem if students' knowledge of fractions is imprecise and informal, so that a fraction can be simultaneously parts-of-a-whole, a ratio, a division, and an operator[5], and a number. Children at that age are probably not given to doubts about the improbability of an object having so many wondrous attributes. At some stage of their mathematical development, however, they will have to make sense of these different "personalities" of a fraction. It is this transition from intuitive knowledge to a more formal and abstract kind of mathematical knowledge that causes the most learning problems. This transition usually takes place in grades 5–7.

There is by now copious mathematics education research[6] on how to facilitate children's learning of the fraction concept at this critical juncture in order to optimize their ability to use fractions efficiently. At present, what most children get from their classroom instruction on fractions is a fragmented picture of a fraction with all these different "personalities" lurking around and coming forward seemingly randomly. What a large part of this research does is to address this fragmentation by emphasizing the cognitive connections between these "personalities". It does so by helping children construct their intuitive knowledge of the different "personalities" of a fraction through the use of problems, hands-on activities, and contextual presentations.

This is a good first step, and yet, if we think through students' mathematical needs beyond grade 7, then we may come to the conclusion that establishing cognitive connections does not go far enough. What students need is an unambiguous definition of a fraction which tells them what a fraction really is. They also need to be exposed to direct, mathematical, connections between this definition and the other "personalities" of a fraction. They have to learn that mathematics is simple and understandable, in the sense that if they can hold onto one clear meaning of a fraction and can reason for themselves, then they can learn all about fractions without ever being surprised by any of these other "personalities".

From a mathematician's perspective, this scenario of having to develop a concept with multiple interpretations is all too familiar. In college courses, one approaches rational numbers (both positive and negative fractions) either abstractly as the prime field of characteristic zero, or as the field of quotients of the integers. The problem is that neither is suitable for use with fifth graders. This fact is recognized by mathematics education researchers, as is the fact that from such a precise and abstract definition of rational numbers, one can prove all the assorted "personalities" of rational numbers. If I have read the research literature correctly, these researchers despair of ever being able to offer proofs once they are forced to operate without an abstract definition, and

[5]For example, the fraction can be regarded as a function (operator) which associates to each quantity three-quarters of the same quantity.

[6]Here as elsewhere, I will not supply explicit references because I do not wish to appear to be targeting specific persons or works in my criticism. I will be making generic comments about several general areas.

that is why they opt for establishing cognitive, rather than mathematical connections among the "personalities" of rational numbers. The needs of the classroom would seem to be in conflict with the mathematics. At this point, engineering enters.

It turns out that, by changing the mathematical landscape entirely and leaving quotient fields and ordered pairs behind, it is possible to teach fractions as mathematics in elementary school, by finding an alternate mathematical route around these abstractions that would be suitable for consumption by children in grades 5-7. Without going into details, suffice it to say that at least the mathematical difficulties can be overcome, for example, by identifying fractions with certain points on the number line (for this systematic development, see, e.g., Jensen [11], or Wu [25]). What is of interest in this context is that this approach to fractions is specific to the needs of elementary school and is not likely to be taught, ever, in any other situation. In addition, the working out of the basic properties of fractions from this viewpoint is not quite straightforward, and it definitely requires the expertise of a research mathematician. As to the further pedagogical implementation to render such an approach usable in grades 5–7, the input of teachers and educators would be absolutely indispensable.[7] We therefore get to witness how mathematicians and educators are both needed to turn a piece of abstract mathematics into usable lessons in the school classroom. This is customization of abstract theory for a specific human need, and this is engineering at work.

Through this one example of fractions, we get a glimpse of how the principles of mathematical engineering govern the design of a curriculum. Less obvious but of equal importance is the fact that even mathematics education research cannot be disconnected from the same principles. If, for example, a strong mathematical presence had been integral to the research on fractions and rational numbers, it would be very surprising that the research direction would have developed in the direction it did. Compare the quote by Lagemann at the beginning of this article as well as Lagemann [14].

An entirely analogous discussion of customization can be given to any aspect of mathematics education, but we single out the following for further illustrations:

(a) The design of an "Intervention Program" for at-risk students. Up to this point, the methods devised to help these students are largely a matter of teaching a watered-down version of each topic at reduced pace; this is poor engineering from both the theoretical and the practical point of view. In Milgram-Wu [18], a radically different mathematical engineering design is proposed to deal with this problem.

(b) The teaching of beginning algebra in middle school. The way symbols are usually handled in such courses, which necessitates prolix discussions in the research literature of the subtlety of the equal sign, and the way variable is introduced as the central concept in school algebra are clear indications that the algebra we teach students at present has not yet been properly customized

[7] Some teachers who have worked with me are trying out this approach with their students in San Francisco.

for the needs of school students. See the Preface and Sections 1 and 2 of Wu [30], and also Wu [31], for a more detailed account of both the problems and their proposed solutions.

(c) The writing of mathematics standards at the national or state level. This is an example of what might be called "practical optimization problems", which customize the mathematics to meet diverse, and at times conflicting, needs of different clientele. Cf. Klein [13].

The concept of mathematics education as mathematical engineering also sheds some light on Lee Shulman's concept of pedagogical content knowledge ([20]). There has been a good deal of interest in precisely describing the kind of knowledge a teacher should possess in order to be effective in teaching. In the field of mathematics, at least, this goal has proven to be elusive thus far (but cf. Hill-Rowan-Ball [9]), but Shulman's intuitive and appealing formulation of this concept crystallizes the diverse ideas concerning an essential component of good teaching. From the point of view of mathematical engineering, one of the primary responsibilities of a teacher is to customize her mathematical knowledge in accordance with the needs of each situation for students' consumption. This particular engineering knowledge is the essence of pedagogical content knowledge. Although this approach to pedagogical content knowledge does not add anything new to its conception, it does provide a framework to understand this knowledge within mathematics, one that is different from what one normally encounters in educational discussions. It makes explicit at least three components to effective teaching: a solid mathematical knowledge, a clear perception of the setting defined by students' knowledge, and the flexibility of mind to customize this mathematical knowledge for use in this particular setting without sacrificing mathematical integrity.

The idea of customizing mathematics "without sacrificing mathematical integrity" is central to mathematical engineering. In engineering, it is obvious that, in trying to customize scientific principles to meet the needs of humanity, we cannot contradict nature regardless of how great the human needs may be. In other words, one respects the integrity of science and does not attempt anything so foolish as the construction of anti-gravity or perpetual-motion machines. Likewise, as mathematical engineering, mathematics education accepts the centrality of mathematics as a given. Again using the example of teaching fractions, a mathematics educator would know that no matter how one tries to teach fractions, it must be done in a way that respects the abstract meaning of a fraction even if the latter is never used explicitly. If, for instance, an educator catches himself saying that children must adopt new rules for fractions that often conflict with well-established ideas about whole numbers, then he knows he is teaching fractions the wrong way because, no matter what efforts one puts into making fractions intuitive to children, one cannot do violence to the immutable fact that the rational numbers contain the integers as a sub-ring. The need to teach the arithmetic of fractions as a natural extension of the arithmetic of whole numbers has gone unnoticed for far too long, with the result that too many of our students begin to

harbor the notion that, after the whole numbers, the arithmetic of fractions is a new beginning. Such bad mathematical engineering in curricular designs is unfortunately a common occurrence.

The only way to minimize such engineering errors is to have both mathematicians and educators closely oversee each curricular design. In fact, if we believe in the concept of mathematics education as mathematical engineering, then the two communities must work together in all phases of mathematics education: Any education project in mathematics must begin with a sound conception of the mathematics involved, and there has to be a clear understanding of what the educational goal is before one can talk about customization. In this process, there is little that is purely mathematical or purely educational; almost every step is a mixture of both. Mathematics and education are completely intertwined in mathematical engineering. Mathematicians cannot contribute to K-12 mathematics education if they are treated as outsiders.[8] They have to work alongside the educators on equal footing in the planning, implementation, and evaluation of each project. But this is far from the reality at present.

For at least three decades now, the mathematics and K-12 education communities in the U.S. have not been on speaking terms in the figurative sense. (Cf. Washington Post [21].) The harm this communication gap has brought to K-12 mathematics education can be partially itemized, but before doing that, let me point out three general consequences of a philosophical nature. The first one is that the isolation of the education community from mathematicians causes educational discussions to over-focus on the purely education aspect of mathematics education while seemingly always leaving the mathematics untouched. The result is the emergence of a subtle mathematics avoidance syndrome in the education community, and this syndrome will be seen to weave in and out of the following discussion of the specific harmful effects of this communication gap. Given the central position of mathematics in mathematical engineering, it would be noncontroversial to say that this syndrome should vanish from all discussions in mathematics education as soon as possible.

The fact that many mathematicians teach mathematics and design mathematics courses throughout their careers seems to escape the attention of many educators. Here is a huge reservoir of knowledge and experience in mathematical engineering on tap. The chasm between the two communities in effect denies educators access to this human resource at a time when educators need all the engineering help they can get.

The final consequence can best be understood in terms of the Darwinian dictum that when a system is isolated and allowed to evolve of its own accord, it will inevitably mutate and deviate from the norm. Thus when school mathematics education is isolated from mathematicians, so is school mathematics itself, and, sure enough, the latter evolves into something that in large part no longer bears any resemblance to mathematics. Correct definitions are not given, or if given, they are not put to use (Milgram-Wu [18], Wu [23], [27] and [29]). The organic coherence of mathematics is

[8]This only tells half the story about mathematicians. See the comments near the end of this article.

no longer to be found (Wu [23]), or when "mathematical connections" are intentionally emphasized, such "connections" tend to be the trivial and obvious kind. Logical deduction becomes an afterthought; proofs, once relegated to the secondary school geometry course, were increasingly diluted until by now almost no proofs at all are found there, or anywhere else in the schools (Wu [26]). And so on. This development naturally brings down the quality of many aspects of mathematics education.

The absence of dialog between the two communities has led to many engineering errors in mathematics education, one of them being the unwelcome presence of mathematically incorrect test items in state and other standardized tests (Milgram [16] and [17]). The same kind of defective items also mar many teachers' credentialing tests (Askey [1] and [2]). A more subtle effect of the absence of mathematical input on assessment is the way test scores are routinely misinterpreted. The low test scores have been used to highlight students' dismal mathematical performance, but little or no thought is given to the possibility that they highlight not necessarily students' achievement (or lack thereof) but the pervasive damage done by defective curricular materials, or even the chronic lack of effective teaching. Such a possibility may not be obvious to anyone outside of mathematics, but to a mathematician, it does not take any research to confirm the fact that when students are taught incorrect mathematics, they learn incorrect mathematics. Garbage in, garbage out. If the incorrect mathematics subsequently shows up in students' test scores, how can we separate the errors due to the incorrect information students were given, from the errors due to students' own misconceptions? A more detailed examination of this idea in the narrow area of school algebra is given in Wu [31]. The need for mathematicians' participation in all phases of assessment is all too apparent.

The lack of collaboration between mathematicians and mathematics educators affects professional development as well. The issue of teacher quality is now openly acknowledged and serious discussions of the problem are beginning to be accepted in mathematics education (cf. Ma [15], and Conference Board of the Mathematical Sciences [6][9]). As a result of the inadequate mathematics instruction teachers receive in K-12, their knowledge of mathematics is, by and large, the product of the mathematics courses they take in college.[10] In very crude terms, the number of such required mathematics courses is too low, and in addition, these courses are taught either by mathematicians who are not in close consultation with teachers, and are unaware as to what is needed in the school classroom, or by mathematics educators who are not professional mathematicians. The former kind of course tends to be irrelevant to the classroom, and the latter kind tends to be mathematically shallow or incorrect. It is only natural that teachers coming out of such an environment turn out to be mathematically ill-prepared.

[9]Whatever reservations one may have concerning the details of its content, it is the fact that such a volume could be published under the auspices of a major scientific organization that is important.

[10]It may be useful to also take note of what may be called "the second order effect" of university instruction: teachers' knowledge of mathematics is also conditioned by their own K-12 experiences, but these teachers' teachers were themselves products of the mathematics courses they took in the university.

Similar woes persist in in-service professional development, thereby ensuring that teachers have little access to the mathematical knowledge they need for their profession. For example, the last decade has witnessed the appearance of case books consisting of actual records of lessons given by teachers.[11] The idea is to invite teachers to analyze these lessons, thereby sharpening their pedagogical sensibilities. In too many instances, however, blatant mathematical flaws in the cited cases are overlooked in the editors' commentaries. This raises the specter of bringing up a generation of teachers who are proficient in teaching school students incorrect mathematics. In this instance, it would appear that the need to respect mathematical integrity in mathematical engineering has been all but forgotten.

The most divisive outcome of the noncommunication between the two communities in the U.S. is undoubtedly the conflict engendered by the new (reform) curricula written in the past fifteen years. I take up this discussion last, because it brings us face to face with some subtle issues about mathematicians' participation in K-12 mathematics education. The prelude to the writing of these curricula is the unchecked degeneration in the mathematical integrity of the existing textbooks from major publishers over the period 1970–1990, a fact already alluded to above. This degeneration triggered the reform spearheaded by NCTM (National Council of Teachers of Mathematics [19]). Rightly or wrongly, the new curricula were written under the banner of the NCTM reform, and the manner in which some of the reform texts were imposed on public schools led eventually to the well-known Math Wars (Jackson [10]). The root of the discontent over these texts is the abundance of outright mathematical errors[12], as well as what research mathematicians perceived to be evidence of a lack of understanding of the mathematics. An example of the latter was the promotion of children's invented algorithms at the expense of the standard computation algorithms in the elementary mathematics curriculum. Although the promotion was partly an overreaction to the way the standard algorithms were often inflicted on school children with nary a word of explanation, it also reflected a lack of awareness of the central importance of the mathematical lessons conveyed by the reasoned teaching of these algorithms.

The "subtle issues" mentioned above stem from the fact that the writing of some of the new reform curricula actually had the participation of a few mathematicians. The first thing to note is that the latter are the rare exceptions to the general noncommunication between the mathematics and education communities. The noncommunication is real. At the same time, these exceptions seem to point to an apparent contradiction: How would I reconcile my critical stance toward these reform curricula with the principal recommendation of this article, namely, that mathematicians be equal partners with educators in the mathematics education enterprise? The answer is that there is no contradiction at all. The participation by mathematicians is, in general terms, a prerequisite to any hope of success in K-12 mathematics education, but in no way

[11] Let it be noted explcitly that I am discussing the case books in K-12 mathematics education only.

[12] These errors tend to be different from the earlier ones to be sure, but errors they are.

does it guarantee success. It is helpful in this context to recall similar discussions that routinely took place some eight years ago when some mathematicians first went public with the idea that mathematics teachers must have a solid content knowledge. The usual rejoinder at the time was that "knowing mathematics is not enough (to be a good teacher)". This is a common confusion that mistakes a necessary condition for a sufficient condition.[13] There is no quick fix for something as complex as mathematics education. Getting mathematicians to fully participate is only the beginning; the choice of the mathematicians and the hard work to follow will have a lot to say about the subsequent success or failure.

It is appropriate at this point to recall what was said at the beginning of the article about the power structure of mathematics education: thus far, educators get to make the decisions. Granting this fact, I should amplify a bit on the difficulties of choosing the right mathematicians for education work. Mathematicians have a range of background and experiences and, consequently, often have a range of opinions on matters of education as well. It is important that the range of these opinions be considered in all aspects of education. Many of the less happy incidents of the recent past in K-12 mathematics education were the result of choosing mathematicians of a particular persuasion. In addition, educators must make their own judgement on which among the mathematicians interested in K-12 are knowledgeable about K-12. Among the latter, some possess good judgment and leadership qualities while others don't. Educators must choose at each step. If there are algorithms for making the right choices, I don't happen to know them.

Every mathematician potentially has something to offer in K-12 mathematics education: even an occasional glance at textbooks to check for mathematical correctness can be very valuable. However, if mathematicians want to participate in serious educational work in K-12, what must they bring to the table? I believe the most important thing is the awareness that K-12 mathematics education is not a subset of mathematics, and that there is quite a bit to learn about the process of customization that distinguishes K-12 mathematics education from mathematics. In particular, much (if not most) of the mathematics they teach in the university cannot be brought straight to the school classroom (Wu [22]; Kilpatrick et al. [12], Chapter 10 and especially pp. 375–6), but that it must first go through the engineering process to make it suitable for use in schools. If I may use the example of fractions once again, mathematicians interested in making a contribution to K-12 may find it instructive to get to know the reason that something like "equivalence classes of ordered pairs of integers" is totally opaque to students around the age of twelve. They would also want to know the reason that students of that age nonetheless need a definition of a fraction which is as close to parts-of-a-whole as possible. They should also get to know the appropriate kind of mathematical reasoning for students in this age group, because they will ultimately be called upon to safeguard such reasoning in the curriculum and

[13] And need I point out, there are some who intentionally use this confusion to reject that mathematical content knowledge is important for teachers, or that getting mathematicians to participate in mathematics education is critical for its success.

assessment for these students.

Mathematicians may regard school mathematics as technically primitive (in the sense of skills), but they must take note of its conceptual sophistication (Jensen [11]; Wu [24], [25] and [30]; cf. also Aharoni [1]). Above all, they must know that school mathematics is anything but pedagogically trivial: There is absolutely nothing trivial about putting any material, no matter how simple, into a correct mathematical framework so that it may be profitably consumed by school students. Mathematicians who want to contribute to K-12 mathematics education have to be constantly on the alert to ensure that the minimum requirements of their profession – the orderly and logical progression of ideas, the internal cohesion of the subject, and the clarity and precision in the presentation of concepts, – are still met in mathematics education writings. This is no easy task. If mathematicians want to enter K-12 mathematics education as equal partners with educators, then it is incumbent upon them to uphold their end of the bargain by acquiring this kind of knowledge about mathematical engineering.

The concept of mathematics-education-as-mathematical-engineering does not suggest the creation of any new tools for the solution of the ongoing educational problems. What it does is to provide a usable intellectual framework for mathematics education as a discipline, one that clarifies the relationship between the mathematics and the education components, as well as the role of mathematicians in mathematics education. For example, it would likely lead to a better understanding of why the New Math became the disaster that it did. Most importantly, this concept lays bare the urgent need of the mathematical presence in every aspect of K-12 mathematics education, thereby providing a strong argument against the self-destructive policy of keeping mathematicians as outsiders in mathematics education. The chasm between mathematicians and educators must be bridged if our children are to be better served. I am cautiously optimistic[14] that there are enough people who want to rebuild this bridge (cf. Ball et al. [4]), all the more so because the indications are that the NCTM leadership is also moving in the same direction. I look forward to a future where mathematics education is the joint effort of mathematicians and educators.

**Acknowledgement.** I am first of all indebted to my colleague Norman E. Phillips for providing a critical piece of information about chemistry that got this article off the ground. The suggestion by Tony Gardiner to re-organize an earlier draft, and the penetrating comments on that draft by Helen Siedel, have left an indelible imprint on this article. Tom Parker, Ralph Raimi, and Patsy Wang-Iverson gave me very detailed corrections. David Klein also made corrections and alerted me to one of the references. In addition, the following members of the e-list mathed offered suggestions for improvement: R. A. Askey, R. Bisk, E. Dubinsky, U. Dudley, T. Foregger, T. Fortmann, K. Hoechsmann, R. Howe, W. McCallum, J. Roitman, M. Saul, D. Singer, A. Toom. Cathy Seeley and Skip Fennell also made similar suggestions.

It gives me pleasure to thank them all.

[14] In January of 2006.

## The role of mathematicians in K-12 education: a personal perspective

by *Shiu-Yuen Cheng*

This draft was written after I read Prof. H. Wu's draft on "How mathematicians can contribute to K-12 mathematics education". I therefore have the advantage of adopting the same terms and scope of discussions in writing this draft. For example, I will be using Prof. Wu's definition of the word "mathematician" to mean "research mathematicians". Also, I am impressed and I agree with Prof. H. Wu's philosophical idea of regarding mathematics education as mathematical engineering. I will in the following outline the roles that mathematicians can play for the enhancement of K-12 education. Frequently, I will come back to Prof. Wu's idea of mathematical engineering so that we can do a good job.

The main factors for providing an effective mathematics education are curriculum design, teacher competence and assessment methods. Among these three factors, I think the most important one is teacher competence. I think this is the factor that mathematicians can contribute the most. The processes of designing the curriculum and assessment mechanism vary from place to place and are greatly influenced by the local bureaucratic and political system. In most places, mathematicians do not

get to play much of a role in the design of curriculum and the assessment mechanism. However, this does not mean that we should fold our hand and watch on the sideline. We should always engage in these two factors and make our contributions whenever possible. On the other hand, any curriculum design or assessment method in mathematics would need or welcome mathematicians' stamp of approval. Mathematicians will definitely be involved but we have to vigilantly and patiently engage in the process.

In Hong Kong, the relation between educators and mathematicians is much better than in the US. However, the educators do not call the shot. Instead, the government officials set the agenda and play the most influential role. On paper, it does not seem so because things are supposedly done through committees consisting of teachers, principals, educators and mathematicians. The government officials serve as secretariats in the committees. As the committee members are all busy people taking time off from their work to attend the committee meetings, the secretariat then get to draft all the papers and the agenda. They naturally become most influential. Moreover, as a consequence of the composition of the committees mathematicians are minority. To make things worse, they have few allies. The teachers, school principals in the committee usually assume the mathematicians in the committee have a secret agenda to tailor the curriculum for attracting students to be mathematics majors. Additionally, the educators talk the language of education officials. Their inputs are more helpful to the education officials in filling the reports with popular education jargons. It is then natural that mathematicians' views usually do not prevail. Instead, some compromise can usually be reached if mathematicians engage in the process.

I believe that teacher competence is most important factor as teachers are at the frontline implementing the curriculum and delivering the mathematics education. No matter how hard we work, usually the curriculum and assessment mechanism are far from perfect. A competent teacher can exercise discretions to compensate the inconsistencies and incompleteness of the curriculum and make them work. On the other hand, a teacher who has little confidence and competence in subject knowledge can easily turn a well-designed curriculum or assessment mechanism into disasters. In the area of teacher competence, mathematicians can contribute in two main areas: the university curriculum for mathematics teacher program, and courses and workshops for in-service mathematics teachers. Mathematicians can play major roles in these two areas and can get more colleagues to participate. However, we usually do not pay much attention or do not do the right thing. It was pointed out by Prof. H. Wu and many others that the university curriculums for mathematics majors do not serve the purpose of providing the necessary understanding to be a competent mathematics teacher. The main reason is that the curriculum for mathematics majors is designed with an aim to train research mathematicians. As for courses and workshops for in-service teachers, we need more colleagues to participate and contribute. The ball is in our court but so far we have not made the right play.

In Hong Kong, about fifteen to twenty percent of mathematics graduate become mathematics teachers. This is not a small percentage and is in fact higher than the

percentage of students going for postgraduate study in mathematics. However, the curriculum for mathematics major does not offer much help for those who will pursue the career of a mathematics teacher. Mainly, most mathematicians do not see the necessity of designing and offering some new courses to provide a profound understanding of school mathematics. It is assumed that our courses in abstract algebra, analysis and geometry will do the job and hence nothing needs to be done. As for courses and workshops for in-service teachers, the sad thing is that Hong Kong government does not provide much of this kind of opportunity. Mathematicians have to shoulder this task on a volunteer basis. There are mathematicians willing to contribute but in order to make it sustainable we need to convince the government and the mathematics community the importance of providing courses and workshops for deepening teachers' understanding of the subject knowledge. To do this effectively, we need to communicate well to the community about the concerns of mathematicians about mathematics education. In many places, people are alarmed because "Johnny can't add". In Hong Kong, Johnny can add! In fact, Johnny can do fractions and decimals quite well. In many international studies about the mathematics attainment of school students, Hong Kong routinely occupies one of the top positions. On paper, we should congratulate ourselves and should not even attempt to touch the system as things are not broken. However, anyone in the university or familiar with the situation of the Hong Kong school system knows that the Hong Kong mathematics education is far from achieving the goals. We are able to train our students to do arithmetic and some simple algebra at a tremendous cost. In the process, we suffocate students' creativity and motivation for learning. So far we have not been successful in documenting and communicating our concerns to the Hong Kong public and the government. Mathematics education is then getting little resource from the government as it is doing quite well comparing to our language education. I believe communicating effectively to the public about our views for enhancing mathematics education is crucial and should fall into one of the sub-areas of Prof. Wu's framework of Mathematics Engineering. The banner of Mathematics Engineering is useful for setting a clear goal and rallying support of our fellow mathematicians to contribute to mathematics education.

## The role of mathematicians in K-12 mathematics education

by *U. Kirchgraber and K. Osterwalder*

We begin with a few remarks on the Swiss educational system and on teaching and learning of mathematics in Switzerland. Then we focus on teacher training in Mathematics at the Swiss Federal Institute of Technology (ETH). Finally we sketch an answer to the question posed to the panel.

In international comparative studies like TIMS and PISA Swiss students have demonstrated reasonable achievements in Mathematics. Without overestimating such

results[15] one may wonder whether some specific features of the Swiss educational system might be responsible for this relative success and which measures could serve a further improvement of the results. As we will see some of the possible explanations are related to the topic of the panel.

It is well known Switzerland is not rich in natural resources. This is usually claimed to be one of the major reasons why education is quite highly valued in this country, with a number of important implications: the vast majority of schools are public, teachers on all levels are well trained, the profession of teacher is quite respected, teachers (on all levels) are well paid, schools are well equipped, school buildings are kept in good shape.

The Swiss educational system leaves considerable freedom to teachers on all levels and in particular in upper secondary school, to which we will refer to as Gymnasium[16] level[17]. Gymnasium teachers in general and Gymnasium Mathematics teachers in particular have to follow a certain core curriculum. Yet beyond this guide line they are fairly free to include additional topics, there are hardly any restrictions concerning the type of pedagogy adopted, and teachers are even quite free as to the number and type of tests and examinations they will administer. As to the final examination, in many schools every single mathematics teacher is free to assign a selection of, say, 4-8 problems of his or her choice and depending on the topics he or she has covered in class to his or her students on which they will work during 4 hours. Eventually he or she will correct and grade these works.

ETH offers Gymnasium Teacher Training Programs in the following fields: Biology, Chemistry, Earth Sciences, Mathematics, Physics and Sports. In the following we discuss some features of the Gymnasium Mathematics Teacher Training Program (GMTTP).

A prerequisite for completing the GMTTP is a Master's Degree in Mathematics, though the students are permitted to start with the GMTTP in the third year of the Bachelor's program. Average duration time for completing the GMTTP is six months[18], if studied full time.

The fact that Swiss Gymnasium Mathematics teachers must hold a Master's Degree in Mathematics has – we suppose – far reaching professional and psychological consequences. Having completed a Master's program has at least two implications which, we think, are important for a future Mathematics teacher: a) During the first two years of studies Mathematics students encounter many topics they have seen before yet dealt with in way that is qualitatively very different from what they had

[15] Compared to the host of highly sophisticated tools to measure many quantities in the Sciences and in particular in Physics that have evolved since the time of Gallilei, measuring effectiveness of teaching and learning and similar variables is probably still in its infancy, yet is a fascinating and challenging enterprise.

[16] There are some 150 Gymnasia in Switzerland, every year some 15000 students graduate from the Gymnasia, between 1800 and 2300 enroll at ETH.

[17] This corresponds to grades 9–12.

[18] Starting in fall 2006 federal requirements request studies twice as long. ETH's GMTTP will be extended accordingly and will be renamed as "Master of Advanced Studies in Secondary and Higher Education in Mathematics".

experienced previously. b) In the third year of the Bachelor's and during the Master's program they are exposed to advanced fields, an indispensable experience for gaining a faithful picture of what Mathematics is about.

Based on four and a half years of studies these teacher students can at least potentially be expected to dispose of a degree of mathematical expertise and mathematical maturity which is covered by the terms "content knowledge" and/or "deep understanding" in the Mathematics Education research literature.

As to some practical implications: Being trained as full fledged mathematician a Gymnasium Mathematics teacher may leave school after a few years and start a career in Industry or elsewhere, or vice versa. Therefore requiring a Master's Degree as a prerequisite for teacher training has the benefit of not excluding Gymnasium Mathematics teachers in an early stage of their professional development from the full scale of professional opportunities offered to mathematicians nowadays.

The GMTTP includes courses in the Educational sciences, in Mathematics Education (Didactics of Mathematics), (a small amount of) guided teaching practice, and a fourth component, called Specialized Mathematics courses with an Educational Focus. It is of utmost importance that these components are excellently tuned and multiply intertwined. Moreover they should be accompanied by plenty of student activities[19].

Since the late eighties the Educational course at ETH was designed and continuously updated. The basic concept was to make available both to the Science and Mathematics Educators as well as to their teacher students research grounded results from areas such as psychology, the cognitive sciences, etc. Over the years quite a number of teaching techniques and teaching methods were implemented and probed since they are known – on the basis of meta analyses[20] – to enhance learning[21]. Guided Learning programs[22] for instance are self-contained study materials for pupils covering a learning unit of some 3–30 lessons with the following features: Precisely defined prerequisites, well structured and comprehensibly written explanations, explicitly stated learning goals, adjunct questions and their answers, learning aids, chapter tests to fulfill the so-called Mastery Learning Principle. According to Kulik, Kulik and Bangert-Drowns[23] the effect size of this type of teach ware is of the order of 0.5 in Mathematics and of the order of 0.6 in the Sciences. A few examples of Guided Learning Programs in Mathematics and the Sciences (in German) can be found on www.educeth.ethz.ch[24].

[19] As research has shown, just attending lectures has little impact on future teaching.

[20] See for instance Fraser B. J., Walberg H. J., Welch W. W., Hattie J. A., Syntheses of Educational Productivity Research. *International J. of Educational Research* **11** (1987), 145–252; Walberg, H. J., Productive Teaching and Instruction: Assessing the Knowledge Base. University of Illinois at Chicago, School of Education, 1988, 18 p, mimeographed.

[21] I.e. they have noteworthy effect sizes.

[24] EducETH, a service of ETH to the Public, is ETH's educational server providing teaching materials primarily for upper secondary schools.

In the Mathematics Education courses the thrust is on domain specific aspects of the teaching and learning enterprise. Of course, goals, standards, competencies to be achieved are discussed, subject matter analysis with diverse approaches to selected topics is of central concern and textbooks[25] are analyzed. The teacher students are exposed to Mathematics Education research concepts that prove useful to explain certain phenomena, for instance Talls's and Vinner's distinction between concept definition and concept image which helps to understand students' misconceptions of the notion of function. Topics like the "Expert Blind Spot"-Hypothesis[26], or the influence of teacher's pedagogical content beliefs on learning outcomes[27], and many others are treated. Videos and their transcriptions are analyzed to provide insight into the unpredictability and fragility of learning processes, among other things.

We now turn to the Specialized Mathematics courses with an Educational Focus already mentioned before. It is by now generally accepted that transfer achievements quite often do not emerge automatically. F. Weinert, summarizing years of research at the Max Planck Institut für psychologische Forschung in Munich, explains it roughly speaking as follows. Knowledge a learner acquires systematically – for instance in Mathematics courses as they are usually organized – is likely to be structured and organized in the learners brain in a way not easily retrievable, amenable if the learner is put in a problem situation in which he/she should apply this body of knowledge. Thus, knowledge, which is available in principle, remains inert and unused, though it would be useful and even necessary to handle a certain situation. Weinert's conclusion: To build up an intelligent, flexibly applicable knowledge base the learner needs both, systematic as well as situated learning.

The Specialized Mathematics courses with an Educational Focus take place in the third year (in Switzerland: the last year) of the Bachelor's and during the Master's program. They are open to all students in the Bsc/Msc Mathematics program, but are compulsory for candidates in the GMTTP. These courses with an Educational focus were installed many years ago at ETH (long before there were courses on Mathematics Education!) and have their origin in lectures given by Felix Klein early in the 20th century in Göttingen under the title "Elementarmathematik vom höheren Standpunkt" (elementary mathematics from an advanced point of view) and directed to future Gymnasium Mathematics teacher.

The Specialized Mathematics courses with an Educational Focus serve several goals. Very much in the spirit of Klein's concept they attempt to narrow the gap between Gymnasium Mathematics and University Mathematics. Take a core topic in Mathematics, present at all levels: equations. Linear equations are a topic in grade 9,

[25] After what has been said earlier in this paper it will not come as a big surprise for the reader that Swiss Gymnasium Mathematics teacher are not obliged to use any particular text books. Many in fact do not use a textbook at all but use a variety of sources to assemble handouts, etc., for their students.

[26] See: M. J. Nathan, A. Petrosino: Expert Blind Spot among Pre-service Teachers. *Amer. Educ. Res. J.* **40** (2003), 905–928.

[27] See: Staub, F. C. and Stern, E., The Nature of teachers' Pedagogical Content Beliefs Matters for Students' Achievement Gains. *J. Educational Psychology* **93** (2002), 344–355.

in a course on Linear Algebra in the first year of the Bachelor's program, as well as in specialized courses on Numerical Linear Algebra: Relate the various aspects and draw conclusions for the future teaching of linear equations in grade 9[28]!

Pupils usually encounter nonlinear equations first in connection with the quadratic equation. Most emphasis is usually put on reducing a general quadratic equation[29] to a "purely quadratic" equation[30]. It is of course a marvelous discovery that arbitrary quadratic equations can be reduced to purely quadratic ones. It is a challenging design task for teacher students to compose a series of assignments that guides pupils to discover this phenomenon by themselves.

Yet from a more general point of view the question of solving purely quadratic equations is even more intriguing. One encounters a pattern that is prevalent in (University) Mathematics: Equations are not always solvable. More often than not mathematicians have to invent a setting such that the equation becomes solvable: Loosely speaking – mathematicians make equations solvable! A second such instance comes up when complex numbers are invented to make all quadratic equations solvable with the totally unexpected benefit that in this setting all polynomial equations have solutions.

The Fundamental Theorem of Algebra brings up another very interesting phenomenon: we may be able to prove that an equation has a solution and even that this solution is unique without being able to compute the solution. If complex numbers are treated at the Gymnasium[31] level an intuitive proof of the Fundamental Theorem of Algebra can be offered to Gymnasium students. In a Specialized Mathematics course with an Educational Focus dedicated to equations, teacher students would not only design a learning unit for pupils around such a heuristic proof, but learn in addition how such a proof is made rigorous (not an easy task!), topics like Rouché's Theorem would have to be discussed and an introduction to the Brouwer and Leray–Schauder Degree theory with applications to periodic solutions of differential equations would allow for a glance of the breadth of the field.

Another aspect to which Specialized Mathematics courses with an Educational Focus can contribute concerns curricular development. School Mathematics curricula are often blamed for covering material only that was invented centuries ago. Of course, most subjects that are hot research topics in Mathematics are far too remote and far too specialized for being accessible at the Gymnasium level. Yet there are marvelous exceptions: The Diffie-Hellman Key Exchange and RSA Cryptography, invented in

[28] Maybe you conclude that the 9th grade program on linear equation should contain a modest introduction to Computerized Tomography, as we did, see the Leitprogramm entitled "Gleichungen" at www.educeth.ethz.ch. Maybe you conclude that the program, in addition to Gaussian elimination, should include a homeopathic introduction to solving linear equations by iteration (a topic you might touch on again, when you treat Banach fixed point iteration in one dimension in connection with Kepler's equation). Maybe you conclude that the question of what it means that two linear systems of equations are equivalent, and how one obtains equivalent systems from a given one, deserves to become (a small?) Mathematics Education research project.

[29] I.e. one including a linear term with respect to the unknown.

[30] I.e. one in which the linear term is absent.

[31] Gymnasia have various different profiles in Switzerland. Some concentrate on Mathematics and Physics. There complex numbers are treated.

the late seventies, are well suited to give 10th graders an idea of the mathematical enterprise[32].

Euler buckling is probably the earliest example of a bifurcation problem. It was only during the last two or three decades, however, that bifurcation theory became a systematically developed branch of analysis. In a Specialized Mathematics course with an Educational Focus dedicated to an introduction to bifurcation theory as background it is well possible that teacher students adapt some of the material for Gymnasium students, hereby heavily drawing on a classic school subject: the study of the geometrical properties and graphing of functions defined by simple expressions.

Finally we mention ill-posed inverse problems. This again is a relatively new field of Applied Mathematics. It is of great theoretical and practical interest, the way ill-posed inverse problems are treated mathematically is surprising and they lend themselves outstandingly for treatments on various different levels[33].

We expect that Specialized Mathematics courses with an Educational Focus deepen the teacher students' mathematical expertise, that they strengthen the link between University and Gymnasium level Mathematics, that they contribute to develop the secondary school Mathematics curricula, that they support the prospective teachers to teach Mathematics at the same time more mathematically and in such a way that their students can learn to value Mathematics as a human activity and for its significance in our world.

What is eventually the role of mathematicians in K-12 in our system?

Research mathematician can and do contribute in a number of ways. Via the Bachelor's and Master's program they shape lastingly the knowledge base, the picture and the skills our teacher students develop. They can substantially contribute to the Specialized Mathematics courses with an Educational Focus. They can contribute to the design of substantial teaching units.

In Mathematics Education research highly interesting developments have just begun. We mentioned the paper by Staub and Stern entitled: "The Nature of teachers' Pedagogical Content Beliefs Matters for Students' Achievement Gains." Another paper in the same realm is by Hill, Rowan and Ball[34]. It is entitled: "Effects of teachers' mathematical knowledge for teaching on student achievement." These papers provide results on primary school teachers and primary school pupils. We certainly need many more results on "what has which impact on student learning" and very much so in higher grades. In fact, very little seems to be known as to the upper Gymnasium level.

[32]Here are some aspects: Fermat's (little) Theorem on which RSA cryptography is based, though elementary, is far from being obvious. The way it is proven illustrates the power of mathematical ideas. 350 years after its discovery it became the key ingredient to affirmatively answer a questions one hardly dares to ask: Is it possible that two persons, who cannot communicate but publicly, can agree on keys which permit them to exchange messages which cannot be decoded except by the person who is entitled to read the message?

[33]See Kirchgraber, U., Kirsch, A., Stoffer, D. : Schlecht gestellte Probleme – oder wenn das Ungenaue genauer ist. *Math. Semesterber.* **51** (2004), 175–2005.

[34]Hill, H. C., Rowan, B., Ball, D. L.: Effects of teachers' mathematical knowledge for teaching on student achievement. *Amer. Educ. Res. J.* **42** (2005), 371–406.

Earlier we noted that educational measurement techniques are probably still in their infancy. How can we suitably measure mathematical achievements, teachers' pedagogical content knowledge, the nature of teachers' pedagogical content beliefs, and many more variables of this type? This is certainly a field, where research mathematician can and should contribute.

Research mathematicians in Switzerland are welcome as members in school boards, and/or as experts in the final examinations at Gymnasium Schools. Research mathematicians are welcome to offer lectures to in-service teachers or to participate in study weeks for Gymnasium students, or to visit schools and give talks.

To summarize: The main contribution of research mathematicians to the second half of K-12 is to train Mathematics teachers as knowledgeable mathematicians and to develop with them methods to narrow the gap between "Gymnasium Mathematics" and University Mathematics. Other possible contributions are manifold, crucial and indispensable.

# On the origins of Hilbert's sixth problem: physics and the empiricist approach to axiomatization

Leo Corry

**Abstract.** The sixth of Hilbert's famous 1900 list of twenty-three problems is a programmatic call for the axiomatization of physical sciences. Contrary to a prevalent view this problem was naturally rooted at the core of Hilbert's conception of what axiomatization is all about. The axiomatic method embodied in his work on geometry at the turn of the twentieth-century originated in a preoccupation with foundational questions related with empirical science, including geometry and other physical disciplines at a similar level. From all the problems in the list, the sixth is the only one that continually engaged his efforts over a very long period, at least between 1894 and 1932.

**Mathematics Subject Classification (2000).** Primary 01A60; Secondary 03-03, 70-03, 83-03.

**Keywords.** David Hilbert, axiomatization, physics.

## 1. Introduction

Of the many important and brilliant plenary talks delivered in ICMs ever since the inception of this institution in 1897 in Zurich, none has so frequently been quoted and, possibly, none has had the kind of pervasive influence, as the one delivered by David Hilbert in 1900 at the second ICM in Paris, under the title of "Mathematical Problems". Rather than summarizing the state of the art in a central branch of mathematics, Hilbert attempted to "lift the veil" and peer into the development of mathematics in the century that was about to begin. He chose to present a list of twenty-three problems that in his opinion would and should occupy the efforts of mathematicians in the years to come. This famous list has been an object of mathematical and historical interest ever since.

The sixth problem of the list deals with the axiomatization of physics. It was suggested to Hilbert by his own recent research on the foundations of geometry. He proposed "to treat in the same manner, by means of axioms, those physical sciences in which mathematics plays an important part." This problem differs from most others on Hilbert's list in essential ways, and its inclusion has been the object of noticeable reaction from mathematicians and historians who have discussed it throughout the years. Thus, in reports occasionally written about the current state of research on the twenty-three problems, the special status of the sixth problem is readily visible: not only has it been difficult to decide to what extent the problem was actually solved (or not), but one gets the impression that, of all the problems on the list, this one received

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

the least attention from mathematicians throughout the century and that relatively little effort was directed at solving it ([11], [25]).

Many a historical account simply dismissed the sixth problem as a slip on Hilbert's side, as a curiosity, and as an artificial addition to what would otherwise appear as an organically conceived list, naturally connected to his broad range of mathematical interests (e.g., [26], p. 159). In fact, this is how Hilbert's interest in physical topics in general as well as his few, well-known incursions into physical problems have been traditionally seen. According to this view, these are seen as sporadic incursions into foreign territory, mainly for the purposes of finding some new applications to what would otherwise be purely mathematically motivated ideas. This is the case, for instance, with Hilbert's solution of the Boltzmann equation in kinetic theory of gases in 1912. Starting in 1902, most of Hilbert's mathematical energies had been focused on research related with the theory of linear integral equations, and his solution of the Boltzmann equation could thus be seen as no more than an application of the techniques developed as part of that theory to a particular situation, the physical background of which would be of no direct interest to Hilbert. An account in this spirit appears in Stephen G. Brush's authoritative book on the development of kinetic theory, according to which:

> When Hilbert decided to include a chapter on kinetic theory in his treatise on integral equations, it does not appear that he had any particular interest in the physical problems associated with gases. He did not try to make any detailed calculations of gas properties, and did not discuss the basic issues such as the nature of irreversibility and the validity of mechanical interpretations which had exercised the mathematician Ernst Zermelo in his debate with Boltzmann in 1896–97. A few years later, when Hilbert presented his views on the contemporary problems of physics, he did not even mention kinetic theory. We must therefore conclude that he was simply looking for another possible application of his mathematical theories, and when he had succeeded in finding and characterizing a special class of solutions (later called "normal") …his interest in the Boltzmann equation and in kinetic theory was exhausted. ([4], p. 448)

A further important physical context where Hilbert's appeared prominently concerns the formulation of the gravitational field-equations of the general theory of relativity (GTR). On November 20, 1915, Hilbert presented to the Royal Scientific Society in Göttingen his version of the equations, in the framework of what he saw as an axiomatically formulated foundation for the whole of physics. During that same month of November, Einstein had been struggling with the final stages of his own effort to formulate the generally covariant equations that lie at the heart of GTR. He presented three different versions at the weekly meetings of the Prussian Academy of Sciences in Berlin, before attaining his final version, on November 25, that is, five days *after* Hilbert had presented his own version.

Einstein had visited Göttingen in the summer of 1915 to lecture on his theory and on the difficulties currently encountered in his work. Hilbert was then in the audience and Einstein was greatly impressed by him. Earlier accounts of Hilbert's involvement with problems associated with GTR had in general traced it back to this visit of Einstein or, at the earliest, to the years immediately preceding it. As in the case of kinetic theory, this contribution of Hilbert was often seen as a more or less furtive incursion into physics, aimed at illustrating the power and the scope of validity of the "axiomatic method" and as a test of Hilbert's mathematical abilities while trying to "jump onto the bandwagon of success" of Einstein's theory.

In biographical accounts of Hilbert, his lively interest in physics has never been overlooked, to be sure, but it mostly has been presented as strictly circumscribed in time and scope. Thus for instance, in his obituary of Hilbert, Hermann Weyl ([24], p. 619) asserted that Hilbert's work comprised five separate, and clearly discernible main periods: (1) Theory of invariants (1885–1893); (2) Theory of algebraic number fields (1893–1898); (3) Foundations, (a) of geometry (1898–1902), (b) of mathematics in general (1922–1930); (4) Integral equations (1902–1912); (5) Physics (1910–1922). Weyl's account implies that the passage from any of these fields to the next was always clear-cut and irreversible, and a cursory examination of Hilbert's published works may confirm this impression. But as Weyl himself probably knew better than many, the list of Hilbert's publications provides only a partial, rather one-sided perspective of his intellectual horizons, and this is particularly the case when it comes to his activities related to physics.

Recent historical research has brought to light a very different picture of Hilbert's involvement with physics, and in particular of the real, truly central place of the ideas embodied in the sixth problem within the general edifice of Hilbert's scientific outlook. Hilbert's involvement with physical issues spanned most of his active scientific life, and the essence of his mathematical conceptions cannot be understood without reference to that involvement. More importantly, the famous "axiomatic approach" that came to be identified with Hilbert's mathematical achievements and with his pervasive influence on twentieth-century mathematics is totally misunderstood if it is not seen, in the first place, as connected with his physical interests. Under this perspective, the involvement with kinetic theory and GTR are seen as a natural outgrowth of the development of Hilbert's world of ideas, and by no means as sporadic, isolated incursions into unknown territories. Moreover, contrary to a commonly held view, the sixth problem is the only one in the entire list of 1900 that refers to an idea that continually engaged the active attention of Hilbert for a very long period of time, at least between 1894 and 1932 ([5]).

The key to a balanced understanding of the role of physics within Hilbert's intellectual horizon is found not so much in his publications, as it is in the complex academic network of personal interactions and diverse activities that he was continually part of. Especially worthy of attention is his teaching, first at Königsberg and – more importantly – after 1895 at Göttingen. At the mathematical institute established by Felix Klein, Hilbert became the leader of a unique scientific center that brought

together a gallery of world-class researchers in mathematics and physics. One cannot exaggerate the significance of the influence exerted by Hilbert's thought and personality on all who came out of this institution. More often than not, these lectures were far from systematic and organized presentations of well-known results and established theories. Rather, Hilbert often used his lectures as a public stage where he could explore new ideas and think aloud about the issues that occupied his mind at any point in time. In a lecture held in commemorating his seventieth birthday, Hilbert vividly recalled how these lectures provided important occasions for the free exploration of yet untried ideas. He thus said:

> The closest conceivable connection between research and teaching became a decisive feature of my mathematical activity. The interchange of scientific ideas, the communication of what one found by himself and the elaboration of what one had heard, was from my early years at Königsberg a pivotal aspect of my scientific work. …In my lectures, and above all in the seminars, my guiding principle was not to present material in a standard and as smooth as possible way, just to help the student keep clean and ordered notebooks. Above all, I always tried to illuminate the problems and difficulties and to offer a bridge leading to currently open questions. It often happened that in the course of a semester the program of an advanced lecture was completely changed, because I wanted to discuss issues in which I was currently involved as a researcher and which had not yet by any means attained their definite formulation. ([16], p. 79)

The collection of Hilbert's lecture notes offers an invaluable source of information for anyone interested in understanding his scientific horizon and contributions.

## 2. Axiomatics and formalism

A main obstacle in historically understanding the significance of the sixth problem has been the widespread image of Hilbert as the champion of formalism in modern mathematics. The traditional association of Hilbert's name with the term "formalism" has often proved to be misleading, since the term can be understood in two completely different senses that are sometimes conflated. One sense refers to the so-called "Hilbert program" that occupied much of Hilbert's efforts from abut 1920. Although involving significant philosophical motivations, at the focus of this program stood a very specific, technical mathematical problem, namely, the attempt to prove the consistency of arithmetic with strictly finitist arguments. The point of view embodied in the program was eventually called the "formalist" approach to the foundations of mathematics, and it gained much resonance when it became a main contender in the so-called "foundational crisis" in mathematics early in the twentieth century.

Even though Hilbert himself did not use the term "formalism" in this context,

associating his name with term conceived in this narrow sense seems to be essentially justified. It is misleading, however, to extend the term "Hilbert program" – and the concomitant idea of formalism – to refer to Hilbert's overall conception of the essence of mathematics. Indeed, a second meaning of the term formalism refers to a general attitude towards the practice of mathematics and the understanding of the essence of mathematical knowledge that gained widespread acceptance in the twentieth century, especially under the aegis of the Bourbaki group. Jean Dieudonné, for instance, explained what he saw as the essence of Hilbert's *mathematical* conceptions in a well-known text where he referred to the analogy with a game of chess. In the latter, he said, one does not speak about truths but rather about following correctly a set of stipulated rules. If we translate this into mathematics we obtain the putative, "formalist" conception often attributed to Hilbert ([6], p. 551): "mathematics becomes a *game*, whose pieces are graphical *signs* that are distinguished from one another by their form."

Understanding the historical roots and development of the sixth problem goes hand in hand with an understanding of Hilbert's overall conception of mathematics as being far removed from Dieudonné's chess-game metaphor. It also comprises a clear separation between the "Hilbert program" for the foundations of arithmetic, on the one hand, and Hilbert's lifetime research program for mathematics and physics and its variations throughout the years, on the other hand. In this regard, and even before one starts to look carefully at Hilbert's mathematical ideas and practice throughout his career, it is illustrative to look at a quotation from around 1919 – the time when Hilbert began to work out the finitist program for the foundations of arithmetic in collaboration with Paul Bernays – that expounds a view diametrically opposed to that attributed to him many years later by Dieudonné, and that is rather widespread even today. Thus Hilbert said:

> We are not speaking here of arbitrariness in any sense. Mathematics is not like a game whose tasks are determined by arbitrarily stipulated rules. Rather, it is a conceptual system possessing internal necessity that can only be so and by no means otherwise. ([16], p. 14)

The misleading conflation of the formalist aspect of the "Hilbert program" with Hilbert's overall views about mathematics and its relationship with physics is also closely related with a widespread, retrospective misreading of his early work on the foundations of geometry in purely formalist terms. However, the centrality attributed by Hilbert to the axiomatic method in mathematics and in science is strongly connected with thoroughgoing empiricist conceptions, that continually increased in strength as he went on to delve into ever new physical disciplines, and that reached a peek in 1915–17, the time of his most intense participation in research associated with GTR.

The axiomatic approach was for Hilbert, above all, a tool for retrospectively investigating the logical structure of *well-established and elaborated* scientific theories, and the possible difficulties encountered in their study, and never the starting point for

the creation of new fields of enquiry. The role that Hilbert envisaged for the axiomatic analysis of theories is succinctly summarized in the following quotation taken from a course on the axiomatic method taught in 1905. Hilbert thus said:

> The edifice of science is not raised like a dwelling, in which the foundations are first firmly laid and only then one proceeds to construct and to enlarge the rooms. Science prefers to secure as soon as possible comfortable spaces to wander around and only subsequently, when signs appear here and there that the loose foundations are not able to sustain the expansion of the rooms, it sets about supporting and fortifying them. This is not a weakness, but rather the right and healthy path of development. ([5], p. 127)

## 3. Roots and early stages

Physics and mathematics were inextricably interconnected in Hilbert's scientific horizon ever since his early years as a young student in his native city of Königsberg, where he completed his doctorate in 1885 and continued to teach until 1895. Hilbert's dissertation and all of his early published work dealt with the theory of algebraic invariants. Subsequently he moved to the theory of algebraic number fields. But his student notebooks bear witness to a lively interest in, and a systematic study of, an astounding breadth of topics in both mathematics and physics. Particularly illuminating is a notebook that records his involvement as a student with the *Lehrbuch der Experimentalphysik* by Adolph Wüllner (1870). This was one of many textbooks at the time that systematically pursued the explicit reduction of all physical phenomena (particularly the theories of heat and light, magnetism and electricity) to mechanics, an approach that underlies all of Hilbert's early involvement with physics, and that he abandoned in favor of electrodynamical reductionism only after 1912.

In the intimate atmosphere of this small university, the student Hilbert participated in a weekly seminar organized under the initiative of Ferdinand Lindemann – who was also Hilbert's doctoral advisor – that was also attended by his good friends Adolf Hurwitz and Hermann Minkowski, by the two local physicist, Woldemar Voigt and Paul Volkmann, and by another fellow student Emil Wiechert, who would also become Hilbert's colleague in Göttingen and the world's leading geophysicist. The participants discussed recent research in all of branches of mathematics and physics, with special emphasis on hydrodynamics and electrodynamics, two topics of common interest for Hilbert and Minkowski throughout their careers. From very early on, fundamental methodological questions began to surface as part of Hilbert's involvement with both mathematics and physics.

On the mathematical side one may mention the intense research activity associated with the names of Cayley and Klein in projective geometry, concerning both the main body of results and the foundations of this discipline; the questions sparked by the discovery and publication of non-Euclidean geometries, which raised philosoph-

ical concerns to a larger extent than they elicited actual mathematical research; the introduction by Riemann of the manifold approach to the analysis of space and its elaboration by Lie and Helmholtz; the question of the arithmetization of the continuum as analyzed by Dedekind, which had also important foundational consequences for analysis; the gradual re-elaboration of axiomatic techniques and perspectives as a main approach to foundational questions in mathematics, especially in the hands of Grassmann and of the Italian geometers. Hilbert's intellectual debts to each of these traditions and to the mathematicians that partook in it – even though more complex and subtle than may appear on first sight – belong to the directly visible, received image of Hilbert the geometer.

What is remarkable, and virtually absent from the traditional historiography until relatively recently, is the extent to which similar parallel developments in physics played a fundamental role in shaping Hilbert's views on axiomatization. Very much like geometry, also physics underwent major changes throughout the nineteenth century. These changes affected the contents of the discipline, its methodology, its institutional setting, and its image in the eyes of its practitioners. They were accompanied by significant foundational debates that intensified considerably toward the end of the century, especially among German-speaking physicists. Part of these debates also translated into specific attempts to elucidate the role of basic laws or principles in physical theories, parallel in certain respects to that played by axioms in mathematical theories. As with geometry, foundational questions attracted relatively limited attention from practitioners of the discipline, but some leading figures were indeed involved in them.

From about 1850 on, physics became focused on quantification and the search for universal mathematical laws as its fundamental methodological principles, on the conservation of energy as a fundamental unifying principle, and very often on mechanical explanation of all physical phenomena as a preferred research direction. If explanations based on imponderable "fluids" had dominated so far, mechanical explanations based on the interaction of particles of ordinary matter now became much more frequent. In particular, the mechanical theory of ether gave additional impulse to the concept of "field" that would eventually require a mechanical explanation. Likewise, the kinetic theory of gases gave additional support to the foundational role of mechanics as a unifying, explanatory scheme. On the other hand, these very developments gave rise to many new questions that would eventually challenge the preferential status of mechanics and lead to the formulation of significant alternatives to it, especially in the form of the so-called "electromagnetic worldview", as well as in the "energicist" and the phenomenological approaches.

Beginning in the middle of the century, several physicists elaborated on the possibility of systematically clarifying foundational issues of this kind in physical theories, based on the use of "axioms", "postulates" or "principles". This was not, to be sure, a really central trend that engaged the leading physicists in lively discussions. Still, given the vivid interest on Volkmann in the topic, Hilbert became keenly aware of many of these developments and discussed them with his colleagues at the seminar.

Above all, the ideas of Heinrich Hertz and Ludwig Boltzmann on the foundations of physics strongly influenced him, not only at the methodological level, but also concerning his strong adherence to the mechanical reductionist point of view.

The lecture notes of courses in geometry taught by Hilbert in Königsberg illuminatingly exemplify the confluence of the various points mentioned in the preceding paragraphs. Central to this is his conception of geometry as a *natural* science, close in all respects to mechanics and the other physical disciplines, and opposed to arithmetic and other mathematical fields of enquiry. This was a traditional separation, adopted with varying degrees of commitment, among the German mathematicians (especially in Göttingen) since the time of Gauss. Even geometers like Moritz Pasch, who had stressed a thoroughly axiomatic approach in their presentations of projective geometry [20], would support such an empiricist view of geometry. In the introduction to a course taught in 1891, for instance, Hilbert expressed his views as follows:

> Geometry is the science dealing with the properties of space. It differs essentially from pure mathematical domains such as the theory of numbers, algebra, or the theory of functions. The results of the latter are obtained through pure thinking …The situation is completely different in the case of geometry. I can never penetrate the properties of space by pure reflection, much the same as I can never recognize the basic laws of mechanics, the law of gravitation or any other physical law in this way. Space is not a product of my reflections. Rather, it is given to me through the senses. ([5], p. 84)

The connection between this view and the axiomatic approach as a proper way to deal with this kind of sciences was strongly supported by the work of Hertz. Hilbert had announced another course in geometry for 1893, but for lack of students registered it was postponed until 1894. Precisely at this time, Hertz's *Principles of Mechanics* [13] was posthumous published, and Hilbert got enthusiastic notice of the book from his friend Minkowski. Minkowski had been in Bonn since 1885 where he came under the strong influence of Hertz, to the point that the latter became his main source of scientific inspiration ([15], p. 355). In the now famous introduction to his book, Hertz described physical theories as "pictures" (*Bilder*) that we form for ourselves of natural phenomena, and suggested three criteria to evaluate among several possible images of one and the same object: permissibility, correctness, and appropriateness. Permissibility corresponds very roughly to consistency, whereas correctness and appropriateness are closer to the kind of criteria that will appear later on in Hilbert's *Grundlagen der Geometrie* (*GdG* – see below).

In the lecture notes of his 1893–94 course, Hilbert referred once again to the natural character of geometry and explained the possible role of axioms in elucidating its foundations. As he had time to correct the notes, he now made explicit reference to Hertz's characterization of a "correct" scientific image (*Bild*) or theory. Thus Hilbert wrote ([5], p. 87):

> Nevertheless the origin [of geometrical knowledge] is in experience. The axioms are, as Hertz would say, images or symbols in our mind, such that consequents of the images are again images of the consequences, i.e., what we can logically deduce from the images is itself valid in nature.

Hilbert also pointed out the need of establishing the independence of the axioms of geometry, while alluding, once again, to the kind of demand stipulated by Hertz. Stressing the objective and factual character of geometry, Hilbert wrote:

> The problem can be formulated as follows: What are the necessary, sufficient, and mutually independent conditions that must be postulated for a system of things, in order that any of their properties correspond to a geometrical fact and, conversely, in order that a complete description and arrangement of all the geometrical facts be possible by means of this system of things.

The axioms of geometry and of physical disciplines, Hilbert said, "express observations of facts of experience, which are so simple that they need no additional confirmation by physicists in the laboratory."

The empirical character of geometry has its clear expression in the importance attributed to Gauss's measurement of the sum of angles of a triangle formed by three mountain peaks in Hannover. Hilbert found these measurements convincing enough to indicate the correctness of Euclidean geometry as a true description of physical space. Nevertheless, he envisaged the possibility that some future measurement would yield a different result. This example would arise very frequently in Hilbert's lectures on physics in years to come, as an example of how the axiomatic method should be applied in physics, where new empirical facts are often found by experiment. Faced with new such findings that seem to contradict an existing theory, the axiomatic analysis would allow making the necessary modifications on some of the basic assumptions of the theory, without however having to modify its essential logical structure. Hilbert stressed that the axiom of parallels is likely to be the one to be modified in geometry if new experimental discoveries would necessitate so. Geometry was especially amenable to a full axiomatic analysis only because of its very advanced stage of development and elaboration, and not because of any other specific, essential trait concerning its nature that would set it apart from other disciplines of physics. Thus, in a course on mechanics taught in 1899, the year of publication of *GdG*, he said:

> Geometry also [like mechanics] emerges from the observation of nature, from experience. To this extent, it is an *experimental science*.…But its experimental foundations are so irrefutably and so *generally acknowledged*, they have been confirmed to such a degree, that no further proof of them is deemed necessary. Moreover, all that is needed is to derive these foundations from a minimal set of *independent axioms* and thus to construct the whole edifice of geometry by *purely logical means*. In this way [i.e., by means of the axiomatic treatment] geometry is turned into a *pure mathematical* science. In mechanics it is also

> the case that all physicists recognize its most basic facts. But the *arrangement* of the basic concepts is still subject to changes in perception …and therefore mechanics cannot yet be described today as a *pure mathematical* discipline, at least to the same extent that geometry is. ([5], p. 90. Emphasis in the original)

Thus, at the turn of the century, Hilbert consolidated his view of the axiomatic method as a correct methodology to be applied, in parallel and with equal importance, to geometry and to all other physical disciplines. The publication of *GdG* helped spread his ideas very quickly and in strong association with geometry alone. But the idea of applying the same point of view to physics, although made known to the public only in the 1900 list of problems, was for him natural and evident from the outset. In his course of 1899, Hilbert devoted considerable effort to discussing the technical details of, as well as the logical and conceptual interrelations among, the main principles of analytical mechanics: the energy conservation principle, the principle of virtual velocities and the D'Alembert principle, the principles of straightest path and of minimal constraint, and the principles of Hamilton and Jacobi. All of this will appear prominently in Hilbert's later own elaboration of the program for the axiomatization of physics.

## 4. *Grundlagen der Geometrie*

Hilbert's *Grundlagen der Geometrie* embodied his first published, comprehensive presentation of an axiomatized mathematical discipline. Based on a course taught in the winter semester of 1898–99, it appeared in print in June of 1899. The declared aim of the book was to lay down a "simple" and "complete" system of "mutually independent" axioms, from which all known theorems of geometry might be deduced. The axioms were formulated for three systems of undefined objects named "points", "lines", and "planes", and they establish mutual relations that these objects must satisfy. The axioms were grouped into five categories: axioms of incidence, of order, of congruence, of parallels, and of continuity. From a purely logical point of view, the groups have no real significance in themselves. However, from the geometrical point of view they are highly significant, for they reflect Hilbert's actual conception of the axioms as an expression of spatial intuition: each group expresses a particular way that these intuitions manifest themselves in our understanding.

Hilbert's first requirement, that the axioms be independent, is the direct manifestation of the foundational concerns that guided his research. When analyzing independence, his interest focused mainly on the axioms of congruence, continuity and of parallels, since this independence would specifically explain how the various basic theorems of Euclidean and projective geometry are logically interrelated. This requirement had already appeared – albeit more vaguely formulated – in Hilbert's early lectures on geometry, as a direct echo of Hertz's demand for "appropriateness" of physical theories (i.e., the demand of "distinctness and simplicity" for the axioms

of the theory). This time Hilbert also provided the tools to prove systematically the mutual independence among the individual axioms within the groups and among the various groups of axioms in the system. However, this was not for Hilbert an exercise in analyzing abstract relations among systems of axioms and their possible models. The motivation for enquiring about the mutual independence of the axioms remained, essentially, a geometrical one. For this reason, Hilbert's original system of axioms was not the most economical one from the logical point of view. Indeed, several mathematicians noticed quite soon that Hilbert's system of axioms, seen as a single collection rather than as a collection of five groups, contained a certain degree of redundancy ([19], [23]). Hilbert's own aim was to establish the interrelations among the groups of axioms, embodying the various manifestations of space intuition, rather than among individual axioms belonging to different groups.

The second one, simplicity is also related to Hertz's appropriateness. Unlike the other requirements, it did not become standard as part of the important mathematical ideas to which *GdG* eventually led. Through this requirement Hilbert wanted to express the desideratum that an axiom should contain "no more than a single idea." However, he did not provide any formal criterion to decide when an axiom is simple. Rather this requirement remained implicitly present in *GdG*, as well as in later works of Hilbert, as a merely aesthetic guideline that was never transformed into a mathematically controllable feature.

The idea of a complete axiomatic system became pivotal to logic after 1930 following the works of Gödel, and in connection with the finitist program for the foundations of arithmetic launched by Hilbert and his collaborators around 1920. This is not, however, what Hilbert had in mind in 1899, when he included a requirement under this name in the analysis presented in *GdG*. Rather, he was thinking of a kind of "pragmatic" completeness. In fact, what Hilbert was demanding here is that an adequate axiomatization of a mathematical discipline should allow for an actual derivation of *all* the theorems already known in that discipline. This was, Hilbert claimed, what the totality of his system of axioms did for Euclidean geometry or, if the axiom of parallels is ignored, for the so-called absolute geometry, namely that which is valid independently of the latter.

Also the requirement of consistency was to become of paramount importance thereafter. Still, as part of *GdG*, Hilbert devoted much less attention to it. For one thing, he did not even mention this task explicitly in the introduction to the book. For another, he devoted just two pages to discussing the consistency of his system in the body of the book. In fact, it is clear that Hilbert did not intend to give a direct proof of consistency of geometry here, but even an indirect proof of this fact does not explicitly appear in *GdG*, since a systematic treatment of the question implied a full discussion of the structure of the system of real numbers, which was not included. Rather, Hilbert suggested that it would suffice to show that the specific kind of synthetic geometry derivable from his axioms could be translated into the standard Cartesian geometry, if the axes are taken as representing the entire field of real numbers. Only in the second edition of *GdG*, published in 1903, Hilbert added an additional axiom,

the so-called "axiom of completeness" (*Vollständigkeitsaxiom*), meant to ensure that, although infinitely many incomplete models satisfy all the other axioms, there is only one complete model that satisfies this last axiom as well, namely, the usual Cartesian geometry.

Hilbert's axiomatic analysis of geometry was not meant to encourage the possibility of choosing arbitrary combinations of axioms within his system, and of exploring their consequences. Rather, his analysis was meant to enhance our understanding of those systems with a more intuitive, purely geometrical significance – Euclidean geometry, above all – and that made evident the connection of his work with long-standing concerns of the discipline throughout the nineteenth century [8]. As already stressed, the definition of systems of abstract axioms and the kind of axiomatic analysis described above was meant to be carried out always retrospectively, and only for "concrete", *well-established and elaborated* mathematical entities.

The publication of the *Grundlagen* was followed by many further investigations into Hilbert's technical arguments, as well as by more general, methodological and philosophical discussions. One important such discussion appeared in the correspondence between Hilbert and Gottlob Frege. This interchange has drawn considerable attention of historians and philosophers, especially for the debate it contains between Hilbert and Frege concerning the nature of mathematical truth. But this frequently-emphasized issue is only one side of a more complex picture advanced by Hilbert in his letters. In particular, it is interesting to notice Hilbert's explanation to Frege, concerning the main motivations for undertaking his axiomatic analysis: the latter had arisen, in the first place, from difficulties Hilbert had encountered when dealing with *physical*, rather than mathematical theories. Echoing once again ideas found in the introduction to Hertz's textbook, and clearly having in mind the problematic conceptual situation of the kinetic theory of gases at the turn of the century, Hilbert stressed the need to analyze carefully the process whereby physicists continually add new assumptions to existing physical theories, without properly checking whether or not the former contradict the latter, or consequences of the latter. In a letter of December 29, 1899, Hilbert wrote to Frege:

> After a concept has been fixed completely and unequivocally, it is on my view completely illicit and illogical to add an axiom – a mistake made very frequently, especially by physicists. By setting up one new axiom after another in the course of their investigations, without confronting them with the assumptions they made earlier, and without showing that they do not contradict a fact that follows from the axioms they set up earlier, physicists often allow sheer nonsense to appear in their investigations. One of the main sources of mistakes and misunderstandings in modern physical investigations is precisely the procedure of setting up an axiom, appealing to its truth, and inferring from this that it is compatible with the defined concepts. One of the main purposes of my *Festschrift* was to avoid this mistake. ([9], p. 40)

In a different passage of the same letter, Hilbert commented on the possibility of substituting the basic objects of an axiomatically formulated theory by a different system of objects, provided the latter can be put in a one-to-one, invertible relation with the former. In this case, the known theorems of the theory are equally valid for the second system of objects. Concerning physical theories, Hilbert wrote:

> All the statements of the theory of electricity are of course valid for any other system of things which is substituted for the concepts magnetism, electricity, etc., provided only that the requisite axioms are satisfied. But the circumstance I mentioned can never be a defect in a theory [footnote: it is rather a tremendous advantage], and it is in any case unavoidable. However, to my mind, the application of a theory to the world of appearances always requires a certain measure of good will and tactfulness: e.g., that we substitute the smallest possible bodies for points and the longest possible ones, e.g., light-rays, for lines. At the same time, the further a theory has been developed and the more finely articulated its structure, the more obvious the kind of application it has to the world of appearances, and it takes a very large amount of ill will to want to apply the more subtle propositions of [the theory of surfaces] or of Maxwell's theory of electricity to other appearances than the ones for which they were meant …([9], p. 41)

Hilbert's letters to Frege help understanding the importance of the link between physical and mathematical theories on the development of his axiomatic point of view. The latter clearly did not involve either an empty game with arbitrary systems of postulates nor a conceptual break with the classical, nineteenth-century entities and problems of mathematics and empirical science. Rather it sought after an improvement in the mathematician's understanding of the latter. This motto was to guide much of Hilbert's incursions into several domains of physics over the years to come.

## 5. Physics and the 1900 list of problems

In the introductory section of his Paris talk, Hilbert stressed the important role he accorded to empirical motivations as a fundamental source of nourishment for what he described as a "living organism", in which mathematics and the physical sciences appear tightly interrelated. The empirical motivations underlying mathematical ideas, Hilbert said, should by no means be taken as opposed to rigor. On the contrary, contrasting an "opinion occasionally advocated by eminent men", Hilbert insisted that the contemporary quest for rigor in analysis and arithmetic should in fact be *extended to both geometry and the physical sciences*. He was alluding here, most probably, to Kronecker and Weierstrass, and the Berlin purist tendencies that kept geometry and applications out of their scope of interest. Rigorous methods are often simpler and easier to understand, Hilbert said, and therefore, a more rigorous treatment would

only perfect our understanding of these topics, and at the same time would provide mathematics with ever new and fruitful ideas. In explaining why rigor should not be sought only within analysis, Hilbert actually implied that this rigor should actually be pursued in axiomatic terms. He thus wrote:

> Such a one-sided interpretation of the requirement of rigor would soon lead to the ignoring of all concepts arising from geometry, mechanics and physics, to a stoppage of the flow of new material from the outside world, and finally, indeed, as a last consequence, to the rejection of the ideas of the continuum and of irrational numbers. But what an important nerve, vital to mathematical science, would be cut by rooting out geometry and mathematical physics! On the contrary I think that wherever mathematical ideas come up, whether from the side of the theory of knowledge or in geometry, or from the theories of natural or physical science, the problem arises for mathematics to investigate the principles underlying these ideas and to establish them upon a simple and complete system of axioms, so that the exactness of the new ideas and their applicability to deduction shall be in no respect inferior to those of the old arithmetical concepts. (Quoted from [12], p. 245)

Using a rhetoric reminiscent of Volkmann's work, Hilbert described the development of mathematical ideas as an ongoing, dialectical interplay between the two poles of thought and experience. He also added an idea that was of central importance to Göttingen scientists for many decades, namely, the conception of the "pre-established harmony" between mathematics and nature ([21]). The importance of investigating the foundations of mathematics does not appear as an isolated concern, but rather as an organic part of the manifold growth of the discipline in several directions. Hilbert thus said:

> Indeed, the study of the foundations of a science is always particularly attractive, and the testing of these foundations will always be among the foremost problems of the investigator …[But] a thorough understanding of its special theories is necessary for the successful treatment of the foundations of the science. Only that architect is in the position to lay a sure foundation for a structure who knows its purpose thoroughly and in detail. (Quoted from [12], p. 258)

The first two problems in Hilbert's list are Cantor's continuum hypothesis and the compatibility of the axioms of arithmetic. In formulating the second problem on his list, Hilbert stated more explicitly than ever before, that among the tasks related to investigating an axiomatic system, proving its consistency would be the most important one. Yet, Hilbert was still confident that this would be a rather straightforward task, easily achievable "by means of a careful study and suitable modification of the known methods of reasoning in the theory of irrational numbers." Clearly Hilbert meant his remarks in this regard to serve as an argument against Kronecker's negative

reactions to unrestricted use of infinite collections in mathematics, and therefore he explicitly asserted that a consistent system of axioms could prove the existence of higher Cantorian cardinals and ordinals. Hilbert's assertion is actually the first published mention of the paradoxes of Cantorian set theory, which here were put forward with no special fanfare ([7], p. 301). He thus established a clear connection between the two first problems on his list through the axiomatic approach. Still, Hilbert was evidently unaware of the difficulties involved in realizing this point of view, and, more generally, he most likely had no precise idea of what an elaborate theory of systems of axioms would involve. On reading the first draft of the Paris talk, several weeks earlier, Minkowski understood at once the challenging implications of Hilbert's view, and he hastened to write to his friend:

> In any case, it is highly original to proclaim as a problem for the future, one that mathematicians would think they had already completely possessed for a long time, such as the axioms for arithmetic. What might the many laymen in the auditorium say? Will their respect for us grow? And you will also have a though fight on your hands with the philosophers. ([22], p. 129)

Frege's reaction to the *GdG* proved Minkowski's concern to be justified, as his main criticism referred to the status of axioms as implicit definitions.

The next three problems in the list are directly related with geometry and, although not explicitly formulated in axiomatic terms, they address the question of finding the correct relationship between specific assumptions and specific, significant geometrical facts. The fifth problem, for instance, relates to the question of the foundations of geometry as it had evolved over the last third of the nineteenth century along two parallel paths. On the one hand, there was the age-old tradition of elementary synthetic geometry, where the question of foundations more naturally arises in axiomatic terms. On the other hand, there was the tradition associated with the Helmholtz–Lie problem, that derived directly from the work of Riemann and that had a more physically-grounded orientation connected with the question of spaces that admit the free mobility of rigid bodies. Whereas Helmholtz had only assumed *continuity* as underlying the motion of rigid bodies, in applying his theory of groups of transformations to this problem, Lie was also assuming the *differentiability* of the functions involved. Hilbert's work on the foundations of geometry, especially in the context that led to *GdG*, had so far been connected with the first of these two traditions, while devoting much less attention to the second one. Now in his fifth problem, he asked whether Lie's conditions, rather than assumed, could actually be deduced from the group concept together with other geometrical axioms.

As a mathematical problem, the fifth one led to interesting, subsequent developments. Not long after his talk, in November 18, 1901, Hilbert himself proved that, in the plane, the answer is positive, and he did so with the help of a then innovative, essentially topological, approach [14]. That the answer is positive in the general case was satisfactorily proved only in 1952 ([10], [18]). The inclusion of this problem in

the 1900 list underscores the actual scope of Hilbert's views over the question of the foundations of geometry and over the role of axiomatics. Hilbert suggested here the pursuit of an intricate kind of conceptual clarification involving assumptions about motion, differentiability and symmetry, such as they appear intimately interrelated in the framework of a well-elaborate mathematical theory, namely, that of Lie. This quest, that also became typical of the spirit of Hilbert's axiomatic involvement with physical theories, suggests that his foundational views on geometry were very broad and open-ended, and did not focus on those aspects related with the synthetic approach to geometry. In particular, the fifth problem emphasizes the prominent role that Hilbert assigned to physical considerations in his approach to geometry. In the long run, this aspect of Hilbert's view resurfaced at the time of his involvement with GTR ([5], Ch. 7–8). In its more immediate context, however, it makes the passage from geometry to the sixth problem appear as a natural one within the list.

Indeed, if the first two problems in the list show how the ideas deployed in *GdG* led in one direction towards foundational questions in arithmetic, then the fifth problem suggests how they also naturally led, in a different direction, to Hilbert's call for the axiomatization of physical science in the sixth problem. The problem was thus formulated as follows:

> The investigations on the foundations of geometry suggest the problem: To treat in the same manner, by means of axioms, those physical sciences in which mathematics plays an important part; in the first rank are the theory of probabilities and mechanics. (Quoted in [12], p. 258)

As examples of what he had in mind Hilbert mentioned several existing and well-known works: the fourth edition of Mach's *Die Mechanik in ihrer Entwicklung*, Hertz's *Prinzipien*, Boltzmann's 1897 *Vorlesungen Über die Principien der Mechanik*, and also Volkmann's 1900 *Einführung in das Studium der theoretischen Physik*. Boltzmann's work offered a good example of what axiomatization would offer, as he had indicated, though only schematically, that limiting processes could be applied, starting from an atomistic model, to obtain the laws of motion of continua. Hilbert thought it convenient to go in the opposite direction also, i.e., to derive the laws of motions of rigid bodies by limiting processes, starting from a system of axioms that describe space as filled with continuous matter in varying conditions. Thus one could investigate the equivalence of different systems of axioms, an investigation that Hilbert considered to be of the highest theoretical importance.

This is one of the few places where Hilbert emphasized Boltzmann's work over Hertz's in this regard, and this may give us the clue to the most immediate trigger that was in the back of Hilbert's mind when he decided to include this problem in the list. Indeed, Hilbert had met Boltzmann several months earlier in Munich, where the latter gave a talk on recent developments in physics. Boltzmann had not only discussed ideas connected with the task that Hilbert was now calling for, but he also adopted a rhetoric that seems to have appealed very much to Hilbert. In fact, Boltzmann

had suggested that one could follow up the recent history of physics with a look at future developments. Nevertheless, he said, "I will not be so rash as to lift the veil that conceals the future" ([2], p. 79). Hilbert, on the contrary, opened the lecture by asking precisely, "who among us would not be glad to lift the veil behind which the future lies hidden" and the whole trust of his talk implied that he, the optimistic Hilbert, was helping the mathematical community to do so.

Together with the well-known works on mechanics referred to above, Hilbert also mentioned a recent work by the Göttingen actuarial mathematician Georg Bohlmann on the foundations of the calculus of probabilities [1]. The latter was important for physics, Hilbert said, for its application to the method of mean values and to the kinetic theory of gases. Hilbert's inclusion of the theory of probabilities among the main physical theories whose axiomatization should be pursued has often puzzled readers of this passage. The notes of a course taught in 1905 on the axiomatic method show that this was a main point in Hilbert's views on physics because of the use of probabilities also in insurance mathematics and in problems of observational error calculation in astronomy. It is also remarkable that Hilbert did not mention electrodynamics among the physical disciplines to be axiomatized, even though the second half of the *Gauss–Weber Festschrift*, where Hilbert's *GdG* was published, contained a parallel essay by Wiechert on the foundations of electrodynamics. At any rate, Wiechert's presentation was by no means axiomatic, in any sense of the term. On the other hand, the topics addressed by Wiechert would start attracting Hilbert's attention over the next years, at least since 1905.

This sixth problem is not really a problem in the strict sense of the word, but rather a general task for whose complete fulfillment Hilbert set no clear criteria. Thus, Hilbert's detailed account in the opening remarks of his talk as to what a meaningful problem in mathematics is, and his stress on the fact that a solution to a problem should be attained in a finite number of steps, does not apply in any sense to the sixth one. On the other hand, the sixth problem has important connections with three other problems on Hilbert's list: the nineteenth ("Are all the solutions of the Lagrangian equations that arise in the context of certain typical variational problems necessarily analytic?"), the twentieth (dealing with the existence of solutions to partial differential equations with given boundary conditions), closely related to the nineteenth and at the same time to Hilbert's long-standing interest on the Dirichlet Principle, and, finally, the twenty-third (an appeal to extend and refine the existing methods of variational calculus). Like the sixth problem, the latter two are general tasks rather than specific mathematical problems with a clearly identifiable, possible solution. All these three problems are also strongly connected to physics, though unlike the sixth, they are also part of mainstream, traditional research concerns in mathematics. In fact, their connections to Hilbert's own interests are much more perspicuous and, in this respect, they do not raise the same kind of historical questions that Hilbert's interest in the axiomatization of physics does.

A balanced assessment of the influence of the problems on the development of mathematics throughout the century must take into account not only the intrinsic

importance of the problems, but also the privileged institutional role of Göttingen in the mathematical world with the direct and indirect implications of its special status. However, if Hilbert wished to influence the course of mathematics over the coming century with his list, then it is remarkable that his own career was only very partially shaped by it. Part of the topics covered by the list belonged to his previous domains of research, while others belonged to domains where he never became active. On the contrary, domains that he devoted much effort to over the next years, such as the theory of integral equations, were not contemplated in the list. In spite of the enormous influence Hilbert had on his students, the list did not become a necessary point of reference of preferred topics for dissertations. To be sure, some young mathematicians, both in Göttingen and around the world, did address problems on the list and sometimes came up with important mathematical achievements that helped launch their own international careers. But this was far from the only way for talented young mathematicians to reach prominence in or around Göttingen. But, ironically, the sixth problem, although seldom counted among the most influential of the list, can actually be counted among those that received greater attention from Hilbert himself and from his collaborators and students over the following years.

## 6. Concluding remarks

For all its differences and similarities with other problems on the list, the important point that emerges from the above account is that the sixth problem was in no sense disconnected from the evolution of Hilbert's early axiomatic conception at its very core. Nor was it artificially added in 1900 as an afterthought about the possible extensions of an idea successfully applied in 1899 to the case of geometry. Rather, Hilbert's ideas concerning the axiomatization of physical science arose simultaneously with his increasing enthusiasm for the axiomatic method and they fitted naturally into his overall view of pure mathematics, geometry and physical science – and the relationship among them – by that time.

From 1900 on, the idea of axiomatizing physical theories was a main thread that linked much of Hilbert's research and teaching. Hilbert taught every semester at least one course dealing with a physical discipline, and by the end of his career he had covered most of the important fields that were at the cutting edge of physics, currently attracting the best research efforts of young and promising minds (see the appendix to this article). The axiomatic point of view provided a unifying methodology from which to approach many of the topics in which Hilbert became interested. In 1905 he taught a course on the axiomatic method where he presented for the first time a panoramic view of various physical disciplines from an axiomatic perspective: mechanics, thermodynamics, probability calculus, kinetic theory, insurance mathematics, electrodynamics, psychophysics. The variety of physical topics pursued only grew over the years. The extent of the influence of Hilbert's ideas on physics on contemporary research is a more complex question that cannot be discussed here for lack

of space. Still, it is relevant to quote here an account of Hilbert's ideas as described by the physicist on whom Hilbert's influence became most evident, Max Born. On the occasion of Hilbert's sixtieth birthday, at a time when he was deeply involved together with Bernays in the technical difficulties raised by the finitist program, Born wrote the following words:

> The physicist set outs to explore how things are in nature; experiment and theory are thus for him only a means to attain an aim. Conscious of the infinite complexities of the phenomena with which he is confronted in every experiment, he resists the idea of considering a theory as something definitive. He therefore abhors the word "Axiom", which in its usual usage evokes the idea of definitive truth. The physicist is thus acting in accordance with his healthy instinct, that dogmatism is the worst enemy of natural science. The mathematician, on the contrary, has no business with factual phenomena, but rather with logic interrelations. In Hilbert's language the axiomatic treatment of a discipline implies in no sense a definitive formulation of specific axioms as eternal truths, but rather the following methodological demand: specify the assumptions at the beginning of your deliberation, stop for a moment and investigate whether or not these assumptions are partly superfluous or contradict each other. ([3])

The development of physics from the beginning of the century, and especially *after* 1905, brought many surprises that Hilbert could not have envisaged in 1900 or even when he lectured at Göttingen on the axioms of physics in 1905; yet, Hilbert was indeed able to accommodate these new developments to the larger picture of physics afforded by his program for axiomatization. In fact, some of his later contributions to mathematical physics, particularly his contributions to GTR, came by way of realizing the vision embodied in this program.

# Method versus calculus in Newton's criticisms of Descartes and Leibniz

Niccolò Guicciardini

**Abstract.** In my talk I will consider Newton's views on mathematical method. Newton never wrote extensively about this issue. However, in his polemic writings addressed against Descartes and Leibniz he expressed the idea that his method was superior to the ones proposed by the French and the German. Considering these writings can help us in understanding the role attributed to algebra and calculus in Newton's mathematical thought.

**Mathematics Subject Classification (2000).** Primary 01A45; Secondary 00A30.

**Keywords.** 17th century, philosophy of mathematics, Newton, Descartes, Leibniz.

## 1. Newton's memorandum on his early discoveries

Newton blossomed as a creative mathematician in 1665–1666, the so-called *anni mirabiles*, about four years after matriculating at Cambridge.[1] A Newtonian memorandum, written about fifty years later, gives an account that has been basically confirmed by manuscript evidence:

> In the beginning of the year 1665 I found the Method of approximating series & the Rule for reducing any dignity of any Binomial into such a series. The same year in May I found the method of Tangents of Gregory & Slusius, & in November had the direct method of fluxions & the next year in January had the theory of Colours & in May following I had entrance into y$^{e}$ inverse method of fluxions. And the same year I began to think of gravity extending to y$^{e}$ orb of the Moon [...] All this was in the two plague years of 1665–1666. For in those days I was in the prime of my age for invention & minded Mathematicks & Philosophy more than any time since. ([1])

There would be much to say in order to decipher and place into context Newton's discourse. For instance, the task of commenting on the meaning of the term 'philosophy' would require space and scholarship not at my disposal [2].

[1] Readers interested in Newton's mathematics should read Tom Whiteside's introductions and commentaries in [9].

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

Figure 1. Newton's home at Woolsthorpe where – he claimed – he made his early discoveries in mathematics and natural philosophy when Cambridge University was evacuated because of the plague during the biennium 1665–1666. As a matter of fact, he did important work in mathematics during periods in which he returned to the University. Further, his juvenile insights – particularly those concerning gravitation – had to be elaborated during the next decades. Source: [1], 54.

Let me note three things about the above memorandum. The 'Method of approximating series' is the method of series expansion via long division and root extraction (as well as other methods which were later subsumed under more general techniques usually attributed to Puiseux) that allowed Newton to go beyond the limitation of what he termed 'common analysis' – where 'finite equations' were deployed – and express certain curves locally in terms of infinite fractional power series, which Newton called 'infinite equations'. The 'Rule for reducing any dignity of any Binomial' is what we call the 'binomial theorem'. Such methods of series expansion were crucial for attaining two goals: the calculation of areas of curvilinear surfaces and the rectification of curves (see Figure 2). Notice that Newton does not talk about a theorem, but rather about 'methods' and a 'rule'. This last fact is of utmost importance and deserves our commentary in Sections 2, 3, and 4, before turning in Section 5 to the direct and inverse methods of fluxions which are the Newtonian equivalent of the Leibnizian differential and integral calculus.[2]

[2]For a recent evaluation of Newton's early mathematical researches see [3].

*Examples, where the Square Root muſt be extracted.*

15. If it be $\sqrt{aa+xx}=y$, I extract the Root thus:

$aa+xx\left(a+\frac{x^2}{2a}-\frac{x^4}{8a^3}+\frac{x^6}{16a^5}-\frac{5x^8}{128a^7}\ \&c.\right.$

$aa$

$0+x^2$

$x^2+\frac{x^4}{4a^2}$

$0-\frac{x^4}{4a^2}$

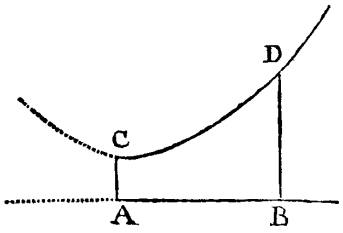
$-\frac{x^4}{4a^2}-\frac{x^6}{8a^4}+\frac{x^8}{64a^6}$

$0+\frac{x^6}{8a^4}-\frac{x^8}{64a^6}$

$+\frac{x^6}{8a^4}+\frac{x^8}{16a^6}-\frac{x^{10}}{64a^8}+\frac{x^{12}}{256a^{10}}$

$0-\frac{5x^8}{64a^6}+\frac{x^{10}}{64a^8}-\frac{x^{12}}{256a^{10}}$

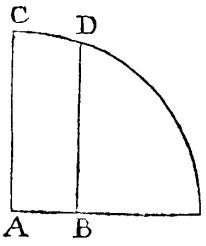
$\&c.$



Whence for the Equation $\sqrt{aa+xx}=y$, a new one is produced, *viz.* $y=a+\frac{x^2}{2a}-\frac{x^4}{8a^3}+\frac{x^6}{16a^5}-\frac{5x^8}{128a^7}\ \&c.$ And (by the ſecond Rule) You will have the Area ſought ABDC $=ax+\frac{x^3}{6a}-\frac{x^5}{40a^3}+\frac{x^7}{112a^5}-\frac{5x^9}{1152a^7}\ \&c.$

And this is the Quadrature of the Hyperbola.

16. After the ſame Manner if it be $\sqrt{aa-xx}=y$, it's Root will be $a-\frac{x^2}{2a}-\frac{x^4}{8a^3}-\frac{x6}{16a^5}-\frac{5x^8}{128a^7}\ \&c.$ and therefore the Area ſought ABDC will be equal to $ax-\frac{x^3}{6a}-\frac{x^5}{40a^3}-\frac{x^7}{112a^5}-\frac{5x^9}{1152a^7}\ \&c.$ And this is the Quadrature of the Circle.



17.

Figure 2. Calculation of areas of hyperbolic and circular surfaces via extraction of root of $\sqrt{aa+xx}=y$ and $\sqrt{aa-xx}=y$. This technique of series expansion and termwise integration was basic in Newton's early mathematical work and was displayed in a tract entitled *On the analysis by means of infinite equations* (written in 1669, but printed only in 1711), an extension of 'common analysis' which proceeds via 'finite equations' only. Source: [8], vol. 1, 8.

## 2. Pappus on the method of analysis and synthesis

Newton belonged to a mathematical community in which the distinction between theorems and problems was articulated according to criteria sanctioned by the venerated Greek tradition. Most notably in the work of the late Hellenistic compiler Pappus entitled *Mathematical Collection* which appeared in 1588 in Latin translation Newton – who avidly read this dusty work – could find a distinction between 'theorematic and problematic analysis'.

In the 7th book of the *Collection* there was a description of works (mostly lost and no longer available to early modern mathematicians) which – according to Pappus – had to do with a heuristic method followed by the ancient geometers. The opening of the seventh book is often quoted. It is an obscure passage whose decoding was top in the agenda of early modern European mathematicians, convinced as they were that here lay hidden the key to the method of discovery of the ancients. Given the importance this passage had for Newton, it is worth quoting at length:

> That which is called the *Domain of Analysis*, my son Hermodorus, is, taken as a whole, a special resource that was prepared, after the composition of the *Common Elements*, for those who want to acquire a power in geometry that is capable of solving problems set to them; and it is useful for this alone. It was written by three men: Euclid the Elementarist, Apollonius of Perge, and Aristaeus the elder, and its approach is by analysis and synthesis.
>
> Now analysis is the path from what one is seeking, as if it were established, by way of its consequences, to something that is established by synthesis. That is to say, in analysis we assume what is sought as if it has been achieved, and look for the thing from which it follows, and again what come before that, until by regressing in this way we come upon some one of the things that are already known, or that occupy the rank of a first principle. We call this kind of method 'analysis', as if to say *anapalin lysis* (reduction backward). In synthesis, by reversal, we assume what was obtained last in the analysis to have been achieved already, and, setting now in natural order, as precedents, what before were following, and fitting them to each other, we attain the end of the construction of what was sought.
>
> There are two kinds of analysis: one of them seeks after the truth, and is called 'theorematic': while the other tries to find what was demanded, and is called 'problematic'. In the case of the theorematic kind, we assume what is sought as a fact and true, then advancing through its consequences, as if they are true facts according to the hypothesis, to something established, if this thing that has been established is a truth, then that which was sought will also be true, and its proof the reverse of the analysis; but if we should meet with something established to be false, then the thing that was sought too will be false. In the case of the problematic kind, we assume the proposition as something we know, then, proceeding through its consequences, as if true, to something

> established, if the established thing is possible and obtainable, which is what mathematicians call 'given', the required thing will also be possible, and again the proof will be the reverse of the analysis; but should we meet with something established to be impossible, then the problem too will be impossible. ([4])

Pappus here made a distinction between analysis and synthesis. Analysis ('resolutio' in Latin) was often conceived of as a method of discovery, or a method of problem solving, which, working step by step backwards from what is sought as if it had already been achieved, eventually arrives at what is known. Synthesis ('compositio' or 'constructio') goes the other way round: it starts from what is known and, working through the consequences, arrives at what is sought. On the basis of Pappus' authority it was often stated that synthesis 'reverses' the steps of analysis. It was synthesis which provided the rigorous proof. Thus the belief – widespread in early modern Europe – that the ancients had kept the method of analysis hidden and had published only the rigorous synthesis, either because they considered the former not wholly demonstrative, or because they wanted to hide the method of discovery.

Another distinction which was of momentous importance for early modern mathematicians is that between problems and theorems. A problem asks a construction for its solution. It starts from certain elements considered as already constructed either by postulate or by previously established constructions. Such elements are the 'givens' (in Latin the 'data') of the problem. A problem ends with a 'Q.E.I.' or with a 'Q.E.F.' ('quod erat inveniendum' – 'what was to be discovered'–, and 'quod erat faciendum' – 'what was to be done'–, respectively). A theorem asks for a deductive proof, a sequence of propositions each following from the previous one by allowed inference rules. The starting point of the deductive chain can be either axioms or previously proved theorems. A theorem ends with 'Q.E.D.' ('quod erat demonstrandum'– 'what was to be demonstrated'). According to Pappus, therefore, there are two kinds of analysis: the former referred to problems, the latter to theorems. But it is clear from classical sources that the most important, or at least the most practiced kind, was problematic analysis: and indeed early modern European mathematicians were mainly concerned with the analysis of geometrical problems.

Another powerful idea that began to circulate in Europe at the end of the seventeenth century was that the analysis of the Greeks was not geometrical but rather symbolical: i.e. the Greeks were supposed to have had algebra and to have applied it to geometrical problem solving. The evidence that symbolic algebra was within the reach of the ancients was provided by a far from philological reading of the work of Diophantus and of parts of Euclid's *Elements*. The approach of Renaissance culture towards the classics, in sculpture, architecture, music, philosophy, and so on, was characterized by admiration united to a desire to restore the forgotten conquests of the ancients. This approach often confined with worship, a conviction of the occurrence of a decay from a glorious, golden past. The works of Euclid, Apollonius, Archimedes were considered unsurpassable models by many Renaissance mathematicians. The question that often emerged was: how could the Greeks have achieved such a wealth

of results? In the decades following the publication of the *Collection* the belief in the existence of a lost, or hidden, 'Treasure of analysis' promoted many efforts aimed at 'restoring' the ancients' method of discovery. Not everybody trod in the steps of the classicists. Typically, many promoters of the new symbolic algebra were proud to define themselves as innovators, rather than as restorers. It was common, however, even among creative algebraists such as François Viète, John Wallis and Isaac Newton, to relate symbolic algebra to the ancient analysis, to the hidden problem solving techniques of the ancients.

## 3. Descartes' method of problem solving and problem construction

Newton was deeply embedded in the conceptual space defined by Pappus and by his readers, interpreters and critics. Mainly he referred his views on mathematical method to Descartes' *Géométrie* (1637), an early source of inspiration for him and soon a target of his fierce criticisms ([5]). From this tradition Newton derived the idea that a problem, once analyzed (resolved), must be synthesized (composed or constructed).

How did Descartes define his canon of problem solving and the role of algebra in the analysis and synthesis of geometrical problems? The historian who has done most to clarify this issue is Henk Bos. It is to his work that we now turn for advice ([6]).

In book 1 of the *Géométrie* Descartes explained how one could translate a geometric problem into an equation. Descartes was able to do so by a revolutionary departure from tradition. In fact he interpreted algebraic operations as closed operations on segments. For instance, if $a$ and $b$ represent lengths of segments the product $ab$ is not conceived by Descartes as representing an area but rather another length. As he wrote: 'it must be observed that by $a^2$, $b^3$, and similar expressions, I ordinarily mean any simple lines', while before the *Géométrie* such expressions represented an area and a volume respectively (see Figure 3).

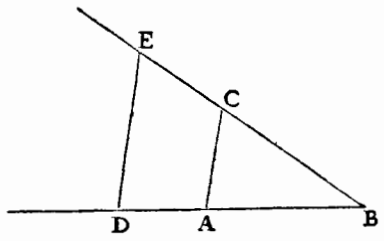
Descartes' interpretation of algebraic operations was indeed a gigantic innovation, but he proceeded wholly in line with Pappus' method of analysis and synthesis, to which he explicitly referred. In fact, according to Descartes, one has – following Pappus' prescriptions– to 'start by assuming that the problem was solved and consider a figure incorporating the solution'.[3] The segments in the figure are then denoted by letters, $a, b, c, \ldots$, for segments which are given, $x, y, z, \ldots$, for segments which are unknown. Geometrical relationships holding between the segments are then translated into corresponding equations. It is thus that one obtains a system of equations which symbolically express the assumption that the problem is solved. In fact, here we are at the very beginning of the analytic process: the unknown segments are treated as if they were known and manipulated in the equations on a par with the givens of the problem. The resolution of the equation allows the expression of the unknown $x$ in terms of given segments. We have thus moved from the assumption that the problem is solved

[3] [6] on p. 303.

298 LA GEOMETRIE.

eſt a l'autre, ce qui eſt le meſme que la Diuiſion; ou enfin trouuer vne, ou deux, ou pluſieurs moyennes proportionnelles entre l'vnité, & quelque autre ligne; ce qui eſt le meſme que tirer la racine quarrée, ou cubique, &c. Et ie ne craindray pas d'introduire ces termes d'Arithmetique en la Geometrie, affin de me rendre plus intelligibile.

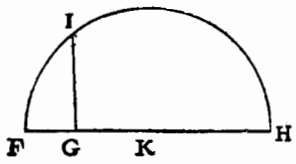
La Multiplication.



Soit par exemple A B l'vnité, & qu'il faille multiplier B D par B C, ie n'ay qu'a ioindre les poins A & C, puis tirer D E parallele a C A, & B E eſt le produit de cete Multiplication.

La Diuiſion. Ou bien s'il faut diuiſer B E par B D, ayant ioint les poins E & D, ie tire A C parallele a D E, & B C eſt le produit de cete diuiſion.

l'Extraction dela racine quarrée.



Ou s'il faut tirer la racine quarrée de G H, ie luy adiouſte en ligne droite F G, qui eſt l'vnité, & diuiſant F H en deux parties eſgales au point K, du centre K ie tire le cercle F I H, puis eſleuant du point G vne ligne droite iuſques à I, à angles droits ſur F H, c'eſt G I la racine cherchée. Ie ne dis rien icy de la racine cubique, ny des autres, à cauſe que i'en parleray plus commodement cy aprés.

Commẽt on peut Mais ſouuent on n'a pas beſoin de tracer ainſi ces ligne

4

Figure 3. Descartes' geometric interpretation of algebraic operations. He writes: 'For example, let $AB$ be taken as unity, and let it be required to multiply $BD$ by $BC$. I have only to join the points $A$ and $C$, and draw $DE$ parallel to $CA$; and then $BE$ is the product of $BD$ and $BC$'. So, given a unit segment, the product of two segments is represented by another segment, not by a surface. The second diagram is the construction of the square root of $GH$. Given $GH$ and a unit segment $FG$, one draws the circle of diameter $FG + GH$ and erects $GI$, the required root. Source: [5], 4.

(the first step of the analysis) to a reduction of the unknown, sought magnitude to the givens. This is why Descartes, and the other early-modern promoters of algebra, associated algebra with the method of analysis.

The *resolution* of the equation is not, however, the *solution* of the problem. In fact, the solution of the problem must be a geometrical construction of the sought magnitude in terms of legitimate geometrical operations performed on the givens ('Q.E.F.'!). We now have to move from algebra back to geometry again. Descartes understood this process from algebra to geometry as follows: the real roots of the equation (for him if there are no real roots, then the problem admits no solution) must be geometrically constructed. After Descartes, this process was known as the 'construction of the equation'. This is where the synthetic, compositive part of the whole process begins.

Descartes accepted from tradition the idea that such constructions must be performed by intersection of curves. That is to say, the real roots are geometrically represented by segments, and such segments are to be constructed by intersection of curves. As a matter of fact, the construction of the equation presented the geometer with a *new* problem: not always an easy one. One had to choose two curves, position and scale them, such that their intersections determine points from which segments – whose lengths geometrically represent the roots of the equation – can be drawn (see Figure 4).

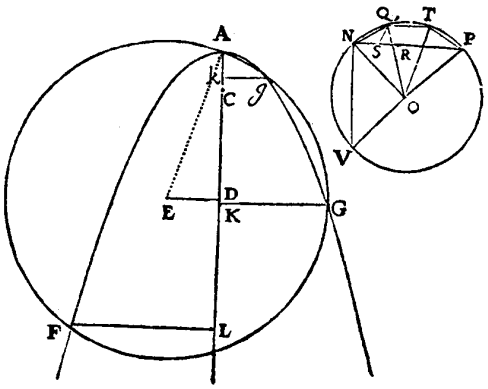


Figure 4. Construction of a third-degree equation in Descartes' *Géométrie*. The problem of trisecting angle $NOP$ is *resolved* ('resolutio' is the Latin translation of the Greek 'analysis') by a third-degree equation. Descartes *constructs* the roots ('constructio' or 'compositio' translate 'synthesis') via intersection of circle and parabola. The segments $kg$, $KG$ and $LF$ represent two positive and one negative root. The smaller of the two positive roots $kg$ must be 'taken as the length of the required line $NQ$'. $KG$ is equal to $NV$, 'the chord subtended by one-third the arc $NVP$'. Source: [5], 208.

The synthetic part of Descartes' process of problem-solving gave rise to two questions: which curves are admissible in the construction of equations? which curves,

among the admissible, are to be preferred in terms of simplicity? In asking himself these questions Descartes was continuing a long debate concerning the role and classification of curves in the solution of problems. A tradition that, once again, stems from Pappus, and the interpretations of Pappus given by mathematicians such as Viète, Ghetaldi, Kepler, and Fermat. His answer was that only 'geometrical curves' (we would say 'algebraic curves') are admissible in the construction of the roots of equations and that one has to choose the curves of the lowest possible degree as these are the simplest. Descartes instead excluded 'mechanical curves' (we would say transcendental curves) as legitimate tools of construction.

Notice that Descartes presented his canon of problem resolution and construction in aggressively anti-classicist terms. His algebraic method, he claimed, was superior to the ones followed by the ancients. He gave pride of place to a problem discussed in Pappus' *Mathematical Collection* that – according to Descartes – neither Euclid nor Apollonius could solve. He proudly showed to the readers of the slim *Géométrie* that, by applying algebra to geometry, he could easily achieve a solution not included in the ponderous Pappusian tomes.[4]

## 4. Newton versus Descartes

Newton sharply criticized Descartes' canon of problematic analysis and construction.[5] Newton's point was that geometrical constructions have to be carried on in terms independent from algebra. Newton elaborated his criticism to Descartes in his Lucasian Lectures on Algebra which were held before 1684 and which, in somewhat modified form, appeared in 1707 as *Arithmetica Universalis* ([8], vol. 2, 3–135). The *Arithmetica Universalis* ends with an Appendix devoted to the 'construction of equations' which abounds with oft-quoted statements in favour of pure geometry and against the 'Moderns' (read Descartes) who have lost the 'Elegance' of geometry:

> Geometry was invented that we might expeditiously avoid, by drawing Lines, the Tediousness of Computation. Therefore these two sciences [Geometry and Arithmetical Computation] ought not be confounded. The Ancients did so industriously distinguish them from one another, that they never introduced Arithmetical Terms into Geometry. And the Moderns, by confounding both, have lost the Simplicity in which all the Elegance of Geometry consists.[6]

[4] Briefly said, Pappus problem requires the determination of the locus of points $P$ such that their distances $d_i$ $(i = 1, 2, 3, 4)$ from four lines given in position are such that $d_1 d_2 = k(d_3 d_4)$. In the *Géométrie* Descartes introduces a system of oblique coordinates, and notices that the distance of a point from a line is given by an expression of the form $ax + by + c$. Therefore Pappus 4-lines locus has a second-degree defining equation: namely it will be a conic section. The algebraic approach immediately allowed Descartes to generalize Pappus problem for any number of lines.

[5] Further information on Newton's criticisms to Descartes can be gained from [7].

[6] [8], vol. 2, 228.

Such statements have often puzzled commentators since they occur in a work devoted to algebra and in which the advantage of algebraic analysis is displayed in a long section on the resolution of geometrical problems. Why was Newton turning his back to 'arithmetic'[7] now saying that algebra and geometry should be kept apart? In order to understand this seemingly paradoxical position we have to briefly recall that according to Descartes the demarcation between admissible and inadmissible curves as means of construction was that between geometrical and mechanical curves. Ultimately, Descartes was forced to make recourse to algebraic criteria of demarcation and simplicity: in fact, algebraic curves coincided for him with the loci of polynomial equations, and the degree of the equation allowed him to rank curves in terms of their simplicity.

As far as demarcation is concerned, in the *Arithmetica Universalis* Newton maintained that it would be wrong to think that a curve can be accepted or rejected in terms of its defining equation. He wrote:

> It is not the Equation, but the Description that makes the Curve to be a Geometrical one. The Circle is a Geometrical Line, not because it may be expressed by an Equation, but because its Description is a Postulate.[8]

Further, Descartes' classification of curves in function of the degree of the equation – Newton claimed – is not relevant for the geometrician, who will choose curves in function of the simplicity of their description. Newton, for instance, observed that the equation of a parabola is simpler than the equation of the circle. However, it is the circle which is simpler and to be preferred in the construction of problems:

> It is not the simplicity of its equation, but the ease of its description, which primarily indicates that a line is to be admitted into the construction of problems. […] On the simplicity, indeed, of a construction the algebraic representation has no bearing. Here the descriptions of curves alone come into the reckoning.[9]

Newton observed that from this point of view, the conchoid, a fourth degree curve, is quite simple. Independently of considerations about its equation, its mechanical description – he claimed – is one of the simplest and most elegant; only the circle is simpler. Descartes' algebraic criterion of simplicity is thus deemed alien to the constructive, synthetical, stage of problem solving. The weakness of Newton's position is that the concepts of simplicity of tracing, or of elegance, to which he continuously refers are qualitative and subjective. One should be aware that no compelling reason is given in support of Newton's evaluations on the simplicity of his preferred constructions: his are largely aesthetic criteria. Considering them is however crucial for our understanding of Newton's views concerning mathematical method.

[7] Notice that Newton employed the term 'universal arithmetic' for algebra, since it is concerned with the doctrine of operations, not applied to numbers, but to general symbols.

[8] [8], vol. 2, 226.

[9] [9], vol. 5, 425–7.

As a matter of fact, Newton – this master of algebraic manipulations – in the mid 1670s developed a deep distaste for symbolism and distanced himself from the mathematics of the 'moderns'. He wrote:

> The Modern Geometers are too fond of the Speculation of Equations. The Simplicity of these is of an Analytick Consideration. [in the Appendix to the *Arithmetica Universalis*] [w]e treat of Composition, and Laws are not given to Composition from Analysis. Analysis does lead to Composition: but it is not true Composition before it is freed from Analysis. If there be never so little Analysis in Composition, that Composition is not yet real. Composition in it self is perfect, and far from a Mixture of Analytick Speculations.[10]

This position, let me restate it, does not exclude the use of algebra in the analysis; it does, however, rule out algebraic criteria of demarcation and simplicity from the synthesis. As Newton was to affirm in a manuscript dating from the early 1690s:

> if a question be answered […] that question is resolved by the discovery of the equation and composed by its construction, but it is not solved before the construction's enunciation and its complete demonstration is, with the equation now neglected, composed.[11]

But, around 1680, Newton moved a step forward in his opposition to the method proposed in the *Géométrie*: not only Cartesian synthesis, but also Cartesian analysis fell under his fierce attack. He developed a deep admiration for the ancient Greek mathematicians, while he criticized in bitter terms the symbolical analysis pursued by the moderns. He began to doubt that the analysis of the Greeks was algebraical, he rather suspected that Euclid and Apollonius possessed a more powerful *geometrical analysis* displayed in the three lost books on *Porisms* attributed to Euclid and described in Book 7 of the *Mathematical Collection*. So not only the composition (the synthesis) had to be freed from algebra, the algebraic calculus had to be avoided also in the process of resolution (the analysis). His target was often Descartes. For instance in the late 1670s, commenting on Descartes' solution of Pappus problem, he stated with vehemence:

> To be sure, their [the Ancients'] method is more elegant by far than the Cartesian one. For he [Descartes] achieved the result by an algebraic calculus which, when transposed into words (following the practice of the Ancients in their writings), would prove to be so tedious and entangled as to provoke nausea, nor might it be understood. But they accomplished it by certain simple propositions, judging that nothing written in a different style was worthy to be read, and in consequence concealing the analysis by which they found their constructions.[12]

[10] [8], vol. 2, 250.
[11] [9], vol. 7, 307.
[12] [9], vol. 4, 277.

Newton was not alone in his battle against the algebraists. Similar statements can be found in the polemic works of Thomas Hobbes. But probably the deepest influence on Newton in this matter was played by his mentor Isaac Barrow. Newton's quest for the ancient, non-algebraical, porismatic analysis led him to develop an interest in projective geometry (see Figure 5).

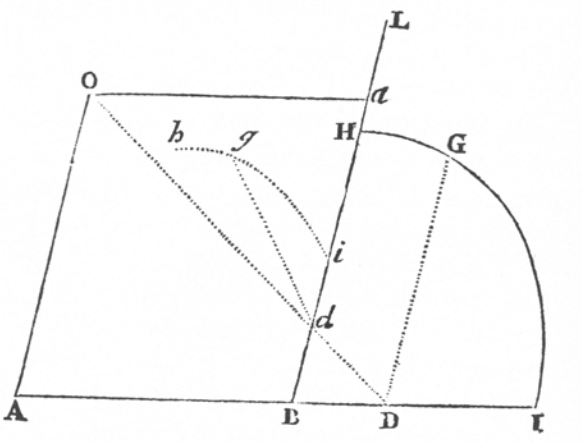

Figure 5. Newton was interested in using projective transformations as a heuristic analytic tool. Here we reproduce the diagram for Lemma 22, Book 1, of the *Principia*. In this Lemma we are taught how 'To change figures into other figures of the same class' (namely, algebraic curves of the same degree). The figure to be transmuted is the curve $HGI$. Draw the straight parallel lines $AO$ and $BL$ cutting any given third line $AB$ in $A$ and $B$. Then from some point $O$ in the line $AO$ draw the straight line $OD$. From the point $d$ erect the ordinate $dg$ (you can choose any angle between the 'new ordinate' $dg$ and the 'new abscissa' $ad$). The new ordinate and abscissa have to satisfy the following conditions: $AD = (AO \times AB)/ad$ and $DG = (AO \times dg)/ad$. These transformations are exactly those occurring between figures projected from one plane into another. Now suppose that point $G$ 'be running through all the points in the first figure [$HGI$] with a continual motion; then point $g$ – also with a continual motion – will run through all the points in the new figure [$hgi$]'. Source: [11], 162.]

He convinced himself that the ancients had used projective properties of conic sections in order to achieve their results. Moving along these lines he classified cubics into five projective classes.[13]

[13] From his work on cubics ([8], vol. 2, 137–161) Newton derived two lessons. First, Descartes' classification of curves by degree is an algebraic criterion which has little to do with simplicity. Indeed, cubics have rather complex shapes compared to mechanical (transcendental) curves such as the Archimedean spiral. Second, it is by making recourse to projective classification that one achieves order and generality.

## 5. Newton's new analysis

Now that we know more about Newton's views concerning the role of algebraic symbolism in the method of problem solving, we are in the position to step back to Newton's memorandum on his early mathematical discoveries that I quoted in Section 1. There he mentions the direct and the inverse methods of fluxions. The direct method allowed the determination of tangents (and curvature) to plane curves. Newton approached this problem by conceiving curves as generated by the continuous 'flow' of a point. He called the geometric magnitudes generated by motion 'fluents', while 'fluxions' are the instantaneous rates of flow. In the 1690s he denoted fluxions with overdots, so that the fluxion of $x$ is $\dot{x}$. He deployed a variety of strategies in order to determine tangents. Some of them are algorithmic, but in many cases Newton made recourse to kinematic methods. In Newton's mathematical writings the algorithm is indeed deeply intertwined with geometrical speculations.

By resolving motion into rectilinear components Newton could determine the tangent by composition of motions, even in the case of mechanical lines (see Figure 6). Indeed, the possibility to deal with transcendental curves (as the spiral and the cycloid) was top in Newton's agenda. Or one could focus attention on the 'moment of the arc' generated in a very short interval of time (Newton termed the infinitesimal increment acquired in an infinitesimal interval of time a 'moment') and establish a proportion between the moment of the abscissa and the moment of the ordinate and other finite lines embedded in the figure. When the curve was expressed symbolically via an equation Newton had 'rules' which allowed him to calculate the tangent (see Figure 7). One recognizes here rules which are 'equivalent' to those of the differential calculus; but the reader should be reminded that this equivalence was, and still is, object of debate.

The inverse method of fluxions was Newton's masterpiece. It is this method that allowed him to approach the problem of 'squaring curves'. By conceiving a surface $t$ as generated by the flow of the ordinate $y$ which slides at a right angle over the abscissa $z$, he understood that the rate of flow of the surface's area is equal to the ordinate (he stated $\dot{t}/\dot{z} = y/1$). This is how the idea of integration as anti-differentiation was born in Newton's mind. His approach consisted in applying the direct method to 'equations at will [which] define the relationship of $t$ to $z$'. One thus obtains an equation for $\dot{t}$ and $\dot{z}$, and so 'two equations will be had, the latter of which will define the curve, the former its area'.[14] Following this strategy Newton constructed a 'Catalogue of curves' which can be squared by means of 'finite equations' (see Figure 8). In Leibnizian terms, he built the first integral tables in the history of mathematics.

Newton attached much importance to the inverse method. With almost visionary mathematical understanding of what is truly revolutionary, while still in his early years, he wrote:

> If two Bodys $A$ & $B$, by their velocitys $p$ & $q$ describe y$^{e}$ lines $x$ & $y$.

[14] [9], vol. 3, 197.

& an Equation bee given expressing y$^{e}$ relation twixt one of y$^{e}$ lines $x$, & ye ratio $q/p$ of their motions $q$ & $p$; To find y$^{e}$ other line $y$. Could this ever bee done all problems whatever might bee resolved.[15]

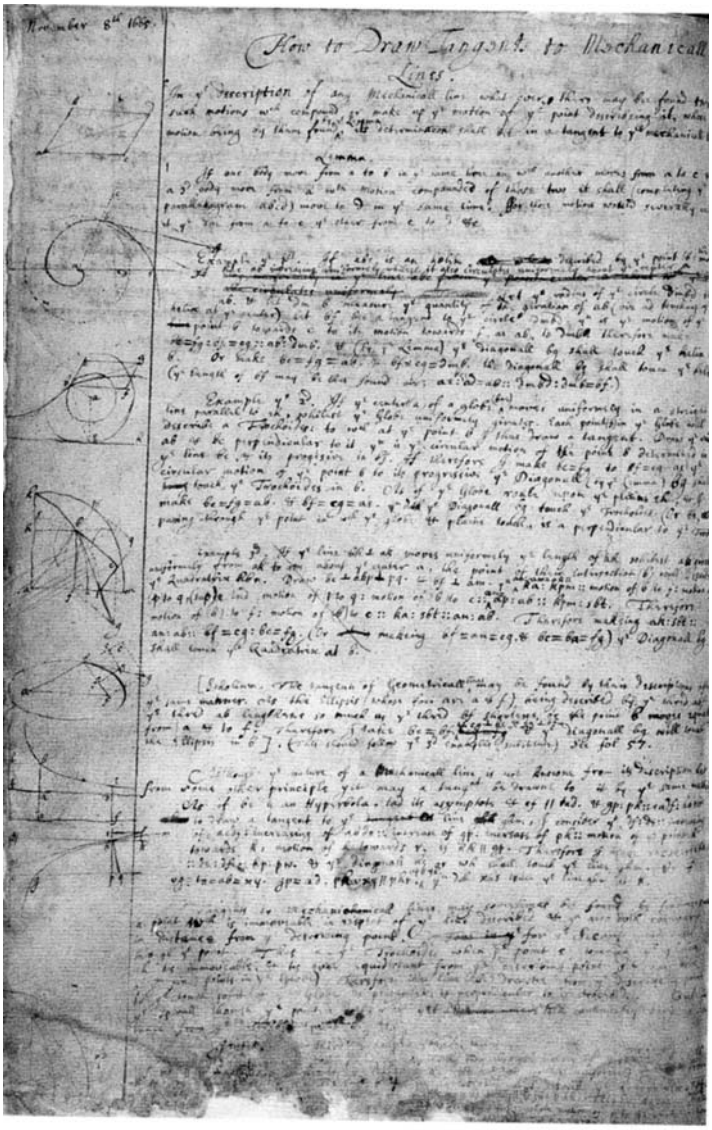

Figure 6. Newton's early work (November 1666) on tangents to 'mechanicall lines' (i.e. transcendental plane curves). His technique consisted in conceiving curves as generated by motion and resolving motion into components. Source: [9], vol. 1, 378.

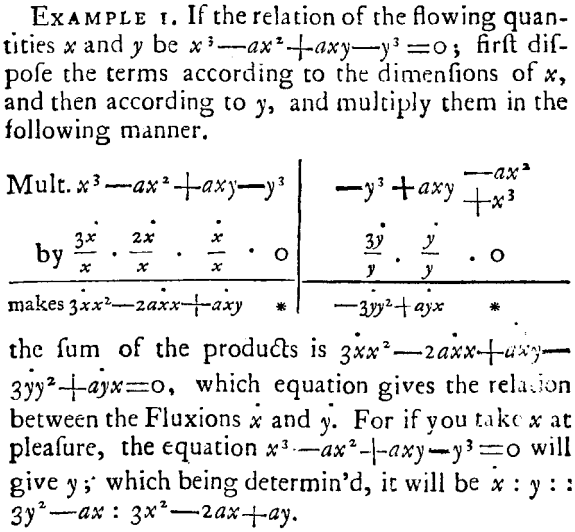
[15] [9], vol. 1, 403.



EXAMPLE 1. If the relation of the flowing quantities $x$ and $y$ be $x^3 - ax^2 + axy - y^3 = 0$; firſt diſpoſe the terms according to the dimenſions of $x$, and then according to $y$, and multiply them in the following manner.

Mult. $x^3 - ax^2 + axy - y^3$ | $-y^3 + axy \frac{-ax^2}{+x^3}$

by $\frac{3\dot{x}}{x} \cdot \frac{2\dot{x}}{x} \cdot \frac{\dot{x}}{x} \cdot 0$ | $\frac{3\dot{y}}{y} \cdot \frac{\dot{y}}{y} \cdot 0$

makes $3\dot{x}x^2 - 2a\dot{x}x + a\dot{x}y$ * | $-3\dot{y}y^2 + a\dot{y}x$ *

the ſum of the products is $3\dot{x}x^2 - 2a\dot{x}x + a\dot{x}y - 3\dot{y}y^2 + a\dot{y}x = 0$, which equation gives the relation between the Fluxions $\dot{x}$ and $\dot{y}$. For if you take $x$ at pleaſure, the equation $x^3 - ax^2 + axy - y^3 = 0$ will give $y$; which being determin'd, it will be $\dot{x} : \dot{y} :: 3y^2 - ax : 3x^2 - 2ax + ay$.

Figure 7. Newton's algorithm for the direct method of fluxions. In this example he calculates the relation between fluxions (instantaneous speeds) $\dot{x}$ and $\dot{y}$ of fluent quantities (magnitudes changing continuously in time) $x$ and $y$ related by the equation $x^3 - ax^2 + axy - y^3 = 0$. Source: [8], vol. 1, 50.

In this context Newton developed techniques equivalent to integration by parts and substitution.

Newton labelled the techniques of series expansion, tangent determination and squaring of curves as the 'method of series and fluxions'. This was, he proudly stated, a 'new analysis' which extended itself to objects that Descartes had banished from his 'common analysis' – such as mechanical curves – thanks to the use of infinite series:

> And whatever common analysis performs by equations made up of a finite number of terms (whenever it may be possible), this method may always perform by infinite equations: in consequence, I have never hesitated to bestow on it also the name of analysis.[16]

According to Newton, the 'limits of analysis are enlarged by [...] infinite equations: [...] by their help analysis reaches to all problems'.[17]

| IV 4 | $\frac{dz^{4n-1}}{\sqrt{e+fz^n}}=y$ | $\frac{-96e^3+48e^2fz^n-36ef^2z^{2n}+30f^3z^{3n}}{105nf^4}dR=t$ |

*pag.* 137.

Figure 8. The beginning of Newton's table of curves (an integral table, in Leibnizian terms), obtained thanks to understanding of what we call the 'fundamental theorem of calculus'. Here Newton lists the first four 'orders'. $z$ is the abscissa, $y$ the ordinate, $t$ the area. In Newton's notation $\dot{t}/\dot{z} = y/1$. Notice that $d, e, f, g, h$ are constants ($d$ is a constant!), $\eta$ is integer or fractional, and $R$ stands for $\sqrt{e+fz^\eta}$ or $\sqrt{e+fz^\eta+gz^{2\eta}}$. Source: [8], vol. 1, 105.

## 6. Newton's synthetical method

One should recall that the 'new analysis' occupied in Newton's agenda a place which, according to the Pappusian canon, was subsidiary to the synthesis or construction, and that the construction had to be carried on in terms independent of algebraic criteria. For instance, as to the squaring of curves (in Leibnizian terms, integration) he wrote:

> After the area of some curve has thus been found, careful considerations should be given to fabricating a demonstration of the construction which

> as far as permissible has no algebraic calculation, so that the theorem embellished with it may turn out worthy of public utterance.[18]

Newton therefore devoted great efforts to providing geometrical demonstrations, somewhat reminiscent of Archimedean exhaustion techniques, of his 'analytical' quadratures. Only such demonstrations were deemed by him 'worthy of public utterance'.

It is in this context that Newton in the 1670s began reworking his early discoveries in 'new analysis' in terms that he conceived concordant with the constructive geometrical methods of the ancients. He termed this more rigorous approach the 'synthetical method of fluxions' and codified it around 1680 in a treatise entitled *Geometria curvilinea* ([9], vol. 4, 420–521). In this method no infinitesimals, or 'moments', occurred and no algebraic symbols were deployed. Everything was based upon geometric limit procedures that Newton termed the 'method of first ratios of nascent quantities and last ratios of vanishing quantities'. It is this method that was widely deployed in the *Principia* (1687) (see Figure 9). It is somewhat astonishing to see one of the most

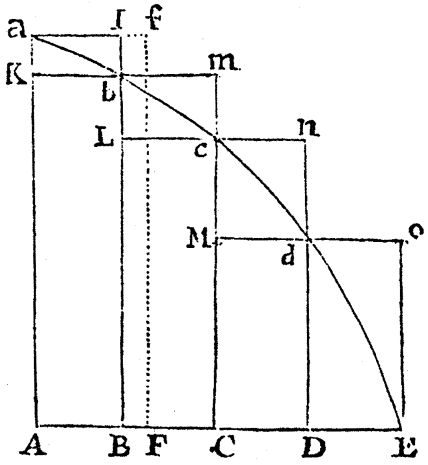

Figure 9. In Section 1, Book 1 of the *Principia* Newton lays down his 'method of first and last ratios', a geometric limit procedure that allows him to avoid infinitesimals. In Lemma 2 Newton shows that a curvilinear area $AabcdE$ can be approached as the limit of inscribed $AKbLcMdD$ or circumscribed $AalbmcndoE$ rectilinear areas. Each rectilinear surface is composed of a finite number of rectangles with equal bases $AB$, $BC$, $CD$, etc. The proof is magisterial in its simplicity. Its structure is still retained in present day calculus textbooks in the definition of the Riemann integral. It consists in showing that the difference between the areas of the circumscribed and the inscribed figures tends to zero, as the number of rectangles is 'increased *in infinitum*'. In fact this difference is equal to the area of rectangle $ABla$ which, 'because its width $AB$ is diminished *in infinitum*, becomes less than any given rectangle'. In Newton's terms $AB$ is a 'vanishing quantity'. Source: [11], 74.

[18] [9], vol. 3, 279.

creative algebraists of the history of mathematics spend so much time and effort in reformulating his analytical results in geometric terms, but Newton had compelling reasons to do so.

First, Newton in his programme of reformation of natural philosophy attributed an important role to mathematics as a source of certainty. From the early 1670s he expressed his distaste for the probabilism and hypotheticism that was characteristic of the natural philosophy[19] practiced at the Royal Society by people like Robert Hooke and Robert Boyle. His recipe was to inject mathematics into natural philosophy. As he stated:

> by the help of philosophical geometers and geometrical philosophers, instead of the conjectures and probabilities that are being blazoned about everywhere, we shall finally achieve a science of nature supported by the highest evidence. ([12])

But if mathematics has to provide certainty to natural philosophy her methods must be above dispute, and Newton was keenly aware of the fact that the new analysis was far from being rigorous.

Second, Newton soon developed a deep anti-Cartesianism associated with a conviction of the superiority of the ancients over the moderns. From his point of view Descartes was the champion of an impious mechanistic philosophy which, conceiving nature as an autonomous mechanism, denied any role to God's providence. Newton conceived himself as a restorer of an ancient, forgotten philosophy according to which nature is always open to the providential intervention of God. Indeed, he thought that, according to the theory of gravitation – which he was convinced the ancient Hebrews possessed–, the quantity of motion in the universe was bound to decline if divine intervention had not prevented the 'corruption of the heavens'. The modern philosophers were dangerous from a theological point of view and had to be opposed on all grounds. Therefore, also in mathematics Newton looked with admiration to ancient exemplars and conceived himself as a restorer of their glory. It goes without saying that the above reasons led Newton into a condition of strain, since his philosophical values were at odds with his mathematical practice, which was innovative, symbolical, and – pace Newton – deeply Cartesian.

Several hitherto unexplained aspects of Newton's mathematical work are related to this condition of stress and strain that characterizes his thoughts on mathematical method. Why did Newton fail to print his method of series and fluxions before the inception of the priority dispute with Leibniz? Why did he hide his competence in quadratures when writing the *Principia*, which are written mostly in geometrical style? Even though there is no single answer to these vexed questions, I believe that Newton's conviction that the analytical symbolical method is only a heuristic tool,

[19] For Newton the aim of 'natural philosophy' is to deduce the forces from phenomena established by experiment, and – once established the forces – to deduce new phenomena from them. Nowadays we would call this enterprise 'physics'.

not 'worthy of public utterance', can in part explain a policy of publication which was to have momentous consequences in the polemic with Leibniz.

## 7. Leibniz's views

When the war with Leibniz exploded in 1710 Newton had to confront an opponent who not only advanced mathematical results equivalent to his, but was promoting a different view concerning mathematics.[20]

The rhetoric on the novelty of the calculus pervades Leibniz's writings. Reference to the ancient mathematicians generally took the rather abused form of a tribute to Archimedes' 'method of exhaustion'. Leibniz in most of his declarations concerning the calculus wished to highlight the novelty and the revolutionary character of his algorithm, rather than continuity with ancient exemplars. This approach is quite at odds with Newton's 'classicism'. Furthermore, Leibniz often referred to the heuristic character of the calculus understood as an algorithm independent from geometrical interpretation. It is exactly this independence that would render the calculus so efficacious in the process of discovery. The calculus, according to Leibniz, should also be seen as an *ars inveniendi* (an art of discovery): as such it should be valued by its fruitfulness, rather than by its referential content. We can calculate, according to Leibniz, with symbols devoid of referential content (for instance, with $\sqrt{-1}$), provided the calculus is structured in such a way as to lead to correct results.[21]

Writing to Christiaan Huygens in September 1691, Leibniz affirmed with pride:

> It is true, Sir, as you correctly believe, that what is better and more useful in my new calculus is that it yields truths by means of a kind of analysis, and without any effort of the imagination, which often works as by chance. ([13])

[20] The circumstances surrounding the controversy between Newton and Leibniz have been analysed in detail by Rupert Hall [15] and Tom Whiteside [9], vol.8. In broad outlines let me recall a few bare facts. Newton formulated his method of series and fluxions between 1665 and 1669. Leibniz had worked out the differential and integral calculus around 1675 and printed it in a series of papers from 1684. It is clear from manuscript evidence that he arrived at his results independently from Newton. It is only in part in Wallis' *Algebra* in 1685 and *Works* in 1693 and 1699, and in full in an appendix to the *Opticks* in 1704, however, that Newton printed his method. In 1710 a British mathematician, John Keill, stated in the *Philosophical Transactions of the Royal Society* that Leibniz had plagiarized Newton. After Leibniz's protest a committee of the Royal Society secretly guided by its President, Isaac Newton, produced a publication – the so-called *Commercium epistolicum* (1713) – in which it was maintained that Newton was the 'first inventor' and that '[Leibniz's] Differential Method is one and the same with [Newton's] Method of Fluxions'. It was also suggested that Leibniz, after his visits to London in 1673 and 1676, and after receiving letters from Newton's friends, and from Newton himself (in fact Newton addressed two letters to Leibniz in 1676) had gained sufficient information about Newton's method to allow him to publish the calculus as his own discovery, after changing the symbols. It is only after the work of historians such as Fleckenstein, Hofmann, Hall and Whiteside that we have the proof that this accusation was unjust. Newton and Leibniz arrived at equivalent results independently and following different paths of discovery.

[21] Complex numbers received a geometric interpretation only around 1800 thanks to Jean Robert Argand, Carl Friedrich Gauss, and Caspar Wessel.

Leibniz was thus praising the calculus as a *cogitatio caeca* and promoted the 'blind use of reasoning' among his disciples. Nobody, according to Leibniz, could follow a long reasoning without freeing the mind from the 'effort of imagination'.[22]

Leibniz conceived of himself as the promoter of new methods of reasoning, rather than 'just' a mathematician. The calculus was just one successful example of the power of algorithmic thinking. The German diplomat was interested in promoting in Europe the formation of a group of intellectuals who could extend a universal knowledge achieved thanks to a new algorithm that he termed *universal characteristic*. He thus helped to form a school of mathematicians who distinguished themselves by their ability in handling the differentials and the integrals and by their innovative publication strategy. Thanks to Leibniz's recommendation, they colonized chairs of mathematics all over Europe. The efficacy of this new algorithm was affirmed to be independent from metaphysical or cosmological questions. The persons who practised it had to be professional mathematicians, rather than 'geometrical philosophers', able to teach and propagate knowledge of calculus.

A typical Leibnizian attitude emerges in the context of the vexed question of the existence of infinitesimals. The new calculus was often attacked, since – it was maintained – it employed symbols devoid of meaning, such as differentials ordered into a bewildering hierarchy of orders. Newton, as we know, was particularly sensitive to such criticisms, and tried in his synthetical method to dispense with infinitely small quantities. Leibniz, on the other hand, repeated many times that for him the question of the existence of infinitesimals had to be distinguished from that of their usefulness as algorithmic devices. While he was leaning, for philosophical reasons, towards a denial of the existence of infinitesimals, he also wanted to stress that this ontological question was somewhat extraneous to mathematics. A typical statement, written in the early years of the eighteenth century, is the following:

> We have to make an effort in order to keep pure mathematics chaste from metaphysical controversies. This we will achieve if, without worrying whether the infinites and infinitely smalls in quantities, numbers and lines are real, we use infinites and infinitely smalls as an appropriate expression for abbreviating reasonings. ([14])

Leibniz was thus leaving to his disciples the choice of maintaining, *philosophically speaking*, different approaches to the ontological question on the existence of infinitesimals. What he wished to defend was their utility as symbols in mathematical calculation.

## 8. The war against Leibniz: methodological aspects

When Newton had to confront Leibniz in the squabble over priority he was concerned in building up a forensic and historical document whose purpose was to prove

[22] [14], 205.

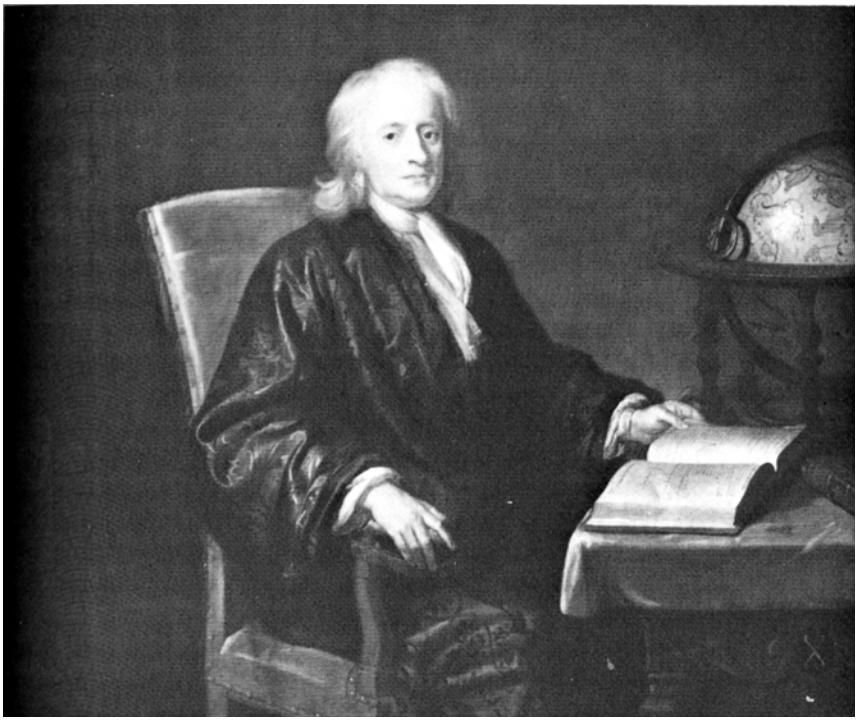

Figure 10. A portrait of Newton in old age (Source: [1], 831). He proudly opens the *Principia* at a page devoted to the attraction of extended bodies. In dealing with this problem Newton made recourse to his 'inverse method of fluxions' (the equivalent of Leibniz's integral calculus) which allowed him to 'square curves'. As a matter of fact, only by making recourse to his tables of curves ('integral tables'), see Figure 8, could Newton solve several problems in the *Principia*. Such analytic methods were not, however, made explicit to the reader. In the polemic with the Leibnizians – who claimed that absence of calculus from the *Principia* was proof positive of Newton's ignorance of quadrature techniques prior to 1687 – Newton was forced to maintain, with some exaggeration, that 'By the help of this new Analysis Mr Newton found out most of the Propositions in his *Principia Philosophiae*. But because the Ancients for making things certain admitted nothing into Geometry before it was demonstrated synthetically, he demonstrated the Propositions synthetically that the systeme of the heavens might be founded upon good Geometry. And this makes it now difficult for unskillful men to see the Analysis by w$^{ch}$ those Propositions were found out.' ([9], vol. 8, 599). On the issue of Newton's use of analytic methods in the *Principia* see [16].

Leibniz's plagiarism. But he did not do only this, he also wished to highlight the superiority of his *method* over Leibniz's *calculus*. The mathematical programme that Leibniz was promoting with so much success was at odds with Newton's deeply felt values.

There is not only mathematics in this story, of course. Leibniz had to be opposed for a series of reasons that have to do with the Hannoverian succession. The German,

in fact, who was employed by the Hannover family, wished to move to London as Royal Historian. The idea of having in England such a towering intellectual who was defending a philosophical view which contradicted Newton's voluntarist theology and who was promoting the unification of the Christian Churches was anathema for Newton and his supporters.

For our purposes, it is interesting to turn to some passages that Newton penned in 1715 contained in an anonymous 'Account' to a collection of letters, the *Commercium epistolicum*, that the Royal Society produced in order to demonstrate Leibniz's plagiarism.

In the 'Account', speaking of himself in the third person, Newton made it clear that Leibniz had only approached the analytical, heuristic part of the problem-solving method. He wrote:

> Mr. Newton's Method is also of greater Use and Certainty, being adapted either to the ready finding out of a Proposition by such Approximations as will create no Error in the Conclusion, or to the demonstrating it exactly; Mr. Leibniz's is only for finding it out.[23]

So according to Newton, Leibniz had achieved only the first stage of the Pappusian method and had not attained the rigorous, constructive demonstration. This, as we know, had to be carried on in purely geometric terms.

Further, Newton insisted on the fact that the emphasis with which Leibniz praised the power of his symbolism was excessive. Algorithm is certainly important for Newton, but it has to be viewed only as a component of the method:

> Mr Newton — he wrote – doth not place his Method in Forms of Symbols, nor confine himself to any particular Sort of Symbols.[24]

Finally, Newton noticed that in his method of first and last ratios no infinitesimals occur, everything being performed according to limiting procedures. From Newton's point of view the avoidance of infinitesimals and the possibility of interpreting algebraic symbols as geometric magnitudes had the double advantage of rendering his method endowed with referential content and consonant with ancient mathematics:

> We have no ideas of infinitely little quantities & therefore Mr Newton introduced fluxions into his method that it might proceed by finite quantities as much as possible. It is more natural & geometrical because founded on *primae quantitatum nascentium rationes* [first ratios of nascent quantities] w$^{ch}$ have a being in Geometry, whilst *indivisibles* upon which the Differential method is founded have no being either in Geometry or in nature. […] Nature generates quantities by continual flux or increase, & the ancient Geometers admitted such a generation of areas & solids […]. But the summing up of indivisibles to compose an area or solid was never yet admitted into Geometry.[25]

[23] Cited in [15], 296.
[24] Cited in [15], 294.

Nature and geometry are the two key concepts: they allow Newton to defend his method because of its continuity with ancient tradition as well as its ontological content.

In his polemic writings against Leibniz Newton engineered an attack which was aimed at proving the German's plagiarism. One of Newton's priorities was to assemble evidence which proved Leibniz guilty, and he did so with means that show his ability to employ archival sources as well as his prejudice and egotism. However, Newton also defended positions concerning mathematical method that have deep roots in his protracted opposition against Descartes and the 'modern mathematicians' who, by confounding geometry and algebra, 'have lost the Simplicity in which all the Elegance of Geometry consists'.

# e-learning mathematics*

Sebastià Xambó Descamps† (*moderator*)
Hyman Bass, Gilda Bolaños Evia, Ruedi Seiler‡, and
Mika Seppälä§ (*panelists*)

**Abstract.** In addition to the current state of knowledge about the learning of mathematics and its aims in today's society, the main purpose of this paper is discussing ways of improving the process of learning, and especially, in that regard, the role of e-learning technologies. We chart the situation of e-learning mathematics as of December, 2005, including distance-learning or open university courses, and then we consider a number of areas where e-learning is likely to develop. Finally, we assess the impact of e-learning on the role of the new educators in mathematics.

**Mathematics Subject Classification (2000).** Primary: 97-xx, 97Uxx; Secondary: 00-xx.

**Keywords.** Online material, distance learning, e-learning, metadata.

## Presentation

by *Sebastià Xambó Descamps*

Following a suggestion of the Executive Committee (EC) of ICM2006 that came forth in the Fall of 2004, this panel has been promoted by the Conference of Spanish Mathematics' Deans [1].

After having formally accepted the invitation on December 16, 2004, the CDM Executive Committee discussed possible topics, until "e-Learning Mathematics" (eLM) was chosen and approved by both the CDM and the EC of ICM2006. Names to be invited as panelists were also decided, and it is a great satisfaction, and an honour, to be able to say that all accepted. On behalf of the CDM, my sincerest thanks to all.

If e-learning is learning by means of systems built on current computer and communications technologies, then the main interest of eLM is on what advantages e-learning can offer in the case of mathematics.

The main reason for choosing eLM is that the accelerated evolution of the e-Learning field is having, and will most likely continue to have, a major worldwide impact

*Panel promoted by the Spanish Conference of Mathematics' Deans.

Proceedings of the International Congress
of Mathematicians, Madrid, Spain, 2006

on many aspects of the teaching-learning systems, at all levels, while offering, at the same time, new opportunities to professional mathematicians and to existing or new institutions, as for example in life-long learning. It is thus a topic that should greatly interest not only mathematicians in all walks of life, but also academic and political authorities everywhere.

This is why we imagined that the panel could aim at describing the situation of eLM as of 2006, outlining the most likely trends of its evolution in the next few years, indicating what the strongest impacts (positive or negative) in the mathematics teaching-learning systems will be, and charting the sorts of opportunities that will arise.

We are of course aware that such aims can only be attained by the panel in very broad terms, although this should be enough to bring forward a generally useful picture. For those wanting to have more detailed views, the references provided by the panelists should be a valuable resource to continue a journey that by all evidence has no return. For example, the articles in the recent book [2] will quite likely be serviceable to a wide range of readers seeking to know more about e-learning in general.

Let me continue with a few general remarks on learning, teaching and e-learning.

Mathematics, or mathematics knowledge, is a vast universe (let me call it $M$). It has many smaller interelated universes, of which we have a dim glimpse in the standard classifications.

Because of the increasing number of research mathematicians, and the availability of ever more sophisticated computational and communication tools, $M$ has undergone an extraordinary growth, and all indications are that this trend will continue in the coming years. To a large extend this blooming is explained because $M$ is both a source of deep beauty and the only precision method we have for modelling the physical universe.

In any case, the number of university students required to take mathematics courses is globally increasing, but at the same time the number of professional mathematicians that seek a teaching position is most likely decreasing, as there are, on one side, ever newer job profiles, and, on the other side, the number of students in mathematics degrees is decreasing in most countries. Moreover, in the last decade a steady decline in the mathematical skills of the students beginning higher education has been reported (see, for example, [3]).

Can eLM help to face this situation in a more positive mood?

The expectations created by e-learning are certainly high, at all levels, and we may wonder how much of it is going to be true, and up to what point can it help in the case of mathematics.

The reasons behind the high expectations on e-learning stem from well-known characteristics of the e-learning systems:

- In principle, access is possible from anywhere and at any time, thus making possible flexible (even just-for-me) and just-in-time courses of learning.

- The teacher can also be anywhere and do most of his teaching job at any time (preparing materials or following-up and coaching his students).
- It allows for synchronous activities of a teacher and a group (at an agreed time), but again without restriction on the location of the people involved, and, what is more, with the possibility of addressing a much larger audience than a conventional class.
- Assessment can be automated to a large extend and final grading can be integrated seamlessly into the institution's information system.
- The learning materials and experiences can be richer in many ways, and they can be easily maintained and updated (as compared to preparing, say, a new edition of a paper book).
- There are also indications that it may induce deeper understanding and stronger retention.

So the main question is how can we harness all that potential for improving the quantity and quality of the learning of mathematics. Since there are many levels that we ought to consider, and many variations in each level, we cannot expect a universal recipe. And even if we restrict ourselves to a very particular situation, say remedial mathematics for freshman in engineering schools or mathematical modules for prospective secondary school teachers, we cannot expect a formula that would satisfy everybody.

A sensible starting point is just looking at people, groups and institutions that are leading the way in one direction or another. This is the idea behind the purpose and composition of this panel. Since it is not feasible, and perhaps not even desirable, under the circumstances, to have a comprehensive survey of eLM, the best alternative is having experts in a few areas that have a major bearing on what eLM is and can be, and on how it is evolving. Before going into their reports, let me briefly introduce them.

**Hyman Bass**

Hyman Bass is Roger Lyndon Collegiate Professor of Mathematics and Professor of Mathematics Education at the University of Michigan. A graduate of Princeton, Dr. Bass earned his Ph.D. from the University of Chicago under Irving Kaplansky. He has had visiting appointments at sixteen different universities in ten countries. The many honors and prizes that Dr. Bass has received include the Cole Prize in algebra. He is an elected member of the American Academy of Arts and Sciences and the National Academy of Arts and Sciences, and the Third World Academy of Sciences, and was elected Fellow of the American Association for the Advancement of Science. He is former president of the American Mathematical Society and current president of ICMI. He has been both a Sloan and Guggenheim Fellow. Dr. Bass has published eighty-six papers in mathematics and seventeen in mathematics education.

**Gilda Bolaños**

Dr. Bolaños is a certified teacher and trainer in the didactical techniques of Problem Based Learning (PBL) and Project Oriented Learning (POL). She is the author of several certified Blackboard courses. With classroom technologies based on Maple and Minitab, she has worked extensively on problems and materials for her online courses.

**Ruedi Seiler**

Full Professor for Mathematics at the Technische Universität Berlin, Ruedi Seiler's main fields of interest are Mathematical Physics, Quantum-Hall Systems, Information Theory, Data Compression, and E-Math: Teaching, Learning, Research. Member of the Research Center "Mathematics for Key Technologies" (DFG), and of the Executive Committee of the International Association of Mathematical Physics (IAMP), his most recent undertakings, culminating an extensive experience in organizing events and participating in projects, are MUMIE and MOSES. More specifically, he is leading, since 2001, the project "Multimedial Mathematical Education for Engineers", a project developed in Cooperation between the Berlin University of Technology, the Munich University of Technology, the Aachen University of Technology and the University Potsdam (funded by the German Federal Ministry of Education and Research within the programme "New Media in Education"), and, within the program "Notebook-University" of the German Federal Ministry of Education and Research, he is co-manager, since 2002, of the TU Berlin project "MOSES – Mobile Service for Students".

**Mika Seppälä**

Dr. Seppälä is Professor of Mathematics at Florida State University and Professor of Computer Aided Mathematics at the University of Helsinki. He was the Co-ordinator of the HCM network "Editing and Computing" (1995–1996) which initiated the development that lead to the MathML and OpenMath languages allowing the inclusion of mathematical formulae on the web pages in a meaningful way. He is currently the Secretary of the OpenMath Society, and the co-ordinator of the eContent Project "Web Advanced Learning Technologies" (WebALT). The main goal of the WebALT Project is to use MathML and OpenMath to create tools and content for multilingual on-line mathematics. Seppälä was the President of the Finnish Mathematical Society for the period 1992–1996.

**Sebastià Xambó Descamps**

Full Professor of Information and Coding Theory at the Universitat Politècnica de Catalunya (UPC, Barcelona, Spain), and former Full Professor of Algebra at the Departamento de Algebra of the Universidad Complutense of Madrid (1989–1993), is serving as Dean of the "Facultat de Matemàtiques i Estadística" of the UPC. Member

of the EU eContent Project "Web Advanced Learning Technologies". In the period 1994-2000 led the team that developed the mathematical engine of Wiris ([4], [5]) and authored the e-book [6]. Cofounder of Maths for More ([7]). Has served as President of the Societat Catalana de Matemàtiques (1995–2002) and of the Executive Committee of the 3rd European Congress of Mathematics (Barcelona, 2000), and as Vicerector of Information and Documentation Systems of the UPC (1998–2002). Since the Fall of 2004 he serves as President of the Spanish Conference of Mathematics' Deans.

## The instructional potential of digital technologies

by *Hyman Bass*

**Educational uses of technology.** Digital technology continues to rapidly transform all aspects of life and work, even (and perhaps all the more so) in the developing world. It is designed, and presumed, to bring great benefit and empowerment to its users, as well as profit to its developers. Yet, as it opens new and even unanticipated possibilities, it poses as many problems as it solves, some new, and some techno-versions of classical problems, all of them important and interesting. And technology, for its novelty and glamorous aspirations, is greedy for our attention, liking to take center stage in every arena it enters.

Education, and mathematics education in particular, is the context in which this panel is examining these transformations. I find it helpful here to distinguish three broad kinds of roles that technology can play in mathematics education. They are of course not disjoint.

I. ***Transmission:*** Use of technology (web, video conferencing, etc.) to transmit, perhaps interactively, instruction and/or instructional materials that are conceptually of a traditional genre – lectures, demonstrations, problem sets, assessments, etc. These are the kinds of uses that fundamentally support distance learning, for example.

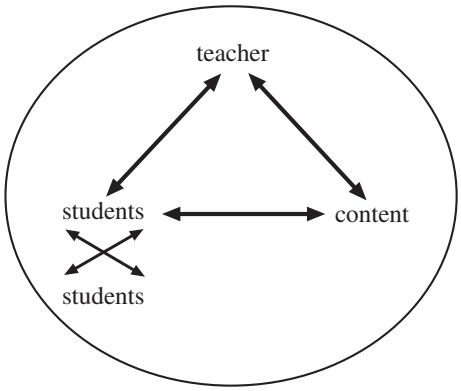
II. ***Power, speed, and visualization:*** Use of technology to carry out quickly and more accurately and completely, mathematical processes of a traditional nature – perform large or complex calculations, solve equations, approximate integrals, exhibit function graphs, study effects of variation of parameters, produce vivid and accurate images of geometric figures, etc.

III. ***New ways to explore the*** (***mathematical and experiential***) ***universes:*** Use of technology to do things we have never previously been able to do. Such capability affects mathematics itself, not just mathematics education. Examples include the study of long-term evolution of dynamical systems, and the images of fractal geometry that emerge there from. (This had an effect on dynamics comparable with that of the telescope in astronomy and the microscope in biology.) Software development gave life to the field of computational complexity, with its applications to coding and cryptography. Mathematical modeling and computer simulation supports a virtually empirical study of physical systems and designs. Dynamic geometry offers unprecedented opportunities to visually explore and analyze geometric structures, and to produce evocative imagery of dimensions three and four (using time). Computer algebra systems furnish unprecedented resources for solving equations. Much of this new technological power is now within reach of many students, and this raises possibilities of thereby expanding the horizons of the mathematics curriculum.

At a pragmatic level, technology thus offers resources to address two fundamental challenges of contemporary education – distance and demographics. Distance because many learners in need are physically remote from the sources of quality instruction and materials. Gilda Bolaños offers us an excellent survey of diverse modes of distance learning formats. Demographics because class sizes, particularly in introductory level mathematics courses, are too large to afford adequate instructor attention to individual student learning. (Bounding class sizes is often done at the cost of using instructors of highly variable quality.) In this case, technology affords various interactive formats for student work and assessment. These include the "virtual laboratories" described by Ruedi Seiler, and the interactive online materials (lectures, automatically graded homework, etc.) discussed by Mika Seppälä.

But independently of these practical needs, technology also offers possibilities for improving mathematics instruction itself. And the fundamental questions about the quality of teaching and learning do not recede when the instruction is mediated by technology; they only change their form.

**Instruction.** By "instruction" I mean the dynamic interaction among teacher, content, and students. I rely here on the "instructional triangle" that Cohen and Ball use to depict the set of interactions that they call "instruction" (Cohen and Ball, 1999).



Viewed in this way, instruction can go wrong in some simple but profound ways, for its quality depends on the relations among all of these three elements. When they misconnect, students' opportunities for learning are impaired. For example, if a teacher is not able to make the content accessible to students, framing it in ways that are incomprehensible to them, the chances that they may misunderstand are great. If students' interpretations of a task are different from the teacher's or the textbook author's intentions, then their work may be misrouted or take the work in unhelpful directions.

It may seem slightly strange, in the context of this panel, to propose the above representation of instruction. For, if you think about it, most descriptions of instructional uses of technology appear to reside exclusively on the bottom edge of the instructional triangle, absent the teacher. A tacit premise of some of this thinking is that somehow, the technology, with its interactive features, actually substitutes for the teacher, or renders the teacher obsolete, except perhaps as a manager of the environment. The viability of this view is a deep and important question, one that I shall not enter here except to make a couple of observations. One is that, in the most successful models of distance learning, it was found to be essential to have a tutor or facilitator available at the remote sites of reception of the materials, to respond to the many questions and requests that students would have, and that were not adequately responded by the technology environment. In addition, it was found to be important to have real time online questioning of the primary source available at certain times. In other words, prepared and transmitted material alone no more teaches a learner than does a textbook, unmediated by a teacher. The other comment is that interactive technology formats can at best provide well-prepared instructional materials and tasks, and respond to the student productions and questions that the software developers have anticipated and for which they have programmed responses. There are many domains of procedural learning and performance where this can be somewhat successful, though

the software, no more than a skilled teacher, cannot completely predict and prepare for all of what students may come up with. Moreover this uncertainty is all the greater once one enters into territory that is less procedural and involves more conceptual reasoning and problem solving.

In what follows, I identify five persistent problems of mathematics instruction and discuss ways in which technology can be deployed to address these. How these are actually used, however, would affect the degree to which they were helpful, so for each case, I point out its possible pitfalls.

**1. Making mathematically accurate and pedagogically skillful diagrams.** One problem faced by mathematics teachers at all levels is how to make clear and accurate diagrams that make the essential mathematical ideas plain to learners, and how to do so in ways that are manipulable for mathematical reasoning. Doing this by hand is often no easy task, whether the sketch is of slices of an ellipsoid in calculus, or sixteenths of a rectangle in fifth grade. Mathematical accuracy is one dimension of the challenge; featuring is a second - that is, making the instructionally key features visible to learners. In addition, instructors must manage these challenges fluently, using class time effectively. An instructor who can make diagrams accurately and helpfully, but who must use 10 minutes of class time to do so, loses effectiveness. Diagrams are also used for a variety of purposes: explorationally, to investigate what happens if certain elements are allowed to vary, or presentationally, to demonstrate an idea, an explanation, or a solution. This means, sometimes, the need for dynamics - translations, rotations, rescaling, variation of parameters. Often diagrams must be made in ways that map clearly to algebraic or numerical representations. Drawing software, or other design tools, can help. Important is the capacity to produce carefully-scaled diagrams, with the capacity for color or shading, and to be able to move elements of a diagram. Its use must be fast and flexible, helpful both for carefully designed lectures and for improvisation on the fly, in response to a student's question. Such software or tools can provide significant support for the use of diagrams in class, by both students and instructor. Making such software accessible to students increases their capacity for individual explorations and preparation for contributions in class. Students can quickly put their diagrams up for others' inspection, or support a point in class, in ways that are difficult to do when students go to the board to generate representations by hand. Using software tools to support the visual dimensions of mathematical work in instruction can significantly alter a major dimension of instruction and do so in ways that are mathematically accurate, pedagogically useful, and sensitive to the real-time challenges of classroom instruction where class periods are finite and time is a critical resource.

Software tools to support the making of diagrams can create problems, too. For example, if the tools are rigid or interfere with the purposes for making diagrams, or cannot be manipulated as desired, the representations may not be as useful as needed. Another problem may be that the use of such tools inhibits students from developing personal skills of appraisal and construction. If the tools quickly make

correct diagrams, students may not develop a critical eye with which to inspect them. If they never have to make a diagram themselves, they may remain entirely dependent on the software and not develop independent capacities for drawing.

**2. Making records of class work and using them cumulatively across time.** A second pervasive problem of mathematics instruction can be seen in the overflowing blackboards full of work and the slippery sheets of transparencies filled with notation and sketches, generated in class, and that vanish into weak memory when class ends. The record of class work (not just text or prepared materials), whether lecture, discussion, or exploration, is an important product of instruction. Under ordinary circumstances, this product vanishes and is thus unavailable for study or future reference, use, or modification. So acute is this problem that, too often, even during a single class, such work is erased (in the case of chalkboards) or slid away (as in transparencies). The work of that single class period is weakened for not being able to secure its place in evolution of ideas in the course. Moreover it is not available for students who may have missed a class.

When the work done in class is created or preserved in digital form, an archive of the mathematical progress of the class can become a resource for ongoing learning. It can then be easily accessed and transmitted remotely to others. Doing it "live" in class requires skill and dexterity on the part of the instructor. Making records of classwork afterwards (i.e., photographing the board with a digital camera) is easier but possibly less manipulable for subsequent class work. Important, too, is that everyone who needs to access these records can work on a common platform or that the format will work reliably across platforms.

**3. Alignment between classes and textbook.** Instructors, perhaps in response to student ideas or productions, may choose to depart from the text - in topic treatment or sequencing, or even topic coverage, and in the design of student activities and tasks. If the instructor creates these variations and alternative paths in electronic form, then a new text is created based on the instructor's design. This affords students access to the substance and course of the lessons. This gives license to flexible and innovative instruction, by affording the means to do so without disadvantaging students through disconnection from a text to be perused and revisited over time.

**4. Ease of access to the instructor between classes.** In the developed world, it is hard to imagine university instructors who do not maintain email (and web) connection with their students. This has made much more fluent and elastic the traditional functions of "office hours." Most student questions can be handled expeditiously, in timely fashion (though asynchronously), by email (perhaps with attachments), thus greatly reducing the need for face-to-face meetings, with their scheduling difficulties. And, as with the discussion above, these exchanges can contribute significantly to the record of the student's work and progress. When appropriate, an exchange between one student and the instructor can easily be made available to other students, thus changing an individual "office hour" into a group discussion. Pitfalls can exist with electronic

communications, of course. Misunderstanding is frequent when communication is restricted to text, without gesture, intonation, and the ability to demonstrate or show.

**5. The repetitive nature of individual outside-of-class sessions.** One feature of traditional office hours, or help sessions, is that they tend to be repetitive, processing over and over again the same questions and assistance with each new student or group of students. When such assistance is administered electronically, and it is seen to be germane to the interests of the whole class, it is an easy matter to copy the whole class, or perhaps selected individuals, on such exchanges. This puts to collective profit the considerable instructional investment made in one student, or group of students, and everyone gains, not least the instructor. An important consideration here is sensitivity to privacy issues and confidentiality. In particular, making individual student communications requires prior consent.

**Conclusion.** Technology continues to transform all aspects of our lives and work. It is already difficult to imagine how we once functioned without email and the web. We are still at the early stages of trying to understand and design the best uses of technology for mathematics instruction. I have pointed to some promising uses of technology to address some endemic problems of even traditional instruction. I have also tried to signal that the fundamental problem of developing quality teaching does not disappear just because instruction is mediated in technological environments.

## Distance learning today

by *Gilda Bolaños Evia*

The definition of distance learning has been modified over time, and today we have a variety of definitions. We will adopt the definition of Greenberg, in [Greenberg98], where contemporary distance learning is defined as "a planned teaching/learning experience that uses a wide spectrum of technologies to reach learners at a distance and is designed to encourage learner interaction and certification of learning".

In this section we will discuss the effects of some of the technologies used in distance learning education on mathematics and its effects on student's knowledge.

**Video taped lectures.** Since the introduction of videos to instruct students on different areas, many studies have been conducted to determine the effectiveness of these

methods. Some examples are [Beare 89], [Moore 96], [Russell 97], and [Pflieger 61]. On all of these studies the conclusion is that there is no significant difference on the achievement of students on video classes and regular classes. A three-year study involving 200,000 students and 800 public schools states:

> "... whereas most comparisons showed no significant differences, 119 were significant in favor of TV-taught students, and 44 in favor of conventionally taught students." [Pflieger 61].

We have to observe that on these studies the quality of the taught material was the same for video students and traditional students. Due to the lack of availability of similar studies for Latin America, we asked some professors and authorities that have been part of the VIBAS (video high school system) about the effectiveness of the system. In general they think that there is a significant difference in favor of traditional education, but this difference is not because of the video system, but mainly because of quality of materials and lack of availability of tutors. Moore and Kearsky converge to the same opinion in [Moore 96]. They also estimate that the difference is bigger in mathematics and physics. Coordinators of mathematics departments in public universities in Guanajuato State, Mexico, have noticed that students coming from video systems have a higher probability to fail its first math courses. They argue that their math knowledge is lower compared with regular students.

In the opinion of these authorities video taped lectures will tend to disappear, but not in the near future, at least for underdeveloped countries, because it is one of the cheapest forms to deliver distance education. They will be replaced by technologies as videoconferences.

At some universities video taped lectures are used inside the classroom for very specific concepts within the syllabus to present an expert opinion. Teachers at the Instituto Tecnológico y de Estudios Superiores de Monterrey (ITESM) highly recommend this instrument for advanced courses and also to present interesting and attractive applications on elementary courses.

**Video conference.** Video conference has been used within higher education for more than a decade. Video conferencing is highly used for teaching sessions, teachers training, seminars and research. At many universities video conference is used as a tool to bring into the class an international experimented and recognized teacher to a large number of students. From the experience at ITESM, has been determined that the success of a video conference class depends on such factors as:

a) Quality of sound, images and degree of interaction.

b) Compatibility of the equipment with ingoing and outgoing signal places.

c) Availability and quality of material presented in the video conference.

d) Quick response to students questions.

e) A tutor on the conference classroom. At ITESM and at the University of Salle Bajío, coordinators of the video conference programs have found that for subjects such as mathematics, statistics and classes with "heavy contents", the presence of a tutor capable of answering students questions regarding the content of the conference makes a significant difference to the students learning and grades.

f) Tutor-student oral communication is very important, because when listening to the student, the teacher might understand some questions better orally than using other types of methods like the internet. Especially in the case of mathematics and statistics, it is very hard for students to write down some of their doubts, and this may cause problems, like using the mathematical language improperly, or overcoming technological barriers that make an extremely difficult task to write down a mathematical sign in a computer.

According to the Faculty of Education at The University of Plymouth [Plymouth], the future of videoconferencing is to incorporate video conference into web based systems, so teachers and presenters can sit in their own office or in a nearby studio and present a 'live' lecture in front of a camera attached to a web server. Using a simple switching device and several cameras, the presenter can provide remote participants with graphics, whiteboard, flipchart and other visual aids as well as alternative views of the local classroom, lecture room, etc.

**Online courses.** By experience at ITESM, the first step to success for online mathematics and statistics courses it is to convince students about the feasibility of the project. At this institution, full online courses are offered just for graduate students. It is also very important to have a quick response to student's questions, so they feel that "there is someone supporting them on the other side of the line".

A second step is to make sure that students can manage technology properly and have all necessary means to remain on line and to send and download information, documents, graphics, etc.

On a study conducted by Karr, Weck, Sunal and Cook [Karr 2003] at the University of Alabama to analyze the effectiveness of online learning in a graduate engineering mathematics course, they divided the class into three groups: Group A (Online course only), Group B (traditional for the first two thirds of the course and traditional and online for the final third of the course, Group C (traditional on the first third, online for the second third and traditional and online for the final third of the course). On this study they found that:

a) Students perform better on the analytical portion of the course when they had used the online mode of delivery. According to the teachers and students feedback this is due to the consistency of online materials and the fact that they have to "face the problem on their own"

b) Students taking the class by traditional mode perform better on the in-class portions of examinations. This might have been because of the instructor

dropping inadvertently little hints about which aspects of the class might be on the test.

c) The two groups with a traditional mode segment perform better when they have access to both modes of deliver, traditional and online.

d) There was no significant difference on the overall performance of the groups.

From my personal experience and from some non formal studies conducted on high school and undergraduate courses it is reasonable to believe that similar results will be obtained for high school and undergraduate mathematics courses.

Many universities as ITESM consider, even for traditional courses, that online sections and online materials should be included to make courses more attractive to students and to enhance the student's performance, especially in traditionally difficult courses as mathematics.

**Online problems and materials.** Online problems are widely used to improve students learning on mathematics courses. Within the experience of Professor Maritza Sirvent and me, some advantages of using online problems on web based programs for mathematics problems are:

a) The bank of problems is large and includes a big variety of questions.

b) The students know immediately if their answer is correct, so they get engaged and they try the problem as many times as necessary to get the right answer.

c) Some students feel that using the computer helps them in their homework.

d) It is clear that the correctness of the problem is independent of the procedure used on the resolution. So they try their own ideas to solve the problem and use techniques as approximations using calculators. After that they study a method that will work at different situations.

e) Problems solved for students at the same class are similar but not the same so they can't copy the homework from a classmate.

f) Student's attitude toward mathematics problems seems to improve.

A disadvantage of online problems might be that, when entering the answer to a problem, sometimes the student makes a typing mistake or forgets some parenthesis and then gets an incorrect answer even if he has solved the problem correctly. Also students are not forced to write down the complete procedure, so when they are tested on a traditional writing test, they have no training on that.

WeBWorK is an internet based program to deliver homework to students on internet. It was designed by the University of Rochester. On a study conducted at Rutgers University to measure how effective WeBWorK was in improving learning measured by student's performance in Calculus [Weibel 2002], they divided students in two sections: Sections where WeBWorK homework was required weekly and it counts as part of the final grade, and sections where traditional written homework was required. Two thirds of calculus students were on WeBWorK sections, and they found the following:

a) Students in WeBWorK section did slightly better than students on traditional section. However, within WeBWorK sections, students who did over 80% of the WeBWorK problems performed dramatically better (by a full letter grade) than those who did less than half of the WeBWorK problems.

b) First year calculus students were very responsive to WeBWorK and most of them attempted every problem. They found that there is a 2-letter grade difference (on the average, from B to D) between students who do well on WeBWorK and those who do not attempt it. For upper class students taking calculus there is a 3-letter grade difference (on the average, from B to F) between students who do well on WeBWorK and those who do not attempt it. These upper class students are not very responsive to WeBWorK.

c) Students repeating calculus are not responsive to WeBWorK, and there is no significant difference on grades even for those that perform well on WeBWorK.

Online didactical material helps students to understand some concepts that might be difficult to them. Some students express that it is easier for them to read online materials than books, because they are usually more attractive and often interactive. For them it is the perfect complement for text books.

There is a bright future for online mathematics problems and didactical material. Each year the number of teachers convinced of the effectiveness of online mathematics problems and didactical material is increasing. Internet-based methods to deliver homework to students are improving and making it easier for teachers and students, saving a considerately amount of time on grading. For instance, projects such as WebALT [WebALT] aim at using existing technology standards for representing mathematics on the web and existing linguistic technologies to produce not just online mathematics problems, but language-independent mathematical didactical material.

**Problem based learning (PBL) and project oriented learning (POL).** These learning methodologies have been applied from elementary school to graduate programs. It is based on the principle that learning occurs not by absorbing information but by interpreting it. These methodologies are ideal for distance learning, but require that students work in teams, an arrangement that may be very difficult for some students that prefer to work individually. With these didactical techniques, learning is generated by solving a realistic situation that requires learning new concepts and applying them to solve a problem. At some universities the full curricula is build around PBL or POL techniques, while at some other universities (as ITESM) these methodologies are mixed with traditional methods [Bolaños 2003], [Watson 2002]. PBL and POL are excellent tools to introduce students on the more difficult tasks of the syllabus. The results are excellent, as statistics show that students perform better with the concepts when introduced by PBL or POL than when introduced on traditional lectures.

On these methodologies the role of the tutor is very important. The tutor is responsible for the direction of students and to help in team conflicts. The tutor has to

address the student's efforts in the right direction and make suggestions about working lines. Students communicate online with their teammates and the tutor, also the final report of all teams is placed online, and so all teams might look at the similarities and differences with the solutions of the others teams.

These are just some aspects of the big world of distance learning and were choosen because we consider that they might be applied on very different teaching environments. Distance learning will continue modifying our teaching practices.

# Virtual labs in mathematics education: concepts and deployment

by *Ruedi Seiler*[1]

**Background.** The work field of engineers, as well as that of scientists and mathematicians, is undergoing drastical changes: as numeric software and computer-algebra-systems are capable of performing intensive and complex arithmetical calculations, other abilities, such as the fast acquisition of new knowledge and new methodologies, are growing in significance. Thus, learning and teaching methods that promote life-long, efficient and independent learning have to be conveyed.

The traditional teaching methods employed at universities are of only limited success in this respect: Teacher-centered lessons provide the essential basic knowledge, but it hardly allows for a more active approach to the subject-matter. Classical experiments, in contrast, while targeted at independent knowledge acquisition, soon stumble across limits imposed by the reality of a university: high and constantly increasing numbers of participants in a course, limited access to and inadequate equipment. In addition, the experimental approach to knowledge acquisition in "real laboratories" is by its very nature limited to certain fields of studies, while more theoretical fields, such as mathematics and theoretical physics are either completely precluded or only peripherally touched upon by the existing experimental concepts.

The deployment of new media and technology in class thus represents a turning point: *Virtual Labs* are environments based on physical labs in which computer aided experiments can be designed, created, implemented and evaluated. Experiments are implemented in the form of computer-based algorithms, representing either real tools and objects or even theoretical concepts and objects.

Such explorative learning environments can be placed at the disposal of every student and teacher, independent of time and place. In the framework of the classical experimental sciences, virtual labs are capable of complementing real laboratories by allowing the concise elaboration of the actual "phenomenon" and diminishing the influence of metrological problems. As, however, the handling of the equipment and the mentioned problems represent a vital part of the acquired competence, real laboratory experiments should not be set aside completely in the experimental disciplines. In theoretical subjects, on the other hand, these technologies make abstract phenomena visually comprehensible.

In this article, we will offer detailed requirements on Virtual Labs and describe the consequences of the implementation along the lines of a prototypical Virtual Lab for Statistical Mechanics.

**Pedagogical requirements.** In the following, we present a list of pedagogical requirements we demand from modern e-learning technology, especially from virtual

[1] In collaboration with Thomas Richter (TU, Berlin, thor@math.tu-berlin.de) and Sabina Jeschke (TU, Berlin, sabina@math.tu-berlin.de).

laboratories. In comparison with most other e-learning environments, though, virtual labs do not define learning goals by themselves. Rather, they put "learning spaces" at the disposal of teachers and students.

A laboratory should provide the necessary equipment – or, in the case of virtual labs, the necessary algorithms – that facilitate the independent development and testing of *problem solving strategies*, incorporating typical problems of mathematics, physics and engineering science in order to prepare the student for his or her professional life.

Laboratories offer students the unique opportunity to control their learning, without outside interference and consequently being able to make an independent decision about their learning process. We divide the support of self-directed learning into the following categories:

First of all, (Virtual) Laboratories support explorative learning by allowing their users to work independently and efficiently with the technical equipment in order to investigate interconnections independently and to build an intuitive understanding of the subject. Therefore, it is vital that Virtual Laboratories should allow and encourage unconventional approaches, options, work flows, etc.

Second, the support of different learning styles is one of the utmost features of the deployment of multimedia technologies in education, even though the first generation of e-learning technologies [1] did not yet allow individual approaches to the subject. Similarly, pre-fabricated experiments might not fit into the previous knowledge of the user, strictly limited specific environments and learning goals might not fit the individual interests, failing to motivate the user. Thus, virtual laboratories must enable the user to setup and control the experiment *freely*.

Laboratories should ideally be adaptable to different application scenarios. This includes the deployment of the same basic lab in different courses, stressing different field-specific foci on the one hand, and the use in different scenarios ranging from demonstration through practice to examination on the other hand. For that reason, a virtual laboratory should not be limited to a fixed set of experiments or aimed at the requirements of one single lecture or one specific audience; for each different target audience arise different requirements. Typical application scenarios might reach from simple demonstrational support within lectures, over experiments in the classroom teaching for training and tutorials up to self-study and deployment in research applications.

Both research and engineering achievements are increasingly the result of cooperations between distributed, separated teams. Thus, team work and team-oriented projects have to be an integral part of any modern scientific education, and thus must be actively supported by virtual laboratories as well.

Laboratories must offer appropriate interfaces that will allow the integration of or linking with standard elements as Maple or Mathematica; experimental set-ups should include these elements correspondingly, for their use and handling should be a part of the scope of learning.

Laboratory elements should be detachable from the actual lab through the application of open interfaces and thus should be reusable. Such requirements not only

allow the efficient construction of new laboratories from existing elements, they also ease the integration of laboratories in more complex experiments requiring additional support from outside software components.

**Consequences for the implementation.** The pedagogical requirements on virtual laboratories pose various demands on the software design which we demonstrate for the laboratory VideoEasel developed at the DFG Research Center. The technical focus of this laboratory is in a first, prototype phase with application to the field of statistical mechanics and related areas. Statistical problems are here modeled through the use of cellular automata, which are well-suited to design statistical models, covering many interesting areas ranging from the Ising model, statistical image denoising, lattice-gas models to Turing completeness.

In order to be able to support different and varying deployment scenarios while imposing as few restrictions on the labs themselves, it must be possible to combine the elements of laboratory equipment flexibly and creatively. This leads to a "strictly anti-monolithic", fine-granular software design, its basic structure characterized by the tripartition into simulation and arithmetic modules implementing the mathematical modules, an interface layer that serves as link between the equimentments, that allows the free combination of the software modules into an experiment, and last, graphical user interfaces allowing to control the experimental setup conveniently.

The experiments in the lab VideoEasel are implemented as small, modular units, independent of the lab's actual core, that can be created and loaded on demand. The elementary units can be separated into two distinct classes, "automata" for the algorithmic definition of physical phenomena – e.g. the Ising model – and "measuring tools" to measure certain quantities arising within the experiment – e.g. the Free Energy. VideoEasel offers basic methods for evaluation of measurements, but does not provide any numerical tools for more complex analysis or a build-in process control for more elaborate experiments. Such functions are taken over to specialized tools by utilizing the software interfaces of the laboratory, which are here realized in the middle-ware CORBA [2]. Mappings are available to many languages, such as Java, C and Python, thus facilitating the connection to various other external tools. Presently, in addition to the native Java-interfaces, there is a Python-connection for script-control, as well as a C-implementation of a Maple-connection available.

Cooperative learning strategies in virtual laboratories imply in particular that several users from different working locations can work simultaneously on a single experiment while being well aware of the actions of their partners. Therefore, the need of designing the laboratory as a multi-part network application becomes self-evident: experiments are, for example, run on a server accessible by students.

VideoEasel follows a classical client-server approach where the students control the simulations run on the server by Java front-ends. In the most simple case – as for support of a lecture in a auditorium – server and client are run on the same computer; in cooperative learning settings, the server synchronizes more clients.

Reading the above arguments concerning the requirements in implementing a virtual laboratories drafted in the previous paragraph might create the impression of a "canonical" approach. However, most existing virtual laboratories posses a narrow technical focus on specific areas and follow a monolithic design.

The second remark concerns tutorials, user guidance and the "usability" of such laboratories: The afore-mentioned flexible granular structure of the software inevitably leads to a more complex user interface and consequently to a higher adaptation time for the teaching staff as well as the students. Problems arising from the initial contact with technical problems present a prominent "motivation killer" in e-learning. In some cases, it is not easy to find the ideal compromises; to overcome this problem, one should then provide several, separate user interfaces, as for example found in VideoEasel:

For simple demonstrational applications in lectures, a Java Applet is available that allows only minimal control of an experiment. For deployment in student groups and classroom teaching, a simple but efficient Java interface has been developed; it provides more options to influence the experiment, while keeping the complexity rather low. Additional menus allow the adjustment of all kinds of parameters within the experiment. The drawing surface, though, is very similar to the applet and mimics that of standard software tools.

A more refined and complete interface was created through the Oorange toolkit [3] – also developed at the TU Berlin – allowing the purely graphic set-up of an experiment, as well as the integration and connection to other elements through "Java Beans" [4]. The server provides templates available for existing experiments, similar to the ones for the Java interfaces; these templates are transformed client-side into a Oorange compatible XML-representation. Different from the more basic interfaces, the user has the option of changing, modifying or completing the experiment at will. This access to VideoEasel does not have the pretense of being particularly easy to navigate, as it was conceived primarily for the use in research and not in teaching or in practice. Therefore, it is acceptable to require the user to go through a reasonable adaptation phase.

Last but not least, VideoEasel is also completely controlable from within the computer algebra program Maple for applications whenever the Oorange toolkit is not able to deliver the mathematical algorithms required for research purposes. This interface uses, similar to all others, the CORBA technology to exchange data between the components.

Now, in retrospective, we analyze how the required didactic concepts are implemented within VideoEasel: the field of cellular automata is rich enough to simulate interesting physical effects, yet straightforward enough to avoid undue obstacles in easy access. The basic principle of such automata can be learned quickly and allows for the execution of interesting (and esthetically pleasing) experiments through quite basic tools. Through the integration of time-proven, well known concepts – drawing programs and measuring tools – and the choice of an appropriate interface, the user is encouraged to experiment. Comprehension of the behavior of the effect to be under-

stood is achieved through practice in the laboratory. Explorative learning is promoted through the connection of esthetical and academical contents.

The availability of various surfaces allows us to address several user groups with very different demands on the laboratories and diverse application purposes ranging from pure demonstration to research applications.

Cooperative deployment scenarios become viable through the two-part set-up as a client/server network architecture. Thus, acquisition and research between teams geographically far separated is feasible.

Finally, CORBA-interfaces allow the docking and linking of the core laboratory with other laboratories, algebra-systems and connectors to demonstrate even more complex facts and to avoid locking the user in one single laboratory technology.

**Future developments.** In conclusion, we will discuss some aspects of important relevance to our original aims, which are improving university education through the use of virtual laboratories:

Virtual labs, including the presented VideoEasel, are still mostly at a prototype stage. Thus, practical experience about their deployment in e-learning environments are still rare. It has to be expected that use and evaluation will result in extensive adaptations and expansions of the existing concepts, particularly in the field of usability.

To realize the pedagogical goals as presented above, it is necessary to integrate virtual laboratories into the framework of larger virtual knowledge spaces. VideoEasel does provide a number of generic interfaces which will have to be specified in more detail. More experiences with laboratories from other fields of science and engineering are necessary to define a standardized data-exchange between different laboratories.

Finally, the virtual laboratories are becoming more and more complex to use as a direct result of the diversity of addressed learning scenarios, the desired interconnectability of different applications and the broad variety of the learning contents. To counter this effect it might be desirable to extend laboratories by "digital assistants" [5]. New concepts developed in the field of artificial intelligence in recent years have to be expanded and applied to virtual knowledge spaces and their components.

## Roles for the new mathematics educators

by *Mika Seppälä*

**The future is here. It is just not evenly distributed.** We are living interesting times! The industrial revolution is on its way in education, publishing, and business. Ways to conserve knowledge and transfer it from generation to generation are changing. Libraries are becoming digital and classes virtual. This development opens extraordinary opportunities to those willing and capable to profit from them. It also opens possibilities to spectacular failures of which we saw many some years ago.

"Emergent technology is, by its very nature, out of control, and leads to unpredictable outcomes." This certainly applies to the current development in e-learning, including e-learning mathematics. "The Future is here. It is just not evenly distributed." Both quotes are by William Gibson.

So in order to understand what lies in the future we can simply look at what our colleagues are doing today. There is no doubt that the information network and the advanced technology are going to change the way we write, publish and teach all disciplines, including mathematics, in the future. This will happen because it is possible, and because proper usage of technology will enhance our current ways to work.

To understand how educators work in 2016, we simply need to understand which, of the currently existing ways to use information technology in education, have most potential. These are likely to emerge as general paradigms and set examples that many will follow.

**Changing the educational system.** Not only instruction, but the whole educational system is changing. New interdisciplinary fields are emerging at a fast pace. Largely this is due to mathematics becoming more applicable thanks to the various advanced mathematics systems like Maple, Mathematica or Matlab. It is now possible to use mathematical modeling in a fundamentally deeper way than before. This is true in practically all fields, perhaps most notably in biology and medicine.

In the past, applications of mathematics in biology or medicine have been, from the mathematical point of view, rather simple. Now more complex methods can be used. This requires expertise in mathematics, computer science, and in the subject matter to which mathematics is being applied. Hence interdisciplinary study programs have been created to educate experts capable of developing these new applications.

**The new roles of mathematics educators.** In the past, and in many cases even today, the teaching of mathematics has been the responsibility of instructors, and the learning that of students. At most European universities, basic mathematics courses are being taught in very large sections. A typical undergraduate calculus class may have well over 100 students. In some cases these classes have hundreds of students.

The instruction is lecturing with little or no personal interactive contact between the students and the professor. Instructors simply cannot follow the day-to-day progress of their students.

Technology can be very useful here. Using systems like Maple TA or STACK, it is possible to offer automated private instruction to students and to monitor the progress of individual students even in large classes. This will empower professors and enhance traditional contact instruction in a dramatic way.

Instruction, even in the case of large classes, becomes student centered instead of instructor centered. Professors will take responsibility of their students in a way that has not been usual in the past. The emerging new role of instructors is very similar to that of coaches. Athletes have their personal coaches, so will students as well. The future instructors work like sports coaches today assisting students to achieve goals they could not achieve on their own. Empowered with advanced learning technologies, instructors can provide individual assistance to their students in a way that was not possible earlier. Interactivity can now be provided, using the web, in a way that is likely to permanently change the way we work.

**Educating new educators.** The inertia of the academia resists changes and delays the necessary development. Instructors in general are not ready to change the way they work. There is also a good reason for the resistance. Moving from traditional contact instruction to computer aided learning is not easy. The data in the table below are generally accepted estimates of the efforts needed for various types of teaching.

All these forms of teaching, except lecturing and small group teaching, will require additional technical support. The large spreads in the first four items reflect the fact that experienced educators can work much faster than beginning professors. There is no spread in the table for computer aided learning and interactive video. Here also experience will eventually help, but for now there are not many instructors having extensive experience in computer aided learning.

**Academic work to produce one hour of student learning** ([2])

| | |
|---|---|
| Lecturing | 2–10 |
| Small group teaching | 1–10 |
| Videotaped lectures | 3–10 |
| Authoring a text | 50–100 |
| Computer aided learning | 200 |
| Interactive video | 300 |

Using the figures of the above table, the development of a typical one semester course will amount to over five years of full time work of the author in addition to the required technical support.

Regardless of the above, some professors are developing content for computer aided learning. They are driven by the vision of greatly improved education once

the necessary content is in place and available in the same ways as books are now available to students and professors.

**Metadata.** Developing content for computer aided learning is very costly. Furthermore, today the materials developed by professors are mostly being used only by the authors themselves and their students. Sharing does not happen, not to speak of shared development of content. To address this problem, the European Commission is currently investing heavily into projects which enhance existing content with metadata. This metadata will make content cross border usable, and shared creation of content a real possibility. The development of metadata is likely to dramatically change the way we work. It will make the hard work to develop premium on-line content cost effective and worthwhile.

**Best practices.** All of the above applies really to all disciplines. Problems related to the teaching of mathematics or of sciences more generally, focus on the presentation of mathematical formulae. Almost all mathematics is being written using LaTeX today. Also these proceedings have been prepared by LaTeX.

LaTeX and TeX generate extremely high quality typesetting of scientific text. These systems produce content ready for printing and publishing in the traditional way. New LaTeX classes for producing high quality presentations have been created. Practically all mathematicians are using LaTeX.

Intelligent interactivity ([3] and [4]) requires that mathematical formulae are presented in the on-line materials so that the meaning of the formulae can be automatically understood. MathML and OpenMath make this possible. To embed mathematical formulae in a proper way to web content requires the usage of these languages. LaTeX or TeX do not support MathML or OpenMath. In spite of the fact that TeX enthusiasts are working hard to develop solutions to this problem, the use of MS Word and PowerPoint together with products like MathType often makes the content development much easier.

Searching the web one can find, for example, a variety of electronic presentations of calculus or linear algebra courses. Most of these are pdf presentations of printed materials, and are not designed to be studied from the computer monitor. The new media, the computer screen, requires a different presentation of the content than what is used on printed materials. The resolution of a printed page is much higher than the resolution of the best monitors. Hence printed pages are easier to read than computer monitors. To overcome this problem, content, for the computer screen, needs to be presented in a very condensed way. For instruction based on the computer screen, the presentation of the materials needs to follow the general design principles implemented, for example, in PowerPoint.

On-line content has many important advantages which greatly overcome the handicap that computer monitors have with respect to printed pages. These advantages include hyperlinking, live interactive and adaptive content, student performance track-

ing, and, most recently, multilinguality. The WebALT encoding of mathematical content uses an extension of OpenMath and is such that the content can be generated in many languages automatically. Hence the content is truly multilingual, or rather, language independent. This is a serious advantage in view of the high cost of the development of on-line content.

**A case study: on-line calculus at the University of Helsinki.** The lesson learned from previous experiences at Florida State University was that on-line materials should use standard tools as much as possible, not require students to install new programs, and that the illustrations of mathematics should be done so that the required technicalities are completely hidden.

With these points in mind, the development of new on-line materials for calculus was started at the University of Helsinki in the Fall of 2001. These materials consist of a collection of lectures presented by PowerPoint, a collection of PowerPoint presentations of solved problems, a collection of calculus calculators empowered by MapleNET, and a repository of problems delivered to students using Maple TA, a system for the delivery and automatic grading of homework, quizzes, and examinations.

Students reactions to these new on-line materials have been overwhelmingly positive. During the Fall of 2004, a basic course in calculus was offered, at the same time, as a fully on-line course, and as a traditional lecture/problem session course. Both courses were based on the on-line materials, and had the same exercises and examinations. For the on-line students, the examinations were the only events that took place on campus and were proctored.

The results were surprising: the on-line students fared better than the traditional students in both examinations, and the retention rate was higher among the on-line students than among the traditional students.

**Automatic assessment.** Systems providing automatic assessment of homework problems, quizzes and examinations have been used in lower level mathematics instruction at Florida State University with spectacular results for several years. The failure rates of precalculus courses have gone down by about 50%. This is due to students being able to practice for examinations at home so that they get immediate feed-back from the system.

Currently the most advanced automatic assessment systems are Maple TA, STACK, the forthcoming LeActive Math System and the WebALT System. Common to all of these is that they offer the possibility to create algorithmic problems which are programs that generate a different version of a problem every time the program is invoked. In addition to the others, the WebALT System will also be able to generate the problem in many languages.

The algorithmic problems really make a difference. Consider, for example, the method of partial fraction decompositions. Students of calculus will have to learn that. It is relatively simple to write a program which generates over a million different but

equally hard problems of partial fraction decompositions. Hence the examination about partial fraction decompositions can be published to the students before the test! Students can take the partial fraction decomposition test as many times as they want at home, get individual feed-back including full solutions. Learning by heart is not helpful, because regardless how many times they take the same test at home, they are going to get different questions in the examinations.

Such algorithmic problems were used in instruction at Florida State University in Spring 2005. Most students reacted very positively, and used the system a lot to their benefit. Some students solved even hundreds of problems on computing limits, for example. Starting in Fall 2006, students at Florida State University are required to have a laptop computer. Then the automatic assessment systems can be used in class, and examinations can be based on the use of these systems.

**Conclusions.** The development on-line education in mathematics at the university level has been very slow. Administrators at national agencies and ministries in various countries see the great potential that on-line content can bring to education, but largely this potential has not been realized in mathematics and, more generally, in sciences.

This is partly due to problems that one has in the presentation of scientific content on the web. The majority of on-line materials present mathematical formulae as pictures only. This is not a satisfactory solution. One cannot use a picture as a key word in a database search.

MathML and OpenMath provide solutions to this. Commercial editors, such as MS Word and PowerPoint together with MathType, provide a convenient way to produce content in which mathematics is embedded using MathML. Authoring tools are available, robust and easy to use.

Missing synchronous interactivity has been another problem in on-line instruction. Together with the introduction of tools like Skype and the various easy-to-use conferencing systems, this problem has suddenly disappeared. Virtual on-line courses can provide more personal interaction between instructors and students than a regular class with hundreds of students attending the same lectures. This development is new, and we have not yet seen how that will change instruction. The effect is likely to be impressive, however.

To use the available technology to the maximum places large demands on instructors. They have to rethink their roles and convert themselves from lecturers to coaches. And they have to be able to use technology in a fluent way. Most instructors resist doing this mainly because the transition requires a lot of work.

The main remaining obstacle in this development is the fact that premium on-line content is expensive to produce and hard to find. Extensive funding programs, like the European Commission supported Content Enhancement Projects of eContent Plus, are likely to make a dramatic difference with respect to these remaining obstacles.

The most important lessons learned were that it is necessary to keep the use of technology as simple as possible while still providing advanced functionalities. Pretty

good is good enough. For the student, everything has to work right out of the box. Technicalities have to be hidden. On-line content satisfying this criteria is going to have large and permanent value. In 2016 we cannot understand how education without the information network and its services was possible.
